EMNLP 2008

2008 Conference on Empirical Methods in Natural Language Processing

Proceedings of the Conference

25–27 October 2008
Honolulu, Hawaii, USA

A meeting of SIGDAT, a Special Interest Group of the ACL

Production and Manufacturing by
Omnipress Inc.
2600 Anderson Street
Madison, WI 53707
USA

Preface

Welcome to the 2008 Conference on Empirical Methods in Natural Language Processing! The conference is organized under the auspices of SIGDAT, the ACL Special Interest Group for linguistic data and corpus-based approaches to natural language processing. It is co-located this year with AMTA 2008 and the International Workshop on Spoken Language Translation, in Honolulu, Hawaii.

EMNLP received 385 submissions. We were able to accept 116 papers in total (an acceptance rate of 30%). 81 of the papers (21%) were accepted for oral presentation, and 35 (9%) for poster presentation. Two poster papers were subsequently withdrawn after acceptance. The papers were selected by a program committee of 15 area chairs, from Asia, Europe, and North America, assisted by a panel of 339 reviewers. This year EMNLP introduced an author response period. Authors were able to read and respond to the reviews of their paper before the program committee made a final decision. They were asked to correct factual errors in the reviews and answer questions raised in the reviewer comments. The intention was to help produce more accurate reviews. In some cases, reviewers changed their scores in view of the authors' response and the area chairs read all responses carefully prior to making recommendations for acceptance.

First and foremost, we would like to thank the authors who submitted their work to EMNLP. The sheer number of submissions reflects how broad and active our field is. We are deeply indebted to the area chairs and the reviewers for their hard work. They enabled us to select an exciting program and to provide valuable feedback to the authors. We are grateful to our invited speakers Oren Etzioni, Tom Griffiths, and Fernando Pereira who graciously agreed to give talks at EMNLP. Additional thanks to the Publications Chair, Sebastian Padó, who put this volume together. Jason Eisner helped us immensely by compiling a web site on "How to Serve as Program Chair of a Conference" (`http://www.cs.jhu.edu/~jason/advice/how-to-chair-a-conference.html`). Special thanks to David Yarowsky and Ken Church of SIGDAT who provided much valuable advice and assistance over the past months. David also helped raise important financial support for the conference. We are most grateful to Priscilla Rasmussen who helped us with various logistic and organizational aspects of the conference. Rich Gerber and the START team responded to our questions quickly, and helped us manage the large number of submissions smoothly. Finally, thanks are due to our webmaster, Francesco Figari, who revamped our conference website on very short notice.

We hope you enjoy the conference!

Mirella Lapata and Hwee Tou Ng
EMNLP 2008 Program Co-Chairs

Reviewers:

Table of Contents

Conference Program Overview

Saturday, October 25, 2008

9:15–10:30	Session 1: Plenary Session
10:30–11:00	Morning Break
11:00–12:15	Sessions 2a, 2b and 2c
12:15–14:00	Lunch
14:00–15:15	Sessions 3a, 3b and 3c
15:15–15:45	Afternoon Break
15:45–17:00	Sessions 4a, 4b and 4c
18:00–21:00	Session 5: All Posters

Sunday, October 26, 2008

9:30–10:30	Session 6: Plenary Session
10:30–11:00	Morning Break
11:00–12:15	Sessions 7a, 7b and 7c
12:15–14:00	Lunch
14:00–15:15	Sessions 8a, 8b and 8c
15:15–15:45	Afternoon Break
15:45–17:00	Sessions 9a, 9b and 9c

Monday, October 27, 2008

9:30–10:30	Session 10: Plenary Session
10:30–11:00	Morning Break
11:00–12:15	Sessions 11a, 11b and 11c
12:15-13:00	SIGDAT Business Meeting
13:00–14:00	Lunch
14:00–15:15	Sessions 12a, 12b and 12c
15:15–15:45	Afternoon Break
15:45–17:00	Sessions 13a, 13b and 13c

Conference Program

Saturday, October 25, 2008

	Session 1: Plenary Session
9:15–9:30	Opening Remarks
9:30–10:30	Invited Talk: *We KnowItAll: Lessons from a Quarter Century of Web Extraction Research* Oren Etzioni, University of Washington
10:30-11:00	**Morning Break**
	Session 2a: Information Extraction
11:00–11:25	*Revealing the Structure of Medical Dictations with Conditional Random Fields* Jeremy Jancsary, Johannes Matiasek and Harald Trost
11:25–11:50	*It's a Contradiction – no, it's not: A Case Study using Functional Relations* Alan Ritter, Stephen Soderland, Doug Downey and Oren Etzioni
11:50–12:15	*Regular Expression Learning for Information Extraction* Yunyao Li, Rajasekar Krishnamurthy, Sriram Raghavan, Shivakumar Vaithyanathan and H. V. Jagadish
	Session 2b: Machine Learning
11:00–11:25	*Modeling Annotators: A Generative Approach to Learning from Annotator Rationales* Omar Zaidan and Jason Eisner
11:25–11:50	*One-Class Clustering in the Text Domain* Ron Bekkerman and Koby Crammer
11:50–12:15	*Refining Generative Language Models using Discriminative Learning* Ben Sandbank

Abstract

Automatic processing of medical dictations poses a significant challenge. We approach the problem by introducing a statistical framework capable of identifying types and boundaries of sections, lists and other structures occurring in a dictation, thereby gaining explicit knowledge about the function of such elements. Training data is created semi-automatically by aligning a parallel corpus of corrected medical reports and corresponding transcripts generated via automatic speech recognition. We highlight the properties of our statistical framework, which is based on conditional random fields (CRFs) and implemented as an efficient, publicly available toolkit. Finally, we show that our approach is effective both under ideal conditions and for real-life dictation involving speech recognition errors and speech-related phenomena such as hesitation and repetitions.

1 Introduction

It is quite common to dictate reports and leave the typing to typists – especially for the medical domain, where every consultation or treatment has to be documented. Automatic Speech Recognition (ASR) can support professional typists in their work by providing a transcript of what has been dictated. However, manual corrections are still needed. In particular, speech recognition errors have to be corrected. Furthermore, speaker errors, such as hesitations or repetitions, and instructions to the transcriptionist have to be removed. Finally, and most notably, proper structuring and formatting of the report has to be performed. For the medical domain, fairly clear guidelines exist with regard to what has to be dictated, and how it should be arranged. Thus, missing headings may have to be inserted, sentences must be grouped into paragraphs in a meaningful way, enumeration lists may have to be introduced, and so on.

The goal of the work presented here was to ease the job of the typist by formatting the dictation according to its structure and the formatting guidelines. The prerequisite for this task is the identification of the various structural elements in the dictation which will be be described in this paper.

```
complaint dehydration weakness and diarrhea
full stop Mr.  Will Shawn is a 81-year-old
cold Asian gentleman who came in with fever
and Persian diaper was sent to the emergency
department by his primary care physician due
him being dehydrated period ... neck physical
exam general alert and oriented times three
known acute distress vital signs are stable
... diagnosis is one chronic diarrhea with

thromboctopenia probably duty liver cirrhosis
... a plan was discussed with patient in
detail will transfer him to a nurse and
facility for further care ... end of dictation
```

Fig. 1: Raw output of speech recognition

Figure 1 shows a fragment of a typical report as recognized by ASR, exemplifying some of the problems we have to deal with:

- Punctuation and enumeration markers may be dictated or not, thus sentence boundaries and numbered items often have to be inferred;
- the same holds for (sub)section headings;
- finally, recognition errors complicate the task.

```
CHIEF COMPLAINT
Dehydration, weakness and diarrhea.

HISTORY OF PRESENT ILLNESS
Mr.  Wilson is a 81-year-old Caucasian
gentleman who came in here with fever and
persistent diarrhea.  He was sent to the
emergency department by his primary care
physician due to him being dehydrated.
...

PHYSICAL EXAMINATION
  GENERAL: He is alert and oriented times
     three, not in acute distress.

  VITAL SIGNS: Stable.
...

DIAGNOSIS
  1. Chronic diarrhea with dehydration.  He
     also has hypokalemia.

  2. Thromboctopenia, probably due to liver
     cirrhosis.
...

PLAN AND DISCUSSION
The plan was discussed with the patient
in detail.  Will transfer him to a nursing
facility for further care.
...
```

Fig. 2: A typical medical report

When properly edited and formatted, the same dictation appears significantly more comprehensible, as can be seen in figure 2. In order to arrive at this result it is necessary to identify the inherent structure of the dictation, i.e. the various hierarchically nested segments. We will recast the segmentation problem as a multi-tiered tagging problem and show that indeed a good deal of the structure of medical dictations can be revealed.

The main contributions of our paper are as follows: First, we introduce a generic approach that can be integrated seamlessly with existing ASR solutions and provides structured output for medical dictations. Second, we provide a freely available toolkit for factorial conditional random fields (CRFs) that forms the basis of aforementioned approach and is also applicable to numerous other problems (see section 6).

2 Related Work

The structure recognition problem dealt with here is closely related to the field of *linear text segmentation* with the goal to partition text into coherent blocks, but on a single level. Thus, our task generalizes linear text segmentation to multiple levels.

A meanwhile classic approach towards domain-independent linear text segmentation, *C99*, is presented in Choi (2000). *C99* is the baseline which many current algorithms are compared to. Choi's algorithm surpasses previous work by Hearst (1997), who proposed the *Texttiling* algorithm. The best results published to date are – to the best of our knowledge – those of Lamprier et al. (2008).

The automatic detection of (sub)section *topics* plays an important role in our work, since changes of topic indicate a section boundary and appropriate headings can be derived from the section type. Topic detection is usually performed using methods similar to those of *text classification* (see Sebastiani (2002) for a survey).

Matsuov (2003) presents a dynamic programming algorithm capable of segmenting medical reports into sections and assigning topics to them. Thus, the aims of his work are similar to ours. However, he is not concerned with the more fine-grained elements, and also uses a different machinery.

When dealing with tagging problems, statistical frameworks such as HMMs (Rabiner, 1989) or, recently, CRFs (Lafferty et al., 2001) are most commonly applied. Whereas HMMs are generative models, CRFs are discriminative models that can incorporate rich features. However, other approaches to text segmentation have also been pursued. E.g., McDonald et al. (2005) present a model based on multilabel classification, allowing for natural handling of overlapping or non-contiguous segments.

Finally, the work of Ye and Viola (2004) bears similarities to ours. They apply CRFs to the parsing of hierarchical lists and outlines in handwritten notes, and thus have the same goal of finding deep structure using the same probabilistic framework.

3 Problem Representation

For representing our segmentation problem we use a trick that is well-known from chunking and named entity recognition, and recast the problem as a tagging problem in the so-called BIO[1] notation. Since we want to assign a type to every segment, OUTSIDE labels are not needed. However, we perform seg-

[1] BEGIN - INSIDE - OUTSIDE

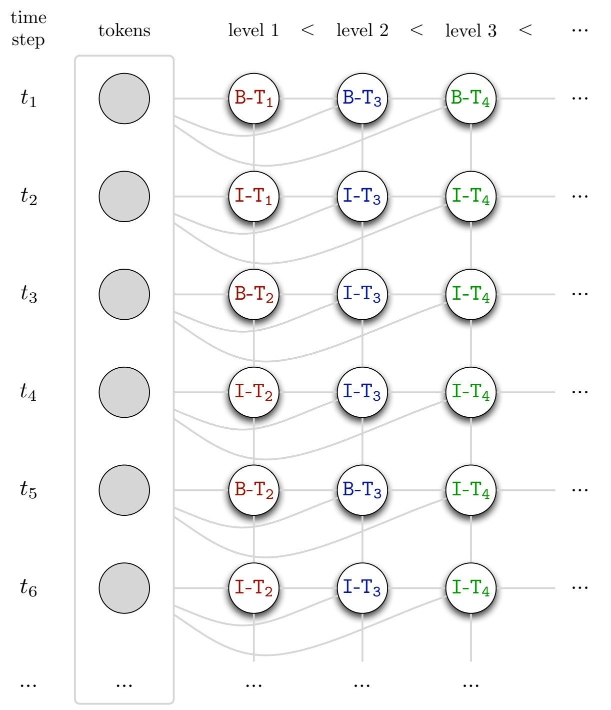

Fig. 3: Multi-level segmentation as tagging problem

mentation on multiple levels, therefore multiple *label chains* are required. Furthermore, we also want to assign *types* to certain segments, thus the labels need an encoding for the type of segment they represent. Figure 3 illustrates this representation: B-T_i denotes the beginning of a segment of type T_i, while I-T_i indicates that the segment of type T_i continues. By adding label chains, it is possible to group the segments of the previous chain into coarser units. Tree-like structures of unlimited depth can be expressed this way[2]. The gray lines in figure 3 denote dependencies between nodes. Node labels also depend on the input token sequence in an arbitrarily wide context window.

4 Data Preparation

The raw data available to us consists of two parallel corpora of 2007 reports from the area of medical consultations, dictated by physicians. The first corpus, C_{RCG}, consists of the raw output of ASR (figure 1), the other one, C_{COR}, contains the corresponding corrected and formatted reports (figure 2).

In order to arrive at an annotated corpus in a format suitable for the tagging problem, we first have to analyze the report structure and define appropriate labels for each segmentation level. Then, every token has to be annotated with the appropriate begin or inside labels. A report has 625 tokens on average, so the manual annotation of roughly 1.25 million tokens seemed not to be feasible. Thus we decided to produce the annotations programmatically and restrict manual work to corrections.

4.1 Analysis of report structure

When inspecting reports in C_{COR}, a human reader can easily identify the various elements a report consists of, such as *headings* – written in bold on a separate line – introducing sections, *subheadings* – written in bold followed by a colon – introducing subsections, and *enumerations* starting with indented numbers followed by a period. Going down further, there are *paragraphs* divided into *sentences*. Using these structuring elements, a hierarchic data structure comprising all report elements can be induced.

Sections and subsections are typed according to their heading. There exist clear recommendations on structuring medical reports, such as E2184-02 (ASTM International, 2002). However, actual medical reports still vary greatly with regard to their structure. Using the aforementioned standard, we assigned the (sub)headings that actually appeared in the data to the closest type, introducing new types only when absolutely necessary. Finally we arrived at a structure model with three label chains:

- **Sentence level**, with 4 labels: `Heading`, `Subheading`, `Sentence`, `Enummarker`
- **Subsection level**, with 45 labels: `Paragraph`, `Enumelement`, `None` and 42 subsection types (e.g. `VitalSigns`, `Cardiovascular` ...)
- **Section level**, with 23 section types (e.g. `ReasonForEncounter`, `Findings`, `Plan` ...)

4.2 Corpus annotation

Since the reports in C_{COR} are manually edited they are reliable to parse. We employed a broad-coverage dictionary (handling also multi-word terms) and a domain-specific grammar for parsing and layout information. A regular heading grammar was used for mapping (sub)headings to the defined (sub)section labels (for details see Jancsary (2008)). The output

[2]Note, that since we omit a redundant top-level chain, this structure technically is a *hedge* rather than a *tree*.

Fig. 4: Mapping labels via alignment

of the parser is a hedge data structure from which the annotation labels can be derived easily.

However, our goal is to develop a model for recognizing the report structure from the *dictation*, thus we have to map the newly created annotation of reports in C_{COR} onto the corresponding reports in C_{RCG}. The basic idea here is to align the tokens of C_{COR} with the tokens in C_{RCG} and to copy the annotations (cf. figure 4[3]). There are some peculiarities we have to take care of during alignment:

1. non-dictated items in C_{COR} (e.g. punctuation, headings)
2. dictated words that do not occur in C_{COR} (meta instructions, repetitions)
3. non-identical but corresponding items (recognition errors, reformulations)

Since it is particularly necessary to correctly align items of the third group, standard string-edit distance based methods (Levenshtein, 1966) need to be augmented. Therefore we use a more sophisticated cost function. It assigns tokens that are similar (either from a semantic or phonetic point of view) a low cost for substitution, whereas dissimilar tokens receive a prohibitively expensive score. Costs for deletion and insertion are assigned inversely. Semantic similarity is computed using Wordnet (Fellbaum, 1998) and UMLS (Lindberg et al., 1993). For phonetic matching, the Metaphone algorithm (Philips, 1990) was used (for details see Huber et al. (2006)).

4.3 Feature Generation

The annotation discussed above is the first step towards building a training corpus for a CRF-based approach. What remains to be done is to provide observations for each time step of the observed entity, i.e. for each token of a report; these are expected to give hints with regard to the annotation labels that are to be assigned to the time step. The observations, associated with one or more annotation labels, are usually called *features* in the machine learning literature. During CRF training, the parameters of these features are determined such that they indicate the significance of the observations for a certain label or label combination; this is the basis for later tagging of unseen reports.

We use the following features for each time step of the reports in C_{COR} and C_{RCG}:

- **Lexical features** covering the local context of ± 2 tokens (e.g., `patient@0`, `the@-1`, `is@1`)
- **Syntactic features** indicating the possible syntactic categories of the tokens (e.g., `NN@0`, `JJ@0`, `DT@-1` and `be+VBZ+aux@1`)
- **Bag-of-word (BOW) features** intend to capture the topic of a text segment in a wider context of ± 10 tokens, without encoding any order. Tokens are lemmatized and replaced by their UMLS *concept IDs*, if available, and weighed by `TF`. Thus, different words describing the same concept are considered equal.
- **Semantic type features** as above, but using UMLS *semantic types* instead of concept IDs provide a coarser level of description.
- **Relative position features**: The report is divided into eight parts corresponding to eight binary features; only the feature corresponding to the part of the current time step is set.

[3]This approach can easily be generalized to multiple label chains.

5 Structure Recognition with CRFs

Conditional random fields (Lafferty et al., 2001) are conditional models in the exponential family. They can be considered a generalization of multinomial logistic regression to output with non-trivial internal structure, such as sequences, trees or other graphical models. We loosely follow the general notation of Sutton and McCallum (2007) in our presentation.

Assuming an undirected graphical model G over an observed entity $\boldsymbol{x}$ and a set of discrete, interdependent random variables[4] $\boldsymbol{y}$, a conditional random field describes the conditional distribution:

$$p(\boldsymbol{y}|\boldsymbol{x};\boldsymbol{\theta}) = \frac{1}{Z(\boldsymbol{x})} \prod_{c \in G} \boldsymbol{\phi}_c(\boldsymbol{y}_c, \boldsymbol{x}; \boldsymbol{\theta}_c) \qquad (1)$$

The normalization term $Z(\boldsymbol{x})$ sums over all possible joint outcomes of $\boldsymbol{y}$, i.e.,

$$Z(\boldsymbol{x}) = \sum_{\boldsymbol{y}'} p(\boldsymbol{y}'|\boldsymbol{x};\boldsymbol{\theta}) \qquad (2)$$

and ensures the probabilistic interpretation of $p(\boldsymbol{y}|\boldsymbol{x})$. The graphical model G describes interdependencies between the variables $\boldsymbol{y}$; we can then model $p(\boldsymbol{y}|\boldsymbol{x})$ via factors $\boldsymbol{\phi}_c(\cdot)$ that are defined over cliques $c \in G$. The factors $\boldsymbol{\phi}_c(\cdot)$ are computed from sufficient statistics $\{f_{ck}(\cdot)\}$ of the distribution (corresponding to the features mentioned in the previous section) and depend on possibly overlapping sets of parameters $\boldsymbol{\theta}_c \subseteq \boldsymbol{\theta}$ which together form the parameters $\boldsymbol{\theta}$ of the conditional distribution:

$$\boldsymbol{\phi}_c(\boldsymbol{y}_c, \boldsymbol{x}; \boldsymbol{\theta_c}) = \exp\left(\sum_{k=1}^{|\boldsymbol{\theta}_c|} \lambda_{ck} f_{ck}(\boldsymbol{x}, \boldsymbol{y}_c)\right) \qquad (3)$$

In practice, for efficiency reasons, independence assumptions have to be made about variables $y \in \boldsymbol{y}$, so G is restricted to small cliques (say, $(|c| \leq 3)$. Thus, the sufficient statistics only depend on a limited number of variables $\boldsymbol{y_c} \subseteq \boldsymbol{y}$; they can, however, access the whole observed entity $\boldsymbol{x}$. This is in contrast to generative approaches which model a joint distribution $p(\boldsymbol{x}, \boldsymbol{y})$ and therefore have to extend the independence assumptions to elements $x \in \boldsymbol{x}$.

[4]In our case, the discrete outcomes of the random variables $\boldsymbol{y}$ correspond to the annotation labels described in the previous section.

The factor-specific parameters $\boldsymbol{\theta}_c$ of a CRF are typically tied for certain cliques, according to the problem structure (i.e., $\boldsymbol{\theta}_{c_1} = \boldsymbol{\theta}_{c_2}$ for two cliques c_1, c_2 with tied parameters). E.g., parameters are usually tied across time if G is a sequence. The factors can then be partitioned into a set of *clique templates* $\mathcal{C} = \{C_1, C_2, \ldots C_P\}$, where each clique template C_p is a set of factors with tied parameters $\boldsymbol{\theta}_p$ and corresponding sufficient statistics $\{f_{pk}(\cdot)\}$. The CRF can thus be rewritten as:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{x})} \prod_{C_p \in \mathcal{C}} \prod_{\boldsymbol{\phi}_c \in C_p} \boldsymbol{\phi}_c(\boldsymbol{y}_c, \boldsymbol{x}; \boldsymbol{\theta}_p) \qquad (4)$$

Furthermore, in practice, the sufficient statistics $\{f_{pk}(\cdot)\}$ are computed from a subset $\boldsymbol{x}_c \subseteq \boldsymbol{x}$ that is relevant to a factor $\boldsymbol{\phi}_c(\cdot)$. In a sequence labelling task, tokens $x \in \boldsymbol{x}$ that are in temporal proximity to an output variable $y \in \boldsymbol{y}$ are typically most useful. Nevertheless, in our notation, we will let factors depend on the whole observed entity $\boldsymbol{x}$ to denote that all of $\boldsymbol{x}$ can be accessed if necessary.

For our structure recognition task, the graphical model G exhibits the structure shown in figure 3, i.e., there are multiple connected chains of variables with factors defined over single-node cliques and two-node cliques within and between chains; the parameters of factors are tied across time. This corresponds to the *factorial CRF* structure described in Sutton and McCallum (2005). Structure recognition using conditional random fields then involves two separate steps: *parameter estimation*, or training, is concerned with selecting the parameters of a CRF such that they fit the given training data. *Prediction*, or testing, determines the best label assignment for unknown examples.

5.1 Parameter estimation

Given IID training data $\mathcal{D} = \{\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)}\}_{i=1}^{N}$, parameter estimation determines:

$$\boldsymbol{\theta}^* = \underset{\boldsymbol{\theta}'}{\operatorname{argmax}} \left(\sum_{i}^{N} p(\boldsymbol{y}^{(i)}|\boldsymbol{x}^{(i)}; \boldsymbol{\theta}')\right) \qquad (5)$$

i.e., those parameters that maximize the conditional probability of the CRF given the training data.

In the following, we will not explicitly sum over $_{i=1}^{N}$; as Sutton and McCallum (2007) note, the training instances $\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)}$ can be considered disconnected components of a single undirected model G.

We thus assume G and its factors $\boldsymbol{\phi}_c(\cdot)$ to extend over all training instances. Unfortunately, (5) cannot be solved analytically. Typically, one performs maximum likelihood estimation (MLE) by maximizing the conditional log-likelihood numerically:

$$\ell(\boldsymbol{\theta}) = \sum_{C_p \in \mathcal{C}} \sum_{\boldsymbol{\phi}_c \in C_p} \sum_{k=1}^{|\boldsymbol{\theta}_p|} \lambda_{pk} f_{pk}(\boldsymbol{x}, \boldsymbol{y}_c) - \log Z(\boldsymbol{x}) \tag{6}$$

Currently, limited-memory gradient-based methods such as LBFGS (Nocedal, 1980) are most commonly employed for that purpose[5]. These require the partial derivatives of (6), which are given by:

$$\frac{\partial \ell}{\partial \lambda_{pk}} = \sum_{\boldsymbol{\phi}_c \in C_p} f_{pk}(\boldsymbol{x}, \boldsymbol{y}_c) - \sum_{\boldsymbol{y}'_c} f_{pk}(\boldsymbol{x}, \boldsymbol{y}'_c) p(\boldsymbol{y}'_c|\boldsymbol{x}) \tag{7}$$

and expose the intuitive form of a difference between the expectation of a sufficient statistic according to the empiric distribution and the expectation according to the model distribution. The latter term requires marginal probabilities for each clique c, denoted by $p(\boldsymbol{y}'_c|\boldsymbol{x})$. Inference on the graphical model G (see sec 5.2) is needed to compute these.

Depending on the structure of G, inference can be very expensive. In order to speed up parameter estimation, which requires inference to be performed for every training example and for every iteration of the gradient-based method, alternatives to MLE have been proposed that do not require inference. We show here a factor-based variant of pseudolikelihood as proposed by Sanner et al. (2007):

$$\ell_p(\boldsymbol{\theta}) = \sum_{C_p \in \mathcal{C}} \sum_{\boldsymbol{\phi}_c \in C_p} \log p(\boldsymbol{y}_c|\boldsymbol{x}, MB(\boldsymbol{\phi}_c)) \tag{8}$$

where the factors are conditioned on the Markov blanket, denoted by MB[6]. The gradient of (8) can be computed similar to (7), except that the marginals $p_c(\boldsymbol{y}'_c|\boldsymbol{x})$ are also conditioned on the Markov blanket, i.e., $p_c(\boldsymbol{y}'_c|\boldsymbol{x}, MB(\boldsymbol{\phi}_c))$. Due to its dependence on the Markov blanket of factors, pseudolikelihood cannot be applied to prediction, but only to parameter estimation, where the "true" assignment of a blanket is known.

5.1.1 Regularization

We employ a Gaussian prior for training of CRFs in order to avoid overfitting. Hence, if $f(\boldsymbol{\theta})$ is the original objective function (e.g., log-likelihood or log-pseudolikelihood), we optimize a penalized version $f'(\boldsymbol{\theta})$ instead, such that:

$$f'(\boldsymbol{\theta}) = f(\boldsymbol{\theta}) - \sum_{k=1}^{|\boldsymbol{\theta}|} \frac{\lambda_k^2}{2\sigma^2} \quad \text{and} \quad \frac{\partial f'}{\partial \lambda_k} = \frac{\partial f}{\partial \lambda_k} - \frac{\lambda_k}{\sigma^2}.$$

The tuning parameter σ^2 determines the strength of the penalty; lower values lead to less overfitting. Gaussian priors are a common choice for parameter estimation of log-linear models (cf. Sutton and McCallum (2007)).

5.2 Inference

Inference on a graphical model G is needed to efficiently compute the normalization term $Z(\boldsymbol{x})$ and marginals $p_c(\boldsymbol{y}'_c|\boldsymbol{x})$ for MLE, cf. equation (6).

Using belief propagation (Yedidia et al., 2003), more precisely its sum-product variant, we can compute the beliefs for all cliques $c \in G$. In a tree-shaped graphical model G, these beliefs correspond exactly to the marginal probabilities $p_c(\boldsymbol{y}'_c|\boldsymbol{x})$. However, if the graph contains cycles, so-called loopy belief propagation must be performed. The message updates are then re-iterated according to some schedule until the messages converge. We use a TRP schedule as described by Wainwright et al. (2002). The resulting beliefs are then only approximations to the true marginals. Moreover, loopy belief propagation is not guaranteed to terminate in general – we investigate this phenomenon in section 6.5.

With regard to the normalization term $Z(\boldsymbol{x})$, as equation (2) shows, naive computation requires summing over all assignments of $\boldsymbol{y}$. This is too expensive to be practical. Fortunately, belief propagation produces an alternative factorization of $p(\boldsymbol{y}|\boldsymbol{x})$; i.e., the conditional distribution defining the CRF can be expressed in terms of the marginals gained during sum-product belief propagation. This representation does not require any additional normalization, so $Z(\boldsymbol{x})$ need not be computed.

[5]Recently, stochastic gradient descent methods such as Online LBFGS (Schraudolph et al., 2007) have been shown to perform competitively.

[6]Here, the Markov blanket of a factor $\boldsymbol{\phi}_c$ denotes the set of variables occurring in factors that share variables with $\boldsymbol{\phi}_c$, non-inclusive of the variables of $\boldsymbol{\phi}_c$

5.3 Prediction

Once the parameters $\boldsymbol{\theta}$ have been estimated from training data, a CRF can be used to predict the labels of unknown examples. The goal is to find:

$$\boldsymbol{y}^* = \underset{\boldsymbol{y}'}{\operatorname{argmax}} \left(p(\boldsymbol{y}'|\boldsymbol{x};\boldsymbol{\theta}) \right) \tag{9}$$

i.e., the assignment of $\boldsymbol{y}$ that maximizes the conditional probability of the CRF. Again, naive computation of (9) is intractable. However, the max-product variant of loopy belief propagation can be applied to approximately find the MAP assignment of $\boldsymbol{y}$ (max-product can be seen as a generalization of the well-known Viterbi algorithm to graphical models).

For structure recognition in medical reports, we employ a post-processing step after label prediction with the CRF model. As in Jancsary (2008), this step enforces the constraints of the `BIO` notation and applies some trivial non-local heuristics that guarantee a consistent global view of the resulting structure.

6 Experiments and Results

For evaluation, we generally performed 3-fold cross-validation for all performance measures. We created training data from the reports in C_{COR} so as to simulate a scenario under ideal conditions, i.e., perfect speech recognition and proper dictation of punctuation and headings, without hesitation or repetitions. In contrast, the data from C_{RCG} reflects real-life conditions, with a wide variety of speech recognition error rates and speakers frequently hesitating, repeating themselves and omitting punctuation and/or headings.

Depending on the experiment, two different subsets of the two corpora were considered:

- $C_{\{COR,RCG\}\text{-}ALL}$: All 2007 reports were used, resulting in 1338 training examples and 669 testing examples at each CV-iteration.
- $C_{\{COR,RCG\}\text{-}BEST}$: The corpus was restricted to those 1002 reports that yielded the lowest word error rate during alignment (see section 4.2). Each CV-iteration hence amounts to 668 training examples and 334 testing examples.

From the crossvalidation runs, a 95%-confidence interval for each measure was estimated as follows:

$$\bar{Y} \pm t_{(\alpha/2,N-1)} \frac{s}{\sqrt{N}} = \bar{Y} \pm t_{(0.025,2)} \frac{s}{\sqrt{3}} \tag{10}$$

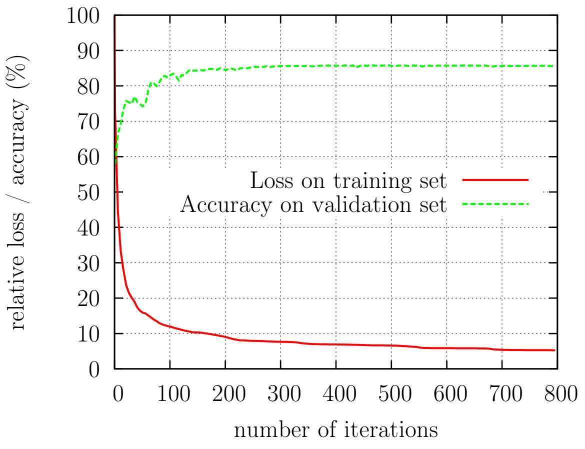

Fig. 5: Accuracy vs. loss function on $C_{RCG\text{-}ALL}$

where $\bar{Y}$ is the sample mean, s is the sample standard deviation, N is the sample size (3), α is the desired significance level (0.05) and $t_{(\alpha/2,N-1)}$ is the upper critical value of the t-distribution with $N-1$ degrees of freedom. The confidence intervals are indicated in the $\pm$ column of tables 1, 2 and 3.

For CRF training, we minimized the penalized, negative log-pseudolikelihood using LBFGS with $m = 3$. The variance of the Gaussian prior was set to $\sigma^2 = 1000$. All supported features were used for univariate factors, while the bivariate factors within chains and between chains were restricted to bias weights. For testing, loopy belief propagation with a TRP schedule was used in order to determine the maximum a posteriori (MAP) assignment. We use *VieCRF*, our own implementation of factorial CRFs, which is freely available at the author's homepage[7].

6.1 Analysis of training progress

In order to determine the number of required training iterations, an experiment was performed that compares the progress of the Accuracy measure on a validation set to the progress of the loss function on a training set. The data was randomly split into a training set (2/3 of the instances) and a validation set. Accuracy on the validation set was computed using the intermediate CRF parameters $\boldsymbol{\theta}_t$ every 5 iterations of LBFGS. The resulting plot (figure 5) demonstrates that the progress of the loss function corresponds well to that of the Accuracy measure,

thus an "early stopping" approach might be tempting to cut down on training times. However, during earlier stages of training, the CRF parameters seem to be strongly biased towards high-frequency labels, so other measures such as macro-averaged F1 might suffer from early stopping. Hence, we decided to allow up to 800 iterations of LBFGS.

6.2 Accuracy of structure prediction

Table 1 shows estimated accuracies for $C_{COR\text{-}ALL}$ and $C_{RCG\text{-}ALL}$. Overall, high accuracy ($> 97\%$) can be achieved on $C_{COR\text{-}ALL}$, showing that the approach works very well under ideal conditions. Performance is still fair on the noisy data ($C_{RCG\text{-}ALL}$; $\text{Accuracy} > 86\%$). It should be noted that the labels are unequally distributed, especially in *chain 0* (there are very few BEGIN labels). Thus, the baseline is substantially high for this chain, and other measures may be better suited for evaluating segmentation quality (cf. section 6.4).

6.3 On the effect of noisy training data

Measuring the effect of the imprecise reference annotation of C_{RCG} is difficult without a corresponding, manually created golden standard. However, to get a feeling for the impact of the noise induced by speech recognition errors and sloppy dictation on the quality of the semi-automatically generated annotation, we conducted an experiment with subsets $C_{COR\text{-}BEST}$ and $C_{RCG\text{-}BEST}$. The results are shown in table 2. Comparing these results to table 1, one can see that overall accuracy *decreased* for $C_{COR\text{-}BEST}$, whereas we see an *increase* for $C_{RCG\text{-}BEST}$. This effect can be attributed to two different phenomena:

- In $C_{COR\text{-}BEST}$, no quality gains in the annotation could be expected. The smaller number of training examples therefore results in lower accuracy.
- Fewer speech recognition errors and more consistent dictation in $C_{RCG\text{-}BEST}$ allow for better alignment and thus a better reference annotation. This increases the actual prediction performance and, furthermore, reduces the number of label predictions that are erroneously counted as a misprediction.

Thus, it is to be expected that manual correction of the automatically created annotation results in significant performance gains. Preliminary annotation experiments have shown that this is indeed the case.

Chain 2	0.118	0.013

(b) $C_{RCG\text{-}ALL}$

Table 3: Per-chain $\mathrm{WindowDiff}$ on the full corpus

6.4 Segmentation quality

$\mathrm{Accuracy}$ is not the best measure to assess segmentation quality, therefore we also conducted experiments using the $\mathrm{WindowDiff}$ measure as proposed by Pevzner and Hearst (2002). $\mathrm{WindowDiff}$ returns 0 in case of a perfect segmentation; 1 is the worst possible score. However, it only takes into account segment boundaries and disregards segment types. Table 3 shows the $\mathrm{WindowDiff}$ scores for $C_{COR\text{-}ALL}$ and $C_{RCG\text{-}ALL}$. Overall, the scores are quite good and are consistently below 0.2. Furthermore, $C_{RCG\text{-}ALL}$ scores do not suffer as badly from inaccurate reference annotation, since "near misses" are penalized less strongly.

	Converged (%)	Iterations (∅)
$C_{COR\text{-}ALL}$	0.999	15.4
$C_{RCG\text{-}ALL}$	0.911	66.5
$C_{COR\text{-}BEST}$	0.999	14.2
$C_{RCG\text{-}BEST}$	0.971	37.5

Table 4: Convergence behaviour of loopy BP

6.5 Convergence of loopy belief propagation

In section 5.2, we mentioned that loopy BP is not guaranteed to converge in a finite number of iterations. Since we optimize pseudolikelihood for parameter estimation, we are not affected by this limitation in the training phase. However, we use loopy BP with a TRP schedule during testing, so we must expect to encounter non-convergence for some examples. Theoretical results on this topic are discussed by Heskes (2004). We give here an empirical observation of convergence behaviour of loopy BP in our setting; the maximum number of iterations of the TRP schedule was restricted to 1,000. Table 4 shows the percentage of examples converging within this limit and the average number of iterations required by the converging examples, broken down by the different corpora. From these results, we conclude that there is a connection between the quality of the annotation and the convergence behaviour of loopy BP. In practice, even though loopy BP didn't converge for some examples, the solutions after 1,000 iterations where satisfactory.

7 Conclusion and Outlook

We have presented a framework which allows for identification of structure in report dictations, such as sentence boundaries, paragraphs, enumerations, (sub)sections, and various other structural elements; even if no explicit clues are dictated. Furthermore, meaningful types are automatically assigned to subsections and sections, allowing – for instance – to automatically assign headings, if none were dictated.

For the preparation of training data a mechanism has been presented that exploits the potential of parallel corpora for automatic annotation of data. Using manually edited formatted reports and the corresponding raw output of ASR, reference annotation can be generated that is suitable for learning to identify structure in ASR output.

For the structure recognition task, a CRF framework has been employed and multiple experiments have been performed, confirming the practicability of the approach presented here.

One result deserving further investigation is the effect of noisy annotation. We have shown that segmentation results improve when fewer errors are present in the automatically generated annotation. Thus, manual correction of the reference annotation will yield further improvements.

Finally, the framework presented in this paper opens up exciting possibilities for future work. In particular, we aim at automatically transforming report dictations into properly formatted and rephrased reports that conform to the requirements of the relevant domain. Such tasks are greatly facilitated by the explicit knowledge gained during structure recognition.

Acknowledgments

The work presented here has been carried out in the context of the Austrian KNet competence network COAST. It's a Contradiction—No, it's Not: A Case Study using Functional Relations

Abstract

Contradiction Detection (CD) in text is a difficult NLP task. We investigate CD over functions (*e.g.*, BornIn(Person)=Place), and present a domain-independent algorithm that automatically discovers phrases denoting functions with high precision. Previous work on CD has investigated hand-chosen sentence pairs. In contrast, we automatically harvested from the Web pairs of sentences that *appear* contradictory, but were surprised to find that most pairs are in fact consistent. For example, "Mozart was born in Salzburg" does *not* contradict "Mozart was born in Austria" despite the functional nature of the phrase "was born in". We show that background knowledge about meronyms (*e.g.*, Salzburg is in Austria), synonyms, functions, and more is essential for success in the CD task.

1 Introduction and Motivation

Detecting contradictory statements is an important and challenging NLP task with a wide range of potential applications including analysis of political discourse, of scientific literature, and more (de Marneffe et al., 2008; Condoravdi et al., 2003; Harabagiu et al., 2006). De Marneffe *et al.* present a model of CD that defines the task, analyzes different types of contradictions, and reports on a CD system. They report 23% precision and 19% recall at detecting contradictions in the RTE-3 data set (Voorhees, 2008). Although RTE-3 contains a wide variety of contradictions, it does not reflect the prevalence of *seeming* contradictions and the paucity of *genuine* contradictions, which we have found in our corpus.

1.1 Contradictions and World Knowledge

Our paper is motivated in part by de Marneffe *et al.*'s work, but with some important differences. First, we introduce a simple logical foundation for the CD task, which suggests that extensive world knowledge is essential for building a domain-independent CD system. Second, we automatically generate a large corpus of *apparent* contradictions found in arbitrary Web text. We show that most of these apparent contradictions are actually consistent statements due to meronyms (Alan Turing was born in London *and* in England), synonyms (George Bush is married to *both* Mrs. Bush and Laura Bush), hypernyms (Mozart died of *both* renal failure and kidney disease), and reference ambiguity (one John Smith was born in 1997 and a *different* John Smith in 1883). Next, we show how background knowledge enables a CD system to discard seeming contradictions and focus on genuine ones.

De Marneffe *et al.* introduced a typology of contradiction in text, but focused primarily on contradictions that can be detected from linguistic evidence (*e.g.* negation, antonymy, and structural or lexical disagreements). We extend their analysis to a class of contradictions that can only be detected utilizing background knowledge. Consider for example the following sentences:

1) "Mozart was born in Salzburg."
2) "Mozart was born in Vienna."
3) "Mozart visited Salzburg."
4) "Mozart visited Vienna."

Sentences 1 & 2 are contradictory, but 3 & 4 are not. Why is that? The distinction is not syntactic. Rather, sentences 1 and 2 are contradictory because the relation expressed by the phrase "was born in" can be characterized here as a *function* from people's names to their unique birthplaces. In contrast, "visited" does not denote a functional relation.[1]

We cannot assume that a CD system knows, in advance, all the functional relations that might appear in a corpus. Thus, a central challenge for a function-based CD system is to determine which relations are functional based on a corpus. Intuitively, we might expect that "functional phrases" such as "was born in" would typically map person names to unique place names, making function detection easy. But, in fact, function detection is surprisingly difficult because name ambiguity (*e.g.*, John Smith), common nouns (*e.g.*, "dad" or "mom"), definite descriptions (*e.g.*, "the president"), and other linguistic phenomena can mask functions in text. For example, the two sentences "John Smith was born in 1997." and "John Smith was born in 1883." can be viewed as either evidence that "was born in" does not denote a function or, alternatively, that "John Smith" is ambiguous.

1.2 A CD System Based on Functions

We report on the AUCONTRAIRE CD system, which addresses each of the above challenges. First, AUCONTRAIRE identifies "functional phrases" statistically (Section 3). Second, AUCONTRAIRE uses these phrases to automatically create a large corpus of apparent contradictions (Section 4.2). Finally, AUCONTRAIRE sifts through this corpus to find genuine contradictions using knowledge about synonymy, meronymy, argument types, and ambiguity (Section 4.3).

Instead of analyzing sentences directly, AUCONTRAIRE relies on the TEXTRUNNER Open Information Extraction system (Banko et al., 2007; Banko and Etzioni, 2008) to map each sentence to one or more tuples that represent the entities in the sentences and the relationships between them (*e.g.*, *was_born_in(Mozart,Salzburg)*). Using extracted tuples greatly simplifies the CD task, because numerous syntactic problems (*e.g.*, anaphora, relative clauses) and semantic challenges (*e.g.*, quantification, counterfactuals, temporal qualification) are delegated to TEXTRUNNER or simply ignored. Nevertheless, extracted tuples are a convenient approximation of sentence content, which enables us to focus on function detection and function-based CD.

Our contributions are the following:

- We present a novel model of the Contradiction Detection (CD) task, which offers a simple logical foundation for the task and emphasizes the central role of background knowledge.
- We introduce and evaluate a new EM-style algorithm for detecting whether phrases denote functional relations and whether nouns (*e.g.*, "dad") are ambiguous, which enables a CD system to identify functions in arbitrary domains.
- We automatically generate a corpus of seeming contradictions from Web text, and report on a set of experiments over this corpus, which provide a baseline for future work on statistical function identification and CD. [2]

2 A Logical Foundation for CD

On what basis can a CD system conclude that two statements T and H are contradictory? Logically, contradiction holds when $T \models \neg H$. As de Marneffe *et al.* point out, this occurs when T and H contain antonyms, negation, or other lexical elements that suggest that T and H are directly contradictory. But other types of contradictions can only be detected with the help of a body of background knowledge K: In these cases, T and H *alone* are mutually consistent. That is,

$$T \not\models \neg H \wedge H \not\models \neg T$$

A contradiction between T and H arises only in the context of K. That is:

$$((K \wedge T) \models \neg H) \vee ((K \wedge H) \models \neg T)$$

Consider the example of Mozart's birthplace in the introduction. To detect a contradiction, a CD system must know that A) "Mozart" refers to the same entity in both sentences, that B) "was born in" denotes a functional relation, and that C) Vienna and Salzburg are inconsistent locations.

[1] Although we focus on function-based CD in our case study, we believe that our observations apply to other types of CD as well.

[2] The corpus is available at `http://www.cs.washington.edu/research/aucontraire/`

Of course, world knowledge, and reasoning about text, are often uncertain, which leads us to associate probabilities with a CD system's conclusions. Nevertheless, the knowledge base K is essential for CD.

We now turn to a probabilistic model that helps us simultaneously estimate the functionality of relations (B in the above example) and ambiguity of argument values (A above). Section 4 describes the remaining components of AUCONTRAIRE.

3 Detecting Functionality and Ambiguity

This section introduces a formal model for computing the probability that a phrase denotes a function based on a set of extracted tuples. An extracted tuple takes the form $R(x, y)$ where (roughly) x is the subject of a sentence, y is the object, and R is a phrase denoting the relationship between them. If the relation denoted by R is functional, then typically the object y is a function of the subject x. Thus, our discussion focuses on this possibility, though the analysis is easily extended to the symmetric case.

Logically, a relation R is functional in a variable x if it maps it to a unique variable y: $\forall x, y_1, y_2 \; R(x, y_1) \wedge R(x, y_2) \Rightarrow y_1 = y_2$. Thus, given a large random sample of ground instances of R, we could detect with high confidence whether R is functional. In text, the situation is far more complex due to ambiguity, polysemy, synonymy, and other linguistic phenomena. Deciding whether R is functional becomes a probabilistic assessment based on aggregated textual evidence.

The main evidence that a relation $R(x, y)$ is functional comes from the distribution of y values for a given x value. If R denotes a function and x is unambiguous, then we expect the extractions to be predominantly a single y value, with a few outliers due to noise. We aggregate the evidence that R is *locally* functional for a particular x value to assess whether R is *globally* functional for all x.

We refer to a set of extractions with the same relation R and argument x as a *contradiction set* $R(x, \cdot)$. Figure 1 shows three example contradiction sets. Each example illustrates a situation commonly found in our data. Example A in Figure 1 shows strong evidence for a functional relation. 66 out of 70 TEXTRUNNER extractions for *was_born_in (Mozart, PLACE)* have the same y value. An ambiguous x argument, however, can make a functional relation *appear* non-functional. Example B depicts a distribution of y values that appears less functional due to the fact that "John Adams" refers to multiple, distinct real-world individuals with that name. Finally, example C exhibits evidence for a non-functional relation.

Figure 1: Functional relations such as example A have a different distribution of y values than non-functional relations such as C. However, an ambiguous x argument as in B, can make a functional relation *appear* non-functional.

3.1 Formal Model of Functions in Text

To decide whether R is functional in x for all x, we first consider how to detect whether R is *locally functional* for a particular value of x. The local functionality of R with respect to x is the probability that R is functional estimated solely on evidence from the distribution of y values in a contradiction set $R(x, \cdot)$.

To decide the probability that R is a function, we define global functionality as the average local functionality score for each x, weighted by the probability that x is unambiguous. Below, we outline an EM-style algorithm that alternately estimates the probability that R is functional and the probability that x is ambiguous.

Let R^*_x indicate the event that the relation R is locally functional for the argument x, and that x is locally unambiguous for R. Also, let D indicate the set of observed tuples, and define $D_{R(x,\cdot)}$ as the multi-set containing the frequencies for extractions of the form $R(x, \cdot)$. For example the distribution of extractions from Figure 1 for example A is

$D_{\mathrm{W}as\_born\_in(\mathrm{M}ozart,\cdot)} = \{66, 3, 1\}$.

Let θ^f_R be the probability that $R(x, \cdot)$ is locally functional for a random x, and let Θ^f be the vector of these parameters across all relations R. Likewise, θ^u_x represents the probability that x is locally unambiguous for random R, and Θ^u the vector for all x.

We wish to determine the *maximum a posteriori* (MAP) functionality and ambiguity parameters given the observed data D, that is $\arg\max_{\Theta^f,\Theta^u} P(\Theta^f, \Theta^u|D)$. By Bayes Rule:

$$P(\Theta^f, \Theta^u|D) = \frac{P(D|\Theta^f, \Theta^u)P(\Theta^f, \Theta^u)}{P(D)} \quad (1)$$

We outline a generative model for the data, $P(D|\Theta^f, \Theta^u)$. Let us assume that the event R^*_x depends only on θ^f_R and θ^u_x, and further assume that given these two parameters, local ambiguity and local functionality are conditionally independent. We obtain the following expression for the probability of R^*_x given the parameters:

$$P(R^*_x|\Theta^f, \Theta^u) = \theta^f_R\theta^u_x$$

We assume each set of data $D_{R(x,\cdot)}$ is generated independently of all other data and parameters, given R^*_x. From this and the above we have:

$$P(D|\Theta^f, \Theta^u) = \prod_{R,x} \Big(P(D_{R(x,\cdot)}|R^*_x)\theta^f_R\theta^u_x + P(D_{R(x,\cdot)}|\neg R^*_x)(1-\theta^f_R\theta^u_x)\Big) \quad (2)$$

These independence assumptions allow us to express $P(D|\Theta^f, \Theta^u)$ in terms of distributions over $D_{R(x,\cdot)}$ given whether or not R^*_x holds. We use the URNS model as described in (Downey et al., 2005) to estimate these probabilities based on binomial distributions. In the single-urn URNS model that we utilize, the extraction process is modeled as draws of labeled balls from an urn, where the labels are either correct extractions or errors, and different labels can be repeated on varying numbers of balls in the urn.

Let $k = \max D_{R(x,\cdot)}$, and let $n = \sum D_{R(x,\cdot)}$; we will approximate the distribution over $D_{R(x,\cdot)}$ in terms of k and n. If $R(x,\cdot)$ is locally functional and unambiguous, there is exactly one correct extraction label in the urn (potentially repeated multiple times). Because the probability of correctness tends to increase with extraction frequency, we make the simplifying assumption that the most frequently extracted element is correct.[3] In this case, k is the number of correct extractions, which by the URNS model has a binomial distribution with parameters n and p, where p is the precision of the extraction process. If $R(x,\cdot)$ is *not* locally functional and unambiguous, then we expect k to typically take on smaller values. Empirically, the underlying frequency of the most frequent element in the $\neg R^*_x$ case tends to follow a Beta distribution.

Under the model, the probability of the evidence given R^*_x is:

$$P(D_{R(x,\cdot)}|R^*_x) \approx P(k,n|R^*_x) = \binom{n}{k} p^k(1-p)^{n-k}$$

And the probability of the evidence given $\neg R^*_x$ is:

$$P(D_{R(x,\cdot)}|\neg R^*_x) \approx P(k,n|\neg R^*_x)$$
$$= \tbinom{n}{k} \int_0^1 \frac{p'^{k+\alpha_f-1}(1-p')^{n+\beta_f-1-k}}{B(\alpha_f,\beta_f)} dp'$$
$$= \frac{\binom{n}{k}\Gamma(n-k+\beta_f)\Gamma(\alpha_f+k)}{B(\alpha_f,\beta_f)\Gamma(\alpha_f+\beta_f+n)} \quad (3)$$

where n is the sum over $D_{R(x,\cdot)}$, Γ is the Gamma function and B is the Beta function. α_f and β_f are the parameters of the Beta distribution for the $\neg R^*_x$ case. These parameters and the prior distributions are estimated empirically, based on a sample of the data set of relations described in Section 5.1.

3.2 Estimating Functionality and Ambiguity

Substituting Equation 3 into Equation 2 and applying an appropriate prior gives the probability of parameters Θ^f and Θ^u given the observed data D. However, Equation 2 contains a large product of sums—with two independent vectors of coefficients, Θ^f and Θ^u—making it difficult to optimize analytically.

If we knew which arguments were ambiguous, we would ignore them in computing the functionality of a relation. Likewise, if we knew which relations were non-functional, we would ignore them in computing the ambiguity of an argument. Instead, we initialize the Θ^f and Θ^u arrays randomly, and then execute an algorithm similar to Expectation-Maximization (EM) (Dempster et al., 1977) to arrive at a high-probability setting of the parameters.

Note that if Θ^u is fixed, we can compute the expected fraction of locally unambiguous arguments x for which R is locally functional, using $D_{R(x',\cdot)}$ and

[3]As this assumption is invalid when there is not a unique maximal element, we default to the prior $P(R^*_x)$ in that case.

Equation 3. Likewise, for fixed Θ^f, for any given x we can compute the expected fraction of locally functional relations R that are locally unambiguous for x.

Specifically, we repeat until convergence:

1. Set $\theta^f_R = \frac{1}{s_R}\sum_x P(R^*_x|D_{R(x,\cdot)})\theta^u_x$ for all R.
2. Set $\theta^u_x = \frac{1}{s_x}\sum_R P(R^*_x|D_{R(x,\cdot)})\theta^f_R$ for all x.

In both steps above, the sums are taken over only those x or R for which $D_{R(x,\cdot)}$ is non-empty. Also, the normalizer $s_R = \sum_x \theta^u_x$ and likewise $s_x = \sum_R \theta^f_R$.

As in standard EM, we iteratively update our parameter values based on an expectation computed over the unknown variables. However, we alternately optimize two disjoint sets of parameters (the functionality and ambiguity parameters), rather than just a single set of parameters as in standard EM. Investigating the optimality guarantees and convergence properties of our algorithm is an item of future work.

By iteratively setting the parameters to the expectations in steps 1 and 2, we arrive at a good setting of the parameters. Section 5.2 reports on the performance of this algorithm in practice.

4 System Overview

AuContraire identifies phrases denoting functional relations and utilizes these to find contradictory assertions in a massive, open-domain corpus of text.

AuContraire begins by finding extractions of the form $R(x, y)$, and identifies a set of relations R that have a high probability of being functional. Next, AuContraire identifies contradiction sets of the form $R(x, \cdot)$. In practice, most contradiction sets turned out to consist overwhelmingly of seeming contradictions—assertions that do not actually contradict each other for a variety of reasons that we enumerate in section 4.3. Thus, a major challenge for AuContraire is to tease apart which pairs of assertions in $R(x, \cdot)$ represent genuine contradictions.

Here are the main components of AuContraire as illustrated in Figure 2:

Extractor: Create a set of extracted assertions $\mathcal{E}$ from a large corpus of Web pages or other documents. Each extraction $R(x, y)$ has a probability p of being correct.

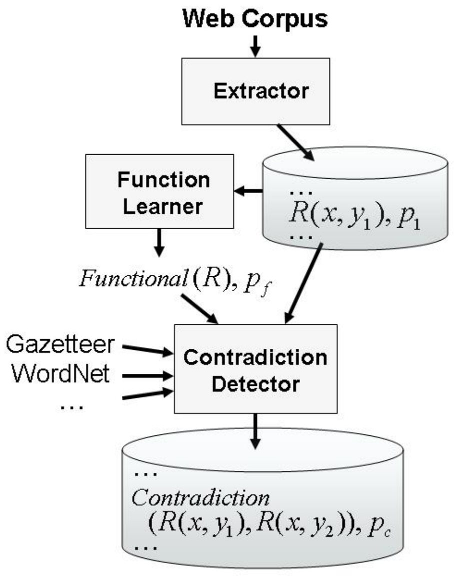

Figure 2: AuContraire architecture

Function Learner: Discover a set of functional relations $\mathcal{F}$ from among the relations in $\mathcal{E}$. Assign to each relation in $\mathcal{F}$ a probability p_f that it is functional.

Contradiction Detector: Query $\mathcal{E}$ for assertions with a relation R in $\mathcal{F}$, and identify sets $\mathcal{C}$ of potentially contradictory assertions. Filter out seeming contradictions in $\mathcal{C}$ by reasoning about synonymy, meronymy, argument types, and argument ambiguity. Assign to each potential contradiction a probability p_c that it is a genuine contradiction.

4.1 Extracting Factual Assertions

AuContraire needs to explore a large set of factual assertions, since genuine contradictions are quite rare (see Section 5). We used a set of extractions $\mathcal{E}$ from the Open Information Extraction system, TextRunner (Banko et al., 2007), which was run on a set of 117 million Web pages.

TextRunner does not require a pre-defined set of relations, but instead uses shallow linguistic analysis and a domain-independent model to identify phrases from the text that serve as relations and phrases that serve as arguments to that relation. TextRunner creates a set of extractions in a single pass over the Web page collection and provides an index to query the vast set of extractions.

Although its extractions are noisy, TextRunner provides a probability that the extractions are correct, based in part on corroboration of facts from different Web pages (Downey et al., 2005).

4.2 Finding Potential Contradictions

The next step of AuContraire is to find contradiction sets in $\mathcal{E}$.

We used the methods described in Section 3 to estimate the functionality of the most frequent relations in $\mathcal{E}$. For each relation R that AuContraire has judged to be functional, we identify contradiction sets $R(x, \cdot)$, where a relation R and domain argument x have multiple range arguments y.

4.3 Handling Seeming Contradictions

For a variety of reasons, a pair of extractions $R(x, y_1)$ and $R(x, y_2)$ may not be actually contradictory. The following is a list of the major sources of false positives—pairs of extractions that are not genuine contradictions, and how they are handled by AuContraire. The features indicative of each condition are combined using Logistic Regression, in order to estimate the probability that a given pair, $\{R(x, y_1), R(x, y_2)\}$ is a genuine contradiction.

Synonyms: The set of potential contradictions *died_from(Mozart,·)* may contain assertions that Mozart died from *renal failure* and that he died from *kidney failure*. These are distinct values of y, but do not contradict each other, as the two terms are synonyms. AuContraire uses a variety of knowledge sources to handle synonyms. WordNet is a reliable source of synonyms, particularly for common nouns, but has limited recall. AuContraire also utilizes synonyms generated by Resolver (Yates and Etzioni, 2007)— a system that identifies synonyms from TextRunner extractions. Additionally, AuContraire uses edit-distance and token-based string similarity (Cohen et al., 2003) between apparently contradictory values of y to identify synonyms.

Meronyms: For some relations, there is no contradiction when y_1 and y_2 share a meronym, *i.e.* "part of" relation. For example, in the set *born_in(Mozart,·)* there is no contradiction between the y values "Salzburg" and "Austria", but "Salzburg" conflicts with "Vienna". Although this is only true in cases where y occurs in an upward monotone context (MacCartney and Manning, 2007), in practice genuine contradictions between y-values sharing a meronym relationship are extremely rare. We therefore simply assigned contradictions between meronyms a probability close to zero. We used the Tipster Gazetteer[4] and WordNet to identify meronyms, both of which have high precision but low coverage.

Argument Typing: Two y values are not contradictory if they are of different argument types. For example, the relation *born_in* can take a date or a location for the y value. While a person can be born in only one year and in only one city, a person can be born in both a year and a city. To avoid such false positives, AuContraire uses a simple named-entity tagger[5] in combination with large dictionaries of person and location names to assign high-level types (person, location, date, other) to each argument. AuContraire filters out extractions from a contradiction set that do not have matching argument types.

Ambiguity: As pointed out in Section 3, false contradictions arise when a single x value refers to multiple real-world entities. For example, if the contradiction set *born_in(John Sutherland, ·)* includes birth years of both 1827 and 1878, is one of these a mistake, or do we have a grandfather and grandson with the same name? AuContraire computes the probability that an x value is unambiguous as part of its Function Learner (see Section 3). An x value can be identified as ambiguous if its distribution of y values is non-functional for multiple functional relations.

If a pair of extractions, $\{R(x, y_1), R(x, y_2)\}$, does not fall into any of the above categories and R is functional, then it is likely that the sentences underlying the extractions are indeed contradictory. We combined the various knowledge sources described above using Logistic Regression, and used 10-fold cross-validation to automatically tune the weights associated with each knowledge source. In addition, the learning algorithm also utilizes the following features:

- Global functionality of the relation, θ_R^f
- Global unambiguity of x, θ_x^u

[4] `http://crl.nmsu.edu/cgi-bin/Tools/CLR/clrcat`

[5] `http://search.cpan.org/~simon/Lingua-EN-NamedEntity-1.1/NamedEntity.pm`

- Local functionality of $R(x, \cdot)$
- String similarity (a combination of token-based similarity and edit-distance) between y_1 and y_2
- The argument types (person, location, date, or other)

The learned model is then used to estimate how likely a potential contradiction $\{R(x, y_1), R(x, y_2)\}$ is to be genuine.

5 Experimental Results

We evaluated several aspects of AUCONTRAIRE: its ability to detect functional relations and to detect ambiguous arguments (Section 5.2); its precision and recall in contradiction detection (Section 5.3); and the contribution of AUCONTRAIRE's key knowledge sources (Section 5.4).

5.1 Data Set

To evaluate AUCONTRAIRE we used TEXTRUNNER's extractions from a corpus of 117 million Web pages. We restricted our data set to the 1,000 most frequent relations, in part to keep the experiments tractable and also to ensure sufficient statistical support for identifying functional relations.

We labeled each relation as functional or not, and computed an estimate of the probability it is functional as described in section 3.2. Section 5.2 presents the results of the Function Learner on this set of relations. We took the top 2% (20 relations) as $\mathcal{F}$, the set of functional relations in our experiments. Out of these, 75% are indeed functional. Some examples include: *was born in*, *died in*, and *was founded by*.

There were 1.2 million extractions for all thousand relations, and about 20,000 extractions in 6,000 contradiction sets for all relations in $\mathcal{F}$.

We hand-tagged 10% of the contradiction sets $R(x, \cdot)$ where $R \in \mathcal{F}$, discarding any sets with over 20 distinct y values since the x argument for that set is almost certainly ambiguous. This resulted in a data set of 567 contradiction sets containing a total of 2,564 extractions and 8,844 potentially contradictory pairs of extractions.

We labeled each of these 8,844 pairs as contradictory or not. In each case, we inspected the original sentences, and if the distinction was unclear, consulted the original source Web pages, Wikipedia articles, and Web search engine results.

In our data set, genuine contradictions over functional relations are surprisingly rare. We found only 110 genuine contradictions in the hand-tagged sample, only 1.2% of the potential contradiction pairs.

5.2 Detecting Functionality and Ambiguity

We ran AUCONTRAIRE's EM algorithm on the thousand most frequent relations. Performance converged after 5 iterations resulting in estimates of the probability that each relation is functional and each x argument is unambiguous. We used these probabilities to generate the precision-recall curves shown in Figure 3.

The graph on the left shows results for functionality, while the graph on the right shows precision at finding unambiguous arguments. The solid lines are results after 5 iterations of EM, and the dashed lines are from computing functionality or ambiguity without EM (*i.e.* assuming uniform values of Θ^c when computing Θ^f and vice versa). The EM algorithm improved results for both functionality and ambiguity, increasing area under curve (AUC) by 19% for functionality and by 31% for ambiguity.

Of course, the ultimate test of how well AUCONTRAIRE can identify functional relations is how well the Contradiction Detector performs on automatically identified functional relations.

5.3 Detecting Contradictions

We conducted experiments to evaluate how well AUCONTRAIRE distinguishes genuine contradictions from false positives.

The bold line in Figure 4 depicts AUCONTRAIRE performance on the distribution of contradictions and seeming contradictions found in actual Web data. The dashed line shows the performance of AUCONTRAIRE on an artificially "balanced" data set that we constructed to contain 50% genuine contradictions and 50% seeming ones.

Previous research in CD presented results on manually selected data sets with a relatively balanced mix of positive and negative instances. As Figure 4 suggests, this is a much easier problem than CD "in the wild". The data gathered from the Web is badly skewed, containing only 1.2% genuine contradictions.

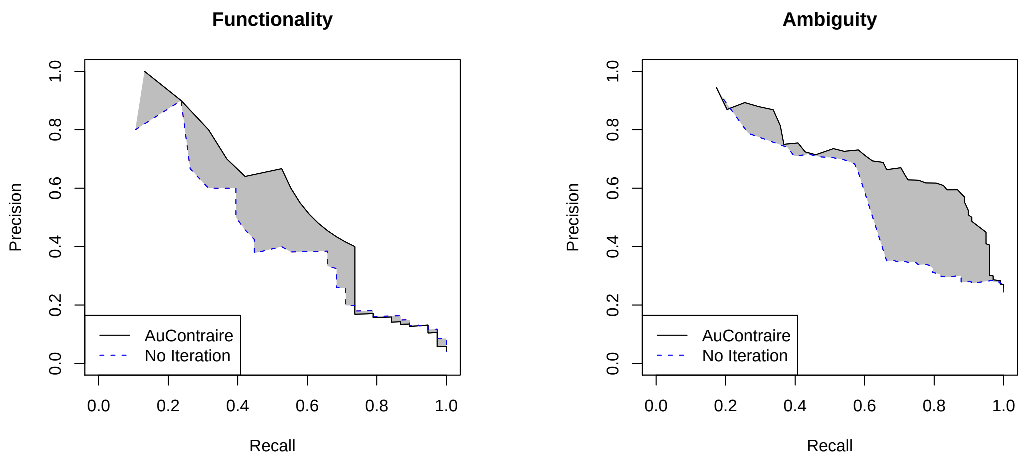

Figure 3: After 5 iterations of EM, AUCONTRAIRE achieves a 19% boost to area under the precision-recall curve (AUC) for functionality detection, and a 31% boost to AUC for ambiguity detection.

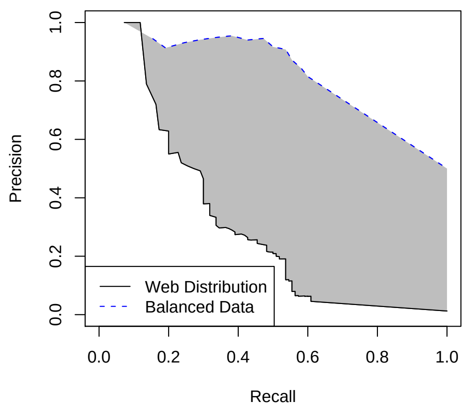

Figure 4: Performance of AUCONTRAIRE at distinguishing genuine contradictions from false positives. The bold line is results on the actual distribution of data from the Web. The dashed line is from a data set constructed to have 50% positive and 50% negative instances.

5.4 Contribution of Knowledge Sources

We carried out an ablation study to quantify how much each knowledge source contributes to AUCONTRAIRE's performance. Since most of the knowledge sources do not apply to numeric argument values, we excluded the extractions where y is a number in this study. As shown in Figure 5, performance of AUCONTRAIRE degrades with no knowledge of synonyms (NS), with no knowledge of meronyms (NM), and especially without argument typing (NT). Conversely, improvements to any of these three components would likely improve the performance of AUCONTRAIRE.

The relatively small drop in performance from no meronyms does not indicate that meronyms are not essential to our task, only that our knowledge sources for meronyms were not as useful as we hoped. The Tipster Gazetteer has surprisingly low coverage for our data set. It contains only 41% of the y values that are locations. Many of these are matches on a different location with the same name, which results in incorrect meronym information. We estimate that a gazetteer with complete coverage would *increase* area under the curve by approximately 40% compared to a system with meronyms from the Tipster Gazetteer and WordNet.

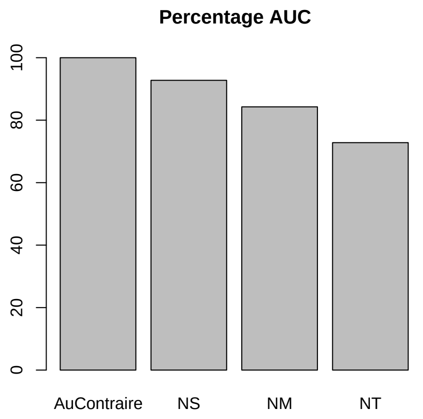

Figure 5: Area under the precision-recall curve for the full AUCONTRAIRE and for AUCONTRAIRE with knowledge removed. NS has no synonym knowledge; NM has no meronym knowledge; NT has no argument typing.

To analyze the errors made by AUCONTRAIRE, we hand-labeled all false-positives at the point of maximum F-score: 29% Recall and 48% Precision.

Figure 6 reveals the central importance of world knowledge for the CD task. About half of the errors (49%) are due to ambiguous x-arguments, which we found to be one of the most persistent obstacles to discovering genuine contradictions. A sizable portion is due to missing meronyms (34%) and missing synonyms (14%), suggesting that lexical resources with broader coverage than WordNet and the Tipster Gazetteer would substantially improve performance. Surprisingly, only 3% are due to errors in the extraction process.

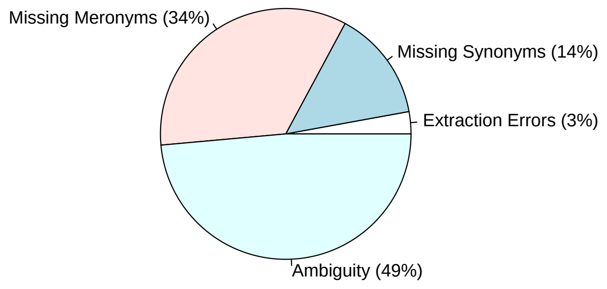

Figure 6: Sources of errors in contradiction detection.

All of our experimental results are based on the automatically discovered set of functions $\mathcal{F}$. We would expect AuContraire's performance to improve substantially if it were given a large set of functional relations as input.

6 Related Work

Condoravdi *et al.* (2003) first proposed contradiction detection as an important NLP task, and Harabagiu *et al.* (2006) were the first to report results on contradiction detection using negation, although their evaluation corpus was a balanced data set built by manually negating entailments in a data set from the Recognizing Textual Entailment conferences (RTE) (Dagan et al., 2005). De Marneffe *et al.* (2008) reported experimental results on a contradiction corpus created by annotating the RTE data sets.

RTE-3 included an optional task, requiring systems to make a 3-way distinction: {entails, contradicts, neither} (Voorhees, 2008). The average performance for contradictions on the RTE-3 was precision 0.11 at recall 0.12, and the best system had precision 0.23 at recall 0.19. We did not run AuContraire on the RTE data sets because they contained relatively few of the "functional contradictions" that AuContraire tackles. On our Web-based data sets, we achieved a precision of 0.62 at recall 0.19, and precision 0.92 at recall 0.51 on the balanced data set. Of course, comparisons across very different data sets are not meaningful, but merely serve to underscore the difficulty of the CD task.

In contrast to previous work, AuContraire is the first to do CD on data automatically extracted from the Web. This is a much harder problem than using an artificially balanced data set, as shown in Figure 4.

Automatic discovery of functional relations has been addressed in the database literature as *Functional Dependency Mining* (Huhtala et al., 1999; Yao and Hamilton, 2008). This focuses on discovering functional relationships between sets of attributes, and does not address the ambiguity inherent in natural language.

7 Conclusions and Future Work

We have described a case study of contradiction detection (CD) based on functional relations. In this context, we introduced and evaluated the AuContraire system and its novel EM-style algorithm for determining whether an arbitrary phrase is functional. We also created a unique "natural" data set of *seeming contradictions* based on sentences drawn from a Web corpus, which we make available to the research community.

We have drawn two key lessons from our case study. First, many seeming contradictions (approximately 99% in our experiments) are not genuine contradictions. Thus, the CD task may be much harder on natural data than on RTE data as suggested by Figure 4. Second, extensive background knowledge is necessary to tease apart seeming contradictions from genuine ones. We believe that these lessons are broadly applicable, but verification of this claim is a topic for future work.

Abstract

Regular expressions have served as the dominant workhorse of practical information extraction for several years. However, there has been little work on reducing the manual effort involved in building high-quality, complex regular expressions for information extraction tasks. In this paper, we propose ReLIE, a novel transformation-based algorithm for learning such complex regular expressions. We evaluate the performance of our algorithm on multiple datasets and compare it against the CRF algorithm. We show that ReLIE, in addition to being an order of magnitude faster, outperforms CRF under conditions of limited training data and cross-domain data. Finally, we show how the accuracy of CRF can be improved by using features extracted by ReLIE.

1 Introduction

A large class of entity extraction tasks can be accomplished by the use of carefully constructed regular expressions (regexes). Examples of entities amenable to such extractions include *email addresses* and *software names* (web collections), *credit card numbers* and *social security numbers* (email compliance), and *gene and protein names* (bioinformatics), etc. These entities share the characteristic that their key representative patterns (features) are expressible in standard constructs of regular expressions. At first glance, it may seem that constructing a regex to extract such entities is fairly straightforward. In reality, robust extraction requires the use of rather complex expressions, as illustrated by the following example.

Example 1 (Phone number extraction)**.** *An obvious pattern for identifying phone numbers is "blocks of digits separated by hyphens" represented as* R_1 = `(\d+\-)+\d+`.[1] *While* R_1 *matches valid phone numbers like* 800-865-1125 *and* 725-1234, *it suffers from both "precision" and "recall" problems. Not only does* R_1 *produce incorrect matches (e.g., social security numbers like* 123-45-6789*), it also fails to identify valid phone numbers such as* 800.865.1125*, and* (800)865-CARE. *An improved regex that addresses these problems is* R_2 = `(\d{3}[-.\ ()]){1,2}[\dA-Z]{4}`.

While multiple machine learning approaches have been proposed for information extraction in recent years (McCallum et al., 2000; Cohen and McCallum, 2003; Klein et al., 2003; Krishnan and Manning, 2006), manually created regexes remain a widely adopted practical solution for information extraction (Appelt and Onyshkevych, 1998; Fukuda et al., 1998; Cunningham, 1999; Tanabe and Wilbur, 2002; Li et al., 2006; DeRose et al., 2007; Zhu et al., 2007). Yet, with a few notable exceptions, which we discuss later in Section 1.1, there has been very little work in reducing this human effort through the use of automatic learning techniques. In this paper, we propose a novel formulation of the problem of learn-

[*]Supported in part by NSF 0438909 and NIH 1-U54-DA021519.

[1]Throughout this paper, we use the syntax of the standard Java regex engine (Java, 2008).

ing regexes for information extraction tasks. We demonstrate that high quality regex extractors can be learned with significantly reduced manual effort. To motivate our approach, we first discuss prior work in the area of learning regexes and describe some of the limitations of these techniques.

1.1 Learning Regular Expressions

The problem of inducing regular languages from positive and negative examples has been studied in the past, even outside the context of information extraction (Alquezar and Sanfeliu, 1994; Dupont, 1996; Firoiu et al., 1998; Garofalakis et al., 2000; Denis, 2001; Denis et al., 2004; Fernau, 2005; Galassi and Giordana, 2005; Bex et al., 2006). Much of this work assumes that the target regex is small and compact thereby allowing the learning algorithm to exploit this information. Consider, for example, the learning of patterns motivated by DNA sequencing applications (Galassi and Giordana, 2005). Here the input sequence is viewed as multiple atomic events separated by gaps. Since each atomic event is easily described by a small and compact regex, the problem reduces to one of learning simple regexes. Similarly, in XML DTD inference (Garofalakis et al., 2000; Bex et al., 2006), it is possible to exploit the fact that the XML documents of interest are often described using simple DTDs. E.g., in an online books store, each book has a title, one or more authors and price. This information can be described in a DTD as $\langle \mathsf{book} \rangle \leftarrow \langle \mathsf{title} \rangle \langle \mathsf{author} \rangle + \langle \mathsf{price} \rangle$. However, as shown in Example 1, regexes for information extraction rely on more complex constructs.

In the context of information extraction, prior work has concentrated primarily on learning regexes over relatively small alphabet sizes. A common theme in (Soderland, 1999; Ciravegna, 2001; Wu and Pottenger, 2005; Feldman et al., 2006) is the problem of learning regexes over tagged tokens produced by other text-processing steps such as POS tagging, morphological analysis, and gazetteer matching. Thus, the alphabet is defined by the space of possible tags output by these analysis steps. A similar approach has been proposed in (Brill, 2000) for POS disambiguation. In contrast, our paper addresses extraction tasks that require "fine-grained" control to accurately capture the structural features of the entity of interest. Consequently, the domain of interest consists of *all characters* thereby dramatically increasing the size of the alphabet. To enable this scale-up, the techniques presented in this paper exploit advanced syntactic constructs (such as character classes and quantifiers) supported by modern regex languages.

Finally, we note that almost all of the above described work define the learning problem over a restricted class of regexes. Typically, the restrictions involve either disallowing or limiting the use of Kleene disclosure and disjunction operations. However, our work imposes no such restrictions.

1.2 Contributions

In a key departure from prior formulations, the learning algorithm presented in this work takes as input not just labeled examples but also an *initial regular expression*. The use of an initial regex has two major advantages. First, this expression provides a natural mechanism for a domain expert to provide domain knowledge about the structure of the entity being extracted. Second, as we show in Section 2, the space of output regular expressions under consideration can be meaningfully restricted by appropriately defining their relationship to the input expression. Such a principled approach to restrict the search space permits the learning algorithm to consider complex regexes in a tractable manner. In contrast, prior work defined a tractable search space by placing restrictions on the target class of regular expressions. Our specific contributions are:

- A novel regex learning problem consisting of learning an "improved" regex given an initial regex and labeled examples
- Formulation of this learning task as an optimization problem over a search space of regexes
- ReLIE, a regex learning algorithm that employs transformations to navigate the search space
- Extensive experimental results over multiple datasets to show the effectiveness of ReLIE and a comparison study with the Conditional Random Field (CRF) algorithm
- Finally, experiments that demonstrate the benefits of using ReLIE as a feature extractor for CRF and possibly other machine learning algorithms.

2 The Regex Learning Problem

Consider the task of identifying instances of some entity $\mathcal{E}$. Let R_0 denote the input regex provided by the user and let $\mathrm{M}(R_0, \mathcal{D})$ denote the set of matches obtained by evaluating R_0 over a document collection $\mathcal{D}$. Let $\mathrm{M_p}(R_0,\mathcal{D}) = \{x \in \mathrm{M}(R_0,\mathcal{D}) : x \text{ instance of } \mathcal{E}\}$ and $\mathrm{M_n}(R_0,\mathcal{D}) = \{x \in \mathrm{M}(R_0,\mathcal{D}) : x \text{ not an instance of } \mathcal{E}\}$ denote the set of positive and negative matches for R_0. Note that a match is positive if it corresponds to an instance of the entity of interest and is negative otherwise. The goal of our learning task is to produce a regex that is "better" than R_0 at identifying instances of $\mathcal{E}$.

Given a candidate regex R, we need a mechanism to judge whether R is indeed a better extractor for $\mathcal{E}$ than R_0. To make this judgment even for just the original document collection $\mathcal{D}$, we must be able to label each instance matched by R (i.e., each element of $\mathrm{M}(R,\mathcal{D})$) as positive or negative. Clearly, this can be accomplished if the set of matches produced by R are contained within the set of available labeled examples, i.e., if $\mathrm{M}(R,\mathcal{D}) \subseteq \mathrm{M}(R_0,\mathcal{D})$. Based on this observation, we make the following assumption:

Assumption 1. *Given an input regex R_0 over some alphabet Σ, any other regex R over Σ is a candidate for our learning algorithm only if* $\mathrm{L}(R) \subseteq \mathrm{L}(R_0)$. *(L(R) denotes the language accepted by R).*

Even with this assumption, we are left with a potentially infinite set of candidate regexes from which our learning algorithm must choose one. To explore this set in a principled fashion, we need a mechanism to move from one element in this space to another, i.e., from one candidate regex to another. In addition, we need an objective function to judge the extraction quality of each candidate regex. We address these two issues below.

Regex Transformations To systematically explore the search space, we introduce the concept of *regex transformations*.

Definition 1 (Regex Transformation). *Let $\mathcal{R}_\Sigma$ denote the set of all regular expressions over some alphabet Σ. A regex transformation is a function $\boldsymbol{T} : \mathcal{R}_\Sigma \to 2^{\mathcal{R}_\Sigma}$ such that $\forall R' \in \boldsymbol{T}(R)$, $\mathrm{L}(R') \subseteq \mathrm{L}(R)$.*

For example, by replacing different occurrences of the quantifier + in R_1 from Example 1 with specific ranges (such as `{1,2}` or `{3}`), we obtain expressions such as R_3 = `(\d+\-){1,2}\d+` and R_4 = `(\d{3}\-)+\d+`. The operation of replacing quantifiers with restricted ranges is an example of a particular class of transformations that we describe further in Section 3. For the present, it is sufficient to view a transformation as a function applied to a regex R that produces, as output, a set of regexes that accept sublanguages of $\mathrm{L}(R)$. We now define the search space of our learning algorithm as follows:

Definition 2 (Search Space). *Given an input regex R_0 and a set of transformations $\mathcal{T}$, the search space of our learning algorithm is $\mathcal{T}(R_0)$, the set of all regexes obtained by (repeatedly) applying the transformations in $\mathcal{T}$ to R_0.*

For instance, if the operation of restricting quantifiers that we described above is part of the transformation set, then R_3 and R_4 are in the search space of our algorithm, given R_1 as input.

Objective Function We now define an objective function, based on the well known F-measure, to compare the extraction quality of different candidate regexes in our search space. Using $\mathrm{M_p}(R,\mathcal{D})$ (resp. $\mathrm{M_n}(R,\mathcal{D})$) to denote the set of positive (resp. negative) matches of a regex R, we define

$$\mathrm{precision}(R,\mathcal{D}) = \frac{\mathrm{M_p}(R,\mathcal{D})}{\mathrm{M_p}(R,\mathcal{D}) + \mathrm{M_n}(R,\mathcal{D})}$$

$$\mathrm{recall}(R,\mathcal{D}) = \frac{\mathrm{M_p}(R,\mathcal{D})}{\mathrm{M_p}(R_0,\mathcal{D})}$$

$$\mathcal{F}(R,\mathcal{D}) = \frac{2 \cdot \mathrm{precision}(R,\mathcal{D}) \cdot \mathrm{recall}(R,\mathcal{D})}{\mathrm{precision}(R,\mathcal{D}) + \mathrm{recall}(R,\mathcal{D})}$$

The regex learning task addressed in this paper can now be formally stated as the following optimization problem:

Definition 3 (**Regex Learning Problem**). *Given an input regex R_0, a document collection $\mathcal{D}$, labeled sets of positive and negative examples $\mathrm{M_p}(R_0,\mathcal{D})$ and $\mathrm{M_n}(R_0,\mathcal{D})$, and a set of transformations $\mathcal{T}$, compute the output regex $R_f = \mathrm{argmax}_{R \in \mathcal{T}(R_0)} \mathcal{F}(R,\mathcal{D})$.*

3 Instantiating Regex Transformations

In this section, we describe how transformations can be implemented by exploiting the syntactic constructs of modern regex engines. To help with our description, we introduce the following task:

Example 2 (Software name extraction). *Consider the task of identifying names of software products in text. A simple pattern for this task is: "one or more capitalized words followed by a version number", represented as R_5 =* `([A-Z]\w*\s*)+[Vv]?(\d+\.?)+`.

When applied to a collection of University web pages, we discovered that R_5 identified correct instances such as *Netscape 2.0*, *Windows 2000* and *Installation Designer v1.1*. However, R_5 also extracted incorrect instances such as course numbers (e.g. *ENGLISH 317*), room numbers (e.g. *Room 330*), and section headings (e.g. *Chapter 2.2*). To eliminate spurious matches such as *ENGLISH 317*, let us enforce the condition that "each word is a single upper-case letter followed by one or more lower-case letters". To accomplish this, we focus on the sub-expression of R_5 that identifies capitalized words, R_{5_1} = `([A-Z]\w*\s*)+`, and replace it with $R_{5_{1a}}$ = `([A-Z][a-z]*\s*)+`. The regex resulting from R_5 by replacing R_{5_1} with $R_{5_{1a}}$ will avoid matches such as *ENGLISH 317*.

An alternate way to improve R_5 is by explicitly disallowing matches against strings like *ENGLISH*, *Room* and *Chapter*. To accomplish this, we can exploit the negative lookahead operator supported in modern regex engines. Lookaheads are special constructs that allow a sequence of characters to be checked for matches against a regex without the characters themselves being part of the match. As an example, `(?!`R_a`)`R_b ("`?!`" being the negative lookahead operator) returns matches of regex R_b but only if they do not match R_a. Thus, by replacing R_{5_1} in our original regex with $R_{5_{1b}}$ =`(?! ENGLISH|Room|Chapter)[A-Z]\w*\s*`, we produce an improved regex for software names.

The above examples illustrate the general principle of our transformation technique. In essence, we isolate a sub-expression of a given regex R and modify it such that the resulting regex accepts a sub-language of R. We consider two kinds of modifications – drop-disjunct and include-intersect. In drop-disjunct, we operate on a sub-expression that corresponds to a disjunct and drop one or more operands of that disjunct. In include-intersect, we restrict the chosen sub-expression by intersecting it with some other regex. Formally,

Definition 4 (Drop-disjunct Transformation). *Let $R \in \mathcal{R}_\Sigma$ be a regex of the form $R = R_a\rho(X)R_b$, where $\rho(X)$ denotes the disjunction $R_1|R_2|\ldots|R_n$ of any non-empty set of regexes $X = \{R_1, R_2, \ldots, R_n\}$. The drop-disjunct transformation $\mathrm{DD}(R, X, Y)$ for some $Y \subset X$, $Y \neq \emptyset$ results in the new regex $R_a\rho(Y)R_b$.*

Definition 5 (Include-Intersect Transformation). *Let $R \in \mathcal{R}_\Sigma$ be a regex of the form $R = R_aXR_b$ for some $X \in \mathcal{R}_\Sigma$, $X \neq \emptyset$. The include-intersect transformation $\mathrm{II}(R, X, Y)$ for some $Y \in \mathcal{R}_\Sigma$, $Y \neq \emptyset$ results in the new regex $R_a(X \cap Y)R_b$.*

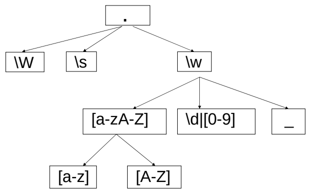

Figure 1: Sample Character Classes in Regex

We state the following proposition (proof omitted in the interest of space) that guarantees that both drop-disjunct and include-intersect restrict the language of the resulting regex, and therefore are valid transformations according to Definition 1.

Proposition 1. *Given regexes R, X_1, Y_1, X_2 and Y_2 from $\mathcal{R}_\Sigma$ such that $\mathrm{DD}(R, X_1, Y_1)$ and $\mathrm{II}(R, X_2, Y_2)$ are applicable, $\mathrm{L}(\mathrm{DD}(R, X_1, Y_1)) \subseteq \mathrm{L}(R)$ and $\mathrm{L}(\mathrm{II}(R, X_2, Y_2)) \subseteq \mathrm{L}(R)$.*

We now proceed to describe how we use different syntactic constructs to apply drop-disjunct and include-intersect transformations.

Character Class Restrictions Character classes are short-hand notations for denoting the disjunction of a set of characters (`\d` is equivalent to `(0|1...|9)`; `\w` is equivalent to `(a|...|z|A|...|Z|0|1...|9|_)`; etc.).[2] Figure 1 illustrates a character class hierarchy in which each node is a stricter class than its parent (e.g., `\d` is stricter than `\w`). A replacement of any of these character classes by one of its descendants is an instance of the *drop-disjunct* transformation. Notice that in Example 2, when replacing R_{5_1} with $R_{5_{1a}}$, we were in effect applying a character class restriction.

Quantifier Restrictions Quantifiers are used to define the range of valid counts of a repetitive sequence. For instance, `a{m,n}` looks for a sequence of `a`'s of length at least `m` and at most `n`. Since quantifiers are also disjuncts (e.g., `a{1,3}` is equivalent to `a|aa|aaa`), the replacement of an expression $R\{m, n\}$ with an expression $R\{m_1, n_1\}$ ($m \leq m_1 \leq n_1 \leq n$) is an instance of the *drop-disjunct* transformation. For example, given a subexpression of the form `a{1,3}`, we can replace it with

[2]Note that there are two distinct character classes `\W` and `\w`

one of `a{1,1}`, `a{1,2}`, `a{2,2}`, `a{2,3}`, or `a{3,3}`. Note that, before applying this transformation, wildcard expressions such as `a+` and `a*` are replaced by `a{0,maxCount}` and `a{1,maxCount}` respectively, where `maxCount` is a user configured maximum length for the entity being extracted.

Negative Dictionaries Observe that the include-intersect transformation (Definition 5) is applicable for every possible sub-expression of a given regex R. Note that a valid *sub-expression* in R is any portion of R where a capturing group can be introduced.[3] Consider a regex $R = R_a X R_b$ with a sub-expression X; the application of *include-intersect* requires another regex Y to yield $R_a(X \cap Y)R_b$. We would like to construct Y such that $R_a(X \cap Y)R_b$ is "better" than R for the task at hand. Therefore, we construct Y as $\neg Y'$ where Y' is a regex constructed from negative matches of R. Specifically, we look at each negative match of R and identify the substring of the match that corresponds to X. We then apply a greedy heuristic (see below) to these substrings to yield a *negative dictionary* Y'. Finally, the transformed regex $R_a(X \cap \neg Y')R_b$ is implemented using the negative lookahead expression R_a`(?! Y')X`R_b.

Greedy Heuristic for Negative Dictionaries Implementation of the above procedure requires certain judicious choices in the construction of the negative dictionary to ensure tractability of this transformation. Let $S(X)$ denote the distinct strings that correspond to the sub-expression X in the negative matches of R.[4] Since any subset of $S(X)$ is a candidate negative dictionary, we are left with an exponential number of possible transformations. In our implementation, we used a greedy heuristic to pick a single negative dictionary consisting of all those elements of $S(X)$ that *individually* improve the F-measure. For instance, in Example 2, if the independent substitution of R_{5_1} with `(?!ENGLISH)[A-Z]\w*\s*`, `(?!Room)[A-Z]\w*\s*`, and `(?!Chapter)[A-Z]\w*\s*` each improves the F-measure, we produce a negative dictionary consisting of `ENGLISH`, `Room`, and `Chapter`. This is precisely how the disjunct `ENGLISH|Room|Chapter` is constructed in $R_{5_{1b}}$.

[3]For instance, the sub-expressions of `ab{1,2}c` are `a`, `ab{1,2}`, `ab{1,2}c`, `b`, `b{1,2}`, `b{1,2}c`, and `c`.

[4]S(X) can be obtained automatically by identifying the substring corresponding to the group X in each entry in $\mathrm{M_n}(R,\mathcal{D})$

```
Procedure ReLIE($\mathcal{M}_{tr}$,$\mathcal{M}_{val}$,$R_0$,$\mathcal{T}$)
// $\mathcal{M}_{tr}$: set of labeled matches used as training data
// $\mathcal{M}_{val}$: set of labeled matches used as validation data
// $R_0$: user-provided regular expression
// $\mathcal{T}$: set of transformations
begin
 1. $R_{new} = R_0$
 2. do {
 3.     for each transformation $t_i \in \mathcal{T}$
 4.         Candidate$_i$=ApplyTransformations($R_{new}, t_i$)
 5.     let Candidates = $\bigcup_i$ Candidate$_i$
 6.     let $R'$ = $\text{argmax}_{R \in \text{Candidates}} \mathcal{F}(R, \mathcal{M}_{tr})$
 7.     if ($\mathcal{F}(R', \mathcal{M}_{tr}) <= \mathcal{F}(R_{new}, \mathcal{M}_{tr})$) return $R_{new}$
 8.     if ($\mathcal{F}(R', \mathcal{M}_{val}) < \mathcal{F}(R_{new}, \mathcal{M}_{val})$) return $R_{new}$
 9.     $R_{new}$ = $R'$
10. } while(true)
end
```

Figure 2: ReLIE Search Algorithm

4 ReLIE Search Algorithm

Figure 2 describes the ReLIE algorithm for the Regex Learning Problem (Definition 3) based on the transformations described in Section 3. ReLIE is a greedy hill climbing search procedure that chooses, at every iteration, the regex with the highest F-measure. An iteration in ReLIE consists of:

- Applying every transformation on the current regex R_{new} to obtain a set of candidate regexes
- From the candidates, choosing the regex R' whose F-measure over the training dataset is maximum

To avoid overfitting, ReLIE terminates when either of the following conditions is true: (i) there is no improvement in F-measure over the training set; (ii) there is a drop in F-measure when applying R' on the validation set.

The following proposition provides an upper bound for the running time of the ReLIE algorithm.

Proposition 2. *Given any valid set of inputs $\mathcal{M}_{tr}$, $\mathcal{M}_{val}$, R_0, and $\mathcal{T}$, the ReLIE algorithm terminates in at most $|\,\mathrm{M_n}(R_0, \mathcal{M}_{tr})|$ iterations. The running time of the algorithm $T_{Total}(R_0, \mathcal{M}_{tr}, \mathcal{M}_{val}) \leq |\,\mathrm{M_n}(R_0, \mathcal{M}_{tr})| * t_0$, where t_0 is the time taken for the first iteration of the algorithm.*

Proof. With reference to Figure 2, in each iteration, the F-measure of the "best" regex R' is strictly better than R_{new}. Since $L(R') \subseteq L(R_{new})$, R' eliminates at least one additional negative match compared to R_{new}. Hence, the maximum number of iterations is $|\,\mathrm{M_n}(R_0, \mathcal{M}_{tr})|$.

For a regular expression R, let $n_{cc}(R)$ and $n_q(R)$ denote, respectively, the number of character classes and quantifiers in R. The maximum number of possible sub-expressions in R is $|R|^2$, where $|R|$ is the length of R. Let $MaxQ(R)$ denote the maximum number of ways in which a single quantifier appearing in R can be restricted to a smaller range. Let F_{cc} denote the maximum fanout[5] of the character class hierarchy. Let $T_{ReEval}(\mathcal{D})$ denote the average time taken to evaluate a regex over dataset $\mathcal{D}$.

Let R_i denote the regex at the beginning of iteration i. The number of candidate regexes obtained by applying the three transformations is

$$\textit{NumRE}(R_i, \mathcal{M}_{tr}) \leq n_{cc}(R_i) * F_{cc} + n_q(R_i) * \textit{MaxQ}(R_i) + |R_i|^2$$

The time taken to enumerate the character class and quantifier restriction transformations is proportional to the resulting number of candidate regexes. The time taken for the negative dictionaries transformation is given by the running time of the greedy heuristic (Section 3). The total time taken to enumerate all candidate regexes is given by (for some constant c)

$$T_{Enum}(R_i, \mathcal{M}_{tr}) \leq c * (n_{cc}(R_i) * F_{cc} + n_q(R_i) * \textit{MaxQ}(R_i) + |R_i|^2 * \mathrm{M_n}(R_i, \mathcal{M}_{tr}) * T_{ReEval}(\mathcal{M}_{tr}))$$

Choosing the best transformation involves evaluating each candidate regex over the training and validation corpus and the time taken for this step is

$$T_{PickBest}(R_i, \mathcal{M}_{tr}, \mathcal{M}_{val}) = \textit{NumRE}(R_i, \mathcal{M}_{tr}) * (T_{ReEval}(\mathcal{M}_{tr}) + T_{ReEval}(\mathcal{M}_{val}))$$

The total time taken for an iteration can be written as

$$T_I(R_i, \mathcal{M}_{tr}, \mathcal{M}_{val}) = T_{Enum}(R_i, \mathcal{M}_{tr}) + T_{PickBest}(R_i, \mathcal{M}_{tr}, \mathcal{M}_{val})$$

It can be shown that the time taken in each iteration decreases monotonically (details omitted in the interest of space). Therefore, the total running time of the algorithm is given by

$$T_{Total}(R_0, \mathcal{M}_{tr}, \mathcal{M}_{val}) = \sum T_I(R_i, \mathcal{M}_{tr}, \mathcal{M}_{val}) \leq |\mathrm{M_n}(R_0, \mathcal{M}_{tr})| * t_0.$$

where $t_0 = T_I(R_0, \mathcal{M}_{tr}, \mathcal{M}_{val})$ is the running time of the first iteration of the algorithm. $\square$

5 Experiments

In this section, we present an empirical study of the ReLIE algorithm using four extraction tasks over three real-life data sets. The goal of this study is to evaluate the effectiveness of ReLIE in learning complex regexes and to investigate how it compares with standard machine learning algorithms.

5.1 Experimental Setup

Data Set The datasets used in our experiments are:

- **`EWeb:`** A collection of 50,000 web pages crawled from a corporate intranet.
- **`AWeb:`** A set of 50,000 web pages obtained from the publicly available University of Michigan Web page collection (Li et al., 2006), including a subcollection of 10,000 pages (**`AWeb-S`**).
- **`Email:`** A collection of 10,000 emails obtained from the publicly available Enron email collection (Minkov et al., 2005).

Extraction Tasks *SoftwareNameTask*, *CourseNumberTask* and *PhoneNumberTask* were evaluated on `EWeb`, `AWeb` and `Email`, respectively. Since web pages have large number of URLs, to keep the labeling task manageable, *URLTask* was evaluated on `AWeb-S`.

Gold Standard For each task, the gold standard was created by manually labeling all matches for the initial regex. Note that only exact matches with the gold standard are considered correct in our evaluations. [6]

Comparison Study To evaluate ReLIE for entity extraction vis-a-vis existing algorithms, we used the popular conditional random field (CRF). Specifically, we used the MinorThird (Cohen, 2004) implementation of CRF to train models for all four extraction tasks. For training the CRF we provided it with the set of positive and negative matches from the initial regex with a context of 200 characters on either side of each match[7]. Since it is unlikely that useful features are located far away from the entity, we believe that 200 characters on either side is sufficient context. The CRF used the base features described in (Cohen et al., 2005). To ensure fair comparison with ReLIE, we also included the matches corresponding to the input regex as a feature to the CRF. In practice, more complex features (e.g., dictionaries, simple regexes) derived by domain experts are often provided to CRFs. However, such features can also be used to refine the initial regex given to ReLIE. Hence, with a view to investigating the "raw" learning capability of the two approaches, we chose to run all our experiments without any additional manually derived features. In fact, the patterns learned by ReLIE through transformations are often similar

[5]Fanout is the number of ways in which a character class may be restricted as defined by the hierarchy (e.g. Figure 1).

[6]The labeled data will be made publicly available at `http://www.eecs.umich.edu/db/regexLearning/`.

[7]Ideally, we would have preferred to let MinorThird extract appropriate features from complete documents in the training-set but could not get it to load our large datasets.

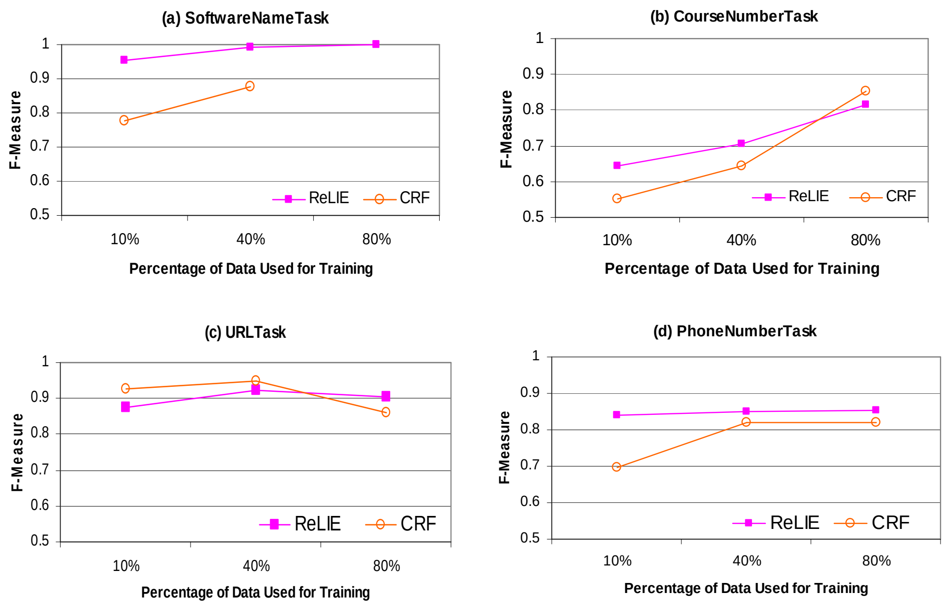

Figure 3: Extraction Quality[a]

[a]For *SoftwareNameTask*, with 80% training data we could not obtain results for CRF as the program failed repeatedly during the training phase.

to the features that domain experts may provide to CRF. We will revisit this issue in Section 5.4.

Evaluation We used the standard F-measure to evaluate the effectiveness of ReLIE and CRF. We divided each dataset into 10 equal parts and used X% of the dataset for training (X=10, 40 and 80), 10% for validation, and remaining (90-X)% for testing. All results are reported on the test set.

5.2 Results

Four extraction tasks were chosen to reflect the entities commonly present in the three datasets.

- *SoftwareNameTask*: Extracting software names such as Lotus Notes 8.0, Open Office Suite 2007.
- *CourseNumberTask*: Extracting university course numbers such as EECS 584, Pharm 101.
- *PhoneNumberTask*: Extracting phone numbers such as 1-800-COMCAST, (425)123 5678.
- *URLTask*: Extracting URLs such as http:\\www.abc.com and lsa.umich.edu/ foo/.[8]

This section summarizes the results of our empirical evaluation comparing ReLIE and CRF.

Raw Extraction Quality The cross-validated results across all four tasks are presented in Figure 3.

- With 10% training data, ReLIE outperforms CRF on three out of four tasks with a difference in F-measure ranging from 0.1 to 0.2.
- As training data increases, both algorithms perform better with the gap between the two reducing for all the four tasks. For *CourseNumberTask* and *URLTask*, CRF does slightly better than ReLIE for larger training dataset. For the other two tasks, ReLIE retains its advantage over CRF.[9]

The above results indicate that ReLIE performs comparably with CRF with a slight edge in conditions of limited training data. Indeed, the capability to learn high-quality extractors using a small training set is important because labeled data is often expensive to obtain. For precisely this same reason, we would ideally like to learn the extractors once and then apply them to other datasets as needed. Since these other datasets may be from a different domain, we next performed a cross-domain test (i.e., training

[8]*URLTask* may appear to be simplistic. However, extracting URLs without the leading protocol definitions (e.g. `http`) can be challenging.

[9]For *SoftwareNameTask*, with 80% training data we could not obtain results for CRF as the program failed repeatedly during the training phase.

and testing on different domains).

Cross-domain Evaluation Table 1 summarizes the results of training the algorithms on one data set and testing on another. The scenarios chosen are: (i) *SoftwareNameTask* trained on `EWeb` and tested on `AWeb`, (ii) *URLTask* trained on `AWeb` and tested on `Email`, and (iii) *PhoneNumberTask* trained on `Email` and tested on `AWeb`.[10] We can see that ReLIE significantly outperforms CRF for all three tasks, even when provided with a large training dataset. Compared to testing on the same dataset, there is a reduction in F-measure (less than 0.1 in many cases) when the regex learned by ReLIE is applied to a different dataset, while the drop for CRF is much more significant (over 0.5 in many cases).[11]

Task(Training, Testing) \ Data for Training	10%		40%		80%	
	ReLIE	CRF	ReLIE	CRF	ReLIE	CRF
SoftwareNameTask(`EWeb`,`AWeb`)	**0.920**	0.297	**0.977**	0.503	**0.971**	N/A
URLTask(`AWeb-S`,`Email`)	**0.690**	0.209	**0.784**	0.380	**0.801**	0.507
PhoneNumberTask(`Email`,`AWeb`)	**0.357**	0.130	**0.475**	0.125	**0.513**	0.120

Table 1: Cross Domain Test (F-measure).

Technique	*SoftwareNameTask*		*CourseNumberTask*		*URLTask*		*PhoneNumberTask*	
	training	testing	training	testing	training	testing	training	testing
ReLIE	511.7	20.6	69.3	18.4	73.8	7.7	39.4	1.1
CRF	7597.0	2315.8	482.5	75.4	438.7	53.8	434.8	57.7
$\frac{t(\text{ReLIE})}{t(\text{CRF})}$	0.067	0.009	0.144	0.244	0.168	0.143	0.091	0.019

Table 2: Average Training/Testing Time (sec)(with 40% data for training)

Task(Extra Feature) \ Data for Training	10%		40%		80%	
	CRF	C+RL	CRF	C+RL	CRF	C+RL
CourseNumberTask(Negative Dictionary)	0.553	**0.624**	0.644	**0.764**	**0.854**	0.845
PhoneNumberTask(Quantifier)	0.695	**0.893**	0.820	**0.937**	0.821	**0.964**

Table 3: ReLIE as Feature Extractor (C+RL is CRF enhanced with features learned by ReLIE).

Training Time Another issue of practical consideration is the efficiency of the learning algorithm. Table 2 reports the average training and testing time for both algorithms on the four tasks. On average ReLIE is *an order of magnitude faster* than CRF in both building the model and applying the learnt model.

Robustness to Variations in Input Regexes The transformations done by ReLIE are based on the structure of the input regex. Therefore given different input regexes, the final regexes learned by ReLIE will be different. To evaluate the impact of the structure of the input regex on the quality of the regex learned by ReLIE, we started with different regexes[12]

for the same task. We found that ReLIE is robust to variations in input regexes. For instance, on *SoftwareNameTask*, the standard deviation in F-measure of the final regexes generated from six different input regexes was less than 0.05. Further details of this experiment are omitted in the interest of space.

5.3 Discussion

The results of our comparison study (Figure 3) indicates that for raw extraction quality ReLIE has a slight edge over CRF for small training data. However, in cross-domain performance (Table 1) ReLIE is significantly better than CRF (by 0.41 on average) . To understand this discrepancy, we examined the final regex learned by ReLIE and compared that with the features learned by CRF. Examples of initial regexes with corresponding final regexes learnt by ReLIE with 10% training data are listed in Table 4. Recall, from Section 3, that ReLIE transformations include character class restrictions, quantifier restrictions and addition of negative dictionaries. For instance, in the *SoftwareNameTask*, the final regex listed was obtained by restricting `[a-zA-Z]` to `[a-z]`, `\w` to `[a-zA-Z]`, and adding the negative dictionary `(Copyright|Fall|···|Issue)`. Similarly, for the *PhoneNumberTask*, the final regex involved two negative dictionaries (expressed as `(?![,])` and `(?![,:])`) [13] and quantifier restrictions (e.g. the first `[A-Z\d]{2,4}` was transformed

[10]We do not report results for *CourseNumberTask* as course numbers are specific to academic webpages and do not appear in the other two domains

[11]Similar cross-domain performance deterioration for a machine learning approach has been observed by (Guo et al., 2006).

[12]Recall that the search space of ReLIE is limited by $L(R_0)$ (Assumption 1). Thus to ensure meaningful comparison, for the same task any two given input regexes R_0 and R'_0 are chosen in such a way that although their structures are different, $\mathrm{M_p}(R_0, \mathcal{D}) = \mathrm{M_p}(R'_0, \mathcal{D})$ and $\mathrm{M_n}(R_0, \mathcal{D}) = \mathrm{M_n}(R'_0, \mathcal{D})$.

[13]To obtain these negative dictionaries, ReLIE not only needs to correctly identify the dictionary entries from negative matches but also has to place the corresponding negative lookahead expression at the appropriate place in the regex.

SoftwareNameTask	R_0	`\b([A-Z][a-zA-Z]{1,10}\s){1,5}\s*(\w{0,2}\d[\.]?){1,4}\b`
	R_{final}	`\b((?!(Copyright|Page|Physics|Question|···|Article|Issue))[A-Z][a-z]{1,10}\s){1,5}\s*([a-zA-Z]{0,2}\d[\.]?){1,4}\b`
PhoneNumberTask	R_0	`\b(1\W+)?\W?\d{3,3}\W*\s*\W?[A-Z\d]{2,4}\s*\W?[A-Z\d]{2,4}\b`
	R_{final}	`\b(1\W+)?\W?\d{3,3}((?![,])\W*)\s*\W?[A-Z\d]{3,3}\s*((?![,:])\W?)[A-Z\d]{3,4}\b`
CourseNumberTask	R_0	`\b([A-Z][a-zA-Z]+)\s+\d{3,3}\b`
	R_{final}	`\b(((?!(At|Between|···Contact|Some|Suite|Volume))[A-Z][a-zA-Z]+))\s+\d{3,3}\b`
URLTask	R_0	`\b(\w+://)?(\w+\.){0,2}\w+\.\w+(/[^\s]+){0,20}\b`
	R_{final}	`\b((?!(Response_20010702_1607.csv|···))((\w+://)?(\w+\.){0,2}\w+\.(?!(ppt|···doc))[a-zA-Z]{2,3}))(/[^\s]+){0,20}\b`

Table 4: Sample Regular Expressions Learned by ReLIE(R_0: input regex; R_{final}: final regex learned; the parts of R_0 modified by ReLIE and the corresponding parts in R_{final} are highlighted.)

into `[A-Z\d]{3,3}`).

After examining the features learnt by CRF, it was clear that while CRF could learn features such as the negative dictionary it is unable to learn character-level features. This should not be surprising since our CRF was trained with primarily tokens as features (cf. Section 5.1). While this limitation was less of a factor in experiments involving data from the same domain (some effects were seen with smaller training data), it does explain the significant difference between the two algorithms in cross-domain tasks where the vocabulary can be significantly different. Indeed, in practical usage of CRF, the main challenge is to come up with additional complex features (often in the form of dictionary and regex patterns) that need to be given to the CRF (Minkov et al., 2005). Such complex features are largely hand-crafted and thus expensive to obtain. Since the ReLIE transformations are operations over characters, a natural question to ask is: "Can the regex learned by ReLIE be used to provide features to CRF?" We answer this question below.

5.4 ReLIE as Feature Extractor for CRF

To understand the effect of incorporating ReLIE-identified features into CRF, we chose the two tasks (*CourseNumberTask* and *PhoneNumberTask*) with the least F-measure in our experiments to determine raw extraction quality. We examined the final regex produced by ReLIE and manually extracted portions to serve as features. For example, the negative dictionary learned by ReLIE for the *CourseNumberTask* `(At|Between|···|Volume)` was incorporated as a feature into CRF. To help isolate the effects, for each task, we only incorporated features corresponding to a single transformation: negative dictionaries for *CourseNumberTask* and quantifier restrictions for *PhoneNumberTask*. The results of these experiments are shown in Table 3. The first point worthy of note is that performance has improved in all but one case. Second, despite the F-measure on *CourseNumberTask* being lower than *PhoneNumberTask* (presumably more potential for improvement), the improvements on *PhoneNumberTask* are significantly higher. This observation is consistent with our conjecture in Section 5.1 that CRF learns token-level features; therefore incorporating negative dictionaries as extra feature provides only limited improvement. Admittedly more experiments are needed to understand the full impact of incorporating ReLIE-identified features into CRF. However, we do believe that this is an exciting direction of future research.

6 Summary and Future Work

We proposed a novel formulation of the problem of learning complex character-level regexes for entity extraction tasks. We introduced the concept of regex transformations and described how these could be realized using the syntactic constructs of modern regex languages. We presented ReLIE, a powerful regex learning algorithm that exploits these ideas. Our experiments demonstrate that ReLIE is very effective for certain classes of entity extraction, particularly under conditions of cross-domain and limited training data. Our preliminary results also indicate the possibility of using ReLIE as a powerful feature extractor for CRF and other machine learning algorithms. Further investigation of this aspect of ReLIE presents an interesting avenue of future work.

Modeling Annotators: A Generative Approach to Learning from Annotator Rationales[*]

Omar F. Zaidan and **Jason Eisner**
Dept. of Computer Science, Johns Hopkins University
Baltimore, MD 21218, USA
{ozaidan,jason}@cs.jhu.edu

Abstract

A human annotator can provide hints to a machine learner by highlighting contextual "rationales" for each of his or her annotations (Zaidan et al., 2007). How can one exploit this side information to better learn the desired parameters θ? We present a generative model of how a given annotator, knowing the true θ, stochastically chooses rationales. Thus, observing the rationales helps us infer the true θ. We collect substring rationales for a sentiment classification task (Pang and Lee, 2004) and use them to obtain significant accuracy improvements for each annotator. Our new generative approach exploits the rationales more effectively than our previous "masking SVM" approach. It is also more principled, and could be adapted to help learn other kinds of probabilistic classifiers for quite different tasks.

1 Background

Many recent papers aim to reduce the amount of annotated data needed to train the parameters of a statistical model. Well-known paradigms include active learning, semi-supervised learning, and either domain adaptation or cross-lingual transfer from existing annotated data.

A rather different paradigm is to change the actual *task* that is given to annotators, giving them a greater hand in shaping the learned classifier. After all, human annotators themselves are more than just black-box classifiers to be run on training data. They possess some introspective knowledge about their own classification procedure. The hope is to mine this knowledge rapidly via appropriate questions and use it to help train a machine classifier. *How* to do this, however, is still being explored.

1.1 Hand-crafted rules

An obvious option is to have the annotators directly express their knowledge by hand-crafting rules. This approach remains "data-driven" if the annotators repeatedly refine their system against a corpus of labeled or unlabeled examples. This achieves high performance in some domains, such as NP chunking (Brill and Ngai, 1999), but requires more analytical skill from the annotators. One empirical study (Ngai and Yarowsky, 2000) found that it also required more annotation time than active learning.

1.2 Feature selection by humans

More recent work has focused on statistical classifiers. Training such classifiers faces the "credit assignment problem." Given a training example x with many features, which features are responsible for its annotated class y? It may take many training examples to distinguish useful vs. irrelevant features.[1]

To reduce the number of training examples needed, one can ask annotators to examine or propose some candidate features. This is possible even for the very large feature sets that are typically used in NLP. In document classification, Raghavan et al. (2006) show that feature selection by an oracle could be helpful, and that humans are both rapid and reasonably good at distinguishing highly useful n-gram features from randomly chosen ones, even when viewing these n-grams out of context.

Druck et al. (2008) show annotators some features f from a fixed feature set, and ask them to choose a class label y such that $p(y \mid f)$ is as high as possible. Haghighi and Klein (2006) do the reverse: for each class label y, they ask the annotators to propose a few "prototypical" features f such that $p(y \mid f)$ is as high as possible.

1.3 Feature selection in context

The above methods consider features out of context. An annotator might have an easier time examining

[*]This work was supported by National Science Foundation grant No. 0347822 and the JHU WSE/APL Partnership Fund. Special thanks to Christine Piatko for many useful discussions.

[1]Most NLP systems use thousands or millions of features, because it is helpful to include lexical features over a large vocabulary, often conjoined with lexical or non-lexical context.

features *in context* to recognize whether they appear relevant. This is particularly true for features that are only modestly or only sometimes helpful, which may be abundant in NLP tasks.

Thus, Raghavan et al. (2006) propose an active learning method in which, while classifying a training document, the annotator also identifies some features of *that* document as particularly relevant. E.g., the annotator might highlight particular unigrams as he or she reads the document. In their proposal, a feature that is highlighted in any document is assumed to be globally more relevant. Its dimension in feature space is scaled by a factor of 10 so that this feature has more influence on distances or inner products, and hence on the learned classifier.

1.4 Concerns about marking features

Despite the success of the above work, we have several concerns about asking annotators to identify globally relevant features.

First, a feature in isolation really does not have a well-defined worth. A feature may be useful only in conjunction with other features,[2] or be useful only to the extent that other correlated features are *not* selected to do the same work.

Second, it is not clear how an annotator would easily view and highlight features in context, except for the simplest feature sets. In the phrase Apple shares up 3%, there may be several features that fire on the substring Apple—responding to the string Apple, its case-invariant form apple, its lemma apple- (which would also respond to apples), its context-dependent sense Apple_2, its part of speech noun, etc. How does the annotator indicate which of these features are relevant?

Third, annotating features is only appropriate when the feature set can be easily understood by a human. This is not always the case. It would be hard for annotators to read, write, or evaluate a description of a complex syntactic configuration in NLP or a convolution filter in machine vision.

Fourth, traditional annotation efforts usually try to remain agnostic about the machine learning methods and features to be used. The project's cost is justified by saying that the annotations will be reused by many researchers (perhaps in a "shared task"), who are free to compete on how they tackle the learning problem. Unfortunately, feature annotation commits to a particular feature set at annotation time. Subsequent research cannot easily adjust the definition of the features, or obtain annotation of new features.

2 Annotating Rationales

To solve these problems, we propose that annotators should not *select features* but rather *mark relevant portions of the example*. In earlier work (Zaidan et al., 2007), we called these markings "rationales."

For example, when classifying a movie review as positive or negative, the annotator would also highlight phrases that supported that judgment. Figure 1 shows two such rationales.

A multi-annotator timing study (Zaidan et al., 2007) found that highlighting rationale phrases while reading movie reviews only doubled annotation time, although annotators marked 5–11 rationale substrings in addition to the simple binary class. The benefit justified the extra time. Furthermore, much of the benefit could have been obtained by giving rationales for only a fraction of the reviews.

In the visual domain, when classifying an image as containing a zoo, the annotator might circle some animals or cages and the sign reading "Zoo." The Peekaboom *game* (von Ahn et al., 2006) was in fact built to elicit such approximate yet relevant regions of images. Further scenarios were discussed in (Zaidan et al., 2007): rationale annotation for named entities, linguistic relations, or handwritten digits.

Annotating rationales does not require the annotator to think about the feature space, nor even to know anything about it. Arguably this makes annotation easier and more flexible. It also preserves the reusability of the annotated data. Anyone is free to reuse our collected rationales (section 4) to aid in learning a classifier with richer features, or a different kind of classifier altogether, using either our procedures or novel procedures.

3 Modeling Rationale Annotations

As rationales are more indirect than explicit features, they present a trickier machine learning problem.

[2]For example, a linear classifier can learn that most training examples satisfy $A \rightarrow B$ by setting $\theta_A = -5$ and $\theta_{A \wedge B} = +5$, but this solution requires selecting both A and $A \wedge B$ as features. More simply, a polynomial kernel can consider the conjunction $A \wedge B$ only if both A and B are selected as features.

We wish to learn the parameters θ of some classifier. How can the annotator's rationales help us to do this without many training examples? We will have to exploit a presumed relationship between the rationales and the optimal value of θ (i.e., the value that we would learn on an infinite training set).

This paper exploits an explicit, parametric model of that relationship. The model's parameters ϕ are intended to capture what that annotator is doing when he or she marks rationales. Most importantly, they capture how he or she is influenced by the true θ. Given this, our learning method will prefer values of θ that would adequately explain the rationales (as well as the training classifications).

3.1 A generative approach

For concreteness, we will assume that the task is document classification. Our training data consists of n triples $\{(x_1, y_1, r_1), ..., (x_n, y_n, r_n)\}$), where x_i is a document, y_i is its annotated class, and r_i is its rationale markup. At test time we will have to predict y_{n+1} from x_{n+1}, without any r_{n+1}.

We propose to jointly choose parameter vectors θ and ϕ to maximize the following regularized conditional likelihood:[3]

$$\prod_{i=1}^{n} p(y_i, r_i \mid x_i, \theta, \phi) \cdot p_{\text{prior}}(\theta, \phi) \tag{1}$$
$$\overset{\text{def}}{=} \prod_{i=1}^{n} p_\theta(y_i \mid x_i) \cdot p_\phi(r_i \mid x_i, y_i, \theta) \cdot p_{\text{prior}}(\theta, \phi)$$

Here we are trying to model all the annotations, both y_i and r_i. The first factor predicts y_i using an ordinary probabilistic classifier p_θ, while the novel second factor predicts r_i using a model p_ϕ of how annotators generate the rationale annotations.

The crucial point is that the second factor depends on θ (since r_i is supposed to reflect the relation between x_i and y_i that is modeled by θ). As a result, the learner has an incentive to modify θ in a way that increases the second factor, even if this somewhat decreases the first factor on training data.[4]

After training, one should simply use the first factor $p_\theta(y \mid x)$ to classify test documents x. The second factor is irrelevant for test documents, since they have not been annotated with rationales r.

The second factor may likewise be omitted for any training documents i that have not been annotated with rationales, as there is no r_i to predict in those cases. In the extreme case where no documents are annotated with rationales, equation (1) reduces to the standard training procedure.

3.2 Noisy channel design of rationale models

Like ordinary class annotations, rationale annotations present us with a "credit assignment problem," albeit a smaller one that is limited to features that fire "in the vicinity" of the rationale r. Some of these θ-features were likely responsible for the classification y and hence triggered the rationale. Other such θ-features were just innocent bystanders.

Thus, the interesting part of our model is $p_\phi(r \mid x, y, \theta)$, which models the rationale annotation process. *The rationales r reflect θ, but in noisy ways.*

Taking this noisy channel idea seriously, $p_\phi(r \mid x, y, \theta)$ should consider two questions when assessing whether r is a plausible set of rationales given θ. First, it needs a "language model" of rationales: does r consist of rationales that are well-formed *a priori*, i.e., before θ is considered? Second, it needs a "channel model": does r faithfully signal the features of θ that strongly support classifying x as y?

If a feature contributes heavily to the classification of document x as class y, then the **channel model** should tell us which *parts* of document x tend to be highlighted as a result.

The channel model must know about the particular kinds of features that are extracted by f and scored by θ. Suppose the feature not . . . gripping,[5] with weight θ_h, is predictive of the annotated class y. This raises the probabilities of the annotator's highlighting each of various words, or combinations of words, in a phrase like not the most gripping banquet on film. The channel model parameters in ϕ

[3]It would be preferable to integrate out ϕ (and even θ), but more difficult.

[4]Interestingly, even examples where the annotation y_i is wrong or unhelpful can provide useful information about θ via the pair (y_i, r_i). Two annotators marking the same movie review might disagree on whether it is overall a positive or negative review—but the second factor still allows learning positive features from the first annotator's positive rationales, and negative features from the second annotator's negative rationales.

[5]Our current experiments use only unigram features, to match past work, but we use this example to outline how our approach generalizes to complex linguistic (or visual) features.

should specify how *much* each of these probabilities is raised, based on the magnitude of $\theta_h \in \mathbb{R}$, the class y, and the fact that the feature is an instance of the template <Neg> ... <Adjective>. (Thus, ϕ has no parameters specific to the word gripping; it is a low-dimensional vector that only describes the annotator's general style in translating θ into r.)

The **language model**, however, is independent of the feature set θ. It models what rationales tend to look like in the input domain—e.g., documents or images. In the document case, ϕ should describe: How frequent and how long are typical rationales? Do their edges tend to align with punctuation or major syntactic boundaries in x? Are they rarer in the middle of a document, or in certain documents?[6]

Thanks to the language model, we do not need to posit high θ features to explain every word in a rationale. The language model can "explain away" some words as having been highlighted only because this annotator prefers not to end a rationale in mid-phrase, or prefers to sweep up close-together features with a single long rationale rather than many short ones. Similarly, the language model can help explain why some words, though important, might *not* have been included in any rationale of r.

If there are multiple annotators, one can learn different ϕ parameters for each annotator, reflecting their different annotation styles.[7] We found this to be useful (section 8.2).

We remark that our generative modeling approach (equation (1)) would also apply if r were not rationale markup, but some other kind of so-called "side information," such as the *feature* annotations discussed in section 1. For example, Raghavan et al. (2006) assume that if feature h is relevant—a binary distinction—iff it was selected in at least one document. But it might be more informative to observe that h was selected in 3 of the 10 documents where it appeared, and to predict this via a model $p_\phi(3 \text{ of } 10 \mid \theta_h)$, where ϕ describes (e.g.) how to derive a binomial parameter nonlinearly from θ_h. This approach would not *how often* h was marked and infer *how relevant* is feature h (i.e., infer θ_h). In this case, p_ϕ is a simple channel that transforms relevant features into direct indicators of the feature. Our side information merely requires a more complex transformation—from relevant features into well-formed rationales, modulated by documents.

4 Experimental Data: Movie Reviews

In Zaidan et al. (2007), we introduced the "Movie Review Polarity Dataset Enriched with Annotator Rationales."[8] It is based on the dataset of Pang and Lee (2004),[9] which consists of 1000 positive and 1000 negative movie reviews, tokenized and divided into 10 folds (F_0–F_9). All our experiments use F_9 as their final blind test set.

The enriched dataset adds rationale annotations produced by an annotator A0, who annotated folds F_0–F_8 of the movie review set with rationales (in the form of textual substrings) that supported the gold-standard classifications. We will use A0's data to determine the improvement of our method over a (log-linear) baseline model without rationales. We also use A0 to compare against the "masking SVM" method and SVM baseline of Zaidan et al. (2007).

Since ϕ can be tuned to a particular annotator, we would also like to know how well this works with data from annotators other than A0. We randomly selected 100 reviews (50 positive and 50 negative) and collected both class and rationale annotation data from each of six new annotators A3–A8,[10] following the same procedures as (Zaidan et al., 2007). We report results using only data from A3–A5, since we used the data from A6–A8 as development data in the early stages of our work.

We use this new rationale-enriched dataset[8] to determine if our method works well across annotators. We will only be able to carry out that comparison

[6]Our current experiments do not model this last point. However, we imagine that if the document only has a few θ-features that support the classification, the annotator will probably mark most of them, whereas if such features are abundant, the annotator may lazily mark only a few of the strongest ones. A simple approach would equip ϕ with a different "bias" or "threshold" parameter ϕ_x for each rationale training document x, to modulate the *a priori* probability of marking a rationale in x. By fitting this bias parameter, we deduce how lazy the annotator was (for whatever reason) on document x. If desired, a prior on ϕ_x could consider whether x has many strong θ-features, whether the annotator has recently had a coffee break, etc.

[7]Given insufficient rationale data to recover some annotator's ϕ well, one could smooth using data from other annotators. But in our situation, ϕ had relatively few parameters to learn.

[8]Available at http://cs.jhu.edu/∼ozaidan/rationales.

[9]Polarity dataset version 2.0.

[10]We avoid annotator names A1–A2, which were already used in (Zaidan et al., 2007).

Figure 1: Rationales as sequence annotation: the annotator highlighted two textual segments as rationales for a positive class. Highlighted words in $\vec{x}$ are tagged I in $\vec{r}$, and other words are tagged O. The figure also shows some ϕ-features. For instance, $g_{O(,)\text{-}I}$ is a count of O−I transitions that occur with a comma as the left word. Notice also that g_{rel} is the sum of the underlined values.

at small training set sizes, due to limited data from A3–A8. The larger A0 dataset will still allow us to evaluate our method on a range of training set sizes.

5 Detailed Models

5.1 Modeling class annotations with p_θ

We define the basic classifier p_θ in equation (1) to be a standard conditional log-linear model:

$$p_\theta(y \mid x) \overset{\text{def}}{=} \frac{\exp(\vec{\theta} \cdot \vec{f}(x, y))}{Z_\theta(x)} \overset{\text{def}}{=} \frac{u(x, y)}{Z_\theta(x)} \qquad (2)$$

where $\vec{f}(\cdot)$ extracts a feature vector from a classified document, $\vec{\theta}$ are the corresponding weights of those features, and $Z_\theta(x) \overset{\text{def}}{=} \sum_y u(x, y)$ is a normalizer.

We use the same set of binary features as in previous work on this dataset (Pang et al., 2002; Pang and Lee, 2004; Zaidan et al., 2007). Specifically, let $V = \{v_1, ..., v_{17744}\}$ be the set of word types with count ≥ 4 in the full 2000-document corpus. Define $f_h(x, y)$ to be y if v_h appears at least once in x, and 0 otherwise. Thus $\theta \in \mathbb{R}^{17744}$, and positive weights in θ favor class label $y = +1$ and equally discourage $y = -1$, while negative weights do the opposite.

This standard unigram feature set is linguistically impoverished, but serves as a good starting point for studying rationales. Future work should consider more complex features and how *they* are signaled by rationales, as discussed in section 3.2.

5.2 Modeling rationale annotations with p_ϕ

The rationales collected in this task are textual segments of a document to be classified. The document itself is a word token sequence $\vec{x} = x_1, ..., x_M$. We encode its rationales as a corresponding tag sequence $\vec{r} = r_1, ..., r_M$, as illustrated in Figure 1. Here $r_m \in \{\texttt{I}, \texttt{O}\}$ according to whether the token x_m is **in** a rationale (i.e., x_m was at least partly highlighted) or **outside** all rationales. x_1 and x_M are special boundary symbols, tagged with O.

We predict the full tag sequence $\vec{r}$ at once using a conditional random field (Lafferty et al., 2001). A CRF is just another conditional log-linear model:

$$p_\phi(r \mid x, y, \vec{\theta}) \overset{\text{def}}{=} \frac{\exp(\vec{\phi} \cdot \vec{g}(r, x, y, \vec{\theta}))}{Z_\phi(x, y, \vec{\theta})} \overset{\text{def}}{=} \frac{u(r, x, y, \vec{\theta})}{Z_\phi(x, y, \vec{\theta})}$$

where $\vec{g}(\cdot)$ extracts a feature vector, $\vec{\phi}$ are the corresponding weights of those features, and $Z_\phi(x, y, \vec{\theta}) \overset{\text{def}}{=} \sum_r u(r, x, y, \vec{\theta})$ is a normalizer.

As usual for linear-chain CRFs, $\vec{g}(\cdot)$ extracts two kinds of features: first-order "emission" features that relate r_m to (x_m, y, θ), and second-order "transition" features that relate r_m to r_{m-1} (although some of these also look at x).

These two kinds of features respectively capture the "channel model" and "language model" of section 3.2. The former says r_m is I because x_m is associated with a relevant θ-feature. The latter says r_m is I simply because it is next to another I.

5.3 Emission ϕ-features ("channel model")

Recall that our θ-features (at present) correspond to unigrams. Given $(\vec{x}, y, \vec{\theta})$, let us say that a unigram $w \in \vec{x}$ is **relevant**, **irrelevant**, or **anti-relevant** if $y \cdot \theta_w$ is respectively $\gg 0$, ≈ 0, or $\ll 0$. That is, w is relevant if its presence in x strongly supports the annotated class y, and anti-relevant if its presence strongly supports the opposite class $-y$.

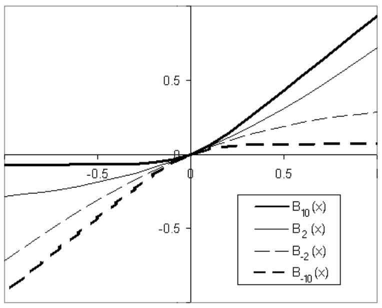

Figure 2: The function family B_s in equation (3), shown for $s \in \{10, 2, -2, -10\}$.

We would like to learn the extent ϕ_{rel} to which annotators try to *include* relevant unigrams in their rationales, and the (usually lesser) extent ϕ_{antirel} to which they try to *exclude* anti-relevant unigrams. This will help us infer $\vec{\theta}$ from the rationales.

The details are as follows. ϕ_{rel} and ϕ_{antirel} are the weights of two emission features extracted by $\vec{g}$:

$$g_{\text{rel}}(\vec{x}, y, \vec{r}, \vec{\theta}) \stackrel{\text{def}}{=} \sum_{m=1}^{M} I(r_m = \mathtt{I}) \cdot B_{10}(y \cdot \theta_{x_m})$$

$$g_{\text{antirel}}(\vec{x}, y, \vec{r}, \vec{\theta}) \stackrel{\text{def}}{=} \sum_{m=1}^{M} I(r_m = \mathtt{I}) \cdot B_{-10}(y \cdot \theta_{x_m})$$

Here $I(\cdot)$ denotes the indicator function, returning 1 or 0 according to whether its argument is true or false. Relevance and negated anti-relevance are respectively measured by the differentiable nonlinear functions B_{10} and B_{-10}, which are defined by

$$B_s(a) = (\log(1 + \exp(a \cdot s)) - \log(2))/s \qquad (3)$$

and graphed in Figure 2. Sample values of B_{10} and g_{rel} are shown in Figure 1.

How does this work? The g_{rel} feature is a sum over all unigrams in the document $\vec{x}$. It does not fire strongly on the irrelevant or anti-relevant unigrams, since B_{10} is close to zero there.[11] But it fires positively on relevant unigrams w if they are tagged with I, and the strength of such firing increases approximately linearly with θ_w. Since the weight $\phi_{\text{rel}} > 0$ in practice, this means that raising a relevant unigram's θ_w (if $y = +1$) will proportionately raise its log-odds of being tagged with I. Symmetrically, since $\phi_{\text{antirel}} > 0$ in practice, lowering an anti-relevant unigram's θ_w (if $y = +1$) will proportionately lower its log-odds of being tagged with I, though not necessarily at the same rate as for relevant unigrams.[12]

Should ϕ also include traditional CRF emission features, which would recognize that particular words like great tend to be tagged as I? No! Such features would undoubtedly do a better job predicting the rationales and hence increasing equation (1). However, crucially, our true goal is not to predict the rationales but to recover the classifier parameters θ. Thus, if great tends to be highlighted, then the model should not be permitted to explain this directly by increasing some feature ϕ_{great}, but only indirectly by increasing θ_{great}. We therefore permit our rationale prediction model to consider only the two emission features g_{rel} and g_{antirel}, which see the words in $\vec{x}$ only through their θ-values.

5.4 Transition ϕ-features ("language model")

Annotators highlight more than just the relevant unigrams. (After all, they aren't told that our current θ-features are unigrams.) They tend to mark full phrases, though perhaps taking care to exclude anti-relevant portions. ϕ models these phrases' shape, via weights for several "language model" features.

Most important are the 4 traditional CRF tag transition features $g_{\mathtt{O}\text{-}\mathtt{O}}, g_{\mathtt{O}\text{-}\mathtt{I}}, g_{\mathtt{I}\text{-}\mathtt{I}}, g_{\mathtt{I}\text{-}\mathtt{O}}$. For example, $g_{\mathtt{O}\text{-}\mathtt{I}}$ *counts* the number of O-to-I transitions in $\vec{r}$ (see Figure 1). Other things equal, an annotator with high $\phi_{\mathtt{O}\text{-}\mathtt{I}}$ is predicted to have many rationales per 1000 words. And if $\phi_{\mathtt{I}\text{-}\mathtt{I}}$ is high, rationales are predicted to be long phrases (including more irrelevant unigrams around or between the relevant ones).

We also learn more refined versions of these features, which consider how the transition probabilities are influenced by the punctuation and syntax of the document $\vec{x}$ (independent of $\vec{\theta}$). These refined features are more specific and hence more sparsely trained. Their weights reflect deviations from the simpler, "backed-off" transition features such as $g_{\mathtt{O}\text{-}\mathtt{I}}$. (Again, see Figure 1 for examples.)

Conditioning on left word. A feature of the form $g_{t_1(v)\text{-}t_2}$ is specified by a pair of tag types $t_1, t_2 \in \{\mathtt{I}, \mathtt{O}\}$ and a vocabulary word type v. It counts the

[11] B_{10} sets the threshold for relevance to be about 0. One could also include versions of the g_{rel} feature that set a higher threshold, using $B_{10}(y \cdot \theta_{x_m} - \text{threshold})$.

[12] If the two rates *are* equal ($\phi_{\text{rel}} = \phi_{\text{antirel}}$), we get a simpler model in which the log-odds change exactly linearly with θ_w for each w, regardless of w's relevance/irrelevance/anti-relevance. This follows from the fact that $B_s(a) + B_{-s}(a)$ simplifies to a.

number of times an t_1–t_2 transition occurs in $\vec{r}$ conditioned on v appearing as the first of the two word tokens where the transition occurs. Our experiments include $g_{t_1(v)\text{-}t_2}$ features that tie `I-O` and `O-I` transitions to the 4 most frequent punctuation marks v (comma, period, ?, !).

Conditioning on right word. A feature $g_{t_1\text{-}t_2(v)}$ is similar, but v must appear as the second of the two word tokens where the transition occurs. Again here, we use $g_{t_1\text{-}t_2(v)}$ features that tie `I-O` and `O-I` transitions to the four punctuation marks mentioned above. We also include five features that tie `O-I` transitions to the words *no*, *not*, *so*, *very*, and *quite*, since in our development data, those words were more likely than others to start rationales.[13]

Conditioning on syntactic boundary. We parsed each rationale-annotated training document (no parsing is needed at test time).[14] We then marked each word bigram x_1-x_2 with three nonterminals: N_{End} is the nonterminal of the largest constituent that contains x_1 and not x_2, N_{Start} is the nonterminal of the largest constituent that contains x_2 and not x_1, and N_{Cross} is the nonterminal of the *smallest* constituent that contains both x_1 and x_2.

For a nonterminal N and pair of tag types (t_1, t_2), we define three features, $g_{t_1\text{-}t_2/\text{E}=N}$, $g_{t_1\text{-}t_2/\text{S}=N}$, and $g_{t_1\text{-}t_2/\text{C}=N}$, which count the number of times a t_1-t_2 transition occurs in $\vec{r}$ with N matching the N_{End}, N_{Start}, or N_{Cross} nonterminal, respectively. Our experiments include these features for 11 common nonterminal types N (DOC, TOP, S, SBAR, FRAG, PRN, NP, VP, PP, ADJP, QP).

6 Training: Joint Optimization of θ and ϕ

To train our model, we use L-BFGS to locally maximize the log of the objective function (1):[15]

$$\sum_{i=1}^{n} \log p_\theta(y_i \mid x_i) - \frac{1}{2\sigma_\theta^2}\|\theta\|^2$$
$$+C\Big(\sum_{i=1}^{n} \log p_\phi(r_i \mid x_i, y_i, \theta)\Big) - \frac{1}{2\sigma_\phi^2}\|\phi\|^2 \qquad (4)$$

This defines p_{prior} from (1) to be a standard diagonal Gaussian prior, with variances σ_θ^2 and σ_ϕ^2 for the two sets of parameters. We optimize σ_θ^2 in our experiments. As for σ_ϕ^2, different values did not affect the results, since we have a large number of $\{$`I`,`O`$\}$ rationale tags to train relatively few ϕ weights; so we simply use $\sigma_\phi^2 = 1$ in all of our experiments.

Note the new C factor in equation (4). Our initial experiments showed that optimizing equation (4) without C led to an increase in the likelihood of the rationale data at the expense of classification accuracy, which degraded noticeably. This is because the second sum in (4) has a much larger magnitude than the first: in a set of 100 documents, it predicts around 74,000 binary $\{$`I`,`O`$\}$ tags, versus the one hundred binary class labels. While we are willing to reduce the log-likelihood of the training classifications (the first sum) to a certain extent, focusing too much on modeling rationales (the second sum) is clearly not our ultimate goal, and so we optimize C on development data to achieve some balance between the two terms of equation (4). Typical values of C range from $\frac{1}{300}$ to $\frac{1}{50}$.[16]

We perform alternating optimization on θ and ϕ:

1. Initialize θ to maximize equation (4) but with $C = 0$ (i.e. based only on class data).
2. Fix θ, and find ϕ that maximizes equation (4).
3. Fix ϕ, and find θ that maximizes equation (4).
4. Repeat 2 and 3 until convergence.

The L-BFGS method requires calculating the gradient of the objective function (4). The partial derivatives with respect to components of θ and ϕ involve calculating expectations of the feature functions, which can be computed in linear time (with respect to the size of the training set) using the forward-backward algorithm for CRFs. The partial derivatives also involve the derivative of (3), to determine how changing θ will affect the firing strength of the emission features g_{rel} and g_{antirel}.

[13]These are the function words with count ≥ 40 in a random sample of 100 documents, and which were associated with the `O-I` tag transition at more than twice the average rate. We do not use any other lexical ϕ-features that reference $\vec{x}$, for fear that they would enable the learner to explain the rationales without changing θ as desired (see the end of section 5.3).

[14]We parse each sentence with the Collins parser (Collins, 1999). Then the document has one big parse tree, whose root is `DOC`, with each sentence being a child of `DOC`.

[15]One might expect this function to be convex because p_θ and p_ϕ are both log-linear models with no hidden variables. However, $\log p_\phi(r_i \mid x_i, y_i, \theta)$ is not necessarily convex in θ.

[16]C also balances our confidence in the classifications y against our confidence in the rationales r; either may be noisy.

7 Experimental Procedures

We report on two sets of experiments. In the first set, we use the annotation data that A3–A5 provided for the small set of 100 documents (as well as the data from A0 on those same 100 documents). In the second set, we used A0's abundant annotation data to evaluate our method with training set sizes up to 1600 documents, and compare it with three other methods: log-linear baseline, SVM baseline, and the SVM masking method of (Zaidan et al., 2007).

7.1 Learning curves

The learning curves reported in section 8.1 are generated exactly as in (Zaidan et al., 2007). Each curve shows classification accuracy at training set sizes $T = 1, 2, ..., 9$ folds (i.e. $200, 400, ..., 1600$ training documents). For a given size T, the reported accuracy is an average of 9 experiments with different subsets of the entire training set, each of size T:

$$\frac{1}{9}\sum_{i=0}^{8} acc(F_9 \mid F_{i+1} \cup \ldots \cup F_{i+T}) \qquad (5)$$

where F_j denotes the fold numbered $j \bmod 9$, and $acc(F_9 \mid Y)$ means classification accuracy on the held-out test set F_9 after training on set Y.

We use an appropriate paired permutation test, detailed in (Zaidan et al., 2007), to test differences in (5). We call a difference significant at $p < 0.05$.

7.2 Comparison to "masking SVM" method

We compare our method to the "masking SVM" method of (Zaidan et al., 2007). Briefly, that method used rationales to construct several so-called *contrast examples* from every training example. A contrast example is obtained by "masking out" one of the rationales highlighted to support the training example's class. A *good* classifier should have more trouble on this modified example. Hence, Zaidan et al. (2007) required the learned SVM to classify each contrast example with a smaller margin than the corresponding original example (and did not require it to be classified correctly).

The masking SVM learner relies on a simple geometric principle; is trivial to implement on top of an existing SVM learner; and works well. However, we believe that the generative method we present here is more interesting and should apply more broadly.

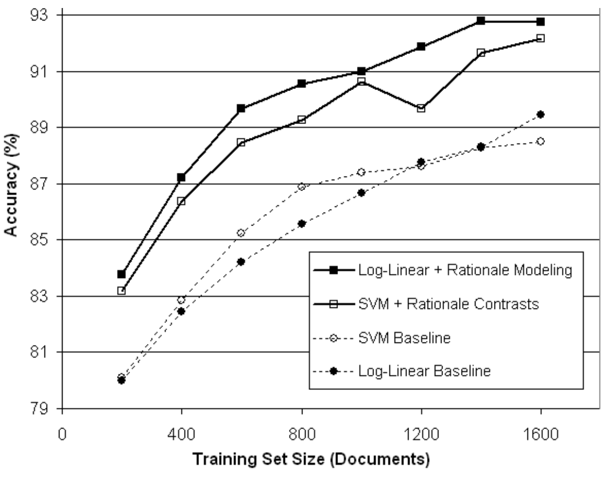

Figure 3: Classification accuracy curves for the 4 methods: the two baseline learners that only utilize class data, and the two learners that also utilize rationale annotations. The SVM curves are from (Zaidan et al., 2007).

First, the masking method is specific to improving an SVM learner, whereas our method can be used to improve any classifier by adding a rationale-based regularizer (the second half of equation (4)) to its objective function during training.

More important, there are tasks where it is unclear how to generate contrast examples. For the movie review task, it was natural to mask out a rationale by pretending its words never occurred in the document. After all, most word types do not appear in most documents, so it is natural to consider the non-presence of a word as a "default" state to which we can revert. But in an image classification task, how should one modify the image's features to ignore some spatial region marked as a rationale? There is usually no natural "default" value to which we could set the pixels. Our method, on the other hand, eliminates contrast examples altogether.

8 Experimental Results and Analysis

8.1 The added benefit of rationales

Fig. 3 shows learning curves for four methods. A log-linear model shows large and significant improvements, at all training sizes, when we incorporate rationales into its training via equation (4). Moreover, the resulting classifier consistently outperforms[17] prior work, the masking SVM, which starts with a slightly better baseline classifier (an SVM) but incorporates the rationales more crudely.

[17]Differences are not significant at sizes 200, 1000, and 1600.

	size	A0	A3	A4	A5
SVM baseline	100	72.0	72.0	72.0	70.0
SVM+contrasts	100	*75.0*	*73.0*	*74.0*	*72.0*
Log-linear baseline	100	71.0	*73.0*	71.0	70.0
Log-linear+rats	100	**76.0**	**76.0**	**77.0**	**74.0**
SVM baseline	20	63.4	*62.2*	60.4	62.6
SVM+contrasts	20	*65.4*	*63.4*	*62.4*	**64.8**
Log-linear baseline	20	63.0	*62.2*	60.2	62.4
Log-linear+rats	20	**65.8**	**63.6**	**63.4**	**64.8**

Table 1: Accuracy rates using each annotator's data. In a given column, a value in *italics* is not significantly different from the highest value in that column, which is **boldfaced**. The size=20 results average over 5 experiments.

To confirm that we could successfully model annotators other than A0, we performed the same comparison for annotators A3–A5; each had provided class and rationale annotations on a small 100-document training set. We trained a separate ϕ for each annotator. Table 1 shows improvements over baseline, usually significant, at 2 training set sizes.

8.2 Analysis

Examining the learned weights $\vec{\phi}$ gives insight into annotator behavior. High weights include `I-O` and `O-I` transitions conditioned on punctuation, e.g., $\phi_{\texttt{I(.)-O}} = 3.55$,[18] as well as rationales ending at the end of a major phrase, e.g., $\phi_{\texttt{I-O/E=VP}} = 1.88$.

The large emission feature weights, e.g., $\phi_{\text{rel}} = 14.68$ and $\phi_{\text{antirel}} = 15.30$, tie rationales closely to θ values, as hoped. For example, in Figure 1, the word w = succeeds, with $\theta_w = 0.13$, drives up $p(\texttt{I})/p(\texttt{O})$ by a factor of 7 (in a positive document) relative to a word with $\theta_w = 0$.

In fact, feature ablation experiments showed that almost all the classification benefit from rationales can be obtained by using only these 2 emission ϕ-features and the 4 unconditioned transition ϕ-features. Our full ϕ (115 features) merely improves our ability to predict the rationales (whose likelihood does increase significantly with more features).

We also checked that annotators' styles differ enough that it helps to tune ϕ to the "target" annotator A who gave the rationales. Table 3 shows that a ϕ model trained on A's *own* rationales does best at predicting new rationales from A. Table 2 shows that as

[18]When trained on folds F_4–F_8 with A0's rationales.

	ϕ_{A0}	ϕ_{A3}	ϕ_{A4}	ϕ_{A5}	Baseline
θ_{A0}	**76.0**	*73.0*	*74.0*	*73.0*	71.0
θ_{A3}	*73.0*	**76.0**	*74.0*	*73.0*	*73.0*
θ_{A4}	*75.0*	73.0	**77.0**	*74.0*	71.0
θ_{A5}	**74.0**	*71.0*	*72.0*	**74.0**	70.0

Table 2: Accuracy rate for an annotator's θ (rows) obtained when using some other annotator's ϕ (columns). Notice that the diagonal entries and the baseline column are taken from rows of Table 1 (size=100).

	ϕ_{A0}	ϕ_{A3}	ϕ_{A4}	ϕ_{A5}	Trivial model
$-L(r_{A0})$	**0.073**	0.086	*0.077*	0.088	0.135
$-L(r_{A3})$	0.084	**0.068**	*0.071*	**0.068**	0.130
$-L(r_{A4})$	0.088	0.084	**0.075**	0.085	0.153
$-L(r_{A5})$	0.058	**0.044**	*0.047*	**0.044**	0.111

Table 3: Cross-entropy per tag of rationale annotations $\vec{r}$ for each annotator (rows), when predicted from that annotator's $\vec{x}$ and $\vec{\theta}$ via a possibly different annotator's ϕ (columns). For comparison, the trivial model is a bigram model of $\vec{r}$, which is trained on the target annotator but ignores $\vec{x}$ and $\vec{\theta}$. 5-fold cross-validation on the 100-document set was used to prevent testing on training data.

a result, classification performance on the test set is usually best if it was A's *own* ϕ that was used to help learn θ from A's rationales. In both cases, however, a different annotator's ϕ is better than nothing.

9 Conclusions

We have demonstrated a effective method for eliciting extra knowledge from *naive* annotators, in the form of lightweight "rationales" for their annotations. By explicitly modeling the annotator's rationale-marking process, we are able to infer a better model of the original annotations.

We showed that our method performs significantly better than two strong baseline classifiers, and also outperforms our previous discriminative method for exploiting rationales (Zaidan et al., 2007). We also saw that it worked across four annotators who have different rationale-marking styles.

In future, we are interested in new domains that can adaptively solicit rationales for some or all training examples. Our new method, being essentially Bayesian inference, is potentially extensible to many other situations—other tasks, classifier architectures, and more complex features.

Abstract

Having seen a news title "Alba denies wedding reports", how do we infer that it is primarily about Jessica Alba, rather than about weddings or reports? We probably realize that, in a randomly driven sentence, the word "Alba" is less anticipated than "wedding" or "reports", which adds value to the word "Alba" if used. Such anticipation can be modeled as a ratio between an empirical probability of the word (in a given corpus) and its estimated probability in general English. Aggregated over all words in a document, this ratio may be used as a measure of the document's topicality. Assuming that the corpus consists of on-topic and off-topic documents (we call them *the core* and *the noise*), our goal is to determine which documents belong to the core. We propose two unsupervised methods for doing this. First, we assume that words are sampled i.i.d., and propose an information-theoretic framework for determining the core. Second, we relax the independence assumption and use a simple graphical model to rank documents according to their likelihood of belonging to the core. We discuss theoretical guarantees of the proposed methods and show their usefulness for Web Mining and Topic Detection and Tracking (TDT).

1 Introduction

Many intelligent applications in the text domain aim at determining whether a document (a sentence, a snippet etc.) is on-topic or off-topic. In some applications, topics are explicitly given. In binary text classification, for example, the topic is described in terms of positively and negatively labeled documents. In information retrieval, the topic is imposed by a query. In many other applications, the topic is unspecified, however, its existence is assumed. Examples of such applications are within text summarization (extract the most topical sentences), text clustering (group documents that are close topically), novelty detection (reason whether or not test documents are on the same topic as training documents), spam filtering (reject incoming email messages that are too far topically from the content of a personal email repository), etc.

Under the (standard) Bag-Of-Words (BOW) representation of a document, *words* are the functional units that bear the document's topic. Since some words are topical and some are not, the problem of detecting on-topic documents has a dual formulation of detecting topical words. This paper deals with the following questions: (a) Which words can be considered topical? (b) How can topical words be detected? (c) How can on-topic documents be detected given a set of topical words?

The BOW formalism is usually translated into the generative modeling terms by representing documents as multinomial word distributions. For the on-topic/off-topic case, we assume that words in a document are sampled from a mixture of two multinomials: one over topical words and another one over general English (i.e. the background). Obviously enough, the support of the "topic" multinomial is significantly smaller than the support of the background. A document's topicality is then determined by aggregating the topicality of its words (see below for details). Note that by introducing the background distribution we refrain from explicitly modeling the class of off-topic documents—a document is supposed to be off-topic if it is "not topical enough".

Such a formulation of topicality prescribes using the *one-class* modeling paradigm, as opposed to sticking to the *binary* case. Besides being much

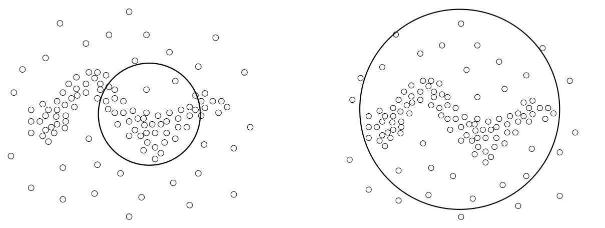

Figure 1: The problem of hyperspherical decision boundaries in one-class models for text, as projected on 2D: (left) a too small portion of the core is captured; (right) too much space around the core is captured.

less widely studied and therefore much more attractive from the scientific point of view, one-class models appear to be more adequate for many real-world tasks, where negative examples are not straightforwardly observable. One-class models separate the desired class of data instances (*the core*) from other data instances (*the noise*). Structure of noise is either unknown, or too complex to be explicitly modeled.

One-class problems are traditionally approached using vector-space methods, where a convex decision boundary is built around the data instances of the desired class, separating it from the rest of the universe. In the text domain, however, those vector-space models are questionably applicable—unlike effective *binary* vector-space models. In binary models, decision boundaries are linear[1], whereas in (vector-space) one-class models, the boundaries are usually *hyperspherical*. Intuitively, since core documents tend to lie on a lower-dimensional manifold (Lebanon, 2005), inducing hyperspherical boundaries may be sub-optimal as they tend to either capture just a portion of the core, or capture too much space around it (see illustration in Figure 1). Here we propose alternative ways for detecting the core, which work well in text.

One-class learning problems have been studied as either outlier detection or identifying a small coherent subset. In one-class outlier detection (Tax and Duin, 2001; Schölkopf et al., 2001), the goal is to identify *a few* outliers from the given set of examples, where the vast majority of the examples are considered relevant. Alternatively, a complementary goal is to distill a subset of relevant examples, in the space with many outliers (Crammer and Chechik, 2004; Gupta and Ghosh, 2005; Crammer et al., 2008). Most of the one-class approaches employ geometrical concepts to capture the notion of relevancy (or irrelevancy) using either hyperplanes (Schölkopf et al., 2001) or hyperspheres (Tax and Duin, 2001; Crammer and Chechik, 2004; Gupta and Ghosh, 2005). In this paper we adopt the latter approach: we formulate one-class clustering in text as an optimization task of identifying the *most coherent* subset (*the core*) of k documents drawn from a given pool of $n > k$ documents.[2]

Given a collection $\mathcal{D}$ of on-topic and off-topic documents, we assume that on-topic documents share a portion of their vocabulary that consists of "relatively rare" words, i.e. words that are used in $\mathcal{D}$ more often than they are used in general English. We call them *topical* words. For example, if some documents in $\mathcal{D}$ share words such as "Bayesian", "classifier", "reinforcement" and other machine learning terms (infrequent in general English), whereas other documents do not seem to share any subset of words (besides stopwords), then we conclude that the machine learning documents compose the core of $\mathcal{D}$, while non-machine learning documents are noise.

We express the level of topicality of a word w in terms of the ratio $\rho(w) = \frac{p(w)}{q(w)}$, where $p(w)$ is w's empirical probability (in $\mathcal{D}$), and $q(w)$ is its estimated probability in general English. We discuss an interesting characteristic of $\rho(w)$: if $\mathcal{D}$ is large enough, then, with high probability, $\rho(w)$ values are greater for topical words than for non-topical words. Therefore, $\rho(w)$ can be used as a mean to measure the topicality of w.

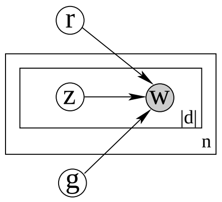
Obviously, the quality of this measure depends on the quality of estimating $q(w)$, i.e. the general English word distribution, which is usually estimated over a large text collection. The larger the collection is, the better would be the estimation. Recently, Google has released the `Web 1T` dataset[3] that provides $q(w)$ estimated on a text collection of one trillion tokens. We use it in our experimentation.

We propose two methods that use the ρ ratio to

[1]As such, or after applying the *kernel trick* (Cristianini and Shawe-Taylor, 2000)

[2]The parameter k is analogous to the number of clusters in (multi-class) clustering, as well as to the number of outliers (Tax and Duin, 2001) or the radius of Bregmanian ball (Crammer and Chechik, 2004)—in other formulations of one-class clustering.

[3]`http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2006T13`



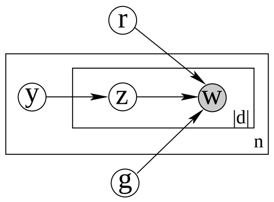


Figure 2: (left) A simple generative model; (right) Latent Topic/Background model (Section 4).

solve the one-class clustering problem. First, we express documents' topicality in terms of aggregating their words' ρ ratios into an information-theoretic "topicality measure". The core is then composed of k documents with the highest topicality measure. We show that the proposed measure is optimal for constructing the core cluster among documents of equal length. However, our method is not useful in a setup where some long documents have a topical *portion*: such documents should be considered on-topic, but their heavy tail of background words overcomes the topical words' influence. We generalize our method to non-equally-long documents by first extracting words that are supposed to be topical and then projecting documents over those words. Such projection preserves the optimality characteristic and results in constructing a more accurate core cluster in practice. We call such a method of choosing both topical words and core documents *One-Class Co-Clustering (OCCC)*.

It turns out that our OCCC method's performance depends heavily on choosing the number of topical words. We propose a heuristic for setting this number. As another alternative, we propose a method that does not require tuning this parameter: we use words' ρ ratios to initialize an EM algorithm that computes the likelihood of documents to belong to the core—we then choose k documents of maximal likelihood. We call this model the *Latent Topic/Background (LTB)* model. LTB outperforms OCCC in most of our test cases.

Our one-class clustering models have interesting cross-links with models applied to other Information Retrieval tasks. For example, a model that resembles our OCCC, is proposed by Zhou and Croft (2007) for *query performance prediction*. Tao and Zhai (2004) describe a *pseudo-relevance feedback* model that is similar to our LTB. These types of cross-links are common for the models that are

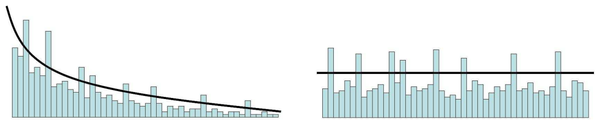

Figure 3: (left) Words' $p(w)$ values when sorted by their $q(w)$ values; (right) words' $\rho(w)$ values.

general enough and relatively simple. In this paper we put particular emphasis on the simplicity of our models, such that they are feasible for theoretical analysis as well as for efficient implementation.

2 Motivation for using ρ ratios

Recall that we use the $\rho(w) = \frac{p(w)}{q(w)}$ ratios to express the level of our "surprise" of seeing the word w. A high value of $\rho(w)$ means that w is used in the corpus more frequently than in general English, which, we assume, implies that w is topical. The more topical words a document contains, the more "topical" it is—k most topical documents compose the core $\mathcal{D}^k \subset \mathcal{D}$.

An important question is whether or not the ρ ratios are sufficient to detecting the *actually* topical words. To address this question, let us model the corpus $\mathcal{D}$ using a simple graphical model (Figure 2 left). In this model, the word distribution $p(w)$ is represented as a mixture of two multinomial distributions: p_r over a set $\mathcal{R}$ of topical words, and p_g over all the words $\mathcal{G} \supset \mathcal{R}$ in $\mathcal{D}$. For each word w_{ij} in a document d_i, we toss a coin Z_{ij}, such that, if $Z_{ij} = 1$, then w_{ij} is sampled from p_r, otherwise it is sampled from p_g. Define $\pi \triangleq p(Z_{ij} = 1)$.

If $|\mathcal{G}| \gg |\mathcal{R}| \gg 0$, and if $\pi \gg 0$, then topical words would tend to appear more often than non-topical words. However, we cannot simply base our conclusions on word counts, as some words are naturally more frequent than others (in general English). Figure 3 (left) illustrates this observation: it shows words' $p(w)$ values sorted by their $q(w)$ values. It is hard to fit a curve that would separate between $\mathcal{R}$ and $\mathcal{G} \setminus \mathcal{R}$. We notice however, that we can "flatten" this graph by drawing $\rho(w)$ values instead (see Figure 3 right). Here, naturally frequent words are penalized by the q factor, so we can assume that, when re-normalized, $\rho(w)$ behaves as a mixture of two discrete *uniform* distributions. A simple threshold can then separate between $\mathcal{R}$ and $\mathcal{G} \setminus \mathcal{R}$.

Proposition 1 *Under the uniformity assumption, it is sufficient to have a* log-linear *size sample (in $|\mathcal{G}|$) in order to determine the set $\mathcal{R}$ with high probability.*

See Bekkerman (2008) for the proof. The proposition states that in corpora of practical size[4] the set of topical words can be almost perfectly detected, simply by taking words with the highest ρ ratios. Consequently, the core $\mathcal{D}^k$ will consist of k documents, each of which contains more topical words than any document from $\mathcal{D} \setminus \mathcal{D}^k$.

To illustrate this theoretical result, we followed the generative process as described above, and constructed an artificial dataset with characteristics similar to those of our WAD dataset (see Section 5.1). In particular, we fixed the size of the artificial dataset to be equal to the size of the WAD dataset ($N = 330,000$). We set the ratio of topical words to 0.2 and assumed uniformity of the ρ values. In this setup, we were able to detect the set of topical words with a 98.5% accuracy.

2.1 Max-KL Algorithm

In this section, we propose a simple information-theoretic algorithm for identifying the core $\mathcal{D}^k$, and show that it is optimal under the uniformity assumption. Given the ρ ratios of words, the *aggregated topicality* of the corpus $\mathcal{D}$ can be expressed in terms of the KL-divergence:

$$\begin{aligned} KL(p||q) &= \sum_{w \in \mathcal{G}} p(w) \log \frac{p(w)}{q(w)} \\ &= \sum_{d \in \mathcal{D}, w \in \mathcal{G}} p(d,w) \log \frac{p(w)}{q(w)}. \end{aligned}$$

A document d's contribution to the aggregated topicality measure will assess the topicality of d:

$$KL_d(p||q) = \sum_{w \in \mathcal{G}} p(d,w) \log \frac{p(w)}{q(w)}. \qquad (1)$$

The core $\mathcal{D}^k$ will be composed of documents with the highest topicality scores. A simple, greedy algorithm for detecting $\mathcal{D}^k$ is then:

1. Sort documents according to their topicality value (1), in decreasing order.
2. Select the first k documents.

[4] $N = O(m \log m)$, where N is the number of word tokens in $\mathcal{D}$, and $m = |\mathcal{G}|$ is the size of the vocabulary.

Since the algorithm chooses documents with high values of the KL divergence we call it the *Max-KL* algorithm. We now argue that it is optimal under the uniformity assumption. Indeed, if the corpus $\mathcal{D}$ is large enough, then according to Proposition 1 (with high probability) any topical word w has a lower ρ ratio than any non-topical word. Assume that all documents are of the same length ($|d|$ is constant). The Max-KL algorithm chooses documents that contain more topical words than any other document in the corpus—which is exactly the definition of the core, as presented in Section 1. We summarize this observation in the following proposition:

Proposition 2 *If the corpus $\mathcal{D}$ is large enough, and all the documents are of the same length, then the Max-KL algorithm is optimal for the one-class clustering problem under the uniformity assumption.*

In contrast to the (quite natural) uniformity assumption, the all-the-same-length assumption is quite restrictive. Let us now propose an algorithm that overcomes this issue.

3 One-Class Co-Clustering (OCCC)

As accepted in Information Retrieval, we decide that a document is on-topic if it has a topical *portion*, no matter how long its non-topical portion is. Therefore, we decide about documents' topicality based on topical words only—non-topical words can be completely disregarded. This observation leads us to proposing a one-class *co-clustering* (OCCC) algorithm: we first detect the set $\mathcal{R}$ of topical words, represent documents over $\mathcal{R}$, and then detect $\mathcal{D}^k$ based on the new representation.[5]

We reexamine the document's topicality score (1) and omit non-topical words. The new score is then:

$$KL_d^r(p||q) = \sum_{w \in \mathcal{R}} p'(d,w) \log \frac{p(w)}{q(w)}, \qquad (2)$$

where $p'(d,w) = p(d,w)/(\sum_{w \in \mathcal{R}} p(d,w))$ is a joint distribution of documents and (only) topical words. The OCCC algorithm first uses $\rho(w)$ to

[5] OCCC is the simplest, *sequential* co-clustering algorithm, where words are clustered prior to clustering documents (see, e.g., Slonim and Tishby (2000)). In OCCC, word clustering is analogous to *feature selection*. More complex algorithms can be considered, where this analogy is less obvious.

choose the most topical words, then it projects documents on these words and apply the *Max-KL* algorithm, as summarized below:

1. Sort words according to their ρ ratios, in decreasing order.
2. Select a subset $\mathcal{R}$ of the first m_r words.
3. Represent documents as bags-of-words over $\mathcal{R}$ (delete counts of words from $\mathcal{G} \setminus \mathcal{R}$).
4. Sort documents according to their topicality score (2), in decreasing order.
5. Select a subset $\mathcal{D}^k$ of the first k documents.

Considerations analogous to those presented in Section 2.1, lead us to the following result:

Proposition 3 *If the corpus $\mathcal{D}$ is large enough, the OCCC algorithm is optimal for one-class clustering of documents, under the uniformity assumption.*

Despite its simplicity, the OCCC algorithm shows excellent results on real-world data (see Section 5). OCCC's time complexity is particularly appealing: $O(N)$, where N is the number of word tokens in $\mathcal{D}$.

3.1 Choosing size m_r of the word cluster

The choice of $m_r = |\mathcal{R}|$ can be crucial. We propose a useful heuristic for choosing it. We assume that the distribution of ρ ratios for $w \in \mathcal{R}$ is a Gaussian with a mean $\mu_r \gg 1$ and a variance σ_r^2, and that the distribution of ρ ratios for $w \in \mathcal{G} \setminus \mathcal{R}$ is a Gaussian with a mean $\mu_{nr} = 1$ and a variance σ_{nr}^2. We also assume that *all* the words with $\rho(w) < 1$ are non-topical. Since Gaussians are symmetric, we further assume that the number of non-topical words with $\rho(w) < 1$ equals the number of non-topical words with $\rho(w) \geq 1$. Thus, our estimate of $|\mathcal{G} \setminus \mathcal{R}|$ is twice the number of words with $\rho(w) < 1$, and then the number of topical words can be estimated as $m_r = |\mathcal{G}| - 2 \cdot \#\{\text{words with } \rho(w) < 1\}$.

4 Latent Topic/Background (LTB) model

Instead of sharply thresholding topical and non-topical words, we can have them all, *weighted* with a probability of being topical. Also, we notice that our original generative model (Figure 2 left) assumes that words are i.i.d. sampled, which can be relaxed by deciding on the document topicality first. In our new generative model (Figure 2 right), for each document d_i, Y_i is a Bernoulli random variable where

Algorithm 1 EM algorithm for one-class clustering using the LTB model.

```
Input:
  $\mathcal{D}$ – the dataset
  $\rho(w_l) = \frac{p(w_l)}{q(w_l)}$ – $\rho$ scores for each word $w_l|_{l=1}^m$
  $T$ – number of EM iterations
Output: Posteriors $p(Y_i = 1|d_i, \Theta^T)$ for each doc $d_i|_{i=1}^n$

Initialization:
for each document $d_i$ initialize $\pi_i^1$
for each word $w_l$ initialize $p_r^1(w_l) = \Omega_r \rho(w_l)$;
$p_g^1(w_l) = \frac{\Omega_g}{\rho(w_l)}$, s.t. $\Omega_r$ and $\Omega_g$ are normalization factors

Main loop:
for all $t = 1, \ldots, T$ do
  E-step:
  for each document $d_i$ compute $\alpha_i^t = p(Y_i = 1|d_i, \Theta^t)$
  for each word token $w_{ij}$ compute
      $\beta_{ij}^t = p(Z_{ij} = 1|Y_i = 1, w_{ij}, \Theta^t)$
  M-step:
  for each document $d_i$ update $\pi^{t+1} = \frac{1}{|d_i|} \sum_j \beta_{ij}^t$
  for each word $w_l$ update
      $p_r^{t+1}(w_l) = \frac{\sum_i \alpha_i^t \sum_j \delta(w_{ij} = w_l)\, \beta_{ij}^t}{\sum_i \alpha_i^t \sum_j \beta_{ij}^t}$
      $p_g^{t+1}(w_l) = \frac{N_w - \sum_i \alpha_i^t \sum_j \delta(w_{ij} = w_l)\, \beta_{ij}^t}{N - \sum_i \alpha_i^t \sum_j \beta_{ij}^t}$
```

$Y_i = 1$ corresponds to d_i being on-topic. As before, Z_{ij} decides on the topicality of a word token w_{ij}, but now *given* Y_i. Since not all words in a core document are supposed to be topical, then for each word of a core document we make a separate decision (based on Z_{ij}) whether it is sampled from $p_r(W)$ or $p_g(W)$. However, if a document does not belong to the core ($Y_i = 0$), each its word is sampled from $p_g(W)$, i.e. $p(Z_{ij} = 0|Y_i = 0) = 1$.

Inspired by Huang and Mitchell (2006), we use the Expectation-Maximization (EM) algorithm to *exactly* estimate parameters of our model from the dataset. We now describe the model parameters Θ. First, the probability of any document to belong to the core is denoted by $p(Y_i = 1) = \frac{k}{n} = p_d$ (this parameter is fixed and will not be learnt from data). Second, for each document d_i, we maintain a probability of each its word to be topical given that the document is on-topic, $p(Z_{ij} = 1|Y_i = 1) = \pi_i$ for $i = 1, \ldots, n$. Third, for each word w_l (for $k = 1...m$), we let $p(w_l|Z_l = 1) = p_r(w_l)$ and $p(w_l|Z_l = 0) = p_g(w_l)$. The overall number of parameters is $n + 2m + 1$, one of which (p_d) is preset. The dataset likelihood is then:

$$\begin{aligned} p(\mathcal{D}) &= \prod_{i=1}^{n} [p_d\, p(d_i|Y_i = 1) + (1 - p_d)p(d_i|Y_i = 0)] \\ &= \prod_{i=1}^{n} \left[p_d \prod_{j=1}^{|d_i|} [\pi_i p_r(w_{ij}) + (1 - \pi_i) p_g(w_{ij})] \right. \\ &\quad \left. + (1 - p_d) \prod_{j=1}^{|d_i|} p_g(w_{ij}) \right]. \end{aligned}$$

At each iteration t of the EM algorithm, we first perform the E-step, where we compute the posterior distribution of hidden variables $\{Y_i\}$ and $\{Z_{ij}\}$ given the current parameter values Θ^t and the data $\mathcal{D}$. Then, at the M-step, we compute the new parameter values Θ^{t+1} that maximize the model log-likelihood given Θ^t, $\mathcal{D}$ and the posterior distribution.

The initialization step is crucial for the EM algorithm. Our pilot experimentation showed that if distributions $p_r(W)$ and $p_g(W)$ are initialized as uniform, the EM performance is close to random. Therefore, we decided to initialize word probabilities using normalized ρ scores. We do not propose the optimal way to initialize π_i parameters, however, as we show later in Section 5, our LTB model appears to be quite robust to the choice of π_i.

The EM procedure is presented in Algorithm 1. For details, see Bekkerman (2008). After T iterations, we sort the documents according to α_i in decreasing order and choose the first k documents to be the core. The complexity of Algorithm 1 is linear: $O(TN)$. To avoid overfitting, we set T to be a small number: in our experiments we fix $T = 5$.

5 Experimentation

We evaluate our OCCC and LTB models on two applications: a *Web Mining* task (Section 5.1), and a *Topic Detection and Tracking (TDT)* (Allan, 2002) task (Section 5.2).

To define our evaluation criteria, let C be the constructed cluster and let C_r be its portion consisting of documents that actually belong to the core. We define precision as Prec $= |C_r|/|C|$, recall as Rec $= |C_r|/k$ and F-measure as (2 Prec Rec)/(Prec+Rec). Unless stated otherwise, in our experiments we fix $|C| = k$, such that precision equals recall and is then called *one-class clustering accuracy*, or just *accuracy*.

We applied our one-class clustering methods in four setups:

- **OCCC with the heuristic to choose** m_r (from Section 3.1).
- **OCCC with optimal** m_r**.** We *unfairly* choose the number m_r of topical words such that the resulting accuracy is maximal. This setup can be considered as the upper limit of the OCCC's performance, which can be hypothetically achieved if a better heuristic for choosing m_r is proposed.
- **LTB initialized with** $\pi_i = 0.5$ **(for each** i**).** As we show in Section 5.1 below, the LTB model demonstrates good performance with this straightforward initialization.
- **LTB initialized with** $\pi_i = p_d$**.** Quite naturally, the number of topical words in a dataset depends on the number of core documents. For example, if the core is only 10% of a dataset, it is unrealistic to assume that 50% of all words are topical. In this setup, we condition the ratio of topical words on the ratio of core documents.

We compare our methods with two existing algorithms: (a) One-Class SVM clustering[6] (Tax and Duin, 2001); (b) One-Class Rate Distortion (OC-RD) (Crammer et al., 2008). The later is considered a state-of-the-art in one-class clustering. Also, to establish the lowest baseline, we show the result of a random assignment of documents to the core $\mathcal{D}^k$.

The OC-RD algorithm is based on rate-distortion theory and expresses the one-class problem as a lossy coding of each instance into a few possible instance-dependent codewords. Each document is represented as a distribution over words, and the KL-divergence is used as a distortion function (generally, it can be any Bregman function). The algorithm also uses an "inverse temperature" parameter (denoted by β) that represents the tradeoff between compression and distortion. An annealing process is employed, in which the algorithm is applied with a sequence of increasing values of β, when initialized with the result obtained at the previous itera-

[6]We used Chih-Jen Lin's `LibSVM` with the `-s 2` parameter. We provided the core size using the `-n` parameter.

Method	WAD	TW
Random assignment	38.7%	$34.9 \pm 3.1\%$
One-class SVM	46.3%	$45.2 \pm 3.2\%$
One-class rate distortion	48.8%	$63.6 \pm 3.5\%$
OCCC with the m_r heuristic	80.2%	$61.4 \pm 4.5\%$
OCCC with optimal m	82.4%	$68.3 \pm 3.6\%$
LTB initialized with $\pi_i = 0.5$	79.8%	$65.3 \pm 7.3\%$
LTB initialized with $\pi_i = p_d$	78.3%	$68.0 \pm 5.9\%$

Table 1: One-class clustering accuracy of our OCCC and LTB models on the WAD and the TW detection tasks, as compared to OC-SVM and OC-RD. For TW, the accuracies are macro-averaged over the 26 weekly chunks, with the standard error of the mean presented after the $\pm$ sign.

tion. The outcome is a sequence of cores with decreasing sizes. The annealing process is stopped once the largest core size is equal to k.

5.1 Web appearance disambiguation

Web appearance disambiguation (WAD) is proposed by Bekkerman and McCallum (2005) as the problem of reasoning whether a particular mention of a person name in the Web refers to the person of interest or to his or her unrelated namesake. The problem is solved given *a few* names of people from one social network, where the objective is to construct a cluster of Web pages that mention names of related people, while filtering out pages that mention their unrelated namesakes.

WAD is a classic one-class clustering task, that is tackled by Bekkerman and McCallum with *simulated* one-class clustering: they use a sophisticated agglomerative/conglomerative clustering method to construct multiple clusters, out of which one cluster is then selected. They also use a simple *link structure (LS)* analysis method that matches hyperlinks of the Web pages in order to compose a cloud of pages that are close to each other in the Web graph. The authors suggest that the best performance can be achieved by a hybrid of the two approaches.

We test our models on the WAD dataset,[7] which consists of 1085 Web pages that mention 12 people names of AI researchers, such as Tom Mitchell and Leslie Kaelbling. Out of the 1085 pages, 420 are on-topic, so we apply our algorithms with $k = 420$. At a preprocessing step, we binarize document vectors and remove low frequent words (both in terms of $p(w)$ and $q(w)$). The results are summarized in the middle column of Table 1. We can see that both OCCC and LTB dramatically outperform their competitors, while showing practically indistinguishable results compared to each other. Note that when the size of the word cluster in OCCC is *unfairly* set to its optimal value, $m_r = 2200$, the OCCC method is able to gain a 2% boost. However, for obvious reasons, the optimal value of m_r may not always be obtained in practice.

Table 2: Most highly ranked words by OCCC and LTB, on the WAD dataset.

Table 2 lists a few most topical words according to the OCCC and LTB models. The OCCC algorithm sorts words according to their ρ scores, such that words that often occur in the dataset but rarely in the Web, are on the top of the list. These are mostly last names or login names of researchers, venues etc. The EM algorithm of LTB is the given ρ scores as an input to initialize $p_r^1(w)$ and $p_g^1(w)$, which are then updated at each M-step. In the LTB columns, words are sorted by $p_r^5(w)$. High quality of the LTB list is due to conditional dependencies in our generative model (via the Y_i nodes).

Solid lines in Figure 4 demonstrate the robustness of our models to tuning their main parameters (m_r for OCCC, and the π_i initialization for LTB). As can be seen from the left panel, OCCC shows robust performance: the accuracy above 80% is obtained when the word cluster is of any size in the 1000–3000 range. The heuristic from Section 3.1 suggests a cluster size of 1000. The LTB is even more robust: practically any value of π_i (besides the very large ones, $\pi_i \approx 1$) can be chosen.

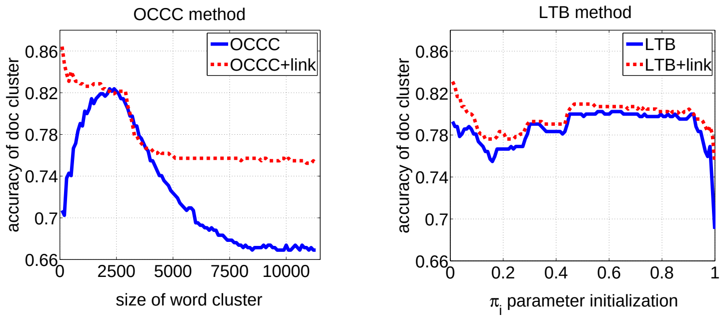

Figure 4: **Web appearance disambiguation:** (left) OCCC accuracy as a function of the word cluster size; (right) LTB accuracy over various initializations of π_i parameters. The red dotted lines show the accuracy of each method's results combined with the Link Structure model results. On the absolute scale, OCCC outperforms LTB, however LTB shows more robust behavior than OCCC.

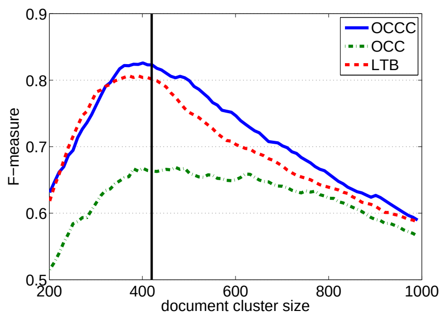

Figure 5: **Web appearance disambiguation:** F-measure as a function of document cluster size: a vertical line indicates the point where precision equals recall (and therefore equals accuracy). "OCC" refers to the OCCC model where all the words are taken as the word cluster (i.e. no word filtering is done).

To perform a fair comparison of our results with those obtained by Bekkerman and McCallum (2005), we construct hybrids of their link structure (LS) analysis model with our OCCC and LTB, as follows. First, we take their LS core cluster, which consists of 360 documents. Second, we pass over all the WAD documents in the order as they were ranked by either OCCC or LTB, and enlarge the LS core with 60 most highly ranked documents that did not occur in the LS core. In either case, we end up with a hybrid core of 420 documents.

Dotted lines in Figure 4 show accuracies of the resulting models. As the F-measure of the hybrid model proposed by Bekkerman and McCallum (2005) is 80.3%, we can see that it is significantly inferior to the results of either OCCC+LS or LTB+LS, when their parameters are set to a small value ($m_r < 3000$ for OCCC, $\pi_i < 0.06$ for LTB). Such a choice of parameter values can be explained by the fact that we need only 60 documents to expand the LS core cluster to the required size $k = 420$. When the values of m_r and π_i are small, both OCCC and LTB are able to build very small and very precise core clusters, which is exactly what we need here. The OCCC+LS hybrid is particularly successful, because it uses non-canonical words (see Table 2) to compose a clean core that almost does not overlap with the LS core. Remarkably, the OCCC+LS model obtains 86.4% accuracy with $m_r = 100$, which is the state-of-the-art result on the WAD dataset.

To answer the question how much our models are sensitive to the choice of the core size k, we computed the F-measure of both OCCC and LTB as a function of k (Figure 5). It turns out that our methods are quite robust to tuning k: choosing any value in the 300–500 range leads to good results.

5.2 Detecting the topic of the week

Real-world data rarely consists of a clean core and uniformly distributed noise. Usually, the noise has some structure, namely, it may contain coherent components. With this respect, one-class clustering can be used to detect the *largest* coherent component in a dataset, which is an integral part of many applications. In this section, we solve the problem of automatically detecting the *Topic of the Week (TW)* in a newswire stream, i.e. detecting all articles in a weekly news roundup that refer to the most broadly discussed event.

We evaluate the TW detection task on the benchmark TDT-5 dataset[8], which consists of 250 news events spread over a time period of half a year, and 9,812 documents in English, Arabic and Chinese (translated to English), annotated by their relationship to those events.[9] The largest event in TDT-5 dataset (#55106, titled *"Bombing in Riyadh, Saudi Arabia"*) has 1,144 documents, while 66 out of the 250 events have only one document each. We split the dataset to 26 weekly chunks (to have 26 full

[8]`http://projects.ldc.upenn.edu/TDT5/`

[9]We take into account only labeled documents, while ignoring unlabeled documents that can be found in the TDT-5 data.

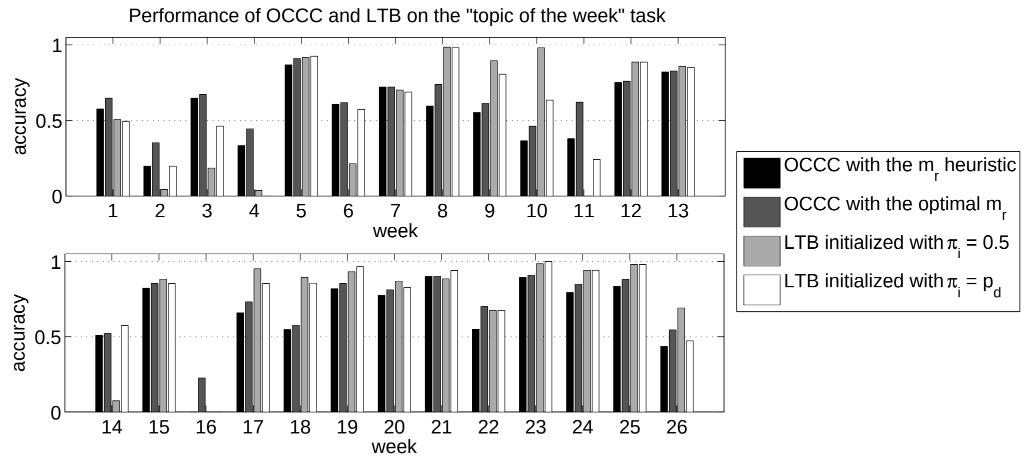

Figure 6: **"Topic of the week" detection task:** Accuracies of two OCCC methods and two LTB methods.

weeks, we delete all the documents dated with the last day in the dataset, which decreases the dataset's size to 9,781 documents). Each chunk contains from 138 to 1292 documents.

The one-class clustering accuracies, macro-averaged over the 26 weekly chunks, are presented in the right column of Table 1. As we can see, both LTB models, as well as OCCC with the optimal m_r, outperform our baselines. Interestingly, even the optimal choice of m_r does not lead OCCC to significantly superior results while compared with LTB. The dataset-dependent initialization of LTB's π_i parameters ($\pi_i = p_d$) appears to be preferable over the dataset-independent one ($\pi_i = 0.5$).

Accuracies *per week* are shown in Figure 6. These results reveal two interesting observations. First, OCCC tends to outperform LTB only on data chunks where the results are quite low in general (less than 60% accuracy). Specifically, on weeks 2, 4, 11, and 16 the LTB models show extremely poor performance. While investigating this phenomenon, we discovered that in two of the four cases LTB was able to construct very clean core clusters, however, those clusters corresponded to the *second* largest topic, while we evaluate our methods on the first largest topic.[10] Second, the (completely unsupervised) LTB model can obtain very good results on some of the data chunks. For example, on weeks 5, 8, 19, 21, 23, 24, and 25 the LTB's accuracy is above 90%, with a striking 100% on week-23.

6 Conclusion

We have developed the theory and proposed practical methods for one-class clustering in the text domain. The proposed algorithms are very simple, very efficient and still surprisingly effective. More sophisticated algorithms (e.g. an *iterative*[11] version of OCCC) are emerging.

Refining Generative Language Models using Discriminative Learning

sandban@post.tau.ac.il

Abstract

We propose a new approach to language modeling which utilizes discriminative learning methods. Our approach is an iterative one: starting with an initial language model, in each iteration we generate 'false' sentences from the current model, and then train a classifier to discriminate between them and sentences from the training corpus. To the extent that this succeeds, the classifier is incorporated into the model by lowering the probability of sentences classified as false, and the process is repeated. We demonstrate the effectiveness of this approach on a natural language corpus and show it provides an 11.4% improvement in perplexity over a modified kneser-ney smoothed trigram.

1 Introduction

Language modeling is a fundamental task in natural language processing and is routinely employed in a wide range of applications, such as speech recognition, machine translation, etc'. Traditionally, a language model is a probabilistic model which assigns a probability value to a sentence or a sequence of words. We refer to these as *generative language models*. A very popular example of a generative language model is the n-gram, which conditions the probability of the next word on the previous *(n-1)*-words.

Although simple and widely-applicable, it has proven difficult to allow n-grams, and other forms of generative language models as well, to take advantage of non-local and overlapping features.[1] These sorts of features, however, pose no problem for standard discriminative learning methods, e.g. large-margin classifiers. For this reason, a new class of language model, the *discriminative language model*, has been proposed recently to augment generative language models (Gao et al., 2005; Roark et al., 2007). Instead of providing probability values, discriminative language models directly classify sentences as either correct or incorrect, where the definition of correctness depends on the application (e.g. grammatical / ungrammatical, correct translation / incorrect translation, etc').

Discriminative learning methods require negative samples. Given that the corpora used for training language models contain only real sentences, i.e. positive samples, obtaining these can be problematic. In most work on discriminative language modeling this was not a major issue as the work was concerned with specific applications, and these provided a natural definition of negative samples. For instance, (Roark et al., 2007) proposed a discriminative language model for a speech recognition task. Given an acoustic sequence, a baseline recognizer was used to generate a set of possible transcriptions. The correct transcription was taken as a positive sample, while the rest were taken as negative samples. More recently, however, Okanohara and Tsujii (2007) showed that a

[1] Conditional maximum entropy models (Rosenfeld, 1996) provide somewhat of a counter-example, but there, too, many kinds of global and non-local features are difficult to use (Rosenfeld, 1997).

discriminative language model can be trained independently of a specific application by using a generative language model to obtain the negative samples. Using a non-linear large-margin learning algorithm, they successfully trained a classifier to discriminate real sentences from sentences generated by a trigram.

In this paper we extend this line of work to study the extent to which discriminative learning methods can lead to better *generative language models per-se*. The basic intuition is the following: if a classifier can be used to discriminate real sentences from 'false' sentences generated by a language model, then it can also be used to improve that language model by taking probability mass away from sentences classified as false and transferring it to sentences classified as real. If the resulting language model can be efficiently sampled from, then this process can be repeated, until generated sentences can no longer be distinguished from real ones.

The remainder of the paper is structured as follows: In the next section we formally develop this intuition, providing a quick overview of the whole-sentence maximum-entropy model and of self-supervised boosting, two previous works on which we rely. We also present the method we use for sampling from the current model, which for the present work is far more efficient than the classical Gibbs sampling. Our experimental results are presented in section 3, and section 4 concludes with a discussion and a future outlook.

2 Learning Framework

2.1 Whole-sentence maximum-entropy model

The vast majority of statistical language models estimate the probability of a given sentence as a product of conditional probabilities via the chain rule:

$$\mathrm{P}(s) \overset{def}{=} \mathrm{P}(w_1 ... w_n) \overset{def}{=} \prod_{i=1}^{n} \mathrm{P}(w_i \mid h_i) \qquad (1)$$

where $h_i \overset{def}{=} w_1 ... w_{i-1}$ is called the *history* of the word w_i. Most work on language modeling therefore is directed at the estimation of $P(w_i \mid h_i)$. While this is theoretically correct, it makes it difficult to incorporate global information about the sentence into the model, e.g. length, grammaticality, etc'. For this reason, the whole-sentence maximum-entropy model was proposed in (Rosenfeld, 1997). In the WSME model the probability of a sentence is defined directly as:

$$P(s) = \frac{1}{Z} P_0(s) \cdot \exp(\sum_i \lambda_i f_i(s)) \qquad (2)$$

Where $P_0(s)$ is some baseline model, $Z \overset{def}{=} \sum_s P_0(s) \cdot \exp(\sum_i \lambda_i f_i(s))$ is a normalization constant and the $\{f_i\}$'s are *features* encoding some information about the sentence. Most generally, a feature is a function from the set of word sequences to *R*, the set of real numbers. However, in most applications, as in our work, the features are taken to be binary. Lastly, the $\{\lambda_i\}$'s are real coefficients encoding the relative importance of their corresponding features. In the WSME framework the set of features $\{f_i\}$ is given ahead of training by the modeler, and learning consists of estimating the coefficients $\{\lambda_i\}$. This is done by stipulating the constraints

$$E_p(f_i) = E_{\tilde{p}}(f_i) \overset{def}{=} \frac{1}{N} \sum_{j=1}^{N} f_i(s_j) \qquad (3)$$

where $\tilde{p}$ is the empirical distribution defined by the training set $\{s_1, ... s_N\}$.[2] If these constraints are consistent then there is a unique solution in $\{\lambda_i\}$ that satisfies them. This solution is guaranteed to be the one closest to P_0 in the Kullback-Leblier sense among all solutions satisfying (3). It is also guaranteed to be the maximum likelihood solution for the exponential family. For more details, see (Chen and Rosenfeld, 1999a).

2.2 Self-supervised boosting

A different approach to learning the same sort of model as in (2) was proposed in (Welling et al., 2003). Here, instead of having all the features pre-given, they are *learned* one at a time along with their corresponding coefficients. Welling et al. show that adding a new feature to (2) can be

[2] Sometimes a smoothed version of (3) is used instead (e.g. Chen and Rosenfeld, 1999b).

interpreted as gradient ascent on the log-likelihood function, and show that the optimal feature is the one that best discriminates real data from data sampled from the current model. To see this, let

$$E(s) = \ln(P_0(s)) + \sum_i \lambda_i f_i(s) \tag{4}$$

denote the *energy* associated with sentence s.[3] Equation (2) can now be rewritten as -

$$P(s) = \frac{1}{Z}\exp(E(s)) \tag{5}$$

where Z is a normalization constant as before. The derivative of the log-likelihood with respect to an arbitrary parameter β is then –

$$\frac{\partial L}{\partial \beta} = -\frac{1}{N}\sum_{i=1}^{N}\frac{\partial E(s_i)}{\partial \beta} + \sum_{s \in S} P(s)\frac{\partial E(s)}{\partial \beta} \tag{6}$$

where $\{s_1, \ldots s_N\}$ is once again the training corpus, and the second sum runs over the set of all word sequences.

Now, suppose we change the energy function by adding an infinitesimal multiple of a new feature f^*. The log-likelihood after adding the feature can be approximated by –

$$L(E(s) + \varepsilon f^*(s)) \approx L(E(s)) + \varepsilon \frac{\partial L}{\partial \varepsilon} \tag{7}$$

where the derivative of L is taken at $\varepsilon = 0$. Because the optimal feature is the one that maximizes the increase in log-likelihood, we are searching for a feature that maximizes this derivative. Using equation (6) and noting that $\frac{\partial E}{\partial \varepsilon} = f^*$ we have –

$$\frac{\partial L}{\partial \varepsilon} = -\frac{1}{N}\sum_{i=1}^{N} f^*(s_i) + \sum_{s \in S} P(s) f^*(s) \tag{8}$$

This expression cannot be computed in practice, because the set of all word sequences S is infinite. The second term however can approximated using samples $\{u_i\}$ from the current model –

$$\frac{\partial L}{\partial \varepsilon} \approx -\frac{1}{N}\sum_{i=1}^{N} f^*(s_i) + \frac{1}{N}\sum_{i=1}^{N} f^*(u_i) \tag{9}$$

[3] In (Welling et al., 2003) the term for P_0 does not appear, which is equivalent to taking the uniform distribution as the baseline model.

In other words, given a set of N samples $\{u_i\}$ from the model, the optimal feature to add is one that gives high scores to sampled sentences and low ones to real sentences. By labeling real sentences with 0 and sampled sentences with 1, the task of learning the feature translates into the task of training a classifier to discriminate between these two classes of sentences.

In the remainder of the paper we will use *feature* and *classifier* interchangeably.

2.3 Rejection sampling

Self-supervised boosting was presented as a general method for density estimation, and was not tested in the context of language modeling. Rather, Welling at al. demonstrated its effectiveness in modeling hand-written digits and on synthetic data. In both cases essentially linear classifiers were used as features. As these are computationally very efficient, the authors could use a variant of Gibbs sampling for generating negative samples. Unfortunately, as shown in (Okanohara and Tsujii, 2007), with the represetation of sentences that we use, linear classifiers cannot discriminate real sentences from sentences sampled from a trigram, which is the model we use as a baseline, so here we resort to a non-linear large-margin classifier (see section 3 for details). While large-margin classifiers consistently out-perform other learning algorithms in many NLP tasks, their non-linear variations are also notoriously slow when it comes to computing their decision function – taking time that can be linear in the size of their training data. This means that MCMC techniques like Gibbs sampling quickly become intractable, even for small corpora, as they require performing very large numbers of classifications. For this reason we use a different sampling scheme which we refer to as *rejection sampling*. This allows us to sample from the true model distribution while requiring a drastically smaller number of classifications, as long as the current model isn't too far removed from the baseline.

We will start by describing the sampling process, and then show that the probability distribution it samples from has the form of equation (2). To sample a sentence from the current model, we generate one from the baseline model, and then pass it through each of the classifiers in the model. If a given classifier classifies the sentence as a model sentence, then it is rejected with a certain probability associated with this classifier. Only if a sentence is accepted by all classifiers is it taken as a sample sentence. Otherwise, the sampling process is restarted.

Let us derive an expression for the probability of a sentence *s* generated in this manner. To simplify notation, assume that at this point we added but a single feature *f* to the baseline model P_0, and let p_{rej} stand for the rejection probability associated with it. Furthermore, let p_- stand for the accuracy of *f* in classifying sentences sampled from P_0 (negative samples). Formally,

$$p_- = E_{P_0}(f) \tag{10}$$

First let's assume that $f(s)=1$. The probability for generating s is a sum of the probabilities of two disjoint outcomes – the probability of generating s as the first sentence and having it survive the rejection, plus the probability of generating in the first iteration some sentence s' such that $f(s')=1$, rejecting that, and then generating s in one of the subsequent iterations. Formally, this means that –

$$P_1(s) = (1-p_{rej})P_0(s) + p_- p_{rej} P_1(s) \tag{11}$$

Rearranging, we have –

$$P_1(s) = \frac{1-p_{rej}}{1-p_- p_{rej}} P_0(s) \tag{12}$$

Similarly, the probability for a sentence s for which $f(s)=0$ is the probability of generating s as the first sentence, plus the probability of generating some other sentence s' for which $f(s')=1$, rejecting it, and then generating s in a future iteration. Formally,

$$P_1(s) = P_0(s) + p_- p_{rej} P_1(s) \tag{13}$$

and hence –

$$P_1(s) = \frac{1}{1-p_- p_{rej}} P_0(s) \tag{14}$$

Letting $Z = 1 - p_- p_{rej}$, and letting $\lambda = \ln(1-p_{rej})$, we have, for all s –

$$P_1(s) = \frac{1}{Z} P_0(s) \cdot \exp(\lambda \cdot f(s)) \tag{15}$$

This process can be trivially generalized for N features. Let –

$$p_-^i = E_{P_{i-1}}(f_i) \tag{16}$$

stand for f_i's accuracy in classifying sentences generated from P_{i-1}, and let p_{rej}^i be the rejection probability associated with the i'th feature. Sampling from the model then proceeds by sampling a sentence *s* from P_0. For each $1 \le i \le N$, in order, if $f_i(s)=1$, then we attempt to reject *s* with probability p_{rej}^i. If *s* survives all the rejection attempts, it is returned as the next sample. Using similar arguments as before it's possible to show that if we take $\lambda_i = \ln(1-p_{rej}^i)$ and –

$$Z = \prod_{i=1}^{N} (1 - p_-^i p_{rej}^i) \tag{17}$$

then the probability of a sentence *s* sampled by this process is given by equation (2). Conversely, this shows that rejection sampling can be used for obtaining negative samples from the model given in (2) by taking $p_{rej}^i = 1 - \exp(\lambda_i)$, as long as $0 < \exp(\lambda_i) \le 1$. In section 3 we show that in our experimental setup, rejection sampling brings about enormous savings in the number of classifications necessary during training, as compared with Gibbs sampling.

2.4 Adding a new feature

Given the current model P_i and a new feature f_{i+1}, we wish to find the optimal λ_{i+1}, or equivalently its optimal rejection probability p_{rej}^{i+1}. In the WSME framework, the weights of the features are set in such a way that the expected value of the features on sentences sampled from the model equals their expected value on real sentences. A possible way to set the weight of a new feature is therefore to set p_{rej}^{i+1} such that the constraint:

$$E_{P_{i+1}}(f_{i+1}) = E_{\tilde{p}}(f_{i+1}) \tag{18}$$

is satistfied, where $\tilde{p}$ is once again the empirical distribution defined by the training set. Intuitively, this means that the new feature could no longer be used to discriminate between sentences sampled from P_{i+1} and real sentences. However, setting

p_{rej}^{i+1} in this manner may violate the constraints (18) associated with the features already existing in the model, thus hampering the model's performance. Therefore, we set the new feature's rejection probability by directly searching for the one that minimizes an estimate of P_{i+1}'s perplexity on a set of held out real sentences. To do this, we first sample a new set of sentences from P_i, independently of the set that was used for training f_{i+1}, and use it to estimate p_{-}^{i+1}. For any arbitrarily determined p_{rej}^{i+1}, this enables us to calculate an estimate for the normalization constant Z (equation 17), and therefore an estimate for P_{i+1}. We do this for a range of possible values for p_{rej}^{i+1} and pick the one that leads to the largest reduction in perplexity on the held out data.[4]

3 Experimental work

We tested our approach on the ATIS natural language corpus (Hemphill et al., 1990). We split the corpus into a training set of 11,000 sentences, a held-out set containing 1,045 sentences, and a test set containing 1,000 sentences which were reserved for measuring perplexity. The corpus was pre-processed so that every word appearing less than three times was replaced by a special UNK symbol. The resulting lexicon contained 603 word types.

Our learning framework leaves open a number of design choices:

1. **Baseline language model**: For P_0 we used a trigram with modified kneser-ney smoothing [Chen and Goodman, 1998], which is still considered one of the best smoothing methods for n-gram language models.

2. **Sentence representation**: Each sentence was represented as the collection of unigrams, bigrams and trigrams it contained. A coordinate was reserved for each such n-gram which appeared in the data, whether real or sampled. The value of the n'th coordinate in the vector representation of sentence s was set to the number of times the corresponding n-gram appeared in s.

3. **Type of classifiers**: For our features we used large-margin classifiers trained using the online algorithm described in (Crammer et al., 2006). The code for the classifier was generously provided by Daisuke Okanohara. This code was extensively optimized to take advantage of the very sparse sentence representation described above. As shown in (Okanohara and Tsujii, 2007), using this representation, a linear classifier cannot distinguish sentences sampled from a trigram and real sentences. Therefore, we used a 3rd order polynomial kernel, which was found to give good results. No special effort was otherwise made in order to optimize the parameters of the classifiers.

4. **Stopping criterion**: The process of adding features to the model was continued until the classification performance of the next feature was within 2% of chance performance.

We refer to the language model obtained by this approach as the *boosted* model to distinguish it from the baseline model. To estimate the boosted model's perplexity we needed to estimate the normalization constant Z in equation (2). Since this constant is equal to $E_{P_0}(\exp(\sum_i \lambda_i f_i))$ it can be estimated from a large-enough sample from P_0. We used 10,000,000 sentences generated from the baseline trigram and took the upper bound of the 95% confidence interval of the sample mean as an upper bound for Z. This means the perplexity estimates we report are upper bounds for the real model perplexity with 95% confidence.[5]

The algorithm converged after 21 features were added to the model. Figure 1 presents the model's perplexity on the test set estimated after each iteration. The perplexity of the final model is 9.02. In comparison, the perplexity of the modified kneser-ney smoothed trigram on this corpus is 10.18. This is an 11.4% improvement relative to the baseline model.

[4] Interestingly, in practice both methods result in near identical rejection probabilities, within a precision of 0.0001. This indicates that satisfying the constraint (18) for the new feature is more important, in terms of perplexity, than preserving the constraints of the previous features, insofar as those get violated.

[5] Alternatively we could have used our estimate for P_N(s) described in section 2.4. A large sample of sentences would still be necessary though, to get a good estimate for equation (16).

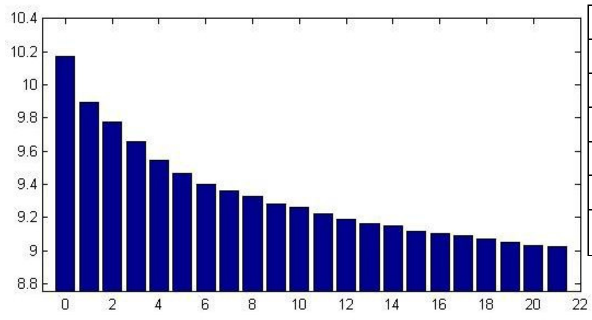

Figure 1. Model perplexity during training. The x-axis denotes the number of features added to the model. The final perplexity after 21 features is 9.02.

Table 2. A sample of sentences generated by the final model

Figure 2 shows the accuracy of the trained features on held-out data. The held-out data was composed of equal parts real and model sentences, so 50% accuracy is chance performance. As might have been expected, the classifiers start out with a relatively high accuracy of 68%, which dwindles down to little over 50% as more features are added to the model. Not surprisingly, there is a strong correlation between the accuracy of a feature and the reduction in perplexity it engenders (spearman correlation coefficient r=0.89, $p<10^{-5}$.)

In tables 1 and 2 we show a representative sample of sentences from the baseline model and from the final model. As the baseline model is a trigram, it cannot capture dependencies that span a range longer than two words. Hence sentences that start out seemingly in one topic and then veer off to another are common. The global information available to the features used by the boosted model greatly reduces this phenomenon. To get a quantitative sense of this, we generated 200 sentences from each model and submitted them for grammaticality testing by a proficient (though non-native) English speaker. Of the trigram-generated sentences, 86 were deemed grammatical (43%), while of those generated by the boosted model 132 were grammatical (66%). This difference is statistically significant with $p<10^{-5}$.

Finally, let us quantify the computational savings obtained from using rejection sampling. Let |V| stand for the lexicon size (here |V|=603) and |L| for the average sentence length (|L|=14). In Gibbs sampling, a sentence is sampled by starting out with a random sequence of words. For each word position, the current word is replaced with each word in the lexicon, and the probability of the resulting sentence is calculated. Then one of the words is randomly selected for this position in proportion to the calculated probabilities. The sentence has to be scanned in this manner several times for the sample to approximate the model distribution. Assuming we perform only 3 scans for each sentence, Gibbs sampling would have thus required us to classify $3|V||L| \approx 25,000$ sentences *per sampled sentence*. Given that in each iteration we generate 12,045 sentences, and that in the *n'th* iteration each sentence has to be classified by *n* features, this gives a total of roughly

$7 \cdot 10^{10}$ classifications after 21 iterations. In contrast, using rejection sampling, we used only $6.7 \cdot 10^{7}$ classifications in total – a difference of over three orders of magnitude.

4 Discussion

In this work we presented a method that enables using discriminative learning methods for refining generative language models. Utilizing large-margin classifiers that are trained to discriminate real sentences from model sentences we showed that sizeable improvements in perplexity over a state-of-the-art smoothed trigram are possible.

Our method bears some similarity to the recently developed *Contrastive Estimation* method (Smith and Eisner, 2004). Contrastive estimation (CE) was proposed as a means for training log-linear probabilistic models. As all training methods, contrastive estimation pushes probability mass unto positive samples. Unlike other methods, CE takes this probability mass from the 'neighborhood' of each positive sample. For example, given a real sentence *s*, CE might give it more probability by taking away probability from similar sentences which are likely to be ungrammatical, for instance sentences that are formed by taking *s* and switching the order of two adjacent words in it. This is intuitively similar to our approach – effectively, our model gives probability mass to positive samples, taking it away from sentences classified as model sentences. A major difference between the two approaches, however, is that in CE the definition of the sentence's neighborhood must be specified in advance by the modeler. In our work, the 'neighborhood' is determined automatically and dynamically as learning proceeds, according to the capabilities of the classifiers used.

The sentence representation we chose for this work is rather simple, and was intended primarily to demonstrate the efficacy of our approach. In future work we plan to experiment with richer representations, e.g. including long-range n-grams (Rosenfeld, 1996), class n-grams (Brown et al., 1992), grammatical features (Amaya and Benedy, 2001), etc'.

The main computational bottleneck in our approach is the generation of negative samples from the current model. Rejection sampling allowed us to use computationally intensive classifiers as our features by reducing the number of classifications that had to be performed during the sampling process. However, if the boosted model strays too far from the baseline P_0, these savings will be negated by the very large sentence rejection probabilities that will ensue. This is likely to be the case when richer representations as suggested above are used, necessitating a return to Gibbs sampling. Therefore, in future work we plan to experiment with classifiers whose decision function is cheaper to compute, such as neural networks and decision trees. Another possible direction would be using the recently proposed Deep Belief Network formalism (Hinton et al., 2006). DBNs utilize semi-linear features which are stacked recursively and thus very efficiently model non-linearities in their data. These have been used in the past for language modeling (Mnih and Hinton, 2007), but not within the whole-sentence framework.

Abstract

We present a discriminative method for learning selectional preferences from unlabeled text. Positive examples are taken from observed predicate-argument pairs, while negatives are constructed from unobserved combinations. We train a Support Vector Machine classifier to distinguish the positive from the negative instances. We show how to partition the examples for efficient training with 57 thousand features and 6.5 million training instances. The model outperforms other recent approaches, achieving excellent correlation with human plausibility judgments. Compared to Mutual Information, it identifies 66% more verb-object pairs in unseen text, and resolves 37% more pronouns correctly in a pronoun resolution experiment.

1 Introduction

Selectional preferences (SPs) tell us which arguments are plausible for a particular predicate. For example, Table 2 (Section 4.4) lists plausible and implausible direct objects (arguments) for particular verbs (predicates). SPs can help resolve syntactic, word sense, and reference ambiguity (Clark and Weir, 2002), and so gathering them has received a lot of attention in the NLP community.

One way to determine SPs is from co-occurrences of predicates and arguments in text. Unfortunately, no matter how much text we use, many acceptable pairs will be missing. Bikel (2004) found that only 1.49% of the bilexical dependencies considered by Collins' parser during decoding were observed during training. In our parsed corpus (Section 4.1), for example, we find *eat* with *nachos*, *burritos*, and *tacos*, but not with the equally tasty *quesadillas*, *chimichangas*, or *tostadas*. Rather than solely relying on co-occurrence counts, we would like to use them to generalize to unseen pairs.

In particular, we would like to exploit a number of arbitrary and potentially overlapping properties of predicates and arguments when we assign SPs. We do this by representing these properties as features in a linear classifier, and training the weights using discriminative learning. Positive examples are taken from observed predicate-argument pairs, while pseudo-negatives are constructed from unobserved combinations. We train a Support Vector Machine (SVM) classifier to distinguish the positives from the negatives. We refer to our model's scores as Discriminative Selectional Preference (DSP). By creating training vectors automatically, DSP enjoys all the advantages of supervised learning, but without the need for manual annotation of examples.

We evaluate DSP on the task of assigning verb-object selectional preference. We encode a noun's textual distribution as feature information. The learned feature weights are linguistically interesting, yielding high-quality similar-word lists as latent information. Despite its representational power, DSP scales to real-world data sizes: examples are partitioned by predicate, and a separate SVM is trained for each partition. This allows us to efficiently learn with over 57 thousand features and 6.5 million examples. DSP outperforms recently proposed alternatives in a range of experiments, and better correlates with human plausibility judgments. It also shows strong gains over a Mutual Information-based co-occurrence model on two tasks: identifying objects of verbs in an unseen corpus and finding pronominal antecedents in coreference data.

2 Related Work

Most approaches to SPs generalize from observed predicate-argument pairs to semantically similar ones by modeling the semantic class of the argument, following Resnik (1996). For example, we might have a class *Mexican Food* and learn that the entire class is suitable for eating. Usually, the classes are from WordNet (Miller et al., 1990), although they can also be inferred from clustering (Rooth et al., 1999). Brockmann and Lapata (2003) compare a number of WordNet-based approaches, including Resnik (1996), Li and Abe (1998), and Clark and Weir (2002), and found that the more sophisticated class-based approaches do not always outperform simple frequency-based models.

Another line of research generalizes using similar words. Suppose we are calculating the probability of a particular noun, n, occurring as the object argument of a given verbal predicate, v. Let $\text{Pr}(n|v)$ be the empirical maximum-likelihood estimate from observed text. Dagan et al. (1999) define the similarity-weighted probability, Pr_{SIM}, to be:

$$\text{Pr}_{\text{SIM}}(n|v) = \sum_{v' \in \text{SIMS}(v)} \textit{Sim}(v', v)\text{Pr}(n|v') \quad (1)$$

where $\textit{Sim}(v', v)$ returns a real-valued similarity between two verbs v' and v (normalized over all pair similarities in the sum). In contrast, Erk (2007) generalizes by substituting similar *arguments*, while Wang et al. (2005) use the cross-product of similar pairs. One key issue is how to define the set of similar words, $\text{SIMS}(w)$. Erk (2007) compared a number of techniques for creating similar-word sets and found that both the Jaccard coefficient and Lin (1998a)'s information-theoretic metric work best. Similarity-smoothed models are simple to compute, potentially adaptable to new domains, and require no manually-compiled resources such as WordNet.

Selectional Preferences have also been a recent focus of researchers investigating the learning of paraphrases and inference rules (Pantel et al., 2007; Roberto et al., 2007). Inferences such as "[*X* wins *Y*] ⇒ [*X* plays *Y*]" are only valid for certain arguments *X* and *Y*. We follow Pantel et al. (2007) in using automatically-extracted semantic classes to help characterize plausible arguments.

Discriminative techniques are widely used in NLP and have been applied to the related tasks of word prediction and language modeling. Even-Zohar and Roth (2000) use a classifier to predict the most likely word to fill a position in a sentence (in their experiments: a verb) from a set of candidates (sets of verbs), by inspecting the context of the target token (e.g., the presence or absence of a particular nearby word in the sentence). This approach can therefore learn which specific arguments occur with a particular predicate. In comparison, our features are second-order: we learn what *kinds* of arguments occur with a predicate by encoding features of the arguments. Recent distributed and latent-variable models also represent words with feature vectors (Bengio et al., 2003; Blitzer et al., 2005). Many of these approaches learn both the feature weights and the feature representation. Vectors must be kept low-dimensional for tractability, while learning and inference on larger scales is impractical. By partitioning our examples by predicate, we can efficiently use high-dimensional, sparse vectors.

Our technique of generating negative examples is similar to the approach of Okanohara and Tsujii (2007). They learn a classifier to disambiguate actual sentences from pseudo-negative examples sampled from an N-gram language model. Smith and Eisner (2005) also automatically generate negative examples. They perturb their input sequence (e.g. the sentence word order) to create a neighborhood of *implicit* negative evidence. We create negatives by substitution rather than perturbation, and use corpus-wide statistics to choose our negative instances.

3 Methodology

3.1 Creating Examples

To learn a discriminative model of selectional preference, we create positive and negative training examples automatically from raw text. To create the positives, we automatically parse a large corpus, and then extract the predicate-argument pairs that have a statistical association in this data. We measure this association using pointwise Mutual Information (MI) (Church and Hanks, 1990). The MI between a verb predicate, v, and its object argument, n, is:

$$\mathrm{MI}(v,n) = \log\frac{\Pr(v,n)}{\Pr(v)\Pr(n)} = \log\frac{\Pr(n|v)}{\Pr(n)} \quad (2)$$

If MI>0, the probability v and n occur together is greater than if they were independently distributed.

We create sets of positive and negative examples separately for each predicate, v. First, we extract all pairs where $\mathrm{MI}(v,n)>\tau$ as positives. For each positive, we create pseudo-negative examples, (v,n'), by pairing v with a new argument, n', that either has MI below the threshold or did not occur with v in the corpus. We require each negative n' to have a similar frequency to its corresponding n. This prevents our learning algorithm from focusing on any accidental frequency-based bias. We mix in K negatives for each positive, sampling without replacement to create all the negatives for a particular predicate. For each v, $\frac{1}{K+1}$ of its examples will be positive. The threshold τ represents a trade-off between capturing a large number of positive pairs and ensuring these pairs have good association. Similarly, K is a trade-off between the number of examples and the computational efficiency. Ultimately, these parameters should be optimized for task performance.

Of course, some negatives will actually be plausible arguments that were unobserved due to sparseness. Fortunately, modern discriminative methods like soft-margin SVMs can learn in the face of label error by allowing slack, subject to a tunable regularization penalty (Cortes and Vapnik, 1995).

If MI is a sparse and imperfect model of SP, what can DSP gain by training on MI's scores? We can regard DSP as learning a view of SP that is orthogonal to MI, in a co-training sense (Blum and Mitchell, 1998). MI labels the data based solely on co-occurrence; DSP uses these labels to identify other regularities – ones that extend beyond co-occurring words. For example, many instances of n where $\mathrm{MI}(\textit{eat},n)>\tau$ also have $\mathrm{MI}(\textit{buy},n)>\tau$ and $\mathrm{MI}(\textit{cook},n)>\tau$. Also, compared to other nouns, a disproportionate number of *eat*-nouns are lower-case, single-token words, and they rarely contain digits, hyphens, or begin with a human first name like *Bob*. DSP encodes these interdependent properties as features in a linear classifier. This classifier can score any noun as a plausible argument of *eat* if indicative features are present; MI can only assign high plausibility to observed (*eat*,n) pairs. Similarity-smoothed models can make use of the regularities across similar verbs, but not the finer-grained string- and token-based features.

Our training examples are similar to the data created for *pseudodisambiguation*, the usual evaluation task for SP models (Erk, 2007; Keller and Lapata, 2003; Rooth et al., 1999). This data consists of triples (v,n,n') where v,n is a predicate-argument pair observed in the corpus and v,n' has not been observed. The models score correctly if they rank observed (and thus plausible) arguments above corresponding unobserved (and thus likely implausible) ones. We refer to this as *Pairwise Disambiguation*. Unlike this task, we classify each predicate-argument pair independently as plausible/implausible. We also use MI rather than frequency to define the positive pairs, ensuring that the positive pairs truly have a statistical association, and are not simply the result of parser error or noise.[1]

3.2 Partitioning for Efficient Training

After creating our positive and negative training pairs, we must select a feature representation for our examples. Let $\mathbf{\Phi}$ be a mapping from a predicate-argument pair (v,n) to a feature vector, $\mathbf{\Phi} : (v,n) \rightarrow \langle\phi_1 ... \phi_k\rangle$. Predictions are made based on a weighted combination of the features, $y = \boldsymbol{\lambda}\cdot\mathbf{\Phi}(v,n)$, where $\boldsymbol{\lambda}$ is our learned weight vector.

We can make training significantly more efficient by using a special form of attribute-value features. Let every feature ϕ_i be of the form $\phi_i(v,n) = \langle v = \hat{v} \wedge f(n)\rangle$. That is, every feature is an intersection of the occurrence of a particular predicate, $\hat{v}$, and some feature of the argument $f(n)$. For example, a feature for a verb-object pair might be, "the verb is *eat* and the object is lower-case." In this representation, features for one predicate will be completely independent from those for every other predicate. Thus rather than a single training procedure, we can actually partition the examples by predicate, and train a

[1]For a fixed verb, MI is proportional to Keller and Lapata (2003)'s conditional probability scores for pseudodisambiguation of (v,n,n') triples: $\Pr(v|n) = \Pr(v,n)/\Pr(n)$, which was shown to be a better measure of association than co-occurrence frequency $f(v,n)$. Normalizing by $\Pr(v)$ (yielding MI) allows us to use a constant threshold across all verbs. MI was also recently used for inference-rule SPs by Pantel et al. (2007).

classifier for each predicate independently. The prediction becomes $y^v = \boldsymbol{\lambda}^v \cdot \boldsymbol{\Phi}^v(n)$, where $\boldsymbol{\lambda}^v$ are the learned weights corresponding to predicate v and all features $\boldsymbol{\Phi}^v(n)$=$\mathbf{f}(n)$ depend on the argument only.

Some predicate partitions may have insufficient examples for training. Also, a predicate may occur in test data that was unseen during training. To handle these instances, we decided to cluster low-frequency predicates. In our experiments assigning SP to verb-object pairs, we cluster all verbs that have less than 250 positive examples, using clusters generated by the CBC algorithm (Pantel and Lin, 2002). For example, the low-frequency verbs *incarcerate*, *parole*, and *court-martial* are all mapped to the same partition, while more-frequent verbs like *arrest* and *execute* each have their own partition. About 5.5% of examples are clustered, corresponding to 30% of the 7367 total verbs. 40% of verbs (but only 0.6% of examples) were not in any CBC cluster; these were mapped to a single backoff partition.

The parameters for each partition, $\boldsymbol{\lambda}^v$, can be trained with any supervised learning technique. We use SVM (Section 4.1) because it is effective in similar high-dimensional, sparse-vector settings, and has an efficient implementation (Joachims, 1999). In SVM, the sign of y^v gives the classification. We can also use the scalar y^v as our DSP score (i.e. the positive distance from the separating SVM hyperplane).

3.3 Features

This section details our argument features, $\mathbf{f}(n)$, for assigning verb-object selectional preference. For a verb predicate (or partition) v and object argument n, the form of our classifier is $y^v = \sum_i \lambda_i^v f_i(n)$.

3.3.1 Verb co-occurrence

We provide features for the empirical probability of the noun occurring as the object argument of other verbs, Pr$(n|v')$. If we were to only use these features (indexing the feature weights by each verb v'), the form of our classifier would be:

$$y^v = \sum_{v'} \lambda_{v'}^v \mathrm{Pr}(n|v') \qquad (3)$$

Note the similarity between Equation (3) and Equation (1). Now the feature weights, $\lambda_{v'}^v$, take the role of the similarity function, *Sim*(v', v). Unlike Equation (1), however, these weights are not set by an external similarity algorithm, but are optimized to discriminate the positive and negative training examples. We need not restrict ourselves to a short list of similar verbs; we include $\mathrm{Pr}_{obj}(n|v')$ features for every verb that occurs more than 10 times in our corpus. $\lambda_{v'}^v$ may be positive or negative, depending on the relation between v' and v. We also include features for the probability of the noun occurring as the *subject* of other verbs, $\mathrm{Pr}_{subj}(n|v')$. For example, nouns that can be the object of *eat* will also occur as the subject of *taste* and *contain*. Other contexts, such as adjectival and nominal predicates, could also aid the prediction, but have not yet been investigated.

The advantage of tuning similarity to the application of interest has been shown previously by Weeds and Weir (2005). They optimize a few meta-parameters separately for the tasks of thesaurus generation and pseudodisambiguation. Our approach, on the other hand, discriminatively sets millions of individual similarity values. Like Weeds and Weir (2005), our similarity values are asymmetric.

3.3.2 String-based

We include several simple character-based features of the noun string: the number of tokens, the case, and whether it contains digits, hyphens, an apostrophe, or other punctuation. We also include a feature for the first and last token, and fire indicator features if any token in the noun occurs on in-house lists of given names, family names, cities, provinces, countries, corporations, languages, etc. We also fire a feature if a token is a corporate designation (like *inc.* or *ltd.*) or a human one (like *Mr.* or *Sheik*).

3.3.3 Semantic classes

Motivated by previous SP models that make use of semantic classes, we generated word clusters using CBC (Pantel and Lin, 2002) on a 10 GB corpus, giving 3620 clusters. If a noun belongs in a cluster, a corresponding feature fires. If a noun is in none of the clusters, a *no-class* feature fires.

As an example, CBC cluster 1891 contains:

> sidewalk, driveway, roadway, footpath, bridge, highway, road, runway, street, alley, path, Interstate, . . .

In our training data, we have examples like *widen highway*, *widen road* and *widen motorway*. If we see that we can widen a highway, we learn that we can also widen a sidewalk, bridge, runway, etc.

We also made use of the person-name/instance pairs automatically extracted by Fleischman et al. (2003).[2] This data provides counts for pairs such as "Edwin Moses, *hurdler*" and "William Farley, *industrialist*." We have features for all *concepts* and therefore learn their association with each verb.

4 Experiments and Results

4.1 Set up

We parsed the 3 GB AQUAINT corpus (Voorhees, 2002) using Minipar (Lin, 1998b), and collected verb-object and verb-subject frequencies, building an empirical MI model from this data. Verbs and nouns were converted to their (possibly multi-token) *root*, and string case was preserved. Passive subjects (*the car was bought*) were converted to objects (*bought car*). We set the MI-threshold, τ, to be 0, and the negative-to-positive ratio, K, to be 2.

Numerous previous pseudodisambiguation evaluations only include arguments that occur between 30 and 3000 times (Erk, 2007; Keller and Lapata, 2003; Rooth et al., 1999). Presumably the lower bound is to help ensure the negative argument is unobserved because it is unsuitable, not because of data sparseness. We wish to use our model on arguments of any frequency, including those that never occurred in the training corpus (and therefore have empty co-occurrence features (Section 3.3.1)). We proceed as follows: first, we exclude pairs whenever the noun occurs less than 3 times in our corpus, removing many misspellings and other noun noise. Next, we omit verb co-occurrence features for nouns that occur less than 10 times, and instead fire a low-count feature. When we move to a new corpus, previously-unseen nouns are treated like these low-count training nouns.

This processing results in a set of 6.8 million pairs, divided into 2318 partitions (192 of which are verb clusters (Section 3.2)). For each partition, we take 95% of the examples for training, 2.5% for development and 2.5% for a final unseen test set. We provide full results for two models: DSP_{cooc} which only uses the verb co-occurrence features, and DSP_{all} which uses all the features mentioned in Section 3.3. Feature values are normalized within each feature type. We train our (linear kernel) discriminative models using SVM^{light} (Joachims, 1999) on each partition, but set meta-parameters C (regularization) and j (cost of positive vs. negative misclassifications: max at $j{=}2$) on the macro-averaged score across all development partitions. Note that we can not use the development set to optimize τ and K because the development examples are obtained *after* setting these values.

[2]Available at http://www.mit.edu/˜mbf/instances.txt.gz

4.2 Feature weights

It is interesting to inspect the feature weights returned by our system. In particular, the weights on the verb co-occurrence features (Section 3.3.1) provide a high-quality, argument-specific similarity-ranking of other verb contexts. The DSP parameters for *eat*, for example, place high weight on features like $\Pr(n|\textit{braise})$, $\Pr(n|\textit{ration})$, and $\Pr(n|\textit{garnish})$. Lin (1998a)'s similar word list for *eat* misses these but includes *sleep* (ranked 6) and *sit* (ranked 14), because these have similar *subjects* to *eat*. Discriminative, context-specific training seems to yield a better set of similar predicates, e.g. the highest-ranked contexts for DSP_{cooc} on the verb *join*,[3]

> lead 1.42, rejoin 1.39, form 1.34, belong to 1.31, found 1.31, quit 1.29, guide 1.19, induct 1.19, launch (*subj*) 1.18, work at 1.14

give a better $\text{SIMS}(\textit{join})$ for Equation (1) than the top similarities returned by (Lin, 1998a):

> participate 0.164, lead 0.150, return to 0.148, say 0.143, rejoin 0.142, sign 0.142, meet 0.142, include 0.141, leave 0.140, work 0.137

Other features are also weighted intuitively. Note that case is a strong indicator for some arguments, for example the weight on being lower-case is high for *become* (0.972) and *eat* (0.505), but highly negative for *accuse* (-0.675) and *embroil* (-0.573) which often take names of people and organizations.

4.3 Pseudodisambiguation

We first evaluate DSP on disambiguating positives from pseudo-negatives, comparing to recently-

[3]Which all correspond to nouns occurring in the object position of the verb (e.g. $\Pr_{obj}(n|\textit{lead})$), except "launch (*subj*)" which corresponds to $\Pr_{subj}(n|\textit{launch})$.

System	*MacroAvg*			*MicroAvg*			*Pairwise*	
	P	R	F	P	R	F	Acc	Cov
Dagan et al. (1999)	0.36	**0.90**	0.51	0.68	**0.92**	0.78	0.58	0.98
Erk (2007)	0.49	0.66	0.56	0.70	0.82	0.76	0.72	0.83
Keller and Lapata (2003)	**0.72**	0.34	0.46	**0.80**	0.50	0.62	0.80	0.57
DSP_{cooc}	0.53	0.72	0.61	0.73	0.94	**0.82**	0.77	**1.00**
DSP_{all}	0.60	0.71	**0.65**	0.77	0.90	**0.83**	**0.81**	**1.00**

Table 1: Pseudodisambiguation results averaged across each example (*MacroAvg*), weighted by word frequency (*MicroAvg*), plus coverage and accuracy of pairwise competition (*Pairwise*).

proposed systems that also require no manually-compiled resources like WordNet. We convert Dagan et al. (1999)'s similarity-smoothed probability to MI by replacing the empirical $\text{Pr}(n|v)$ in Equation (2) with the smoothed Pr_{SIM} from Equation (1). We also test an MI model inspired by Erk (2007):

$$\text{MI}_{\text{SIM}}(n, v) = \log \sum_{n' \in \text{SIMS}(n)} \mathit{Sim}(n', n) \frac{\text{Pr}(v, n')}{\text{Pr}(v)\text{Pr}(n')}$$

We gather similar words using Lin (1998a), mining similar verbs from a comparable-sized parsed corpus, and collecting similar nouns from a broader 10 GB corpus of English text.[4]

We also use Keller and Lapata (2003)'s approach to obtaining web-counts. Rather than mining parse trees, this technique retrieves counts for the pattern "V Det N" in raw online text, where V is any inflection of the verb, Det is *the*, *a*, or the empty string, and N is the singular or plural form of the noun. We compute a web-based MI by collecting $\text{Pr}(n, v)$, $\text{Pr}(n)$, and $\text{Pr}(v)$ using all inflections, except we only use the root form of the noun. Rather than using a search engine, we obtain counts from the Google Web 5-gram Corpus.[5]

All systems are thresholded at zero to make a classification. Unlike DSP, the comparison systems may not be able to provide a score for each example. The similarity-smoothed examples will be undefined if $\text{SIMS}(w)$ is empty. Also, the Keller and Lapata (2003) approach will be undefined if the pair is unobserved on the web. As a reasonable default for these cases, we assign them a negative decision.

We evaluate disambiguation using precision (P), recall (R), and their harmonic mean, F-Score (F). Table 1 gives the results of our comparison. In the *MacroAvg* results, we weight each example equally. For *MicroAvg*, we weight each example by the frequency of the noun. To more directly compare with previous work, we also reproduced *Pairwise Disambiguation* by randomly pairing each positive with one of the negatives and then evaluating each system by the percentage it ranks correctly (Acc). For the comparison approaches, if one score is undefined, we choose the other one. If both are undefined, we abstain from a decision. Coverage (Cov) is the percent of pairs where a decision was made.[6]

Our simple system with only verb co-occurrence features, DSP_{cooc}, outperforms all comparison approaches. Using the richer feature set in DSP_{all} results in a statistically significant gain in performance, up to an F-Score of 0.65 and a pairwise disambiguation accuracy of 0.81.[7] DSP_{all} has both broader coverage and better accuracy than all competing approaches. In the remainder of the experiments, we use DSP_{all} and refer to it simply as DSP.

Some errors are because of plausible but unseen arguments being used as test-set pseudo-negatives. For example, for the verb *damage*, DSP's three most high-scoring false positives are the nouns *jetliner*, *carpet*, and *gear*. While none occur with *damage* in

[4]For both the similar-noun and similar-verb smoothing, we only smooth over similar pairs *that occurred in the corpus*. While averaging over all similar pairs tends to underestimate the probability, averaging over only the observed pairs tends to overestimate it. We tested both and adopt the latter because it resulted in better performance on our development set.

[5]Available from the LDC as LDC2006T13. This collection was generated from approximately 1 trillion tokens of online text. Unfortunately, tokens appearing less than 200 times have been mapped to the ⟨UNK⟩ symbol, and only N-grams appearing more than 40 times are included. Unlike results from search engines, however, experiments with this corpus are replicable.

[6]I.e. we use the "half coverage" condition from Erk (2007).

[7]The differences between DSP_{all} and all comparison systems are statistically significant (McNemar's test, $p<0.01$).

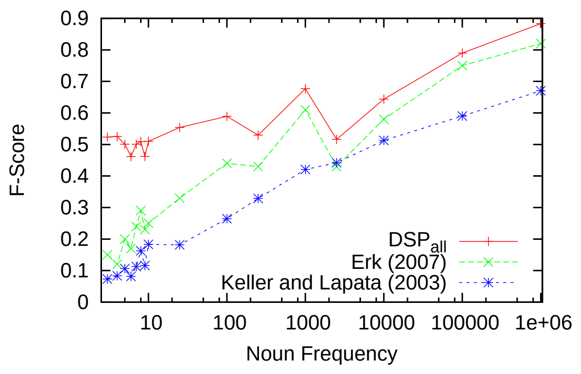

Figure 1: Disambiguation results by noun frequency.

our corpus, all intuitively satisfy the verb's SPs.

MacroAvg performance is worse than *MicroAvg* because all systems perform better on frequent nouns. When we plot F-Score by noun frequency (Figure 1), we see that DSP outperforms comparison approaches across all frequencies, but achieves its biggest gains on the low-frequency nouns. A richer feature set allows DSP to make correct inferences on examples that provide minimal co-occurrence data. These are also the examples for which we would expect co-occurrence models like MI to fail.

As a further experiment, we re-trained DSP but with only the string-based features removed. Overall macro-averaged F-score dropped from 0.65 to 0.64 (a statistically significant reduction in performance). The system scored nearly identically to DSP on the high-frequency nouns, but performed roughly 15% worse on the nouns that occurred less than ten times. This shows that the string-based features are important for selectional preference, and particularly helpful for low-frequency nouns.

4.4 Human Plausibility

Table 2 compares some of our systems on data used by Resnik (1996) (also Appendix 2 in Holmes et al. (1989)). The plausibility of these pairs was initially judged based on the experimenters' intuitions, and later confirmed in a human experiment. We include the scores of Resnik's system, and note that its errors were attributed to sense ambiguity and other limitations of class-based approaches (Resnik, 1996).[8]

[8]For example, *warn-engine* scores highly because engines are in the class *entity*, and physical entities (e.g. people) are often objects of *warn*. Unlike DSP, Resnik's approach cannot learn that for *warn*, "the property of being a person is more important than the property of being an entity" (Resnik, 1996).

Seen Criteria	Unseen Verb-Object Freq.				
	All	$= 1$	$= 2$	$= 3$	> 3
MI > 0	0.44	0.33	0.57	0.70	0.82
Freq. > 0	0.57	0.45	0.76	0.89	0.96
DSP > 0	0.73	0.69	0.80	0.85	0.88

Table 3: Recall on identification of Verb-Object pairs from an unseen corpus (divided by pair frequency).

The other comparison approaches also make a number of mistakes, which can often be traced to a misguided choice of similar word to smooth with.

We also compare to our empirical MI model, trained on our parsed corpus. Although Resnik (1996) reported that 10 of the 16 plausible pairs did not occur in his training corpus, all of them occurred in ours and hence MI gives very reasonable scores on the plausible objects. It has no statistics, however, for many of the implausible ones. DSP can make finer decisions than MI, recognizing that "warning an engine" is more absurd than "judging a climate."

4.5 Unseen Verb-Object Identification

We next compare MI and DSP on a much larger set of plausible examples, and also test how well the models generalize across data sets. We took the MI and DSP systems trained on AQUAINT and asked them to rate observed (and thus likely plausible) verb-object pairs taken from an unseen corpus. We extracted the pairs by parsing the San Jose Mercury News (SJM) section of the TIPSTER corpus (Harman, 1992). Each unique verb-object pair is a single instance in this evaluation.

Table 3 gives recall across all pairs (**All**) and grouped by pair-frequency in the unseen corpus (1, 2, 3, >3). DSP accepts far more pairs than MI (73% vs. 44%), even far more than a system that accepts any previously observed verb-object combination as plausible (57%). Recall is higher on more frequent verb-object pairs, but 70% of the pairs occurred only once in the corpus. Even if we smooth MI by smoothing $\Pr(n|v)$ in Equation 2 using modified KN-smoothing (Chen and Goodman, 1998), the recall of MI>0 on SJM only increases from 44.1% to 44.9%, still far below DSP. Frequency-based models have fundamentally low coverage. As fur-

ther evidence, if we build a model of MI on the SJM corpus and use it in our pseudodisambiguation experiment (Section 4.3), MI>0 gets a *MacroAvg* precision of 86% but a *MacroAvg* recall of only 12%.[9]

4.6 Pronoun Resolution

Finally, we evaluate DSP on a common application of selectional preferences: choosing the correct antecedent for pronouns in text (Dagan and Itai, 1990; Kehler et al., 2004). We study the cases where a pronoun is the direct object of a verb predicate, v. A pronoun's antecedent must obey v's selectional preferences. If we have a better model of SP, we should be able to better select pronoun antecedents.

We parsed the MUC-7 (1997) coreference corpus and extracted all pronouns in a direct object relation. For each pronoun, p, modified by a verb, v, we extracted all preceding nouns within the current or previous sentence. Thirty-nine anaphoric pronouns had an antecedent in this window and are used in the evaluation. For each p, let $N(p)^+$ by the set of preceding nouns coreferent with p, and let $N(p)^-$ be the remaining non-coreferent nouns. We take all (v, n^+) where $n^+ \in N(p)^+$ as positive, and all other pairs (v, n^-), $n^- \in N(p)^-$ as negative.

We compare MI and DSP on this set, classifying every (v, n) with MI>T (or DSP>T) as positive. By varying T, we get a precision-recall curve (Figure 2). Precision is low because, of course, there are many nouns that satisfy the predicate's SPs that are not coreferent. DSP>0 has both a higher recall and higher precision than accepting every pair previously seen in text (the right-most point on MI>T). The DSP>T system achieves higher precision than MI>T for points where recall is greater than 60% (where MI<0). Interestingly, the recall of MI>0 is

[9]Recall that even the Keller and Lapata (2003) system, built on the world's largest corpus, achieves only 34% recall (Table 1) (with only 48% of positives and 27% of all pairs previously observed, but see Footnote 5).

System	Acc
Most-Recent Noun	17.9%
Maximum MI	28.2%
Maximum DSP	38.5%

Table 4: Pronoun resolution accuracy on nouns in current or previous sentence in MUC.

higher here than it is for general verb-objects (Section 4.5). On the subset of pairs with strong empirical association (MI$>$0), MI generally outperforms DSP at equivalent recall values.

We next compare MI and DSP as stand-alone pronoun resolution systems (Table 4). As a standard baseline, for each pronoun, we choose the most recent noun in text as the pronoun's antecedent, achieving 17.9% resolution accuracy. This baseline is quite low because many of the most-recent nouns are subjects of the pronoun's verb phrase, and therefore resolution violates syntactic coreference constraints. If instead we choose the previous noun with the highest MI as antecedent, we get an accuracy of 28.2%, while choosing the previous noun with the highest DSP achieves 38.5%. DSP resolves 37% more pronouns correctly than MI. We leave as future work a full-scale pronoun resolution system that incorporates both MI and DSP as backed-off, interpolated, or separate semantic features.

5 Conclusions and Future Work

We have presented a simple, effective model of selectional preference based on discriminative training. Supervised techniques typically achieve higher performance than unsupervised models, and we duplicate these gains with DSP. Here, however, these gains come at no additional labeling cost, as training examples are generated automatically from unlabeled text. DSP allows an arbitrary combination of features, including verb co-occurrence features that yield high-quality similar-word lists as latent output. This work only scratches the surface of possible feature mining; information from WordNet relations, Wikipedia categories, or parallel corpora could also provide valuable clues to SP. Also, if any other system were to exceed DSP's performance, it could also be included as one of DSP's features.

It would be interesting to expand our co-occurrence features, including co-occurrence counts across more grammatical relations and using counts from external, unparsed corpora like the world wide web. We could also reverse the role of noun and verb in our training, having verb-specific features and discriminating separately for each argument noun. The latent information would then be lists of similar nouns.

Finally, note that while we focused on word-word co-occurrences, sense-sense SPs can also be learned with our algorithm. If our training corpus was sense-labeled, we could run our algorithm over the senses rather than the words. The resulting model would then require sense-tagged input if it were to be used within an application like parsing or coreference resolution. Also, like other models of SP, our technique can also be used for sense disambiguations: the weightings on our semantic class features indicate, for a particular noun, which of its senses (classes) is most compatible with each verb.

Dependency-based Semantic Role Labeling of PropBank

Richard Johansson and **Pierre Nugues**
Lund University, Sweden
{richard, pierre}@cs.lth.se

Abstract

We present a PropBank semantic role labeling system for English that is integrated with a dependency parser. To tackle the problem of joint syntactic–semantic analysis, the system relies on a syntactic and a semantic subcomponent. The syntactic model is a projective parser using pseudo-projective transformations, and the semantic model uses global inference mechanisms on top of a pipeline of classifiers. The complete syntactic–semantic output is selected from a candidate pool generated by the subsystems.

We evaluate the system on the CoNLL-2005 test sets using segment-based and dependency-based metrics. Using the segment-based CoNLL-2005 metric, our system achieves a near state-of-the-art F1 figure of 77.97 on the WSJ+Brown test set, or 78.84 if punctuation is treated consistently. Using a dependency-based metric, the F1 figure of our system is 84.29 on the test set from CoNLL-2008. Our system is the first dependency-based semantic role labeler for PropBank that rivals constituent-based systems in terms of performance.

1 Introduction

Automatic semantic role labeling (SRL), the task of determining *who* does *what* to *whom*, is a useful intermediate step in NLP applications performing semantic analysis. It has obvious applications for template-filling tasks such as information extraction and question answering (Surdeanu et al., 2003; Moschitti et al., 2003). It has also been used in prototypes of NLP systems that carry out complex reasoning, such as entailment recognition systems (Haghighi et al., 2005; Hickl et al., 2006). In addition, role-semantic features have recently been used to extend vector-space representations in automatic document categorization (Persson et al., 2008).

The NLP community has recently devoted much attention to developing accurate and robust methods for performing role-semantic analysis automatically, and a number of multi-system evaluations have been carried out (Litkowski, 2004; Carreras and Màrquez, 2005; Baker et al., 2007; Surdeanu et al., 2008). Following the seminal work of Gildea and Jurafsky (2002), there have been many extensions in machine learning models, feature engineering (Xue and Palmer, 2004), and inference procedures (Toutanova et al., 2005; Surdeanu et al., 2007; Punyakanok et al., 2008).

With very few exceptions (e.g. Collobert and Weston, 2007), published SRL methods have used some sort of syntactic structure as input (Gildea and Palmer, 2002; Punyakanok et al., 2008). Most systems for automatic role-semantic analysis have used constituent syntax as in the Penn Treebank (Marcus et al., 1993), although there has also been much research on the use of shallow syntax (Carreras and Màrquez, 2004) in SRL.

In comparison, dependency syntax has received relatively little attention for the SRL task, despite the fact that dependency structures offer a more transparent encoding of predicate–argument relations. Furthermore, the few systems based on dependencies that have been presented have generally performed much worse than their constituent-based counterparts. For instance, Pradhan et al. (2005) reported that a system using a rule-based dependency parser achieved much inferior results compared to a system using a state-of-the-art statistical constituent parser: The F-measure on WSJ section 23 dropped from 78.8 to 47.2, or from 83.7 to 61.7 when using a head-based evaluation. In a similar vein, Swanson and Gordon (2006) reported that parse tree path features extracted from a rule-based dependency parser are much less reliable than those from a modern constituent parser.

In contrast, we recently carried out a detailed comparison (Johansson and Nugues, 2008b) between constituent-based and dependency-based SRL systems for FrameNet, in which the results of the two types of systems where almost equivalent when using modern statistical dependency parsers. We suggested that the previous lack of progress in dependency-based SRL was due to low parsing accuracy. The experiments showed that the grammatical function information available in dependency representations results in a steeper learning curve when training semantic role classifiers, and it also seemed that the dependency-based role classifiers were more resilient to lexical problems caused by change of domain.

The recent CoNLL-2008 Shared Task (Surdeanu et al., 2008) was an attempt to show that SRL can be accurately carried out using only dependency syntax. However, these results are not easy to compare to previously published results since the task definitions and evaluation metrics were different.

This paper compares the best-performing system in the CoNLL-2008 Shared Task (Johansson and Nugues, 2008a) with previously published constituent-based SRL systems. The system carries out joint dependency-syntactic and semantic analysis. We first describe its implementation in Section 2, and then compare the system with the best system in the CoNLL-2005 Shared Task in Section 3. Since the outputs of the two systems are different, we carry out two types of evaluations: first by using the traditional segment-based metric used in the CoNLL-2005 Shared Task, and then by using the dependency-based metric from the CoNLL-2008 Shared Task. Both evaluations require a transformation of the output of one system: For the segment-based metric, we have to convert the dependency-based output to segments; and for the dependency-based metric, a head-finding procedure is needed to select heads in segments. For the first time for a system using only dependency syntax, we report results for PropBank-based semantic role labeling of English that are close to the state of the art, and for some measures even superior.

2 Syntactic–Semantic Dependency Analysis

The training corpus that we used is the dependency-annotated Penn Treebank from the 2008 CoNLL Shared Task on joint syntactic–semantic analysis (Surdeanu et al., 2008). Figure 1 shows a sentence annotated in this framework. The CoNLL task involved semantic analysis of predicates from PropBank (for verbs, such as *plan*) and NomBank (for nouns, such as *investment*); in this paper, we report the performance on PropBank predicates only since we compare our system with previously published PropBank-based SRL systems.

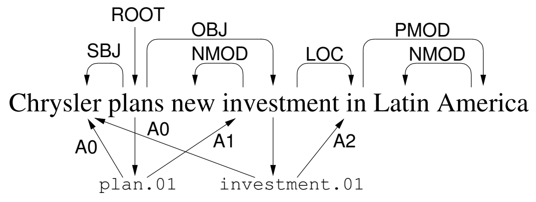

Figure 1: An example sentence annotated with syntactic and semantic dependency structures.

We model the problem of constructing a syntactic and a semantic graph as a task to be solved jointly. Intuitively, syntax and semantics are highly interdependent and semantic interpretation should help syntactic disambiguation, and joint syntactic–semantic analysis has a long tradition in deep-linguistic formalisms. Using a discriminative model, we thus formulate the problem of finding a syntactic tree $\hat{y}_{syn}$ and a semantic graph $\hat{y}_{sem}$ for a sentence $\boldsymbol{x}$ as maximizing a function F_{joint} that scores the complete syntactic–semantic structure:

$$\langle \hat{y}_{syn}, \hat{y}_{sem} \rangle = \arg \max_{y_{syn}, y_{sem}} F_{joint}(\boldsymbol{x}, y_{syn}, y_{sem})$$

The dependencies in the feature representation used to compute F_{joint} determine the tractability of the

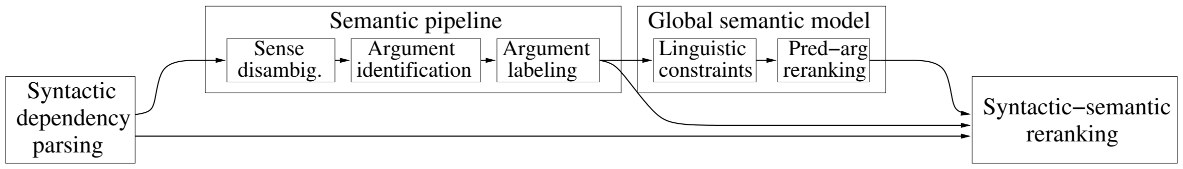

Figure 2: The architecture of the syntactic–semantic analyzer.

search procedure needed to perform the maximization. To be able to use complex syntactic features such as paths when predicting semantic structures, exact search is clearly intractable. This is true even with simpler feature representations – the problem is a special case of multi-headed dependency analysis, which is NP-hard even if the number of heads is bounded (Chickering et al., 1994).

This means that we must resort to a simplification such as an incremental method or a reranking approach. We chose the latter option and thus created syntactic and semantic submodels. The joint syntactic–semantic prediction is selected from a small list of candidates generated by the respective subsystems. Figure 2 shows the architecture.

2.1 Syntactic Submodel

We model the process of syntactic parsing of a sentence $\boldsymbol{x}$ as finding the parse tree $\hat{y}_{syn} = \arg\max_{y_{syn}} F_{syn}(\boldsymbol{x}, y_{syn})$ that maximizes a scoring function F_{syn}. The learning problem consists of fitting this function so that the cost of the predictions is as low as possible according to a cost function ρ_{syn}. In this work, we consider linear scoring functions of the following form:

$$F_{syn}(\boldsymbol{x}, y_{syn}) = \boldsymbol{\Psi}_{syn}(\boldsymbol{x}, y_{syn}) \cdot \boldsymbol{w}$$

where $\boldsymbol{\Psi}_{syn}(\boldsymbol{x}, y_{syn})$ is a numeric feature representation of the pair $(\boldsymbol{x}, y_{syn})$ and $\boldsymbol{w}$ a vector of feature weights. We defined the syntactic cost ρ_{syn} as the sum of link costs, where the link cost was 0 for a correct dependency link with a correct label, 0.5 for a correct link with an incorrect label, and 1 for an incorrect link.

A widely used discriminative framework for fitting the weight vector is the max-margin model (Taskar et al., 2003), which is a generalization of the well-known support vector machines to general cost-based prediction problems. Since the large number of training examples and features in our case make an exact solution of the max-margin optimization problem impractical, we used the online passive–aggressive algorithm (Crammer et al., 2006), which approximates the optimization process in two ways:

- The weight vector $\boldsymbol{w}$ is updated incrementally, one example at a time.
- For each example, only the most violated constraint is considered.

The algorithm is a margin-based variant of the perceptron (preliminary experiments show that it outperforms the ordinary perceptron on this task). Algorithm 1 shows pseudocode for the algorithm.

Algorithm 1 The Online PA Algorithm

```
input Training set $\mathcal{T} = \{(\boldsymbol{x}_t, y_t)\}_{t=1}^{T}$
      Number of iterations $N$
      Regularization parameter $C$
Initialize $w$ to zeros
repeat $N$ times
  for $(\boldsymbol{x}_t, y_t)$ in $\mathcal{T}$
    let $\tilde{y}_t = \arg\max_y F(\boldsymbol{x}_t, y) + \rho(y_t, y)$
    let $\tau_t = \min\left(C, \frac{F(\boldsymbol{x}_t,\tilde{y}_t) - F(\boldsymbol{x}_t,y_t) + \rho(y_t,\tilde{y}_t)}{\|\boldsymbol{\Psi}(\boldsymbol{x},y_t) - \boldsymbol{\Psi}(\boldsymbol{x},\tilde{y}_t)\|^2}\right)$
    $\boldsymbol{w} \leftarrow \boldsymbol{w} + \tau_t(\boldsymbol{\Psi}(\boldsymbol{x}, y_t) - \boldsymbol{\Psi}(\boldsymbol{x}, \tilde{y}_t))$
return $\boldsymbol{w}_{\text{average}}$
```

We used a C value of 0.01, and the number of iterations was 6.

2.1.1 Features and Search

The feature function $\boldsymbol{\Psi}_{syn}$ is a factored representation, meaning that we compute the score of the complete parse tree by summing the scores of its parts, referred to as *factors*:

$$\boldsymbol{\Psi}(\boldsymbol{x}, y) \cdot \boldsymbol{w} = \sum_{f \in y} \psi(\boldsymbol{x}, f) \cdot \boldsymbol{w}$$

We used a second-order factorization (McDonald and Pereira, 2006; Carreras, 2007), meaning that the factors are subtrees consisting of four links: the governor–dependent link, its sibling link, and the leftmost and rightmost dependent links of the dependent.

This factorization allows us to express useful features, but also forces us to adopt the expensive search procedure by Carreras (2007), which extends Eisner's span-based dynamic programming algorithm (1996) to allow second-order feature dependencies. This algorithm has a time complexity of $O(n^4)$, where n is the number of words in the sentence. The search was constrained to disallow multiple root links.

To evaluate the $\arg\max$ in Algorithm 1 during training, we need to handle the cost function ρ_{syn} in addition to the factor scores. Since the cost function ρ_{syn} is based on the cost of single links, this can easily be integrated into the factor-based search.

2.1.2 Handling Nonprojective Links

Although only 0.4% of the links in the training set are nonprojective, 7.6% of the sentences contain at least one nonprojective link. Many of these links represent long-range dependencies – such as *wh*-movement – that are valuable for semantic processing. Nonprojectivity cannot be handled by span-based dynamic programming algorithms. For parsers that consider features of single links only, the Chu-Liu/Edmonds algorithm can be used instead. However, this algorithm cannot be generalized to the second-order setting – McDonald and Pereira (2006) proved that this problem is NP-hard, and described an approximate greedy search algorithm.

To simplify implementation, we instead opted for the pseudo-projective approach (Nivre and Nilsson, 2005), in which nonprojective links are lifted upwards in the tree to achieve projectivity, and special trace labels are used to enable recovery of the nonprojective links at parse time. The use of trace labels in the pseudo-projective transformation leads to a proliferation of edge label types: from 69 to 234 in the training set, many of which occur only once. Since the running time of our parser depends on the number of labels, we used only the 20 most frequent trace labels.

2.2 Semantic Submodel

Our semantic model consists of three parts:

- A SRL classifier pipeline that generates a list of candidate predicate–argument structures.
- A constraint system that filters the candidate list to enforce linguistic restrictions on the global configuration of arguments.
- A global reranker that assigns scores to predicate–argument structures in the filtered candidate list.

Rather than training the models on gold-standard syntactic input, we created an automatically parsed training set by 5-fold cross-validation. Training on automatic syntax makes the semantic classifiers more resilient to parsing errors, in particular adjunct labeling errors.

2.2.1 SRL Pipeline

The SRL pipeline consists of classifiers for predicate disambiguation, argument identification, and argument labeling. For the predicate disambiguation classifiers, we trained one subclassifier for each lemma. All classifiers in the pipeline were L2-regularized linear logistic regression classifiers, implemented using the efficient LIBLINEAR package (Lin et al., 2008). For multiclass problems, we used the one-vs-all binarization method, which makes it easy to prevent outputs not allowed by the PropBank frame.

Since our classifiers were logistic, their output values could be meaningfully interpreted as probabilities. This allowed us to combine the scores from subclassifiers into a score for the complete predicate–argument structure. To generate the candidate lists used by the global SRL models, we applied beam search based on these scores using a beam width of 4.

The argument identification classifier was preceded by a pruning step similar to the constituent-based pruning by Xue and Palmer (2004).

The features used by the classifiers are listed in Table 1, and are described in Appendix A. We selected the feature sets by greedy forward subset selection.

Table 1: Classifier features in predicate disambiguation (PredDis), argument identification (ArgId), and argument labeling (ArgLab).

2.2.2 Linguistically Motivated Global Constraints

The following three global constraints were used to filter the candidates generated by the pipeline.

Core Argument Consistency. Core argument labels must not appear more than once.

Discontinuity Consistency. If there is a label C-X, it must be preceded by a label X.

Reference Consistency. If there is a label R-X and the label is inside an attributive relative clause, it must be preceded by a label X.

2.2.3 Predicate–Argument Reranker

Toutanova et al. (2005) have showed that a global model that scores the complete predicate–argument structure can lead to substantial performance gains. We therefore created a global SRL classifier using the following global features in addition to the features from the pipeline:

Core Argument Label Sequence. The complete sequence of core argument labels. The sequence also includes the predicate and voice, for instance `A0`+*break.01*/Active+`A1`.

Missing Core Argument Labels. The set of core argument labels declared in the PropBank frame that are not present in the predicate–argument structure.

Similarly to the syntactic submodel, we trained the global SRL model using the online passive–aggressive algorithm. The cost function ρ was defined as the number of incorrect links in the predicate–argument structure. The number of iterations was 20 and the regularization parameter C was 0.01. Interestingly, we noted that the global SRL model outperformed the pipeline even when no global features were added. This shows that the global learning model can correct label bias problems introduced by the pipeline architecture.

2.3 Syntactic–Semantic Reranking

As described previously, we carried out reranking on the candidate set of complete syntactic–semantic structures. To do this, we used the top 16 trees from the syntactic module and applied a linear model:

$$F_{joint}(\boldsymbol{x}, y_{syn}, y_{sem}) = \boldsymbol{\Psi}_{joint}(\boldsymbol{x}, y_{syn}, y_{sem}) \cdot \boldsymbol{w}$$

Our baseline joint feature representation $\boldsymbol{\Psi}_{joint}$ contained only three features: the log probability of the syntactic tree and the log probability of the semantic structure according to the pipeline and the global model, respectively. This model was trained on the complete training set using cross-validation. The probabilities were obtained using the multinomial logistic function ("softmax").

We carried out an initial experiment with a more complex joint feature representation, but failed to improve over the baseline. Time prevented us from exploring this direction conclusively.

3 Comparisons with Previous Results

To compare our results with previously published results in SRL, we carried out an experiment comparing our system to the top system (Punyakanok et al., 2008) in the CoNLL-2005 Shared Task. However, comparison is nontrivial since the output of the CoNLL-2005 systems was a set of labeled segments, while the CoNLL-2008 systems (including ours) produced labeled semantic dependency links.

To have a fair comparison of our link-based system against previous segment-based systems, we carried out a two-way evaluation: In the first evaluation, the dependency-based output was converted to segments and evaluated using the segment scorer from CoNLL-2005, and in the second evaluation, we applied a head-finding procedure to the output of a segment-based system and scored the result using the link-based CoNLL-2008 scorer.

It can be discussed which of the two metrics is most correlated with application performance. The traditional metric used in the CoNLL-2005 task treats SRL as a *bracketing problem*, meaning that the entities scored by the evaluation procedure are labeled snippets of text; however, it is questionable whether this is the proper way to evaluate a task whose purpose is to find *semantic relations* between logical entities. We believe that the same criticisms that have been leveled at the PARSEVAL metric for constituent structures are equally valid for the bracket-based evaluation of SRL systems. The inappropriateness of the traditional metric has led to a number of alternative metrics (Litkowski, 2004; Baker et al., 2007; Surdeanu et al., 2008).

3.1 Segment-based Evaluation

To be able to score the output of a dependency-based SRL system using the segment scorer, a conversion step is needed. Algorithm 2 shows how a set of segments is constructed from an argument dependency node. For each argument node, the algorithm computes the yield Y of the argument node, i.e. the set of dependency nodes to include in the bracketing. This set is then partitioned into contiguous parts, from which the segments are computed. In most cases, the yield is just the subtree dominated by the argument node. However, if the argument dominates the predicate, then the branch containing the predicate is removed.

Table 2 shows the performance figures of our system on the WSJ and Brown corpora: precision, recall, F_1-measure, and complete proposition accuracy (PP). These figures are compared to the best-performing system in the CoNLL-2005 Shared Task (Punyakanok et al., 2008), referred to as Punyakanok in the table, and the best result currently published (Surdeanu et al., 2007), referred to as Surdeanu. To validate the sanity of the segment creation algorithm, the table also shows the result of applying segment creation to gold-standard syntactic–semantic trees. We see that the two conversion procedures involved (constituent-to-dependency conversion by the CoNLL-2008 Shared Task organizers, and our dependency-to-segment conversion) work satisfactorily although the process is not completely lossless.

During inspection of the output, we noted that many errors arise from inconsistent punctuation attachment in PropBank/Treebank. We therefore normalized the segments to exclude punctuation at the beginning or end of a segment. The results of this evaluation is shown in Table 3. This table does not include the Surdeanu system since we did not have

Algorithm 2 Segment creation from an argument dependency node.

```
input Predicate node $p$, argument node $a$
if $a$ does not dominate $p$
    $Y \leftarrow \{n : a \text{ dominates } n\}$
else
    $c \leftarrow$ the child of $a$ that dominates $p$
    $Y \leftarrow \{n : a \text{ dominates } n\} \setminus \{n : c \text{ dominates } n\}$
end if
$S \leftarrow$ partition of $Y$ into contiguous subsets
return $\{(\text{min-index } s, \text{max-index } s) : s \in S\}$

Table 3: Evaluation with normalized segments.

The results on the WSJ test set clearly show that dependency-based SRL systems can rival constituent-based systems in terms of performance – it clearly outperforms the Punyakanok system, and has a higher recall and complete proposition accuracy than the Surdeanu system. We interpret the high recall as a result of the dependency syntactic representation, which makes the parse tree paths simpler and thus the arguments easier to find.

For the Brown test set, on the other hand, the dependency-based system suffers from a low precision compared to the constituent-based systems. Our error analysis indicates that the domain change caused problems with prepositional attachment for the dependency parser – it is well-known that prepositional attachment is a highly lexicalized problem, and thus sensitive to domain changes. We believe that the reason why the constituent-based systems are more robust in this respect is that they utilize a combination strategy, using inputs from two different full constituent parsers, a clause bracketer, and a chunker. However, caution is needed when drawing conclusions from results on the Brown test set, which is only 7,585 words, compared to the 59,100 words in the WSJ test set.

3.2 Dependency-based Evaluation

It has previously been noted (Pradhan et al., 2005) that a segment-based evaluation may be unfavorable to a dependency-based system, and that an evaluation that scores argument *heads* may be more indicative of its true performance. We thus carried out an evaluation using the evaluation script of the CoNLL-2008 Shared Task. In this evaluation method, an argument is counted as correctly identified if its head and label are correct. Note that this is not equivalent to the segment-based metric: In a perfectly identified segment, we may still pick out the wrong head, and if the head is correct, we may infer an incorrect segment. The evaluation script also scores predicate disambiguation performance; we did not include this score since the 2005 systems did not output predicate sense identifiers.

Since CoNLL-2005-style segments have no internal tree structure, it is nontrivial to extract a head. It is conceivable that the output of the parsers used by the Punyakanok system could be used to extract heads, but this is not recommendable because the Punyakanok system is an ensemble system and a segment does not always exactly match a constituent in a parse tree. Furthermore, the CoNLL-2008 constituent-to-dependency conversion method uses a richer structure than just the raw constituents: empty categories, grammatical functions, and named entities. To recreate this additional information, we would have to apply automatic systems and end up with unreliable results.

Instead, we thus chose to find an *upper bound* on the performance of the segment-based system. We applied a simple head-finding procedure (Algorithm 3) to find a set of head nodes for each segment. Since the CoNLL-2005 output does not include dependency information, the algorithm uses gold-standard dependencies and intersects segments with the gold-standard segments. This will give us an upper bound, since if the segment contains the correct head, it will always be counted as correct.

The algorithm looks for dependencies leaving the segment, and if multiple outgoing edges are found, a couple of simple heuristics are applied. We found that the best performance is achieved when selecting only one outgoing edge. “Small clauses,” which are split into an object and a predicative complement in the dependency framework, are the only cases where we select two heads.

Table 4 shows the results of the dependency-based evaluation. In the table, the output of the

Algorithm 3 Finding head nodes in a segment.

```
input Argument segment $a$
if $a$ overlaps with a segment in the gold standard
    $a \leftarrow$ intersection of $a$ and gold standard
$F \leftarrow \{n :$ governor of $n$ outside $a\}$
if $|F| = 1$
    return $F$
remove punctuation nodes from $F$
if $|F| = 1$
    return $F$
if $F = \{n_1, n_2, \ldots\}$ where $n_1$ is an object and $n_2$ is
  the predicative part of a small clause
    return $\{n_1, n_2\}$
if $F$ contains a node $n$ that is a subject or an object
    return $\{n\}$
else
    return $\{n\}$, where $n$ is the leftmost node in $F$
```

dependency-based system is compared to the semantic dependency links automatically extracted from the segments of the Punyakanok system.

WSJ	P	R	F1	PP
Our system	**88.46**	**83.55**	**85.93**	**61.97**
Punyakanok	87.25	81.59	84.32	58.17

Brown	P	R	F1	PP
Our system	77.67	**69.63**	73.43	**41.32**
Punyakanok	**80.29**	68.59	**73.98**	37.28

WSJ+Brown	P	R	F1	PP
Our system	**87.07**	**81.68**	**84.29**	**59.22**
Punyakanok	86.94	80.21	83.45	55.39

Table 4: Dependency-based evaluation.

In this evaluation, the dependency-based system has a higher F1-measure than the Punyakanok system on both test sets. This suggests that the main advantage of using a dependency-based semantic role labeler is that it is better at finding the heads of semantic arguments, rather than finding segments. The results are also interesting in comparison to the multi-view system described by Pradhan et al. (2005), which has a reported head F1 measure of 85.2 on the WSJ test set. The figure is not exactly compatible with ours, however, since that system used a different head extraction mechanism.

4 Conclusion

We have described a dependency-based system[1] for semantic role labeling of English in the PropBank framework. Our evaluations show that the performance of our system is close to the state of the art. This holds regardless of whether a segment-based or a dependency-based metric is used. Interestingly, our system has a complete proposition accuracy that surpasses other systems by nearly 3 percentage points. Our system is the first semantic role labeler based only on syntactic dependency that achieves a competitive performance.

Evaluation and comparison is a difficult issue since the natural output of a dependency-based system is a set of semantic links rather than segments, as is normally the case for traditional systems. To handle this situation fairly to both types of systems, we carried out a two-way evaluation: conversion of dependencies to segments for the dependency-based system, and head-finding heuristics for segment-based systems. However, the latter is difficult since no structure is available inside segments, and we had to resort to computing upper-bound results using gold-standard input; despite this, the dependency-based system clearly outperformed the upper bound of the performance of the segment-based system. The comparison can also be slightly misleading since the dependency-based system was optimized for the dependency metric and previous systems for the segment metric.

Our evaluations suggest that the dependency-based SRL system is biased to finding argument heads, rather than argument text snippets, and this is of course perfectly logical. Whether this is an advantage or a drawback will depend on the application – for instance, a template-filling system might need complete segments, while an SRL-based vector space representation for text categorization, or a reasoning application, might prefer using heads only.

In the future, we would like to further investigate whether syntactic and semantic analysis could be integrated more tightly. In this work, we used a sim-

[1]Our system is freely available for download at `http://nlp.cs.lth.se/lth_srl`.

plistic loose coupling by means of reranking a small set of complete structures. The same criticisms that are often leveled at reranking-based models clearly apply here too: The set of tentative analyses from the submodules is too small, and the correct analysis is often pruned too early. An example of a method to mitigate this shortcoming is the forest reranking by Huang (2008), in which complex features are evaluated as early as possible.

A Classifier Features

Features Used in Predicate Disambiguation

PREDWORD, PREDLEMMA. The lexical form and lemma of the predicate.

PREDPARENTWORD and PREDPARENTPOS. Form and part-of-speech tag of the parent node of the predicate.

CHILDDEPSET, CHILDWORDSET, CHILDWORDDEPSET, CHILDPOSSET, CHILDPOSDEPSET. These features represent the set of dependents of the predicate using combinations of dependency labels, words, and parts of speech.

DEPSUBCAT. Subcategorization frame: the concatenation of the dependency labels of the predicate dependents.

PREDRELTOPARENT. Dependency relation between the predicate and its parent.

Features Used in Argument Identification and Labeling

PREDLEMMASENSE. The lemma and sense number of the predicate, e.g. *give.01*.

VOICE. For verbs, this feature is Active or Passive. For nouns, it is not defined.

POSITION. Position of the argument with respect to the predicate: Before, After, or On.

ARGWORD and ARGPOS. Lexical form and part-of-speech tag of the argument node.

LEFTWORD, LEFTPOS, RIGHTWORD, RIGHTPOS. Form/part-of-speech tag of the leftmost/rightmost dependent of the argument.

LEFTSIBLINGWORD, LEFTSIBLINGPOS. Form/part-of-speech tag of the left sibling of the argument.

PREDPOS. Part-of-speech tag of the predicate.

RELPATH. A representation of the complex grammatical relation between the predicate and the argument. It consists of the sequence of dependency relation labels and link directions in the path between predicate and argument, e.g. `IM↑OPRD↑OBJ↓`.

VERBCHAINHASSUBJ. Binary feature that is set to true if the predicate verb chain has a subject. The purpose of this feature is to resolve verb coordination ambiguity as in Figure 3.

CONTROLLERHASOBJ. Binary feature that is true if the link between the predicate verb chain and its parent is OPRD, and the parent has an object. This feature is meant to resolve control ambiguity as in Figure 4.

FUNCTION. The grammatical function of the argument node. For direct dependents of the predicate, this is identical to the RELPATH.

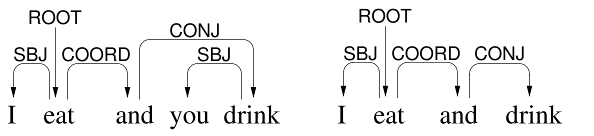

Figure 3: Coordination ambiguity: The subject *I* is in an ambiguous position with respect to *drink*.

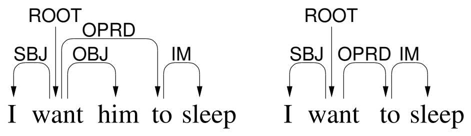

Figure 4: Subject/object control ambiguity: *I* is in an ambiguous position with respect to *sleep*.

Scaling Textual Inference to the Web

Abstract

Most Web-based Q/A systems work by finding pages that contain an *explicit* answer to a question. These systems are helpless if the answer has to be inferred from multiple sentences, possibly on different pages. To solve this problem, we introduce the HOLMES system, which utilizes *textual inference* (TI) over tuples extracted from text.

Whereas previous work on TI (*e.g.*, the literature on textual entailment) has been applied to paragraph-sized texts, HOLMES utilizes knowledge-based model construction to scale TI to a corpus of 117 million Web pages. Given only a few minutes, HOLMES doubles recall for example queries in three disparate domains (geography, business, and nutrition). Importantly, HOLMES's runtime is *linear* in the size of its input corpus due to a surprising property of many textual relations in the Web corpus—they are "approximately" functional in a well-defined sense.

1 Introduction and Motivation

Numerous researchers have identified the Web as a rich source of answers to factual questions, *e.g.*, (Kwok et al., 2001; Brill et al., 2002), but often the desired information is not stated *explicitly* even in a textual corpus as massive as the Web. Consider the question "What vegetables help prevent osteoporosis?" Since there is likely no sentence on the Web directly stating "Kale prevents osteoporosis", a system must *infer* that kale is an answer by combining facts from multiple sentences, possibly from different pages, which justify that conclusion: *i.e.*, that kale is a vegetable, kale contains calcium, and calcium helps prevent osteoporosis.

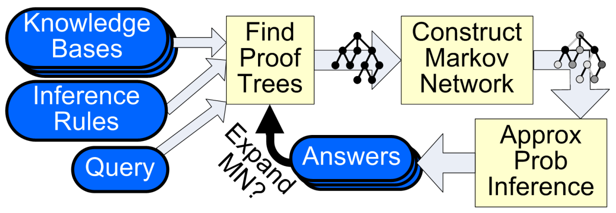

Figure 1: The architecture of HOLMES.

Textual Inference (TI) methods have advanced in recent years. For example, textual entailment techniques aim to determine whether one textual fragment (the *hypothesis*) follows from another (the *text*) (Dagan et al., 2005). While most TI researchers have focused on high-quality inferences from a small source text, we seek to utilize sizable chunks of the Web corpus as our source text. In order to do this, we must confront two major challenges. The first is uncertainty: TI is an imperfect process, particularly when applied to the Web corpus, hence probabilistic methods help to assess the confidence in inferences. The second challenge is scalability: how does inference time scale given increasingly large corpora as input?

1.1 HOLMES: A Scalable TI System

This paper describes HOLMES, an implemented system, which addresses both challenges by carrying out scalable, probabilistic inference over ground assertions extracted from the Web. The input to HOLMES is a conjunctive query, a set of inference rules expressed as Horn clauses, and large sets of ground assertions extracted from the Web, WordNet, and other knowledge bases. As shown in Figure 1, HOLMES chains backward from the query, using the inference rules to construct a forest of proof trees from the ground assertions. This forest is converted into a Markov network (a form of Knowledge-Based Model Construction (KBMC) (Wellman et al., 1992)) and evaluated using approximate probabilistic inference. HOLMES operates in an *anytime* fashion — if desired it can keep iterating: searching for more proofs, and elaborating the Markov network.

HOLMES makes some important simplifying assumptions. Specifically, we use simple ground tuples to represent extracted assertions (*e.g.*, `contains(kale, calcium)`). Syntactic problems (*e.g.*, anaphora, relative clauses) and semantic challenges (*e.g.*, quantification, counterfactuals, temporal qualification) are delegated to the extraction system or simply ignored. This paper focuses on scalability for this subset of the TI task.

1.2 Summary of Experimental Results

We tested HOLMES on 183 million distinct ground assertions extracted from the Web by the TEXTRUNNER system (Banko et al., 2007), coupled with 159 thousand ground assertions from WordNet (Miller et al., 1990), and a compact set of hand-coded inference rules. Given a total of 55 to 145 seconds, HOLMES was able to produce high-quality inferences that doubled the number of answers to example queries in three disparate domains: geography, business, and nutrition.

We also evaluated how the speed of HOLMES scaled with the size of its input corpus. In the general case, logical inference over a Horn theory (needed in order to produce the probabilistic network) is polynomial in the number of ground assertions, and hence in the size of the textual corpus.[1] Unfortunately, this is prohibitive, since even low-order polynomial growth is fatal on a 117 million-page corpus, let alone the full Web.

1.3 Why HOLMES Scales Linearly

Fortunately, the Web's long tail works in our favor. The relations we extract from text are *approximately pseudo-functional* (APF), as we formalize in Section 3, and this property leads to runtime that scales *linearly* with the corpus. To see the underlying intuition, consider the APF relation denoted by the phrase "is married to;" most of the time it maps a person's name to a small number of spousal names so this relation is APF. Section 3 shows why this APF property ensures linear scaling, and Section 4 demonstrates linear scaling in practice.

[1] In fact, it is P-complete — as hard as any polynomial-time problem.

2 An Overview of HOLMES

HOLMES is a system designed to answer complex queries over large, noisy knowledge bases. As a motivating example, we consider the question "What vegetables help prevent osteoporosis?" As of this writing, Google has no pages explicitly stating 'kale helps prevent osteoporosis', making it challenging to return "kale" as an answer. However, there are numerous web pages stating that "kale is high in calcium" and others declaring that "calcium helps prevent osteoporosis". If we could combine those facts we could easily infer that "kale" is an answer to the question "What vegetables help prevent osteoporosis?" HOLMES was designed to make such inferences while accounting for uncertainty in the process.

Given a query, expressed as a conjunctive Datalog rule, HOLMES generates a probabilistic model using knowledge-based model construction (KBMC) (Wellman et al., 1992). Specifically, HOLMES utilizes fast, logical inference to find the subset of ground assertions and inference rules that may influence the answers to the query — enabling the construction of a small and focused Markov network. Since this graphical model is much smaller than one incorporating *all* ground assertions, probabilistic inference will be much faster than if naive compilation were used.

Figure 1 summarizes the operation of HOLMES. As with many theorem provers or KBMC systems, HOLMES takes three inputs:

1. A set of knowledge bases — databases of ground relational assertions, each with an estimate of its probability, which can be generated by TextRunner (Banko et al., 2007) or Kylin (Wu and Weld, 2007). In our example, we would extract the assertions `IsHighIn(kale, calcium)` and `Prevents(calcium, osteoporosis)` from those sentences.
2. A domain theory – A set of probabilistic inference rules written as Markov logic Horn clauses, which can be used to derive new assertions. The weight associated with each clause specifies its reliability.

Figure 2: Partial proof 'tree' (DAG) for the query "What vegetables help prevent osteoporosis?" Rectangles depict ground assertions from a knowledge base, rounded boxes are inferred assertions, and shaded squared represent the application of inference rules. HOLMES converts this DAG into a Markov network in order to estimate the probability of each node.

In Section 2.3 we identify several domain-independent rules, but a user may (optionally) specify additional, domain-specific rules if desired. In our example, we assume we are given the domain-specific rule: `Prevents(X,Z) :- IsHighIn(X,Y) ∧ Prevents(Y,Z)`

3. A conjunctive query is specified as a Datalog rule. For example, the question "What vegetables help prevent osteoporosis?" could be written as: `query(X) :- IS-A(X,Vegetable) ∧ Prevents(X,osteoporosis)`

and returns a set of answers to the query, each with an associated probability.

2.1 Basic Operation

To find these answers and their associated probabilities, HOLMES first finds all ground assertions in the knowledge bases that are potentially relevant to the query. This is efficiently done using the inference rules to chain backwards from the query. Note that the generated candidate answers, themselves, are less important than the associated proof trees. Furthermore, since HOLMES uses these 'trees' (actually, DAGs) to generate a probabilistic graphical model, HOLMES seeks to find as many proof trees as possible for each query result — each may influence the final belief in that result. Figure 2 shows a partial proof tree for our example query.

To handle uncertainty, HOLMES now constructs a ground Markov network from the proof trees and the Markov-logic-encoded inference rules. Markov networks (Pearl, 1988) model the joint distribution of a set of variables by creating an undirected graph with one node for each random variable, and representing dependencies between variables with cliques in the graph. Each clique has a corresponding potential function ϕ_k, which returns a non-negative value based on the state of variables in the clique. The probability of a state, x, is given by

$$P(x) = \frac{1}{Z} \prod \phi_k(x_{\{k\}})$$

where the partition function Z is a normalizing term, and $x_{\{k\}}$ denotes the state of all the variables in clique k.

HOLMES converts the proof trees into a Markov network in a manner pioneered by the Markov Logic framework of Richardson and Domingos (2006). A Boolean variable is created to represent the truth of each assertion in the proof forest. Next, HOLMES adds edges to the Markov network to create a clique corresponding to each application of an inference rule in the proof forest.

Following the Markov Logic framework, the potential function of a clique has form $\phi(x) = e^w$ if all member nodes are true (w denotes the weight of the inference rule), and $\phi(x) = 1$ otherwise. The probabilities of leaf nodes are derived from the underlying knowledge base,[2] and inferred nodes are biased with an exponential prior.

Finally, HOLMES computes the approximate probability of each answer by running a variant of loopy belief propagation (Pearl, 1988) over the Markov network. In our experience this method performs well on networks derived from our Horn clause proof forest, but one could use Monte Carlo techniques or even exact methods if desired.

Note that this architecture allows HOLMES to combine information from *multiple* web pages to infer assertions not explicitly seen in the textual corpus. Because this inference is done using a Markov network, it correctly handles uncertain extractions and probabilistic dependencies. By using KBMC to create a custom, focused network for each query, the

[2]In our experiments, ground assertions from WordNet get a uniformly high probability of correctness (0.9), but those extracted from the Web are assigned probabilities derived from redundancy statistics, following the intuition that frequently extracted facts are more likely to be true (Etzioni et al., 2005).

amount of probabilistic inference is reduced to manageable proportions.

2.2 Anytime, Incremental Expansion

Because exact probabilistic inference is #P-complete, HOLMES uses approximate methods, but even these techniques have problems if the Markov network gets too large. As a result, HOLMES creates the network incrementally. After the first proof trees are generated, HOLMES creates the model and performs approximate probabilistic inference. If more time is available then HOLMES searches for additional proof trees and updates the network (Figure 1). This incremental process allows HOLMES to return initial results (with preliminary probability estimates) as soon as they are discovered.

For efficiency, HOLMES exploits standard Datalog optimizations (*e.g.*, it only expands proofs of recently added nodes and it uses an approximation to magic sets (Ullman, 1989), rather than simple backwards chaining). For tractability, we also allow the user to limit the number of transitive inference steps for any inference rule.

HOLMES also includes a few enhancements for dealing with information extracted from natural language. For example, HOLMES's inference rules support substring/regex matching of ground assertions, to accommodate simple variations in text. HOLMES also can be restricted to only operate over proper nouns, which is useful for queries involving named entities.

2.3 Markov Logic Inference Rules

HOLMES is given the following set of six domain-independent rules, which are similar to the upward monotone rules introduced by (MacCartney and Manning, 2007).

1. Observed relations are likely to be true:
   `R(X,Y) :- ObservedInCorpus(X, R, Y)`
2. Synonym substitution preserves meaning:
   R_{TR}`(X',Y) :-` R_{TR}`(X,Y)` $\wedge$ `Synonym(X, X')`
3. R_{TR}`(X,Y') :-` R_{TR}`(X,Y)` $\wedge$ `Synonym(Y, Y')`
4. Generalizations preserve meaning:
   R_{TR}`(X',Y) :-` R_{TR}`(X,Y)` $\wedge$ `IS-A(X, X')`
5. R_{TR}`(X,Y') :-` R_{TR}`(X,Y)` $\wedge$ `IS-A(Y, Y')`
6. Transitivity of Part Meronyms:
   R_{TR}`(X,Y') :-` R_{TR}`(X,Y)` $\wedge$ `Part-Of(Y, Y')`
   where R_{TR} matches '* in' (*e.g.*, 'born in').

For example, if `Q(X):-BornIn(X,'France')`, and we know from WordNet that Paris is in France, then by inference rule 6, we know that `BornIn(X,'Paris')` will yield valid results for `Q(X)`. Although all of these rules contain at most two relations in the body, HOLMES allows an arbitrary number of relations in the query and rule bodies. However, we have found that even simple rules can dramatically improve some queries.

We set the rule weights to capture the intuition that deeper inferences decrease the likelihood (as there are more chances to make mistakes), whereas additional, independent proof trees increase the likelihood (as there is more supporting evidence). Specifically, in our experiments we set the prior on inferred facts to -0.75, the weight on rule 1 to 1.5, and the weights on all other rules to 0.6.

At present, we define these weights manually, but we expect to learn the parameter values in the future.

3 Scaling Inference to the Web

If TI is applied to a corpus containing hundreds of millions or even billions of pages, its run time has to be at most linear in the size of the corpus. This section shows that under some reasonable assumptions inference *does* scale linearly.

We start our analysis with two simplifications. First, we assume that the number of distinct, ground assertions in the KBs, $|A|$, grows at most linearly with the size of the textual corpus. This is certainly true for assertions extracted by TextRunner and Kylin, and follows from our exclusion of texts with complex quantified sentences. Our analysis now proceeds to consider scaling with respect to $|A|$ for a fixed query and set of inference rules.

Our second assumption is that the size of every proof tree is bounded by some constant, m. This is a strong assumption and one that depends on the precise set of inference rules and pattern of ground assertions. However, it holds in our experience, and if necessary could be enforced by terminating the search for proof trees at a certain depth, *e.g.*, $\log(m)$.

HOLMES's knowledge-based model construction has two parts: construction of the proof forest and conversion of the forest into a Markov network. Since the Markov network is essentially isomorphic to the proof forest, the conversion will be $\mathcal{O}(|A|)$ if the forest is linear in size, which is ensured if the time to construct the proof trees is $\mathcal{O}(|A|)$. We show this in the remainder of this section.

Recall that HOLMES requires inference rules to be function-free Horn clauses. While this limits expressivity to some degree, it provides a huge speed benefit — logical inference over Horn clauses can be done in polynomial time, whereas general propositional inference (*i.e.*, from grounded first-order rules) is NP-complete.

Alas, even low-order polynomial blowup is unacceptable when the textual corpus reaches Web scale; we seek linear growth. Intuitively, there are two places where polynomial expansion could cause trouble. First, the number of different *types* of proofs (*i.e.*, first order proofs) could grow too quickly, and secondly, a given type of proof tree might apply to too many ground assertions ("tuples" in database lingo). We treat these issues in turn.

Under our assumptions, each proof tree can be represented as an expression in relational algebra with at most m equijoins (Ullman, 1989),[3] each stemming from the application of an inference rule. Since the number of rules is fixed, as is m, there are a constant number of possible first-order proof trees.

The bigger concern is that any one of these first-order trees might result in a polynomial number of ground trees; if so, the size of the ground forest (and corresponding Markov network) could grow too quickly. In fact, polynomial growth is a common phenomena in database query evaluation. Luckily, most relations in the Web corpus behave more favorably. We introduce a property of relations that ensures m-way joins, and therefore all proof trees up to size m, can be computed in $\mathcal{O}(|A|)$ time.

The intuition is that most relations derived from large corpora have a 'heavy-tailed' distribution, wherein a few objects appear many times in a relation, but most appear only once or twice, thus joins involving rare objects lead to a small number of results, and so the main limitation on scalability is common objects. We now prove that if these common objects account for a small enough fraction of the relation, then joins will still scale linearly. We focus on binary relations, but these results can easily be extended to relations of larger arity.

[3]Note that an inference rule of the form `H(X) :- R1(X,Y),R2(Y,Z)` is equivalent to the algebraic expression $\pi_X(R_1 \bowtie R_2)$. First a join is performed between R_1 and R_2 testing for equality between values of Y; then a projection eliminates all columns besides X.

Definition 1 *A relation,* $R = \{(x_i, y_i)\} \subseteq \mathcal{X} \times \mathcal{Y}$, *is* pseudo-functional *(PF)* in x with degree k, *if* $\forall x \in \mathcal{X} : |\{y|(x,y) \in R\}| \leq k$. *When the precise variable and degree is irrelevant to discussion, we simply say "R is PF."*

An m-way equijoin over relations that are PF in the join variables will have at most $k^m * |R|$ results. Since k^m is constant for a given join and $|R|$ scales linearly in the size of the textual corpus, proof tree construction over PF relations also scales linearly.

However, due to their heavy-tailed distributions, most relations extracted from the Web fit the pseudo-functional definition in most, but not all values of $\mathcal{X}$. Fortunately, it turns out that in most cases these "bad" values of $\mathcal{X}$ are rare and hence don't influence the join size significantly. We formalize this intuition by defining a class of approximately pseudo-functional (APF) relations and proving that joining two APF relations produces at most a linear number of results.

Definition 2 *A relation, R, is* approximately pseudo-functional *(APF)* in x with degree k, *if* $\mathcal{X}$ *can be partitioned into two sets* $\mathcal{X}_G$ *and* $\mathcal{X}_B$ *such that for all* $x \in \mathcal{X}_G$ *R is PF with degree k and*

$$\sum_{x \in \mathcal{X}_B} |\{y|(x,y) \in R\}| \leq k * log(|R|)$$

Theorem 1. *If relation* R_1 *is APF in* y *with degree* k_1 *and* R_2 *is APF in* y *with degree* k_2 *then the relation* $Q = R_1 \bowtie R_2$ *has size at most* $\mathcal{O}(max(|R_1|, |R_2|))$.

Proof. Since R_1 and R_2 are APF, we know that $\mathcal{Y}$ can be partitioned into four groups: $\mathcal{Y}_{BB} = \mathcal{Y}_{B1} \bigcap \mathcal{Y}_{B2}$, $\mathcal{Y}_{BG} = \mathcal{Y}_{B1} \bigcap \mathcal{Y}_{G2}$, $\mathcal{Y}_{GB} = \mathcal{Y}_{G1} \bigcap \mathcal{Y}_{B2}$, $\mathcal{Y}_{GG} = \mathcal{Y}_{G1} \bigcap \mathcal{Y}_{G2}$.[4] We can show that each group leads to at most $\mathcal{O}(|A|)$ entries in Q. For $y \in \mathcal{Y}_{BB}$ there are at most $k_1 * k_2 * log(|R_1|) * log(|R_2|)$ entries in Q. The $y \in \mathcal{Y}_{GB}$ and $y \in \mathcal{Y}_{BG}$ lead to at most $k_1 * k_2 * log(|R_2|)$ and $k_1 * k_2 * log(|R_1|)$ entries, respectively. For $y \in \mathcal{Y}_{GG}$ there are at most $k_1 * k_2 * max(|R_1|, |R_2|)$. Summing the results from the four partitions, we see that $|Q|$ is $\mathcal{O}(max(|R_1|, |R_2|))$, thus it is $\mathcal{O}(|A|)$. □

This theorem and proof can easily be extended to

[4]$\mathcal{Y}_{BB}$ are the "doubly bad" values of y that violate the PF definition for both relations, $\mathcal{Y}_{GG}$ are the values that do not violate the PF definition for either relation, and $\mathcal{Y}_{BG}$ and $\mathcal{Y}_{GB}$ are the values that violate it in only R_1 or R_2, resp.

an m-way equijoin, as long as each relation is APF in all arguments that are being joined.

Theorem 2. *If Q is the relation obtained by an equijoin over m relations $R_{1..m}$, each having size at most $\mathcal{O}(|A|)$, and if all $R_{1..m}$ are APF in all arguments that they are joined in with degree at most k_{max}, and if $\prod_{1 \le i \le m} log(|R_i|) \le |A|$, then $|Q|$ is $\mathcal{O}(|A|)$.*

The inequality in Theorem 2 relates the sizes of the relations ($|R|$), the join (m) and the number of ground assertions ($|A|$). However, in many cases we are interested in much smaller values of m than the inequality enables. We can relax the APF definition to allow a broader, but still scalable, class of m-way-APF relations.

Corollary 3. *If Q is the relation obtained by an m-way join, and if each participating relation is APF in their joined variables with a bound of $k_i * \sqrt[m]{|R_i|}$ instead of $k_i * log(|R_i|)$, then the join is $\mathcal{O}(|A|)$.*

The final step in our scaling argument concerns probabilistic inference, which is #P-Complete if performed exactly. This is addressed in two ways. First, HOLMES uses approximate methods, *e.g.*, loopy belief propagation, which avoids the cost of exact inference — at the cost of reduced precision. Secondly, at a practical level, HOLMES's incremental construction of the graphical model (Figure 1) allows it to bound the size of the network by terminating the search for additional proofs.

4 Experimental Results

This section reports on measurements that confirm that linear scaling with $|A|$ occurs in practice, and that HOLMES's inference is not only scalable but also improves precision/recall on sample queries in a diverse set of domains. After describing the experimental domains and queries, Section 4.2 reports on the boost to the area under the precision/recall curve for a set of example queries in three domains: geography, business, and nutrition. Section 4.3 then shows that APF relations are very common in the Web corpus, and finally Section 4.4 demonstrates empirically that HOLMES's inference time scales linearly with the number of pages in the corpus.

4.1 Experimental Setup

HOLMES utilized two knowledge bases in these experiments: TEXTRUNNER and WordNet. TEXTRUNNER contains approximately 183 million distinct ground assertions extracted from over 117 million web pages, and WordNet contains 159 thousand manually created IS-A, Part-Of, and Synonym assertions.

In all queries, HOLMES utilizes the domain-independent inference rules described in Section 2.3. HOLMES additionally makes use of two domain-specific inference rules in the Nutrition domain, to demonstrate the benefits of including domain-specific information. Estimating the precision and relative recall of HOLMES requires extensive and careful manual tagging of HOLMES output. To make this feasible, we restricted ourselves to a set of twenty queries in three domains, but made the domains diverse to illustrate the broad scope of the system.

We now describe each domain briefly.

Geography: the query issued is: "Who was born in one of the following countries?" More formally, `Q(X) :- BornIn(X,{country})` where {country} is bound to each of the following nine countries in turn {France, Germany, China, Thailand, Kenya, Morocco, Peru, Columbia, Guatemala}, yielding a total of nine queries.

Because Web text often refers to a person's birth city rather than birth country, this query illustrates how combining an ground assertion (*e.g.*, `BornIn(Alberto Fujimori, Lima)`) with background knowledge (*e.g.*, `LocatedIn(Lima, Peru)`) enables the system to draw new conclusions (*e.g.*, `BornIn(Alberto Fujimori, Peru)`).

Business: we issued the following two queries.

1) Which companies are acquiring software companies? Formally, `Q(X) :- Acquired(X, Y)` $\wedge$ `Develops(Y, 'software')` This query tests HOLMES's ability to scalably join a large number of assertions from multiple pages.

2) Which companies are headquartered in the USA? `Q(X) :- HeadquarteredIn(X, 'USA')` $\wedge$ `IS-A(X, 'company')`

Answering this query comprehensively requires HOLMES to combine a join (over the relations HeadquarteredIn and IS-A) with transitive inference on PartOf (*e.g.*, Seattle is PartOf Washington which is PartOf the USA) and on IS-A (*e.g.*, Microsoft IS-A software company which IS-A company). The IS-A assertions came from both TEXTRUNNER (using patterns from (Hearst, 1992)) and WordNet.

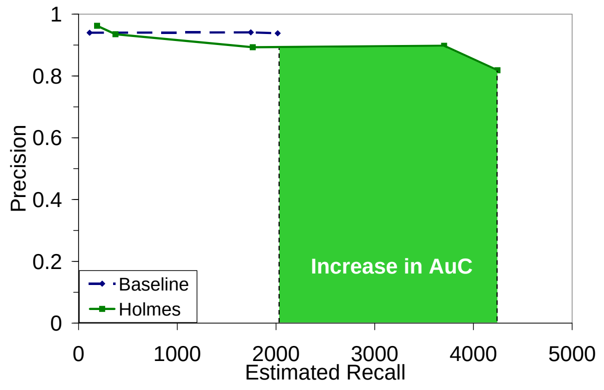

Figure 3: PR Curve for BornIn(X, {country}). Inference boosts the Area under the PR Curve (AuC) by 102 %.

Domain	Increase in AuC	Total Inference Time
Geography	+102%	55 s
Business	+2,643%	145 s
Nutrition	+5,595%	64 s

Table 1: Improvement in the AuC of HOLMES over the BASELINE and total inference time taken by HOLMES. Results are summed over all queries in the geography, business, and nutrition domains. Inference time measured on unoptimized prototype.

Nutrition: the nine queries issued are instances of "What foods prevent disease?" Where a food is a member of one of the classes: fruit, vegetable, or grain, and a disease is one of: anemia, scurvy, or osteoporosis. More formally, `Q(X, {disease}) :- Prevents(X, {disease})` $\wedge$ `IS-A(X, {food})`

Our experiments in the nutrition domain utilized two domain-specific inference rules in addition to the ones presented in Section 2.3:

`Prevents(X,Y):-HighIn(X,Z)` $\wedge$ `Prevents(Z,Y)`

`Prevents(X,Y):-Contains(X,Z)` $\wedge$ `Prevents(Z,Y)`

4.2 Effect of Inference on Recall

To measure the cost and benefit of HOLMES's inference we need to define a baseline for comparison. Answering the conjunctive queries in the business and nutrition domains requires computing joins, which TEXTRUNNER does not do. Thus, we defined a baseline system, BASELINE, which has access to the underlying Knowledge Bases (KBs) (TEXTRUNNER and WordNet), and the ability to compute joins using information explicitly stated in either KB, but does *not* have the ability to infer new assertions.

We compared HOLMES with BASELINE in all three domains. Figure 3 depicts the combined precision/relative recall curves for the nine Geography queries. HOLMES yields substantially higher recall (the shaded region) at modestly lower precision, doubling the area under the precision/recall curve (AuC). The other precision/recall curves also showed a slight drop in precision for substantial gains in recall. Table 1 summarizes the results, along with the total runtime needed for inference. Because relations in the business domain are much larger than in the other domains (*i.e.*, 100x ground assertions), inference is slower in this domain.

We note that inference is particularly helpful with rarely mentioned instances. However, inference can lead to errors when the proof tree contains joins on generic terms (*e.g.*, "company") or common extraction errors (*e.g.*, "LLC" as a company name). This is a key area for future work.

4.3 Prevalence of APF Relations

To determine the prevalence of APF relations in Web text, we examined a sample of 500 binary relations selected randomly from TEXTRUNNER's ground assertions. The surface forms of the relations and arguments may misrepresent the true properties of the underlying concepts, so to better estimate the true properties we merged synonymous values as given by Resolver (Yates and Etzioni, 2007) or the most frequent sense of the word in WordNet. For example, we would consider `BornIn(baby, hospital)` and `BornAt(infant, infirmary)` to represent the same concept, and so would merge them into one instance of the 'Born In' relation. The largest two relations had over 1.25 million unique instances each, and 52% of the relations had more than 10,000 instances.

For each relation R, we first found all instances of R extracted by TEXTRUNNER and merged all synonymous instances as described above. Then, for each argument of R we computed the smallest value, K_{min}, such that R is APF with degree K_{min}. Since many interesting assertions can be inferred by simply joining two relations, we also considered the special case of 2-way joins using Corollary 3. We computed the smallest value, $K_{2\bowtie}$, such that the relation is two-way-APF with degree $K_{2\bowtie}$.

Figure 4 shows the fraction of relations with K_{min} and $K_{2\bowtie}$ of at most K as a function of varying

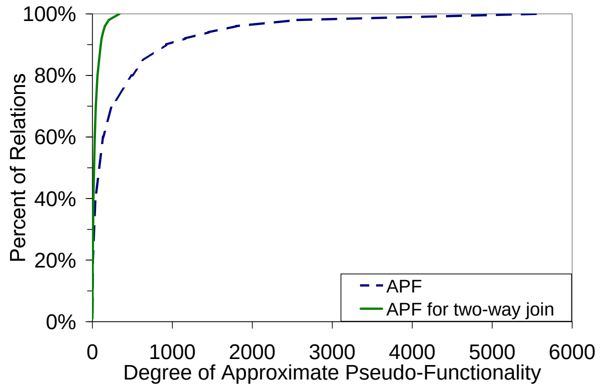

Figure 4: Prevalence of APF relations in Web text. The x-axis depicts the *degree* of pseudo-functionality, *e.g.*, K_{min} and $K_{2\bowtie}$, (see definition 2); the y-axis lists the percent of relations that are APF with that degree. Results are averaged over both arguments.

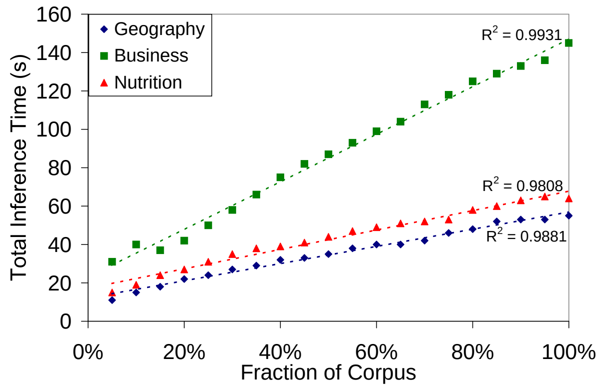

Figure 5: The effects of corpus size on total inference time. We see approximately linear growth in all domains, and display the best fit lines and coefficient of determination (R^2) of each.

values of K. The results are averaged over both arguments of each binary relation. For arbitrary joins in this KB, 80% of the relations are APF with degree less than 496; for 2-way joins (like the ones in our inference rules and test queries), 80% of the relations are APF with degree less than 65. These results indicate that the majority of relations TEXTRUNNER extracted from text are APF, and so we can expect HOLMES's techniques will allow efficient inference over most relations.

While Theorem 2 guarantees that joins over those relations will be $\mathcal{O}(|R|)$, that notation hides a potentially large constant factor of ${K_{min}}^m$. Fortunately the constant factor is significantly smaller in practice. To see why, we re-examine the proof: the large factor comes from assuming that *all* of R's first arguments which meet the PF definition are associated with exactly K_{min} distinct second arguments. However, in our corpus 83% of first arguments are associated with only *one* second argument. Clearly, our worst-case analysis substantially over-estimates inference time for most queries. Moreover, in additional experiments (omitted due to space limitations), measured join sizes grew linearly in the size of the corpus, but were on average two to three orders of magnitude smaller than the bounds given in the theory. This observation held across relations with different sizes and values of K_{min}.

While the results in Figure 4 may vary for other sets of relations, we believe the general trends hold. This is promising for Question Answering and Textual Inference systems, since if true it implies that combining information from multiple difference source is feasible, and can allow such systems to infer answers not explicitly seen in any source.

4.4 Scalability of Inference Speed

Since the previous subsection showed that most relations are APF in their arguments, our theory predicts HOLMES's inference will scale linearly. We tested this hypothesis empirically by running inference over the test queries in our three domains, while varying the number of pages in the textual corpus.

Figure 5 shows how the inference time HOLMES used to answer all queries in each domain scales with KB size. For these queries, and several others we tested (not shown here), inference time grows linearly with the size of the KB. Based on these results we believe that HOLMES can provide scalable inference over a wide variety of domains.

5 Related Work

Textual Entailment systems are given two textual fragments, text T and hypothesis H, and attempt to decide if the meaning of H can be inferred from the meaning of T (Dagan et al., 2005). While many approaches have addressed this problem, our work is most closely related to that of (Raina et al., 2005; MacCartney and Manning, 2007; Tatu and Moldovan, 2006; Braz et al., 2005), which convert the inputs into logical forms and then attempt to 'prove' H from T plus a set of axioms. For instance, (Braz et al., 2005) represents T, H, and a set of rewrite rules in a description logic framework, and determines entailment by solving an integer linear program derived from that representation.

These approaches and related ones (*e.g.*, (Van Durme and Schubert, 2008)) use highly expressive representations, enabling them to express negation, temporal information, and more. HOLMES's representation is much simpler—Markov Logic Horn Clauses for inference rules coupled with a massive database of ground assertions. However, this simplification allows HOLMES to tackle a "text" of enormously larger size: 117 million Web pages versus a single paragraph. A second, if smaller, difference stems from the fact that instead of determining whether a single hypothesis sentence, H, follows from the text, HOLMES tries to find all consequents that match a conjunctive query.

HOLMES is also related to open-domain question-answering systems such as Mulder (Kwok et al., 2001), AskMSR (Brill et al., 2002), and others (Harabagiu et al., 2000; Brill et al., 2001). However, these Q/A systems attempt to find individual documents or sentences containing the answer. They often perform deep analysis on promising texts, and back off to shallower, less reliable methods if those fail. In contrast, HOLMES utilizes TI and attempts to combine information from multiple different sentences in a scalable way.

While its ability to combine information from multiple sources is promising, HOLMES has several limitations these Q/A systems do not have. Since HOLMES relies on an information extraction system to convert sentences into ground predicates, any limitations of the IE system will be propagated to HOLMES. Additionally, the logical representation HOLMES uses limits the reasoning and types of questions it can answer. HOLMES is geared towards answering questions which are naturally expressed as properties and relations of entities, and is not well suited to answering more abstract or open ended questions. Although we have demonstrated that HOLMES is scalable, further work is needed to make it to run at interactive speeds.

Finally, research in statistical relational learning such as MLNs (Richardson and Domingos, 2006), RMNs (Taskar et al., 2002), and others (Getoor and Taskar, 2007) have studied techniques for combining logical and probabilistic inference. Our inference rules are more restrictive than those allowed in MLNs, but this trade-off allows us to efficiently scale inference to large, open domain corpora. By constructing only cliques for satisfied inference rules, HOLMES explicitly models the intuition behind LazySAT inference (Singla and Domingos, 2006) as used in MLNs. *I.e.*, most Horn clause inference rules will be trivially satisfied since their antecedents will be false, so we only need to worry about ones where the antecedent is true.

6 Conclusions

This paper makes three main contributions:

1. We introduce and evaluate the HOLMES system, which leverages KBMC methods in order to scale a class of TI methods to the Web.

2. We define the notion of *Approximately Pseudo-Functional* (APF) relations and prove that, for a APF relations, HOLMES's inference time increases *linearly* with the size of the input corpus. We show empirically that APF relations appear to be prevalent in our Web corpus (Figure 4), and that HOLMES's runtime does scale linearly with the size of its input (Figure 5), taking only a few CPU minutes when run over 183 million distinct ground assertions.

3. We present experiments demonstrating that, for a set of queries in the domains of geography, business, and nutrition, HOLMES substantially improves the quality of answers (measured by AuC) relative to a "no inference" baseline.

In the future, we plan more extensive tests to characterize when HOLMES's inference is helpful. We also hope to examine in what cases jointly performing extraction and inference (as opposed to performing them separately) is feasible at scale. Finally, we plan to examine methods for HOLMES to learn both rule weights and new inference rules.

Abstract

This paper proposes a novel maximum entropy based rule selection (MERS) model for syntax-based statistical machine translation (SMT). The MERS model combines local contextual information around rules and information of sub-trees covered by variables in rules. Therefore, our model allows the decoder to perform context-dependent rule selection during decoding. We incorporate the MERS model into a state-of-the-art linguistically syntax-based SMT model, the tree-to-string alignment template model. Experiments show that our approach achieves significant improvements over the baseline system.

1 Introduction

Syntax-based statistical machine translation (SMT) models (Liu et al., 2006; Galley et al., 2006; Huang et al., 2006) capture long distance reorderings by using rules with structural and linguistical information as translation knowledge. Typically, a translation rule consists of a source-side and a target-side. However, the source-side of a rule usually corresponds to multiple target-sides in multiple rules. Therefore, during decoding, the decoder should select a correct target-side for a source-side. We call this *rule selection*.

Rule selection is of great importance to syntax-based SMT systems. Comparing with word selection in word-based SMT and phrase selection in phrase-based SMT, rule selection is more generic and important. This is because that a rule not only contains terminals (words or phrases), but also contains nonterminals and structural information. Terminals indicate lexical translations, while nonterminals and structural information can capture short or long distance reorderings. See rules in Figure 1 for illustration. These two rules share the same syntactic tree on the source side. However, on the target side, either the translations for terminals or the phrase reorderings for nonterminals are quite different. During decoding, when a rule is selected and applied to a source text, both lexical translations (for terminals) and reorderings (for nonterminals) are determined. Therefore, rule selection affects both lexical translation and phrase reordering.

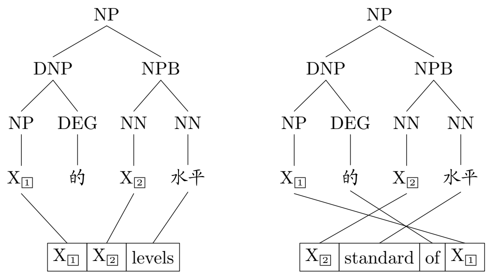

Figure 1: Example of translation rules

However, most of the current syntax-based systems ignore contextual information when they selecting rules during decoding, especially the information of sub-trees covered by nonterminals. For example, the information of $X_{\boxed{1}}$ and $X_{\boxed{2}}$ is not recorded when the rules in Figure 1 extracted from the training examples in Figure 2. This makes the decoder hardly distinguish the two rules. Intuitively, information of sub-trees covered by nonterminals as well as contextual information of rules are believed

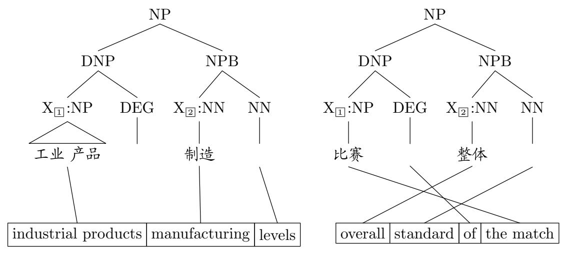

Figure 2: Training examples for rules in Figure 1

to be helpful for rule selection.

Recent research showed that contextual information can help perform word or phrase selection. Carpuat and Wu (2007b) and Chan et al. (2007) showed improvents by integrating word-sense-disambiguation (WSD) system into a phrase-based (Koehn, 2004) and a hierarchical phrase-based (Chiang, 2005) SMT system, respectively. Similar to WSD, Carpuat and Wu (2007a) used contextual information to solve the ambiguity problem for phrases. They integrated a phrase-sense-disambiguation (PSD) model into a phrase-based SMT system and achieved improvements.

In this paper, we propose a novel solution for rule selection for syntax-based SMT. We use the maximum entropy approach to combine rich contextual information around a rule and the information of sub-trees covered by nonterminals in a rule. For each ambiguous source-side of translation rules, a maximum entropy based rule selection (MERS) model is built. Thus the MERS models can help the decoder to perform a context-dependent rule selection.

Comparing with WSD (or PSD), there are some advantages of our approach:

- Our approach resolves ambiguity for rules with multi-level syntactic structure, while WSD resolves ambiguity for strings that have no structures;
- Our approach can help the decoder perform both lexical selection and phrase reorderings, while WSD can help the decoder only perform lexical selection;
- Our method takes WSD as a special case, since a rule may only consists of terminals.

In our previous work (He et al., 2008), we reported improvements by integrating a MERS model into a formally syntax-based SMT model, the hierarchical phrase-based model (Chiang, 2005). In this paper, we incorporate the MERS model into a state-of-the-art linguistically syntax-based SMT model, the tree-to-string alignment template (TAT) model (Liu et al., 2006). The basic differences are:

- The MERS model here combines rich information of source syntactic tree as features since the translation model is linguistically syntax-based. He et al. (2008) did not use this information.
- In this paper, we build MERS models for all ambiguous source-sides, including lexicalized (source-side which only contains terminals), partially lexicalized (source-side which contains both terminals and nonterminals), and unlexicalized (source-side which only contains nonterminals). He et al. (2008) only built MERS models for partially lexicalized source-sides.

In the TAT model, a TAT can be considered as a translation rule which describes correspondence between source syntactic tree and target string. TAT can capture linguistically motivated reorderings at short or long distance. Experiments show that by incorporating MERS model, the baseline system achieves statistically significant improvement.

This paper is organized as follows: Section 2 reviews the TAT model; Section 3 introduces the MERS model and describes feature definitions; Section 4 demonstrates a method to incorporate the MERS model into the translation model; Section 5 reports and analyzes experimental results; Section 6 gives conclusions.

2 Baseline System

Our baseline system is Lynx (Liu et al., 2006), which is a linguistically syntax-based SMT system. For translating a source sentence $f_1^J = f_1 ... f_j ... f_J$, Lynx firstly employs a parser to produce a source syntactic tree $T(f_1^J)$, and then uses the source syntactic tree as the input to search translations:

$$(1)\ \widetilde{e}_1^I = \text{argmax}_{e'^I_1} Pr(e_1^I|f_1^J)$$
$$= \text{argmax}_{e'^I_1} Pr(T(f_1^J)|f_1^J) Pr(e_1^I|T(f_1^J))$$

In doing this, Lynx uses tree-to-string alignment template to build relationship between source syntactic tree and target string. A TAT is actually a translation rule: the source-side is a parser tree with leaves consisting of words and nonterminals, the target-side is a target string consisting of words and nonterminals.

TAT can be learned from word-aligned, source-parsed parallel corpus. Figure 4 shows three types of TATs extracted from the training example in Figure 3: lexicalized (the left), partially lexicalized (the middle), unlexicalized (the right). Lexicalized TAT contains only terminals, which is similar to phrase-to-phrase translation in phrase-based model except that it is constrained by a syntactic tree on the source-side. Partially lexicalized TAT contains both terminals and non-terminals, which can be used for both lexical translation and phrase reordering. Unlexicalized TAT contains only nonterminals and can only be used for phrase reordering.

Lynx builds translation model in a log-linear framework (Och and Ney, 2002):

$$(2)\quad P(e_1^I|T(f_1^J)) = \frac{\exp[\sum_m \lambda_m h_m(e_1^I, T(f_1^J))]}{\sum_{e'} \exp[\sum_m \lambda_m h_m(e_1^I, T(f_1^J))]}$$

Following features are used:

- Translation probabilities: $P(\widetilde{e}|\widetilde{T})$ and $P(\widetilde{T}|\widetilde{e})$;
- Lexical weights: $P_w(\widetilde{e}|\widetilde{T})$ and $P_w(\widetilde{T}|\widetilde{e})$;
- TAT penalty: $exp(1)$, which is analogous to phrase penalty in phrase-based model;
- Language model $P_{lm}(e_1^I)$;
- Word penalty I.

In Lynx, rule selection mainly depends on translation probabilities and lexical weights. These four scores describe how well a source tree links to a target string, which are estimated on the training corpus according to occurrence times of $\widetilde{e}$ and $\widetilde{T}$. There are no features in Lynx that can capture contextual information during decoding, except for the n-gram language model which considers the left and right neighboring n-1 target words. But this information it very limited.

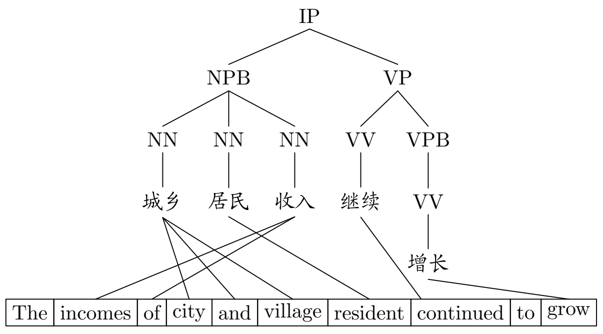

Figure 3: Word-aligned, source-parsed training example.

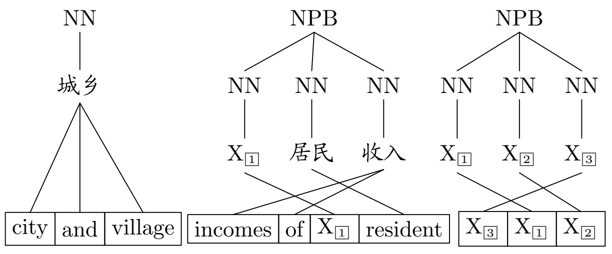

Figure 4: TATs learned from the training example in Figure 3.

3 The Maximum Entropy based Rule Selection Model

3.1 The model

In this paper, we focus on using contextual information to help the TAT model perform context-dependent rule selection. We consider the rule selection task as a multi-class classification task: for a source syntactic tree $\widetilde{T}$, each corresponding target string $\widetilde{e}$ is a label. Thus during decoding, when a TAT $\langle \widetilde{T}, \widetilde{e'} \rangle$ is selected, $\widetilde{T}$ is classified into label $\widetilde{e'}$, actually.

A good way to solve the classification problem is the maximum entropy approach:

$$(3)\quad P_{rs}(\widetilde{e}|\widetilde{T}, T(X_k)) = \frac{\exp[\sum_i \lambda_i h_i(\widetilde{e}, C(\widetilde{T}), T(X_k))]}{\sum_{\widetilde{e'}} \exp[\sum_i \lambda_i h_i(\widetilde{e'}, C(\widetilde{T}), T(X_k))]}$$

where $\widetilde{T}$ and $\widetilde{e}$ are the source tree and target string of a TAT, respectively. h_i is a binary feature functions and λ_i is the feature weight of h_i. $C(\widetilde{T})$ defines local contextual information of $\widetilde{T}$. X_k is a nonterminal in the source tree $\widetilde{T}$, where k is an index. $T(X_k)$ is the source sub-tree covered by X_k.

The advantage of the MERS model is that it uses rich contextual information to compute posterior probability for $\widetilde{e}$ given $\widetilde{T}$. However, the translation probabilities and lexical weights in Lynx ignore these information.

Note that for each ambiguous source tree, we build a MERS model. That means, if there are N source trees extracted from the training corpus are ambiguous (the source tree which corresponds to multiple translations), thus for each ambiguous source tree T_i ($i = 1, ..., N$), a MERS model M_i ($i = 1, ..., N$) is built. Since a source tree may correspond to several hundreds of target translations at most, the feature space of a MERS model is not prohibitively large. Thus the complexity for training a MERS model is low.

3.2 Feature Definition

Let $\langle \widetilde{T}, \widetilde{e} \rangle$ be a translation rule in the TAT model. We use $f(\widetilde{T})$ to represent the source phrase covered by $\widetilde{T}$. To build a MERS model for the source tree $\widetilde{T}$, we explore various features listed below.

1. Lexical Features (LF)
   These features are defined on source words. Specifically, there are two kinds of lexical features: **external** features f_{-1} and f_{+1}, which are the source words immediately to the left and right of $f(\widetilde{T})$, respectively; **internal** features $f_L(T(X_k))$ and $f_R(T(X_k))$, which are the left most and right most boundary words of the source phrase covered by $T(X_k)$, respectively.

   See Figure 5 (a) for illustration. In this example, f_{-1}=tígāo, f_{+1}=zhìzào, $f_L(T(X_1))$=gōngyè, $f_R(T(X_1))$=chǎnpǐn.

2. Parts-of-speech (POS) Features (POSF)
   These features are the POS tags of the source words defined in the lexical features: P_{-1}, P_{+1}, $P_L(T(X_k))$, $P_R(T(X_k))$ are the POS tags of f_{-1}, f_{+1}, $f_L(T(X_k))$, $f_R(T(X_k))$, re-

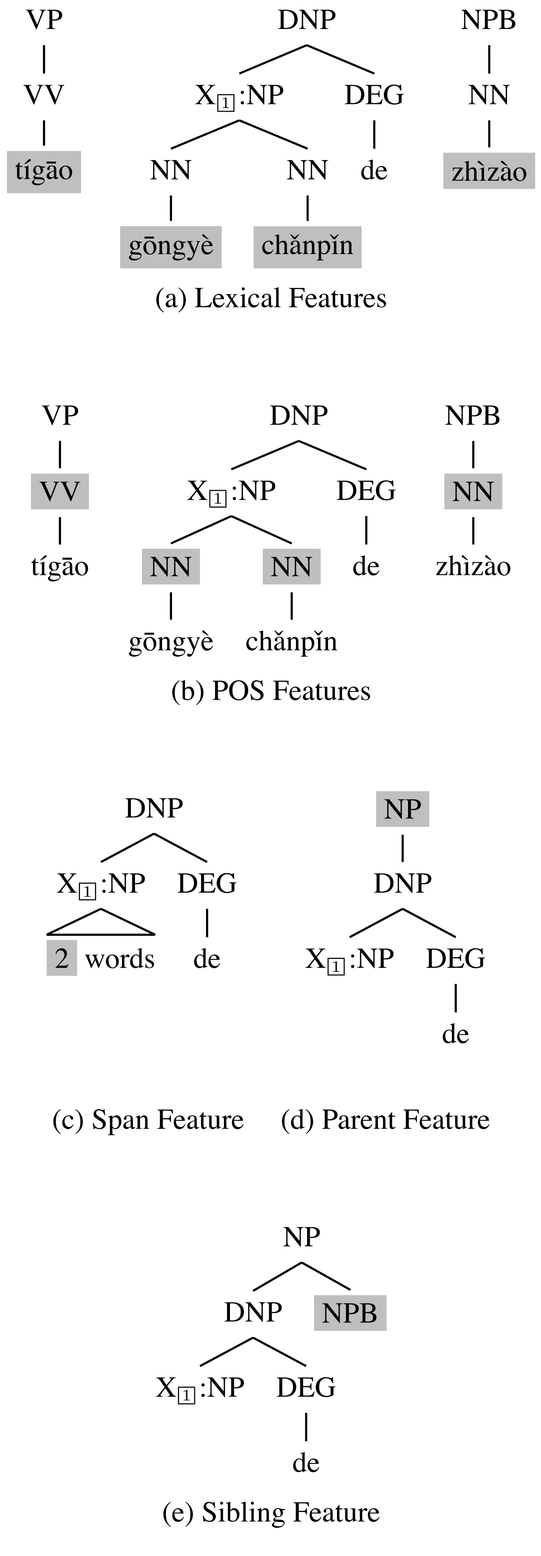

Figure 5: Illustration of features of the MERS model. The source tree of the TAT is ⟨ DNP(NP $X_{\boxed{1}}$) (DEG de)⟩. Gray nodes denote information included in the feature.

spectively. POS tags can generalize over all training examples.

Figure 5 (b) shows POS features. P_{-1}=VV, P_{+1}=NN, $P_L(T(X_1))$=NN, $P_R(T(X_1))$=NN.

3. Span Features (SPF)
These features are the length of the source phrase $f(T(X_k))$ covered by $T(X_k)$. In Liu's TAT model, the knowledge learned from a short span can be used for a larger span. This is not reliable. Thus we use span features to allow the MERS model to learn a preference for short or large span.

   In Figure 5 (c), the span of $X_{\boxed{1}}$ is 2.

4. Parent Feature (PF)
The parent node of $\widetilde{T}$ in the parser tree of the source sentence. The same source sub-tree may have different parent nodes in different training examples. Therefore, this feature may provide information for distinguishing source sub-trees.

   Figure 5 (d) shows that the parent is a *NP* node.

5. Sibling Features (SBF)
The siblings of the root of $\widetilde{T}$. This feature considers neighboring nodes which share the same parent node.

   In Figure 5 (e), the source tree has one sibling node *NPB*.

Those features make use of rich information around a rule, including the contextual information of a rule and the information of sub-trees covered by nonterminals. They are never used in Liu's TAT model.

Figure 5 shows features for a partially lexicalized source tree. Furthermore, we also build MERS models for lexicalized and unlexicalized source trees. Note that for lexicalized tree, features do not include the information of sub-trees since there is no nonterminals.

The features can be easily obtained by modifying the TAT extraction algorithm described in (Liu et al., 2006). When a TAT is extracted from a word-aligned, source-parsed parallel sentence, we just record the contextual features and the features of the sub-trees. Then we use the toolkit implemented by Zhang (2004) to train MERS models for the ambiguous source syntactic trees separately. We set the iteration number to 100 and Gaussian prior to 1.

4 Integrating the MERS Models into the Translation Model

We integrate the MERS models into the TAT model during the translation of each source sentence. Thus the MERS models can help the decoder perform context-dependent rule selection during decoding.

For integration, we add two new features into the log-linear translation model:

- $P_{rs}(\widetilde{e}|\widetilde{T}, T(X_k))$. This feature is computed by the MERS model according to equation (3), which gives a probability that the model selecting a target-side $\widetilde{e}$ given an ambiguous source-side $\widetilde{T}$, considering rich contextual information.

- $P_{ap} = exp(1)$. During decoding, if a source tree has multiple translations, this feature is set to $exp(1)$, otherwise it is set to $exp(0)$. Since the MERS models are only built for ambiguous source trees, the first feature $P_{rs}(\widetilde{e}|\widetilde{T}, T(X_k))$ for non-ambiguous source tree will be set to 1.0. Therefore, the decoder will prefer to use non-ambiguous TATs. However, non-ambiguous TATs usually occur only once in the training corpus, which are not reliable. Thus we use this feature to reward ambiguous TATs.

The advantage of our integration is that we need not change the main decoding algorithm of Lynx. Furthermore, the weights of the new features can be trained together with other features of the translation model.

5 Experiments

5.1 Corpus

We carry out experiments on Chinese-to-English translation. The training corpus is the FBIS corpus, which contains 239k sentence pairs with 6.9M Chinese words and 8.9M English words. For the language model, we use SRI Language Modeling Toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1998) to train two tri-gram language models on the English portion of

Type	No. of TATs	No. of source trees	No. of ambiguous source trees	% ambiguous
Lexicalized	333,077	16,367	14,380	87.86
Partially Lexicalized	342,767	38,497	28,397	73.76
Unlexicalized	83,024	7,384	5,991	81.13
Total	758,868	62,248	48,768	78.34

Table 1: Statistical information of TATs filtered by test sets of NIST MT 2003 and 2005.

System	Features									
	$P(\widetilde{e}\|\widetilde{T})$	$P(\widetilde{T}\|\widetilde{e})$	$P_w(\widetilde{e}\|\widetilde{T})$	$P_w(\widetilde{T}\|\widetilde{e})$	lm_1	lm_2	TP	WP	P_{rs}	AP
Lynx	0.210	0.016	0.081	0.051	0.171	0.013	-0.055	0.403	-	-
+MERS	0.031	0.008	0.020	0.080	0.152	0.014	0.027	0.270	0.194	0.207

Table 2: Feature weights obtained by minimum error rate training on the development set. The first 8 features are used by Lynx. TP=TAT penalty, WP=word penalty, AP=ambiguous TAT penalty. Note that in fact, the positive weight for WP and AP indicate a reward.

the training corpus and the Xinhua portion of the Gigaword corpus, respectively. NIST MT 2002 test set is used as the development set. NIST MT 2003 and NIST MT 2005 test sets are used as the test sets. The translation quality is evaluated by BLEU metric (Papineni et al., 2002), as calculated by mteval-v11b.pl with case-insensitive matching of n-grams, where $n = 4$.

5.2 Training

To train the translation model, we first run GIZA++ (Och and Ney, 2000) to obtain word alignment in both translation directions. Then the word alignment is refined by performing "grow-diag-final" method (Koehn et al., 2003). We use a Chinese parser developed by Deyi Xiong (Xiong et al., 2005) to parse the Chinese sentences of the training corpus.

Our TAT extraction algorithm is similar to Liu et al. (2006), except that we make some tiny modifications to extract contextual features for MERS models. To extract TAT, we set the maximum height of the source sub-tree to $h = 3$, the maximum number of direct descendants of a node of sub-tree to $c = 5$. See (Liu et al., 2006) for specific definitions of these parameters.

Table 1 shows statistical information of TATs which are filtered by the two test sets. For each type (lexicalized, partially lexicalized, unlexicalized) of TATs, a great portion of the source trees are ambiguous. The number of ambiguous source trees accounts for 78.34% of the total source trees. This indicates that the TAT model faces serious rule selection problem during decoding.

5.3 Results

We use Lynx as the baseline system. Then the MERS models are incorporated into Lynx, and the system is called Lynx+MERS. To run the decoder, Lynx and Lynx+MERS share the same settings: tatTable-limit=30, tatTable-threshold=0, stack-limit=100, stack-threshold=0.00001. The meanings of the pruning parameters are the same to Liu et al. (2006).

We perform minimum error rate training (Och, 2003) to tune the feature weights for the log-linear model to maximize the systems's BLEU score on the development set. The weights are shown in Table 2.

These weights are then used to run Lynx and Lynx+MERS on the test sets. Table 3 shows the results. Lynx obtains BLEU scores of 26.15 on NIST03 and 26.09 on NIST05. Using all features described in Section 3.2, Lynx+MERS finally obtains BLEU scores of 27.05 on NIST03 and 27.28 on NIST05. The absolute improvements is 0.90 and 1.19, respectively. Using the sign-test described by Collins et al. (2005), both improvements are statistically significant at $p < 0.01$. Moreover, Lynx+MERS also achieves higher n-gram precisions than Lynx.

Test Set	System	BLEU-4	Individual n-gram precisions			
			1	2	3	4
NIST03	Lynx	26.15	71.62	35.64	18.64	9.82
	+MERS	**27.05**	72.00	36.72	19.51	10.37
NIST05	Lynx	26.09	70.39	35.12	18.53	10.11
	+MERS	**27.28**	71.16	36.19	19.62	10.95

Table 3: BLEU-4 scores (case-insensitive) on the test sets.

5.4 Analysis

The baseline system only uses four features for rule selection: the translation probabilities $P(\widetilde{e}|\widetilde{T})$ and $P(\widetilde{T}|\widetilde{e})$; and the lexical weights $P_w(\widetilde{e}|\widetilde{T})$ and $P_w(\widetilde{T}|\widetilde{e})$. These features are estimated on the training corpus by the maximum likelihood approach, which does not allow the decoder to perform a context dependent rule selection. Although Lynx uses language model as feature, the n-gram language model only considers the left and right n-1 neighboring target words.

The MERS models combines rich contextual information as features to help the decoder perform rule selection. Table 4 shows the effect of different feature sets. We test two classes of feature sets: the single feature (the top four rows of Table 4) and the combination of features (the bottom five rows of Table 4). For the single feature set, the POS tags are the most useful and stable features. Using this feature, Lynx+MERS achieves improvements on both the test sets. The reason is that POS tags can be generalized over all training examples, which can alleviate the data sparseness problem.

Although we find that some single features may hurt the BLEU score, they are useful in combination of features. This is because one of the strengths of the maximum entropy model is that it can incorporate various features to perform classification. Therefore, using all features defined in Section 3.2, we obtain statistically significant improvements (the last row of Table 4). In order to know how the MERS models improve translation quality, we inspect the 1-best outputs of Lynx and Lynx+MERS. We find that the first way that the MERS models help the decoder is that they can perform better selection for words or phrases, similar to the effect of WSD or PSD. This is because that lexicalized and partially lexicalized TAT contains terminals. Considering the following examples:

Feature Sets	NIST03	NIST05
LF	26.12	26.32
POSF	26.36	26.21
PF	26.17	25.90
SBF	26.47	26.08
LF+POSF	26.61	26.59
LF+POSF+SPF	26.70	26.44
LF+POSF+PF	26.81	26.56
LF+POSF+SBF	26.68	26.89
LF+POSF+SPF+PF+SBF	27.05	27.28

Table 4: BLEU-4 scores on different feature sets.

- Source: 马耳他 <u>位于</u> 欧洲 南部
- Reference: Malta <u>is located in</u> southern Europe
- Lynx: Malta <u>in</u> southern Europe
- Lynx+MERS: Malta <u>is located in</u> southern Europe

Here the Chinese word "位 于" is incorrectly translated into "in" by the baseline system. Lynx+MERS produces the correct translation "is located in". That is because, the MERS model considers more contextual information for rule selection. In the MERS model, $P_{rs}(\text{in}|\text{位于}) = 0.09$, which is smaller than $P_{rs}(\text{is located in}|\text{位于}) = 0.14$. Therefore, the MERS model prefers the translation "is located in". Note that here the source tree (VV 位于) is lexicalized, and the role of the MERS model is actually the same as WSD.

The second way that the MERS models help the decoder is that they can perform better phrase reorderings. Considering the following examples:

- Source: 按照 [在 中国 市场]$_1$ 的 [发展 战略]$_2$ ...
- Reference: According to its [development strategy]$_2$ [in the Chinese market]$_1$ ...
- Lynx: Accordance with [the Chinese market]$_1$ [development strategy]$_2$ ...
- Lynx+MERS: According to the [development strategy]$_2$ [in the Chinese market]$_1$

The syntactic tree of the Chinese phrase "在 中国 市场 的 发展 战略" is shown in Figure 6. However, there are two TATs which can be applied to the source tree, as shown in Figure 7. The baseline system selects the left TAT and produces a monotone translation of the subtrees "$X_{\boxed{1}}$:PP" and "$X_{\boxed{2}}$:NPB". However, Lynx+MERS uses the right TAT and performs correct phrase reordering by swapping the two source phrases. Here the source tree is partially lexicalized, and both the contextual information and the information of sub-trees covered by nonterminals are considered by the MERS model.

6 Conclusion

In this paper, we propose a maximum entropy based rule selection model for syntax-based SMT. We use two kinds information as features: the local-contextual information of a rule, the information of sub-trees matched by nonterminals in a rule. During decoding, these features allow the decoder to perform a context-dependent rule selection. However, this information is never used in most of the current syntax-based SMT models.

The advantage of the MERS model is that it can help the decoder not only perform lexical selection, but also phrase reorderings. We demonstrate one way to incorporate the MERS models into a state-of-the-art linguistically syntax-based SMT model, the tree-to-string alignment model. Experiments show that by incorporating the MERS models, the baseline system achieves statistically significant improvements.

We find that rich contextual information can improve translation quality for a syntax-based SMT system. In future, we will explore more sophisticated features for the MERS model. Moreover, we will test the performance of the MERS model on large scale corpus.

Abstract

This paper presents a new hypothesis alignment method for combining outputs of multiple machine translation (MT) systems. An indirect hidden Markov model (IHMM) is proposed to address the synonym matching and word ordering issues in hypothesis alignment. Unlike traditional HMMs whose parameters are trained via maximum likelihood estimation (MLE), the parameters of the IHMM are estimated *indirectly* from a variety of sources including word semantic similarity, word surface similarity, and a distance-based distortion penalty. The IHMM-based method significantly outperforms the state-of-the-art TER-based alignment model in our experiments on NIST benchmark datasets. Our combined SMT system using the proposed method achieved the best Chinese-to-English translation result in the constrained training track of the 2008 NIST Open MT Evaluation.

1 Introduction

System combination has been applied successfully to various machine translation tasks. Recently, confusion-network-based system combination algorithms have been developed to combine outputs of multiple machine translation (MT) systems to form a consensus output (Bangalore, et al. 2001, Matusov et al., 2006, Rosti et al., 2007, Sim et al., 2007). A confusion network comprises a sequence of sets of alternative words, possibly including *null*'s, with associated scores. The consensus output is then derived by selecting one word from each set of alternatives, to produce the sequence with the best overall score, which could be assigned in various ways such as by voting, by using posterior probability estimates, or by using a combination of these measures and other features.

Constructing a confusion network requires choosing one of the hypotheses as the backbone (also called "skeleton" in the literature), and other hypotheses are aligned to it at the word level. High quality hypothesis alignment is crucial to the performance of the resulting system combination. However, there are two challenging issues that make MT hypothesis alignment difficult. First, different hypotheses may use different synonymous words to express the same meaning, and these synonyms need to be aligned to each other. Second, correct translations may have different word orderings in different hypotheses and these words need to be properly reordered in hypothesis alignment.

In this paper, we propose an indirect hidden Markov model (IHMM) for MT hypothesis alignment. The HMM provides a way to model both synonym matching and word ordering. Unlike traditional HMMs whose parameters are trained via maximum likelihood estimation (MLE), the parameters of the IHMM are estimated *indirectly* from a variety of sources including word semantic similarity, word surface similarity, and a distance-based distortion penalty, without using large amount of training data. Our combined SMT system using the proposed method gave the best result on the Chinese-to-English test in the constrained training track of the 2008 NIST Open MT Evaluation (MT08).

2 Confusion-network-based MT system combination

The current state-of-the-art is confusion-network-based MT system combination as described by

[*] Mei Yang performed this work when she was an intern with Microsoft Research.

Rosti and colleagues (Rosti et al., 2007a, Rosti et al., 2007b). The major steps are illustrated in Figure 1. In Fig. 1 (a), hypotheses from different MT systems are first collected. Then in Fig. 1 (b), one of the hypotheses is selected as the backbone for hypothesis alignment. This is usually done by a sentence-level minimum Bayes risk (MBR) method which selects a hypothesis that has the minimum average distance compared to all hypotheses. The backbone determines the word order of the combined output. Then as illustrated in Fig. 1 (c), all other hypotheses are aligned to the backbone. Note that in Fig. 1 (c) the symbol ε denotes a *null* word, which is inserted by the alignment normalization algorithm described in section 3.4. Fig. 1 (c) also illustrates the handling of synonym alignment (e.g., aligning "car" to "sedan"), and word re-ordering of the hypothesis. Then in Fig. 1 (d), a confusion network is constructed based on the aligned hypotheses, which consists of a sequence of sets in which each word is aligned to a list of alternative words (including *null*) in the same set. Then, a set of global and local features are used to decode the confusion network.

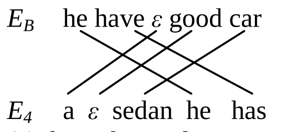
E_1	he have good car
E_2	he has nice sedan
E_3	it a nice car
E_4	a sedan he has

(a) hypothesis set

$$E_B = \arg\min_{E' \in \mathbf{E}} \sum_{E \in \mathbf{E}} TER(E', E)$$

e.g., $E_B = E_1$

(b) backbone selection



E_B he have ε good car
E_4 a ε sedan he has

(c) hypothesis alignment

he	have	ε	good	car
he	has	ε	nice	sedan
it	ε	a	nice	car
he	has	a	ε	sedan

(d) confusion network

3 Indirect-HMM-based Hypothesis Alignment

In confusion-network-based system combination for SMT, a major difficulty is aligning hypotheses to the backbone. One possible statistical model for word alignment is the HMM, which has been widely used for bilingual word alignment (Vogel et al., 1996, Och and Ney, 2003). In this paper, we propose an indirect-HMM method for monolingual hypothesis alignment.

3.1 IHMM for hypothesis alignment

Let $e_1^I = (e_1, ..., e_I)$ denote the backbone, $e_1'^J = (e_1', ..., e_J')$ a hypothesis to be aligned to e_1^I, and $a_1^J = (a_1, ..., a_J)$ the alignment that specifies the position of the backbone word aligned to each hypothesis word. We treat each word in the backbone as an HMM state and the words in the hypothesis as the observation sequence. We use a first-order HMM, assuming that the emission probability $p(e_j' | e_{a_j})$ depends only on the backbone word, and the transition probability $p(a_j | a_{j-1}, I)$ depends only on the position of the last state and the length of the backbone. Treating the alignment as hidden variable, the conditional probability that the hypothesis is generated by the backbone is given by

$$p(e_1'^J | e_1^I) = \sum_{a_1^J} \prod_{j=1}^{J} \left[p(a_j | a_{j-1}, I) p(e_j' | e_{a_j}) \right] \quad (1)$$

As in HMM-based bilingual word alignment (Och and Ney, 2003), we also associate a *null* with each backbone word to allow generating hypothesis words that do not align to any backbone word.

In HMM-based hypothesis alignment, emission probabilities model the similarity between a backbone word and a hypothesis word, and will be referred to as the similarity model. The transition probabilities model word reordering, and will be called the distortion model.

3.2 Estimation of the similarity model

The similarity model, which specifies the emission probabilities of the HMM, models the similarity between a backbone word and a hypothesis word. Since both words are in the same language, the similarity model can be derived based on both semantic similarity and surface similarity, and the overall similarity model is a linear interpolation of the two:

$$p(e_j' | e_i) = \alpha \cdot p_{sem}(e_j' | e_i) + (1 - \alpha) \cdot p_{sur}(e_j' | e_i) \quad (2)$$

where $p_{sem}(e'_j \mid e_i)$ and $p_{sur}(e'_j \mid e_i)$ reflect the semantic and surface similarity between e'_j and e_i, respectively, and α is the interpolation factor.

Since the semantic similarity between two target words is source-dependent, the semantic similarity model is derived by using the source word sequence as a hidden layer:

$$\begin{aligned} & p_{sem}(e'_j \mid e_i) \\ & = \sum_{k=0}^{K} p(f_k \mid e_i) p(e'_j \mid f_k, e_i) \\ & \approx \sum_{k=0}^{K} p(f_k \mid e_i) p(e'_j \mid f_k) \end{aligned} \tag{3}$$

where $f_1^K = (f_1, ..., f_K)$ is the source sentence. Moreover, in order to handle the case that two target words are synonyms but neither of them has counter-part in the source sentence, a *null* is introduced on the source side, which is represented by f_0. The last step in (3) assumes that first e_i generates all source words including *null*. Then e_j' is generated by all source words including *null*.

In the common SMT scenario where a large amount of bilingual parallel data is available, we can estimate the translation probabilities from a source word to a target word and vice versa via conventional bilingual word alignment. Then both $p(f_k \mid e_i)$ and $p(e'_j \mid f_k)$ in (3) can be derived:

$$p(e'_j \mid f_k) = p_{s2t}(e'_j \mid f_k)$$

where $p_{s2t}(e'_j \mid f_k)$ is the translation model from the source-to-target word alignment model, and $p(f_k \mid e_i)$, which enforces the sum-to-1 constraint over all words in the source sentence, takes the following form,

$$p(f_k \mid e_i) = \frac{p_{t2s}(f_k \mid e_i)}{\sum_{k=0}^{K} p_{t2s}(f_k \mid e_i)}$$

where $p_{t2s}(f_k \mid e_i)$ is the translation model from the target-to-source word alignment model. In our method, $p_{t2s}(null \mid e_i)$ for all target words is simply a constant p_{null}, whose value is optimized on held-out data[1].

The surface similarity model can be estimated in several ways. A very simple model could be based on exact match: the surface similarity model, $p_{sur}(e'_j \mid e_i)$, would take the value 1.0 if $e' = e$, and 0 otherwise[2]. However, a smoothed surface similarity model is used in our method. If the target language uses alphabetic orthography, as English does, we treat words as letter sequences and the similarity measure can be the length of the longest matched prefix (LMP) or the length of the longest common subsequence (LCS) between them. Then, this raw similarity measure is transformed to a surface similarity score between 0 and 1 through an exponential mapping,

$$p_{sur}(e'_j \mid e_i) = \exp\left\{\rho \cdot \left[s(e'_j, e_i) - 1\right]\right\} \tag{4}$$

where $s(e'_j, e_i)$ is computed as

$$s(e'_j, e_i) = \frac{M(e'_j, e_i)}{\max(|e'_j|, |e_i|)}$$

and $M(e'_j, e_i)$ is the raw similarity measure of e_j' e_i, which is the length of the LMP or LCS of e_j' and e_i. and ρ is a smoothing factor that characterizes the mapping, Thus as ρ approaches infinity, $p_{sur}(e'_j \mid e_i)$ backs off to the exact match model. We found the smoothed similarity model of (4) yields slightly better results than the exact match model. Both LMP- and LCS- based methods achieve similar performance but the computation of LMP is faster. Therefore, we only report results of the LMP-based smoothed similarity model.

3.3 Estimation of the distortion model

The distortion model, which specifies the transition probabilities of the HMM, models the first-order dependencies of word ordering. In bilingual HMM-based word alignment, it is commonly assumed that transition probabilities

[1] The other direction, $p_{s2t}(e'_i \mid null)$, is available from the source-to-target translation model.

[2] Usually a small back-off value is assigned instead of 0.

$p(a_j = i \mid a_{j-1} = i', I)$ depend only on the jump distance $(i - i')$ (Vogel et al., 1996):

$$p(i \mid i', I) = \frac{c(i-i')}{\sum_{l=1}^{I} c(l-i')} \tag{5}$$

As suggested by Liang et al. (2006), we can group the distortion parameters $\{c(d)\}$, $d = i - i'$, into a few buckets. In our implementation, 11 buckets are used for $c(\leq -4)$, $c(-3)$, ... $c(0)$, ..., $c(5)$, $c(\geq 6)$. The probability mass for transitions with jump distance larger than 6 and less than -4 is uniformly divided. By doing this, only a handful of $c(d)$ parameters need to be estimated. Although it is possible to estimate them using the EM algorithm on a small development set, we found that a particularly simple model, described below, works surprisingly well in our experiments.

Since both the backbone and the hypothesis are in the same language, It seems intuitive that the distortion model should favor monotonic alignment and only allow non-monotonic alignment with a certain penalty. This leads us to use a distortion model of the following form, where K is a tuning factor optimized on held-out data.

$$c(d) = \left(1 + |d-1|\right)^{-K}, \; d = -4, \ldots, 6 \tag{6}$$

As shown in Fig. 2, the value of distortion score peaks at d=1, i.e., the monotonic alignment, and decays for non-monotonic alignments depending on how far it diverges from the monotonic alignment.

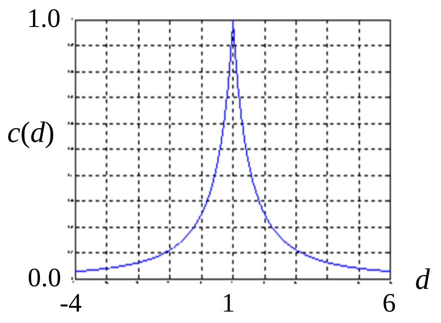

Figure 2, the distance-based distortion parameters computed according to (6), where K=2.

Following Och and Ney (2003), we use a fixed value p_0 for the probability of jumping to a *null* state, which can be optimized on held-out data, and the overall distortion model becomes

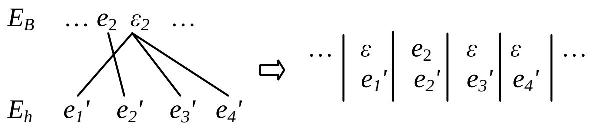
$$\tilde{p}(i \mid i', I) = \begin{cases} p_0 & \text{if } i = \textit{null} \text{ state} \\ (1-p_0) \cdot p(i \mid i', I) & \text{otherwise} \end{cases}$$

3.4 Alignment normalization

Given an HMM, the Viterbi alignment algorithm can be applied to find the best alignment between the backbone and the hypothesis,

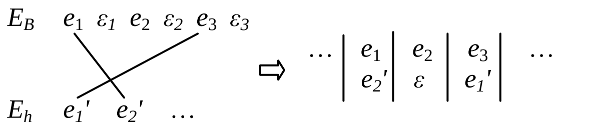
$$\hat{a}_1^J = \underset{a_1^J}{\arg\max} \prod_{j=1}^{J} \left[p(a_j \mid a_{j-1}, I) \, p(e'_j \mid e_{a_j}) \right] \tag{7}$$

However, the alignment produced by the algorithm cannot be used directly to build a confusion network. There are two reasons for this. First, the alignment produced may contain 1-N mappings between the backbone and the hypothesis whereas 1-1 mappings are required in order to build a confusion network. Second, if hypothesis words are aligned to a *null* in the backbone or vice versa, we need to insert actual *null*s into the right places in the hypothesis and the backbone, respectively. Therefore, we need to normalize the alignment produced by Viterbi search.



E_B … e_2 ε_2 …
E_h e_1' e_2' e_3' e_4'
… | ε e_1' | e_2 e_2' | ε e_3' | ε e_4' | …

(a) hypothesis words are aligned to the backbone *null*



E_B e_1 ε_1 e_2 ε_2 e_3 ε_3
E_h e_1' e_2' …
… | e_1 e_2' | e_2 ε | e_3 e_1' | …

(b) a backbone word is aligned to no hypothesis word

Figure 3: illustration of alignment normalization

First, whenever more than one hypothesis words are aligned to one backbone word, we keep the link which gives the highest occupation probability computed via the forward-backward algorithm. The other hypothesis words originally aligned to the backbone word will be aligned to the *null* associated with that backbone word.

Second, for the hypothesis words that are aligned to a particular *null* on the backbone side, a set of *null*s are inserted around that backbone word associated with the *null* such that no links cross each other. As illustrated in Fig. 3 (a), if a hypothesis word e_2' is aligned to the backbone word e_2, a *null* is inserted in front of the backbone word e_2 linked to the hypothesis word e_1' that comes before e_2'. *Null*s are also inserted for other hypothesis words such as e_3' and e_4' after the backbone word e_2. If there is no hypothesis word aligned to that backbone word, all *null*s are inserted after that backbone word .[3]

For a backbone word that is aligned to no hypothesis word, a null is inserted on the hypothesis side, right after the hypothesis word which is aligned to the immediately preceding backbone word. An example is shown in Fig. 3 (b).

4 Related work

The two main hypothesis alignment methods for system combination in the previous literature are GIZA++ and TER-based methods. Matusov et al. (2006) proposed using GIZA++ to align words between different MT hypotheses, where all hypotheses of the test corpus are collected to create hypothesis pairs for GIZA++ training. This approach uses the conventional HMM model bootstrapped from IBM Model-1 as implemented in GIZA++, and heuristically combines results from aligning in both directions. System combination based on this approach gives an improvement over the best single system. However, the number of hypothesis pairs for training is limited by the size of the test corpus. Also, MT hypotheses from the same source sentence are correlated with each other and these hypothesis pairs are not i.i.d. data samples. Therefore, GIZA++ training on such a data set may be unreliable.

Bangalore et al. (2001) used a multiple string-matching algorithm based on Levenshtein edit distance, and later Sim et al. (2007) and Rosti et al. (2007) extended it to a TER-based method for hypothesis alignment. TER (Snover et al., 2006) measures the minimum number of edits, including substitution, insertion, deletion, and shift of blocks of words, that are needed to modify a hypothesis so that it exactly matches the other hypothesis. The best alignment is the one that gives the minimum number of translation edits. TER-based confusion network construction and system combination has demonstrated superior performance on various large-scale MT tasks (Rosti. et al, 2007). However, when searching for the optimal alignment, the TER-based method uses a strict surface hard match for counting edits. Therefore, it is not able to handle synonym matching well. Moreover, although TER-based alignment allows phrase shifts to accommodate the non-monotonic word ordering, all non-monotonic shifts are penalized equally no matter how short or how long the move is, and this penalty is set to be the same as that for substitution, deletion, and insertion edits. Therefore, its modeling of non-monotonic word ordering is very coarse-grained.

In contrast to the GIZA++-based method, our IHMM-based method has a similarity model estimated using bilingual word alignment HMMs that are trained on a large amount of bi-text data. Moreover, the surface similarity information is explicitly incorporated in our model, while it is only used implicitly via parameter initialization for IBM Model-1 training by Matusov et al. (2006). On the other hand, the TER-based alignment model is similar to a coarse-grained, non-normalized version of our IHMM, in which the similarity model assigns no penalty to an exact surface match and a fixed penalty to all substitutions, insertions, and deletions, and the distortion model simply assigns no penalty to a monotonic jump, and a fixed penalty to all other jumps, equal to the non-exact-match penalty in the similarity model.

There have been other hypothesis alignment methods. Karakos, et al. (2008) proposed an ITG-based method for hypothesis alignment, Rosti et al. (2008) proposed an incremental alignment method, and a heuristic-based matching algorithm was proposed by Jayaraman and Lavie (2005).

5 Evaluation

In this section, we evaluate our IHMM-based hypothesis alignment method on the Chinese-to-English (C2E) test in the constrained training track

[3] This only happens if no hypothesis word is aligned to a backbone word but some hypothesis words are aligned to the *null* associated with that backbone word.

of the 2008 NIST Open MT Evaluation (NIST, 2008). We compare to the TER-based method used by Rosti et al. (2007). In the following experiments, the NIST BLEU score is used as the evaluation metric (Papineni et al., 2002), which is reported as a percentage in the following sections.

5.1 Implementation details

In our implementation, the backbone is selected with MBR. Only the top hypothesis from each single system is considered as a backbone. A uniform posteriori probability is assigned to all hypotheses. TER is used as loss function in the MBR computation.

Similar to (Rosti et al., 2007), each word in the confusion network is associated with a word posterior probability. Given a system *S*, each of its hypotheses is assigned with a rank-based score of $1/(1+r)^{\eta}$, where *r* is the rank of the hypothesis, and η is a rank smoothing parameter. The system specific rank-based score of a word *w* for a given system *S* is the sum of all the rank-based scores of the hypotheses in system *S* that contain the word *w* at the given position (after hypothesis alignment). This score is then normalized by the sum of the scores of all the alternative words at the same position and from the same system *S* to generate the system specific word posterior. Then, the total word posterior of *w* over all systems is a sum of these system specific posteriors weighted by system weights.

Beside the word posteriors, we use language model scores and a word count as features for confusion network decoding.

Therefore, for an *M*-way system combination that uses *N* LMs, a total of M+N+1 decoding parameters, including M-1 system weights, one rank smoothing factor, *N* language model weights, and one weight for the word count feature, are optimized using Powell's method (Brent, 1973) to maximize BLEU score on a development set[4] .

Two language models are used in our experiments. One is a trigram model estimated from the English side of the parallel training data, and the other is a 5-gram model trained on the English GigaWord corpus from LDC using the MSRLM toolkit (Nguyen et al, 2007).

[4] The parameters of IHMM are not tuned by maximum-BLEU training.

In order to reduce the fluctuation of BLEU scores caused by the inconsistent translation output length, an unsupervised length adaptation method has been devised. We compute an expected length ratio between the MT output and the source sentences on the development set after maximum-BLEU training. Then during test, we adapt the length of the translation output by adjusting the weight of the word count feature such that the expected output/source length ratio is met. In our experiments, we apply length adaptation to the system combination output at the level of the whole test corpus.

5.2 Development and test data

The development (dev) set used for system combination parameter training contains 1002 sentences sampled from the previous NIST MT Chinese-to-English test sets: 35% from MT04, 55% from MT05, and 10% from MT06-newswire. The test set is the MT08 Chinese-to-English "current" test set, which includes 1357 sentences from both newswire and web-data genres. Both dev and test sets have four references per sentence.

As inputs to the system combination, 10-best hypotheses for each source sentence in the dev and test sets are collected from each of the eight single systems. All outputs on the MT08 test set were true-cased before scoring using a log-linear conditional Markov model proposed by Toutanova et al. (2008). However, to save computation effort, the results on the dev set are reported in case insensitive BLEU (ciBLEU) score instead.

5.3 Experimental results

In our main experiments, outputs from a total of eight single MT systems were combined. As listed in Table 1, Sys-1 is a tree-to-string system proposed by Quirk et al., (2005); Sys-2 is a phrase-based system with fast pruning proposed by Moore and Quirk (2008); Sys-3 is a phrase-based system with syntactic source reordering proposed by Wang et al. (2007a); Sys-4 is a syntax-based pre-ordering system proposed by Li et. al. (2007); Sys-5 is a hierarchical system proposed by Chiang (2007); Sys-6 is a lexicalized re-ordering system proposed by Xiong et al. (2006); Sys-7 is a two-pass phrase-based system with adapted LM proposed by Foster and Kuhn (2007); and Sys-8 is a hierarchical system with two-pass rescoring using a parser-based LM proposed by Wang et al., (2007b). All systems were trained within the confines of the constrained training condition of NIST MT08 evaluation. These single systems are optimized with maximum-BLEU training on different subsets of the previous NIST MT test data. The bilingual translation models used to compute the semantic similarity are from the word-dependent HMMs proposed by He (2007), which are trained on two million parallel sentence-pairs selected from the training corpus allowed by the constrained training condition of MT08.

5.3.1 Comparison with TER alignment

In the IHMM-based method, the smoothing factor for surface similarity model is set to $\rho = 3$, the interpolation factor of the overall similarity model is set to $\alpha = 0.3$, and the controlling factor of the distance-based distortion parameters is set to K=2. These settings are optimized on the dev set. Individual system results and system combination results using both IHMM and TER alignment, on both the dev and test sets, are presented in Table 1. The TER-based hypothesis alignment tool used in our experiments is the publicly available TER Java program, TERCOM (Snover et al., 2006). Default settings of TERCOM are used in the following experiments.

On the dev set, the case insensitive BLEU score of the IHMM-based 8-way system combination output is about 5.8 points higher than that of the best single system. Compared to the TER-based method, the IHMM-based method is about 1.5 BLEU points better. On the MT08 test set, the IHMM-based system combination gave a case sensitive BLEU score of 30.89%. It outperformed the best single system by 4.7 BLEU points and the TER-based system combination by 1.0 BLEU points. Note that the best single system on the dev set and the test set are different. The different single systems are optimized on different tuning sets, so this discrepancy between dev set and test set results is presumably due to differing degrees of mismatch between the dev and test sets and the various tuning sets.

Table 1. Results of single and combined systems on the dev set and the MT08 test set

System	Dev ciBLEU%	MT08 BLEU%
System 1	34.08	21.75
System 2	33.78	20.42
System 3	34.75	21.69
System 4	37.85	25.52
System 5	37.80	24.57
System 6	37.28	24.40
System 7	32.37	25.51
System 8	34.98	26.24
TER	42.11	29.89
IHMM	43.62	30.89

In order to evaluate how well our method performs when we combine more systems, we collected MT outputs on MT08 from seven additional single systems as summarized in Table 2. These systems belong to two groups. Sys-9 to Sys-12 are in the first group. They are syntax-augmented hierarchical systems similar to those described by Shen et al. (2008) using different Chinese word segmentation and language models. The second group has Sys-13 to Sys-15. Sys-13 is a phrasal system proposed by Koehn et al. (2003), Sys-14 is a hierarchical system proposed by Chiang (2007), and Sys-15 is a syntax-based system proposed by Galley et al. (2006). All seven systems were trained within the confines of the constrained training condition of NIST MT08 evaluation.

We collected 10-best MT outputs only on the MT08 test set from these seven extra systems. No MT outputs on our dev set are available from them at present. Therefore, we directly adopt system combination parameters trained for the previous 8-way system combination, except the system weights, which are re-set by the following heuristics: First, the total system weight mass 1.0 is evenly divided among the three groups of single systems: {Sys-1~8}, {Sys-9~12}, and {Sys-13~15}. Each group receives a total system weight mass of 1/3. Then the weight mass is further divided in each group: in the first group, the original weights of systems 1~8 are multiplied by 1/3; in the second and third groups, the weight mass is evenly distributed within the group, i.e., 1/12 for each system in group 2, and 1/9 for each system in group 3[5]. Length adaptation is applied to control the final output length, where the same expected length ratio of the previous 8-way system combination is adopted.

The results of the 15-way system combination are presented in Table 3. It shows that the IHMM-based method is still about 1 BLEU point better than the TER-based method. Moreover, combining 15 single systems gives an output that has a NIST BLEU score of 34.82%, which is 3.9 points better than the best submission to the NIST MT08 constrained training track (NIST, 2008). To our knowledge, this is the best result reported on this task.

Table 2. Results of seven additional single systems on the NIST MT08 test set

System	MT08 BLEU%
System 9	29.59
System 10	29.57
System 11	29.64
System 12	29.85
System 13	25.53
System 14	26.04
System 15	29.70

Table 3. Results of the 15-way system combination on the NIST MT08 C2E test set

Sys. Comb.	MT08 BLEU%
TER	33.81
IHMM	34.82

5.3.2 Effect of the similarity model

In this section, we evaluate the effect of the semantic similarity model and the surface similarity model by varying the interpolation weight α of (2). The results on both the dev and test sets are reported in Table 4. In one extreme case, $\alpha = 1$, the overall similarity model is based only on semantic similarity. This gives a case insensitive BLEU score of 41.70% and a case sensitive BLEU score of 28.92% on the dev and test set, respectively. The accuracy is significantly improved to 43.62% on the dev set and 30.89% on test set when $\alpha = 0.3$. In another extreme case, $\alpha = 0$, in which only the surface similarity model is used for the overall similarity model, the performance degrades by about 0.2 point. Therefore, the surface similarity information seems more important for monolingual hypothesis alignment, but both sub-models are useful.

[5] This is just a rough guess because no dev set is available. We believe a better set of system weights could be obtained if MT outputs on a common dev set were available.

Table 4. Effect of the similarity model

	Dev ciBLEU%	Test BLEU%
$\alpha = 1.0$	41.70	28.92
$\alpha = 0.7$	42.86	30.50
$\alpha = 0.5$	43.11	30.94
$\alpha = 0.3$	43.62	30.89
$\alpha = 0.0$	43.35	30.73

5.3.3 Effect of the distortion model

We investigate the effect of the distance-based distortion model by varying the controlling factor K in (6). For example, setting K=1.0 gives a linear-decay distortion model, and setting K=2.0 gives a quadratic smoothed distance-based distortion model. As shown in Table 5, the optimal result can be achieved using a properly smoothed distance-based distortion model.

Table 5. Effect of the distortion model

	Dev ciBLEU%	Test BLEU%
K=1.0	42.94	30.44
K=2.0	43.62	30.89
K=4.0	43.17	30.30
K=8.0	43.09	30.01

6 Conclusion

Synonym matching and word ordering are two central issues for hypothesis alignment in confusion-network-based MT system combination. In this paper, an IHMM-based method is proposed for hypothesis alignment. It uses a similarity model for synonym matching and a distortion model for word ordering. In contrast to previous methods, the similarity model explicitly incorporates both semantic and surface word similarity, which is critical to monolingual word alignment, and a smoothed distance-based distortion model is used to model the first-order dependency of word ordering, which is shown to be better than simpler approaches.

Our experimental results show that the IHMM-based hypothesis alignment method gave superior results on the NIST MT08 C2E test set compared to the TER-based method. Moreover, we show that our system combination method can scale up to combining more systems and produce a better output that has a case sensitive BLEU score of 34.82, which is 3.9 BLEU points better than the best official submission of MT08.

Coarse-to-Fine Syntactic Machine Translation using Language Projections

Abstract

The intersection of tree transducer-based translation models with n-gram language models results in huge dynamic programs for machine translation decoding. We propose a multipass, coarse-to-fine approach in which the language model complexity is incrementally introduced. In contrast to previous *order-based* bigram-to-trigram approaches, we focus on *encoding-based* methods, which use a clustered encoding of the target language. Across various encoding schemes, and for multiple language pairs, we show speed-ups of up to 50 times over single-pass decoding while improving BLEU score. Moreover, our entire decoding cascade for trigram language models is faster than the corresponding bigram pass alone of a bigram-to-trigram decoder.

1 Introduction

In the absence of an n-gram language model, decoding a synchronous CFG translation model is very efficient, requiring only a variant of the CKY algorithm. As in monolingual parsing, dynamic programming items are simply indexed by a source language span and a syntactic label. Complexity arises when n-gram language model scoring is added, because items must now be distinguished by their initial and final few target language words for purposes of later combination. This lexically exploded search space is a root cause of inefficiency in decoding, and several methods have been suggested to combat it. The approach most relevant to the current work is Zhang and Gildea (2008), which begins with an initial bigram pass and uses the resulting chart to guide a final trigram pass. Substantial speed-ups are obtained, but computation is still dominated by the initial bigram pass. The key challenge is that unigram models are too poor to prune well, but bigram models are already huge. In short, the problem is that there are too many words in the target language. In this paper, we propose a new, coarse-to-fine, multipass approach which allows much greater speedups by translating into *abstracted languages*. That is, rather than beginning with a *low-order* model of a still-large language, we exploit *language projections*, hierarchical clusterings of the target language, to effectively reduce the size of the target language. In this way, initial passes can be very quick, with complexity phased in gradually.

Central to coarse-to-fine language projection is the construction of sequences of word clusterings (see Figure 1). The clusterings are deterministic mappings from words to clusters, with the property that each clustering refines the previous one. There are many choice points in this process, including how these clusterings are obtained and how much refinement is optimal for each pass. We demonstrate that likelihood-based hierarchical EM training (Petrov et al., 2006) and cluster-based language modeling methods (Goodman, 2001) are superior to both rank-based and random-projection methods. In addition, we demonstrate that more than two passes are beneficial and show that our computation is equally distributed over all passes. In our experiments, passes with less than 16-cluster language models are most advantageous, and even a single pass with just two word clusters can reduce decoding time greatly.

To follow related work and to focus on the effects of the language model, we present translation results under an inversion transduction grammar (ITG) translation model (Wu, 1997) trained on the Europarl corpus (Koehn, 2005), described in detail in Section 3, and using a trigram language model. We show that, on a range of languages, our coarse-to-fine decoding approach greatly outperforms baseline beam pruning and bigram-to-trigram pruning on time-to-BLEU plots, reducing decoding times by up to a factor of 50 compared to single pass decoding. In addition, coarse-to-fine decoding increases BLEU scores by up to 0.4 points. This increase is a mixture of improved search and subtly advantageous coarse-to-fine effects which are further discussed below.

2 Coarse-to-Fine Decoding

In coarse-to-fine decoding, we create a series of initially simple but increasingly complex search problems. We then use the solutions of the simpler problems to prune the search spaces for more complex models, reducing the total computational cost.

2.1 Related Work

Taken broadly, the coarse-to-fine approach is not new to machine translation (MT) or even syntactic MT. Many common decoder precomputations can be seen as coarse-to-fine methods, including the A*-like forward estimates used in the Moses decoder (Koehn et al., 2007). In an ITG framework like ours, Zhang and Gildea (2008) consider an approach in which the results of a bigram pass are used as an A* heuristic to guide a trigram pass. In their two-pass approach, the coarse bigram pass becomes computationally dominant. Our work differs in two ways. First, we use posterior pruning rather than A* search. Unlike A* search, posterior pruning allows multipass methods. Not only are posterior pruning methods simpler (for example, there is no need to have complex multipart bounds), but they can be much more effective. For example, in monolingual parsing, posterior pruning methods (Goodman, 1997; Charniak et al., 2006; Petrov and Klein, 2007) have led to greater speedups than their more cautious A* analogues (Klein and Manning, 2003; Haghighi et al., 2007), though at the cost of guaranteed optimality.

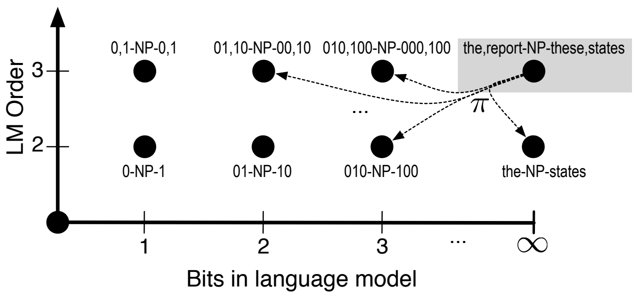

Figure 2: Possible state projections π for the target noun phrase *"the report for these states"* using the clusters from Figure 1. The number of bits used to encode the target language vocabulary is varied along the x-axis. The language model order is varied along the y-axis.

Second, we focus on an orthogonal axis of abstraction: the size of the target language. The introduction of abstract languages gives better control over the granularity of the search space and provides a richer set of intermediate problems, allowing us to adapt the level of refinement of the intermediate, coarse passes to minimize total computation.

Beyond coarse-to-fine approaches, other related approaches have also been demonstrated for syntactic MT. For example, Venugopal et al. (2007) considers a greedy first pass with a full model followed by a second pass which bounds search to a region near the greedy results. Huang and Chiang (2007) searches with the full model, but makes assumptions about the the amount of reordering the language model can trigger in order to limit exploration.

2.2 Language Model Projections

When decoding in a syntactic translation model with an n-gram language model, search states are specified by a grammar nonterminal X as well as the the n-1 left-most target side words $l_{n-1}, \ldots, l_1$ and right-most target side words $r_1, \ldots, r_{n-1}$ of the generated hypothesis. We denote the resulting lexicalized state as $l_{n-1}, \ldots, l_1$-X-$r_1, \ldots, r_{n-1}$. Assuming a vocabulary V and grammar symbol set G, the state space size is up to $|V|^{2(n-1)}|G|$, which is immense for a large vocabulary when $n > 1$. We consider two ways to reduce the size of this search space. First, we can reduce the order of the language model. Second, we can reduce the number of words in the vocabulary. Both can be thought of as *projections* of the search space to smaller ab-

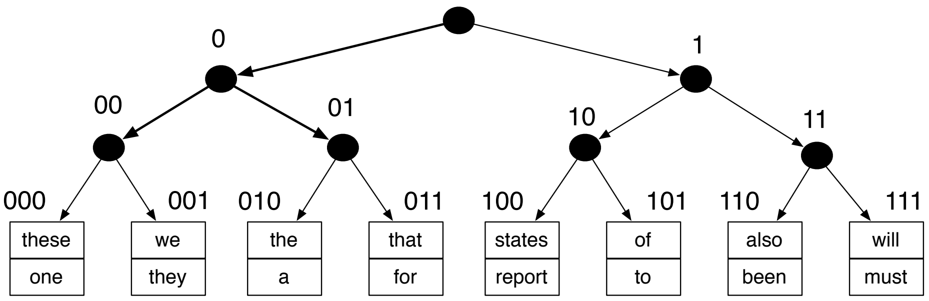

Figure 1: An example of hierarchical clustering of target language vocabulary (see Section 4). Even with a small number of clusters our divisive HMM clustering (Section 4.3) captures sensible syntactico-semantic classes.

stracted spaces. Figure 2 illustrates those two orthogonal axes of abstraction.

Order-based projections are simple. As shown in Figure 2, they simply strip off the appropriate words from each state, collapsing dynamic programming items which are identical from the standpoint of their left-to-right combination in the lower order language model. However, having only order-based projections is very limiting. Zhang and Gildea (2008) found that their computation was dominated by their bigram pass. The only lower-order pass possible uses a unigram model, which provides no information about the interaction of the language model and translation model reorderings. We therefore propose *encoding-based* projections. These projections reduce the size of the target language vocabulary by deterministically projecting each target language word to a word cluster. This projection extends to the whole search state in the obvious way: assuming a bigram language model, the state l-X-r projects to $c(l)$-X-$c(r)$, where $c(\cdot)$ is the deterministic word-to-cluster mapping.

In our multipass approach, we will want a sequence $c_1 \dots c_n$ of such projections. This requires a *hierarchical clustering* of the target words, as shown in Figure 1. Each word's cluster membership can be represented by an n-bit binary string. Each prefix of length k declares that word's cluster assignment at the k-bit level. As we vary k, we obtain a sequence of projections $c_k(\cdot)$, each one mapping words to a more refined clustering. When performing inference in a k-bit projection, we replace the detailed original language model over words with a coarse language model LM$_k$ over the k-bit word clusters. In addition, we replace the phrase table with a projected phrase table, which further increases the speed of projected passes. In Section 4, we describe the various clustering schemes explored, as well as how the coarse LM$_k$ are estimated.

2.3 Multipass Decoding

Unlike previous work, where the state space exists only at two levels of abstraction (i.e. bigram and trigram), we have multiple levels to choose from (Figure 2). Because we use both encoding-based and order-based projections, our options form a lattice of coarser state spaces, varying from extremely simple (a bigram model with just two word clusters) to nearly the full space (a trigram model with 10 bits or 1024 word clusters).

We use this lattice to perform a series of coarse passes with increasing complexity. More formally, we decode a source sentence multiple times, in a sequence of state spaces $S_0, S_1, \dots, S_n{=}S$, where each S_i is a refinement of S_{i-1} in either language model order, language encoding size, or both. The state spaces S_i and S_j ($i < j$) are related to each other via a projection operator $\pi_{j \to i}(\cdot)$ which maps refined states deterministically to coarser states.

We start by decoding an input x in the simplest state space S_0. In particular, we compute the chart of the posterior distributions $p_0(s) = P(s|x)$ for all states $s \in S_0$. These posteriors will be used to prune the search space S_1 of the following pass. States s whose posterior falls below a threshold t trigger the removal of all more refined states s' in the subsequent pass (see Figure 3). This technique is *posterior pruning*, and is different from A* methods in two main ways. First, it can be iterated in a multipass setting, and, second, it is generally more effi-

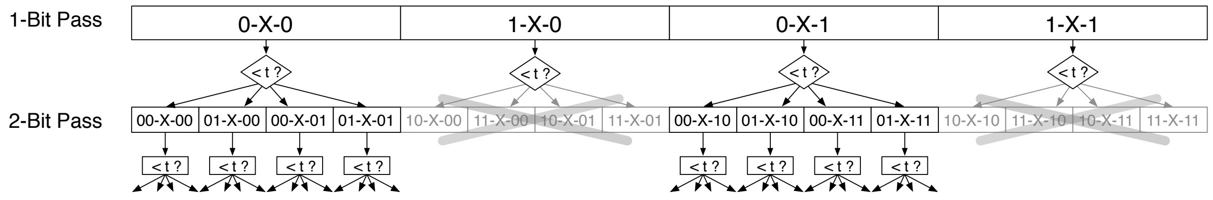

Figure 3: Example of state pruning in coarse-to-fine decoding using the language encoding projection (see Section 2.2). During the coarse one-bit word cluster pass, two of the four possible states are pruned. Every extension of the pruned one-bit states (indicated by the grey shading) are not explored during the two-bit word cluster pass.

cient with a potential cost of increased search errors (see Section 2.1 for more discussion).

Looking at Figure 2, multipass coarse-to-fine decoding can be visualized as a walk from a coarse point somewhere in the lower left to the most refined point in the upper right of the grid. Many coarse-to-fine schedules are possible. In practice, we might start decoding with a 1-bit word bigram pass, followed by an 3-bit word bigram pass, followed by a 5-bit word trigram pass and so on (see Section 5.3 for an empirical investigation). In terms if time, we show that coarse-to-fine gives substantial speed-ups. There is of course an additional memory requirement, but it is negligible. As we will see in our experiments (Section 5) the largest gains can be obtained with extremely coarse language models. In particular, the largest coarse model we use in our best multipass decoder uses a 4-bit encoding and hence has only 16 distinct words (or at most 4096 trigrams).

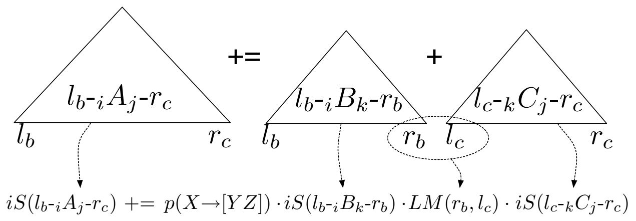
3 Inversion Transduction Grammars

While our approach applies in principle to a variety of machine translation systems (phrase-based or syntactic), we will use the inversion transduction grammar (ITG) approach of Wu (1997) to facilitate comparison with previous work (Zens and Ney, 2003; Zhang and Gildea, 2008) as well as to focus on language model complexity. ITGs are a subclass of synchronous context-free grammars (SCFGs) where there are only three kinds of rules. Preterminal unary productions produce terminal strings on both sides (words or phrases): $X \rightarrow \mathbf{e}/\mathbf{f}$. Binary in-order productions combine two phrases monotonically ($X \rightarrow [YZ]$). Finally, binary inverted productions invert the order of their children ($X \rightarrow \langle YZ \rangle$). These productions are associated with rewrite weights in the standard way.

Without a language model, SCFG decoding is just like (monolingual) CFG parsing. The dynamic programming states are specified by ${}_iX_j$, where $\langle i, j \rangle$ is a source sentence span and X is a nonterminal. The only difference is that whenever we apply a CFG production on the source side, we need to remember the corresponding synchronous production on the target side and store the best obtainable translation via a backpointer. See Wu (1996) or Melamed (2004) for a detailed exposition.

Once we integrate an n-gram language model, the state space becomes lexicalized and combining dynamic programming items becomes more difficult. Each state is now parametrized by the initial and final $n-1$ words in the target language hypothesis: $l_{n-1}, ..., l_1\text{-}{}_iX_j\text{-}r_1, ..., r_{n-1}$. Whenever we combine two dynamic programming items, we need to score the fluency of their concatentation by incorporating the score of any language model features which cross the target side boundaries of the two concatenated items (Chiang, 2005). Decoding with an integrated language model is computationally expensive for two reasons: (1) the need to keep track of a large number of lexicalized hypotheses for each source span, and (2) the need to frequently query the large language model for each hypothesis combination.

Multipass coarse-to-fine decoding can alleviate both computational issues. We start by decoding in an extremely coarse bigram search space, where there are very few possible translations. We compute standard inside/outside probabilities (iS/oS), as follows. Consider the application of non-inverted binary rule: we combine two items $l_b\text{-}{}_iB_k\text{-}r_b$ and $l_c\text{-}{}_kC_j\text{-}r_c$ spanning $\langle i, k \rangle$ and $\langle k, j \rangle$ respectively to form a larger item $l_b\text{-}{}_iA_j\text{-}r_c$, spanning $\langle i, j \rangle$. The



l_b-$_i A_j$-r_c
+=
l_b-$_i B_k$-r_b
+
l_c-$_k C_j$-r_c
l_b
r_c
l_b
r_b
l_c
r_c
$iS(l_b\text{-}_iA_j\text{-}r_c)$ += $p(X\rightarrow[YZ]) \cdot iS(l_b\text{-}_iB_k\text{-}r_b) \cdot LM(r_b,l_c) \cdot iS(l_c\text{-}_kC_j\text{-}r_c)$

Figure 4: Monotonic combination of two hypotheses during the inside pass involves scoring the fluency of the concatenation with the language model.

inside score of the new item is incremented by:

$$iS(l_b\text{-}_iA_j\text{-}r_c) \mathrel{+}= p(X \rightarrow [YZ]) \cdot iS(l_b\text{-}_iB_k\text{-}r_b) \cdot iS(l_c\text{-}_kC_j\text{-}r_c) \cdot LM(r_b, l_c)$$

This process is also illustrated in Figure 4. Of course, we also loop over the split point k and apply the other two rule types (inverted concatenation, terminal generation). We omit those cases from this exposition, as well as the update for the outside pass; they are standard and similar. Once we have computed the inside and outside scores, we compute posterior probabilities for all items:

$$p(l_a\text{-}_iA_j\text{-}r_a) = \frac{iS(l_a\text{-}_iA_j\text{-}r_a)oS(l_a\text{-}_iA_j\text{-}r_a)}{iS(root)}$$

where $iS(root)$ is sum of all translations' scores. States with low posteriors are then pruned away. We proceed to compute inside/outside score in the next, more refined search space, using the projections $\pi_{i\rightarrow i-1}$ to map between states in S_i and S_{i-1}. In each pass, we skip all items whose projection into the previous stage had a probability below a stage-specific threshold. This process is illustrated in Figure 3. When we reach the most refined search space S_∞, we do not prune, but rather extract the Viterbi derivation instead.[1]

4 Learning Coarse Languages

Central to our encoding-based projections (see Section 2.2) are hierarchical clusterings of the target language vocabulary. In the present work, these clusterings are each k-bit encodings and yield sequences of coarse language models LM$_k$ and phrasetables PT$_k$.

[1]Other final decoding strategies are possible, of course, including variational methods and minimum-risk methods (Zhang and Gildea, 2008).

Given a hierarchical clustering, we estimate the corresponding LM$_k$ from a corpus obtained by replacing each token in a target language corpus with the appropriate word cluster. As with our original refined language model, we estimate each coarse language model using the SRILM toolkit (Stolcke, 2002). The phrasetables PT$_k$ are similarly estimated by replacing the words on the target side of each phrase pair with the corresponding cluster. This procedure can potentially map two distinct phrase pairs to the same coarse translation. In such cases we keep only one coarse phrase pair and sum the scores of the colliding originals.

There are many possible schemes for creating hierarchical clusterings. Here, we consider several divisive clustering methods, where coarse word clusters are recursively split into smaller subclusters.

4.1 Random projections

The simplest approach to splitting a cluster is to randomly assign each word type to one of two new subclusters. Random projections have been shown to be a good and computationally inexpensive dimensionality reduction technique, especially for high dimensional data (Bingham and Mannila, 2001). Although our best performance does not come from random projections, we still obtain substantial speed-ups over a single pass fine decoder when using random projections in coarse passes.

4.2 Frequency clustering

In frequency clustering, we allocate words to clusters by frequency. At each level, the most frequent words go into one cluster and the rarest words go into another one. Concretely, we sort the words in a given cluster by frequency and split the cluster so that the two halves have equal token mass. This approach can be seen as a radically simplified version of Brown et al. (1992). It can, and does, result in highly imbalanced cluster hierarchies.

4.3 HMM clustering

An approach found to be effective by Petrov and Klein (2007) for coarse-to-fine parsing is to use likelihood-based hierarchical EM training. We adopt this approach here by identifying each cluster with a latent state in an HMM and determinizing the emissions so that each word type is emitted

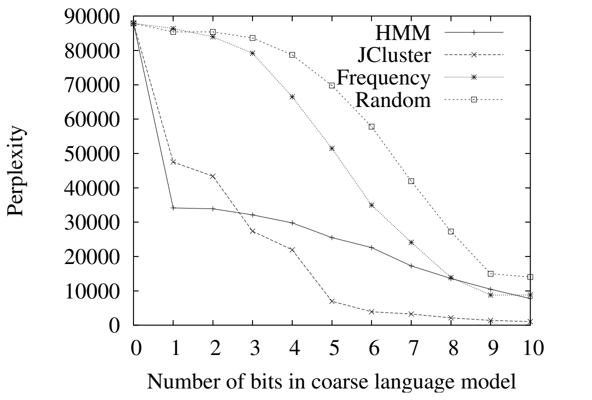


Figure 5: Results of coarse language model perplexity experiment (see Section 4.5). HMM and JClustering have lower perplexity than frequency and random clustering for all number of bits in the language encoding.

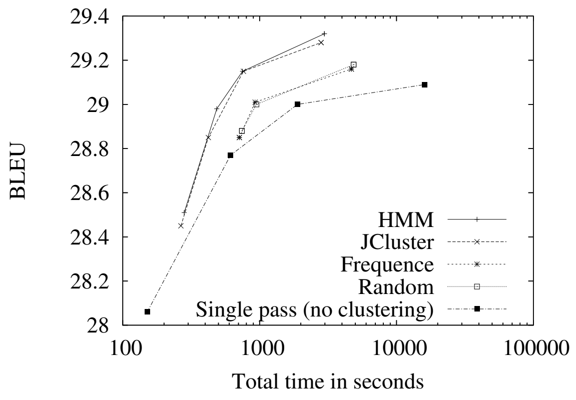

Figure 6: Coarse-to-fine decoding with HMM or JClustering coarse language models reduce decoding times while increasing accuracy.

by only one state. When splitting a cluster s into s_1 and s_2, we initially clone and mildly perturb its corresponding state. We then use EM to learn parameters, which splits the state, and determinize the result. Specifically, each word w is assigned to s_1 if $P(w|s_1) > P(w|s_2)$ and s_2 otherwise. Because of this determinization after each round of EM, a word in one cluster will be allocated to exactly one of that cluster's children. This process not only guarantees that the clusters are hierarchical, it also avoids the state drift discussed by Petrov and Klein (2007). Because the emissions are sparse, learning is very efficient. An example of some of the words associated with early splits can be seen in Figure 1.

4.4 JCluster

Goodman (2001) presents a clustering scheme which aims to minimize the entropy of a word given a cluster. This is accomplished by incrementally swapping words between clusters to locally minimize entropy.[2] This clustering algorithm was developed with a slightly different application in mind, but fits very well into our framework, because the hierarchical clusters it produces are trained to maximize predictive likelihood.

4.5 Clustering Results

We applied the above clustering algorithms to our monolingual language model data to obtain hierarchical clusters. We then trained coarse language models of varying granularity and evaluated them on a held-out set. To measure the quality of the coarse language models we use perplexity (exponentiated cross-entropy).[3] Figure 5 shows that HMM clustering and JClustering have lower perplexity than frequency and random based clustering for all complexities. In the next section we will present a set of machine translation experiments using these coarse language models; the clusterings with better perplexities generally produce better decoders.

5 Experiments

We ran our experiments on the Europarl corpus (Koehn, 2005) and show results on Spanish, French and German to English translation. We used the setup and preprocessing steps detailed in the 2008 Workshop on Statistical Machine Translation.[4] Our baseline decoder uses an ITG with an integrated trigram language model. Phrase translation parameters are learned from parallel corpora with approximately 8.5 million words for each of the language pairs. The English language model is trained on the entire corpus of English parliamentary proceedings provided with the Europarl distribution. We report results on the 2000 development test set sentences of length up to 126 words (average length was 30 words).

[2]The software for this clustering technique is available at `http://research.microsoft.com/˜joshuago/`.

[3]We assumed that each cluster had a uniform distribution over all the words in that cluster.

[4]See `http://www.statmt.org/wmt08` for details.

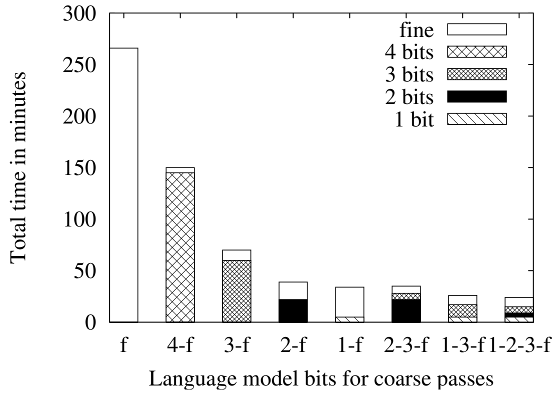

Figure 7: Many passes with extremely simple language models produce the highest speed-ups.

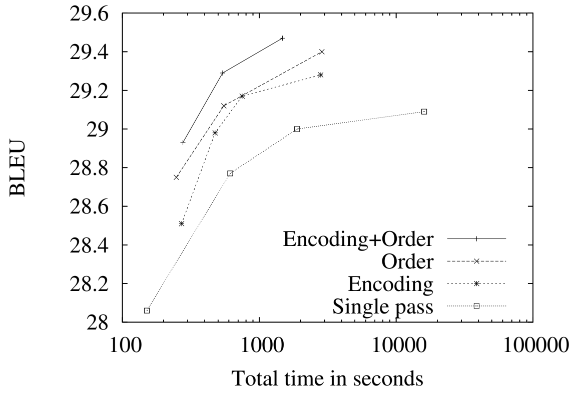

Figure 8: A combination of order-based and encoding-based coarse-to-fine decoding yields the best results.

Our ITG translation model is broadly competitive with state-of-the-art phrase-based-models trained on the same data. For example, on the Europarl development test set, we fall short of Moses (Koehn et al., 2007) by less than one BLEU point. On Spanish-English we get 29.47 BLEU (compared to Moses's 30.40), on French-English 29.34 (vs. 29.95), and 23.80 (vs. 24.64) on German-English. These differences can be attributed primarily to the substantially richer distortion model used by Moses.

The multipass coarse-to-fine architecture that we have introduced presents many choice points. In the following, we investigate various axes individually. We present our findings as BLEU-to-time plots, where the tradeoffs were generated by varying the complexity and the number of coarse passes, as well as the pruning thresholds and beam sizes. Unless otherwise noted, the experiments are on Spanish-English using trigram language models. When different decoder settings are applied to the same model, MERT weights (Och, 2003) from the unprojected single pass setup are used and are kept constant across runs. In particular, the same MERT weights are used for all coarse passes; note that this slightly disadvantages the multipass runs, which use MERT weights optimized for the single pass decoder.

5.1 Clustering

In section Section 4, HMM clustering and JClustering gave lower perplexities than frequency and random clustering when using the same number of bits for encoding the language model. To test how these models perform at pruning, we ran our decoder several times, varying only the clustering source. In each case, we used a 2-bit trigram model as a single coarse pass, followed by a fine output pass. Figure 6 shows that we can obtain significant improvements over the single-pass baseline regardless of the clustering. To no great surprise, HMM clustering and JClustering yield better results, giving a 30-fold speed-up at the same accuracy, or improvements of about 0.3 BLEU when given the same time as the single pass decoder. We discuss this increase in accuracy over the baseline in Section 5.5. Since the performance differences between those two clustering algorithms are negligible, we will use the simpler HMM clustering in all subsequent experiments.

5.2 Spacing

Given a hierarchy of coarse language models, all trigam for the moment, we need to decide on the number of passes and the granularity of the coarse language models used in each pass. Figure 7 shows how decoding time varies for different multipass schemes to achieve the same translation quality. A single coarse pass with a 4-bit language model cuts decoding time almost in half. However, one can further cut decoding time by starting with even coarser language models. In fact, the best results are achieved by decoding in sequence with 1-, 2- and 3-bit language models before running the final fine trigram pass. Interestingly, in this setting, each pass takes about the same amount of time. A similar observation was reported in the parsing literature, where coarse-to-fine inference with multiple passes

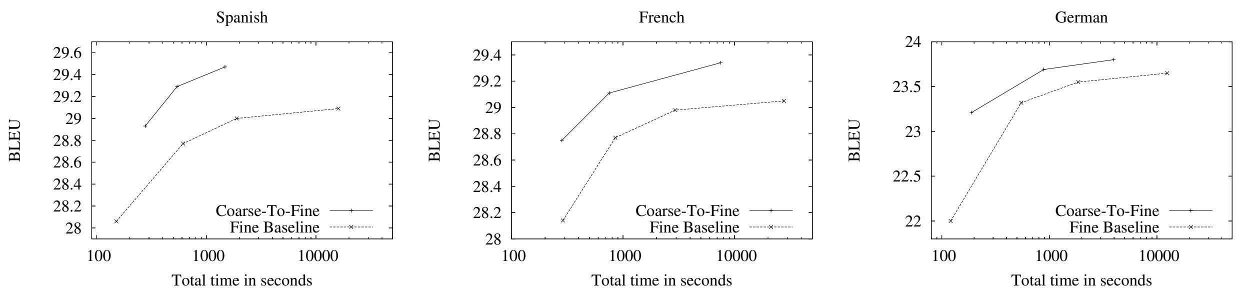

Figure 9: Coarse-to-fine decoding is faster than single pass decoding with a trigram language model and leads to better BLEU scores on all language pairs and for all parameter settings.

of roughly equal complexity produces tremendous speed-ups (Petrov and Klein, 2007).

5.3 Encoding vs. Order

As described in Section 2, the language model complexity can be reduced either by decreasing the vocabulary size (encoding-based projection) or by lowering the language model order from trigram to bigram (order-based projection). Figure 7 shows that both approaches alone yield comparable improvements over the single pass baseline. Fortunately, the two approaches are complimentary, allowing us to obtain further improvements by combining both. We found it best to first do a series of coarse bigram passes, followed by a fine bigram pass, followed by a fine trigram pass.

5.4 Final Results

Figure 9 compares our multipass coarse-to-fine decoder using language refinement to single pass decoding on three different languages. On each language we get significant improvements in terms of efficiency as well as accuracy. Overall, we can achieve up to 50-fold speed-ups at the same accuracy, or alternatively, improvements of 0.4 BLEU points over the best single pass run.

In absolute terms, our decoder translates on average about two Spanish sentences per second at the highest accuracy setting.[5] This compares favorably to the Moses decoder (Koehn et al., 2007), which takes almost three seconds per sentence.

5.5 Search Error Analysis

In multipass coarse-to-fine decoding, we noticed that in addition to computational savings, BLEU scores tend to improve. A first hypothesis is that coarse-to-fine decoding simply improves search quality, where fewer good items fall off the beam compared to a simple fine pass. However, this hypothesis turns out to be incorrect. Table 1 shows the percentage of test sentences for which the BLEU score or log-likelihood changes when we switch from single pass decoding to coarse-to-fine multipass decoding. Only about 30% of the sentences get translated in the same way (if much faster) with coarse-to-fine decoding. For the rest, coarse-to-fine decoding mostly finds translations with lower likelihood, but higher BLEU score, than single pass decoding.[6] An increase of the underlying objectives of interest when pruning despite an increase in model-score search errors has also been observed in monolingual coarse-to-fine syntactic parsing (Charniak et al., 1998; Petrov and Klein, 2007). This effect may be because coarse-to-fine approximates certain minimum Bayes risk objective. It may also be an effect of model intersection between the various passes' models. In any case, both possibilities are often perfectly desirable. It is also worth noting that the number of search errors incurred in the coarse-to-fine approach can be dramatically reduced (at the cost of decoding time) by increasing the pruning thresholds. However, the fortuitous nature of coarse-to-fine search errors seems to be a substantial and desirable effect.

[5]Of course, the time for an average sentence is much lower, since long sentences dominate the overall translation time.

[6]We compared the influence of multipass decoding on the TM score and the LM score; both decrease.

		LL		
		$>$	$=$	$<$
BLEU	$>$	3.6%	-	26.3%
	$=$	1.5%	29.6 %	12.9 %
	$<$	2.2%	-	24.1%

Table 1: Percentage of sentences for which the BLEU score/log-likelihood improves/drops during coarse-to-fine decoding (compared to single pass decoding).

6 Conclusions

We have presented a coarse-to-fine syntactic decoder which utilizes a novel encoding-based language projection in conjunction with order-based projections to achieve substantial speed-ups. Unlike A* methods, a posterior pruning approach allows multiple passes, which we found to be very beneficial for total decoding time. When aggressively pruned, coarse-to-fine decoding can incur additional search errors, but we found those errors to be fortuitous more often than harmful. Our framework applies equally well to other translation systems, though of course interesting new challenges arise when, for example, the underlying SCFGs become more complex.

{jzhao, kliu, gwang}@nlpr.ia.ac.cn

Abstract

In this paper, we present a novel method based on CRFs in response to the two special characteristics of "contextual dependency" and "label redundancy" in sentence sentiment classification. We try to capture the contextual constraints on sentence sentiment using CRFs. Through introducing redundant labels into the original sentimental label set and organizing all labels into a hierarchy, our method can add redundant features into training for capturing the label redundancy. The experimental results prove that our method outperforms the traditional methods like NB, SVM, MaxEnt and standard chain CRFs. In comparison with the cascaded model, our method can effectively alleviate the error propagation among different layers and obtain better performance in each layer.

1 Introduction[*]

There are a lot of subjective texts in the web, such as product reviews, movie reviews, news, editorials and blogs, etc. Extracting these subjective texts and analyzing their orientations play significant roles in many applications such as electronic commercial, etc. One of the most important tasks in this field is sentiment classification, which can be performed in several levels: word level, sentence level, passage level, etc. This paper focuses on sentence level sentiment classification.

Commonly, sentiment classification contains three layers of sub-tasks. From upper to lower, (1) Subjective/Objective classification: the subjective texts are extracted from the corpus teeming with both subjective and objective texts. (2) Polarity classification: a subjective text is classified into "positive" or "negative" according to the sentimental expressions in the text. (3) Sentimental strength rating: a subjective text is classified into several grades which reflect the polarity degree of "positive" or "negative". It is a special multi-class classification problem, where the classes are ordered. In machine learning, this kind of problem is also regarded as an ordinal regression problem (Wei Wu et al. 2005). In this paper, we mainly focus on this problem in sentiment classification.

Sentiment classification in sentence level has its special characteristics compared with traditional text classification tasks. Firstly, the sentiment of each sentence in a discourse is not independent to each other. In other words, the sentiment of each sentence is related to those of other adjacent sentences in the same discourse. The sentiment of a sentence may vary in different contexts. If we detach a sentence from the context, its sentiment may not be inferred correctly. Secondly, there is redundancy among the sentiment classes,

[*] Contact: Jun ZHAO, jzhao@nlpr.ia.ac.cn

especially in sentimental strength classes. For example:

"I love the scenario of "No country for old man" very much!!"

"This movie sounds good."

The first sentence is labeled as "highly praised" class and the second one is labeled as "something good" class. Both the sentences express positive sentiment for the movie, but the former expresses stronger emotion than the latter. We can see that both "highly praised" and "something good" belong to an implicit class "positive", which can be regarded as the relation between them. If we add these implicit classes in the label set, the sentiment classes will form a hierarchical structure. For example, "positive" can be regarded as the parent class of "highly praised" and "something good", "subjective" can be regarded as the parent class of "positive" and "negative". This implicit hierarchical structure among labels should not be neglected because it may be beneficial for improving the accuracy of sentiment classification. In the paper, we call this characteristic of sentiment classification as "label redundancy". Unfortunately, in our knowledge most of the current research treats sentiment classification as a traditional multi-classification task or an ordinal regression task, which regard the sentimental classes being independent to each other and each sentence is also independent to the adjacent sentences in the context. In other words, they neglect the contextual information and the redundancy among sentiment classes.

In order to consider the contextual information in the process of the sentence sentiment classification, some research defines contextual features and some uses special graph-based formulation, like (Bo Pang, et al. 2005). In order to consider the label redundancy, one potential solution is to use a cascaded framework which can combine subjective/objective classification, polarity classification and sentimental strength classification together, where the classification results of the preceding step will be the input of the subsequent one. However, the subsequent classification cannot provide constraint and correction to the results of the preceding step, which will lead to the accumulation and propagation of the classification errors. As a result, the performance of sentiment analysis of sentences is often not satisfactory.

This paper focuses on the above two special characteristics of the sentiment classification problem in the sentence level. To the first characteristic, we regard the sentiment classification as a sequence labeling problem and use conditional random field (CRFs) model to capture the relation between two adjacent sentences in the context. To the second characteristic, we propose a novel method based on a CRF model, in which the original task is mapped to a classification on a hierarchical structure, which is formed by the original label set and some additional implicit labels. In the hierarchical classification framework, the relations between the labels can be represented as the additional features in classification. Because these features are related to the original labels but unobserved, we name them as "redundant features" in this paper. They can be used to capture the redundant and hierarchical relation between different sentiment classes. In this way, not only the performance of sentimental strength rating is improved, the accuracies of subjective/objective classification and polarity classification are also improved compared with the traditional sentiment classification method. And in comparison with the cascaded method, the proposed approach can effectively alleviate error propagation. The experimental results on movie reviews prove the validity of our method.

2 Capturing Contextual Influence for Sentiment Classification

For capturing the influence of the contexts to the sentiment of a sentence, we treat original sentiment classification as a sequence labeling problem. We regard the sentiments of all the sentences throughout a paragraph as a sequential flow of sentiments, and we model it using a conditional model. In this paper, we choose Conditional Random Fields (CRFs) (Lafferty et al, 2001) because it has better performance than other sequence labeling tools in most NLP applications.

CRFs are undirected graphical models used to calculate the conditional probability of a set of labels given a set of input variables. We cite the definitions of CRFs in (Lafferty et al, 2001). It defines the conditional probability proportional to the product of potential functions on cliques of the graph,

$$P_\lambda(Y \mid X) = \frac{\exp \lambda \cdot F(Y,X)}{Z(X)} \quad (1)$$

where X is a set of input random variables and Y is a set of random labels. $F(Y,X)$ is an arbitrary feature function over its arguments, λ is a learned weight for each feature function and $Z(X) = \sum_y \exp(\lambda \cdot F(Y,X))$.

The training of CRFs is based on Maximum Likelihood Principle (Fei Sha et al. 2003). The log likelihood function is

$$L(\lambda) = \sum_k \left[\lambda \cdot F(Y_k, X_k) - \log Z_\lambda(X_k)\right]$$

Therefore, Limited-memory BFGS (L-BFGS) algorithm is used to find this nonlinear optimization parameters.

3 Label Redundancy in Sentiment Classification

In this section, we explain the "label redundancy" in sentiment classification mentioned in the first section. We will analyze the effect of the label redundancy on the performance of sentiment classification from the experimental view.

We conduct the experiments of polarity classification and sentimental strength rating on the corpus which will be introduced in section 5 later. The class set is also illustrated in that section. Polarity classification is a three-class classification process, and sentimental strength rating is a five-class classification process. We use first 200 reviews as the training set which contains 6,079 sentences, and other 49 reviews, totally 1,531 sentences, are used as the testing set. Both the three-class classification and the five-class classification use standard CRFs model with the same feature set. The results are shown in Table 1, 2 and 3, where "Answer" denotes the results given by human, "Results" denotes the results given by CRFs model，"Correct" denotes the number of correct samples which is labeled by CRFs model. We use precision, recall and F1 value as the evaluation metrics.

Table 1 gives the result of sentimental strength rating. Table 2 shows the polarity classification results extracted from the results of sentimental strength rating in Table 1. The extraction process is as follows. In the sentimental strength rating results, we combine the sentences with "PP" class and the sentences with "P" class into "Pos" class, and the sentences with "NN" class and the sentences with "N" class into "Neg" class. So the results of five-class classification are transformed into the results of three-class classification. Table 3 is the results of performing polarity classification in the data set by CRFs directly.

Label	Answer	Results	Correct	Precision	Recall	F1
PP	51	67	5	0.0746	0.0980	0.0847
P	166	177	32	0.1808	0.1928	0.1866
Neu	1190	1118	968	0.8658	0.81.34	0.8388
N	105	140	25	0.1786	0.2381	0.2041
NN	19	29	1	0.0345	0.0526	0.0417
Total	1531	1531	1031	0.67.34	0.6734	0.6734

Table 1. Result of Sentimental Strength Rating

Label	Answer	Results	Correct	Precision	Recall	F1
Pos	217	244	79	0.3238	0.3641	0.3427
Neu	1190	1118	968	0.8658	0.8134	0.8388
Neg	124	169	41	0.2426	0.3306	0.2799
Total	1531	1531	1088	0.7106	0.7106	0.7106

Table 2. Result of Polarity Classification Extracted from Table 1.

Label	Answer	Results	Correct	Precision	Recall	F1
Pos	217	300	108	0.3600	0.4977	0.4178
Neu	1190	1101	971	0.8819	0.8160	0.8477
Neg	124	130	40	0.3077	0.3226	0.3150
Total	1531	1531	1119	0.7309	0.7309	0.7309

Table 3. Result of Polarity Classification

From the results we can find the following phenomena.

(1) The corpus is severely unbalanced, the objective sentences take the absolute majority in the corpus, which leads to the poor accuracy for classifying subjective sentences. The experiment in Table 1 puts polarity classification and sentimental strength rating under a unique CRFs model, without considering the redundancy and hierarchical structure between different classes. As a result, the features for polarity classification will usually cover the features for sentimental strength rating. These reasons can explain why there is only one sample labeled as “NN” correctly and only 5 samples labeled as “PP” correctly.

(2) Comparing Table 2 with 3, we can find that, the F1 value of the polarity classification results extracted from sentimental strength rating results is lower than that of directly conducting polarity classification. That is because the redundancy between sentimental strength labels makes the classifier confused to determine the polarity of the sentence. Therefore, we should deal with the sentiment analysis in a hierarchical frame which can consider the redundancy between the different classes and make full use of the subjective and polarity information implicitly contained in sentimental strength classes.

4 Capturing Label Redundancy for CRFs via Adding Redundant Features

As mentioned above, it’s important for a classifier to consider the redundancy between different labels. However, from the standard CRFs described in formula (1), we can see that the training of CRFs only maximizes the probabilities of the observed labels Y in the training corpus. Actually, the redundant relation between sentiment labels is unobserved. The standard CRFs still treats each class as an isolated item so that its performance is not satisfied.

In this section, we propose a novel method for sentiment classification, which can capture the redundant relation between sentiment labels through adding redundant features. In the following, we firstly show how to add these redundant features, then illustrate the characteristics of this method. After that, for the sentiment analysis task, the process of feature generation will be presented.

4.1 Adding Redundant Features for CRFs

Adding redundant features has two steps. Firstly, an implicit redundant label set is designed, which can form a multi-layer hierarchical structure together with the original labels. Secondly, in the hierarchical classification framework, the implicit labels, which reflect the relations between the original labels, can be used as redundant features in the training process. We will use the following example to illustrate the first step for sentimental strength rating task.

For the task of sentimental strength rating, the original label set is {“PP (highly praised)”, “P (something good)”, “Neu (objective description)”, “N (something that needs improvement)” and “NN (strong aversion)”}. In order to introduce redundant labels, the 5-class classification task is decomposed into the following three layers shown in Figure 1. The label set in the first layer is {“subjective”, “objective”}, The label set in the second layer is for polarity classification {“positive”, “objective”, “negative”}, and the label set in the third layer is the original set. Actually, the labels in the first and second layers are unobserved redundant labels, which will not be reflected in the final classification result obviously.

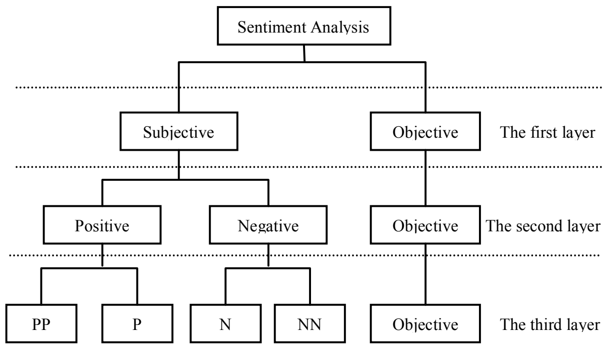

Figure 1. The hierarchical structure of sentimental labels

In the second step, with these redundant labels, some implicit features can be generated for CRFs. So the standard CRFs can be rewritten as follows.

$$P(T \mid X) = \frac{\exp(F(X,T)\cdot\lambda)}{Z_T(X)} = \frac{\exp(\sum_{j=1}^{m} F_j(X,Y_j)\cdot\lambda_j)}{\sum_T \exp(\sum_{j=1}^{m} F_j(X,Y_j)\cdot\lambda_j)} \quad (2)$$

where $T=(Y_1,Y_2,...Y_j...,Y_m)$, and Y_j denotes the label sequence in the j^{th} layer. $F_j(X,Y_j)$ denotes the arbitrary feature function in the j^{th} layer.

From the formula (2), we can see that the original label set is rewritten as $T=(Y_1,Y_2,...Y_j...,Y_m)$, which contains implicit labels in the hierarchical structure shown in Figure 1. The difference between our method and the standard chain CRFs is that we make some implicit redundant features to be active when training. The original feature function $F(Y,X)$ is replaced by $\sum_{j=1}^{m} F_j(X,Y_j)$. We use an example to illustrate the process of feature generation. When a sentence including the word "good" is labeled as "PP", our model not only generate the state feature (good, "PP"), but also two implicit redundant state feature (good, "positive") and (good, "subjective"). Through adding larger-granularity labels "positive" and "negative" into the model, our method can increase the probability of "positive" and decrease the probability of "negative". Furthermore, "P" and "PP" will share the probability gain of "positive", therefore the probability of "P" will be larger than that of "N". For the transition feature, the same strategy is used. Therefore the complexity of its training procedure is $O(M \times N \times \sum_j^m F_j \times l)$ where M is the number of the training samples, N is the average sentence length, F_j is the average number of activated features in the j^{th} layer, l is the number of the original labels and m is the number of the layers. For the complexity of the decoding procedure, our method has $O(N \times \sum_j^m F_j \times l)$.

It's worth noting that, (1) transition features are extracted in each layer separately rather than across different layers. For example, feature (good, "subjective", "positive") will never be extracted because "subjective" and "positive" are from different layers; (2) if one sentence is labeled as "Neu", no implicit redundant features will be generated.

4.2 The Characteristics of Our Method

Our method allows that the label sets are dependent and redundant. As a result, it can improve the performance of not only the classifier for the original sentimental strength rating task, but also the classifiers for other tasks in the hierarchical frame, i.e. polarity classification and subjective/objective classification. This kind of dependency and redundancy can lead to two characteristics of the proposed method for sentiment classification compared with traditional methods, such as the cascaded method.

(1) Error-correction: Two dependent tasks in the neighboring layers can correct the errors of each other relying on the inconsistent redundant information. For example, if in the first layer, the features activated by "objective" get larger scores than the features activated by "subjective", and in the second layer the features activated by "positive" get larger scores than the features activated by "objective", then inconsistency emerges. At this time, our method can globally select the label with maximum probability. This characteristic can make up the deficiency of the cascaded method which may induce error propagation.

(2) Differentiating the ordinal relation among sentiment labels: Our method organizes the ordinal sentiment labels into a hierarchy through introducing redundant labels into standard chain CRFs, in this way the degree of classification errors can be controlled. In the different layers of sentiment analysis task, the granularities of classification are different. Therefore, when an observation cannot be correctly labeled on a smaller-granularity label set, our method will use the larger-granularity labels in the upper layer to control the final classification labels.

4.3 Feature Selection in Different Layers

For feature selection, our method selects different features for each layer in the hierarchical frame.

In the top layer of the frame shown in Figure 1, for subjective/objective classification task, we use not only adjectives and the verbs which contain subjective information (e.g., "believe", "think") as the features, but also the topic words. The topic words are defined as the nouns or noun phases which frequently appear in the corpus. We believe that some topic words contain subjective information.

In the middle and bottom layers, we not only use the features in the first layer, but also some special features as follows.

(1) The prior orientation scores of the sentiment words: Firstly, a sentiment lexicon is generated by extending the synonymies and antonyms in WordNet[2] from a positive and negative seed list. Then, the positive score and the negative score of a sentiment word are individually accumulated and weighted according to the polarity of its synonymies and antonyms. At last we scale the normalized distance of the two scores into 5 levels, which will be the prior orientation of the word. When there is a negative word, like {not, no, can't, merely, never, …}, occurring nearby the feature word in the range of 3 words size window, the orientation of this word will be reversed and "NO" will be added in front of the original feature word for creating a new feature word.

(2) Sentence transition features: We consider two types of sentence transition features. The first type is the conjunctions and the adverbs occurring in the beginning of this sentence. These conjunctions and adverbs are included in a word list which is manually selected, like {and, or, but, though, however, generally, contrarily, …}. The second type of the sentence transition feature is the position of the sentence in one review. The reason lies in that: the reviewers often follow some writing patterns, for example some reviewers prefer to concede an opposite factor before expressing his/her real sentiment. Therefore, we divide a review into five parts, and assign each sentence with the serial number of the part which the sentence belongs to.

5 Experiments

5.1 Data and Baselines

In order to evaluate the performance of our method, we conducted experiments on a sentence level annotation corpus obtained from Purdue University, which is also used in (Mao and Lebanon 07). This corpus contains 249 movie reviews and 7,610 sentences totally, which is randomly selected from the Cornell sentence polarity dataset v1.0. Each sentence was hand-labeled with one of five classes: PP (highly praised), P (something good), Neu (objective description), N (something that needs improvement) and NN (strong aversion), which contained the orientation polarity of each sentence. Based on the 5-class manually labeled results mentioned above, we also assigned each sentence with one of three classes: Pos (positive polarity), Neu (objective description), Neg (negative polarity). Data statistics for the corpus are given in Table 4.

Label	Pos		Neu	Neg		Total
	PP	P	Neu	N	NN	
5 classes	383	860	5508	694	165	7610
3 classes	1243		5508	859		7610

Table 4. Data Statistics for Movies Reviews Corpus

There is a problem in the dataset that more than 70% of the sentences are labeled as "Neu" and labels are seriously unbalanced. As a result, the "Neu" label is over-emphasized. For this problem, Mao and Lebanon (2007) made a balanced data set (equal number sentences for different labels) which is sampled in the original corpus. Since randomly sampling sentences from the original corpus will break the intrinsic relationship between two adjacent sentences in the context, we don't create balanced label data set.

For the evaluation of our method, we choose accuracy as the evaluation metrics and some classical methods as the baselines. They are Naïve Bayes (NB), Support Vector Machine (SVM), Maximum Entropy (MaxEnt) (Kamal Nigam et al. 1999) and standard chain CRFs (Fei et al. 2003). We also regard cascaded-CRFs as our baseline for comparing our method with the cascaded-based method. For NB, we use Laplace smoothing method. For SVM, we use the LibSVM[3] with a linear kernel function[4]. For MaxEnt, we use the implementation in the toolkit *Mallet*[5]. For CRFs,

Table 7. The accuracy of Subjective/Objective Classification

we use the implementation in Flex-CRFs[6]. We set the iteration number to 120 in the training process of the method based on CRFs. In the cascaded model we set 3 layers for sentimental strength rating, where the first layer is subjective/objective classification, the second layer is polarity classification and the last layer is sentimental strength classification. The upper layer passes the results as the input to the next layer.

5.2 Sentimental Strength Rating

In the first experiment, we evaluate the performance of our method for sentimental strength rating. Experimental results for each method are given in Table 5. We not only give the overall accuracy of each method, but also the performance for each sentimental strength label. All baselines use the same feature space mentioned in section 4.3, which combine all the features in the three layers together, except cascaded CRFs and our method. In cascaded-CRFs and our method, we use different features in different layers mentioned in section 4.3. These results were gathered using 5-fold cross validation with one fold for testing and the other 4 folds for training.

From the results, we can obtain the following conclusions. (1) The three versions of CRFs perform consistently better than Naïve Bayes, SVM and MaxEnt methods. We think that is because CRFs model considers the contextual influence of each sentence. (2) Comparing the performance of cascaded CRFs with that of standard sequence CRFs, we can see that not only the overall accuracy but also the accuracy for each sentimental strength label are improved, where the overall accuracy is increased by 3%. It proves that taking the hierarchical relationship between labels into account is very essential for sentiment classification. The reason is that: the cascaded model performs sentimental strength rating in three hierarchical layers, while standard chain CRFs model treats each label as an independent individual. So the performance of the cascaded model is superior to the standard chain CRFs. (3) The experimental results also show that our method performs better than the Cascaded CRFs. The classification accuracy is improved from 71.53% to 75.21%. We think that is because our method adds the label redundancy among the sentimental strength labels into consideration through adding redundant features into the feature sets, and the three subtasks in the cascaded model are merged into a unified model. So the output result is a global optimal result. In this way, the problem of error propagation in the cascaded frame can be alleviated.

[6] http://flexcrfs.sourceforge.net

5.3 Sentiment Polarity Classification

In the second experiment, we evaluate the performance of our method for sentiment polarity classification. Our method is based on a hierarchical frame, which can perform different tasks in different layers at the same time. For example, it can determine the polarity of sentences when sentimental strength rating is performed. Here, the polarity classification results of our method are extracted from the results of the sentimental strength rating mentioned above. In the sentimental strength rating results, we combine the sentences with PP label and the sentences with P label into one set, and the sentences with NN label and the sentences with N label into one set. So the results of 5-class classification are transformed into the results of 3-class classification. Other methods like NB, SVM, MaxEnt, standard chain CRFs perform 3-class classification directly, and their label sets in the training corpus is {Pos, Neu, Neg}. The parameter setting is the same as sentimental strength rating. For the cascaded-CRFs method, we firstly perform subjective/objective classification, and then determine the polarity of the sentences based on the subjective sentences. The experimental results are given in Table 6.

From the experimental results, we can obtain the following conclusion for sentiment polarity classification, which is similar to the conclusion for sentimental strength rating mentioned in section 5.2. That is both our model and the cascaded model can get better performance than other traditional methods, such as NB, SVM, MaxEnt, etc. But the performance of the cascaded CRFs (76.94%) is lower than that of our method (78.55%). This indicates that because our method exploits the label redundancy in the different layers, it can increase the accuracies of both polarity classification and sentimental strength rating at the same time compared with other methods.

5.4 Subjective/Objective Classification

In the last experiment, we test our method for subjective/objective classification. The subjective/objective label of the data is extracted from its original label like section 5.3. As the same as the experiment for polarity classification, all baselines perform subjective/objective classification directly. It's no need to perform the cascaded-based method because it's a 2-class task. The results of our method are extracted from the results of the sentimental strength rating too. The results are shown in Table 7. From it, we can obtain the similar conclusion, i.e. our method outperforms other methods and has the 80.18% classification accuracy. Our method, which introduces redundant features into training, can increase the accuracies of all tasks in the different layers at the same time compared with other baselines. It proves that considering label redundancy are effective for promoting the performance of a sentimental classifier.

6 Related Works

Recently, many researchers have devoted into the problem of the sentiment classification. Most of researchers focus on how to extract useful textual features (lexical, syntactic, punctuation, etc.) for determining the semantic orientation of the sentences using machine learning algorithm (Bo et al. 2002; Kim and Hovy, 2004; Bo et al. 2005, Hu et al. 2004; Alina et al 2008; Alistair et al 2006). But fewer researchers deal with this problem using CRFs model.

For identifying the subjective sentences, there are several research, like (Wiebe et al, 2005). For polarity classification on sentence level, (Kim and Hovy, 2004) judged the sentiment by classifying a pseudo document composed of synonyms of indicators in one sentence. (Pang and Lee, 04) proposed a semi-supervised machine learning method based on subjectivity detection and minimum-cut in graph.

Cascaded models for sentiment classification were studied by (Pang and Lee, 2005). Their work mainly used the cascaded frame for determining the orientation of a document and the sentences. In that work, an initial model is used to determine the orientation of each sentence firstly, then the top subjective sentences are input into a document - level model to determine the document's orientation.

The CRFs has previously been used for sentiment classification. Those methods based on CRFs are related to our work. (Mao et al, 2007) used a sequential CRFs regression model to measure the polarity of a sentence in order to determine the sentiment flow of the authors in reviews. However, this method must manually select a word set for constraints, where each selected word achieved the highest correlation with the sentiment. The performance of isotonic CRFs is strongly related to the selected word set. (McDonald et al 2007; Ivan et al 2008) proposed a structured model based on CRFs for jointly classifying the sentiment of text at varying levels of granularity. They put the sentence level and document level sentiment analysis in an integrated model and employ the orientation of the document to influence the decision of sentence's orientation. Both the above two methods didn't consider the redundant and hierarchical relation between sentimental strength labels. So their methods cannot get better results for the problem mentioned in this paper.

Another solution to this problem is to use a joint multi-layer model, such as dynamic CRFs, multi-layer CRFs, etc. Such kind of models can treat the three sub-tasks in sentiment classification as a multi-task problem and can use a multi-layer or hierarchical undirected graphic to model the sentiment of sentences. The main difference between our method and theirs is that we consider the problem from the feature representation view. Our method expands the feature set according to the number of layers in the hierarchical frame. So the complexity of its decoding procedure is lower than theirs, for example the complexity of the multi-layer CRFs is $O(N \times F \times \prod_j l_j)$ when decoding and our method only has $O(N \times \sum_j F_j \times l)$, where N is the average sentence length, F_j is the average number of activated features in the j^{th} layer, l is the number of the original labels.

7 Conclusion and Future Work

In the paper, we propose a novel method for sentiment classification based on CRFs in response to the two special characteristics of "contextual dependency" and "label redundancy" in sentence sentiment classification. We try to capture the contextual constraints on the sentence sentiment using CRFs. For capturing the label redundancy among sentiment classes, we generate a hierarchical framework through introducing redundant labels, under which redundant features can be introduced. The experimental results prove that our method outperforms the traditional methods (like NB, SVM, ME and standard chain CRFs). In comparison with cascaded CRFs, our method can effectively alleviate error propagation among different layers and obtain better performance in each layer.

For our future work, we will explore other hierarchical models for sentimental strength rating because the experiments presented in this paper prove this hierarchical frame is effective for ordinal regression. We would expand the idea in this paper into other models, such as Semi-CRFs and Hierarchical-CRFs.

Abstract

Although research in other languages is increasing, much of the work in subjectivity analysis has been applied to English data, mainly due to the large body of electronic resources and tools that are available for this language. In this paper, we propose and evaluate methods that can be employed to transfer a repository of subjectivity resources across languages. Specifically, we attempt to leverage on the resources available for English and, by employing machine translation, generate resources for subjectivity analysis in other languages. Through comparative evaluations on two different languages (Romanian and Spanish), we show that automatic translation is a viable alternative for the construction of resources and tools for subjectivity analysis in a new target language.

1 Introduction

We have seen a surge in interest towards the application of automatic tools and techniques for the extraction of opinions, emotions, and sentiments in text (*subjectivity*). A large number of text processing applications have already employed techniques for automatic subjectivity analysis, including automatic expressive text-to-speech synthesis (Alm et al., 2005), text semantic analysis (Wiebe and Mihalcea, 2006; Esuli and Sebastiani, 2006), tracking sentiment timelines in on-line forums and news (Lloyd et al., 2005; Balog et al., 2006), mining opinions from product reviews (Hu and Liu, 2004), and question answering (Yu and Hatzivassiloglou, 2003).

A significant fraction of the research work to date in subjectivity analysis has been applied to English, which led to several resources and tools available for this language. In this paper, we explore multiple paths that employ machine translation while leveraging on the resources and tools available for English, to automatically generate resources for subjectivity analysis for a new target language. Through experiments carried out with automatic translation and cross-lingual projections of subjectivity annotations, we try to answer the following questions.

First, assuming an English corpus manually annotated for subjectivity, can we use machine translation to generate a subjectivity-annotated corpus in the target language? Second, assuming the availability of a tool for automatic subjectivity analysis in English, can we generate a corpus annotated for subjectivity in the target language by using automatic subjectivity annotations of English text and machine translation? Finally, third, can these automatically generated resources be used to effectively train tools for subjectivity analysis in the target language?

Since our methods are particularly useful for languages with only a few electronic tools and resources, we chose to conduct our initial experiments on Romanian, a language with limited text processing resources developed to date. Furthermore, to validate our results, we carried a second set of experiments on Spanish. Note however that our methods do not make use of any target language specific knowledge, and thus they are applicable to any other language as long as a machine translation engine exists between the selected language and English.

2 Related Work

Research in sentiment and subjectivity analysis has received increasingly growing interest from the natural language processing community, particularly motivated by the widespread need for opinion-based applications, including product and movie reviews, entity tracking and analysis, opinion summarization, and others.

Much of the work in subjectivity analysis has been applied to English data, though work on other languages is growing: e.g., Japanese data are used in (Kobayashi et al., 2004; Suzuki et al., 2006; Takamura et al., 2006; Kanayama and Nasukawa, 2006), Chinese data are used in (Hu et al., 2005), and German data are used in (Kim and Hovy, 2006). In addition, several participants in the Chinese and Japanese Opinion Extraction tasks of NTCIR-6 (Kando and Evans, 2007) performed subjectivity and sentiment analysis in languages other than English.

In general, efforts on building subjectivity analysis tools for other languages have been hampered by the high cost involved in creating corpora and lexical resources for a new language. To address this gap, we focus on leveraging resources already developed for one language to derive subjectivity analysis tools for a new language. This motivates the direction of our research, in which we use machine translation coupled with cross-lingual annotation projections to generate the resources and tools required to perform subjectivity classification in the target language.

The work closest to ours is the one reported in (Mihalcea et al., 2007), where a bilingual lexicon and a manually translated parallel text are used to generate the resources required to build a subjectivity classifier in a new language. In that work, we found that the projection of annotations across parallel texts can be successfully used to build a corpus annotated for subjectivity in the target language. However, parallel texts are not always available for a given language pair. Therefore, in this paper we explore a different approach where, instead of relying on manually translated parallel corpora, we use machine translation to produce a corpus in the new language.

3 Machine Translation for Subjectivity Analysis

We explore the possibility of using machine translation to generate the resources required to build subjectivity annotation tools in a given target language. We focus on two main scenarios. First, assuming a corpus manually annotated for subjectivity exists in the source language, we can use machine translation to create a corpus annotated for subjectivity in the target language. Second, assuming a tool for automatic subjectivity analysis exists in the source language, we can use this tool together with machine translation to create a corpus annotated for subjectivity in the target language.

In order to perform a comprehensive investigation, we propose three experiments as described below. The first scenario, based on a corpus manually annotated for subjectivity, is exemplified by the first experiment. The second scenario, based on a corpus automatically annotated with a tool for subjectivity analysis, is subsequently divided into two experiments depending on the direction of the translation and on the dataset that is translated.

In all three experiments, we use English as a source language, given that it has both a corpus manually annotated for subjectivity (MPQA (Wiebe et al., 2005)) and a tool for subjectivity analysis (OpinionFinder (Wiebe and Riloff, 2005)).

3.1 Experiment One: Machine Translation of Manually Annotated Corpora

In this experiment, we use a corpus in the source language manually annotated for subjectivity. The corpus is automatically translated into the target language, followed by a projection of the subjectivity labels from the source to the target language. The experiment is illustrated in Figure 1.

We use the MPQA corpus (Wiebe et al., 2005), which is a collection of 535 English-language news articles from a variety of news sources manually annotated for subjectivity. Although the corpus was originally annotated at clause and phrase level, we use the sentence-level annotations associated with the dataset (Wiebe and Riloff, 2005). From the total of 9,700 sentences in this corpus, 55% of the sentences are labeled as subjective while the rest are objective. After the automatic translation of the cor-

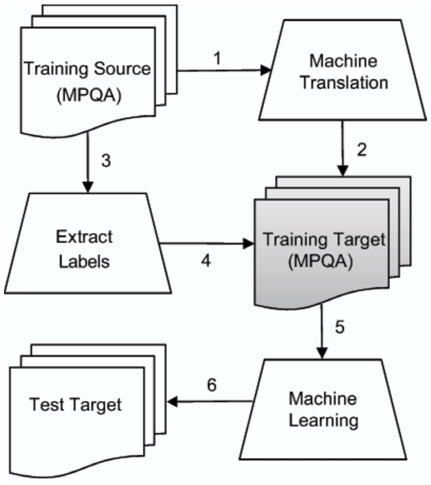

Figure 1: Experiment one: machine translation of manually annotated training data from source language into target language

pus and the projection of the annotations, we obtain a large corpus of 9,700 subjectivity-annotated sentences in the target language, which can be used to train a subjectivity classifier.

3.2 Experiment Two: Machine Translation of Source Language Training Data

In the second experiment, we assume that the only resources available are a tool for subjectivity annotation in the source language and a collection of raw texts, also in the source language. The source language text is automatically annotated for subjectivity and then translated into the target language. In this way, we produce a subjectivity annotated corpus that we can use to train a subjectivity annotation tool for the target language. Figure 2 illustrates this experiment.

In order to generate automatic subjectivity annotations, we use the OpinionFinder tool developed by (Wiebe and Riloff, 2005). OpinionFinder includes two classifiers. The first one is a rule-based high-precision classifier that labels sentences based on the presence of subjective clues obtained from a large lexicon. The second one is a high-coverage classifier that starts with an initial corpus annotated using the high-precision classifier, followed by several bootstrapping steps that increase the size of the lexicon and the coverage of the classifier. For most of our experiments we use the high-coverage classifier.

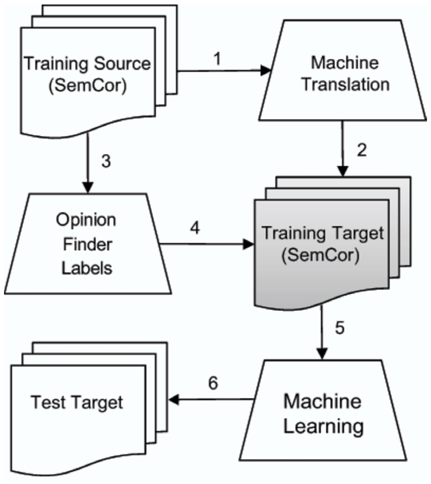

Figure 2: Experiment two: machine translation of raw training data from source language into target language

Table 1 shows the performance of the two OpinionFinder classifiers as measured on the MPQA corpus (Wiebe and Riloff, 2005).

	P	R	F
high-precision	86.7	32.6	47.4
high-coverage	79.4	70.6	74.7

Table 1: Precision (P), Recall (R) and F-measure (F) for the two OpinionFinder classifiers, as measured on the MPQA corpus

As a raw corpus, we use a subset of the SemCor corpus (Miller et al., 1993), consisting of 107 documents with roughly 11,000 sentences. This is a balanced corpus covering a number of topics in sports, politics, fashion, education, and others. The reason for working with this collection is the fact that we also have a manual translation of the SemCor documents from English into one of the target languages used in the experiments (Romanian), which enables comparative evaluations of different scenarios (see Section 4).

Note that in this experiment the annotation of subjectivity is carried out on the original source language text, and thus expected to be more accurate than if it were applied on automatically translated text. However, the training data in the target language is produced by automatic translation, and thus likely to contain errors.

3.3 Experiment Three: Machine Translation of Target Language Training Data

The third experiment is similar to the second one, except that we reverse the direction of the translation. We translate raw text that is available in the target language into the source language, and then use a subjectivity annotation tool to label the automatically translated source language text. After the annotation, the labels are projected back into the target language, and the resulting annotated corpus is used to train a subjectivity classifier. Figure 3 illustrates this experiment.

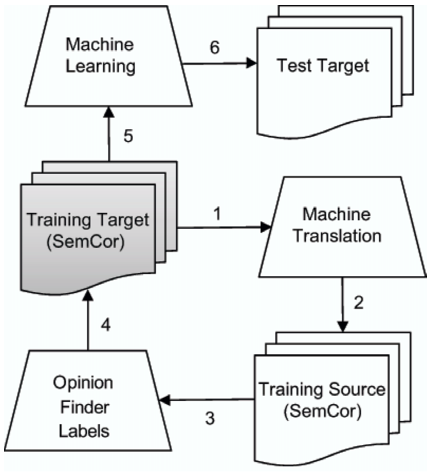

Figure 3: Experiment three: machine translation of raw training data from target language into source language

As before, we use the high-coverage classifier available in OpinionFinder, and the SemCor corpus. We use a manual translation of this corpus available in the target language.

In this experiment, the subjectivity annotations are carried out on automatically generated source text, and thus expected to be less accurate. However, since the training data was originally written in the target language, it is free of translation errors, and thus training carried out on this data should be more robust.

3.4 Upper bound: Machine Translation of Target Language Test Data

For comparison purposes, we also propose an experiment which plays the role of an upper bound on the methods described so far. This experiment involves the automatic translation of the test data from the target language into the source language. The source language text is then annotated for subjectivity using OpinionFinder, followed by a projection of the resulting labels back into the target language.

Unlike the previous three experiments, in this experiment we only generate subjectivity-annotated *resources*, and we do not build and evaluate a standalone subjectivity analysis *tool* for the target language. Further training of a machine learning algorithm, as in experiments two and three, is required in order to build a subjectivity analysis tool. Thus, this fourth experiment is an evaluation of the *resources* generated in the target language, which represents an upper bound on the performance of any machine learning algorithm that would be trained on these resources. Figure 4 illustrates this experiment.

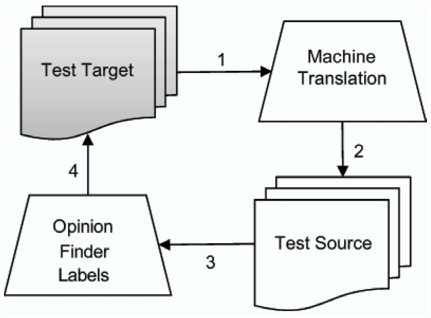

Figure 4: Upper bound: machine translation of test data from target language into source language

4 Evaluation and Results

Our initial evaluations are carried out on Romanian. The performance of each of the three methods is evaluated using a dataset manually annotated for subjectivity. To evaluate our methods, we generate a Romanian training corpus annotated for subjectivity on which we train a subjectivity classifier, which is then used to label the test data.

We evaluate the results against a gold-standard corpus consisting of 504 Romanian sentences manually annotated for subjectivity. These sentences represent the manual translation into Romanian of a small subset of the SemCor corpus, which was removed from the training corpora used in experiments two and three. This is the same evaluation dataset as used in (Mihalcea et al., 2007). Two Romanian native speakers annotated the sentences individually, and the differences were adjudicated through discussions. The agreement of the two annotators is 0.83% (κ = 0.67); when the uncertain annotations are removed, the agreement rises to 0.89 (κ = 0.77). The two annotators reached consensus on all sentences for which they disagreed, resulting in a gold standard dataset with 272 (54%) subjective sentences and 232 (46%) objective sentences. More details about this dataset are available in (Mihalcea et al., 2007).

In order to learn from our annotated data, we experiment with two different classifiers, Naïve Bayes and support vector machines (SVM), selected for their performance and diversity of learning methodology. For Naïve Bayes, we use the multinomial model (McCallum and Nigam, 1998) with a threshold of 0.3. For SVM (Joachims, 1998), we use the LibSVM implementation (Fan et al., 2005) with a linear kernel.

The automatic translation of the MPQA and of the SemCor corpus was performed using Language Weaver,[1] a commercial statistical machine translation software. The resulting text was post-processed by removing diacritics, stopwords and numbers. For training, we experimented with a series of weighting schemes, yet we only report the results obtained for binary weighting, as it had the most consistent behavior.

The results obtained by running the three experiments on Romanian are shown in Table 2. The baseline on this data set is 54.16%, represented by the percentage of sentences in the corpus that are subjective, and the upper bound (UB) is 71.83%, which is the accuracy obtained under the scenario where the test data is translated into the source language and then annotated using the high-coverage OpinionFinder tool.

Perhaps not surprisingly, the SVM classifier outperforms Naïve Bayes by 2% to 6%, implying that SVM may be better fitted to lessen the amount of noise embedded in the dataset and provide more accurate classifications.

The first experiment, involving the automatic translation of the MPQA corpus enhanced with manual annotations for subjectivity at sentence level, does not seem to perform well when compared to the experiments in which automatic subjectivity classification is used. This could imply that a classifier cannot be so easily trained on the cues that humans use to express subjectivity, especially when they are not overtly expressed in the sentence and thus can be lost in the translation. Instead, the automatic annotations produced with a rule-based tool (OpinionFinder), relying on overt mentions of words in a subjectivity lexicon, seems to be more robust to translation, further resulting in better classification results. To exemplify, consider the following subjective sentence from the MPQA corpus, which does not include overt clues of subjectivity, but was annotated as subjective by the human judges because of the structure of the sentence: *It is the Palestinians that are calling for the implementation of the agreements, understandings, and recommendations pertaining to the Palestinian-Israeli conflict.*

Romanian				
Exp	Classifier	P	R	F
E1	Naïve Bayes	60.91	60.91	60.91

E2	Naïve Bayes	63.69	63.69	63.69
	SVM	69.44	69.44	69.44
E3	Naïve Bayes	65.87	65.87	65.87
	SVM	67.86	67.86	67.86
UB	OpinionFinder	71.83	71.83	71.83

Table 2: Precision (P), Recall (R) and F-measure (F) for Romanian experiments

We compare our results with those obtained by a previously proposed method that was based on the manual translation of the SemCor subjectivity-annotated corpus. In (Mihalcea et al., 2007), we used the manual translation of the SemCor corpus into Romanian to form an English-Romanian parallel data set. The English side was annotated using the Opinion Finder tool, and the subjectivity labels were projected on the Romanian text. A Naïve Bayes classifier was then trained on the subjectivity annotated Romanian corpus and tested on the same gold standard as used in our experiments. Table 3 shows the results obtained in those experiments by using the high-coverage OpinionFinder classifier.

Among our experiments, experiments two and three are closest to those proposed in (Mihalcea et al., 2007). By using machine translation, from

[1] http://www.languageweaver.com/

OpinionFinder classifier	P	R	F
high-coverage	67.85	67.85	67.85

Table 3: Precision (P), Recall (R) and F-measure (F) for subjectivity analysis in Romanian obtained by using an English-Romanian parallel corpus

English into Romanian (experiment two) or Romanian into English (experiment three), and annotating this dataset with the high-coverage OpinionFinder classifier, we obtain an F-measure of 63.69%, and 65.87% respectively, using Naïve Bayes (the same machine learning classifier as used in (Mihalcea et al., 2007)). This implies that at most 4% in F-measure can be gained by using a parallel corpus as compared to an automatically translated corpus, further suggesting that machine translation is a viable alternative to devising subjectivity classification in a target language leveraged on the tools existent in a source language.

As English is a language with fewer inflections when compared to Romanian, which accommodates for gender and case as a suffix to the base form of a word, the automatic translation into English is closer to a human translation (experiment three). Therefore labeling this data using the OpinionFinder tool and projecting the labels onto a fully inflected human-generated Romanian text provides more accurate classification results, as compared to a setup where the training is carried out on machine-translated Romanian text (experiment two).

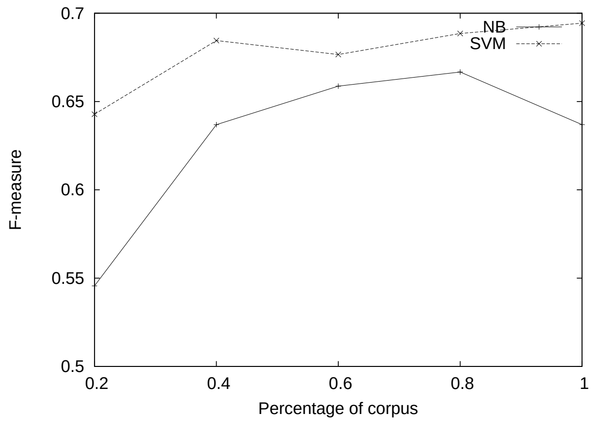

Figure 5: Experiment two: Machine learning F-measure over an incrementally larger training set

We also wanted to explore the impact that the corpus size may have on the accuracy of the classifiers. We re-ran experiments two and three with 20% corpus size increments at a time (Figures 5 and 6). It is interesting to note that a corpus of approximately 6000 sentences is able to achieve a high enough F-measure (around 66% for both experiments) to be considered viable for training a subjectivity classifier. Also, at a corpus size over 10,000 sentences, the Naïve Bayes classifier performs worse than SVM, which displays a directly proportional trend between the number of sentences in the data set and the observed F-measure. This trend could be explained by the fact that the SVM classifier is more robust with regard to noisy data, when compared to Naïve Bayes.

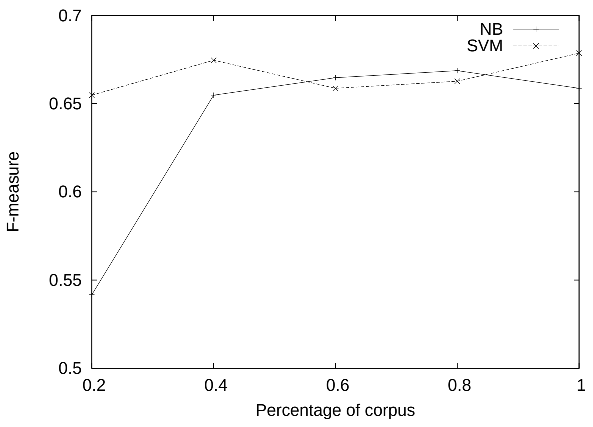

Figure 6: Experiment three: Machine learning F-measure over an incrementally larger training set

5 Portability to Other Languages

To test the validity of the results on other languages, we ran a portability experiment on Spanish.

To build a test dataset, a native speaker of Spanish translated the gold standard of 504 sentences into Spanish. We maintain the same subjectivity annotations as for the Romanian dataset. To create the training data required by the first two experiments, we translate both the MPQA corpus and the SemCor corpus into Spanish using the Google Translation service,[2] a publicly available machine translation engine also based on statistical machine translation. We were therefore able to implement all the experiments but the third, which would have required

[2]http://www.google.com/translate_t

a manually translated version of the SemCor corpus. Although we could have used a Spanish text to carry out a similar experiment, due to the fact that the dataset would have been different, the results would not have been directly comparable.

The results of the two experiments exploring the portability to Spanish are shown in Table 4. Interestingly, all the figures are higher than those obtained for Romanian. We assume this occurs because Spanish is one of the six official United Nations languages, and the Google translation engine is using the United Nations parallel corpus to train their translation engine, therefore implying that a better quality translation is achieved as compared to the one available for Romanian. We can therefore conclude that the more accurate the translation engine, the more accurately the subjective content is translated, and therefore the better the results. As it was the case for Romanian, the SVM classifier produces the best results, with absolute improvements over the Naïve Bayes classifier ranging from 0.2% to 3.5%.

Since the Spanish automatic translation seems to be closer to a human-quality translation, we are not surprised that this time the first experiment is able to generate a more accurate training corpus as compared to the second experiment. The MPQA corpus, since it is manually annotated and of better quality, has a higher chance of generating a more reliable data set in the target language. As in the experiments on Romanian, when performing automatic translation of the test data, we obtain the best results with an F-measure of 73.41%, which is also the upper bound on our proposed experiments.

Spanish

6 Discussion

Based on our experiments, we can conclude that machine translation offers a viable approach to generating resources for subjectivity annotation in a given target language. The results suggest that either a manually annotated dataset or an automatically annotated one can provide sufficient leverage towards building a tool for subjectivity analysis.

Since the use of parallel corpora (Mihalcea et al., 2007) requires a large amount of manual labor, one of the reasons behind our experiments was to asses the ability of machine translation to transfer subjective content into a target language with minimal effort. As demonstrated by our experiments, machine translation offers a viable alternative in the construction of resources and tools for subjectivity classification in a new target language, with only a small decrease in performance as compared to the case when a parallel corpus is available and used.

To gain further insights, two additional experiments were performed. First, we tried to isolate the role played by the quality of the subjectivity annotations in the source-language for the cross-lingual projections of subjectivity. To this end, we used the high-precision OpinionFinder classifier to annotate the English datasets. As shown in Table 1, this classifier has higher precision but lower recall as compared to the high-coverage classifier we used in our previous experiments. We re-ran the second experiment, this time trained on the 3,700 sentences that were classified by the OpinionFinder high-precision classifier as either subjective or objective. For Romanian, we obtained an F-measure of 69.05%, while for Spanish we obtained an F-measure of 66.47%.

Second, we tried to isolate the role played by language-specific clues of subjectivity. To this end, we decided to set up an experiment which, by comparison, can suggest the degree to which the languages are able to accommodate specific markers for subjectivity. First, we trained an English classifier using the SemCor training data automatically annotated for subjectivity with the OpinionFinder high-coverage tool. The classifier was then applied to the English version of the manually labeled test data set (the gold standard described in Section 4). Next, we ran a similar experiment on Romanian, using a classifier trained on the Romanian version of the same

SemCor training data set, annotated with subjectivity labels projected from English. The classifier was tested on the same gold standard data set. Thus, the two classifiers used the same training data, the same test data, and the same subjectivity annotations, the only difference being the language used (English or Romanian).

The results for these experiments are compiled in Table 5. Interestingly, the experiment conducted on Romanian shows an improvement of 3.5% to 9.5% over the results obtained on English, which indicates that subjective content may be easier to learn in Romanian versus English. The fact that Romanian verbs are inflected for mood (such as indicative, conditional, subjunctive, presumptive), enables an automatic classifier to identify additional subjective markers in text. Some moods such as conditional and presumptive entail human judgment, and therefore allow for clear subjectivity annotation. Moreover, Romanian is a highly inflected language, accommodating for forms of various words based on number, gender, case, and offering an explicit lexicalization of formality and politeness. All these features may have a cumulative effect in allowing for better classification. At the same time, English entails minimal inflection when compared to other Indo-European languages, as it lacks both gender and adjective agreement (with very few notable exceptions such as *beautiful girl* and *handsome boy*). Verb moods are composed with the aid of modals, while tenses and expressions are built with the aid of auxiliary verbs. For this reason, a machine learning algorithm may not be able to identify the same amount of information on subjective content in an English versus a Romanian text. It is also interesting to note that the labeling of the training set was performed using a subjectivity classifier developed for English, which takes into account a large, human-annotated, subjectivity lexicon also developed for English. One would have presumed that any classifier trained on this annotated text would therefore provide the best results in English. Yet, as explained earlier, this was not the case.

Exp	Classifier	P	R	F
En	Naïve Bayes	60.32	60.32	60.32
	SVM	60.32	60.32	60.32

7 Conclusion

In this paper, we explored the use of machine translation for creating resources and tools for subjectivity analysis in other languages, by leveraging on the resources available in English. We introduced and evaluated three different approaches to generate subjectivity annotated corpora in a given target language, and exemplified the technique on Romanian and Spanish.

The experiments show promising results, as they are comparable to those obtained using manually translated corpora. While the quality of the translation is a factor, machine translation offers an efficient and effective alternative in capturing the subjective semantics of a text, coming within 4% F-measure as compared to the results obtained using human translated corpora.

In the future, we plan to explore additional language-specific clues, and integrate them into the subjectivity classifiers. As shown by some of our experiments, Romanian seems to entail more subjectivity markers compared to English, and this factor motivates us to further pursue the use of language-specific clues of subjectivity.

Our experiments have generated corpora of about 20,000 sentences annotated for subjectivity in Romanian and Spanish, which are available for download at http://lit.csci.unt.edu/index.php/Downloads, along with the manually annotated data sets.

Ranking Reader Emotions Using Pairwise Loss Minimization and Emotional Distribution Regression

Abstract

This paper presents two approaches to ranking reader emotions of documents. Past studies assign a document to a single emotion category, so their methods cannot be applied directly to the emotion ranking problem. Furthermore, whereas previous research analyzes emotions from the writer's perspective, this work examines readers' emotional states. The first approach proposed in this paper minimizes pairwise ranking errors. In the second approach, regression is used to model emotional distributions. Experiment results show that the regression method is more effective at identifying the most popular emotion, but the pairwise loss minimization method produces ranked lists of emotions that have better correlations with the correct lists.

1 Introduction

Emotion analysis is an increasingly popular research topic due to the emergence of large-scale emotion data on the web. Previous work primarily studies emotional contents of texts from the writer's perspective, where it is typically assumed that a writer expresses only a single emotion in a document. Unfortunately, this premise does not hold when analyzing a document from the reader's perspective, because readers rarely agree unanimously on the emotion that a document instills. Figure 1 illustrates this phenomenon. In the figure, readers' responses are distributed among different emotion categories. In fact, none of the emotions in Figure 1 has a majority (i.e., more than 50%) of the votes. Intuitively, it is better to provide a ranking of emotions according to their popularity rather than associating a single reader emotion with a document. As a result, current writer-emotion analysis techniques for classifying a document into a single emotion category are not suitable for analyzing reader emotions. New methods capable of ranking emotions are required.

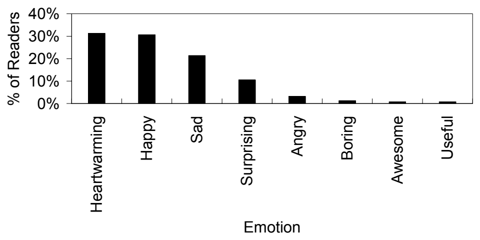

Figure 1. Emotional responses of 626 people after reading a Yahoo! News article about an Iranian refugee mother and her two children who finally reunited with their family in the March of 2007 after been stranded in a Moscow airport for 10 months due to false passports.

Reader-emotion analysis has potential applications that differ from those of writer-emotion analysis. For example, by integrating emotion ranking into information retrieval, users will be able to retrieve documents that contain relevant contents and at the same time produce desired feelings. In addition, reader-emotion analysis can assist writers in foreseeing how their work will influence readers emotionally.

Proceedings of the 2008 Conference on Empirical Methods in Natural Language Processing, pages 136–144,
Honolulu, October 2008. ©2008 Association for Computational Linguistics

In this paper, we present two approaches to ranking reader emotions. The first approach is inspired by the success of the pairwise loss minimization framework used in information retrieval to rank documents. Along a similar line, we devise a novel scheme to minimize the number of incorrectly-ordered emotion pairs in a document. In the second approach, regression is used to model reader-emotion distributions directly. Experiment results show that the regression method is more effective at identifying the most popular emotion, but the pairwise loss minimization method produces ordered lists of emotions that have better correlations with the correct lists.

The rest of this paper is organized as follows. Section 2 describes related work. In Section 3, details about the two proposed approaches are provided. Section 4 introduces the corpus and Section 5 presents how features are extracted from the corpus. Section 6 shows the experiment procedures and results. Section 7 concludes the paper.

2 Related Work

Only a few studies in the past deal with the reader aspect of emotion analysis. For example, Lin et al. (2007; 2008) classify documents into reader-emotion categories. Most previous work focuses on the writer's perspective. Pang et al. (2002) design an algorithm to determine whether a document's author expresses a positive or negative sentiment. They discover that using Support Vector Machines (SVM) with word unigram features results in the best performance. Since then, more work has been done to find features better than unigrams. In (Hu et al., 2005), word sentiment information is exploited to achieve better classification accuracy.

Experiments have been done to extract emotional information from texts at granularities finer than documents. Wiebe (2000) investigates the subjectivity of words, whereas Aman and Szpakowicz (2007) manually label phrases with emotional categories. In 2007, the SemEval-2007 workshop organized a task on the unsupervised annotation of news headlines with emotions (Strapparava and Mihalcea, 2007).

As for the task of ranking, many machine-learning algorithms have been proposed in information retrieval. These techniques generate ranking functions which predict the relevance of a document. One class of algorithms minimizes the errors resulting from ordering document pairs incorrectly. Examples include (Joachims, 2002), (Freund et al., 2003) and (Qin et al., 2007). In particular, the training phase of the Joachims' Ranking SVM (Joachims, 2002) is formulated as the following SVM optimization problem:

$$\min_{\boldsymbol{w}, \xi_{i,j,k}} \tfrac{1}{2}\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w} + C\sum \xi_{i,j,k}$$

subject to:

$$\begin{aligned} &\forall (q_k, d_i), (q_k, d_j) \in V \mid s_{k,i} > s_{k,j} : \\ &\quad \boldsymbol{w}^{\mathrm{T}}(\Phi(q_k, d_i) - \Phi(q_k, d_j)) \geq 1 - \xi_{i,j,k} \qquad (1) \\ &\forall i \forall j \forall k : \xi_{i,j,k} \geq 0 \end{aligned}$$

where V is the training corpus, $\Phi(q_k, d_i)$ is the feature vector of document d_i with respect to query q_k, $s_{k,i}$ is the relevance score of d_i with respect to q_k, $\boldsymbol{w}$ is a weight vector, C is the SVM cost parameter, and $\xi_{i,j,k}$ are slack variables. The set of constraints at (1) means that document pairwise orders should be preserved.

Unfortunately, the above scheme for exploiting pairwise order information cannot be applied directly to the emotion ranking task, because the task requires us to rank emotions within a document rather than provide a ranking of documents. In particular, the definitions of $\Phi(q_k,d_i)$, $\Phi(q_k,d_j)$, $s_{k,i}$ and $s_{k,j}$ do not apply to emotion ranking. In the next section, we will show how the pairwise loss minimization concept is adapted for emotion ranking.

3 Ranking Reader Emotions

In this section, we provide the formal description of the reader-emotion ranking problem. Then we describe the pairwise loss minimization (PLM) approach and the emotional distribution regression (EDR) approach to ranking emotions.

3.1 Problem Specification

The reader emotion ranking problem is defined as follows. Let $D = \{d_1, d_2, \ldots, d_N\}$ be the document space, and $E = \{e_1, e_2, \ldots, e_M\}$ be the emotion space. Let $f_i : E \rightarrow \Re$ be the emotional probability function of $d_i \in D$. That is, $f_i(e_j)$ outputs the fraction of readers who experience emotion e_j after reading document d_i. Our goal is to find a function $r : D \rightarrow E^M$ such that $r(d_i) = (e_{\pi(1)}, e_{\pi(2)}, \ldots, e_{\pi(M)})$ where π is a permutation on $\{1, 2, \ldots, M\}$, and $f_i(e_{\pi(1)}) \geq f_i(e_{\pi(2)}) \geq \ldots \geq f_i(e_{\pi(M)})$.

3.2 Pairwise Loss Minimization

As explained in Section 2, the information retrieval framework for exploiting pairwise order information cannot be applied directly to the emotion ranking problem. Hence, we introduce a novel formulation of the emotion ranking problem into an SVM optimization problem with constraints based on pairwise loss minimization.

Whereas Ranking SVM generates only a single ranking function, our method creates a pairwise ranking function $g_{jk} : D \rightarrow \Re$ for each pair of emotions e_j and e_k, aiming at satisfying the maximum number of the inequalities:

$$\forall d_i \in D \mid f_i(e_j) > f_i(e_k) : g_{jk}(d_i) > 0$$
$$\forall d_i \in D \mid f_i(e_j) < f_i(e_k) : g_{jk}(d_i) < 0$$

In other words, we want to minimize the number of incorrectly-ordered emotion pairs. We further require $g_{jk}(d_i)$ to have the linear form $\boldsymbol{w}^{\mathrm{T}}\Omega(d_i) + b$, where $\boldsymbol{w}$ is a weight vector, b is a constant, and $\Omega(d_i)$ is the feature vector of d_i. Details of feature extraction will be presented in Section 5.

As Joachims (2002) points out, the above type of problem is NP-Hard. However, an approximate solution to finding g_{ik} can be obtained by solving the following SVM optimization problem:

$$\min_{w,\, b,\, \xi_i} \ \tfrac{1}{2}\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w} + C\sum \xi_i$$

subject to:

$$\forall d_i \in Q \mid f_i(e_j) > f_i(e_k) : \boldsymbol{w}^{\mathrm{T}}\Omega(d_i) + b \geq 1 - \xi_i$$
$$\forall d_i \in Q \mid f_i(e_j) < f_i(e_k) : -(\boldsymbol{w}^{\mathrm{T}}\Omega(d_i) + b) \geq 1 - \xi_i$$
$$\forall i : \xi_i \geq 0$$

where C is the SVM cost parameter, ξ_i are slack variables, and Q is the training corpus. We assume each document $d_i \in Q$ is labeled with $f_i(e_j)$ for every emotion $e_j \in E$.

When formulated as an SVM optimization problem, finding g_{jk} is equivalent to training an SVM classifier for classifying a document into the e_j or e_k category. Hence, we use LIBSVM, which is an SVM implementation, to obtain the solution.[1]

[1] http://www.csie.ntu.edu.tw/~cjlin/libsvm/

```
Input: Set of emotion ordered pairs $P$
1. $G \leftarrow$ a graph with emotions as vertices and no edge
2. while ($P \neq \emptyset$)
3.   remove $(e_j,e_k)$ with the highest confidence from $P$
4.   if adding edge $(e_j,e_k)$ to $G$ produces a loop
5.     then add $(e_k,e_j)$ to $G$
6.   else add $(e_j,e_k)$ to $G$
7. return topological sort of $G$
```

Algorithm 1. Merge Pairwise Orders.

We now describe how we rank the emotions of a previously unseen document using the $M(M-1)/2$ pairwise ranking functions g_{jk} created during the training phase. First, all of the pairwise ranking functions are applied to the unseen document, which generates the relative orders of every pair of emotions. These pairwise orders need to be combined together to produce a ranked list of all the emotions. Algorithm 1 does exactly this.

In Algorithm 1, the confidence of an emotion ordered pair at Line 3 is the probability value returned by a LIBSVM classifier for predicting the order. LIBSVM's method for generating this probability is described in (Wu et al., 2003). Lines 4 and 5 resolve the problem of conflicting emotion ordered pairs forming a loop in the ordering of emotions. The ordered list of emotions returned by Algorithm 1 at Line 7 is the final output of the PLM method.

3.3 Emotional Distribution Regression

In the second approach to ranking emotions, we use regression to model f_i directly. A regression function $h_j : D \rightarrow \Re$ is generated for each $e_j \in E$ by learning from the examples $(\Omega(d_i), f_i(e_j))$ for all documents d_i in the training corpus.

The regression framework we adopt is Support Vector Regression (SVR), which is a regression analysis technique based on SVM (Schölkopf et al., 2000). We require h_j to have the form $\boldsymbol{w}^{\mathrm{T}}\Omega(d_i) + b$. Finding h_j is equivalent to solving the following optimization problem:

$$\min_{w,\, b,\, \xi_{i,1},\, \xi_{i,2}} \ \tfrac{1}{2}\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w} + C\sum(\xi_{i,1} + \xi_{i,2})$$

subject to:

$$\forall d_i \in Q :$$
$$f_i(e_j) - (\boldsymbol{w}^{\mathrm{T}}\Omega(d_i) + b) \geq \varepsilon - \xi_{i,1}$$
$$(\boldsymbol{w}^{\mathrm{T}}\Omega(d_i) + b) - f_i(e_j) \geq \varepsilon - \xi_{i,2}$$
$$\forall i : \xi_{i,1}, \xi_{i,2} \geq 0$$

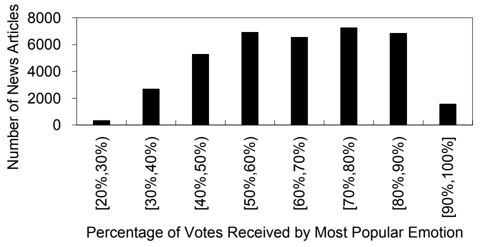

Figure 2. News articles in the entire corpus grouped by the percentage of votes received by the most popular emotion.

where C is the cost parameter, ε is the maximum difference between the predicted and actual values we wish to maintain, $\xi_{i,1}$ and $\xi_{i,2}$ are slack variables, and Q is the training corpus. To solve the above optimization problem, we use SVM^{light}'s SVR implementation.[2]

When ranking the emotions of a previously unseen document d_k, we sort the emotions $e_j \in E$ in descending order of $h_j(d_k)$.

4 Constructing the Corpus

The training and test corpora used in this study comprise Chinese news articles from Yahoo! Kimo News[3], which allows a user to cast a vote for one of eight emotions to express how a news article makes her feel. Each Yahoo! news article contains a list of eight emotions at the bottom of the webpage. A reader may select one of the emotions and click on a submit button to submit the emotion. As with many websites which collect user responses, such as the Internet Movie Database, users are not forced to submit their responses. After submitting a response, the user can view a distribution of emotions indicating how other readers feel about the same article. Figure 1 shows the voting results of a Yahoo! news article.

The eight available emotions are *happy*, *sad*, *angry*, *surprising*, *boring*, *heartwarming*, *awesome*, and *useful*. *Useful* is not a true emotion. Rather, it means that a news article contains practical information. The value $f_i(e_j)$ is derived by normalizing the number of votes for emotion e_j in document d_i by the total number votes in d_i.

The entire corpus consists of 37,416 news articles dating from January 24, 2007 to August 7, 2007. News articles prior to June 1, 2007 form the training corpus (25,975 articles), and the remaining ones form the test corpus (11,441 articles). We collect articles a week after their publication dates to ensure that the vote counts have stabilized.

As mentioned earlier, readers rarely agree unanimously on the emotion of a document. Figure 2 illustrates this. In 41% of all the news articles in the entire corpus, the most popular emotion receives less than 60% of the votes.

5 Extracting Features

After obtaining news articles, the next step is to determine how to convert them into feature vectors for SVM and SVR. That is, we want to instantiate Ω. For this purpose, three types of features are extracted.

The first feature type consists of Chinese character bigrams, which are taken from the headline and content of each news article. The presence of a bigram is indicated by a binary feature value.

Chinese words form the second type of features. Unlike English words, consecutive Chinese words in a sentence are not separated by spaces. To deal with this problem, we utilize Stanford NLP Group's Chinese word segmenter to split a sentence into words.[4] As in the case of bigrams, binary feature values are used.

We use character bigram features in addition to word features to increase the coverage of Chinese words. A Chinese word is formed by one or more contiguous Chinese characters. As mentioned earlier, Chinese words in a sentence are not separated by any boundary symbol (e.g., a space), so a Chinese word segmentation tool is always required to extract words from a sentence. However, a word segmenter may identify word boundaries erroneously, resulting in the loss of correct Chinese words. This problem is particularly severe if there are a lot of out-of-vocabulary words in a dataset. In Chinese, around 70% of all Chinese words are Chinese character bigrams (Chen et al., 1997). Thus, using Chinese character bigrams as features will allow us to identify a lot of Chinese words, which when combined with the words extracted by the word segmenter, will give us a wider coverage of Chinese words.

The third feature type is extracted from news metadata. A news article's metadata are its news

[2] http://svmlight.joachims.org/
[3] http://tw.news.yahoo.com

[4] http://nlp.stanford.edu/software/segmenter.shtml

category, agency, hour of publication, reporter, and event location. Examples of news categories include sports and political. Again, we use binary feature values. News metadata are used because they may contain implicit emotional information.

6 Experiments

The experiments are designed to achieve the following four goals: (i) to compare the ranking performance of different methods, (ii) to analyze the pairwise ranking quality of PLM, (iii) to analyze the distribution estimation quality of EDR, and (iv) to compare the ranking performance of different feature sets. The Yahoo! News training and test corpora presented in Section 4 are used in all experiments.

6.1 Evaluation Metrics for Ranking

We employ three metrics as indicators of ranking quality: ACC@*k*, NDCG@*k* and SACC@*k*.

ACC@*k* stands for accuracy at position *k*. According to ACC@*k*, a predicted ranked list is correct if the list's first *k* items are identical (i.e., same items in the same order) to the true ranked list's first *k* items. If two emotions in a list have the same number of votes, then their positions are interchangeable. ACC@*k* is computed by dividing the number of correctly-predicted instances by the total number of instances.

NDCG@*k*, or normalized discounted cumulative gain at position *k* (Järvelin and Kekäläinen, 2002), is a metric frequently used in information retrieval to judge the quality of a ranked list when multiple levels of relevance are considered. This metric is defined as

$$\text{NDCG}@k = z_k \sum_{i=1}^{k} \frac{rel_i}{\log_2(i+1)}$$

where rel_i is the relevance score of the predicted item at position *i*, and z_k is a normalizing factor which ensures that a correct ranked list has an NDCG@*k* value of 1. In the emotion ranking problem, rel_i is the percentage of reader votes received by the emotion at position *i*. Note that the $\log_2(i+1)$ value in the denominator is a discount factor which decreases the weights of items ranked later in a list. NDCG@*k* has the range [0, 1], where 1 is the best. In the experiment results, NDCG@*k* values are averaged over all instances in the test corpus.

NDCG@*k* is used because ACC@*k* has the disadvantage of not taking emotional distributions into account. Take Figure 1 as an example. In the figure, *heartwarming* and *happy* have 31.3% and 30.7% of the votes, respectively. Since the two percentages are very close, it is reasonable to say that predicting *happy* as the first item in a ranked list may also be acceptable. However, doing so would be completely incorrect according to ACC@*k*. In contrast, NDCG@*k* would consider it to be partially correct, and the extent of correctness depends on how much *heartwarming* and *happy*'s percentages of votes differ. To be exact, if *happy* is predicted as the first item, then the corresponding NDCG@1 would be 30.7% / 31.3% = 0.98.

The third metric is SACC@*k*, or set accuracy at *k*. It is a variant of ACC@*k*. According to SACC@*k*, a predicted ranked list is correct if the set of its first *k* items is the same as the true ranked list's set of first *k* items. In effect, SACC@*k* evaluates a ranking method's ability to place the top *k* most important items in the first *k* positions.

6.2 Tuning SVM and SVR Parameters

SVM and SVR are employed in PLM and EDR, respectively. Both SVM and SVR have the adjustable *C* cost parameter, and SVR has an additional ε parameter. To estimate the optimal *C* value for a combination of SVM and features, we perform 4-fold cross-validation on the Yahoo! News training corpus, and select the *C* value which results in the highest binary classification accuracy during cross-validation. The same procedure is used to estimate the best *C* and ε values for a combination of SVR and features. The C-ε pair which results in the lowest mean squared error during cross-validation is chosen. The candidate *C* values for both SVM and SVR are 2^{-10}, 2^{-9}, …, 2^{-6}. The candidate ε values for SVR are 10^{-2} and 10^{-1}. All cross-validations are performed solely on the training data. The test data are not used to tune the parameters. Also, SVM and SVR allow users to specify the type of kernel to use. Linear kernel is selected for both SVM and SVR.

6.3 Nearest Neighbor Baseline

The nearest neighbor (NN) method is used as the baseline. The ranked emotion list of a news article in the test corpus is predicted as follows. First, the

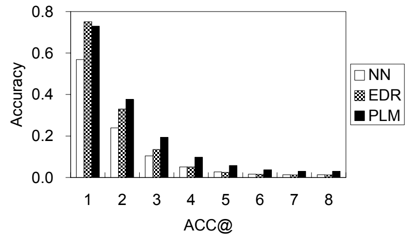

Figure 3. ACC@k

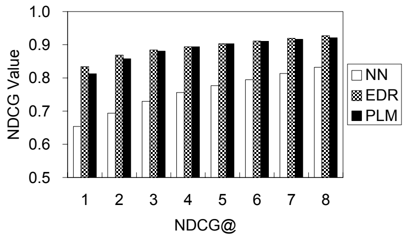

Figure 4. NDCG@k

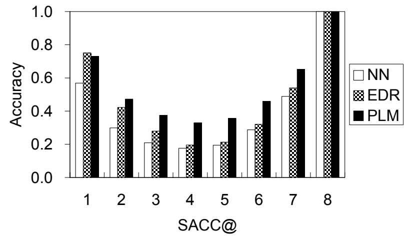

Figure 5. SACC@k

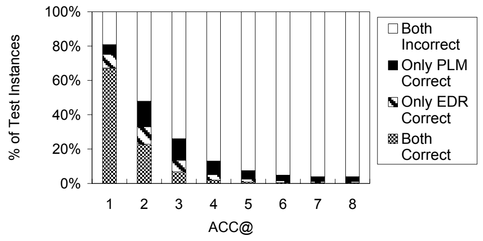

Figure 6. Performance of PLM and EDR.

test news article is compared to every training news article using cosine similarity, which is defined as

$$\cos(d_i, d_j) = \frac{|D_i \cap D_j|}{\sqrt{|D_i| \times |D_i|}}$$

where d_i and d_j are two news articles, and D_i and D_j are sets of Chinese character bigrams in d_i and d_j, respectively. The ranked emotion list of the training article having the highest cosine similarity with the test article is used as the predicted ranked list.

6.4 Comparison of Methods

Figures 3 to 5 show the performance of different ranking methods on the test corpus. For both PLM and EDR, all of the bigram, word, and news metadata features are used.

In Figure 3, EDR's ACC@1 (0.751) is higher than those of PLM and NN, and the differences are statistically significant with p-value < 0.01. So, EDR is the best method at predicting the most popular emotion. However, PLM has the best ACC@k for $k \geq 2$, and the differences from the other two methods are all significant with p-value < 0.01. This means that PLM's predicted ranked lists better resemble the true ranked lists.

Figure 3 displays a sharp decrease in ACC@k values as k increases. This trend indicates the hardness of predicting a ranked list correctly. Looking from a different angle, the ranking task under the ACC@k metric is equivalent to the classification of news articles into one of $8!/(8-k)!$ classes, where we regard each unique emotion sequence of length k as a class. In fact, computing ACC@8 for a ranking method is the same as evaluating the method's ability to classify a news article into one of 8! = 40,320 classes. So, producing a completely-correct ranked list is a difficult task.

In Figure 4, all of PLM and EDR's NDCG@k improvements over NN are statistically significant with p-value < 0.01. For some values of k, the difference in NDCG@k between PLM and EDR is not significant. The high NDCG@k values (i.e., greater than 0.8) of PLM and EDR imply that although it is difficult for PLM and EDR to generate completely-correct ranked lists, these two methods are effective at placing highly popular emotions to the beginning of ranked lists.

In Figure 5, PLM outperforms the other two methods for $2 \leq k \leq 7$, and the differences are all statistically significant with p-value < 0.01. For small values of k (e.g., $2 \leq k \leq 3$), PLM's higher SACC@k values mean that PLM is better at placing the highly popular emotions in the top positions of a ranked list.

To further compare PLM and EDR, we examine their performance on individual test instances. Figure 6 shows the percentage of test instances where both PLM and EDR give incorrect lists, only PLM gives correct lists, only EDR gives ranked lists, and both methods give correct lists. The "Only PLM Correct" and "Only EDR Correct" categories are nonzero, so neither PLM nor EDR is always better than the other.

In summary, EDR is the best at predicting the most popular emotion according to ACC@1, NDCG@1 and SACC@1. However, PLM generates ranked lists that better resemble the correct ranked lists according to ACC@k and SACC@k

Method	Average τ_b	Average p-value
PLM	0.584	0.068
EDR	0.474	0.114
NN	0.392	0.155

for $k \geq 2$. Further analysis shows that neither method is always better than the other.

6.5 Pairwise Ranking Quality of PLM

In this subsection, we evaluate the performance of PLM in predicting pairwise orders.

We first examine the quality of ranked lists generated by PLM in terms of pairwise orders. To do this, we use Kendall's τ_b correlation coefficient, which is a statistical measure for determining the correlation between two ranked lists when there may be ties between two items in a list (Liebetrau, 1983). The value of τ_b is determined based on the number of concordant pairwise orders and the number of discordant pairwise orders between two ranked lists. Therefore, this measure is appropriate for evaluating the effectiveness of PLM at predicting pairwise orders correctly. τ_b has the range [-1, 1], where 1 means a perfect positive correlation, and -1 means two lists are the reverse of each other. When computing τ_b of two ranked lists, we also calculate a p-value to indicate whether the correlation is statistically significant.

We compute τ_b statistics between a predicted ranked list and the corresponding true ranked list. Table 1 shows the results. In Table 1, numbers in the "Average τ_b" and "Average p-value" columns are averaged over all test instances. The statistics for EDR and NN are also included for comparison. From the table, we see that PLM has the highest average τ_b value and the lowest average p-value, so PLM is better at preserving pairwise orders than EDR and NN methods. This observation verifies that PLM's minimization of pairwise loss leads to better prediction of pairwise orders.

We now look at the individual performance of the 28 pairwise emotion rankers g_{jk}. As mentioned in Section 3.2, each pairwise emotion ranker g_{jk} is equivalent to a binary classifier for classifying a document into the e_j or e_k category. So, we look at their classification accuracies in Table 2. In the table, accuracy ranges from 0.75 for the *awesome-surprising* pair to 0.91 for the *useful-boring* pair.

From the psychological perspective, the relatively low accuracy of the *awesome-surprising* pair is expected, because *awesome* is *surprising* in a positive sense. So, readers should have a hard time distinguishing between these two emotions. And the SVM classifier, which models reader responses, should also find it difficult to discern these two emotions. Based on this observation, we suspect that the pairwise classification performance actually reflects the underlying emotional ambiguity experienced by readers. To verify this, we quantify the degree of ambiguity between two emotions, and compare the result to pairwise classification accuracy.

To quantify emotional ambiguity, we introduce the concept of discrimination value between two emotions e_j and e_k in a document d_i, which is defined as follows:

$$\frac{\left| f_i(e_j) - f_i(e_k) \right|}{f_i(e_j) + f_i(e_k)}$$

where f_i is the emotional probability function defined in Section 3.1. Intuitively, the larger the discrimination value is, the smaller the degree of ambiguity between two emotions is.

Figure 7 shows the relationship between pairwise classification accuracy and the average discrimination value of the corresponding emotion

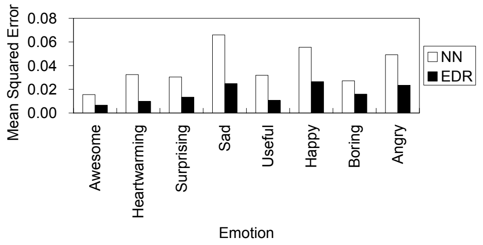

Figure 8. Mean squared error of NN and EDR for estimating the emotional distributions of the test corpus.

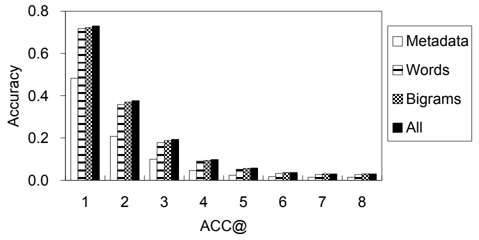

Figure 9. PLM performance using different features.

pair. The general pattern is that as accuracy increases, the discrimination value also increases. To provide concrete evidence, we use Pearson's product-moment correlation coefficient, which has the range of [-1, 1], where 1 means a perfect positive correlation (Moore, 2006). The coefficient for the data in Figure 7 is 0.726 with p-value < 0.01. Thus, pairwise emotion classification accuracy reflects the emotional ambiguity experienced by readers.

In summary, PLM's pairwise loss minimization leads to better pairwise order predictions than EDR and NN. Also, the pairwise classification results reveal the inherent ambiguity between emotions.

6.6 Distribution Estimation Quality of EDR

In this subsection, we evaluate EDR's performance in estimating the emotional probability function f_i.

With the prior knowledge that a news article's f_i values sum to 1 over all emotions, and f_i is between 0 and 1, we adjust EDR's f_i predictions to produce proper distributions. It is done as follows. A predicted f_i value greater than 1 or less than 0 is set to 1 and 0, respectively. Then the predicted f_i values are normalized to sum to 1 over all emotions.

NN's distribution estimation performance is included for comparison. For NN, the predicted f_i values of a test article are taken from the emotional distribution of the most similar training article.

Figure 8 shows the mean squared error of EDR and NN for predicting f_i. In the figure, the error generated by EDR is less than those by NN, and all the differences are statistically significant with p-value < 0.01. Thus, EDR's use of regression leads to better estimation of f_i than the NN.

6.7 Comparison of Features

Figure 9 shows each of the three feature type's ACC@k for predicting test instances' ranked lists when PLM is used. The feature comparison graph for EDR is not shown, because it exhibits a very similar trend as PLM. For both PLM and EDR, bigrams are better than words, which are in turn better than news metadata. In Figure 9, the combination of all three feature sets achieves the best performance. For both PLM and EDR, the improvements in ACC@k of using all features over words and metadata are all significant with p-value < 0.01, and the improvements over bigrams are significant for $k \leq 2$. Hence, in general, it is better to use all three feature types together.

7 Conclusions and Future Work

This paper presents two methods to ranking reader emotions. The PLM method minimizes pairwise loss, and the EDR method estimates emotional distribution through regression. Experiments with significant tests show that EDR is better at predicting the most popular emotion, but PLM produces ranked lists that have higher correlation with the correct lists. We further verify that PLM has better pairwise ranking performance than the other two methods, and EDR has better distribution estimation performance than NN.

As for future work, there are several directions we can pursue. An observation is that PLM exploits pairwise order information, whereas EDR exploits emotional distribution information. We plan to combine these two methods together. Another research direction is to improve EDR by finding better features. We would also like to integrate emotion ranking into information retrieval.

Dependency Parsing by Belief Propagation*

David A. Smith and **Jason Eisner**
Dept. of Computer Science, Johns Hopkins University
Balitmore, MD 21218, USA
{dasmith,eisner}@jhu.edu

Abstract

We formulate dependency parsing as a graphical model with the novel ingredient of global constraints. We show how to apply loopy belief propagation (BP), a simple and effective tool for *approximate* learning and inference. As a parsing algorithm, BP is both asymptotically and empirically efficient. Even with second-order features or latent variables, which would make exact parsing considerably slower or NP-hard, BP needs only $O(n^3)$ time with a small constant factor. Furthermore, such features significantly improve parse accuracy over exact first-order methods. Incorporating additional features would increase the runtime additively rather than multiplicatively.

1 Introduction

Computational linguists worry constantly about runtime. Sometimes we oversimplify our models, trading linguistic nuance for fast dynamic programming. Alternatively, we write down a better but intractable model and then use approximations. The CL community has often approximated using heavy pruning or reranking, but is beginning to adopt other methods from the machine learning community, such as Gibbs sampling, rejection sampling, and certain variational approximations.

We propose borrowing a different approximation technique from machine learning, namely, loopy belief propagation (BP). In this paper, we show that BP can be used to *train* and *decode* complex parsing models. Our approach calls a simpler parser as a subroutine, so it still exploits the useful, well-studied combinatorial structure of the parsing problem.[1]

2 Overview and Related Work

We wish to make a dependency parse's score depend on *higher-order* features, which consider arbitrary interactions among two or more edges in the parse (and perhaps also other latent variables such as part-of-speech tags or edge labels). Such features can help accuracy—as we show. Alas, they raise the polynomial runtime of projective parsing, and render non-projective parsing NP-hard. Hence we seek approximations.

We will show how BP's "message-passing" discipline offers a principled way for *higher-order* features to incrementally adjust the numerical edge weights that are fed to a fast *first-order* parser. Thus the first-order parser is influenced by higher-order interactions among edges—but not asymptotically slowed down by considering the interactions itself.

BP's behavior in our setup can be understood intuitively as follows. Inasmuch as the first-order parser finds that edge e is probable, the higher-order features will kick in and discourage other edges e' to the extent that they prefer not to coexist with e.[2] Thus, the *next* call to the first-order parser assigns lower probabilities to parses that contain these e'. (The method is approximate because a first-order parser must equally penalize *all* parses containing e', even those that do not in fact contain e.)

This behavior is somewhat similar to parser stacking (Nivre and McDonald, 2008; Martins et al., 2008), in which a first-order parser derives some of its input features from the full 1-best output of another parser. In our method, a first-order parser derives such input features from its *own* previous full output (but probabilistic output rather than just 1-best). This circular process is *iterated* to convergence. Our method also permits the parse to interact cheaply with other variables. Thus first-order parsing, part-of-speech tagging, and other tasks on a common input could mutually influence one another.

Our method and its numerical details emerge naturally as an instance of the well-studied loopy BP algorithm, suggesting several potential future im-

*This work was supported by the Human Language Technology Center of Excellence.

[1] As do constraint relaxation (Tromble and Eisner, 2006) and forest reranking (Huang, 2008). In contrast, generic NP-hard solution techniques like Integer Linear Programming (Riedel and Clarke, 2006) know nothing about optimal substructure.

[2] This may be reminiscent of adjusting a Lagrange multiplier on e' until some (hard) constraint is satisfied.

provements to accuracy (Yedidia et al., 2004; Braunstein et al., 2005) and efficiency (Sutton and McCallum, 2007).

Loopy BP has occasionally been used before in NLP, with good results, to handle non-local features (Sutton and McCallum, 2004) or joint decoding (Sutton et al., 2004). However, our application to parsing requires an innovation to BP that we explain in §5—a *global* constraint to enforce that the parse is a tree. The tractability of some such global constraints points the way toward applying BP to other computationally intensive NLP problems, such as syntax-based alignment of parallel text.

3 Graphical Models of Dependency Trees

3.1 Observed and hidden variables

To apply BP, we must formulate dependency parsing as a search for an optimal **assignment** to the variables of a graphical model. We encode a parse using the following variables:

Sentence. The n-word input sentence W is fully observed (not a lattice). Let $W = W_0 W_1 \cdots W_n$, where W_0 is always the special symbol ROOT.

Tags. If desired, the variables $T = T_1 T_2 \cdots T_n$ may specify tags on the n words, drawn from some tagset $\mathcal{T}$ (e.g., parts of speech). These variables are needed iff the tags are to be inferred jointly with the parse.

Links. The $O(n^2)$ boolean variables $\{L_{ij} : 0 \leq i \leq n, 1 \leq j \leq n, i \neq j\}$ correspond to the possible links in the dependency parse.[3] $L_{ij} = \mathsf{true}$ is interpreted as meaning that there exists a dependency link from parent $i \rightarrow$ child j.[4]

Link roles, etc. It would be straightforward to add other variables, such as a binary variable L_{irj} that is true iff there is a link $i \xrightarrow{r} j$ labeled with role r (e.g., AGENT, PATIENT, TEMPORAL ADJUNCT).

3.2 Markov random fields

We wish to define a probability distribution over all configurations, i.e., all joint assignments $\mathcal{A}$ to these variables. Our distribution is simply an undirected graphical model, or Markov random field (MRF):[5]

$$p(\mathcal{A}) \overset{\text{def}}{=} \frac{1}{Z} \prod_m F_m(\mathcal{A}) \tag{1}$$

specified by the collection of **factors** $F_m : \mathcal{A} \mapsto \mathbb{R}^{\geq 0}$. Each factor is a function that consults only a *subset* of $\mathcal{A}$. We say that the factor has **degree** d if it depends on the values of d variables in $\mathcal{A}$, and that it is **unary**, **binary**, **ternary**, or **global** if d is respectively 1, 2, 3, or unbounded (grows with n).

A factor function $F_m(\mathcal{A})$ may also depend freely on the observed variables—the input sentence W and a known (learned) parameter vector θ. For notational simplicity, we suppress these extra arguments when writing and drawing factor functions, and when computing their degree. In this treatment, these observed variables are not specified by $\mathcal{A}$, but instead are absorbed into the very definition of F_m.

In defining a factor F_m, we often define the circumstances under which it **fires**. These are the only circumstances that allow $F_m(\mathcal{A}) \neq 1$. When F_m does not fire, $F_m(\mathcal{A}) = 1$ and does not affect the product in equation (1).

3.3 Hard constraints

A **hard** factor F_m fires only on parses $\mathcal{A}$ that *violate* some specified condition. It has value 0 on those parses, acting as a hard constraint to rule them out.

TREE. A hard global constraint on all the L_{ij} variables at once. It requires that exactly n of these variables be true, and that the corresponding links form a directed tree rooted at position 0.

PTREE. This stronger version of TREE requires further that the tree be **projective**. That is, it prohibits L_{ij} and $L_{k\ell}$ from both being true if $i \rightarrow j$ crosses $k \rightarrow \ell$. (These links are said to **cross** if one of k, ℓ is strictly between i and j while the other is strictly outside that range.)

EXACTLY1. A *family* of $O(n)$ hard global constraints, indexed by $1 \leq j \leq n$. EXACTLY1$_j$ requires that j have exactly one parent, i.e., exactly one of the L_{ij} variables must be true. Note that EXACTLY1 is implied by TREE or PTREE.

[3]"Links" are conventionally called edges, but we reserve the term "edge" for describing the graphical model's factor graph.

[4]We could have chosen a different representation with $O(n)$ integer variables $\{P_j : 1 \leq j \leq n\}$, writing $P_j = i$ instead of $L_{ij} = \mathsf{true}$. This representation can achieve the same asymptotic runtime for BP by using sparse messages, but some constraints and algorithms would be somewhat harder to explain.

[5]Our overall model is properly called a *dynamic* MRF, since we must construct different-size MRFs for input sentences of different lengths. Parameters are shared both across and within these MRFs, so that only finitely many parameters are needed.

ATMOST1. A weaker version. ATMOST1_j requires j to have one or zero parents.

NAND. A *family* of hard binary constraints. NAND$_{ij,k\ell}$ requires that L_{ij} and $L_{k\ell}$ may not both be true. We will be interested in certain subfamilies.

NOT2. Shorthand for the family of $O(n^3)$ binary constraints $\{\text{NAND}_{ij,kj}\}$. These are collectively equivalent to ATMOST1, but expressed via a larger number of simpler constraints, which can make the BP approximation less effective (footnote 30).

NO2CYCLE. Shorthand for the family of $O(n^2)$ binary constraints $\{\text{NAND}_{ij,ji}\}$.

3.4 Soft constraints

A **soft** factor F_m acts as a soft constraint that prefers some parses to others. In our experiments, it is always a log-linear function returning positive values:

$$F_m(\mathcal{A}) \overset{\text{def}}{=} \exp \sum_{h \in \text{features}(F_m)} \theta_h f_h(\mathcal{A}, W, m) \quad (2)$$

where θ is a learned, finite collection of weights and f is a corresponding collection of feature functions, some of which are used by F_m. (Note that f_h is permitted to consult the observed input W. It also sees which factor F_m it is scoring, to support reuse of a single feature function f_h and its weight θ_h by unboundedly many factors in a model.)

LINK. A family of unary soft factors that judge the links in a parse $\mathcal{A}$ individually. LINK$_{ij}$ fires iff L_{ij} = true, and then its value depends on (i, j), W, and θ. Our experiments use the same features as McDonald et al. (2005).

A first-order (or "edge-factored") parsing model (McDonald et al., 2005) contains *only* LINK factors, along with a global TREE or PTREE factor. Though there are $O(n^2)$ link factors (one per L_{ij}), only n of them fire on any particular parse, since the global factor ensures that exactly n are true.

We'll consider various higher-order soft factors:

PAIR. The binary factor PAIR$_{ij,k\ell}$ fires with some value iff L_{ij} and $L_{k\ell}$ are both true. Thus, it penalizes or rewards a pair of links for being simultaneously present. This is a soft version of NAND.

GRAND. Shorthand for the family of $O(n^3)$ binary factors $\{\text{PAIR}_{ij,jk}\}$, which evaluate grandparent-parent-child configurations, $i \to j \to k$. For example, whether preposition j attaches to verb i might depend on its object k. In non-projective parsing, we might prefer (but not require) that a parent and child be on the same side of the grandparent.

SIB. Shorthand for the family of $O(n^3)$ binary factors $\{\text{PAIR}_{ij,ik}\}$, which judge whether two children of the same parent are compatible. E.g., a given verb may not like to have two noun children both to its left.[6] The children do not need to be adjacent.

CHILDSEQ. A family of $O(n)$ global factors. CHILDSEQ$_i$ scores i's sequence of children; hence it consults all variables of the form L_{ij}. The scoring follows the parametrization of a weighted split head-automaton grammar (Eisner and Satta, 1999). If 5 has children $2, 7, 9$ under $\mathcal{A}$, then CHILDSEQ$_i$ is a product of subfactors of the form PAIR$_{5\#,57}$, PAIR$_{57,59}$, PAIR$_{59,5\#}$ (right child sequence) and PAIR$_{5\#,52}$, PAIR$_{52,5\#}$ (left child sequence).

NOCROSS. A family of $O(n^2)$ global constraints. If the parent-to-j link crosses the parent-to-ℓ link, then NOCROSS$_{j\ell}$ fires with a value that depends only on j and ℓ. (If j and ℓ do not each have exactly one parent, NOCROSS$_{j\ell}$ fires with value 0; i.e., it incorporates EXACTLY1_j and EXACTLY1_ℓ.)[7]

TAG$_i$ is a unary factor that evaluates whether T_i's value is consistent with W (especially W_i).

TAGLINK$_{ij}$ is a ternary version of the LINK$_{ij}$ factor whose value depends on L_{ij}, T_i and T_j (i.e., its feature functions consult the tag variables to decide whether a link is likely). One could similarly enrich the other features above to depend on tags and/or link roles; TAGLINK is just an illustrative example.

TRIGRAM is a global factor that evaluates the tag sequence T according to a trigram model. It is a product of subfactors, each of which scores a trigram of adjacent tags T_{i-2}, T_{i-1}, T_i, possibly also considering the word sequence W (as in CRFs).

4 A Sketch of Belief Propagation

MacKay (2003, chapters 16 and 26) provides an excellent introduction to belief propagation, a gen-

[6] A similar binary factor could directly discourage giving the verb two SUBJECTs, if the model has variables for link roles.

[7] In effect, we have combined the $O(n^4)$ binary factors PAIR$_{ij,k\ell}$ into $O(n^2)$ groups, and made them more precise by multiplying in EXACTLYONE constraints (see footnote 30). This will permit $O(n^3)$ total computation if we are willing to sacrifice the ability of the PAIR weights to depend on i and k.

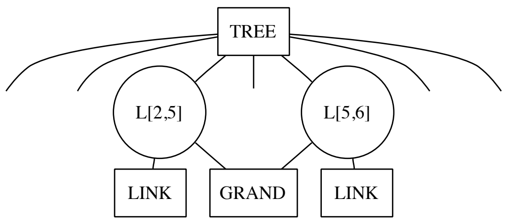

Figure 1: A fragment of a factor graph, illustrating a few of the unary, binary, and global factors that affect variables L_{25} and L_{56}. The GRAND factor induces a loop.

eralization of the forward-backward algorithm that is deeply studied in the graphical models literature (Yedidia et al., 2004, for example). We briefly sketch the method in terms of our parsing task.

4.1 Where BP comes from

The basic BP idea is simple. Variable L_{34} maintains a *distribution* over values true and false—a "belief"—that is periodically recalculated based on the current *distributions* at other variables.[8]

Readers familiar with Gibbs sampling can regard this as a kind of deterministic approximation. In Gibbs sampling, L_{34}'s *value* is periodically resampled based on the current *values* of other variables. Loopy BP works not with random samples but their expectations. Hence it is approximate but tends to converge much faster than Gibbs sampling will mix.

It is convenient to visualize an undirected **factor graph** (Fig. 1), in which each factor is connected to the variables it depends on. Many factors may connect to—and hence influence—a given variable such as L_{34}. If X is a variable *or* a factor, $\mathcal{N}(X)$ denotes its set of neighbors.

4.2 What BP accomplishes

Given an input sentence W and a parameter vector θ, the collection of factors F_m defines a probability distribution (1). The parser should determine the values of the individual variables. In other words, we would like to marginalize equation (1) to obtain the distribution $p(L_{34})$ over L_{34} = true vs. false, the distribution $p(T_4)$ over tags, etc.

If the factor graph is *acyclic*, then BP computes these marginal distributions exactly. Given an HMM, for example, BP reduces to the forward-backward algorithm.

BP's estimates of these distributions are called **beliefs about the variables**. BP also computes **beliefs about the factors**, which are useful in learning θ (see §7). E.g., if the model includes the factor TAGLINK$_{ij}$, which is connected to variables L_{ij}, T_i, T_j, then BP will estimate the marginal joint distribution $p(L_{ij}, T_i, T_j)$ over (boolean, tag, tag) triples.

When the factor graph has loops, BP's beliefs are usually not the true marginals of equation (1) (which are in general intractable to compute). Indeed, BP's beliefs may not be the true marginals of *any* distribution $p(\mathcal{A})$ over assignments, i.e., they may be globally inconsistent. All BP does is to incrementally adjust the beliefs till they are at least *locally* consistent: e.g., the beliefs at factors TAGLINK$_{ij}$ and TAGLINK$_{ik}$ must both imply[9] the same belief about variable T_i, their common neighbor.

4.3 The BP algorithm

This iterated negotiation among the factors is handled by **message passing** along the edges of the factor graph. A **message** to or from a variable is a (possibly unnormalized) probability distribution over the values of that variable.

The variable V sends a message to factor F, saying "My *other* neighboring factors G jointly suggest that I have posterior distribution $q_{V\to F}$ (assuming that they are sending me independent evidence)." Meanwhile, factor F sends messages to V, saying, "Based on my factor function and the messages received from my *other* neighboring variables U about *their* values (and assuming that those messages are independent), I suggest you have posterior distribution $r_{F\to V}$ over *your* values."

To be more precise, BP at each iteration k (until convergence) updates two kinds of messages:

$$q_{V\to F}^{(k+1)}(v) = \kappa \prod_{G\in\mathcal{N}(V)\setminus F} r_{G\to V}^{(k)}(v) \tag{3}$$

from variables to factors, and

$$r_{F\to V}^{(k+1)}(v) = \kappa \sum_{\mathcal{A} \text{ s.t. } \mathcal{A}[V]=v} F(\mathcal{A}) \prod_{U\in\mathcal{N}(F)\setminus V} q_{U\to F}^{(k)}(\mathcal{A}[U]) \tag{4}$$

[8]Or, more precisely—this is the tricky part—based on versions of those other distributions that do not factor in L_{34}'s reciprocal influence on *them*. This prevents (e.g.) L_{34} and T_3 from mutually reinforcing each other's existing beliefs.

[9]In the sense that marginalizing the belief $p(L_{ij}, T_i, T_j)$ at the factor yields the belief $p(T_i)$ at the variable.

from factors to variables. Each message is a probability distribution over values v of V, normalized by a scaling constant κ. Alternatively, messages may be left as unnormalized distributions, choosing $\kappa \neq 1$ only as needed to prevent over- or underflow. Messages are initialized to uniform distributions.

Whenever we wish, we may compute the beliefs at V and F:

$$b^{(k+1)}_{V\rightarrow}(v) \overset{\text{def}}{=} \kappa \prod_{G \in \mathcal{N}(V)} r^{(k)}_{G\rightarrow V}(v) \tag{5}$$

$$b^{(k+1)}_{F\rightarrow}(\mathcal{A}) \overset{\text{def}}{=} \kappa\, F(\mathcal{A}) \prod_{U \in \mathcal{N}(F)} q^{(k)}_{U\rightarrow F}(\mathcal{A}[U]) \tag{6}$$

These beliefs do not truly characterize the expected behavior of Gibbs sampling (§4.1), since the products in (5)–(6) make conditional independence assumptions that are valid only if the factor graph is acyclic. Furthermore, on cyclic ("loopy") graphs, BP might only converge to a local optimum (Weiss and Freedman, 2001), or it might not converge at all. Still, BP often leads to good, fast approximations.

5 Achieving Low Asymptotic Runtime

One iteration of standard BP simply updates all the messages as in equations (3)–(4): one message per edge of the factor graph.

Therefore, adding new factors to the model increases the runtime per iteration *additively*, by increasing the number of messages to update. We believe this is a compelling advantage over dynamic programming—in which new factors usually increase the runtime and space *multiplicatively* by exploding the number of distinct items.[10]

5.1 Propagators for local constraints

But how long does updating each message take? The runtime of summing over all assignments $\sum_{\mathcal{A}}$ in equation (4) may appear prohibitive. Crucially, however, $F(\mathcal{A})$ only depends on the values in $\mathcal{A}$ of F's its neighboring variables $\mathcal{N}(F)$. So this sum is proportional to a sum over *restricted* assignments to just those variables.[11]

For example, computing a message from TAGLINK$_{ij}$ $\rightarrow T_i$ only requires iterating over all (boolean, tag, tag) triples.[12] The runtime to update that message is therefore $O(2 \cdot |\mathcal{T}| \cdot |\mathcal{T}|)$.

5.2 Propagators for global constraints

The above may be tolerable for a ternary factor. But how about global factors? EXACTLY1$_j$ has n neighboring boolean variables: surely we cannot iterate over all 2^n assignments to these! TREE is even worse, with $2^{O(n^2)}$ assignments to consider. We will give specialized algorithms for handling these summations more efficiently.

A historical note is in order. Traditional constraint satisfaction corresponds to the special case of (1) where *all* factors F_m are hard constraints (with values in $\{0, 1\}$). In that case, loopy BP reduces to an algorithm for generalized arc consistency (Mackworth, 1977; Bessière and Régin, 1997; Dechter, 2003), and updating a factor's outgoing messages is known as **constraint propagation**. Régin (1994) famously introduced an efficient propagator for a global constraint, ALLDIFFERENT, by adapting combinatorial bipartite matching algorithms.

In the same spirit, we will demonstrate efficient propagators for our global constraints, e.g. by adapting combinatorial algorithms for *weighted parsing*. We are unaware of any previous work on global factors in sum-product BP, although for *max-product* BP,[13] Duchi et al. (2007) independently showed that a global 1-to-1 alignment constraint—a kind of weighted ALLDIFFERENT—permits an efficient propagator based on weighted bipartite matching.

5.3 Constraint propagators for parsing

Table 1 shows our asymptotic runtimes for all factors in §§3.3–3.4. Remember that if several of these

[10]For example, with unknown tags T, a model with PTREE+TAGLINK will take only $O(n^3 + n^2g^2)$ time for BP, compared to $O(n^3g^2)$ time for dynamic programming (Eisner & Satta 1999). Adding TRIGRAM, which is string-local rather than tree-local, will increase this only to $O(n^3 + n^2g^2 + ng^3)$, compared to $O(n^3g^6)$ for dynamic programming.

Even more dramatic, adding the SIB family of $O(n^3)$ PAIR$_{ij,ik}$ factors will add only $O(n^3)$ to the runtime of BP (Table 1). By contrast, the runtime of dynamic programming becomes exponential, because each item must record its headword's full *set* of current children.

[11]The constant of proportionality may be folded into κ; it is the number of assignments to the *other* variables.

[12]Separately for *each* value v of T_i, get v's probability by summing over assignments to (L_{ij}, T_i, T_j) s.t. $T_i = v$.

[13]Max-product replaces the sums in equations (3)–(6) with maximizations. This replaces the forward-backward algorithm with its Viterbi approximation.

factor family	degree (each)	runtime (each)	count	runtime (total)
TREE	$O(n^2)$	$O(n^3)$	1	$O(n^3)$
PTREE	$O(n^2)$	$O(n^3)$	1	$O(n^3)$
EXACTLY1	$O(n)$	$O(n)$	n	$O(n^2)$
ATMOST1	$O(n)$	$O(n)$	n	$O(n^2)$
NOT2	2	$O(1)$	$O(n^3)$	$O(n^3)$
NO2CYCLE	2	$O(1)$	$O(n^2)$	$O(n^2)$
LINK	1	$O(1)$	$O(n^2)$	$O(n^2)$
GRAND	2	$O(1)$	$O(n^3)$	$O(n^3)$
SIB	2	$O(1)$	$O(n^3)$	$O(n^3)$
CHILDSEQ	$O(n)$	$O(n^2)$	$O(n)$	$O(n^3)$
NOCROSS	$O(n)$	$O(n)$	$O(n^2)$	$O(n^3)$
TAG	1	$O(g)$	$O(n)$	$O(ng)$
TAGLINK	3	$O(g^2)$	$O(n^2)$	$O(n^2g^2)$
TRIGRAM	$O(n)$	$O(ng^3)$	1	$O(ng^3)$

Table 1: Asymptotic runtimes of the propagators for various factors (where n is the sentence length and g is the size of the tag set $\mathcal{T}$). An iteration of standard BP propagates through each factor once. Running a factor's propagator will update all of its outgoing messages, based on its current incoming messages.

factors are included, the total runtime is *additive*.[14]

Propagating the local factors is straightforward (§5.1). We now explain how to handle the global factors. *Our main trick is to work backwards from marginal beliefs.* Let F be a factor and V be one of its neighboring variables. At any time, F has a marginal belief about V (see footnote 9),

$$b^{(k+1)}_{F\rightarrow}(V = v) = \sum_{\mathcal{A} \text{ s.t. } \mathcal{A}[V]=v} b^{(k+1)}_{F\rightarrow}(\mathcal{A}) \qquad (7)$$

a sum over (6)'s products of incoming messages. By the definition of $r_{F\rightarrow V}$ in (4), and distributivity, we can also express the marginal belief (7) as a pointwise product of outgoing and incoming messages[15]

$$b^{(k+1)}_{F\rightarrow}(V = v) = r^{(k+1)}_{F\rightarrow V}(v) \cdot q^{(k)}_{V\rightarrow F}(v) \qquad (8)$$

up to a constant. If we can quickly sum up the marginal belief (7), then (8) says we can divide out *each* particular incoming message $q^{(k)}_{V\rightarrow F}$ to obtain its corresponding outgoing message $r^{(k+1)}_{F\rightarrow V}$.

[14]We may ignore the cost of propagators at the variables. Each outgoing message from a variable can be computed in time proportional to its size, which may be amortized against the cost of generating the corresponding incoming message.

[15]E.g., the familiar product of forward and backward messages that is used to extract posterior marginals from an HMM.

Note that the marginal belief and both messages are unnormalized distributions over values v of V. F and k are clear from context below, so we simplify the notation so that (7)–(8) become

$$b(V = v) \;=\; \sum_{\mathcal{A} \text{ s.t. } \mathcal{A}[V]=v} b(\mathcal{A}) \;=\; r_V(v) \cdot q_V(v)$$

TRIGRAM must sum over assignments to the tag sequence T. The belief (6) in a given assignment is a product of trigram scores (which play the role of transition weights) and incoming messages q_{T_j} (playing the role of emission weights). The marginal belief (7) needed above, $b(T_i = t)$, is found by summing over assignments where $T_i = t$. All marginal beliefs are computed together in $O(ng^3)$ total time by the forward-backward algorithm.[16]

EXACTLY1$_j$ is a *sparse* hard constraint. Even though there are 2^n assignments to its n neighboring variables $\{L_{ij}\}$, the factor function returns 1 on only n assignments and 0 on the rest. In fact, for a given i, $b(L_{ij} = \mathsf{true})$ in (7) is defined by (6) to have exactly one non-zero summand, in which $\mathcal{A}$ puts $L_{ij} = \mathsf{true}$ and all other $L_{i'j} = \mathsf{false}$. We compute the marginal beliefs for all i together in $O(n)$ total time:

1. Pre-compute $\pi \overset{\text{def}}{=} \prod_i q_{L_{ij}}(\mathsf{false})$.[17]
2. For each i, compute the marginal belief $b(L_{ij} = \mathsf{true})$ as $\pi \cdot \bar{q}_{L_{ij}}$, where $\bar{q}_{L_{ij}} \in \mathbb{R}$ denotes the odds ratio $q_{L_{ij}}(\mathsf{true})/q_{L_{ij}}(\mathsf{false})$.[18]
3. The partition function $b()$ denotes $\sum_{\mathcal{A}} b(\mathcal{A})$; compute it in this case as $\sum_i b(L_{ij} = \mathsf{true})$.
4. For each i, compute $b(L_{ij} = \mathsf{false})$ by subtraction, as $b() - b(L_{ij} = \mathsf{true})$.

TREE and PTREE must sum over assignments to the $O(n^2)$ neighboring variables $\{L_{ij}\}$. There are now exponentially many non-zero summands, those in which $\mathcal{A}$ corresponds to a valid tree. Nonetheless,

[16]Which is itself an exact BP algorithm, but on a different graph—a junction tree formed from the graph of TRIGRAM subfactors. Each variable in the junction tree is a *bigram*. If we had simply replaced the global TRIGRAM factor with its subfactors in the full factor graph, we would have had to resort to Generalized BP (Yedidia et al., 2004) to obtain the same exact results.

[17]But taking $\pi = 1$ gives the same results, up to a constant.

[18]As a matter of implementation, this odds ratio $\bar{q}_{L_{ij}}$ can be used to represent the incoming message $q_{L_{ij}}$ everywhere.

we can follow the same approach as for EXACTLY1. Steps 1 and 4 are modified to iterate over all i, j such that L_{ij} is a variable. In step 3, the partition function $\sum_{\mathcal{A}} b(\mathcal{A})$ is now π times the total weight of all trees, where the weight of a given tree is the product of the $\bar{q}_{L_{ij}}$ values of its n edges. In step 2, the marginal belief $b(L_{ij} = \text{true})$ is now π times the total weight of all trees having edge $i \rightarrow j$.

We perform these combinatorial sums *by calling a first-order parsing algorithm,* with edge weights $\bar{q}_{ij}$. Thus, as outlined in §2, a first-order parser is called each time we propagate through the global TREE or PTREE constraint, using edge weights that include the first-order LINK factors but also multiply in any current messages from higher-order factors.

The parsing algorithm simultaneously computes the partition function $b()$, and all $O(n^2)$ marginal beliefs $b(L_{ij} = \text{true})$. For PTREE (projective), it is the inside-outside version of a dynamic programming algorithm (Eisner, 1996). For TREE (non-projective), Koo et al. (2007) and Smith and Smith (2007) show how to employ the matrix-tree theorem. In both cases, the total time is $O(n^3)$.[19]

NOCROSS$_{j\ell}$ must sum over assignments to $O(n)$ neighboring variables $\{L_{ij}\}$ and $\{L_{k\ell}\}$. The non-zero summands are assignments where j and ℓ each have exactly one parent. At step 1, $\pi \overset{\text{def}}{=} \prod_i q_{L_{ij}}(\text{false}) \cdot \prod_k q_{L_{k\ell}}(\text{false})$. At step 2, the marginal belief $b(L_{ij} = \text{true})$ sums over the n non-zero assignments containing $i \rightarrow j$. It is $\pi \cdot \bar{q}_{L_{ij}} \cdot \sum_k \bar{q}_{L_{k\ell}} \cdot \text{PAIR}_{ij,k\ell}$, where $\text{PAIR}_{ij,k\ell}$ is $x_{j\ell}$ if $i \rightarrow j$ crosses $k \rightarrow \ell$ and is 1 otherwise. $x_{j\ell}$ is some factor value defined by equation (2) to penalize or reward the crossing. Steps 3–4 are just as in EXACTLY1$_j$.

The question is how to compute $b(L_{ij} = \text{true})$ for each i in only $O(1)$ time,[20] so that we can propagate each of the $O(n^2)$ NOCROSS$_{j\ell}$ in $O(n)$ time. This is why we allowed $x_{j\ell}$ to depend only on j, ℓ. We can rewrite the sum $b(L_{ij} = \text{true})$ as

$$\pi \cdot \bar{q}_{L_{ij}} \cdot (x_{j\ell} \cdot \sum_{\text{crossing } k} \bar{q}_{L_{k\ell}} + 1 \cdot \sum_{\text{noncrossing } k} \bar{q}_{L_{k\ell}}) \quad (9)$$

To find this in $O(1)$ time, we precompute for each ℓ an array of partial sums $Q_\ell[s,t] \overset{\text{def}}{=} \sum_{s \le k \le t} \bar{q}_{L_{k\ell}}$. Since $Q_\ell[s,t] = Q_\ell[s,t-1] + \bar{q}_{L_{t\ell}}$, we can compute each entry in $O(1)$ time. The total precomputation time over all ℓ, s, t is then $O(n^3)$, with the array Q_ℓ shared across all factors NOCROSS$_{j'\ell}$. The crossing sum is respectively $Q_\ell[0, i-1] + Q_\ell[j+1, n]$, $Q_\ell[i+1, j-1]$, or 0 according to whether $\ell \in (i,j)$, $\ell \notin [i,j]$, or $\ell = i$.[21] The non-crossing sum is $Q_\ell[0,n]$ minus the crossing sum.

CHILDSEQ$_i$, like TRIGRAM, is propagated by a forward-backward algorithm. In this case, the algorithm is easiest to describe by replacing CHILDSEQ$_i$ in the factor graph by a collection of local subfactors, which pass messages in the ordinary way.[22] Roughly speaking,[23] at each $j \in [1,n]$, we introduce a new variable C_{ij}—a hidden state whose value is the position of i's previous child, if any (so $0 \le C_{ij} < j$). So the ternary subfactor on $(C_{ij}, L_{ij}, C_{i,j+1})$ has value 1 if $L_{ij} = \text{false}$ and $C_{i,j+1} = C_{i,j}$; a sibling-bigram score ($\text{PAIR}_{iC_{ij}, iC_{i,j+1}}$) if $L_{ij} = \text{true}$ and $C_{i,j+1} = j$; and 0 otherwise. The sparsity of this factor, which is 0 almost everywhere, is what gives CHILDSEQ$_i$ a total runtime of $O(n^2)$ rather than $O(n^3)$. It is equivalent to forward-backward on an HMM with n observations (the L_{ij}) and n states per observation (the C_j), with a *deterministic* (thus sparse) transition function.

6 Decoding Trees

BP computes local beliefs, e.g. the conditional probability that a link L_{ij} is present. But if we wish to output a single well-formed dependency tree, we need to find a single assignment to all the $\{L_{ij}\}$ that satisfies the TREE (or PTREE) constraint.

Our final belief about the TREE *factor* is a distribution over such assignments, in which a tree's probability is proportional to the probability of its edge weights $\bar{q}_{L_{ij}}$ (incoming messages). We could simply return the mode of this distribution (found by using a 1-best first-order parser) or the k-best trees, or take samples.

[19]A dynamic algorithm could incrementally update the outgoing messages if only a few incoming messages have changed (as in asynchronous BP). In the case of TREE, dynamic matrix inverse allows us to update any row or column (i.e., messages from all parents or children of a given word) and find the new inverse in $O(n^2)$ time (Sherman and Morrison, 1950).

[20]Symmetrically, we compute $b(L_{k\ell} = \text{true})$ for each k.

[21]There are no NOCROSS$_{j\ell}$ factors with $\ell = j$.

[22]We still treat CHILDSEQ$_i$ as a global factor and compute all its correct outgoing messages on a single BP iteration, via *serial* forward and backward sweeps through the subfactors. Handling the subfactors in parallel, (3)–(4), would need $O(n)$ iterations.

[23]Ignoring the treatment of boundary symbols "#" (see §3.4).

In our experiments, we actually take the edge weights to be not the messages $\bar{q}_{L_{ij}}$ from the links, but the full beliefs $\bar{b}_{L_{ij}}$ at the links (where $\bar{b}_{L_{ij}} \overset{\text{def}}{=} \log b_{L_{ij}}(\textsf{true})/b_{L_{ij}}(\textsf{false})$). These are passed into a fast algorithm for maximum spanning tree (Tarjan, 1977) or maximum projective spanning tree (Eisner, 1996). This procedure is equivalent to minimum Bayes risk (MBR) parsing (Goodman, 1996) with a dependency accuracy loss function.

Notice that the above decoding approaches do not enforce any hard constraints other than TREE in the final output. In addition, they only recover values of the L_{ij} variables. They marginalize over other variables such as tags and link roles. This solves the problem of "nuisance" variables (which merely fragment probability mass among refinements of a parse). On the other hand, it may be undesirable for variables whose values we desire to recover.[24]

7 Training

Our training method also uses beliefs computed by BP, but at the *factors*. We choose the weight vector θ by maximizing the log-probability of training data under equation (1), regularizing only by early stopping. If all variables are observed in training, this objective function is *convex* (as for any log-linear model).

The difficult step in computing the gradient of our objective is finding $\nabla_\theta \log Z$, where Z in equation (1) is the normalizing constant (partition function) that sums over all assignments $\mathcal{A}$. (Recall that Z, like each F_m, depends implicitly on W and θ.) As usual for log-linear models,

$$\nabla_\theta \log Z = \sum_m \mathbf{E}_{p(\mathcal{A})}[\nabla_\theta F_m(\mathcal{A})] \qquad (10)$$

Since $\nabla_\theta F_m(\mathcal{A})$ only depends on the assignment $\mathcal{A}$'s values for variables that are connected to F_m in the factor graph, its expectation under $p(\mathcal{A})$ depends only on the marginalization of $p(\mathcal{A})$ to those variables jointly. Fortunately, BP provides an estimate of that marginal distribution, namely, its belief about the factor F_m, given W and θ (§4.2).[25]

Note that the hard constraints do not depend on θ at all; so their summands in equation (10) will be 0.

We employ stochastic gradient descent (Bottou, 2003), since this does not require us to compute the objective function itself but only to (approximately) estimate its gradient as explained above. Alternatively, given any of the MAP decoding procedures from §6, we could use an error-driven learning method such as the perceptron or MIRA.[26]

8 Experiments

We asked: (1) For projective parsing, where higher-order factors have traditionally been incorporated into slow but exact dynamic programming (DP), what are the comparative speed and quality of the BP approximation? (2) How helpful are such higher-order factors—particularly for non-projective parsing, where BP is needed to make them tractable? (3) Do our global constraints (e.g., TREE) contribute to the goodness of BP's approximation?

[24]An alternative is to attempt to find the most probable ("MAP") assignment to all variables—using the max-product algorithm (footnote 13) or one of its recent variants. The estimated marginal beliefs become "max marginals," which assess the 1-best assignment consistent with each value of the variable.

We can indeed build max-product propagators for our global constraints. PTREE still propagates in $O(n^3)$ time: simply change the first-order parser's semiring (Goodman, 1999) to use max instead of sum. TREE requires $O(n^4)$ time: it seems that the $O(n^2)$ max marginals must be computed separately, each requiring a separate call to an $O(n^2)$ maximum spanning tree algorithm (Tarjan, 1977).

If max-product BP converges, we may simply output each variable's favorite value (according to its belief), if unique. However, max-product BP tends to be unstable on loopy graphs, and we may not wish to wait for full convergence in any case. A more robust technique for extracting an assignment is to mimic Viterbi decoding, and "follow backpointers" of the max-product computation along some spanning subtree of the factor graph.

A slower but potentially more stable alternative is deterministic annealing. Replace each factor $F_m(\mathcal{A})$ with $F_m(\mathcal{A})^{1/T}$, where $T > 0$ is a **temperature**. As $T \to 0$ ("quenches"), the distribution (1) retains the same mode (the MAP assignment), but becomes more sharply peaked at the mode, and sum-product BP approaches max-product BP. Deterministic annealing runs sum-product BP while gradually reducing T toward 0 as it iterates. By starting at a high T and reducing T slowly, it often manages in practice to find a good local optimum. We may then extract an assignment just as we do for max-product.

[25]One could use coarser estimates at earlier stages of training, by running fewer iterations of BP.

[26]The BP framework makes it tempting to extend an MRF model with various sorts of latent variables, whose values are not specified in training data. It is straightforward to train under these conditions. When counting which features fire on a training parse or (for error-driven training) on an current erroneous parse, we can find *expected* counts if these parses are not fully observed, by using BP to sum over latent variables.

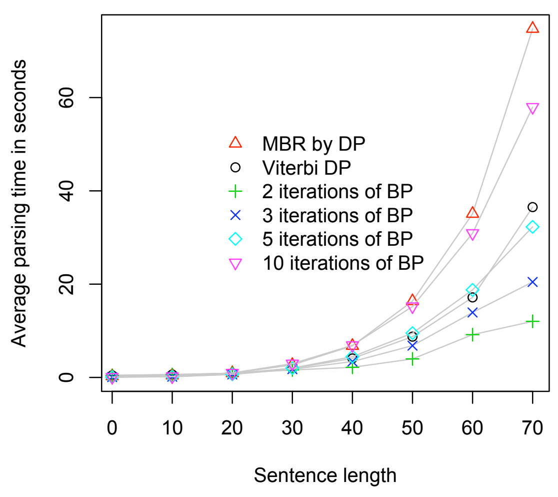

Figure 2: Runtime of BP parser on various sentence lengths compared to $O(n^4)$ dynamic programming.

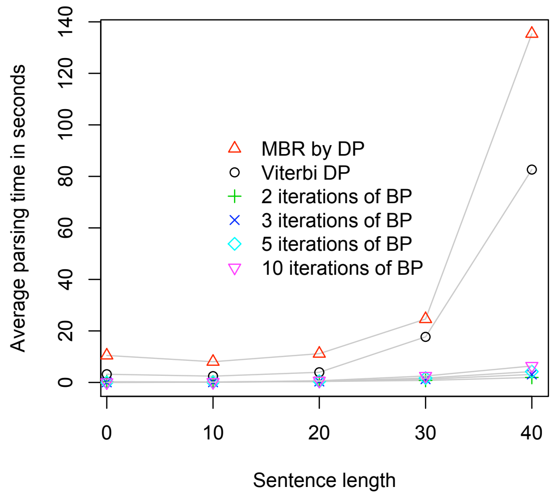

Figure 3: Runtime of BP parser on various sentence lengths compared to $O(n^5)$ dynamic programming. DP is so slow for length > 45 that we do not even show it.

8.1 Data

We trained and tested on three languages from the CoNLL Dependency Parsing Shared Task (Nivre et al., 2007). The English data for that task were converted from the Penn Treebank to dependencies using a trace-recovery algorithm that induced some very slight non-projectivity—about 1% of links crossed other links. Danish is a slightly more non-projective language (3% crossing links). Dutch is the most non-projective language in the corpus (11%). In all cases, the test input W consists of part-of-speech-tagged words, so T variables were not used.

8.2 Features

Although BP makes it cheap to incorporate many non-local features and latent variables at once, we kept our models relatively simple in this paper.

Our first-order LINK$_{ij}$ factors replicate McDonald et al. (2005). Following equation (2), they are defined using binary features that look at words i and j, the distance $j - i$, and the tags (provided in W) of words at, around, and between i and j.

Our second-order features are similar. In the GRAND factors, features fire for particular triples of tags and of coarse tags. A feature also fires if the grandparent falls between the child and parent, inducing crossing dependency links. The CHILD-SEQ factors included features for tags, and likewise coarse tags, on adjacent sibling pairs and parent-sibling-sibling triples. Each of these features also have versions that were conjoined with link direction—pairs of directions in the grandparent case—or with signed link length of the child or farther sibling. Lengths were binned per McDonald et al. (2005). The NOCROSS$_{j\ell}$ factors consider the tag and coarse tag attributes of the two child words j and ℓ, separately or jointly.

8.3 Experimental procedures

We trained all models using stochastic gradient descent (§7). SGD initialized $\vec{\theta} = 0$ and ran for 10 consecutive passes over the data; we picked the stopping point that performed best on held-out data.

When comparing runtimes for projective parsers, we took care to produce comparable implementations. All beliefs and dynamic programming items were stored and indexed using the high-level Dyna language,[27] while all inference and propagation was written in C++. The BP parser averaged 1.8 seconds per sentence for non-projective parsing and 1.5 seconds per sentence for projective parsing (1.2 and 0.9 seconds/sentence for $\leq$ 40 words), using our standard setup, which included five iterations of BP and the final MBR tree decoding pass.

In our tables, we boldface the best result in each column along with any results that are not significantly worse (paired permutation test, $p < .05$).

[27]This dominates runtime, and probably slows down all our parsers by a factor of 4–11 owing to known inefficiencies in the Dyna prototype we used (Eisner et al., 2005).

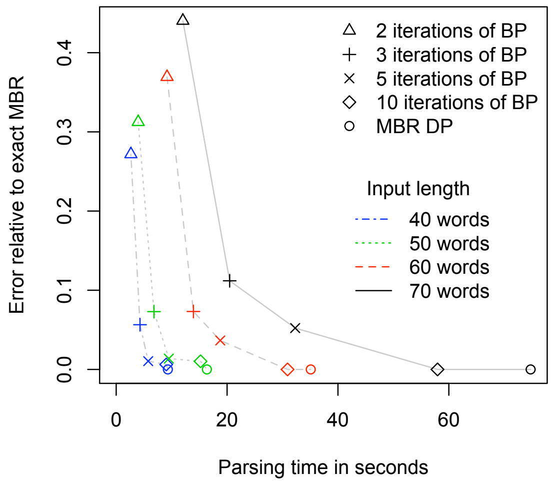

Figure 4: Runtime vs. search error after different numbers of BP iterations. This shows the simpler model of Fig. 2, where DP is still relatively fast.

8.4 Faster higher-order projective parsing

We built a first-order projective parser—one that uses only factors PTREE and LINK—and then compared the cost of incorporating second-order factors, GRAND and CHILDSEQ, by BP versus DP.[28]

Under DP, the first-order runtime of $O(n^3)$ is increased to $O(n^4)$ with GRAND, and to $O(n^5)$ when we add CHILDSEQ as well. BP keeps runtime down to $O(n^3)$—although with a higher constant factor, since it takes several rounds to converge, and since it computes more than just the best parse.[29]

Figures 2–3 compare the empirical runtimes for various input sentence lengths. With only the GRAND factor, exact DP can still find the Viterbi parse (though not the MBR parse[29]) faster than ten iterations of the asymptotically better BP (Fig. 2), at least for sentences with $n \leq 75$. However, once we add the CHILDSEQ factor, BP is always faster—dramatically so for longer sentences (Fig. 3). More complex models would widen BP's advantage.

Fig. 4 shows the tradeoff between runtime and search error of BP in the former case (GRAND only). To determine BP's search error at finding the MBR parse, we measured its dependency accuracy not against the gold standard, but against the optimal MBR parse under the model, which DP is able to find. After 10 iterations, the overall macro-averaged search error compared to $O(n^4)$ DP MBR is 0.4%; compared to $O(n^5)$ (not shown), 2.4%. More BP iterations may help accuracy. In future work, we plan to compare BP's speed-accuracy curve on more complex projective models with the speed-accuracy curve of *pruned* or *reranked* DP.

[28]We trained these parsers using exact DP, using the inside-outside algorithm to compute equation (10). The training and test data were English, and for this section we filtered out sentences with non-projective links.

[29]Viterbi parsing in the log domain only needs the $(\max, +)$ semiring, whereas both BP and any MBR parsing must use the slower $(+, \log+)$ so that they can compute marginals.

		Danish	Dutch	English
(a)	TREE+LINK	85.5	87.3	88.6
	+NOCROSS	86.1	88.3	89.1
	+GRAND	86.1	**88.6**	89.4
	+CHILDSEQ	**86.5**	**88.5**	90.1
(b)	Proj. DP	86.0	84.5	**90.2**
	+hill-climbing	86.1	87.6	**90.2**

Table 2: (a) Percent unlabeled dependency accuracy for various non-projective BP parsers (5 iterations only), showing the cumulative contribution of different features. (b) Accuracy for an projective DP parser with all features. For relatively non-projective languages (Danish and especially Dutch), the exact projective parses can be improved by non-projective hill-climbing—but in those cases, just running our non-projective BP is better and faster.

8.5 Higher-order non-projective parsing

The BP approximation can be used to improve the accuracy of *non*-projective parsing by adding higher-order features. These would be NP-hard to incorporate exactly; DP cannot be used.

We used BP with a non-projective TREE factor to train conditional log-linear parsing models of two highly non-projective languages, Danish and Dutch, as well as slightly non-projective English (§8.1). In all three languages, the first-order non-projective parser greatly overpredicts the number of crossing links. We thus added NOCROSS factors, as well as GRAND and CHILDSEQ as before. All of these significantly improve the first-order baseline, though not necessarily cumulatively (Table 2).

Finally, Table 2 compares loopy BP to a previously proposed "hill-climbing" method for approximate inference in non-projective parsing McDonald and Pereira (2006). Hill-climbing decodes our richest non-projective model by finding the best *projective* parse under that model—using slow, *higher-order* DP—and then greedily modifies words' parents until the parse score (1) stops improving.

Decoding	Danish	Dutch	English
NOT2	81.8 (76.7)	83.3 (75.0)	87.5 (66.4)
ATMOST1	85.4 (82.2)	**87.3** (86.3)	88.5 (84.6)
EXACTLY1	**85.7** (85.0)	87.0 (86.7)	88.6 (86.0)
+ NO2CYCLE	85.0 (**85.2**)	86.2 (86.7)	88.5 (86.2)
TREE	**85.5** (**85.5**)	**87.3** (**87.3**)	88.6 (**88.6**)
PTREE	**85.8**	83.9	**88.8**

Table 3: After training a non-projective first-order model with TREE, decoding it with weaker constraints is asymptotically faster (except for NOT2) but usually harmful. (Parenthetical numbers show that the harm is compounded if the weaker constraints are used in training as well; even though this matches training to test conditions, it may suffer more from BP's approximate gradients.) Decoding the TREE model with the even stronger PTREE constraint can actually be helpful for a more projective language. All results use 5 iterations of BP.

BP for non-projective languages is much faster and more accurate than the hill-climbing method. Also, hill-climbing only produces an (approximate) 1-best parse, but BP also obtains (approximate) marginals of the distribution over *all* parses.

8.6 Importance of global hard constraints

Given the BP architecture, do we even need the hard TREE constraint? Or would it suffice for more local hard constraints to negotiate locally via BP?

We investigated this for non-projective first-order parsing. Table 3 shows that global constraints are indeed important, and that it is essential to use TREE during training. At test time, the weaker but still global EXACTLY1 may suffice (followed by MBR decoding to eliminate cycles), for total time $O(n^2)$.

Table 3 includes NOT2, which takes $O(n^3)$ time, merely to demonstrate how the BP approximation becomes more accurate for training and decoding when we join the simple NOT2 constraints into more global ATMOST1 constraints. This does not change the distribution (1), but makes BP enforce stronger local consistency requirements at the factors, relying less on independence assumptions. In general, one can get better BP approximations by replacing a group of factors $F_m(\mathcal{A})$ with their product.[30]

The above experiments concern *gold-standard* accuracy under a given *first-order*, *non-projective* model. Flipping all three of these parameters for Danish, we confirmed the pattern by instead measuring *search error* under a *higher-order*, *projective* model (PTREE+LINK+GRAND), when PTREE was weakened during decoding. Compared to the MBR parse under that model, the search errors from decoding with weaker hard constraints were 2.2% for NOT2, 2.1% for EXACTLY1, 1.7% for EXACTLY1 + NO2CYCLE, and 0.0% for PTREE.

9 Conclusions and Future Work

Belief propagation improves *non-projective* dependency parsing with features that would make exact inference intractable. For *projective* parsing, it is significantly faster than exact dynamic programming, at the cost of small amounts of search error,

We are interested in extending these ideas to phrase-structure and lattice parsing, and in trying other higher-order features, such as those used in parse reranking (Charniak and Johnson, 2005; Huang, 2008) and history-based parsing (Nivre and McDonald, 2008). We could also introduce new variables, e.g., nonterminal refinements (Matsuzaki et al., 2005), or secondary links M_{ij} (not constrained by TREE/PTREE) that augment the parse with representations of control, binding, etc. (Sleator and Temperley, 1993; Buch-Kromann, 2006).

Other parsing-like problems that could be attacked with BP appear in syntax-based machine translation. Decoding is very expensive with a synchronous grammar composed with an n-gram language model (Chiang, 2007)—but our footnote 10 suggests that BP might incorporate a language model rapidly. String alignment with synchronous grammars is quite expensive even for simple synchronous formalisms like ITG (Wu, 1997)—but Duchi et al. (2007) show how to incorporate bipartite matching into max-product BP.

Finally, we can take advantage of improvements to BP proposed in the context of other applications. For example, instead of updating all messages in parallel at every iteration, it is empirically faster to serialize updates using a priority queue (Elidan et al., 2006; Sutton and McCallum, 2007).[31]

[30]In the limit, one could replace the product (1) with a single all-purpose factor; then BP would be exact—but slow. (In constraint satisfaction, joining constraints similarly makes arc consistency slower but better at eliminating impossible values.)

[31]These methods need alteration to handle our global propagators, which do update all their outgoing messages at once.

Abstract

We explore a stacked framework for learning to predict dependency structures for natural language sentences. A typical approach in graph-based dependency parsing has been to assume a factorized model, where local features are used but a global function is optimized (McDonald et al., 2005b). Recently Nivre and McDonald (2008) used the output of one dependency parser to provide features for another. We show that this is an example of *stacked learning*, in which a second predictor is trained to improve the performance of the first. Further, we argue that this technique is a novel way of approximating rich *non-local features* in the second parser, without sacrificing efficient, model-optimal prediction. Experiments on twelve languages show that stacking transition-based and graph-based parsers improves performance over existing state-of-the-art dependency parsers.

1 Introduction

In this paper we address a representation-efficiency tradeoff in statistical natural language processing through the use of **stacked learning** (Wolpert, 1992). This tradeoff is exemplified in **dependency parsing**, illustrated in Fig. 1, on which we focus in this paper:

- Exact algorithms for dependency parsing (Eisner and Satta, 1999; McDonald et al., 2005b) are tractable only when the model makes very strong, linguistically unsupportable independence assumptions, such as "arc factorization" for non-projective dependency parsing (McDonald and Satta, 2007).
- Feature-rich parsers must resort to search or greediness, (Ratnaparkhi et al., 1994; Sagae and Lavie, 2005; Hall et al., 2006), so that parsing solutions are inexact and learned models may be subject to certain kinds of bias (Lafferty et al., 2001).

A solution that leverages the complementary strengths of these two approaches—described in detail by McDonald and Nivre (2007)—was recently and successfully explored by Nivre and McDonald (2008). Our contribution begins by reinterpreting and generalizing their parser combination scheme as a **stacking of parsers**.

We give a new theoretical motivation for stacking parsers, in terms of extending a parsing model's feature space. Specifically, we view stacked learning as a way of approximating non-local features in a linear model, rather than making empirically dubious independence (McDonald et al., 2005b) or structural assumptions (e.g., projectivity, Eisner, 1996), using search approximations (Sagae and Lavie, 2005; Hall et al., 2006; McDonald and Pereira, 2006), solving a (generally NP-hard) integer linear program (Riedel and Clarke, 2006), or adding latent variables (Titov and Henderson, 2007). Notably, we introduce the use of very rich non-local *approximate* features in one parser, through the output of another parser. Related approaches are the belief propagation algorithm of Smith and Eisner (2008), and the "trading of structure for features" explored by Liang et al.

Figure 1: A projective dependency parse (top), and a non-projective dependency parse (bottom) for two English sentences; examples from McDonald and Satta (2007).

(2008).

This paper focuses on dependency parsing, which has become widely used in relation extraction (Culotta and Sorensen, 2004), machine translation (Ding and Palmer, 2005), question answering (Wang et al., 2007), and many other NLP applications. We show that stacking methods outperform the approximate "second-order" parser of McDonald and Pereira (2006) on twelve languages and can be used within that approximation to achieve even better results. These results are similar in spirit to (Nivre and McDonald, 2008), but with the following novel contributions:

- a stacking interpretation,
- a richer feature set that includes non-local features (shown here to improve performance), and
- a variety of stacking architectures.

Using stacking with rich features, we obtain results competitive with Nivre and McDonald (2008) while preserving the fast quadratic parsing time of arc-factored spanning tree algorithms.

The paper is organized as follows. We discuss related prior work on dependency parsing and stacking in §2. Our model is given in §3. A novel analysis of stacking in linear models is given in §4. Experiments are presented in §5.

2 Background and Related Work

We briefly review work on the NLP task of **dependency parsing** and the machine learning framework known as **stacked learning**.

2.1 Dependency Parsing

Dependency syntax is a lightweight syntactic representation that models a sentence as a graph where the words are vertices and syntactic relationships are directed edges (arcs) connecting heads to their arguments and modifiers.

Dependency parsing is often viewed computationally as a structured prediction problem: for each input sentence x, with n words, exponentially many candidate dependency trees $y \in \mathcal{Y}(x)$ are possible in principle. We denote each tree by its set of vertices and directed arcs, $y = (V_y, A_y)$. A legal dependency tree has $n + 1$ vertices, each corresponding to one word plus a "wall" symbol, $, assumed to be the hidden root of the sentence. In a valid dependency tree, each vertex except the root has exactly one parent. In the *projective* case, arcs cannot cross when depicted on one side of the sentence; in the *non-projective* case, this constraint is not imposed (see Fig. 1).

2.1.1 Graph-based *vs.* transition-based models

Most recent work on dependency parsing can be categorized as *graph-based* or *transition-based*. In graph-based parsing, dependency trees are scored by factoring the tree into its arcs, and parsing is performed by searching for the highest scoring tree (Eisner, 1996; McDonald et al., 2005b). Transition-based parsers model the sequence of decisions of a shift-reduce parser, given previous decisions and current state, and parsing is performed by greedily choosing the highest scoring transition out of each successive parsing state or by searching for the best sequence of transitions (Ratnaparkhi et al., 1994; Yamada and Matsumoto, 2003; Nivre et al., 2004; Sagae and Lavie, 2005; Hall et al., 2006).

Both approaches most commonly use linear models to assign scores to arcs or decisions, so that a score is a dot-product of a feature vector $\mathbf{f}$ and a learned weight vector $\mathbf{w}$.

In sum, these two lines of research use different approximations to achieve tractability. Transition-based approaches solve a sequence of *local* problems in sequence, sacrificing global optimality guarantees and possibly expressive power (Abney et al., 1999). Graph-based methods perform *global* inference using score factorizations that correspond to strong independence assumptions (discussed in

§2.1.2). Recently, Nivre and McDonald (2008) proposed *combining* a graph-based and a transition-based parser and have shown a significant improvement for several languages by letting one of the parsers "guide" the other. Our stacked formalism (to be described in §3) generalizes this approach.

2.1.2 Arc factorization

In the successful graph-based method of McDonald et al. (2005b), an *arc factorization* independence assumption is used to ensure tractability. This assumption forbids any feature that depends on two or more arcs, permitting only "arc-factored" features (i.e. features that depend only on a single candidate arc $a \in A_y$ and on the input sequence x). This induces a decomposition of the feature vector $\mathbf{f}(x, y)$ as:

$$\mathbf{f}(x, y) = \sum_{a \in A_y} \mathbf{f}_a(x).$$

Parsing amounts to solving $\arg\max_{y \in \mathcal{Y}(x)} \mathbf{w}^\top \mathbf{f}(x, y)$, where $\mathbf{w}$ is a weight vector. With a projectivity constraint and arc factorization, the parsing problem can be solved in cubic time by dynamic programming (Eisner, 1996), and with a weaker "tree" constraint (permitting nonprojective parses) and arc factorization, a quadratic-time algorithm exists (Chu and Liu, 1965; Edmonds, 1967), as shown by McDonald et al. (2005b). In the projective case, the arc-factored assumption can be weakened in certain ways while maintaining polynomial parser runtime (Eisner and Satta, 1999), but not in the nonprojective case (McDonald and Satta, 2007), where finding the highest-scoring tree becomes NP-hard.

McDonald and Pereira (2006) adopted an approximation based on $O(n^3)$ projective parsing followed by rearrangement to permit crossing arcs, achieving higher performance. In §3 we adopt a framework that maintains $O(n^2)$ runtime (still exploiting the Chu-Liu-Edmonds algorithm) while approximating non arc-factored features.

2.2 Stacked Learning

Stacked generalization was first proposed by Wolpert (1992) and Breiman (1996) for regression. The idea is to include two "levels" of predictors. The first level, "level 0," includes one or more predictors $g_1, \ldots, g_K : \mathbb{R}^d \to \mathbb{R}$; each receives input $\mathbf{x} \in \mathbb{R}^d$ and outputs a prediction $g_k(\mathbf{x})$. The second level, "level 1," consists of a single function $h : \mathbb{R}^{d+K} \to \mathbb{R}$ that takes as input $\langle \mathbf{x}, g_1(\mathbf{x}), \ldots g_K(\mathbf{x}) \rangle$ and outputs a final prediction $\hat{y} = h(\mathbf{x}, g_1(\mathbf{x}), \ldots g_K(\mathbf{x}))$. The predictor, then, combines an ensemble (the g_k) with a meta-predictor (h).

Training is done as follows: the training data are split into L partitions, and L instances of the level 0 predictor are trained in a "leave-one-out" basis. Then, an augmented dataset is formed by letting each instance output predictions for the partition that was left out. Finally, each level 0 predictor is trained using the original dataset, and the level 1 predictor is trained on the augmented dataset, simulating the test-time setting when h is applied to a new instance $\mathbf{x}$ concatenated with $\langle g_k(\mathbf{x}) \rangle_k$.

This framework has also been applied to classification, for example with structured data. Some applications (including here) use only one classifier at level 0; recent work includes sequence labeling (Cohen and de Carvalho, 2005) and inference in conditional random fields (Kou and Cohen, 2007). Stacking is also intuitively related to transformation-based learning (Brill, 1993).

3 Stacked Dependency Parsing

We next describe how to use stacked learning for efficient, rich-featured dependency parsing.

3.1 Architecture

The architecture consists of two levels. At level 0 we include a single dependency parser. At runtime, this "level 0 parser" g processes an input sentence x and outputs the set of predicted edges that make up its estimation of the dependency tree, $\hat{y}_0 = g(x)$. At level 1, we apply a dependency parser—in this work, always a graph-based dependency parser—that uses basic factored features *plus* new ones from the edges *predicted* by the level 0 parser. The final parser predicts parse trees as $h(x, g(x))$, so that the total runtime is additive in calculating $h(\cdot)$ and $g(\cdot)$.

The stacking framework is agnostic about the form of g and h and the methods used to learn them from data. In this work we use two well-known, publicly available dependency parsers, MSTParser (McDonald et al., 2005b),[1] which implements ex-

[1] `http://sourceforge.net/projects/mstparser`

act first-order arc-factored nonprojective parsing (§2.1.2) and approximate second-order nonprojective parsing, and MaltParser (Nivre et al., 2006), which is a state-of-the-art transition-based parser.[2] We do not alter the training algorithms used in prior work for learning these two parsers from data. Using the existing parsers as starting points, we will combine them in a variety of ways.

3.2 Training

Regardless of our choices for the specific parsers and learning algorithms at level 0 and level 1, training is done as sketched in §2.2. Let $\mathcal{D}$ be a set of training examples $\{\langle x_i, y_i \rangle\}_i$.

1. Split training data $\mathcal{D}$ into L partitions $\mathcal{D}^1, \ldots, \mathcal{D}^L$.
2. Train L instances of the level 0 parser in the following way: the l-th instance, g^l, is trained on $\mathcal{D}^{-l} = \mathcal{D} \setminus \mathcal{D}^l$. Then use g^l to output predictions for the (unseen) partition $\mathcal{D}^l$. At the end, an augmented dataset $\tilde{\mathcal{D}} = \bigcup_{l=1}^{L} \tilde{\mathcal{D}}^l$ is built, so that $\tilde{\mathcal{D}} = \{\langle x_i, g(x_i), y_i \rangle\}_i$.
3. Train the level 0 parser g on the original training data $\mathcal{D}$.
4. Train the level 1 parser h on the augmented training data $\tilde{\mathcal{D}}$.

The runtime of this algorithm is $O(LT_0 + T_1)$, where T_0 and T_1 are the individual runtimes required for training level 0 and level 1 alone, respectively.

4 Two Views of Stacked Parsing

We next describe two motivations for stacking parsers: as a way of augmenting the features of a graph-based dependency parser or as a way to approximate higher-order models.

4.1 Adding Input Features

Suppose that the level 1 classifier is an arc-factored graph-based parser. The feature vectors will take the form[3]

$$\begin{aligned} \mathbf{f}(x, y) &= \mathbf{f}_1(x, y) \smile \mathbf{f}_2(x, \hat{y}_0, y) \\ &= \sum_{a \in A_y} \mathbf{f}_{1,a}(x) \smile \mathbf{f}_{2,a}(x, g(x)), \end{aligned}$$

where $\mathbf{f}_1(x, y) = \sum_{a \in A_y} \mathbf{f}_{1,a}(x)$ are regular arc-factored features, and $\mathbf{f}_2(x, \hat{y}_0, y) = \sum_{a \in A_y} \mathbf{f}_{2,a}(x, g(x))$ are the *stacked features*. An example of a stacked feature is a binary feature $f_{2,a}(x, g(x))$ that fires if and only if the arc a was predicted by g, i.e., if $a \in A_{g(x)}$; such a feature was used by Nivre and McDonald (2008).

It is difficult in general to decide whether the inclusion of such a feature yields a better parser, since features strongly correlate with each other. However, a popular heuristic for feature selection consists of measuring the *information gain* provided by each individual feature. In this case, we may obtain a closed-form expression for the information gain that $f_{2,a}(x, g(x))$ provides about the existence or not of the arc a in the actual dependency tree y. Let A and A' be binary random variables associated with the events $a \in A_y$ and $a' \in A_{g(x)}$, respectively. We have:

$$\begin{aligned} I(A; A') &= \sum_{a, a' \in \{0,1\}} p(a, a') \log_2 \frac{p(a, a')}{p(a)p(a')} \\ &= H(A') - \sum_{a \in \{0,1\}} p(a) H(A' | A = a). \end{aligned}$$

Assuming, for simplicity, that at level 0 the probability of false positives equals the probability of false negatives (i.e., $P_{\text{err}} \triangleq p(a' = 0 | a = 1) = p(a' = 1 | a = 0)$), and that the probability of true positives equals the probability of true negatives ($1 - P_{\text{err}} = p(a' = 0 | a = 0) = p(a' = 1 | a = 1)$), the expression above reduces to:

$$\begin{aligned} I(A; A') &= H(A') + P_{\text{err}} \log_2 P_{\text{err}} \\ &+ (1 - P_{\text{err}}) \log_2 (1 - P_{\text{err}}) \\ &= H(A') - H_{\text{err}}, \end{aligned}$$

where H_{err} denotes the entropy of the probability of error on each arc's prediction by the level 0 classifier. If $P_{\text{err}} \leq 0.5$ (i.e. if the level 0 classifier is better than random), then the information gain provided by this simple stacked feature increases with (a) the accuracy of the level 0 classifier, and (b) the entropy $H(A')$ of the distribution associated with its arc predictions.

4.2 Approximating Non-factored Features

Another way of interpreting the stacking framework is as a means to approximate a higher order model,

[2] `http://w3.msi.vxu.se/~jha/maltparser`

[3] We use $\smile$ to denote vector concatenation.

such as one that is not arc-factored, by using stacked features that make use of the predicted structure *around* a candidate arc. Consider a second-order model where the features decompose by arc and by arc *pair*:

$$\mathbf{f}(x,y) = \sum_{a_1 \in A_y} \left(\mathbf{f}_{a_1}(x) \smile \sum_{a_2 \in A_y} \mathbf{f}_{a_1,a_2}(x) \right).$$

Exact parsing under such model, with arbitrary second-order features, is intractable (McDonald and Satta, 2007). Let us now consider a stacked model in which the level 0 predictor outputs a parse $\hat{y}$. At level 1, we use arc-factored features that may be written as

$$\tilde{\mathbf{f}}(x,y) = \sum_{a_1 \in A_y} \left(\mathbf{f}_{a_1}(x) \smile \sum_{a_2 \in A_{\hat{y}}} \mathbf{f}_{a_1,a_2}(x) \right);$$

this model differs from the previous one only by replacing A_y by $A_{\hat{y}}$ in the index set of the second summation. Since $\hat{y}$ is given, this makes the latter model arc-factored, and therefore, tractable. We can now view $\tilde{\mathbf{f}}(x,y)$ as an approximation of $\mathbf{f}(x,y)$; indeed, we can bound the *score approximation error*,

$$\Delta s(x,y) = \left| \tilde{\mathbf{w}}^\top \tilde{\mathbf{f}}(x,y) - \mathbf{w}^\top \mathbf{f}(x,y) \right|,$$

where $\tilde{\mathbf{w}}$ and $\mathbf{w}$ stand respectively for the parameters learned for the stacked model and those that would be learned for the (intractable) exact second order model. We can bound $\Delta s(x,y)$ by spliting it into two terms: $\Delta s(x,y) =$

$$\begin{aligned} &\left| (\tilde{\mathbf{w}} - \mathbf{w})^\top \tilde{\mathbf{f}}(x,y) + \mathbf{w}^\top (\tilde{\mathbf{f}}(x,y) - \mathbf{f}(x,y)) \right| \\ &\leq \underbrace{\left| (\tilde{\mathbf{w}} - \mathbf{w})^\top \tilde{\mathbf{f}}(x,y) \right|}_{\triangleq \Delta s_{\text{tr}}(x,y)} + \underbrace{\left| \mathbf{w}^\top (\tilde{\mathbf{f}}(x,y) - \mathbf{f}(x,y)) \right|}_{\triangleq \Delta s_{\text{dec}}(x,y)}; \end{aligned}$$

where we introduced the terms Δs_{tr} and Δs_{dec} that reflect the portion of the score approximation error that are due to *training error* (i.e., different parameterizations of the exact and approximate models) and *decoding error* (same parameterizations, but different feature vectors). Using Hölder's inequality, the former term can be bounded as:

$$\begin{aligned} \Delta s_{\text{tr}}(x,y) &= \left| (\tilde{\mathbf{w}} - \mathbf{w})^\top \tilde{\mathbf{f}}(x,y) \right| \\ &\leq \|\tilde{\mathbf{w}} - \mathbf{w}\|_1 \cdot \|\tilde{\mathbf{f}}(x,y)\|_\infty \\ &\leq \|\tilde{\mathbf{w}} - \mathbf{w}\|_1; \end{aligned}$$

where $\|.\|_1$ and $\|.\|_\infty$ denote the ℓ_1-norm and sup-norm, respectively, and the last inequality holds when the features are binary (so that $\|\tilde{\mathbf{f}}(x,y)\|_\infty \leq 1$). The proper way to bound the term $\|\tilde{\mathbf{w}} - \mathbf{w}\|_1$ depends on the training algorithm. As for the decoding error term, it can bounded for a given weight vector $\mathbf{w}$, sentence x, candidate tree y, and level 0 prediction $\hat{y}$. Decomposing the weighted vector as $\mathbf{w} = \mathbf{w}_1 \smile \mathbf{w}_2$, $\mathbf{w}_2$ being the sub-vector associated with the second-order features, we have respectively: $\Delta s_{\text{dec}}(x,y) =$

$$\begin{aligned} &\left| \mathbf{w}^\top (\tilde{\mathbf{f}}(x,y) - \mathbf{f}(x,y)) \right| \\ &= \left| \sum_{a_1 \in A_y} \mathbf{w}_2^\top \left(\sum_{a_2 \in A_{\hat{y}}} \mathbf{f}_{a_1,a_2}(x) - \sum_{a_2 \in A_y} \mathbf{f}_{a_1,a_2}(x) \right) \right| \\ &\leq \sum_{a_1 \in A_y} \sum_{a_2 \in A_{\hat{y}} \Delta A_y} \left| \mathbf{w}_2^\top \mathbf{f}_{a_1,a_2}(x) \right| \\ &\leq \sum_{a_1 \in A_y} |A_{\hat{y}} \Delta A_y| \cdot \max_{a_2 \in A_{\hat{y}} \Delta A_y} \left| \mathbf{w}_2^\top \mathbf{f}_{a_1,a_2}(x) \right| \\ &= \sum_{a_1 \in A_y} 2L(y,\hat{y}) \cdot \max_{a_2 \in A_{\hat{y}} \Delta A_y} \left| \mathbf{w}_2^\top \mathbf{f}_{a_1,a_2}(x) \right|, \end{aligned}$$

where $A_{\hat{y}} \Delta A_y \triangleq (A_{\hat{y}} - A_y) \cup (A_y - A_{\hat{y}})$ denotes the *symmetric difference* of the sets $A_{\hat{y}}$ and A_y, which has cardinality $2L(y,\hat{y})$, *i.e.*, twice the Hamming distance between the sequences of heads that characterize y and the predicted parse $\hat{y}$. Using Hölder's inequality, we have both

$$\begin{aligned} \left| \mathbf{w}_2^\top \mathbf{f}_{a_1,a_2}(x) \right| &\leq \|\mathbf{w}_2\|_1 \cdot \|\mathbf{f}_{a_1,a_2}(x)\|_\infty \\ \text{and } \left| \mathbf{w}_2^\top \mathbf{f}_{a_1,a_2}(x) \right| &\leq \|\mathbf{w}_2\|_\infty \cdot \|\mathbf{f}_{a_1,a_2}(x)\|_1. \end{aligned}$$

Assuming that all features are binary valued, we have that $\|\mathbf{f}_{a_1,a_2}(x)\|_\infty \leq 1$ and that $\|\mathbf{f}_{a_1,a_2}(x)\|_1 \leq N_{f,2}$, where $N_{f,2}$ denotes the maximum number of active second order features for any possible pair of arcs (a_1, a_2). Therefore:

$$\Delta s_{\text{dec}}(x,y) \leq 2nL(y,\hat{y}) \min\{\|\mathbf{w}_2\|_1, N_{f,2} \cdot \|\mathbf{w}_2\|_\infty\},$$

where n is the sentence length. Although this bound can be loose, it suggests (intuitively) that the score approximation degrades as the predicted tree $\hat{y}$ gets farther away from the true tree y (in Hamming distance). It also degrades with the magnitude of weights associated with the second-order features,

Name	Description
PredEdge	Indicates whether the candidate edge was present, and what was its label.
Sibling	Lemma, POS, link label, distance and direction of attachment of the previous and and next predicted siblings
GrandParents	Lemma, POS, link label, distance and direction of attachment of the grandparent of the current modifier
PredHead	Predicted head of the candidate modifier (if PredEdge=0)
AllChildren	Sequence of POS and link labels of all the predicted children of the candidate head

Table 1: Feature sets derived from the level 0 parser.

Subset	Description
A	PredEdge
B	PredEdge+Sibling
C	PredEdge+Sibling+GrandParents
D	PredEdge+Sibling+GrandParents+PredHead
E	PredEdge+Sibling+GrandParents+PredHead+ AllChildren

Table 2: Combinations of features enumerated in Table 1 used for stacking. A is a replication of (Nivre and McDonald, 2008), except for the modifications described in footnote 4.

which suggests that a separate regularization of the first-order and stacked features might be beneficial in a stacking framework.

As a side note, if we set each component of the weight vector to one, we obtain a bound on the ℓ_1-norm of the feature vector difference, $\left\|\tilde{\mathbf{f}}(x,y) - \mathbf{f}(x,y)\right\|_1 \leq 2nL(y,\hat{y})N_{f,2}$.

5 Experiments

In the following experiments we demonstrate the effectiveness of stacking parsers. As noted in §3.1, we make use of two component parsers, the graph-based MSTParser and the transition-based MaltParser.

5.1 Implementation and Experimental Details

The publicly available version of MSTParser performs parsing and labeling jointly. We adapted this system to first perform unlabeled parsing, then label the arcs using a log-linear classifier with access to the full unlabeled parse (McDonald et al., 2005a; McDonald et al., 2005b; McDonald and Pereira, 2006). In stacking experiments, the arc labels from the level 0 parser are also used as a feature.[4]

In the following subsections, we refer to our modification of the MSTParser as MST_{1O} (the arc-factored version) and MST_{2O} (the second-order arc-pair-factored version). All our experiments use the non-projective version of this parser. We refer to the MaltParser as $Malt$.

We report experiments on twelve languages from the CoNLL-X shared task (Buchholz and Marsi, 2006).[5] All experiments are evaluated using the *labeled attachment score* (LAS), using the default settings.[6] Statistical significance is measured using Dan Bikel's randomized parsing evaluation comparator with 10,000 iterations.[7] The additional features used in the level 1 parser are enumerated in Table 1 and their various subsets are depicted in Table 2. The PredEdge features are exactly the six features used by Nivre and McDonald (2008) in their **MST**$_{\text{Malt}}$ parser; therefore, feature set A is a replication of this parser except for modifications noted in footnote 4. In all our experiments, the number of partitions used to create $\tilde{\mathcal{D}}$ is $L = 2$.

5.2 Experiment: $MST_{2O} + MST_{2O}$

Our first experiment stacks the highly accurate MST_{2O} parser with itself. At level 0, the parser uses only the standard features (§5.1), and at level 1, these are augmented by various subsets of features of x along with the output of the level 0 parser, $g(x)$ (Table 2). The results are shown in Table 3. While we see improvements over the single-parser baseline

[4]We made other modifications to MSTParser, implementing many of the successes described by (McDonald et al., 2006). Our version of the code is publicly available at `http://www.ark.cs.cmu.edu/MSTParserStacked`. The modifications included an approximation to lemmas for datasets without lemmas (three-character prefixes), and replacing morphology/word and morphology/lemma features with morphology/POS features.

[5]The CoNLL-X shared task actually involves thirteen languages; our experiments do not include Czech (the largest dataset), due to time constraints. Therefore, the average results plotted in the last rows of Tables 3, 4, and 5 are not directly comparable with previously published averages over thirteen languages.

Table 3: Results of stacking MST_{2O} with itself at both level 0 and level 1. Column 2 enumerates LAS for MST_{2O}. Columns 3–6 enumerate results for four different stacked feature subsets. Bold indicates best results for a particular language.

for nine languages, the improvements are small (less than 0.5%). One of the biggest concerns about this model is the fact that it stacks two predictors that are very similar in nature: both are graph-based and share the features $\mathbf{f}_{1,a}(x)$. It has been pointed out by Breiman (1996), among others, that the success of ensemble methods like stacked learning strongly depends on how uncorrelated the individual decisions made by each predictor are from the others' decisions.[8] This experiment provides further evidence for the claim.

5.3 Experiment: $Malt + MST_{2O}$

We next use MaltParser at level 0 and the *second-order* arc-pair-factored MST_{2O} at level 1. This extends the experiments of Nivre and McDonald (2008), replicated in our feature subset A.

Table 4 enumerates the results. Note that the best-performing stacked configuration for each and every language outperforms MST_{2O}, corroborating results reported by Nivre and McDonald (2008). The best performing stacked configuration outperforms $Malt$ as well, except for Japanese and Turkish. Further, our non-arc-factored features largely outperform subset A, except on Bulgarian, Chinese, and Japanese. On average, the best feature configuration is E, which is statistically significant over $Malt$ and MST_{2O} with $p < 0.0001$, and over feature subset A with $p < 0.01$.

5.4 Experiment: $Malt + MST_{1O}$

Finally, we consider stacking MaltParser with the first-order, arc-factored MSTParser. We view this approach as perhaps the most promising, since it is an exact parsing method with the quadratic runtime complexity of MST_{1O}.

Table 5 enumerates the results. For all twelve languages, some stacked configuration outperforms MST_{1O} and also, surprisingly, MST_{2O}, the second order model. This provides empirical evidence that using rich features from MaltParser at level 0, a stacked level 1 first-order MSTParser can outperform the second-order MSTParser.[9] In only two cases (Japanese and Turkish), the MaltParser slightly outperforms the stacked parser.

On average, feature configuration D performs the best, and is statistically significant over $Malt$, MST_{1O}, and MST_{2O} with $p < 0.0001$, and over feature subset A with $p < 0.05$. Encouragingly, this configuration is barely outperformed by configura-

[8]This claim has a parallel in the cotraining method (Blum and Mitchell, 1998), whose performance is bounded by the degree of independence between the two feature sets.

[9]Recall that MST_{2O} uses approximate *search*, as opposed to stacking, which uses approximate *features*.

Table 4: Results of stacking *Malt* and MST_{2O} at level 0 and level 1, respectively. Columns 2–4 enumerate LAS for *Malt*, MST_{2O} and $Malt + MST_{2O}$ as in Nivre and McDonald (2008). Columns 5–8 enumerate results for four other stacked feature configurations. Bold indicates best result for a language.

tion A of $Malt + MST_{2O}$ (see Table 4), the difference being statistically insignificant ($p > 0.05$). This shows that stacking *Malt* with the exact, arc-factored MST_{1O} bridges the difference between the individual MST_{1O} and MST_{2O} models, by approximating higher order features, but maintaining an $O(n^2)$ runtime and finding the model-optimal parse.

5.5 Disagreement as a Confidence Measure

In pipelines or semisupervised settings, it is useful when a parser can provide a *confidence* measure alongside its predicted parse tree. Because stacked predictors use ensembles with observable outputs, differences among those outputs may be used to estimate confidence in the final output. In stacked dependency parsing, this can be done (for example) by measuring the Hamming distance between the outputs of the level 0 and 1 parsers, $L(g(x), h(x))$. Indeed, the bound derived in §4.2 suggests that the second-order approximation degrades for candidate parses y that are Hamming-far from $g(x)$; therefore, if $L(g(x), h(x))$ is large, the best score $s(x, h(x))$ may well be "biased" due to misleading neighboring information provided by the level 0 parser.

We illustrate this point with an empirical analysis of the level 0/1 disagreement for the set of experiments described in §5.3; namely, we compare the

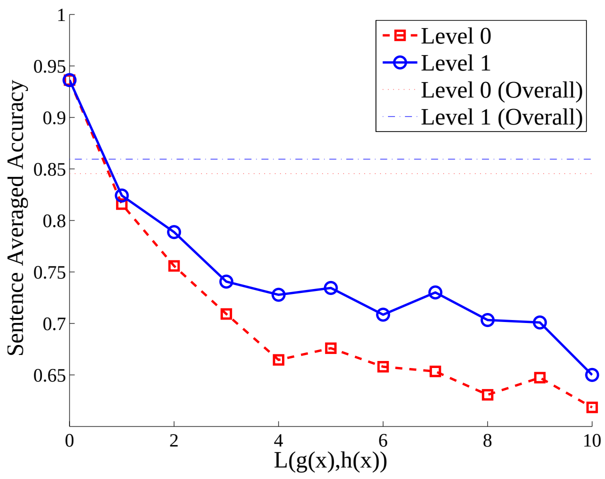

Figure 2: Accuracy as a function of token disagreement between level 0 and level 1. The x-axis is the Hamming distance $L(g(x), h(x))$, i.e., the number of tokens where level 0 and level 1 disagree. The y-axis is the accuracy averaged over sentences that have the specified Hamming distance, both for level 0 and level 1.

Table 5: Results of stacking $Malt$ and MST_{1O} at level 0 and level 1, respectively. Columns 2–4 enumerate LAS for $Malt$, MST_{1O} and MST_{2O}. Columns 5–9 enumerate results for five different stacked feature configurations. Bold indicates the best result for a language.

level 0 and level 1 predictions under the best overall configuration (configuration E of $Malt + MST_{2O}$). Figure 2 depicts accuracy as a function of level 0-level 1 disagreement (in number of tokens), averaged over all datasets.

We can see that performance degrades steeply when the disagreement between levels 0 and 1 increases in the range 0–4, and then behaves more irregularly but keeping the same trend. This suggests that the Hamming distance $L(g(x), h(x))$ is informative about parser performance and may be used as a confidence measure.

6 Conclusion

In this work, we made use of stacked learning to improve dependency parsing. We considered an architecture with two layers, where the output of a standard parser in the first level provides new features for a parser in the subsequent level. During learning, the second parser learns to correct mistakes made by the first one. The novelty of our approach is in the exploitation of higher-order predicted edges to simulate non-local features in the second parser. We provided a novel interpretation of stacking as feature approximation, and our experimental results show rich-featured stacked parsers outperforming state-of-the-art single-layer and ensemble parsers. Notably, using a simple arc-factored parser at level 1, we obtain an exact $O(n^2)$ stacked parser that outperforms earlier approximate methods (McDonald and Pereira, 2006).

Abstract

We present a study on how grammar binarization empirically affects the efficiency of the CKY parsing. We argue that binarizations affect parsing efficiency primarily by affecting the number of incomplete constituents generated, and the effectiveness of binarization also depends on the nature of the input. We propose a novel binarization method utilizing rich information learnt from training corpus. Experimental results not only show that different binarizations have great impacts on parsing efficiency, but also confirm that our learnt binarization outperforms other existing methods. Furthermore we show that it is feasible to combine existing parsing speed-up techniques with our binarization to achieve even better performance.

1 Introduction

Binarization, which transforms an n-ary grammar into an equivalent binary grammar, is essential for achieving an $O(n^3)$ time complexity in the context-free grammar parsing. $O(n^3)$ tabular parsing algorithms, such as the CKY algorithm (Kasami, 1965; Younger, 1967), the GHR parser (Graham et al., 1980), the Earley algorithm (Earley, 1970) and the chart parsing algorithm (Kay, 1980; Klein and Manning, 2001) all convert their grammars into binary branching forms, either explicitly or implicitly (Charniak et al., 1998).

In fact, the number of all possible binarizations of a production with $n+1$ symbols on its right hand side is known to be the nth *Catalan Number* $C_n = \frac{1}{n+1}\binom{2n}{n}$. All binarizations lead to the same parsing accuracy, but maybe different parsing efficiency, i.e. parsing speed. We are interested in investigating whether and how binarizations will affect the efficiency of the CKY parsing.

Do different binarizations lead to different parsing efficiency? Figure 1 gives an example to help answer this question. Figure 1(a) illustrates the correct parse of the phrase "*get the bag and go*". We assume that $NP \rightarrow NP\ CC\ NP$ is in the original grammar. The symbols enclosed in square brackets in the figure are intermediate symbols.

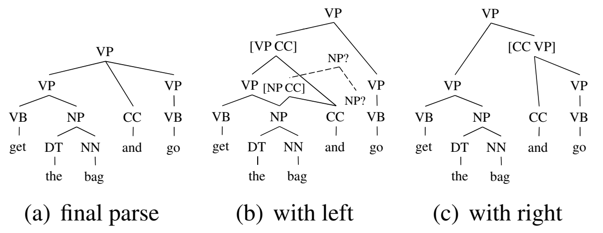

Figure 1: Parsing with left and right binarization.

If a left binarized grammar is used, see Figure 1(b), an extra constituent $[NP\,CC]$ spanning "*the bag and*" will be produced. Because rule $[NP\,CC] \rightarrow NP\,CC$ is in the left binarized grammar and there is an NP over "*the bag*" and a CC over the right adjacent "*and*". Having this constituent is unnecessary, because it lacks an NP to the right to complete the production. However, if a right binarization is used, as shown in Figure 1(c), such unnecessary constituent can be avoided.

One observation from this example is that different binarizations affect constituent generation, thus affect parsing efficiency. Another observation is that

[*]This work was done when Xinying Song and Shilin Ding were visiting students at Microsoft Research Asia.

for rules like $X \to Y\,C\,C\,Y$, it is more suitable to binarize them in a right branching way. This can be seen as a linguistic nature: for "*and*", usually the right neighbouring word can indicate the correct parse. A good binarization should reflect such liguistic nature.

In this paper, we aim to study the effect of binarization on the efficiency of the CKY parsing. To our knowledge, this is the first work on this problem.

We propose the problem to find the optimal binarization in terms of parsing efficiency (Section 3). We argue that binarizations affect parsing efficiency primarily by affecting the number of incomplete constituents generated, and the effectiveness of binarization also depends on the nature of the input (Section 4). Therefore we propose a novel binarization method utilizing rich information learnt from training corpus (Section 5). Experimental results show that our binarization outperforms other existing methods (Section 7.2).

Since binarization is usually a preprocessing step before parsing, we argue that better performance can be achieved by combining other parsing speed-up techniques with our binarization (Section 6). We conduct experiments to confirm this (Section 7.3).

2 Binarization

In this paper we assume that the *original* grammar, perhaps after preprocessing, contains no ϵ-productions or useless symbols. However, we allow the existence of unary productions, since we adopt an extended version of the CKY algorithm which can handle the unary productions. Moreover we do not distinguish nonterminals and terminals explicitly. We treat them as symbols. What we focus on is the procedure of binarization.

Definition 1. A *binarization* is a function π, mapping an n-ary grammar G to an equivalent binary grammar G'. We say that G' is a binarized grammar of G, denoted as $\pi(G)$.

Two grammars are *equivalent* if they define the same probability distribution over strings (Charniak et al., 1998).

We use the most widely used *left binarization* (Aho and Ullman, 1972) to show the procedure of binarization, as illustrated in Table 1, where p and q are the probabilities of the productions.

Original grammar	Left binarized grammar
$Y \to A\,B\,C : p$	$[A\,B] \to A\,B : 1.0$
$Z \to A\,B\,D : q$	$Y \to [A\,B]\,C : p$
	$Z \to [A\,B]\,D : q$

Table 1: Left binarization

In the binarized grammar, symbols of form $[A\,B]$ are *new* (also called *intermediate*) nonterminals. Left binarization always selects the left most pair of symbols and combines them to form an intermediate nonterminal. This procedure is repeated until all productions are binary.

In this paper, we assume that all binarizations follow the fashion above, except that the choice of pair of symbols for combination can be arbitrary. Next we show three other known binarizations.

Right binarization is almost the same with left binarization, except that it always selects the right most pair, instead of left, to combine.

Head binarization always binarizes from the head outward (Klein and Manning, 2003b). Please refer to Charniak et al. (2006) for more details.

Compact binarization (Schmid, 2004) tries to minimize the size of the binarized grammar. It leads to a *compact* grammar. We therefore call it compact binarization. It is done via a greedy approach: it always selects the pair that occurs most on the right hand sides of rules to combine.

3 The optimal binarization

The optimal binarization should help CKY parsing to achieve its best efficiency. We formalize the idea as follows:

Definition 2. The *optimal binarization* is π^*, for a given n-ary grammar G and a test corpus C:

$$\pi^* = \arg\min_{\pi} T(\pi(G), C) \tag{1}$$

where $T(\pi(G), C)$ is the running time for CKY to parse corpus C, using the binarized grammar $\pi(G)$.

It is hard to find the optimal binarization directly from Definition 2. We next give an empirical analysis of the running time of the CKY algorithm and simplify the problem by introducing assumptions.

3.1 Analysis of CKY parsing efficiency

It is known that the complexity of the CKY algorithm is $O(n^3 L)$. The constant L depends on the binarized grammar in use. Therefore binarization will affect L. Our goal is to find a good binarization that makes parsing more efficient.

It is also known that in the inner most loop of CKY as shown in Algorithm 1, the for-statement in Line 1 can be implemented in several different methods. The choice will affect the efficiency of CKY. We present here four possible methods:

M1 Enumerate all rules $X \rightarrow Y\,Z$, and check if Y is in left span and Z in right span.

M2 For each Y in left span, enumerate all rules $X \rightarrow Y\,Z$, and check if Z is in right span.

M3 For each Z in right span, enumerate all rules $X \rightarrow Y\,Z$, and check if Y is in left span.

M4 Enumerate each Y in left span and Z in right span[1], check if there are any rules $X \rightarrow Y\,Z$.

Algorithm 1 The inner most loop of CKY

```
1: for $X \rightarrow Y Z$, $Y$ in left span and $Z$ in right span
2:     Add $X$ to parent span
```

3.2 Model assumption

We have shown that both binarization and the for-statement implementation in the inner most loop of CKY will affect the parsing speed.

About the for-statement implementations, no previous study has addressed which one is superior. The actual choice may affect our study on binarization. If using M1, since it enumerates all rules in the grammar, the optimal binarization will be the one with minimal number of rules, i.e. minimal binarized grammar size. However, M1 is usually not preferred in practice (Goodman, 1997). For other methods, it is hard to tell which binarization is optimal theoretically. In this paper, for simplicity reasons we do not consider the effect of for-statement implementations on the optimal binarization.

On the other hand, it is well known that reducing the number of constituents produced in parsing can greatly improve CKY parsing efficiency. That is how most thresholding systems (Goodman, 1997; Tsuruoka and Tsujii, 2004; Charniak et al., 2006) speed up CKY parsing. Apparently, the number of constituents produced in parsing is not affected by for-statement implementations.

Therefore we assume that the running time of CKY is primarily determined by the number of constituents generated in parsing. We simplify the optimal binarization to be:

$$\pi^* \approx \arg\min_{\pi} E(\pi(G), C) \qquad (2)$$

where $E(\pi(G), C)$ is the number of constituents generated when CKY parsing C with $\pi(G)$.

We next discuss how binarizations affect the number of constituents generated in parsing, and present our algorithm for finding a good binarization.

4 How binarizations affect constituents

Throughout this section and the next, we will use an example to help illustrate the idea. The grammar is:

$$\begin{array}{rl} X & \rightarrow A\ B\ C\ D \\ Y & \rightarrow A\ B\ C \\ C & \rightarrow C\ D \\ Z & \rightarrow A\ B\ C\ E \\ W & \rightarrow F\ C\ D\ E \end{array}$$

The input sentence is ${}_0A_1B_2C_3D_4E_5$, where the subscripts are used to indicate the positions of spans. For example, $[1,3]$ stands for $B\,C$. The final parse[2] is shown in Figure 2. Symbols surrounded by dashed circles are fictitious, which do not actually exist in the parse.

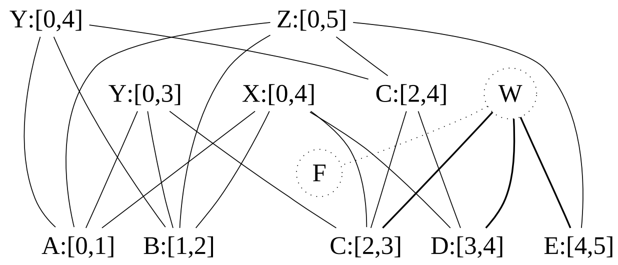

Figure 2: Parse of the sentence $A\,B\,C\,D\,E$

4.1 Complete and incomplete constituents

In the procedure of CKY parsing, there are two kinds of constituents generated: *complete* and *incomplete*.

Complete constituents (henceforth CCs) are those composed by the original grammar symbols and

[1]Note that we should skip Y (Z) if it never appears as the first (second) symbol on the right hand side of any rule.

[2]More precisely, it is more than a parse tree for it contains all symbols recognized in parsing.

spans. For example in Figure 2, $X:[0,4]$, $Y:[0,3]$ and Y:$[0,4]$ are all CCs.

Incomplete constituents (henceforth ICs) are those labeled by intermediate symbols. Figure 2 does not show them directly, but we can still read the possible ones. For example, if the binarized grammar in use contains an intermediate symbol $[A\,B\,C]$, then there will be two related ICs $[A\,B\,C]$:$[0,3]$ and $[A\,B\,C]$:$[0,4]$ (the latter is due to C:$[2,4]$) produced in parsing. ICs represent the intermediate steps to recognize and complete CCs.

4.2 Impact on complete constituents

Binarizations do not affect whether a CC will be produced. If there is a CC in the parse, whatever binarization we use, it will be produced. The difference merely lies on what intermediate ICs are used. Therefore given a grammar and an input sentence, no matter what binarization is used, the CKY parsing will generate the same set of CCs.

For example in Figure 2 there is a CC $X:[0,4]$, which is associated with rule $X \rightarrow A\,B\,C\,D$. No matter what binarization we use, this CC will be recognized eventually. For example if using left binarization, we will get $[A\,B]$:$[0,2]$, $[A\,B\,C]$:$[0,3]$ and finally $X:[0,4]$; if using right binarization, we will get $[C\,D]$:$[2,4]$, $[B\,C\,D]$:$[1,4]$ and again X:$[0,4]$.

4.3 Impact on incomplete constituents

Binarizations do affect the generation of ICs, because they generate different intermediate symbols. We discuss the impact on two aspects:

Shared IC. Some ICs can be used to generate multiple CCs in parsing. We call them *shared*. If a binarization can lead to more shared ICs, then overall there will be fewer ICs needed in parsing.

For example, in Figure 2, if we use left binarization, then $[A\,B]$:$[0,2]$ can be shared to generate both $X:[0,4]$ and $Y:[0,3]$, in which we can save one IC overall. However, if right binarization is used, there will be no common ICs to share in the generation steps of $X:[0,4]$ and $Y:[0,3]$, and overall there are one more IC generated.

Failed IC. For a CC, if it can be recognized eventually by applying an original rule of length k, whatever binarization to use, we will have to generate the same number of $k-2$ ICs before we can complete the CC. However, if the CC cannot be fully recognized but only partially recognized, then the number of ICs needed will be quite different.

For example, in Figure 2, the rule $W \rightarrow F\,C\,D\,E$ can be only partially recognized over $[2,5]$, so it cannot generate the corresponding CC. Right binarization needs two ICs ($[D\,E]$:$[3,5]$ and $[C\,D\,E]$:$[2,5]$) to find that the CC cannot be recognized, while left binarization needs none.

As mentioned earlier, ICs are auxiliary means to generate CCs. If an IC cannot help generate any CCs, it is totally useless and even harmful. We call such an IC *failed*, otherwise it is *successful*. Therefore, if a binarization can help generate fewer failed ICs then parsing would be more efficient.

4.4 Binarization and the nature of the input

Now we show that the impact of binarization also depends on the actual input. When the input changes, the impact may also change.

For example, in the previous example about the rule $W \rightarrow F\,C\,D\,E$ in Figure 2, we believe that left binarization is better based on the observation that there are more snippets of $[C\,D\,E]$ in the input which lack for F to the left. If there are more snippets of $[F\;C\;D]$ in the input lacking for E to the right, then right binarization would be better.

The discussion above confirms such a view: the effect of binarization depends on the nature of the input language, and a good binarization should reflect this nature. This accords with our intuition. So we use training corpus to learn a good binarization. And we verify the effectiveness of the learnt binarization using a test corpus with the same nature.

In summary, binarizations affect the efficiency of parsing primarily by affecting the number of ICs generated, where more shared and fewer failed ICs will help lead to higher efficiency. Meanwhile, the effectiveness of binarization also depends on the nature of its input language.

5 Towards a good binarization

Based on the analysis in the previous section, we employ a greedy approach to find a good binarization. We use training corpus to compute metrics for every possible intermediate symbol. We use this information to greedily select the best pair to combine.

5.1 Algorithm

Given the original grammar G and training corpus C, for every sentence in C, we firstly obtain the final parse (like Figure 2). For every possible intermediate symbol, i.e. every ngram of the original symbols, denoted by w, we compute the following two metrics:

1. How many ICs labeled by w can be generated in the final parse, denoted by $num(w)$ (number of related ICs).

2. How many CCs can be generated via ICs labeled by w, denoted by $ctr(w)$ (contribution of related ICs).

For example in Figure 2, for a possible intermediate symbol $[A\,B\,C]$, there are two related ICs ($[A\,B\,C] : [0, 3]$ and $[A\,B\,C] : [0, 4]$) in the parse, so we have $num([A\,B\,C]) = 2$. Meanwhile, four CCs ($Y : [0, 3]$, $X : [0, 4]$, $Y : [0, 4]$ and $Z : [0, 5]$) can be generated from the two related ICs. Therefore $ctr([A\,B\,C]) = 4$. We list the two metrics for every ngram in Figure 2 in Table 2. We will discuss how to compute these two metrics in Section 5.2.

w	num	ctr	w	num	ctr
$[A\,B]$	1	4	$[B\,C\,E]$	1	1
$[A\,B\,C]$	2	4	$[C\,D]$	1	2
$[A\,B\,C\,D]$	1	1	$[C\,D\,E]$	1	0
$[A\,B\,C\,E]$	1	1	$[C\,E]$	1	1
$[B\,C]$	2	4	$[D\,E]$	1	0
$[B\,C\,D]$	1	1			

Table 2: Metrics of every ngram

The two metrics indicate the goodness of a possible intermediate symbol w: $num(w)$ indicates how many ICs labeled by w are likely to be generated in parsing; while $ctr(w)$ represents how much w can *contribute* to the generation of CCs. If $ctr(w)$ is larger, the corresponding ICs are more likely to be shared. If ctr is zero, those ICs are surely failed. Therefore the smaller $num(w)$ is and the larger $ctr(w)$ is, the better w would be.

Combining num and ctr, we define a *utility* function for each ngram w in the original grammar:

$$utility(w) = f(num(w), ctr(w)) \qquad (3)$$

where f is a ranking function, satisfying that $f(x, y)$ is larger when x is smaller and y is larger. We will discuss more details about it in Section 5.3.

Using *utility* as the ranking function, we sort all pairs of symbols and choose the best to combine. The formal algorithm is as follows:

S1 For every symbol pair of $\langle v_1, v_2\rangle$ (where v_1 and v_2 can be original symbols or intermediate symbols generated in previous rounds), let w_1 and w_2 be the ngrams of original symbols represented by v_1 and v_2, respectively. Let $w = w_1 w_2$ be the ngram represented by the symbol pair. Compute $utility(w)$.

S2 Select the ngram w with the highest $utility(w)$, let it be w^* (in case of a tie, select the one with a smaller num). Let the corresponding symbol pair be $\langle v_1^*, v_2^*\rangle$.

S3 Add a new intermediate symbol v^*, and replace all the occurrences of $\langle v_1^*, v_2^*\rangle$ on the right hand sides of rules with v^*.

S4 Add a new rule $v^* \rightarrow v_1^* v_2^* : 1.0$.

S5 Repeat S1 $\sim$ S4, until there are no rules with more than two symbols on the right hand side.

5.2 Metrics computing

In this section, we discuss how to compute num and ctr in details.

Computing ctr is straightforward. First we get final parses like in Figure 2 for training sentences. From a final parse, we traverse along every parent node and enumerate every subsequence of its child nodes. For example in Figure 2, from the parent node of $X : [0, 4]$, we can enumerate the following: $[A\,B] : [0, 2]$, $[A\,B\,C] : [0, 3]$, $[A\,B\,C\,D] : [0, 4]$, $[B\,C]$:[1, 3], $[B\,C\,D]$:[1, 4], $[C\,D]$:[2, 4]. We add 1 to all the ctr of these ngrams, respectively.

To compute num, we resort to the same idea of dynamic programming as in CKY. We perform a normal left binarization except that we add all ngrams in the original grammar G as intermediate symbols into the binarized grammar G'. For example, for the rule of $S \rightarrow A\,B\,C : p$, the constructed grammar is as follows:

$$\begin{aligned} [A\,B] &\rightarrow A\,B : 1.0 \\ S &\rightarrow [A\,B]\,C : p \\ [B\,C] &\rightarrow B\,C : 1.0 \end{aligned}$$

Using the constructed G', we employ a normal CKY parsing on the training corpus and compute how many constituents are produced for each ngram. The result is num. Suppose the length of the training sentence is n, the original grammar G has N symbols, and the maximum length of rules is k, then the complexity of this method can be written as $O(N^k n^3)$.

5.3 Ranking function

We discuss the details of the ranking function f used to compute the $utility$ of each ngram w. We come up with two forms for f: linear and log-linear

1. linear: $f(x, y) = -\lambda_1 x + \lambda_2 y$
2. log-linear[3]: $f(x, y) = -\lambda_1 \log(x) + \lambda_2 \log(y)$

where λ_1 and λ_2 are non-negative weights subject to $\lambda_1 + \lambda_2 = 1$[4].

We will use development set to determine which form is better and to learn the best weight settings.

6 Combination with other techniques

Binarization usually plays a role of preprocessing in the procedure of parsing. Grammars are binarized before they are fed into the stage of parsing. There are many known works on speeding up the CKY parsing. So we can expect that if we replace the part of binarization by a better one while keeping the subsequent parsing unchanged, the parsing will be more efficient. We will conduct experiment to confirm this idea in the next section.

We would like to make more discussions before we advance to the experiments. The first is about parsing accuracy in combining binarization with other parsing speed-up techniques. Binarization itself does not affect parsing accuracy. When combined with exact inference algorithms, like the iterative CKY (Tsuruoka and Tsujii, 2004), the accuracy will be the same. However, if combined with other inexact pruning techniques like beam-pruning (Goodman, 1997) or coarse-to-fine parsing (Charniak et al., 2006), binarization may interact with those pruning methods in a complicated way to affect parsing accuracy. This is due to different binarizations generate different sets of intermediate symbols. With the same complete constituents, one binarization might derive incomplete constitutes that could be pruned while another binarization may not. This would affect the accuracy. We do not address this interaction on in this paper, but leave it to the future work. In Section 7.3 we will use the iterative CKY for testing.

In addition, we believe there exist some speed-up techniques which are incompatible with our binarization. One such example may be the top-down left-corner filtering (Graham et al., 1980; Moore, 2000), which seems to be only applicable to the process of left binarization. A detailed investigation on this problem will be left to the future work.

The last issue is how our binarization performs on a lexicalized parser, like Collins (1997). Our intuition is that we cannot apply our binarization to Collins (1997). The key fact in lexicalized parsers is that we cannot explicitly write down all rules and compute their probabilities precisely, due to the great number of rules and the severe data sparsity problem. Therefore in Collins (1997) grammar rules are already factorized into a set of probabilities. In order to capture the dependency relationship between lexcial heads Collins (1997) breaks down the rules from head outwards, which prevents us from factorizing them in other ways. Therefore our binarization cannot apply to the lexicalized parser. However, there are state-of-the-art unlexicalized parsers (Klein and Manning, 2003b; Petrov et al., 2006), to which we believe our binarization can be applied.

7 Experiments

We conducted two experiments on Penn Treebank II corpus (Marcus et al., 1994). The first is to compare the effects of different binarizations on parsing and the second is to test the feasibility to combine our work with iterative CKY parsing (Tsuruoka and Tsujii, 2004) to achieve even better efficiency.

7.1 Experimental setup

Following conventions, we learnt the grammar from Wall Street Journal (WSJ) section 2 to 21 and modified it by discarding all functional tags and empty nodes. The parser obtained this way is a pure unlexicalized context-free parser with the raw treebank grammar. Its accuracy turns out to be 72.46% in

[3]For log-linear form, if $num(w) = 0$ (and consequently $ctr(w) = 0$), we set $f(num(w), ctr(w)) = 0$; if $num(w) > 0$ but $ctr(w) = 0$, we set $f(num(w), ctr(w)) = -\infty$.

[4]Since f is used for ranking, the magnitude is not important.

terms of F1 measure, quite the same as 72.62% as stated in Klein and Manning (2003b). We adopt this parser in our experiment not only because of simplicity but also because we focus on parsing efficiency.

For all sentences with no more than 40 words in section 22, we use the first 10% as the development set, and the last 90% as the test set. There are 158 and 1,420 sentences in development set and test set, respectively. We use the whole 2,416 sentences in section 23 as the training set.

We use the development set to determine the better form of the ranking function f as well as to tune its weights. Both metrics of num and ctr are normalized before use. Since there is only one free variable in λ_1 and λ_2, we can just enumerate $0 \leq \lambda_1 \leq 1$, and set $\lambda_2 = 1 - \lambda_1$. The increasing step is firstly set to 0.05 for the approximate location of the optimal weight, then set to 0.001 to learn more precisely around the optimal.

We find that the optimal is 5,773,088 (constituents produced in parsing development set) with $\lambda_1 = 0.014$ for linear form, while for log-linear form the optimal is 5,905,292 with $\lambda_1 = 0.691$. Therefore we determine that the better form for the ranking function is linear with $\lambda_1 = 0.014$ and $\lambda_2 = 0.986$.

The size of each binarized grammar used in the experiment is shown in Table 3. "Original" refers to the raw treebank grammar. "Ours" refers to the learnt binarized grammar by our approach. For the rest please refer to Section 2.

	# of Symbols	# of Rules
Original	72	14,971
Right	10,654	25,553
Left	12,944	27,843
Head	11,798	26,697
Compact	3,644	18,543
Ours	8,407	23,306

Table 3: Grammar size of different binarizations

We also tested whether the size of the training set would have significant effect. We use the first 10%, 20%, $\cdots$, up to 100% of section 23 as the training set, respectively, and parse the development set. We find that all sizes examined have a similar impact, since the numbers of constituents produced are all around 5,780,000. It means the training corpus does not have to be very large.

The entire experiments are conducted on a server with an Intel Xeon 2.33 GHz processor and 8 GB memory.

7.2 Experiment 1: compare among binarizations

In this part, we use CKY to parse the entire test set and evaluate the efficiency of different binarizations.

The for-statement implementation of the inner most loop of CKY will affect the parsing time though it won't affect the number of constituents produced as discussed in Section 3.2. The best implementations may be different for different binarized grammars. We examine M1$\sim$M4, testing their parsing time on the development set. Results show that for right binarization the best method is M3, while for the rest the best is M2. We use the best method for each binarized grammar when comparing the parsing time in Experiment 1.

Table 4 reports the total number of constituents and total time required for parsing the entire test set. It shows that different binarizations have great impacts on the efficiency of CKY. With our binarization, the number of constituents produced is nearly 20% of that required by right binarization and nearly 25% of that by the widely-used left binarization. As for the parsing time, CKY with our binarization is about 2.5 times as fast as with right binarization and about 1.75 times as fast as with left binarization. This illustrates that our binarization can significantly improve the efficiency of the CKY parsing.

Binarization	Constituents	Time (s)
Right	241,924,229	5,747
Left	193,238,759	3,474
Head	166,425,179	3,837
Compact	94,257,478	2,302
Ours	**52,206,466**	**2,182**

Table 4: Performance on test set

Figure 3 reports the detailed number of complete constituents, successful incomplete constituents and failed incomplete constituents produced in parsing. The result proves that our binarization can significantly reduce the number of failed incomplete constituents, by a factor of 10 in contrast with left binarization. Meanwhile, the number of successful incomplete constituents is also reduced by a factor of 2 compared to left binarization.

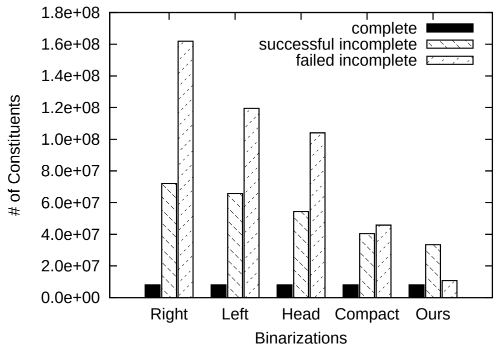

Figure 3: Comparison on various constituents

Another interesting observation is that parsing with a smaller grammar does not always yield a higher efficiency. Our binarized grammar is more than twice the size of compact binarization, but ours is more efficient. It proves that parsing efficiency is related to both the size of grammar in use as well as the number of constituents produced.

In Section 1, we used an example of "*get the bag and go*" to illustrate that for rules like $X \rightarrow Y\,CC\,Y$, right binarization is more suitable. We also investigated the corresponding linguistic nature that the word to the right of "*and*" is more likely to indicate the true relationship represented by "*and*". We argued that a better binarization can reflect such linguistic nature of the input language. To our surprise, our learnt binarization indeed captures this linguistic insight, by binarizing $NP \rightarrow NP\,CC\,NP$ from right to left.

Finally, we would like to acknowledge the limitation of our assumption made in Section 3.2. Table 4 shows that the parsing time of CKY is not always monotonic increasing with the number of constituents produced. Head binarization produces fewer constituents than left binarization but consumes more parsing time.

7.3 Experiment 2: combine with iterative CKY

In this part, we test the performance of combining our binarization with the iterative CKY (Tsuruoka and Tsujii, 2004) (henceforth T&T) algorithm.

Iterative CKY is a procedure of multiple passes of normal CKY: in each pass, it uses a threshold to prune bad constituents; if it cannot find a successful parse in one pass, it will relax the threshold and start another; this procedure is repeated until a successful parse is returned. T&T used left binarization. We re-implement their experiments and combine iterative CKY with our binarization. Note that iterative CKY is an exact inference algorithm that guarantees to return the optimal parse. As discussed in Section 6, the parsing accuracy is not changed in this experiment.

T&T used a held-out set to learn the best step of threshold decrease. They reported that the best step was 11 (in log-probability). We found that the best step was indeed 11 for left binarization; for our binarizaiton, the best step was 17. T&T used M4 as the for-statement implementation of CKY. In this part, we follow the same method.

The result is shown in Table 5. We can see that iterative CKY can achieve better performance by using a better binarization. We also see that the reduction by binarization with pruning is less significant than without pruning. It seems that the pruning itself in iterative CKY can counteract the reduction effect of binarization to some extent. Still the best performance is archieved by combining iterative CKY with a better binarization.

CKY + Binarization	Constituents	Time (s)
Tsuruoka and Tsujii (2004)		
CKY + Left	45,406,084	1,164
Iterative CKY + Left	17,520,427	613
Reimplement		
CKY + Left	52,128,941	932
CKY + Ours	14,892,203	571
Iterative CKY + Left	23,267,594	377
Iterative CKY + Ours	**10,966,272**	**314**

Table 5: Combining with iterative CKY parsing

8 Related work

Almost all work on parsing starts from a binarized grammar. Usually binarization plays a role of preprocessing. Left binarization is widely used (Aho and Ullman, 1972; Charniak et al., 1998; Tsuruoka and Tsujii, 2004) while right binarization is rarely used in the literature. Compact binarization was introduced in Schmid (2004), based on the intuition that a more compact grammar will help acheive a highly efficient CKY parser, though from our experiment it is not always true.

We define the fashion of binarizations in Section 2, where we encode an intermediate symbol using the ngrams of original symbols (content) it derives. This encoding is known as the Inside-Trie (I-Trie) in Klein and Manning (2003a), in which they also mentioned another encoding called Outside-Trie (O-Trie). O-Trie encodes an intermediate symbol using the its parent and the symbols surrounding it in the original rule (context). Klein and Manning (2003a) claimed that O-Trie is superior for calculating estimates for A* parsing. We plan to investigate binarization defined by O-Trie in the future.

Both I-Trie and O-Trie are equivalent encodings, resulting in equivalent grammars, because they both encode using the complete content or context information of an intermediate symbol. If we use part of the information to encode, for example just parent in O-Trie case, the encoding will be non-equivalent.

Proper non-equivalent encodings are used to generalize the grammar and prevent the binarized grammar becoming too specific (Charniak et al., 2006). It is equipped with head binarization to help improve parsing accuracy, following the traditional linguistic insight that phrases are organized around the head (Collins, 1997; Klein and Manning, 2003b). In contrast, we focus our attention on parsing efficiency not accuracy in this paper.

Binarization also attracts attention in the syntax-based models for machine translation, where translation can be modeled as a parsing problem and binarization is essential for efficient parsing (Zhang et al., 2006; Huang, 2007).

Wang et al. (2007) employs binarization to decompose syntax trees to acquire more re-usable translation rules in order to improve translation accuracy. Their binarization is restricted to be a mixture of left and right binarization. This constraint may decrease the power of binarization when applied to speeding up parsing in our problem.

9 Conclusions and future work

We have studied the impact of grammar binarization on parsing efficiency and presented a novel binarization which utilizes rich information learnt from training corpus. Experiments not only showed that our learnt binarization outperforms other existing ones in terms of parsing efficiency, but also demonstrated the feasibility to combine our binarization with known parsing speed-up techniques to achieve even better performance.

An advantage of our approach to finding a good binarization would be that the training corpus does not need to be parsed sentences. Only POS tagged sentences will suffice for training. This will save the effort to adapt the model to a new domain.

Our approach is based on the assumption that the efficiency of CKY parsing is primarily determined by the number of constituents produced. This is a fairly sound one, but not always true, as shown in Section 7.2. One future work will be relaxing the assumption and finding a better appraoch.

Another future work will be to apply our work to chart parsing. It is known that binarization is also essential for an $O(n^3)$ complexity of chart parsing, where *dotted rules* are used to binarize the grammar implicitly from left. As shown in Charniak et al. (1998), we can binarize explicitly and use intermediate symbols to replace dotted rules in chart parsing. Therefore chart parsing can use multiple binarizations. We expect that a better binarization will also help improve the efficiency of chart parsing.

Sentence Fusion via Dependency Graph Compression

Katja Filippova and **Michael Strube**
EML Research gGmbH
Schloss-Wolfsbrunnenweg 33
69118 Heidelberg, Germany
http://www.eml-research.de/nlp

Abstract

We present a novel unsupervised sentence fusion method which we apply to a corpus of biographies in German. Given a group of related sentences, we align their dependency trees and build a dependency graph. Using integer linear programming we compress this graph to a new tree, which we then linearize. We use GermaNet and Wikipedia for checking semantic compatibility of co-arguments. In an evaluation with human judges our method outperforms the fusion approach of Barzilay & McKeown (2005) with respect to readability.

1 Introduction

Automatic text summarization is a rapidly developing field in computational linguistics. Summarization systems can be classified as either extractive or abstractive ones (Spärck Jones, 1999). To date, most systems are extractive: sentences are selected from one or several documents and then ordered. This method exhibits problems, because input sentences very often overlap and complement each other at the same time. As a result there is a trade-off between *non-redundancy* and *completeness* of the output. Although the need for abstractive approaches has been recognized before (e.g. McKeown et al. (1999)), so far almost all attempts to get closer to abstractive summarization using scalable, statistical techniques have been limited to sentence compression.

The main reason why there is little progress on abstractive summarization is that this task seems to require a conceptual representation of the text which is not yet available (see e.g. Hovy (2003, p.589)). Sentence fusion (Barzilay & McKeown, 2005), where a new sentence is generated from a group of related sentences and where complete semantic and conceptual representation is not required, can be seen as a middle-ground between extractive and abstractive summarization. Our work regards a corpus of biographies in German where multiple documents about the same person should be merged into a single one. An example of a fused sentence (3) with the source sentences (1,2) is given below:

(1)

Bohr	studierte	an	der	Universität	Kopenhagen
Bohr	studied	at	the	University	Copenhagen
und	erlangte	dort	seine	Doktorwürde.	
and	got	there	his	PhD	

'Bohr studied at the University of Copenhagen and got his PhD there'

(2)

Nach	dem	Abitur	studierte	er	Physik	und
After	the	school	studied	he	physics	and
Mathematik	an	der	Universität	Kopenhagen.		
mathematics	at	the	University	Copenhagen		

'After school he studied physics and mathematics at the University of Copenhagen'

(3)

Nach	dem	Abitur	studierte	Bohr	Physik	und
After	the	school	studied	Bohr	physics	and
Mathematik	an	der	Universität	Kopenhagen		
mathematics	at	the	University	Copenhagen		
und	erlangte	dort	seine	Doktorwürde.		
and	got	there	his	PhD		

'After school Bohr studied physics and mathematics at the University of Copenhagen and got his PhD there'

Having both (1) and (2) in a summary would make it redundant. Selecting only one of them would not give all the information from the input. (3), fused from both (1) and (2), conveys the necessary information without being redundant and is more appropriate for a summary.

To this end, we present a novel sentence fusion method based on dependency structure alignment and semantically and syntactically informed phrase aggregation and pruning. We address the problem in an unsupervised manner and use integer linear programming (ILP) to find a globally optimal solution. We argue that our method has three important advantages compared to existing methods. First, we address the grammaticality issue empirically by means of knowledge obtained from an automatically parsed corpus. We do not require such resources as subcategorization lexicons or hand-crafted rules, but decide to retain a dependency based on its syntactic importance score. The second point concerns integrating semantics. Being definitely important, *"this source of information remains relatively unused in work on aggregation*[1] *within NLG"* (Reiter & Dale, 2000, p.141). To our knowledge, in the text-to-text generation field, we are the first to use semantic information not only for alignment but also for aggregation in that we check coarguments' compatibility. Apart from that, our method is not limited to sentence fusion and can be easily applied to sentence compression. In Filippova & Strube (2008) we compress English sentences with the same approach and achieve state-of-the-art performance.

The paper is organized as follows: Section 2 gives an overview of related work and Section 3 presents our data. Section 4 introduces our method and Section 5 describes the experiments and discusses the results of the evaluation. The conclusions follow in the final section.

2 Related Work

Most studies on text-to-text generation concern sentence compression where the input consists of exactly one sentence (Jing, 2001; Hori & Furui, 2004; Clarke & Lapata, 2008, inter alia). In such setting, redundancy, incompleteness and compatibility issues do not arise. Apart from that, there is no obvious way of how existing sentence compression methods can be adapted to sentence fusion.

Barzilay & McKeown (2005) present a sentence fusion method for multi-document news summarization which crucially relies on the assumption that information appearing in many sources is important. Consequently, their method produces an intersection of input sentences by, first, finding the centroid of the input, second, augmenting it with information from other sentences and, finally, pruning a predefined set of constituents (e.g. PPs). The resulting structure is not necessarily a tree and allows for extraction of several trees, each of which can be linearized in many ways.

Marsi & Krahmer (2005) extend the approach of Barzilay & McKeown to do not only *intersection* but also *union* fusion. Like Barzilay & McKeown (2005), they find the best linearization with a language model which, as they point out, often produces inadequate rankings being unable to deal with word order, agreement and subcategorization constraints. In our work we aim at producing a valid dependency tree structure so that most grammaticality issues are resolved *before* the linearization stage.

Wan et al. (2007) introduce a global revision method of how a novel sentence can be generated from a set of input words. They formulate the problem as a search for a maximum spanning tree which is incrementally constructed by connecting words or phrases with dependency relations. The grammaticality issue is addressed by a number of hard constraints. As Wan et al. point out, one of the problems with their method is that the output built up from dependencies found in a corpus might have a meaning different from the intended one. Since we build our trees from the input dependencies, this problem does not arise with our method. Apart from that, in our opinion, the optimization formulation we adopt is more appropriate as it allows to integrate many constraints without complex rescoring rules.

3 Data

The comparable corpus we work with is a collection of about 400 biographies in German gathered from

[1]We follow Barzilay & McKeown (2005) and refer to aggregation within text-to-text generation as sentence fusion.

the Internet[2]. These biographies describe 140 different people, and the number of articles for one person ranges from 2 to 4, being 3 on average. Despite obvious similarities between articles about one person, neither identical content nor identical ordering of information can be expected.

Fully automatic preprocessing in our system comprises the following steps: sentence boundaries are identified with a Perl CPAN module[3]. Then the sentences are split into tokens and the TnT tagger (Brants, 2000) and the TreeTagger (Schmid, 1997) are used for tagging and lemmatization respectively. Finally, the biographies are parsed with the CDG dependency parser (Foth & Menzel, 2006). We also identify references to the biographee (pronominal as well as proper names) and temporal expressions (absolute and relative) with a few rules.

4 Our Method

Groups of related sentences serve as input to a sentence fusion system and thus need to be identified first (4.1). Then the dependency trees of the sentences are modified (4.2) and aligned (4.3). Syntactic importance (4.4) and word informativeness (4.5) scores are used to extract a new dependency tree from a graph of aligned trees (4.6). Finally, the tree is linearized (4.7).

4.1 Sentence Alignment

Sentence alignment for comparable corpora requires methods different from those used in machine translation for parallel corpora. For example, given two biographies of a person, one of them may follow the timeline from birth to death whereas the other may group events thematically or tell only about the scientific contribution of the person. Thus one cannot assume that the sentence order or the content is the same in two biographies. Shallow methods like word or bigram overlap, (weighted) cosine or Jaccard similarity are appealing as they are cheap and robust. In particular, Nelken & Schieber (2006) demonstrate the efficacy of a sentence-based *tf*idf* score when applied to comparable corpora. Following them, we define the similarity of two sentences *sim*(s_1, s_2) as

$$\frac{S_1 \cdot S_2}{|S_1| \cdot |S_2|} = \frac{\sum_t w_{S_1}(t) \cdot w_{S_2}(t)}{\sqrt{\sum_t w^2_{S_1}(t) \sum_t w^2_{S_2}(t)}} \qquad (1)$$

where S is the set of all lemmas but stop-words from s, and $w_S(t)$ is the weight of the term t:

$$w_S(t) = S(t)\frac{1}{N_t} \qquad (2)$$

where $S(t)$ is the indicator function of S, N_t is the number of sentences in the biographies of one person which contain t. We enhance the similarity measure by looking up synonymy in GermaNet (Lemnitzer & Kunze, 2002).

We discard identical or nearly identical sentences ($sim(s_1, s_2) > 0.8$) and greedily build sentence clusters using a hierarchical groupwise-average technique. As a result, one sentence may belong to one cluster at most. These sentence clusters serve as input to the fusion algorithm.

4.2 Dependency Tree Modification

We apply a set of transformations to a dependency tree to emphasize its important properties and eliminate unimportant ones. These transformations are necessary for the compression stage. An example of a dependency tree and its modifed version are given in Fig. 1.

PREP preposition nodes (*an, in*) are removed and placed as labels on the edges to the respective nouns;

CONJ a chain of conjuncts (*Mathematik und Physik*) is split and each node is attached to the parent node (*studierte*) provided they are not verbs;

APP a chain of words analyzed as appositions by CDG (*Niels Bohr*) is collapsed into one node;

FUNC function words like determiners (*der*), auxiliary verbs or negative particles are removed from the tree and memorized with their lexical heads (memorizing negative particles preserves negation in the output);

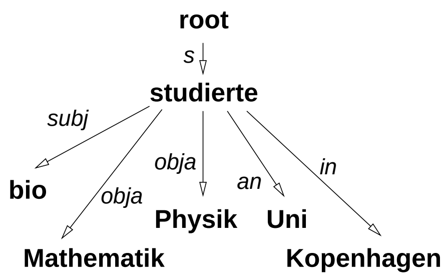
(a) Dependency tree



(b) Modified tree

Figure 1: The dependency tree of the sentence *Bohr studierte Mathematik und Physik an der Uni in Kopenhagen (Bohr studied mathematics and physics at university in Copenhagen)* as produced by the parser (a) and after all transformations applied (b)

ROOT every dependency tree gets an explicit root which is connected to every verb node;

BIO all occurrences of the biographee (*Niels Bohr*) are replaced with the *bio* tag.

4.3 Node Alignment

Once we have a group of two to four strongly related sentences and their transformed dependency trees, we aim at finding the best node alignment. We use a simple, fast and transparent method and align any two words provided that they

1. are content words;
2. have the same part-of-speech;
3. have identical lemmas or are synonyms.

In case of multiple possibilities, which are extremely rare in our data, the choice is made randomly. By merging all aligned nodes we get a dependency graph which consists of all dependencies from the input trees. In case it contains a cycle, one of the alignments from the cycle is eliminated.

We prefer this very simple method to bottom-up ones (Barzilay & McKeown, 2005; Marsi & Krahmer, 2005) for two main reasons. Pursuing local subtree alignments, bottom-up methods may leave identical words unaligned and thus prohibit fusion of complementary information. On the other hand, they may force alignment of two unrelated words if the subtrees they root are largely aligned. Although in some cases it helps discover paraphrases, it considerably increases chances of generating ungrammatical output which we want to avoid at any cost.

4.4 Syntactic Importance Score

Given a dependency graph we want to get a new dependency tree from it. Intuitively, we want to retain obligatory dependencies (e.g. *subject*) while removing less important ones (e.g. *adv*). When deciding on pruning an argument, previous approaches either used a set of hand-crafted rules (e.g. Barzilay & McKeown (2005)), or utilized a subcategorization lexicon (e.g. Jing (2001)). The hand-crafted rules are often too general to ensure a grammatical argument structure for different verbs (e.g. *PPs can be pruned*). Subcategorization lexicons are not readily available for many languages and cover only verbs. E.g. they do not tell that the noun *son* is very often modified by a PP using the preposition *of*, as in *the son of Niels Bohr*, and that the NP without a PP modifier may appear incomplete.

To overcome these problems, we decide on pruning an edge by estimating the conditional probability of its label given its head, $P(l|h)$[4]. For example, $P(subj|studieren)$ – the probability of the label *subject* given the verb *study* – is higher than $P(in|studieren)$, and therefore the subject will be preserved whereas the prepositional label and thus the whole PP can be pruned, if needed. Table 1 presents the probabilities of several labels given that the head is *studieren* and shows that some prepositions are more important than other ones. Note that if we did not apply the PREP modification we would be unable to distinguish between different prepositions and could only calculate $P(pp|studieren)$

[4]The probabilities are calculated from a corpus of approx. 3,000 biographies from Wikipedia which we annotated automatically as described in Section 3.

which would not be very informative.

subj	obja	in	an	nach	mit	zu
0.88	0.74	0.44	0.42	0.09	0.02	0.01

Table 1: Probabilities of *subj, obja(ccusative), in, at, after, with, to* given the verb *studieren* (*study*)

4.5 Word Informativeness Score

We also want to retain informative words in the output tree. There are many ways in which word importance can be defined. Here, we use a formula introduced by Clarke & Lapata (2008) which is a modification of the significance score of Hori & Furui (2004):

$$I(w_i) = \frac{l}{N} \cdot f_i \log \frac{F_A}{F_i} \tag{3}$$

w_i is the topic word (either noun or verb), f_i is the frequency of w_i in the aligned biographies, F_i is the frequency of w_i in the corpus, and F_A is the sum of frequencies of all topic words in the corpus. l is the number of clause nodes above w and N is the maximum level of embedding of the sentence which w belongs to. By defining word importance differently, e.g. as relatedness of a word to the topic, we could apply our method to topic-based summarization (Krahmer et al., 2008).

4.6 New Sentence Generation

We formulate the task of getting a tree from a dependency graph as an optimization problem and solve it with ILP[5]. In order to decide which edges of the graph to remove, for each directed dependency edge from head h to word w we introduce a binary variable $x^l_{h,w}$, where *l* stands for the label of the edge:

$$x^l_{h,w} = \begin{cases} 1 & \text{if the dependency is preserved} \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

The goal is to find a subtree of the graph which gets the highest score of the objective function (5) to which both the probability of dependencies ($P(l|h)$) and the importance of dependent words ($I(w)$) contribute:

[5]We use `lp_solve` in our implementation `http://sourceforge.net/projects/lpsolve`.

$$f(X) = \sum_x x^l_{h,w} \cdot P(l|h) \cdot I(w) \tag{5}$$

The objective function is subject to four types of constraints presented below (W stands for the set of graph nodes minus root, i.e. the set of words).

STRUCTURAL constraints allow to get a tree from the graph: (6) ensures that each word has one head at most. (7) ensures connectivity in the tree. (8) is optional and restricts the size of the resulting tree to α words ($\alpha = \min(0.\bar{6} \cdot |W|, 10)$).

$$\forall w \in W, \sum_{h,l} x^l_{h,w} \leq 1 \tag{6}$$

$$\forall w \in W, \sum_{h,l} x^l_{h,w} - \frac{1}{|W|} \sum_{u,l} x^l_{w,u} \geq 0 \tag{7}$$

$$\sum_x x^l_{h,w} \leq \alpha \tag{8}$$

SYNTACTIC constraints ensure the syntactic validity of the output tree and explicitly state which arguments should be preserved. We have only one syntactic constraint which guarantees that a subordinating conjunction (*sc*) is preserved (9) if and only if the clause it belongs to serves as a subordinate clause (*sub*) in the output.

$$\forall x^{sc}_{w,u}, \sum_{h,l} x^{sub}_{h,w} - x^{sc}_{w,u} = 0 \tag{9}$$

SEMANTIC constraints restrict coordination to semantically compatible elements. The idea behind these constraints is the following (see Fig. 2). It can be that one sentence says *He studied math* and another one *He studied physics*, so the output may unite the two words under coordination: *He studied math and physics*. But if the input sentences are *He studied physics* and *He studied sciences*, then one should not unite both, because *sciences* is the generalization of *physics*. Neither should one unite two unrelated words: *He studied with pleasure* and *He studied with Bohr* cannot be fused into *He studied with pleasure and Bohr*.

To formalize these intuitions we define two functions *hm(w,u)* and *rel(w,u)*: *hm(w,u)* is a binary function, whereas *rel(w,u)* returns a value from $[0, 1]$. We

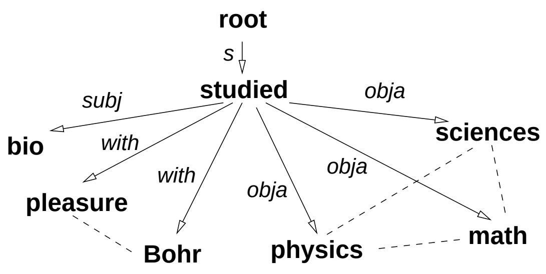


Figure 2: Graph obtained from sentences *He studied sciences with pleasure* and *He studied math and physics with Bohr*

also introduce additional variables $y^l_{w,u}$ (represented by dashed lines in Fig. 2):

$$y^l_{w,u} = \begin{cases} 1 & \text{if } \exists h, l : x^l_{h,w} = 1 \wedge x^l_{h,u} = 1 \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

For two edges sharing a head and having identical labels to be retained we check in GermaNet and in the taxonomy derived from Wikipedia (Kassner et al., 2008) that their dependents are not in the *h*yponymy or *m*eronymy relation (11). We prohibit verb coordination unless it is found in one of the input sentences. If the dependents are nouns, we also check that their semantic relatedness as measured with WikiRelate! (Strube & Ponzetto, 2006) is above a certain threshold (12). We empirically determined the value of $\beta = 0.36$ by calculating an average similarity of coordinated nouns in the corpus.

$$\forall y^l_{w,u}, \mathtt{hm}(w,u) \cdot y^l_{w,u} = 0 \tag{11}$$

$$\forall y^l_{w,u}, (\mathtt{rel}(w,u) - \beta) \cdot y^l_{w,u} \geq 0 \tag{12}$$

(11) prohibits that *physics* (or *math*) and *sciences* appear together since, according to GermaNet, *physics* (*Physik*) is a hyponym of *science* (*Wissenschaft*). (12) blocks taking both *pleasure* (*Freude*) and *Bohr* because *rel(Freude,Bohr)* $= 0.17$. *math* and *physics* are neither in *ISA*, nor *part-of* relation and are sufficiently related (*rel(Mathematik, Physik)* $= 0.67$) to become conjuncts.

META constraints (equations (13) and (14)) guarantee that $y^l_{w,u} = x^l_{h,w} \times x^l_{h,u}$ i.e. they ensure that the semantic constraints are applied only if both the labels from h to w and from h to u are preserved.

$$\forall y^l_{w,u}, x^l_{h,w} + x^l_{h,u} \geq 2y^l_{w,u} \tag{13}$$

$$\forall y^l_{w,u}, 1 - x^l_{h,w} + 1 - x^l_{h,u} \geq 1 - y^l_{w,u} \tag{14}$$

4.7 Linearization

The "overgenerate-and-rank" approach to statistical surface realization is very common (Langkilde & Knight, 1998). Unfortunately, in its simplest and most popular version, it ignores syntactical constraints and may produce ungrammatical output. For example, an inviolable rule of German grammar states that the finite verb must be in the second position in the main clause. Since it is hard to enforce such rules with an ngram language model, syntax-informed linearization methods have been developed for German (Ringger et al., 2004; Filippova & Strube, 2007). We apply our recent method to order constituents and, using the CMU toolkit (Clarkson & Rosenfeld, 1997), build a trigram language model from Wikipedia (approx. 1GB plain text) to find the best word order within constituents. Some constraints on word order are inferred from the input. Only interclause punctuation is generated.

5 Experiments and Evaluation

We choose Barzilay & McKeown's system as a non-trivial baseline since, to our knowledge, there is no other system which outperforms theirs (Sec. 5.1). It is important for us to evaluate the fusion part of our system, so the input and the linearization module of our method and the baseline are identical. We are also interested in how many errors are due to the linearization module and thus define the readability upper bound (Sec. 5.2). We further present and discuss the experiments (Sec. 5.3 and 5.5).

5.1 Baseline

The algorithm of Barzilay & McKeown (2005) proceeds as follows: Given a group of related sentences, a dependency tree is built for each sentence. These trees are modified so that grammatical features are eliminated from the representation and memorized; noun phrases are flattened to facilitate alignment. A locally optimal pairwise alignment of modified dependency trees is recursively found with WordNet and a paraphrase lexicon. From the alignment costs the centroid of the group is identified. Then this tree is augmented with information from other trees given that it appears in at least half of the sentences from this group. A rule-based pruning module prunes optional constituents, such as PPs or relative clauses. The linearization of the resulting tree (or graph) is done with a trigram language model.

To adapt this system to German, we use the GermaNet API (Gurevych & Niederlich, 2005) instead of WordNet. We do not use a paraphrase lexicon, because there is no comparable corpus of sufficient size available for German. We readjust the alignment parameters of the system to prevent dissimilar nodes from being aligned. The input to the algorithm is generated as described in Sec. 4.1. The linearization is done as described in Sec. 4.7. In cases when there is a graph to linearize, all possible trees covering the maximum number of nodes are extracted from it and linearized. The most probable string is selected as the final output with a language model. For the rest of the reimplementation we follow the algorithm as presented.

5.2 Readability Upper Bound

To find the upper bound on readability, we select one sentence from the input randomly, parse it and linearize the dependency tree as described in Sec. 4.7. This way we obtain a sentence which may differ in form from the input sentences but whose content is identical to one of them.

5.3 Experiments

It is notoriously difficult to evaluate generation and summarization systems as there are many dimensions in which the quality of the output can be assessed. The goal of our present evaluation is in the first place to check whether our method is able to produce sensible output.

We evaluated the three systems (GRAPH-COMPRESSION, BARZILAY & MCKEOWN and READABILITY UB) with 50 native German speakers on 120 fused sentences generated from 40 randomly drawn related sentences groups (3×40). In an online experiment, the participants were asked to read a fused sentence preceded by the input and to rate its readability (*read*) and informativity in respect to the input (*inf*) on a five point scale. The experiment was designed so that every participant rated 40 sentences in total. No participant saw two sentences generated from the same input. The results are presented in Table 2. *len* is an average length in words of the output.

	read	*inf*	*len*
READABILITY UB	4.0	3.5	12.9
BARZILAY & MCKEOWN	3.1	3.0	15.5
GRAPH-COMPRESSION	3.7	3.1	13.0

Table 2: Average readability and informativity on a five point scale, average length in words

5.4 Error Analysis

The main disadvantage of our method, as well as other methods designed to work on syntactic structures, is that it requires a very accurate parser. In some cases, errors in the preprocessing made extracting a valid dependency tree impossible. The poor rating of READABILITY UB also shows that errors of the parser and of the linearization module affect the output considerably.

Although the semantic constraints ruled out many anomalous combinations, the limited coverage of GermaNet and the taxonomy derived from Wikipedia was the reason for some semantic oddities in the sentences generated by our method. For example, it generated phrases like *aus England und Großbritannien* (*from England and Great Britain*). A larger taxonomy would presumably increase the recall of the semantic constraints which proved helpful. Such errors were not observed in the output of the baseline because it does not fuse within NPs.

Both the baseline and our method made subcategorization errors, although these are more common for the baseline which aligns not only synonyms but also verbs which share some arguments. Also, the baseline pruned some PPs necessary for a sentence to be complete. For example, it pruned *an der Atombombe* (*on the atom bomb*) and generated an incomplete sentence *Er arbeitete* (*He worked*). For the baseline, alignment of flattened NPs instead of words caused generating very wordy and redundant sentences when the input parse trees were incorrect. In other cases, our method made mistakes in linearizing constituents because it had to rely on a language model whereas the baseline used unmodified constituents from the input. Absense of intra-clause commas caused a drop in readability in some otherwise grammatical sentences.

5.5 Discussion

A paired t-test revealed significant differences between the readability ratings of the three systems ($p = 0.01$) but found no significant differences between the informativity scores of our system and the baseline. Some participants reported informativity hard to estimate and to be assessable for grammatical sentences only. The higher readability rating of our method supports our claim that the method based on syntactic importance score and global constraints generates more grammatical sentences than existing systems. An important advantage of our method is that it addresses the subcategorization issue directly without shifting the burden of selecting the right arguments to the linearization module. The dependency structure it outputs is a tree and not a graph as it may happen with the method of Barzilay & McKeown (2005). Moreover, our method can distinguish between more and less obligatory arguments. For example, it knows that *at* is more important than *to* for *study* whereas for *go* it is the other way round. Unlike our differentiated approach, the baseline rule states that PPs can generally be pruned.

Since the baseline generates a new sentence by modifying the tree of an input sentence, in some cases it outputs a compression of this sentence. Unlike this, our method is not based on an input tree and generates a new sentence without being biased to any of the input sentences.

Our method can also be applied to non-trivial sentence compression, whereas the baseline and similar methods, such as Marsi & Krahmer (2005), would then boil down to a few very general pruning rules. We tested our method on the English compression corpus[6] and evaluated the compressions automatically the same way as Clarke & Lapata (2008) did. The results (Filippova & Strube, 2008) were as good as or significantly better than the state-of-the-art, depending on the choice of dependency parser.

[6]The corpus is available from `http://homepages.inf.ed.ac.uk/s0460084/data`.

6 Conclusions

We presented a novel sentence fusion method which formulates the fusion task as an optimization problem. It is unsupervised and finds a globally optimal solution taking semantics, syntax and word informativeness into account. The method does not require hand-crafted rules or lexicons to generate grammatical output but relies on the syntactic importance score calculated from an automatically parsed corpus. An experiment with native speakers demonstrated that our method generates more grammatical sentences than existing systems.

There are several directions to explore in the future. Recently query-based sentence fusion has been shown to be a better defined task than generic sentence fusion (Krahmer et al., 2008). By modifying the word informativeness score, e.g. by giving higher scores to words semantically related to the query, one could force our system to retain words relevant to the query in the output. To generate coherent texts we plan to move beyond sentence generation and add discourse constraints to our system.

Abstract

We combine lexical, syntactic, and discourse features to produce a highly predictive model of human readers' judgments of text readability. This is the first study to take into account such a variety of linguistic factors and the first to empirically demonstrate that discourse relations are strongly associated with the perceived quality of text. We show that various surface metrics generally expected to be related to readability are not very good predictors of readability judgments in our Wall Street Journal corpus. We also establish that readability predictors behave differently depending on the task: predicting text readability or ranking the readability. Our experiments indicate that discourse relations are the one class of features that exhibits robustness across these two tasks.

1 Introduction

The quest for a precise definition of text quality—pinpointing the factors that make text flow and easy to read—has a long history and tradition. Way back in 1944 Robert Gunning Associates was set up, offering newspapers, magazines and business firms consultations on clear writing (Gunning, 1952). In education, teaching good writing technique and grading student writing has always been of key importance (Spandel, 2004; Attali and Burstein, 2006). Linguists have also studied various aspects of text flow, with cohesion-building devices in English (Halliday and Hasan, 1976), rhetorical structure theory (Mann and Thompson, 1988) and centering theory (Grosz et al., 1995) among the most influential contributions.

Still, we do not have unified computational models that capture the interplay between various aspects of readability. Most studies focus on a single factor contributing to readability for a given intended audience. The use of rare words or technical terminology for example can make text difficult to read for certain audience types (Collins-Thompson and Callan, 2004; Schwarm and Ostendorf, 2005; Elhadad and Sutaria, 2007). Syntactic complexity is associated with delayed processing time in understanding (Gibson, 1998) and is another factor that can decrease readability. Text organization (discourse structure), topic development (entity coherence) and the form of referring expressions also determine readability. But we know little about the relative importance of each factor and how they combine in determining perceived text quality.

In our work we use texts from the Wall Street Journal intended for an *educated adult audience* to analyze readability factors including vocabulary, syntax, cohesion, entity coherence and discourse. We study the association between these features and reader assigned readability ratings, showing that discourse and vocabulary are the factors most strongly linked to text quality. In the easier task of text quality ranking, entity coherence and syntax features also become significant and the combination of features allows for ranking prediction accuracy of 88%. Our study is novel in the use of gold-standard discourse features for predicting readability and the simultaneous analysis of various readability factors.

2 Related work

2.1 Readability with respect to intended readers

The definition of what one might consider to be a well-written and readable text heavily depends on the intended audience (Schriver, 1989). Obviously, even a superbly written scientific paper will not be perceived as very readable by a lay person and a great novel might not be appreciated by a third grader. As a result, the vast majority of prior work on readability deals with labeling texts with the appropriate school grade level. A key observation in even the oldest work in this area is that the vocabulary used in a text largely determines its readability. More common words are easier, so some metrics measured text readability by the percentage of words that were not among the N most frequent in the language. It was also observed that frequently occurring words are often short, so word length was used to approximate readability more robustly than using a predefined word frequency list. Standard indices were developed based on the link between word frequency/length and readability, such as Flesch-Kincaid (Kincaid, 1975), Automated Readability Index (Kincaid, 1975), Gunning Fog (Gunning, 1952), SMOG (McLaughlin, 1969), and Coleman-Liau (Coleman and Liau, 1975). They use only a few simple factors that are designed to be easy to calculate and are rough approximations to the linguistic factors that determine readability. For example, Flesch-Kincaid uses the average number of syllables per word to approximate vocabulary difficulty and the average number of words per sentence to approximate syntactic difficulty.

In recent work, the idea of linking word frequency and text readability has been explored for making medical information more accessible to the general public. (Elhadad and Sutaria, 2007) classified words in medical texts as familiar or unfamiliar to a general audience based on their frequencies in corpora. When a description of the unfamiliar terms was provided, the perceived readability of the texts almost doubled.

A more general and principled approach to using vocabulary information for readability decisions has been the use of language models. For any given text, it is easy to compute its likelihood under a given language model, i.e. one for text meant for children, or for text meant for adults, or for a given grade level. (Si and Callan, 2001), (Collins-Thompson and Callan, 2004), (Schwarm and Ostendorf, 2005), and (Heilman et al., 2007) used language models to predict the suitability of texts for a given school grade level. But even for this type of task other factors besides vocabulary use are at play in determining readability. Syntactic complexity is an obvious factor: indeed (Heilman et al., 2007) and (Schwarm and Ostendorf, 2005) also used syntactic features, such as parse tree height or the number of passive sentences, to predict reading grade levels. For the task of deciding whether a text is written for an adult or child reader, (Barzilay and Lapata, 2008) found that adding entity coherence to (Schwarm and Ostendorf, 2005)'s list of features improves classification accuracy by 10%.

2.2 Readability as coherence for competent language users

In linguistics and natural language processing, the text properties rather than those of the reader are emphasized. Text coherence is defined as the ease with which a person (tacitly assumed to be a competent language user) understands a text. Coherent text is characterized by various types of cohesive links that facilitate text comprehension (Halliday and Hasan, 1976).

In recent work, considerable attention has been devoted to entity coherence in text quality, especially in relation to information ordering. In many applications such as text generation and summarization, systems need to decide the order in which selected sentences or generated clauses should be presented to the user. Most models attempting to capture local coherence between sentences were based on or inspired by centering theory (Grosz et al., 1995), which postulated strong links between the center of attention in comprehension of adjacent sentences and syntactic position and form of reference. In a detailed study of information ordering in three very different corpora, (Karamanis et al., to appear) assessed the performance of various formulations of centering. Their results were somewhat unexpected, showing that while centering transition preferences were useful, the most successful strategy for information ordering was based on avoiding rough shifts, that is, sequences of sentences that share no entities in common. This supports previous findings that such types of transitions are associated with poorly written text and can be used to improve the accuracy of automatic grading of essays based on various non-discourse features (Miltsakaki and Kukich, 2000). In a more powerful generalization of centering, Barzilay and Lapata (2008) developed a novel approach which doesn't postulate a preference for any type of transition but rather computes a set of features that capture transitions of all kinds in the text and their relative proportion. Their entity coherence features prove to be very suitable for various tasks, notably for information ordering and reading difficulty level.

Form of reference is also important in well-written text and appropriate choices lead to improved readability. Use of pronouns for reference to highly salient entities is perceived as more desirable than the use of definite noun phrases (Gordon et al., 1993; Krahmer and Theune, 2002). The syntactic forms of first mention—when an entity is first introduced in a text—differ from those of subsequent mentions (Poesio and Vieira, 1998; Nenkova and McKeown, 2003) and can be exploited for improving and predicting text coherence (Siddharthan, 2003; Nenkova and McKeown, 2003; Elsner and Charniak, 2008).

3 Data

The objective of our study is to analyze various readability factors, including discourse relations, because few empirical studies exist that directly link discourse structure with text quality. In the past, subsections of the Penn Treebank (Marcus et al., 1994) have been annotated for discourse relations (Carlson et al., 2001; Wolf and Gibson, 2005). For our study we chose to work with the newly released Penn Discourse Treebank which is the largest annotated resource which focuses exclusively on implicit local relations between adjacent sentences and explicit discourse connectives.

3.1 Discourse annotation

The Penn Discourse Treebank (Prasad et al., 2008) is a new resource with annotations of discourse connectives and their senses in the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1994). All *explicit* relations (those marked with a discourse connective) are annotated. In addition, each adjacent pair of sentences within a paragraph is annotated. If there is a discourse relation, then it is marked *implicit* and annotated with one or more connectives. If there is a relation between the sentences but adding a connective would be inappropriate, it is marked *AltLex*. If the consecutive sentences are only related by entity-based coherence (Knott et al., 2001) they are annotated with *EntRel*. Otherwise, they are annotated with *NoRel*.

Besides labeling the connective, the PDTB also annotates the *sense* of each relation. The relations are organized into a hierarchy. The top level relations are Expansion, Comparison, Contingency, and Temporal. Briefly, an expansion relation means that the second clause continues the theme of the first clause, a comparison relation indicates that something in the two clauses is being compared, contingency means that there is a causal relation between the clauses, and temporal means they occur either at the same time or sequentially.

3.2 Readability ratings

We randomly selected thirty articles from the Wall Street Journal corpus that was used in both the Penn Treebank and the Penn Discourse Treebank.[1] Each article was read by at least three college students, each of whom was given unlimited time to read the texts and perform the ratings.[2] Subjects were asked the following questions:

- How well-written is this article?
- How well does the text fit together?
- How easy was it to understand?
- How interesting is this article?

For each question, they provided a rating between 1 and 5, with 5 being the best and 1 being the worst.

[1]One of the selected articles was missing from the Penn Treebank. Thus, results that do not require syntactic information (Tables 1, 2, 4, and 6) are over all thirty articles, while Tables 3, 5, and 7 report results for the twenty-nine articles with Treebank parse trees.

[2](Lapata, 2006) found that human ratings are significantly correlated with self-paced reading times, a more direct measure of processing effort which we plan to explore in future work.

After collecting the data, it turned out that most of the time subjects gave the same rating to all questions. For competent language users, we view text readability and text coherence as equivalent properties, measuring the extent to which a text is well written. Thus for all subsequent analysis, we will use only the first question ("On a scale of 1 to 5, how well written is this text?"). The score of an article was then the average of all the ratings it received. The article scores ranged from 1.5 to 4.33, with a mean of 3.2008 and a standard deviation of .7242. The median score was 3.286.

We define our task as predicting this average rating for each article. Note that this task may be more difficult than predicting reading level, as each of these articles appeared in the Wall Street Journal and thus is aimed at the same target audience. We suspected that in classifying adult text, more subtle features might be necessary.

4 Identifying correlates of text quality

4.1 Baseline measures

We first computed the Pearson correlation coefficients between the simple metrics that most traditional readability formulas use and the average human ratings. These results are shown in Table 1. We tested *the average number of characters per word*, *average number of words per sentence*, *maximum number of words per sentence*, and *article length* (F_7).[3] Article length (F_7) was the only significant baseline factor, with correlation of -0.37. Longer articles are perceived as less well-written and harder to read than shorter ones. None of the other baseline metrics were close to being significant predictors of readability.

Average Characters/Word	r = -.0859, p = .6519
Average Words/Sentence	r = .1637, p = .3874
Max Words/Sentence	r = .0866, p = .6489
F_7 text length	**r = -.3713, p = .0434**

Table 1: Baseline readability features

[3]For ease of reference, we number each non-baseline feature in the text and tables.

4.2 Vocabulary

We use a unigram language model, where the probability of an article is:

$$\prod_w P(w|M)^{C(w)} \tag{1}$$

$P(w|M)$ is the probability of word-type w according to a background corpus M, and $C(w)$ is the number of times w appears in the article.

The log likelihood of an article is then:

$$\sum_w C(w)\log(P(w|M)) \tag{2}$$

Note that this model will be biased in favor of shorter articles. Since each word has probability less than 1, the log probability of each word is less than 0, and hence including additional words decreases the log likelihood. We compensate for this by performing linear regressions with the unigram log likelihood and with the number of words in the article as an additional variable.

The question then arises as to what to use as a background corpus. We chose to experiment with two corpora: the entire Wall Street Journal corpus and a collection of general AP news, which is generally more diverse than the financial news found in the WSJ. We predicted that the NEWS vocabulary would be more representative of the types of words our readers would be familiar with. In both cases we used Laplace smoothing over the word frequencies and a stoplist.

The vocabulary features we used are *article likelihood estimated from a language model from WSJ* (F_5), and *article likelihood according to a unigram language model from NEWS* (F_6). We also combine the two likelihood features with article length, in order to get a better estimate of the language model's influence on readability independent of the length of the article.

F_5 Log likelihood, WSJ	**r = .3723, p = .0428**
F_6 Log likelihood, NEWS	**r= .4497, p = .0127**
LL with length, WSJ	**r = .3732, p = .0422**
LL with length, NEWS	**r = .6359, p = .0002**

Table 2: Vocabulary features

Both vocabulary-based features (F_5 and F_6) are significantly correlated with the readability judgments, with p-values smaller than 0.05 (see Table 2).

The correlations are positive: the more probable an article was based on its vocabulary, the higher it was generally rated. As expected, the NEWS model that included more general news stories had a higher correlation with people's judgments. When combined with the length of the article, the unigram language model from the NEWS corpus becomes very predictive of readability, with the correlation between the two as high as 0.63.

4.3 Syntactic features

Syntactic constructions affect processing difficulty and so might also affect readability judgments. We examined the four syntactic features used in (Schwarm and Ostendorf, 2005): *average parse tree height* (F_1), *average number of noun phrases per sentence* (F_2), *average number of verb phrases per sentence* (F_3), and *average number of subordinate clauses per sentence(SBARs in the Penn Treebank tagset) (F_4).* The sentence "We're talking about years ago [SBAR before anyone heard of asbestos having any questionable properties]." contains an example of an SBAR clause.

Having multiple noun phrases (entities) in each sentence requires the reader to remember more items, but may make the article more interesting. (Barzilay and Lapata, 2008) found that articles written for adults tended to contain many more entities than articles written for children. While including more verb phrases in each sentence increases the sentence complexity, adults might prefer to have related clauses explicitly grouped together.

F_1 Average Parse Tree Height	r = -.0634, p = .7439
F_2 Average Noun Phrases	r = .2189, p = .2539
F_3 **Average Verb Phrases**	**r = .4213, p = .0228**
F_4 Average SBARs	r = .3405, p = .0707

Table 3: Syntax-related features

The correlations between readability and syntactic features is shown in Table 3. The strongest correlation is that between readability and number of verb phrases (0.42). This finding is in line with prescriptive clear writing advice (Gunning, 1952; Spandel, 2004), but is to our knowledge novel in the computational linguistics literature. As (Bailin and Grafstein, 2001) point out, the sentences in (1) are easier to comprehend than the sentences in (2), even though they are longer.

(1) It was late at night, but it was clear. The stars were out and the moon was bright.

(2) It was late at night. It was clear. The stars were out. The moon was bright.

Multiple verb phrases in one sentence may be indicative of explicit discourse relations, which we will discuss further in section 4.6.

Surprisingly, the use of clauses introduced by a (possibly empty) subordinating conjunction (SBAR), are actually positively correlated (and almost approaching significance) with readability. So while for children or less educated adults these constructions might pose difficulties, they were favored by our assessors. On the other hand, the average parse tree height negatively correlated with readability as expected, but surprisingly the correlation is very weak (-0.06).

4.4 Elements of lexical cohesion

In their classic study of cohesion in English, (Halliday and Hasan, 1976) discuss the various aspects of well written discourse, including the use of cohesive devices such as pronouns, definite descriptions and topic continuity from sentence to sentence.[4] To measure the association between these features and readability rankings, we compute *the number of pronouns per sentence* (F_{11}) and *the number of definite articles per sentence* (F_{12}). In order to qualify topic continuity from sentence to sentence in the articles, we compute *average cosine similarity* (F_8), *word overlap* (F_9) and *word overlap over just nouns and pronouns* (F_{10}) between pairs of adjacent sentences[5]. Each sentence is turned into a vector of word-types, where each type's value is its tf-idf (where document frequency is computed over all the articles in the WSJ corpus). The cosine similarity metric is then:

$$\cos(s,t) = \frac{s \cdot t}{|s|\,|t|} \tag{3}$$

[4]Other cohesion building devises discussed by Halliday and Hansan include lexical reiteration and discourse relations, which we address next.

[5]Similar features have been used for automatic essay grading as well (Higgins et al., 2004).

F_8 Avr. Cosine Overlap	r = -.1012, p = .5947
F_9 Avr. Word Overlap	r = -.0531, p = .7806
F_{10} Avr. Noun+Pronoun Overlap	r = .0905, p = .6345
F_{11} Avr. # Pronouns/Sent	r = .2381, p = .2051
F_{12} Avr # Definite Articles	r = .2309, p = .2196

Table 4: Superficial measures of topic continuity and pronoun and definite description use

None of these features correlate significantly with readability as can be seen from the results in Table 4. The overlap features are particularly bad predictors of readability, with average word/cosine overlap in fact being negatively correlated with readability. The form of reference—use of pronouns and definite descriptions—exhibit a higher correlation with readability (0.23), but these values are not significant for the size of our corpus.

4.5 Entity coherence

We use the Brown Coherence Toolkit[6] to compute entity grids (Barzilay and Lapata, 2008) for each article. In each sentence, an entity is identified as the subject (S), object (O), other (X) (for example, part of a prepositional phrase), or not present (N). The probability of each transition type is computed. For example, an S-O transition occurs when an entity is the subject in one sentence then an object in the next; X-N transition occurs when an entity appears in non-subject or object position in one sentence and not present in the next, etc.[7] The entity coherence features are the *probability of each of these pairs of transitions*, for a total of 16 features (F_{17-32}; see complete results in Table 5).

None of the entity grid features are significantly correlated with the readability ratings. One very interesting result is that the proportion of S-S transitions in which the same entity was mentioned in subject position in two adjacent sentences, is negatively correlated with readability. In centering theory, this is considered the most coherent type of transition, keeping the same center of attention. Moreover, the feature most strongly correlated with readability is the S-N transition (0.31) in which the subject of one sentence does not appear at all in the following sentence. Of course, it is difficult to interpret the entity grid features one by one, since they are interdependent and probably it is the interaction of features (relative proportions of transitions) that capture overall readability patterns.

[6]http://www.cs.brown.edu/ melsner/manual.html

[7]The Brown Coherence Toolkit identifies NPs as the same entity if they have identical head nouns.

F_{17} Prob. of S-S transition	r = -.1287, p = .5059
F_{18} Prob. of S-O transition	r = -.0427, p = .8261
F_{19} Prob. of S-X transition	r = -.1450, p = .4529
F_{20} Prob. of S-N transition	r = .3116, p = .0999
F_{21} Prob. of O-S transition	r = .1131, p = .5591
F_{22} Prob. of O-O transition	r = .0825, p = .6706
F_{23} Prob. of O-X transition	r = .0744, p = .7014
F_{24} Prob. of O-N transition	r = .2590, p = .1749
F_{25} Prob. of X-S transition	r = .1732, p = .3688
F_{26} Prob. of X-O transition	r = .0098, p = .9598
F_{27} Prob. of X-X transition	r = -.0655, p = .7357
F_{28} Prob. of X-N transition	r = .1319, p = .4953
F_{29} Prob. of N-S transition	r = .1898, p = .3242
F_{30} Prob. of N-O transition	r = .2577, p = .1772
F_{31} Prob. of N-X transition	r = .1854, p = .3355
F_{32} Prob. of N-N transition	r = -.2349, p = .2200

Table 5: Linear correlation between human readability ratings and entity coherence.

4.6 Discourse relations

Discourse relations are believed to be a major factor in text coherence. We computed another language model which is over discourse relations instead of words. We treat each text as a bag of relations rather than a bag of words. Each relation is annotated for both its sense and how it is realized (implicit or explicit). For example, one text might contain {Implicit Comparison, Explicit Temporal, NoRel}. We computed the probability of each of our articles according to a multinomial model, where the probability of a text with n relation tokens and k relation types is:

$$P(n)\frac{n!}{x_1!...x_k!}p_1^{x_1}...p_k^{x_k} \quad (4)$$

$P(n)$ is the probability of an article having length n, x_i is the number of times relation i appeared, and p_i is the probability of relation i based on the Penn Discourse Treebank. $P(n)$ is the maximum likelihood estimation of an article having n discourse relations based on the entire Penn Discourse Treebank (the number of articles with exactly n discourse relations, divided by the total number of articles).

The *log likelihood of an article based on its discourse relations* (F_{13}) feature is defined as:

$$\log(P(n)) + \log(n!) + \sum_{i=1}^{k} (x_i \log(p_i) - \log(x_i!)) \quad (5)$$

The multinomial distribution is particularly suitable, because it directly incorporates length, which significantly affects readability as we discussed earlier. It also captures patterns of relative frequency of relations, unlike the simpler unigram model. Note also that this equation has an advantage over the unigram model that was not present for vocabulary. While every article contains at least one word, some articles do not contain any discourse relations. Since the PDTB annotated all explicit relations and relations between adjacent sentences in a paragraph, an article with no discourse connectives and only single sentence paragraphs would not contain any annotated discourse relations. Under the unigram model, these articles' probabilities cannot be computed. Under the multinomial model, the probability of an article with zero relations is estimated as $Pr(N = 0)$, which can be calculated from the corpus.

As in the case of vocabulary features, the presence of more relations will lead to overall lower probabilities so we also consider the *number of discourse relations* (F_{14}) and *the log likelihood combined with the number of relations* as features. In order to isolate the effect of the type of discourse relation (explicitly expressed by a discourse connective such as "because" or "however" versus implicitly expressed by adjacency), we also compute multinomial model features for the *explicit discourse relations* (F_{15}) and over just the *implicit discourse relations* (F_{16}).

F_{13} **LogL of discourse rels**	**r = .4835, p = .0068**
F_{14} # of discourse relations	r = -.2729, p = .1445
LogL of rels with # of rels	**r = .5409, p = .0020**
# of relations with # of words	**r = .3819, p = .0373**
F_{15} Explicit relations only	r = .1528, p = .4203
F_{16} Implicit relations only	r = .2403, p = .2009

Table 6: Discourse features

The likelihood of discourse relations in the text under a multinomial model is very highly and significantly correlated with readability ratings, especially after text length is taken into account. Correlations are 0.48 and 0.54 respectively. The probability of the explicit relations alone is not a sufficiently strong indicator of readability. This fact is disappointing as the explicit relations can be identified much more easily in unannotated text (Pitler et al., 2008). Note that the sequence of just the implicit relations is also not sufficient. This observation implies that the proportion of explicit and implicit relations may be meaningful but we leave the exploration of this issue for later work.

4.7 Summary of findings

So far, we introduced six classes of factors that have been discussed in the literature as readability correlates. Through statistical tests of associations we identified the individual factors significantly correlated with readability ratings. These are, in decreasing order of association strength:

LogL of Discourse Relations (r = .4835)
LogL, NEWS (r= .4497)
Average Verb Phrases (.4213)
LogL, WSJ (r = .3723)
Number of words (r = -.3713)

Vocabulary and discourse relations are the strongest predictors of readability, followed by average number of verb phrases and length of the text. This empirical confirmation of the significance of discourse relations as a readability factor is novel for the computational linguistics literature. Note though that for our work we use oracle discourse annotations directly from the PDTB and no robust systems for automatic discourse annotation exist today.

The significance of the average number of verb phrases as a readability predictor is somewhat surprising but intriguing. It would lead to reexamination of the role of verbs/predicates in written text, which we also plan to address in future work. None of the other factors showed significant association with readability ratings, even though some correlations had relatively large positive values.

5 Combining readability factors

In this section, we turn to the question of how the combination of various factors improves the prediction of readability. We use the **leaps** package in R to find the best subset of features for linear regression, for subsets of size one to eight. We use the squared multiple correlation coefficient (R^2) to assess the effectiveness of predictions. R^2 is the proportion of variance in readability ratings explained by the model. If the model predicts readability perfectly, $R^2 = 1$, and if the model has no predictive capability, $R^2 = 0$.

F_{13}, $R^2 = 0.2662$
$F_6 + F_7$, $R^2 = 0.4351$
$F_6 + F_7 + F_{13}$, $R^2 = 0.5029$
$F_6 + F_7 + F_{13} + F_{14}$, $R^2 = 0.6308$
$F_1 + F_6 + F_7 + F_{10} + F_{13}$, $R^2 = 0.6939$
$F_1 + F_6 + F_7 + F_{10} + F_{13} + F_{23}$, $R^2 = 0.7316$
$F_1 + F_6 + F_7 + F_{10} + F_{13} + F_{22} + F_{23}$, $R^2 = 0.7557$
$F_1 + F_6 + F_7 + F_{10} + F_{11} + F_{13} + F_{19} + F_{30}$, $R^2 = 0.776$.

The linear regression results confirm the expectation that the combination of different factors is a rather complex issue. As expected, discourse, vocabulary and length which were the significant individual factors appear in the best model for each feature set size. Their combination gives the best result for regression with three predictors, and they explain half of the variance in readability ratings, $R^2 = 0.5029$.

But the other individually significant feature, average number of verb phrases per sentence (F_3) never appears in the best models. Instead, F_1—the depth of the parse tree—appears in the best model with more than four features.

Also unexpectedly, two of the superficial cohesion features appear in the larger models: F_{10} is the average word overlap over nouns and pronouns and F_{11} is the average number of pronouns per sentence. Entity grid features also make their way into the best models when more features are used for prediction: S-X, O-O, O-X, N-O transitions (F_{19}, F_{22}, F_{23}, F_{30}).

6 Readability as ranking

In this section we consider the problem of pairwise ranking of text readability. That is, rather than trying to predict the readability of a single document, we consider pairs of documents and predict which one is better. This task may in fact be the more natural one, since in most applications the main concern is with the relative quality of articles rather than their absolute scores. This setting is also beneficial in terms of data use, because each pair of articles with different average readability scores now becomes a data point for the classification task.

We thus create a classification problem: given two articles, is article 1 more readable than article 2? For each pair of texts whose readability ratings on the 1 to 5 scale differed by at least 0.5, we form one data point for the ranking problem, resulting in 243 examples. The predictors are the differences between the two articles' features. For classification, we used WEKA's linear support vector implementation (SMO) and performance was evaluated using 10-fold cross-validation.

Features	**Accuracy**
None (Majority Class)	50.21%
ALL	88.88%
log_l_discourse_rels	77.77%
number_discourse_rels	74.07%
N-O transition	70.78%
O-N transition	69.95%
Avg_VPs_sen	69.54%
log_l_NEWS	66.25%
number_of_words	65.84%
Grid only	79.42%
Discourse only	77.36%
Syntax only	74.07%
Vocab only	66.66%
Length only	65.84%
Cohesion only	64.60%
no cohesion	89.30%
no vocab	88.88%
no length	88.47%
no discourse	88.06%
no grid	84.36%
no syntax	82.71%

Table 7: SVM prediction accuracy, linear kernel

The classification results are shown in Table 7. When all features are used for prediction, the accuracy is high, 88.88%. The length of the article can serve as a baseline feature—longer articles are ranked lower by the assessors, so this feature can be taken as baseline indicator of readability. Only six features used by themselves lead to accuracies higher than the length baseline. These results indicate that the most important individual factors in the readability ranking task, in decreasing order of importance, are log likelihood of discourse relations, number of discourse relations, N-O transitions, O-N transitions, average number of VPs per sentence and text probability under a general language model.

In terms of classes of features, the 16 entity grid features perform the best, leading to an accuracy of 79.41%, followed by the combination of the four discourse features (77.36%), and syntax features (74.07%). This is evidence for the fact that there is a complex interplay between readability factors: the entity grid factors which individually have very weak correlation with readability combine well, while adding the three additional discourse features to the likelihood of discourses relations actually worsens performance slightly. Similar indication for interplay between features is provided by the class ablation classification results, in which classes of features are removed. Surprisingly, removing syntactic features causes the biggest deterioration in performance, a drop in accuracy from 88.88% to 82.71%. The removal of vocabulary, length, or discourse features has a minimal negative impact on performance, while removing the cohesion features actually boosts performance.

7 Conclusion

We have investigated which linguistic features correlate best with readability judgments. While surface measures such as the average number of words per sentence or the average number of characters per word are not good predictors, there exist syntactic, semantic, and discourse features that do correlate highly. The average number of verb phrases in each sentence, the number of words in the article, the likelihood of the vocabulary, and the likelihood of the discourse relations all are highly correlated with humans' judgments of how well an article is written.

While using any one out of syntactic, lexical, coherence, or discourse features is substantally better than the baseline surface features on the discrimination task, using a combination of entity coherence and discourse relations produces the best performance.

Syntactic Constraints on Paraphrases Extracted from Parallel Corpora

Chris Callison-Burch
Center for Language and Speech Processing
Johns Hopkins University
Baltimore, Maryland
ccb@cs.jhu.edu

Abstract

We improve the quality of paraphrases extracted from parallel corpora by requiring that phrases and their paraphrases be the same syntactic type. This is achieved by parsing the English side of a parallel corpus and altering the phrase extraction algorithm to extract phrase labels alongside bilingual phrase pairs. In order to retain broad coverage of non-constituent phrases, complex syntactic labels are introduced. A manual evaluation indicates a 19% absolute improvement in paraphrase quality over the baseline method.

1 Introduction

Paraphrases are alternative ways of expressing the same information. Being able to identify or generate paraphrases automatically is useful in a wide range of natural language applications. Recent work has shown how paraphrases can improve question answering through query expansion (Riezler et al., 2007), automatic evaluation of translation and summarization by modeling alternative lexicalization (Kauchak and Barzilay, 2006; Zhou et al., 2006; Owczarzak et al., 2006), and machine translation both by dealing with out of vocabulary words and phrases (Callison-Burch et al., 2006) and by expanding the set of reference translations for minimum error rate training (Madnani et al., 2007). While all applications require the preservation of meaning when a phrase is replaced by its paraphrase, some additionally require the resulting sentence to be grammatical.

In this paper we examine the effectiveness of placing syntactic constraints on a commonly used paraphrasing technique that extracts paraphrases from parallel corpora (Bannard and Callison-Burch, 2005). The paraphrasing technique employs various aspects of phrase-based statistical machine translation including phrase extraction heuristics to obtain bilingual phrase pairs from word alignments. English phrases are considered to be potential paraphrases of each other if they share a common foreign language phrase among their translations. Multiple paraphrases are frequently extracted for each phrase and can be ranked using a paraphrase probability based on phrase translation probabilities.

We find that the quality of the paraphrases that are generated in this fashion improves significantly when they are required to be the same syntactic type as the phrase that they are paraphrasing. This constraint:

- Eliminates a trivial but pervasive error that arises from the interaction of unaligned words with phrase extraction heuristics.
- Refines the results for phrases that can take on different syntactic labels.
- Applies both to phrases which are linguistically coherent and to arbitrary sequences of words.
- Results in much more grammatical output when phrases are replaced with their paraphrases.

A thorough manual evaluation of the refined paraphrasing technique finds a 19% absolute improve-

Proceedings of the 2008 Conference on Empirical Methods in Natural Language Processing, pages 196–205,
Honolulu, October 2008. ©2008 Association for Computational Linguistics

ment in the number of paraphrases that are judged to be correct.

This paper is structured as follows: Section 2 describes related work in syntactic constraints on phrase-based SMT and work utilizing syntax in paraphrase discovery. Section 3 details the problems with extracting paraphrases from parallel corpora and our improvements to the technique. Section 4 describes our experimental design and evaluation methodology. Section 5 gives the results of our experiments, and Section 6 discusses their implications.

2 Related work

A number of research efforts have focused on employing syntactic constraints in statistical machine translation. Wu (1997) introduced the inversion transduction grammar formalism which treats translation as a process of parallel parsing of the source and target language via a synchronized grammar. The synchronized grammar places constraints on which words can be aligned across bilingual sentence pairs. To achieve computational efficiency, the original proposal used only a single non-terminal label rather than a linguistic grammar.

Subsequent work used more articulated parses to improve alignment quality by applying cohesion constraints (Fox, 2002; Lin and Cherry, 2002). If two English phrases are in disjoint subtrees in the parse, then the phrasal cohesion constraint prevents them from being aligned to overlapping sequences in the foreign sentence. Other recent work has incorporated constituent and dependency subtrees into the translation rules used by phrase-based systems (Galley et al., 2004; Quirk et al., 2005). Phrase-based rules have also been replaced with synchronous context free grammars (Chiang, 2005) and with tree fragments (Huang and Knight, 2006).

A number of techniques for generating paraphrases have employed syntactic information, either in the process of extracting paraphrases from monolingual texts or in the extracted patterns themselves. Lin and Pantel (2001) derived paraphrases based on the distributional similarity of paths in dependency trees. Barzilay and McKeown (2001) incorporated part-of-speech information and other morphosyntactic clues into their co-training algorithm. They extracted paraphrase patterns that incorporate this information. Ibrahim et al. (2003) generated structural paraphrases capable of capturing long-distance dependencies. Pang et al. (2003) employed a syntax-based algorithm to align equivalent English sentences by merging corresponding nodes in parse trees and compressing them down into a word lattice.

Perhaps the most closely related work is a recent extension to Bannard and Callison-Burch's paraphrasing method. Zhao et al. (2008b) extended the method so that it is capable of generating richer paraphrase patterns that include part-of-speech slots, rather than simple lexical and phrasal paraphrases. For example, they extracted patterns such as *consider NN* $\rightarrow$ *take NN into consideration*. To accomplish this, Zhao el al. used dependency parses on the English side of the parallel corpus. Their work differs from the work presented in this paper because their syntactic constraints applied to slots within paraphrase patters, and our constraints apply to the paraphrases themselves.

3 Paraphrasing with parallel corpora

Bannard and Callison-Burch (2005) extract paraphrases from bilingual parallel corpora. They give a probabilistic formation of paraphrasing which naturally falls out of the fact that they use techniques from phrase-based statistical machine translation:

$$\hat{e_2} = \arg\max_{e_2 : e_2 \neq e_1} p(e_2|e_1) \tag{1}$$

where

$$\begin{aligned} p(e_2|e_1) &= \sum_f p(f|e_1)p(e_2|f, e_1) && (2) \\ &\approx \sum_f p(f|e_1)p(e_2|f) && (3) \end{aligned}$$

Phrase translation probabilities $p(f|e_1)$ and $p(e_2|f)$ are commonly calculated using maximum likelihood estimation (Koehn et al., 2003):

$$p(f|e) = \frac{count(e, f)}{\sum_f count(e, f)} \tag{4}$$

where the counts are collected by enumerating all bilingual phrase pairs that are consistent with the

opportunities

Figure 1: The interaction of the phrase extraction heuristic with unaligned English words means that the Spanish phrase *la igualdad* aligns with *equal*, *create equal*, and *to create equal*.

word alignments for sentence pairs in a bilingual parallel corpus. Various phrase extraction heuristics are possible. Och and Ney (2004) defined consistent bilingual phrase pairs as follows:

$$\begin{aligned} BP(f_1^J, e_1^I, A) = \{(f_j^{j+m}, e_i^{i+n}) : \\ \forall(i', j') \in A : j \leq j' \leq j+m \leftrightarrow i \leq i' \leq i+n \\ \wedge \exists(i', j') \in A : j \leq j' \leq j+m \wedge \leftrightarrow i \leq i' \leq i+n\} \end{aligned}$$

where f_1^J is a foreign sentence, e_1^I is an English sentence and A is a set of word alignment points.

The heuristic allows unaligned words to be included at the boundaries of the source or target language phrases. For example, when enumerating the consistent phrase pairs for the sentence pair given in Figure 1, *la igualdad* would align not only to *equal*, but also to *create equal*, and *to create equal*. In SMT these alternative translations are ranked by the translation probabilities and other feature functions during decoding.

The interaction between the phrase extraction heuristic and unaligned words results in an undesirable effect for paraphrasing. By Bannard and Callison-Burch's definition, *equal*, *create equal*, and *to create equal* would be considered paraphrases because they are aligned to the same foreign phrase. Tables 1 and 2 show how sub- and super-phrases can creep into the paraphrases: *equal* can be paraphrased as *equal rights* and *create equal* can be paraphrased as *equal*. Obviously when e_2 is substituted for e_1 the resulting sentence will generally be ungrammatical. The first case could result in *equal equal rights*, and the second would drop the verb.

This problem is pervasive. To test its extent we attempted to generate paraphrases for 900,000 phrases using Bannard and Callison-Burch's method trained on the Europarl corpora (as described in Section 4). It generated a total of 3.7 million paraphrases for 400,000 phrases in the list.[1] We observed that 34% of the paraphrases (excluding the phrase itself) were super- or sub-strings of the original phrase. The most probable paraphrase was a super- or sub-string of the phrase 73% of the time.

Table 2: The baseline's paraphrases of *create equal*. Most are clearly bad, and the most probable $e_2 \neq e_1$ is a substring of e_1.

There are a number of strategies that might be adopted to alleviate this problem:

- Bannard and Callison-Burch (2005) rank their paraphrases with a language model when the paraphrases are substituted into a sentence.

- Bannard and Callison-Burch (2005) sum over multiple parallel corpora C to reduce the problems associated with systematic errors in the

[1]The remaining 500,000 phrases could not be paraphrased either because $e_2 \neq e_1$ or because they were not consistently aligned to any foreign phrases.

word alignments in one language pair:

$$\hat{e_2} = \arg\max_{e_2} \sum_{c \in C} \sum_{f} p(f|e_1)p(e_2|f) \qquad (5)$$

- We could change the phrase extraction heuristic's treatment of unaligned words, or we could attempt to ensure that we have fewer unaligned items in our word alignments.
- The paraphrase criterion could be changed from being $e_2 \neq e_1$ to specifying that $e2$ is not sub- or super-string of $e1$.

In this paper we adopt a different strategy. The essence of our strategy is to constrain paraphrases to be the same syntactic type as the phrases that they are paraphrasing. Syntactic constraints can apply in two places: during phrase extraction and when substituting paraphrases into sentences. These are described in sections 3.1 and 3.2.

3.1 Syntactic constraints on phrase extraction

When we apply syntactic constraints to the phrase extraction heuristic, we change how bilingual phrase pairs are enumerated and how the component probabilities of the paraphrase probability are calculated.

We use the syntactic type s of e_1 in a refined version of the paraphrase probability:

$$\hat{e_2} = \arg\max_{e_2 : e_2 \neq e_1 \wedge s(e_2) = s(e_1)} p(e_2|e_1, s(e_1)) \qquad (6)$$

where $p(e_2|e_1, s(e_1))$ can be approximated as:

$$\sum_{c \in C} \frac{\sum_f p(f|e_1, s(e_1))p(e_2|f, s(e_1))}{|C|} \qquad (7)$$

We define a new phrase extraction algorithm that operates on an English parse tree P along with foreign sentence f_1^J, English sentence e_1^I, and word alignment A. We dub this SBP for *syntactic bilingual phrases*:

$$\begin{aligned} SBP(f_1^J, e_1^I, A, P) = \{(f_j^{j+m}, e_i^{i+n}, s(e_i^{i+n})) : \\ \forall (i', j') \in A : j \leq j' \leq j+m \leftrightarrow i \leq i' \leq i+n \\ \wedge \exists (i', j') \in A : j \leq j' \leq j+m \wedge \leftrightarrow i \leq i' \leq i+n \\ \wedge \exists \text{ subtree } \in P \text{ with label } s \text{ spanning words } (i, i+n)\} \end{aligned}$$

equal

JJ	equal	.60	similar	.02
	same	.14	equivalent	.01
	fair	.02		
ADJP	equal	.79	the same	.01
	necessary	.02	equal in law	.01
	similar	.02	equivalent	.01
	identical	.02		

Table 3: Syntactically constrained paraphrases for *equal* when it is labeled as an adjective or adjectival phrase.

The SBP phrase extraction algorithm produces tuples containing a foreign phrase, an English phrase and a syntactic label (f, e, s). After enumerating these for all phrase pairs in a parallel corpus, we can calculate $p(f|e_1, s(e_1))$ and $p(e_2|f, s(e_1))$ as:

$$\begin{aligned} p(f|e_1, s(e_1)) &= \frac{count(f, e_1, s(e_1))}{\sum_f count(f, e_1, s(e_1))} \\ p(e_2|f, s(e_1)) &= \frac{count(f, e_2, s(e_1))}{\sum_{e_2} count(f, e_2, s(e_1))} \end{aligned}$$

By redefining the probabilities in this way we partition the space of possible paraphrases by their syntactic categories.

In order to enumerate all phrase pairs with their syntactic labels we need to parse the English side of the parallel corpus (but not the foreign side). This limits the potential applicability of our refined paraphrasing method to languages which have parsers.

Table 3 gives an example of the refined paraphrases for *equal* when it occurs as an adjective or adjectival phrase. Note that most of the paraphrases that were possible under the baseline model (Table 1) are now excluded. We no longer get the noun *equality*, the verb *equals*, the adverb *equally*, the determier *the* or the NP *equal rights*. The paraphrases seem to be higher quality, especially if one considers their fidelity when they replace the original phrase in the context of some sentence.

We tested the rate of paraphrases that were sub- and super-strings when we constrain paraphrases based on non-terminal nodes in parse trees. The percent of the best paraphrases being substrings dropped from 73% to 24%, and the overall percent of paraphrases subsuming or being subsumed by the original phrase dropped from 34% to 12%. However, the number of phrases for which we were able

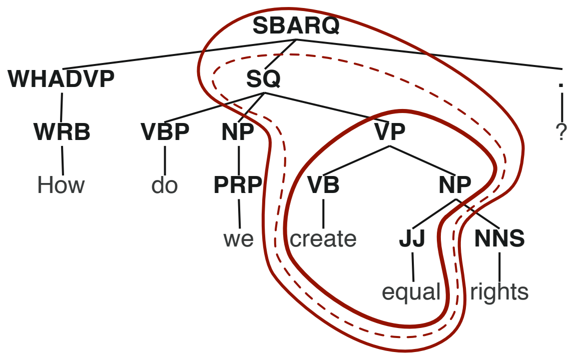

Figure 2: In addition to extracting phrases that are dominated by a node in the parse tree, we also generate labels for non-syntactic constituents. Three labels are possible for *create equal*.

to generated paraphrases dropped from 400,000 to 90,000, since we limited ourselves to phrases that were valid syntactic constituents. The number of unique paraphrases dropped from several million to 800,000.

The fact that we are able to produce paraphrases for a much smaller set of phrases is a downside to using syntactic constraints as we have initially proposed. It means that we would not be able to generate paraphrases for phrases such as *create equal*. Many NLP tasks, such as SMT, which could benefit from paraphrases require broad coverage and may need to paraphrases for phrases which are not syntactic constituents.

Complex syntactic labels

To generate paraphrases for a wider set of phrases, we change our phrase extraction heuristic again so that it produces phrase pairs for arbitrary spans in the sentence, including spans that aren't syntactic constituents. We assign every span in a sentence a syntactic label using CCG-style notation (Steedman, 1999), which gives a syntactic role with elements missing on the left and/or right hand sides.

$$\begin{aligned} SBP(f_1^J, e_1^I, A, P) = \{(f_j^{j+m}, e_i^{i+n}, s) : \\ \forall (i', j') \in A : j \le j' \le j+m \leftrightarrow i \le i' \le i+n \\ \wedge \exists (i', j') \in A : j \le j' \le j+m \wedge \leftrightarrow i \le i' \le i+n \\ \wedge \exists s \in \mathit{CCG\text{-}labels}(e_i^{i+n}, P)\} \end{aligned}$$

The function $\mathit{CCG\text{-}labels}$ describes the set of CCG-labels for the phrase spanning positions i to $i+n$ in a parse tree P. It generates three complex syntactic labels for the non-syntactic constituent phrase *create equal* in the parse tree given in Figure 2:

1. VP/(NP/NNS) – This label corresponds to the innermost circle. It indicates that *create equal* is a verb phrase missing a noun phrase to its right. That noun phrase in turn missing a plural noun (NNS) to its right.

2. SQ\VBP NP/(VP/(NP/NNS)) – This label corresponds to the middle circle. It indicates that *create equal* is an SQ missing a VBP and a NP to its left, and the complex VP to its right.

3. SBARQ\WHADVP (SQ\VBP NP/(VP/(NP/NNS)))/. – This label corresponds to the outermost circle. It indicates that *create equal* is an SBARQ missing a WHADVP and the complex SQ to its left, and a punctuation mark to its right.

We can use these complex labels instead of atomic non-terminal symbols to handle non-constituent phrases. For example, Table 4 shows the paraphrases and syntactic labels that are generated for the non-constituent phrase *create equal*. The paraphrases are significantly better than the paraphrases generated for the phrase by the baseline method (refer back to Table 2).

The labels shown in the figure are a fraction of those that can be derived for the phrase in the parallel corpus. Each of these corresponds to a different

create equal		
VP/(NP/NNS)	create equal	.92
	creating equal	.08
VP/(NP/NNS) PP	create equal	.96
	promote equal	.03
	establish fair	.01
VP/(NP/NNS) PP PP	create equal	.80
	creating equal	.10
	provide equal	.06
	create genuinely fair	.04
VP/(NP/(NP/NN) PP)	create equal	.83
	create a level playing	.17
VP/(NP/(NP/NNS) PP)	create equal	.83
	creating equal	.17

Table 4: Paraphrases and syntactic labels for the non-constituent phrase *create equal*.

syntactic context, and each has its own set of associated paraphrases.

We increase the number of phrases that are paraphrasable from the 90,000 in our initial definition of SBP to 250,000 when we use complex CCG labels. The number of unique paraphrases increases from 800,000 to 3.5 million, which is nearly as many paraphrases that were produced by the baseline method for the sample.

3.2 Syntactic constraints when substituting paraphrases into a test sentence

In addition to applying syntactic constraints to our phrase extraction algorithm, we can also apply them when we substitute a paraphrase into a sentence. To do so, we limit the paraphrases to be the same syntactic type as the phrase that it is replacing, based on the syntactic labels that are derived from the phrase tree for a test sentence. Since each phrase normally has a set of different CCG labels (instead of a single non-termal symbol) we need a way of choosing which label to use when applying the constraint.

There are several different possibilities for choosing among labels. We could simultaneously choose the best paraphrase and the best label for the phrase in the parse tree of the test sentence:

$$\hat{e_2} = \arg\max_{e_2:e_2\neq e_1} \arg\max_{s\in CCG\text{-}labels(e_1,P)} p(e_2|e_1,s) \tag{8}$$

Alternately, we could average over all of the labels that are generated for the phrase in the parse tree:

$$\hat{e_2} = \arg\max_{e_2:e_2\neq e_1} \sum_{s\in CCG\text{-}labels(e_1,P)} p(e_2|e_1,s) \tag{9}$$

The potential drawback of using Equations 8 and 9 is that the CCG labels for a particular sentence significantly reduces the paraphrases that can be used. For instance, VP/(NP/NNS) is the only label for the paraphrases in Table 4 that is compatible with the parse tree given in Figure 2.

Because the CCG labels for a given sentence are so specific, many times there are no matches. Therefore we also investigated a looser constraint. We choose the highest probability paraphrase with any label (i.e. the set of labels extracted from all parse trees in our parallel corpus):

$$\hat{e_2} = \arg\max_{e_2:e_2\neq e_1} \arg\max_{s\in\cap_{\forall T \text{ in } C} CCG\text{-}labels(e_1,T)} p(e_2|e_1,s) \tag{10}$$

Equation 10 only applies syntactic constraints during phrase extraction and ignores them during substitution.

In our experiments, we evaluate the quality of the paraphrases that are generated using Equations 8, 9 and 10. We compare their quality against the Bannard and Callison-Burch (2005) baseline.

4 Experimental design

We conducted a manual evaluation to evaluate paraphrase quality. We evaluated whether paraphrases retained the meaning of their original phrases and whether they remained grammatical when they replaced the original phrase in a sentence.

4.1 Training materials

Our paraphrase model was trained using the Europarl corpus (Koehn, 2005). We used ten parallel corpora between English and (each of) Danish, Dutch, Finnish, French, German, Greek, Italian, Portuguese, Spanish, and Swedish, with approximately 30 million words per language for a total of 315 million English words. Automatic word alignments were created for these using Giza++ (Och and Ney, 2003). The English side of each parallel corpus was parsed using the Bikel parser (Bikel, 2002). A total of 1.6 million unique sentences were parsed. A trigram language model was trained on these English sentences using the SRI language modeling toolkit (Stolcke, 2002).

The paraphrase model and language model for the Bannard and Callison-Burch (2005) baseline were trained on the same data to ensure a fair comparison.

4.2 Test phrases

The test set was the English portion of test sets used in the shared translation task of the ACL-2007 Workshop on Statistical Machine Translation (Callison-Burch et al., 2007). The test sentences were also parsed with the Bikel parser.

The phrases to be evaluated were selected such that there was an even balance of phrase lengths (from one word long up to five words long), with half of the phrases being valid syntactic constituents and half being arbitrary sequences of words. 410 phrases were selected at random for evaluation. 30 items were excluded from our results subsequent to evaluation on the grounds that they consisted solely of punctuation and stop words like determiners, prepositions and pronouns. This left a total of 380 unique phrases.

4.3 Experimental conditions

We produced paraphrases under the following eight conditions:

1. **Baseline** – The paraphrase probability defined by Bannard and Callison-Burch (2005). Calculated over multiple parallel corpora as given in Equation 5. Note that under this condition the best paraphrase is the same for each occurrence of the phrase irrespective of which sentence it occurs in.

2. **Baseline + LM** – The paraphrase probability (as above) combined with the language model probability calculated for the sentence with the phrase replaced with the paraphrase.

3. **Extraction Constraints** – This condition selected the best paraphrase according to Equation 10. It chooses the single best paraphrase over all labels. Conditions 3 and 5 only apply the syntactic constraints at the phrase extraction stage, and do not require that the paraphrase have the same syntactic label as the phrase in the sentence that it is being subtituted into.

4. **Extraction Constraints + LM** – As above, but the paraphrases are also ranked with a language model probability.

5. **Substitution Constraints** – This condition corresponds to Equation 8, which selects the highest probability paraphrase which matches at least one of the syntactic labels of the phrase in the test sentence. Conditions 5–8 apply the syntactic constraints both and the phrase extraction and at the substitution stages.

6. **Syntactic Constraints + LM** – As above, but including a language model probability as well.

7. **Averaged Substitution Constraints** – This condition corresponds to Equation 9, which averages over all of the syntactic labels for the phrase in the sentence, instead of choosing the single one which maximizes the probability.

	MEANING
5	All of the meaning of the original phrase is retained, and nothing is added
4	The meaning of the original phrase is retained, although some additional information may be added but does not transform the meaning
3	The meaning of the original phrase is retained, although some information may be deleted without too great a loss in the meaning
2	Substantial amount of the meaning is different
1	The paraphrase doesn't mean anything close to the original phrase
	GRAMMAR
5	The sentence with the paraphrase inserted is perfectly grammatical
4	The sentence is grammatical, but might sound slightly awkward
3	The sentence has an agreement error (such as between its subject and verb, or between a plural noun and singular determiner)
2	The sentence has multiple errors or omits words that would be required to make it grammatical
1	The sentence is totally ungrammatical

Table 5: Annotators rated paraphrases along two 5-point scales.

8. **Averaged Substitution Constraints + LM** – As above, but including a language model probability.

4.4 Manual evaluation

We evaluated the paraphrase quality through a substitution test. We retrieved a number of sentences which contained each test phrase and substituted the phrase with automatically-generated paraphrases. Annotators judged whether the paraphrases had the same meaning as the original and whether the resulting sentences were grammatical. They assigned two values to each sentence using the 5-point scales given in Table 5. We considered an item to have the same meaning if it was assigned a score of 3 or greater, and to be grammatical if it was assigned a score of 4 or 5.

We evaluated several instances of a phrase when it occurred multiple times in the test corpus, since paraphrase quality can vary based on context (Szpektor et al., 2007). There were an average of 3.1 instances for each phrase, with a maximum of 6. There were a total of 1,195 sentences that paraphrases were substituted into, with a total of 8,422 judgements collected. Note that 7 different paraphrases were judged on average for every instance. This is because annotators judged paraphrases for eight conditions, and because we collected judgments for the 5-best paraphrases for many of the conditions.

We measured inter-annotator agreement with the Kappa statistic (Carletta, 1996) using the 1,391 items that two annotators scored in common. The two annotators assigned the same absolute score 47% of the time. If we consider chance agreement to be 20% for 5-point scales, then $K = 0.33$, which is commonly interpreted as "fair" (Landis and Koch, 1977). If we instead measure agreement in terms of how often the annotators both judged an item to be above or below the thresholds that we set, then their rate of agreement was 80%. In this case chance agreement would be 50%, so $K = 0.61$, which is "substantial".

4.5 Data and code

In order to allow other researchers to recreate our results or extend our work, we have prepared the following materials for download[2]:

- The complete set of paraphrases generated for the test set. This includes the 3.7 million paraphrases generated by the baseline method and the 3.5 million paraphrases generated with syntactic constraints.
- The code that we used to produce these paraphrases and the complete data sets (including all 10 word-aligned parallel corpora along with their English parses), so that researchers can extract paraphrases for new sets of phrases.
- The manual judgments about paraphrase quality. These may be useful as development material for setting the weights of a log-linear formulation of paraphrasing, as suggested in Zhao et al. (2008a).

5 Results

Table 6 summarizes the results of the manual evaluation. We can observe a strong trend in the syntactically constrained approaches performing better

[2]Available from `http://cs.jhu.edu/~ccb/`.

	correct meaning	correct grammar	both correct
Baseline	.56	.35	.30
Baseline+LM	.46	.44	.36
Extraction Constraints	**.62**	.57	.46
Extraction Const+LM	.60	.65	.50
Substitution Constraints	.60	.60	.50
Substitution Const+LM	.61	**.68**	.54
Avg Substitution Const	**.62**	.61	.51
Avg Substit Const+LM	.61	**.68**	**.55**

Table 6: The results of the manual evaluation for each of the eight conditions. Correct meaning is the percent of time that a condition was assigned a 3, 4, or 5, and correct grammar is the percent of time that it was given a 4 or 5, using the scales from Table 5.

than the baseline. They retain the correct meaning more often (ranging from 4% to up to 15%). They are judged to be grammatical far more frequently (up to 26% more often without the language model, and 24% with the language model) . They perform nearly 20% better when both meaning and grammaticality are used as criteria.[3]

Another trend that can be observed is that incorporating a language model probability tends to result in more grammatical output (a 7–9% increase), but meaning suffers as a result in some cases. When the LM is applied there is a drop of 12% in correct meaning for the baseline, but only a slight dip of 1-2% for the syntactically-constrained phrases.

Note that for the conditions where the paraphrases were required to have the same syntactic type as the phrase in the parse tree, there was a reduction in the number of paraphrases that could be applied. For the first two conditions, paraphrases were posited for 1194 sentences, conditions 3 and 4 could be applied to 1142 of those sentences, but conditions 5–8 could only be applied to 876 sentences. The substitution constraints reduce coverage to 73% of the test sentences. Given that the extraction constraints have better coverage and nearly identical performance on

[3]Our results show a significantly lower score for the baseline than reported in Bannard and Callison-Burch (2005). This is potentially due to the facts that in this work we evaluated on out-of-domain news commentary data, and we randomly selected phrases. In the pervious work the test phrases were drawn from WordNet, and they were evaluated solely on in-domain European parliament data.

the *meaning* criterion, they might be more suitable in some circumstances.

6 Conclusion

In this paper we have presented a novel refinement to paraphrasing with bilingual parallel corpora. We illustrated that a significantly higher performance can be achieved by constraining paraphrases to have the same syntactic type as the original phrase. A thorough manual evaluation found an absolute improvement in quality of 19% using strict criteria about paraphrase accuracy when comparing against a strong baseline. The syntactically enhanced paraphrases are judged to be grammatically correct over two thirds of the time, as opposed to the baseline method which was grammatically correct under half of the time.

This paper proposed constraints on paraphrases at two stages: when deriving them from parsed parallel corpora and when substituting them into parsed test sentences. These constraints produce paraphrases that are better than the baseline and which are less commonly affected by problems due to unaligned words. Furthermore, by introducing complex syntactic labels instead of solely relying on non-terminal symbols in the parse trees, we are able to keep the broad coverage of the baseline method.

Syntactic constraints significantly improve the quality of this paraphrasing method, and their use opens the question about whether analogous constraints can be usefully applied to paraphrases generated from purely monolingual corpora. Our improvements to the extraction of paraphrases from parallel corpora suggests that it may be usefully applied to other NLP applications, such as generation, which require grammatical output.

Abstract

Translation rule extraction is a fundamental problem in machine translation, especially for *linguistically syntax-based* systems that need parse trees from either or both sides of the bitext. The current dominant practice only uses 1-best trees, which adversely affects the rule set quality due to parsing errors. So we propose a novel approach which extracts rules from a *packed forest* that compactly encodes exponentially many parses. Experiments show that this method improves translation quality by over 1 BLEU point on a state-of-the-art tree-to-string system, and is 0.5 points better than (and twice as fast as) extracting on 30-best parses. When combined with our previous work on forest-based decoding, it achieves a 2.5 BLEU points improvement over the baseline, and even outperforms the hierarchical system of Hiero by 0.7 points.

1 Introduction

Automatic extraction of translation rules is a fundamental problem in statistical machine translation, especially for many syntax-based models where translation rules directly encode linguistic knowledge. Typically, these models extract rules using parse trees from *both* or *either* side(s) of the bitext. The former case, with trees on both sides, is often called *tree-to-tree* models; while the latter case, with trees on either source or target side, include both *tree-to-string* and *string-to-tree* models (see Table 1). Leveraging from structural and linguistic information from parse trees, these models are believed to be better than their phrase-based counterparts in handling non-local reorderings, and have achieved promising translation results.[1]

source target	*examples (partial)*
tree-to-tree	Ding and Palmer (2005)
tree-to-string	Liu et al. (2006); Huang et al. (2006)
string-to-tree	Galley et al. (2006)
string-to-string	Chiang (2005)

Table 1: A classification of syntax-based MT. The first three use *linguistic syntax*, while the last one only *formal syntax*. Our experiments cover the second type using a packed forest in place of the tree for rule-extraction.

However, these systems suffer from a major limitation, that the rule extractor only uses 1-best parse tree(s), which adversely affects the rule set quality due to parsing errors. To make things worse, modern statistical parsers are often trained on domains quite different from those used in MT. By contrast, *formally syntax-based* models (Chiang, 2005) do not rely on parse trees, yet usually perform better than these linguistically sophisticated counterparts.

To alleviate this problem, an obvious idea is to extract rules from k-best parses instead. However, a k-best list, with its limited scope, has too few variations and too many redundancies (Huang, 2008). This situation worsens with longer sentences as the number of possible parses grows exponentially with the sentence length and a k-best list will only capture a tiny fraction of the whole space. In addition, many subtrees are repeated across different parses, so it is

[1]For example, in recent NIST Evaluations, some of these models (Galley et al., 2006; Quirk et al., 2005; Liu et al., 2006) ranked among top 10. See http://www.nist.gov/speech/tests/mt/.

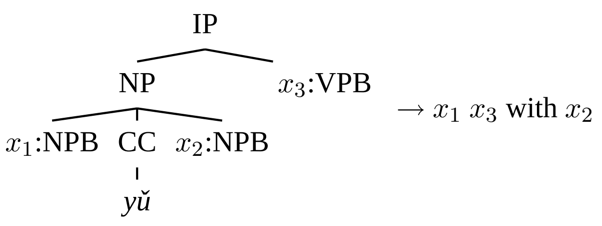

Figure 1: Example translation rule r_1. The Chinese conjunction *yǔ* "and" is translated into English prep. "with".

also inefficient to extract rules separately from each of these very similar trees (or from the cross-product of k^2 similar tree-pairs in tree-to-tree models).

We instead propose a novel approach that extracts rules from *packed forests* (Section 3), which compactly encodes many more alternatives than k-best lists. Experiments (Section 5) show that forest-based extraction improves BLEU score by over 1 point on a state-of-the-art tree-to-string system (Liu et al., 2006; Mi et al., 2008), which is also 0.5 points better than (and twice as fast as) extracting on 30-best parses. When combined with our previous orthogonal work on forest-based decoding (Mi et al., 2008), the forest-forest approach achieves a 2.5 BLEU points improvement over the baseline, and even outperforms the hierarchical system of Hiero, one of the best-performing systems to date.

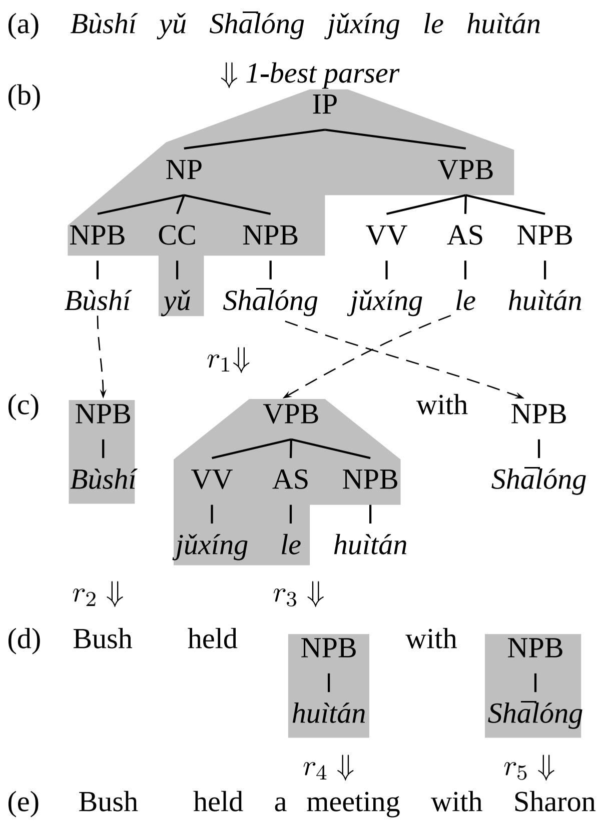
Besides tree-to-string systems, our method is also applicable to other paradigms such as the string-to-tree models (Galley et al., 2006) where the rules are in the reverse order, and easily generalizable to pairs of forests in tree-to-tree models.

2 Tree-based Translation

We review in this section the tree-based approach to machine translation (Liu et al., 2006; Huang et al., 2006), and its rule extraction algorithm (Galley et al., 2004; Galley et al., 2006).

2.1 Tree-to-String System

Current tree-based systems perform translation in two separate steps: parsing and decoding. The input string is first parsed by a parser into a 1-best tree, which will then be converted to a target language string by applying a set of tree-to-string transformation rules. For example, consider the following example translating from Chinese to English:



r_2	NPB(*Bùshí*) → Bush
r_3	VPB(VV(*jǔxíng*) AS(*le*) x_1:NPB) → held x_1
r_4	NPB(*Shālóng*) → Sharon
r_5	NPB(*huìtán*) → a meeting

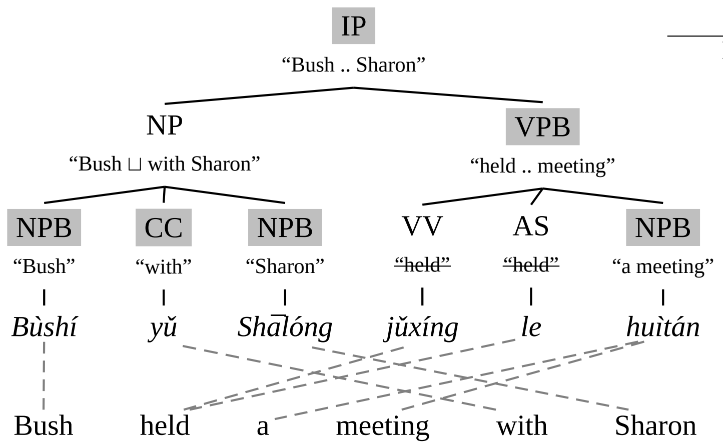
Figure 2: Example derivation of tree-to-string translation, with rules used. Each shaded region denotes a tree fragment that is pattern-matched with the rule being applied.

(1)	*Bùshí*	*yǔ*	*Shālóng*	*jǔxíng*	*le*	*huìtán*
	Bush	and/with	Sharon$_1$	hold	*past.*	meeting$_2$

"Bush held a meeting$_2$ with Sharon$_1$"

Figure 2 shows how this process works. The Chinese sentence (a) is first parsed into a parse tree (b), which will be converted into an English string in 5 steps. First, at the root node, we apply rule r_1 shown in Figure 1, which translates the Chinese coordination construction ("... and ...") into an English prepositional phrase. Then, from step (c) we continue applying rules to untranslated Chinese subtrees, until we get the complete English translation in (e).[2]

[2]We swap the 1-best and 2-best parses of the example sentence from our earlier paper (Mi et al., 2008), since the current 1-best parse is easier to illustrate the rule extraction algorithm.



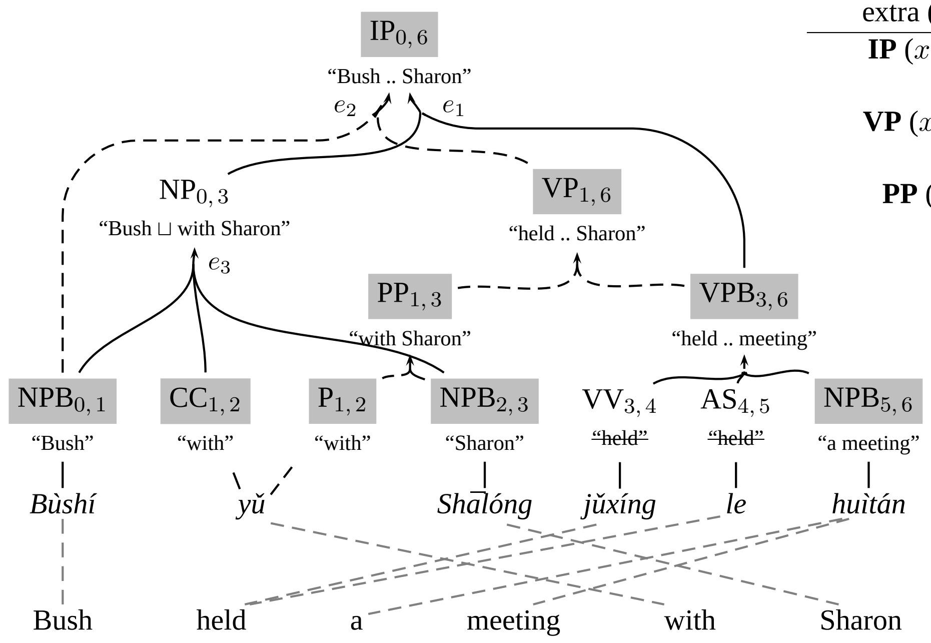
(minimal) rules extracted

IP (NP(x_1:NPB x_2:CC x_3:NPB) x_4:VPB)
$\rightarrow x_1\ x_4\ x_2\ x_3$

CC (*yǔ*) → with
NPB (*Bùshí*) → Bush
NPB (*Shālóng*) → Sharon

VPB (VV(*jǔxíng*) AS(*le*) x_1:NPB)
→ held x_1
NPB (*huìtán*) → a meeting

Figure 3: Tree-based rule extraction (Galley et al., 2004). Each non-leaf node in the tree is annotated with its target span (below the node), where ⊔ denotes a gap, and non-faithful spans are crossed out. Shadowed nodes are **admissible**, with contiguous and faithful spans. The first two rules can be "composed" to form rule r_1 in Figure 1.



extra (minimal) rules extracted

IP (x_1:NPB x_2:VP) → $x_1\ x_2$

VP (x_1:PP x_2:VPB) → $x_2\ x_1$

PP (x_1:P x_2:NPB) → $x_1\ x_2$

P (*yǔ*) → with

Figure 4: Forest-based rule extraction. Solid hyperedges correspond to the 1-best tree in Figure 3, while dashed hyperedges denote the alternative parse interpreting *yǔ* as a preposition in Figure 5.

More formally, a (tree-to-string) **translation rule** (Galley et al., 2004; Huang et al., 2006) is a tuple $\langle lhs(r), rhs(r), \phi(r)\rangle$, where $lhs(r)$ is the source-side tree fragment, whose internal nodes are labeled by nonterminal symbols (like NP and VP), and whose frontier nodes are labeled by source-language words (like "*yǔ*") or variables from a set $\mathcal{X} = \{x_1, x_2, \ldots\}$; $rhs(r)$ is the target-side string expressed in target-language words (like "with") and variables; and $\phi(r)$ is a mapping from $\mathcal{X}$ to nonterminals. Each variable $x_i \in \mathcal{X}$ occurs *exactly once* in $lhs(r)$ and *exactly once* in $rhs(r)$. For example, for rule r_1 in Figure 1,

$$\begin{aligned} lhs(r_1) &= \text{IP (NP(}x_1 \text{ CC(}yǔ\text{) } x_2\text{)} \ \ x_3\text{)},\\ rhs(r_1) &= x_1 \ x_3 \text{ with } x_2,\\ \phi(r_1) &= \{x_1\text{: NPB, } x_2\text{: NPB, } x_3\text{: VPB}\}. \end{aligned}$$

These rules are being used in the reverse direction of the string-to-tree transducers in Galley et al. (2004).

2.2 Tree-to-String Rule Extraction

We now briefly explain the algorithm of Galley et al. (2004) that can extract these translation rules from a word-aligned bitext with source-side parses.

Consider the example in Figure 3. The basic idea is to decompose the source (Chinese) parse into a series of tree fragments, each of which will form a rule with its corresponding English translation. However, not every fragmentation can be used for rule extraction, since it may or may not respect the alignment and reordering between the two languages. So we say a fragmentation is **well-formed** with respect to an alignment if the root node of every tree fragment corresponds to a **contiguous span** on the target side; the intuition is that there is a "translational equivalence" between the subtree rooted at the node and the corresponding target span. For example, in Figure 3, each node is annotated with its corresponding English span, where the NP node maps to a non-contiguous one "Bush $\sqcup$ with Sharon".

More formally, we need a precise formulation to handle the cases of one-to-many, many-to-one, and many-to-many alignment links. Given a source-target sentence pair (σ, τ) with alignment a, the (target) **span** of node v is the set of target words aligned to leaf nodes $yield(v)$ under node v:

$$span(v) \triangleq \{\tau_i \in \tau \mid \exists \sigma_j \in yield(v), (\sigma_j, \tau_i) \in a\}.$$

For example, in Figure 3, every node in the parse tree is annotated with its corresponding span below the node, where most nodes have contiguous spans except for the NP node which maps to a gapped phrase "Bush $\sqcup$ with Sharon". But contiguity alone is not enough to ensure well-formedness, since there might be words within the span aligned to source words uncovered by the node. So we also define a span s to be **faithful** to node v if every word in it is *only* aligned to nodes dominated by v, i.e.:

$$\forall \tau_i \in s, (\sigma_j, \tau_i) \in a \Rightarrow \sigma_j \in yield(v).$$

For example, sibling nodes VV and AS in the tree have non-faithful spans (crossed out in the Figure), because they both map to "held", thus *neither* of them can be translated to "held" alone. In this case, a larger tree fragment rooted at VPB has to be extracted. Nodes with non-empty, contiguous, *and* faithful spans form the **admissible set** (shaded nodes in the figure), which serve as potential cut-points for rule extraction.[3]

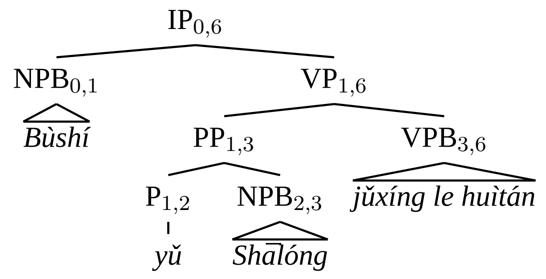


Figure 5: An alternative parse of the Chinese sentence, with *yǔ* as a preposition instead of a conjunction; common parts shared with 1-best parse in Fig. 3 are elided.

With the admissible set computed, rule extraction is as simple as a depth-first traversal from the root: we "cut" the tree at all admissible nodes to form tree fragments and extract a rule for each fragment, with variables matching the admissible descendant nodes. For example, the tree in Figure 3 is cut into 6 pieces, each of which corresponds to a rule on the right.

These extracted rules are called *minimal rules*, which can be glued together to form *composed rules* with larger tree fragments (e.g. r_1 in Fig. 1) (Galley et al., 2006). Our experiments use composed rules.

3 Forest-based Rule Extraction

We now extend tree-based extraction algorithm from the previous section to work with a packed forest representing exponentially many parse trees.

3.1 Packed Forest

Informally, a packed parse forest, or *forest* in short, is a compact representation of all the derivations (i.e., parse trees) for a given sentence under a context-free grammar (Earley, 1970; Billot and Lang, 1989). For example, consider again the Chinese sentence in Example (1) above, which has (at least) two readings depending on the part-of-speech of the word *yǔ*: it can be either a conjunction (CC "and") as shown in Figure 3, or a preposition (P "with") as shown in Figure 5, with only PP and VPB swapped from the English word order.

[3]Admissible set (Wang et al., 2007) is also known as "frontier set" (Galley et al., 2004). For simplicity of presentation, we assume every target word is aligned to at least one source word; see Galley et al. (2006) for handling unaligned target words.

These two parse trees can be represented as a single forest by sharing common subtrees such as $\text{NPB}_{0,1}$ and $\text{VPB}_{3,6}$, as shown in Figure 4. Such a forest has a structure of a *hypergraph* (Huang and Chiang, 2005), where items like $\text{NP}_{0,3}$ are called *nodes*, whose indices denote the source span, and combinations like

$$e_1 : \text{IP}_{0,6} \rightarrow \text{NPB}_{0,3}\ \text{VP}_{3,6}$$

we call *hyperedges*. We denote $head(e)$ and $tails(e)$ to be the consequent and antecedant items of hyperedge e, respectively. For example,

$$head(e_1) = \text{IP}_{0,6},\ \ tails(e_1) = \{\text{NPB}_{0,3}, \text{VP}_{3,6}\}.$$

We also denote $BS(v)$ to be the set of **incoming hyperedges** of node v, being different ways of deriving it. For example, in Figure 4, $BS(\text{IP}_{0,6}) = \{e_1, e_2\}$.

3.2 Forest-based Rule Extraction Algorithm

Like in tree-based extraction, we extract rules from a packed forest F in two steps:

(1) admissible set computation (where to cut), and

(2) fragmentation (how to cut).

It turns out that the exact formulation developed for admissible set in the tree-based case can be applied to a forest without any change. The fragmentation step, however, becomes much more involved since we now face a choice of multiple parse hyperedges at each node. In other words, it becomes *non-deterministic* how to "cut" a forest into tree fragments, which is analogous to the non-deterministic pattern-match in forest-based decoding (Mi et al., 2008). For example there are two parse hyperedges e_1 and e_2 at the root node in Figure 4. When we follow one of them to grow a fragment, there again will be multiple choices at each of its tail nodes. Like in tree-based case, a fragment is said to be **complete** if all its leaf nodes are admissible. Otherwise, an incomplete fragment can grow at any non-admissible frontier node v, where following each parse hyperedge at v will split off a new fragment. For example, following e_2 at the root node will immediately lead us to two admissible nodes, $\text{NPB}_{0,1}$ and $\text{VP}_{1,6}$ (we will highlight admissible nodes by gray shades in this section like in Figures 3 and 4). So this fragment, $frag_1 = \{e_2\}$, is now complete and we can extract a rule,

$$\textbf{IP}\ (x_1\text{:NPB}\ \ x_2\text{:VP}) \rightarrow x_1\ x_2.$$

However, following the other hyperedge e_1

$$\text{IP}_{0,6} \rightarrow \text{NP}_{0,3}\ \text{VPB}_{3,6}$$

will leave the new fragment $frag_2 = \{e_1\}$ *incomplete* with one non-admissible node $\text{NP}_{0,3}$. We then grow $frag_2$ at this node by choosing hyperedge e_3

$$\text{NP}_{0,3} \rightarrow \text{NPB}_{0,1}\ \text{CC}_{1,2}\ \text{NPB}_{2,3},$$

and spin off a new fragment $frag_3 = \{e_1, e_3\}$, which is now complete since all its four leaf nodes are admissible. We then extract a rule with four variables:

$$\textbf{IP}\ (\text{NP}(x_1\text{:NPB}\ x_2\text{:CC}\ x_3\text{:NPB})\ x_4\text{:VPB}) \rightarrow\ x_1\, x_4\, x_2\, x_3.$$

This procedure is formalized by a breadth-first search (BFS) in Pseudocode 1. The basic idea is to visit each frontier node v, and keep a queue *open* of actively growing fragments rooted at v. We keep expanding incomplete fragments from *open*, and extract a rule if a complete fragment is found (line 10). Each fragment is associated with a *frontier* (variable

Algorithm 1 Forest-based Rule Extraction.

```
    Input: forest $F$, target sentence $\tau$, and alignment $a$
    Output: minimal rule set $\mathcal{R}$
 1: $admset \leftarrow \textsc{Admissible}(F, \tau, a)$        ▷ admissible set
 2: for each $v \in admset$ do
 3:     $open \leftarrow \varnothing$                    ▷ queue of active fragments
 4:     for each $e \in BS(v)$ do          ▷ incoming hyperedges
 5:         $front \leftarrow tails(e) \setminus admset$       ▷ initial frontier
 6:         $open$.append($\langle\{e\}, front\rangle$)
 7:     while $open \neq \varnothing$ do
 8:         $\langle frag, front\rangle \leftarrow open$.pop()     ▷ active fragment
 9:         if $front = \varnothing$ then
10:             generate a rule $r$ using fragment $frag$
11:             $\mathcal{R}$.append($r$)
12:         else                    ▷ incomplete: further expand
13:             $u \leftarrow front$.pop()                ▷ a frontier node
14:             for each $e \in BS(u)$ do
15:                 $front' \leftarrow front \cup (tails(e) \setminus admset)$
16:                 $open$.append($\langle frag \cup \{e\}, front'\rangle$)
```

front in the Pseudocode), being the subset of non-admissible leaf nodes (recall that expansion stops at admissible nodes). So each initial fragment along hyperedge e is associated with an initial frontier (line 5), $\mathit{front} = \mathit{tails}(e) \setminus \mathit{admset}$.

A fragment is complete if its frontier is empty (line 9), otherwise we pop one frontier node u to expand, spin off new fragments by following hyperedges of u, and update the frontier (lines 14-16), until all active fragments are complete and *open* queue is empty (line 7).

A single parse tree can also be viewed as a trivial forest, where each node has only one incoming hyperedge. So the Galley et al. (2004) algorithm for tree-based rule extraction (Sec. 2.2) can be considered a special case of our algorithm, where the queue *open* always contains one single active fragment.

3.3 Fractional Counts and Rule Probabilities

In tree-based extraction, for each sentence pair, each rule extracted naturally has a count of one, which will be used in maximum-likelihood estimation of rule probabilities. However, a forest is an implicit collection of many more trees, each of which, when enumerated, has its own probability accumulated from of the parse hyperedges involved. In other words, a forest can be viewed as a virtual weighted k-best list with a huge k. So a rule extracted from a non 1-best parse, i.e., using non 1-best hyperedges, should be penalized accordingly and should have a *fractional count* instead of a unit one, similar to the E-step in EM algorithms.

Inspired by the parsing literature on pruning (Charniak and Johnson, 2005; Huang, 2008) we penalize a rule r by the posterior probability of its tree fragment $\mathit{frag} = \mathit{lhs}(r)$. This posterior probability, notated $\alpha\beta(\mathit{frag})$, can be computed in an Inside-Outside fashion as the product of three parts: the outside probability of its root node, the probabilities of parse hyperedges involved in the fragment, and the inside probabilities of its leaf nodes,

$$\alpha\beta(\mathit{frag}) = \alpha(\mathit{root}(\mathit{frag})) \cdot \prod_{e \in \mathit{frag}} \mathrm{P}(e) \cdot \prod_{v \in \mathit{yield}(\mathit{frag})} \beta(v) \quad (2)$$

where $\alpha(\cdot)$ and $\beta(\cdot)$ denote the outside and inside probabilities of tree nodes, respectively. For example in Figure 4,

$$\alpha\beta(\{e_2, e_3\}) = \alpha(\mathrm{IP}_{0,6}) \cdot \mathrm{P}(e_2) \cdot \mathrm{P}(e_3) \cdot \beta(\mathrm{NPB}_{0,1})\beta(\mathrm{CC}_{1,2})\beta(\mathrm{NPB}_{2,3})\beta(\mathrm{VPB}_{3,6}).$$

Now the fractional count of rule r is simply

$$c(r) = \frac{\alpha\beta(\mathit{lhs}(r))}{\alpha\beta(\mathrm{TOP})} \quad (3)$$

where TOP denotes the root node of the forest.

Like in the M-step in EM algorithm, we now extend the maximum likelihood estimation to fractional counts for three conditional probabilities regarding a rule, which will be used in the experiments:

$$\mathrm{P}(r \mid \mathit{lhs}(r)) = \frac{c(r)}{\sum_{r':\mathit{lhs}(r')=\mathit{lhs}(r)} c(r')}, \quad (4)$$

$$\mathrm{P}(r \mid \mathit{rhs}(r)) = \frac{c(r)}{\sum_{r':\mathit{rhs}(r')=\mathit{rhs}(r)} c(r')}, \quad (5)$$

$$\mathrm{P}(r \mid \mathit{root}(\mathit{lhs}(r))) = \frac{c(r)}{\sum_{r':\mathit{root}(\mathit{lhs}(r'))=\mathit{root}(\mathit{lhs}(r))} c(r')}. \quad (6)$$

4 Related Work

The concept of *packed forest* has been previously used in translation rule extraction, for example in rule composition (Galley et al., 2006) and tree binarization (Wang et al., 2007). However, both of these efforts only use 1-best parses, with the second one packing different *binarizations* of the same tree in a forest. Nevertheless we suspect that their extraction algorithm is in principle similar to ours, although they do not provide details of forest-based fragmentation (Algorithm 1) which we think is non-trivial.

The forest concept is also used in machine translation decoding, for example to characterize the search space of decoding with integrated language models (Huang and Chiang, 2007). The first *direct* application of parse forest in translation is our previous work (Mi et al., 2008) which translates a packed forest from a parser; it is also the base system in our experiments (see below). This work, on the other hand, is in the orthogonal direction, where we utilize forests in rule extraction instead of decoding.

Our experiments will use both default 1-best decoding and forest-based decoding. As we will see in the next section, the best result comes when we combine the merits of both, i.e., using forests in both rule extraction and decoding.

There is also a parallel work on extracting rules from k-best parses and k-best alignments (Venugopal et al., 2008), but both their experiments and our own below confirm that extraction on k-best parses is neither efficient nor effective.

5 Experiments

5.1 System

Our experiments are on Chinese-to-English translation based on a tree-to-string system similar to (Huang et al., 2006; Liu et al., 2006). Given a 1-best tree T, the decoder searches for the best derivation d^* among the set of all possible derivations D:

$$d^* = \arg\max_{d \in D} \lambda_0 \log \mathrm{P}(d \mid T) + \lambda_1 \log \mathrm{P}_{\mathrm{lm}}(\tau(d)) + \lambda_2 |d| + \lambda_3 |\tau(d)| \tag{7}$$

where the first two terms are translation and language model probabilities, $\tau(d)$ is the target string (English sentence) for derivation d, and the last two terms are derivation and translation length penalties, respectively. The conditional probability $\mathrm{P}(d \mid T)$ decomposes into the product of rule probabilities:

$$\mathrm{P}(d \mid T) = \prod_{r \in d} \mathrm{P}(r). \tag{8}$$

Each $\mathrm{P}(r)$ is in turn a product of five probabilities:

$$\begin{aligned} \mathrm{P}(r) &= \mathrm{P}(r \mid \mathit{lhs}(r))^{\lambda_4} \cdot \mathrm{P}(r \mid \mathit{rhs}(r))^{\lambda_5} \\ &\cdot \mathrm{P}(r \mid \mathit{root}(\mathit{lhs}(r)))^{\lambda_6} \\ &\cdot \mathrm{P}_{\mathrm{lex}}(\mathit{lhs}(r) \mid \mathit{rhs}(r))^{\lambda_7} \\ &\cdot \mathrm{P}_{\mathrm{lex}}(\mathit{rhs}(r) \mid \mathit{lhs}(r))^{\lambda_8} \end{aligned} \tag{9}$$

where the first three are conditional probabilities based on fractional counts of rules defined in Section 3.3, and the last two are lexical probabilities. These parameters $\lambda_1 \ldots \lambda_8$ are tuned by minimum error rate training (Och, 2003) on the dev sets. We refer readers to Mi et al. (2008) for details of the decoding algorithm.

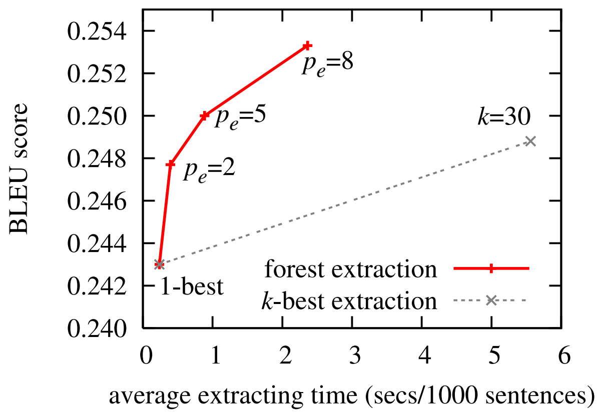

Figure 6: Comparison of extraction time and BLEU score: forest-based vs.1-best and 30-best.

rules from...	extraction	decoding	BLEU
1-best trees	0.24	1.74	0.2430
30-best trees	5.56	3.31	0.2488
forest: p_e=8	2.36	3.40	**0.2533**
Pharaoh	-	-	0.2297

Table 2: Results with different rule extraction methods. Extraction and decoding columns are running times in secs per 1000 sentences and per sentence, respectively.

We use the Chinese parser of Xiong et al. (2005) to parse the source side of the bitext. Following Huang (2008), we also modify this parser to output a packed forest for each sentence, which can be pruned by the marginal probability-based inside-outside algorithm (Charniak and Johnson, 2005; Huang, 2008). We will first report results trained on a small-scaled dataset with detailed analysis, and then scale to a larger one, where we also combine the technique of forest-based decoding (Mi et al., 2008).

5.2 Results and Analysis on Small Data

To test the effect of forest-based rule extraction, we parse the training set into parse forests and use three levels of pruning thresholds: $p_e = 2, 5, 8$.

Figure 6 plots the extraction speed and translation quality of forest-based extraction with various pruning thresholds, compared to 1-best and 30-best baselines. Using more than one parse tree apparently improves the BLEU score, but at the cost of much slower extraction, since each of the top-k trees has to be processed individually although they share many

rules from ...	total #	on dev	new rules used
1-best trees	440k	90k	-
30-best trees	1.2M	130k	8.71%
forest: p_e=8	3.3M	188k	16.3%

Table 3: Statistics of rules extracted from small data. The last column shows the ratio of *new* rules introduced by non 1-best parses being used in 1-best derivations.

extract. \ decoding	1-best tree	forest: p_d=10
1-best trees	0.2560	0.2674
30-best trees	0.2634	0.2767
forest: p_e=5	0.2679	**0.2816**
Hiero	0.2738	

Table 4: BLEU score results trained on large data.

common subtrees. Forest extraction, by contrast, is much faster thanks to packing and produces consistently better BLEU scores. With pruning threshold $p_e = 8$, forest-based extraction achieves a (case insensitive) BLEU score of 0.2533, which is an absolute improvement of 1.0% points over the 1-best baseline, and is statistically significant using the *sign-test* of Collins et al. (2005) ($p < 0.01$). This is also 0.5 points better than (and twice as fast as) extracting on 30-best parses. These BLEU score results are summarized in Table 2, which also shows that decoding with forest-extracted rules is less than twice as slow as with 1-best rules, and only fractionally slower than with 30-best rules.

We also investigate the question of how often rules extracted from non 1-best parses are used by the decoder. Table 3 shows the numbers of rules extracted from 1-best, 30-best and forest-based extractions, and the numbers that survive after filtering on the dev set. Basically in the forest-based case we can use about twice as many rules as in the 1-best case, or about 1.5 times of 30-best extraction. But the real question is, are these extra rules really useful in generating the final (1-best) translation? The last row shows that 16.3% of the rules used in 1-best derivations are indeed *only* extracted from non 1-best parses in the forests. Note that this is a stronger condition than changing the distribution of rules by considering more parses; here we introduce *new* rules never seen on any 1-best parses.

5.3 Final Results on Large Data

We also conduct experiments on a larger training dataset, FBIS, which contains 239K sentence pairs with about 6.9M/8.9M words in Chinese/English, respectively. We also use a bigger trigram model trained on the first 1/3 of the Xinhua portion of Gigaword corpus. To integrate with forest-based decoding, we use both 1-best trees and packed forests during both rule extraction and decoding phases. Since the data scale is larger than the small data, we are forced to use harsher pruning thresholds, with $p_e = 5$ for extraction and $p_d = 10$ for decoding.

The final BLEU score results are shown in Table 4. With both tree-based and forest-based decoding, rules extracted from forests significantly outperform those extracted from 1-best trees ($p < 0.01$). The final result with both forest-based extraction and forest-based decoding reaches a BLEU score of 0.2816, outperforming that of Hiero (Chiang, 2005), one of the best performing systems to date. These results confirm that our novel forest-based rule extraction approach is a promising direction for syntax-based machine translation.

6 Conclusion and Future Work

In this paper, we have presented a novel approach that extracts translation rules from a packed forest encoding exponentially many trees, rather than from 1-best or k-best parses. Experiments on a state-of-the-art tree-to-string system show that this method improves BLEU score significantly, with reasonable extraction speed. When combined with our previous work on forest-based decoding, the final result is even better than the hierarchical system Hiero. For future work we would like to apply this approach to other types of syntax-based translation systems, namely the string-to-tree systems (Galley et al., 2006) and tree-to-tree systems.

Acknowledgement

This work was funded by National Natural Science Foundation of China, Contracts 60736014 and 60573188, and 863 State Key Project No. 2006AA010108 (H. M.), and by NSF ITR EIA-0205456 (L. H.). Probabilistic Inference for Machine Translation

Phil Blunsom and **Miles Osborne**

{pblunsom,miles}@inf.ed.ac.uk

Abstract

We advance the state-of-the-art for discriminatively trained machine translation systems by presenting novel probabilistic inference and search methods for synchronous grammars. By approximating the intractable space of all candidate translations produced by intersecting an ngram language model with a synchronous grammar, we are able to train and decode models incorporating millions of sparse, heterogeneous features. Further, we demonstrate the power of the discriminative training paradigm by extracting structured syntactic features, and achieving increases in translation performance.

1 Introduction

The goal of creating statistical machine translation (SMT) systems incorporating rich, sparse, features over syntax and morphology has consumed much recent research attention. Discriminative approaches are widely seen as a promising technique, potentially allowing us to further the state-of-the-art. Most work on discriminative training for SMT has focussed on linear models, often with margin based algorithms (Liang et al., 2006; Watanabe et al., 2006), or rescaling a product of sub-models (Och, 2003; Ittycheriah and Roukos, 2007).

Recent work by Blunsom et al. (2008) has shown how translation can be framed as a probabilistic log-linear model, where the distribution over translations is modelled in terms of a latent variable on derivations. Their approach was globally optimised and discriminative trained. However, a language model, an information source known to be crucial for obtaining good performance in SMT, was notably omitted. This was because adding a language model would mean that the normalising partition function could no longer be exactly calculated, thereby preventing efficient parameter estimation.

Here, we show how language models can be incorporated into large-scale discriminative translation models, without losing the probabilistic interpretation of the model. The key insight is that we can use Monte-Carlo methods to approximate the partition function, thereby allowing us to tackle the extra computational burden associated with adding the language model. This approach is theoretically justified and means that the model continues to be both probabilistic and globally optimised. As expected, using a language model dramatically increases translation performance.

Our second major contribution is an exploitation of syntactic features. By encoding source syntax as features allows the model to use, or ignore, this information as it sees fit, thereby avoiding the problems of coverage and sparsity associated with directly incorporating the syntax into the grammar (Huang et al., 2006; Mi et al., 2008). We report on translation gains using this approach.

We begin by introducing the synchronous grammar approach to SMT in Section 2. In Section 3 we define the parametric form of our model and describe techniques for approximating the intractable space of all translations for a given source sentence. In Section 4 we evaluate the ability of our model to effectively estimate the highly dependent weights for the sparse features and real-valued language model. In addition we describe how

S ⇒ ⟨X_1 的 。, X_1 .⟩

X_1 ⇒ ⟨X_2 是 昨天 深夜 X_3 , X_2 X_3 late last night⟩

X_2 ⇒ ⟨布朗 , Brown⟩

X_3 ⇒ ⟨从 X_4 抵达 X_5 , arrived in X_5 from X_4⟩

X_4 ⇒ ⟨上海 , Shanghai⟩

X_5 ⇒ ⟨北京 , Beijing⟩

Figure 1. An example SCFG derivation from a Chinese source sentence which yields the English sentence: *"Brown arrived in Shanghai from Beijing late last night."*

our model can easily integrate rich features over source syntax trees and compare our training methods to a state-of-the-art benchmark.

2 Synchronous context free grammar

A synchronous context free grammar (SCFG, (Lewis II and Stearns, 1968)) describes the generation of pairs of strings. A string pair is generated by applying a series of paired context-free rewrite rules of the form, $X \rightarrow \langle \alpha, \gamma, \sim \rangle$, where X is a non-terminal, α and γ are strings of terminals and non-terminals and $\sim$ specifies a one-to-one alignment between non-terminals in α and γ. In the context of SMT, by assigning the source and target languages to the respective sides of a SCFG it is possible to describe translation as the process of parsing the source sentence, while generating the target translation (Chiang, 2007).

In this paper we only consider grammars extracted using the heuristics described for the Hiero SMT system (Chiang, 2007). Note however that our approach is general and could be used with other synchronous grammar transducers (e.g., (Galley et al., 2006)). SCFG productions can specify that the order of the child non-terminals is the same in both languages (a *monotone* production), or is reversed (a *reordering* production). Without loss of generality, here we add the restriction that non-terminals on the source and target sides of the grammar must have the same category. Figure 1 shows an example derivation for Chinese to English translation.

3 Model

We start by defining a log-linear model for the conditional probability distribution over target translations of a given source sentence. A sequence of SCFG rule applications which produce a translation from a source sentence is referred to as a *derivation*, and each translation may be produced by many different derivations. As the training data only provides source and target sentences, the derivations are modelled as a latent variable.

The conditional probability of a derivation, $\mathbf{d}$, for a target translation, $\mathbf{e}$, conditioned on the source, $\mathbf{f}$, is given by:

$$p_\Lambda(\mathbf{d}, \mathbf{e}|\mathbf{f}) = \frac{\exp \sum_k \lambda_k H_k(\mathbf{d}, \mathbf{e}, \mathbf{f})}{Z_\Lambda(\mathbf{f})} \quad (1)$$

$$\text{where} \quad H_k(\mathbf{d}, \mathbf{e}, \mathbf{f}) = \sum_{r \in \mathbf{d}} h_k(\mathbf{f}, r, q(r, \mathbf{d})) \quad (2)$$

Using Equation (1), the conditional probability of a target translation given the source is the sum over all of its derivations:

$$p_\Lambda(\mathbf{e}|\mathbf{f}) = \sum_{\mathbf{d} \in \Delta(\mathbf{e}, \mathbf{f})} p_\Lambda(\mathbf{d}, \mathbf{e}|\mathbf{f})$$

where $\Delta(\mathbf{e}, \mathbf{f})$ is the set of all derivations of the target sentence $\mathbf{e}$ from the source $\mathbf{f}$.

Here k ranges over the model's features, and $\Lambda = \{\lambda_k\}$ are the model parameters (weights for their corresponding features). The function $q(r, \mathbf{d})$ returns the target ngram context, for a language model with order m, of rule r in derivation $\mathbf{d}$. For a rule which spans the target words (i, j) and $target\_yield(\mathbf{d}) = \{t_0, \cdots, t_l\}$:

$$q(r, \mathbf{d}) = \begin{cases} t_i \cdots t_{i+m-2} \star t_{j-m+2} \cdots t_j & \text{if } j - i > m \\ t_i \cdots t_j & \text{otherwise} \end{cases}$$

The feature functions h_k are real-valued functions over the source and target sentences, and can include overlapping and non-independent features of the data. The features must decompose with the derivation and the ngram context defined by the function q, as shown in Equation (2). The features can reference the entire source sentence coupled with each rule, r, and its target context, in a derivation.

By directly incorporating the language model context q into the model formulation, we will not be able to exactly compute the partition function $Z_\Lambda(\mathbf{f})$, which sums over all possible derivations. Even though a dynamic program over this space would still run in polynomial time, as shown by Chiang (2007), a packed chart representation of the partition function for the binary Hiero grammars used in this work would require $\mathcal{O}(n^3|T|^{4(m-1)})$ space,[1] which is far too large to be practical.

Instead we approximate the partition function using a sum over a large subset of the possible derivations ($\Delta(\mathbf{e},\mathbf{f})$):

$$\begin{aligned} Z_\Lambda(\mathbf{f}) &\approx \sum_{\mathbf{e}} \sum_{\mathbf{d}\in\{\subset\Delta(\mathbf{e},\mathbf{f})\}} \exp \sum_k \lambda_k H_k(\mathbf{d},\mathbf{e},\mathbf{f}) \\ &= \tilde{Z}_\Lambda(\mathbf{f}) \end{aligned}$$

This model formulation raises the questions of what an appropriate *large subset* of derivations for training is, and how to efficiently calculate the sum over all derivations in decoding. In the following sections we elucidate and evaluate our solutions to these problems.

3.1 Sampling Derivations

The training and decoding algorithms presented in the following sections rely upon Monte-Carlo techniques, which in turn require the ability to draw derivation samples from the probability distribution defined by our log-linear model. Here we adapt previously presented algorithms for sampling from a PCFG (Goodman, 1998) for use with our synchronous grammar model. Algorithm 1 describes the algorithm for sampling derivations. The sampling algorithm assumes the pre-existance of a packed chart representation of all derivations for a given source sentence. The *inside algorithm* is then used to calculate the scores needed to define a multinomial distribution over all partial derivations associated with expanding a given child rule. These initial steps are performed once and then an unlimited number of samples can be drawn by calling the recursive SAMPLE procedure. MULTI draws a sample from the distribution over rules for a given chart cell, CHILDREN enumerates the chart cells connected to a rule as variables, and DERIVATION is a recursive tree data structure for derivations. The algorithm is

[1]where $|T|$ is the size of the terminal alphabet, i.e. the number of unique English words.

Algorithm 1 Top-down recursive derivation sampling algorithm.

```
1: procedure SAMPLE($X, i, k$)
2:     $rule$ ← MULTI(inside_chart($X, i, k$))
3:     $c = \phi$
4:     for ($child\_category, x, y$) ∈ CHILDREN($rule$) do
5:         $c \leftarrow c \cup$ SAMPLE($child\_category, x, y$)
6:     end for
7:     return DERIVATION(X, children)
8: end procedure
```

first called on a category and chart cell spanning the entire chart, and then proceeds top down by using the function MULTI to draw the next rule to expand from the distribution defined by the inside scores.

3.2 Approximate Inference

Approximating the partition function with $\tilde{Z}_\Lambda(\mathbf{f})$ could introduce biases into inference and in the following discussion we describe measures taken to minimise the effects of the approximation bias.

An obvious approach to approximating the partition function, and the feature expectations required for calculating the derivative in training, is to use the packed chart of derivations produced by running the cube pruning beam search algorithm of Chiang (2007) on the source sentence. In this case $\tilde{Z}_\Lambda(\mathbf{f})$ includes all the derivations that fall within the cube pruning beam, hopefully representing the majority of the probability mass. We denote the partition function estimated with this cube beam approximation as $\tilde{Z}^{cb}_\Lambda(\mathbf{f})$. This approach has the advantage of using the same beam search dynamic program during training as is used for decoding. As the approximated partition function does not contain all derivations, it is possible that some, or all, of the derivations of the reference translation from the parallel corpus may be excluded. We must therefore intersect the packed chart built from the cube beam with that of the reference derivations to ensure consistency.

Although, as would be done using cube-pruning, it would seem intuitively sensible to approximate the partition function using only high probability derivations, it is possible that doing so will bias our model in odd ways. The space of derivations contained within the beam will be tightly clustered about a maximum, and thus a model trained with such an approximation will only see a very small

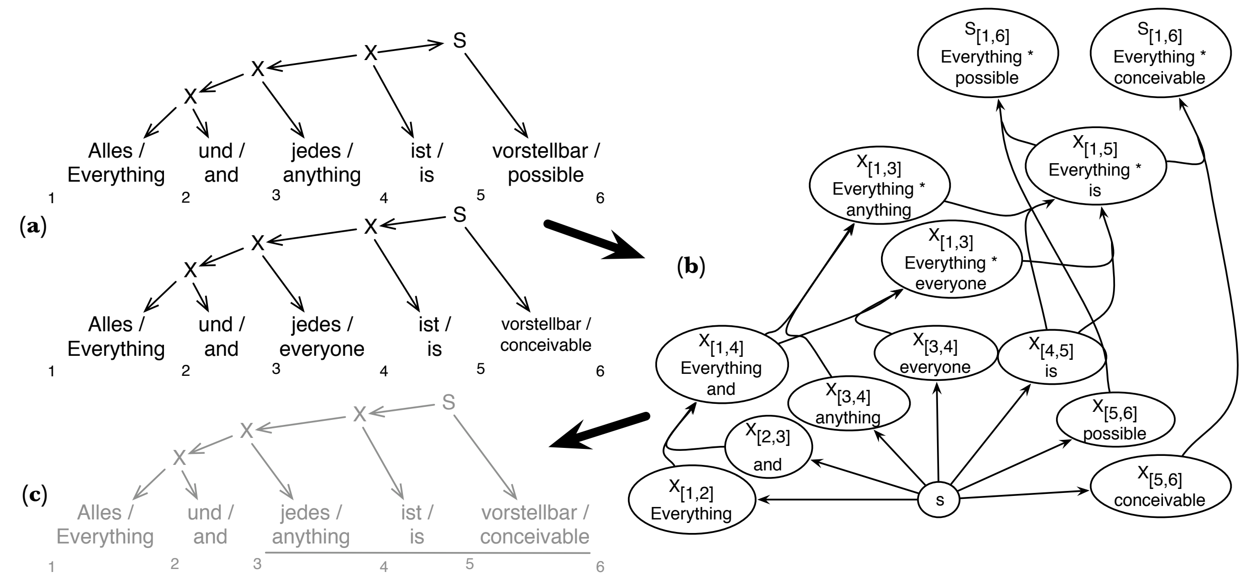

Figure 2. A German-English translation example of building $\tilde{Z}_{\Lambda}^{sam}(\mathbf{f})$ from samples. (a) Two sample derivations are drawn from the model, (b) these samples are then combined into a packed representation, here represented by a hypergraph with target translations elided for a bigram language model. The derivation in (c) is contained within the hypergraph even though it was never explicitly inserted.

part of the overall distribution, possibly leading it astray. Consider the example of a language model feature: as this is a very strong indicator of translation quality, we would expect all derivations within the beam to have a similar (high) language model score, thereby robbing this feature of its discriminating power. However if our model could also see the low probability derivations it would be clear that this feature is indeed very strongly correlated with good translations. Thus a good approximation of the space of derivations is one that includes both good and bad examples, not just a cluster around the maximum.

A principled solution to the problem of approximating the partition function would be to use a Markov Chain Monte Carlo (MCMC) sampler to estimate the sum with a large number of samples. Most of the sampled derivations would be in the high probability region of the distribution, however there would also be a number of samples drawn from the rest of the space, giving the model a more global view of the distribution, avoiding the pitfalls of the narrow view obtained by a beam search. Although effective, the computational cost of such an approach is prohibitive as we would need to draw hundreds of thousands of samples to obtain convergence, for every training iteration.

Here we mediate between the computational advantages of a beam and the broad view of the distribution provided by sampling. Using the algorithm outlined in Section 3.1 we draw samples from the distribution of derivations and then insert these samples into a packed chart representation. This process is illustrated in Figure 2. The packed chart created by intersecting the sample derivations represents a space of derivations much greater than the original samples. In Figure 2 the chart is built from the first two sampled derivations, while the third derivation can be extracted from the chart even though it was never explicitly entered. This approximation of the partition function (denoted $\tilde{Z}_{\Lambda}^{sam}(\mathbf{f})$) allows us to build an efficient packed chart representation of a large number of derivations, centred on those with high probability while still including a significant representation of the low probability space. Derivations corresponding to the reference can be detected during sampling and thus we can build the chart for the reference derivations at the same time as the one approximating the partition function. This could lead to some, or none of, the possible reference derivations being included, as they may not have been sampled. Although we could intersect all of the reference derivations with the sampled chart, this could distort the distribution over derivations, and we believe it to be advantageous to keep the distributions between the partition function and reference charts consistent.

Both of the approximations proposed above, $\tilde{Z}_{\Lambda}^{cb}(\mathbf{f})$ and $\tilde{Z}_{\Lambda}^{sam}(\mathbf{f})$, rely on the pre-existence of a trained translation model in order to either guide the cube-pruning beam, or define the probability distribution from which we draw samples. We solve this chicken and egg problem by first training an exact translation model *without* a language model, and then use this model to create the partition function approximations for training *with* a language model. We denote the distribution without a language model as $p_{\Lambda}^{-LM}(\mathbf{e}|\mathbf{f})$ and that with as $p_{\Lambda}^{+LM}(\mathbf{e}|\mathbf{f})$.

A final training problem that we need to address is the appropriate initialisation of the model parameters. In theory we could simply randomly initialise Λ for $p_{\Lambda}^{+LM}(\mathbf{e}|\mathbf{f})$, however in practice we found that this resulted in poor performance on the development data. This is due to the complex non-convex optimisation function, and the fact that many features will fall outside the approximated charts resulting in random, or zero, weights in testing. We introduce a novel solution in which we use the Gaussian prior over model weights to tie the exact model trained without a language model, which assigns sensible values to all rule features, with the approximated model. The prior over model parameters for $p_{\Lambda}^{+LM}(\mathbf{e}|\mathbf{f})$ is defined as:

$$p^{+LM}(\lambda_k) \propto e^{-\frac{\|\lambda_k - \lambda_k^{-LM}\|^2}{2\sigma^2}}$$

Here we have set the mean parameters of the Gaussian distribution for the approximated model to those learnt for the exact one. This has the effect that any features that fall outside the approximated model will simply retain the weight assigned by the exact model. While for other feature weights the prior will penalise substantial deviations away from Λ^{-LM}, essentially encoding the intuition that the rule rule parameters should not change substantially with the inclusion of language model features.

This results in the following log-likelihood objective and corresponding gradient:

$$\mathcal{L} = \sum_{(\mathbf{e}_i,\mathbf{f}_i)\in\mathcal{D}} \log p_{\Lambda}^{+LM}(\mathbf{e}_i|\mathbf{f}_i) + \sum_k \log p_0^{+LM}(\lambda_k)$$

$$\frac{\partial\mathcal{L}}{\partial\lambda_k} = E_{p_{\Lambda}^{+LM}(\mathbf{d}|\mathbf{e}_i,\mathbf{f}_i)}[h_k] - E_{p_{\Lambda}^{+LM}(\mathbf{e}|\mathbf{f}_i)}[h_k] - \frac{\lambda_k^{+LM} - \lambda_k^{-LM}}{\sigma^2}$$

3.3 Decoding

As stated in Equation 3 the probability of a given translation string is calculated as the sum of the probabilities of all the derivations that yield that string. In decoding, where the reference translation is not known, the exact calculation of this summation is NP-Hard. This problem also arises in monolingual parsing with probabilistic tree substitution grammars and has been tackled in the literature using Monte-Carlo sampling methods (Chappelier and Rajman, 2000). Their approach is directly applicable to our SCFG decoding problem and we can use Algorithm 1 to draw sample translation derivations for the source sentence. The probability of a translation can be calculated simply from the number of times a derivation that yields it was sampled, divided by the total number of samples. For the $p_{\Lambda}^{-LM}(\mathbf{e}|\mathbf{f})$ model we can build the full chart of all possible derivations and thus sample from the true distribution over derivations. For the $p_{\Lambda}^{+LM}(\mathbf{e}|\mathbf{f})$ model we suffer the same problem as in training and cannot build the full chart. Instead a chart is built using the cube-pruning algorithm with a wide beam and we then draw samples from this chart. Although sampling from a reduced chart will result in biased samples, in Section 4 we show this approach to be effective in practice.[2] In Section 4 we compare our sampling approach to the heuristic beam search proposed by Blunsom et al. (2008).

It is of interest to compare our proposed decoding algorithms to minimum Bayes risk (MBR) decoding (Kumar and Byrne, 2004), a commonly used decoding method. From a theoretical standpoint, the summing of derivations for a given translation is exactly

[2]We have experimented with using a Metropolis Hastings sampler, with $p_{\Lambda}^{-LM}(\mathbf{e}|\mathbf{f})$ as the proposal distribution, to sample from the true distribution with the language model. Unfortunately the sample rejection rate was very high such that this method proved infeasibly slow.

equivalent to performing MBR with a 0/1 loss function over derivations. From a practical perspective, MBR is normally performed with $\textsc{Bleu}$ as the loss and approximated using n-best lists. These n-best lists are produced using algorithms tuned to remove multiple derivations of the same translation (which have previously been seen as undesirable). However, it would be simple to extend our sampling based decoding algorithm to calculate the MBR estimate using $\textsc{Bleu}$, in theory providing a lower variance estimate than attained with n-best lists.

4 Evaluation

We evaluate our model on the IWSLT 2005 Chinese to English translation task (Eck and Hori, 2005), using the 2004 test set as development data for tuning the hyperparameters and MERT training the benchmark systems. The statistics for this data are presented in Table 1.[3] The training data made available for this task consisted of 40k pairs of transcribed utterances, drawn from the travel domain. The development and test data for this task are somewhat unusual in that each sentence has a single human translated reference, and fifteen paraphrases of this reference, provided by monolingual annotators. Model performance is evaluated using the standard $\textsc{Bleu}$ metric (Papineni et al., 2002) which measures average n-gram precision, $n \leq 4$, and we use the NIST definition of the brevity penalty for multiple reference test sets. We provide evaluation against both the entire multi-reference sets, and the single human translation.

Our translation grammar is induced using the standard alignment and rule extraction heuristics used in hierarchical translation models (Chiang, 2007).[4] As these heuristics aren't based on a generative model, and don't guarantee that the target translation will be reachable from the source, we discard those sentence pairs for which we cannot produce a derivation, leaving 38,405 sentences for training.

Our base model contains a single feature for each rule which counts the number of times it appeared in a particular derivation. For models which include a language model, we train a standard Kneser-Ney trigram model on the target side of the training corpus. We also include a word penalty feature to compensate for the shortening effect of the language model. In total our model contains 2.9M features.

The aims of our evaluation are: (1) to determine that our proposed training regimes are able to realise performance increase when training sparse rule features and a real valued language model feature together, (2) that the model is able to effectively use rich features over the source sentence, and (3) to confirm that our model obtains performance competitive with the current state-of-the-art.

4.1 Inference and Decoding

We have described a number of modelling choices which aim to compensate for the training biases introduced by incorporating a language model feature through approximate inference. Our a priori knowledge from other SMT systems suggests that incorporating a language model should lead to large increases in $\textsc{Bleu}$ score. In this evaluation we aim to determine whether our training regimes are able to realises these expected gains.

Table 2 shows a matrix of development $\textsc{Bleu}$ scores achieved by varying the approximation of the partition function in training, and varying the decoding algorithm. If we consider the vertical axis we can see that the sampling method for approximating the partition function has a small but consistent advantage over using the cube-pruning beam. The charts produced by the sampling approach occupy roughly half the disc space as those produced by the beam search, so in subsequent experiments we present results using the $\tilde{Z}^{sam}_{\Lambda}(\mathbf{f})$ approximation.

Comparing the decoding algorithms on the horizontal axis we can reconfirm the findings of Blunsom et al. (2008) that the max-translation decoding outperforms the Viterbi max-derivation approximation. It is also of note that this $\textsc{Bleu}$ increase is robust to the introduction of the language model feature, assuaging fears that the max-translation approach may have been doing the job of the language model. We also compare using Monte-Carlo sampling for decoding with the previously proposed heuristic beam search algorithm. The difference between the two algorithms is small, however

[3]Development and test set statistics are for the single human translation reference.

[4]With the exception that we allow unaligned words at the boundary of rules. This improves training set coverage.

	Training		Development		Test	
	Chinese	English	Chinese	English	Chinese	English

$p_\Lambda^{-LM}(\mathbf{e}\|\mathbf{f})$	31.0	32.5	32.6
$p_\Lambda^{+LM}(\mathbf{e}\|\mathbf{f})$ $(\tilde{Z}_\Lambda^{cb}(\mathbf{f}))$	39.1	39.8	39.8
$p_\Lambda^{+LM}(\mathbf{e}\|\mathbf{f})$ $(\tilde{Z}_\Lambda^{sam}(\mathbf{f}))$	39.9	40.5	40.6

Table 2. Development set results for varying the approximation of the partition function in training, $\tilde{Z}_\Lambda^{cb}(\mathbf{f})$ vs. $\tilde{Z}_\Lambda^{sam}(\mathbf{f})$, and decoding using the Viterbi max-derivation algorithm, or the max-translation algorithm with either a beam approximation or Monte-Carlo sampling.

we feeling the sampling approach is more theoretically justified and adopt it for our later experiments.

The most important result from this evaluation is that both our training regimes realise substantial gains from the introduction of the language model feature. Thus we can be confident that our model is capable of modelling the distribution over translations even when the space over all derivations is intractable to dynamically program exactly.

4.2 A Discriminative Syntactic Translation Model

In the previous sections we've described and evaluated a statistical model of translation that is able to estimate a probability distribution over translations using millions of sparse features. A prime motivation for such a model is the ability to define complex features over more than just the surface forms of the source and target strings. There are limitless options for such features, and previous work has focused on defining token based features such as part-of-speech and morphology (Ittycheriah and Roukos, 2007). Although such features are applicable to our model, here we attempt to test the model's ability to incorporate complex features over source-side syntax trees, essentially subsuming and extending previous work on tree-to-string translation models (Huang et al., 2006; Mi et al., 2008).

We first parse the source side of our training, development and test corpora using the Stanford parser.[5] Next, while building the synchronous charts required for training, whenever a rule is used in a derivation a feature is activated which captures: (1) the constituent spanning the rule's source side in the syntax tree (if any) (2) constituents spanning any variables in the rule, and (3) the rule's target side surface form. Figure 3 illustrates this process.

These syntactic features are equivalent to the grammar rules extracted for tree-to-string translation systems. The key difference in our model is that the source syntax tree is treated as conditioning context and it's information encoded as features, thus this information can be used or ignored as the model sees fit. This avoids the problems associated with explicitly encoding the source syntax in the grammar, such as sparsity and overly constraining the model. In addition we could easily incorporate features over multiple source trees, for example mixing labelled syntax trees with dependency graphs.

We limit the extraction of syntactic features to those that appear in at least two training derivations, giving a total of 4.2M syntactic features, for an overall total of 7.1M features.

4.3 Discussion

Table 3 shows the results from applying our described models to the test set. We benchmark our results against a model (Hiero) which was directly trained to optimise $\textsc{Bleu}^{NIST}$ using the standard MERT algorithm (Och, 2003) and the full set of translation and lexical weight features described for the Hiero model (Chiang, 2007). As well as

Reference	i do n't have enough money with me to buy a new airplane ticket .

Table 4. Example test set output produced when: not using a language model, using a language model, also using syntax, output optimised using MERT and finally the reference

$\textsc{Bleu}^{NIST}$ (brevity penalty uses the shortest reference), we also include results from the IBM ($\textsc{Bleu}^{IBM}$) metric (brevity penalty uses the closest reference), and using only the actual human translation in the test set, not the monolingual paraphrase multiple references ($\textsc{Bleu}^{HumanRef}$).

The first result of interest is that we see an increase in performance through the incorporation of the source syntax features. This is an encouraging result as the transcribed speech source sentences are well out of the domain of the data on which the parser was trained, suggesting that our model is able to sift the good information from the noisy in the unreliable source syntax trees. Table 4 shows illustrative system output on the test set.

On the $\textsc{Bleu}^{NIST}$ metric we see that our models under-perform the MERT trained system. We hypothesise that this is predominately due to the interaction of the brevity penalty with the unusual nature of the multiple paraphrase reference training and development data. Their performance is however quite consistent across the different interpretations of the brevity penalty (NIST vs. IBM). This contrasts with the MERT trained model, which clearly over-fits to the NIST metric that it was trained on and underperforms our models when evaluated on the single human test translations. If we directly compare the brevity penalties of the MERT model (0.868) and our discriminative model incorporating source syntax (0.942), on the these single references, we can see that the MERT training has optimised to the shortest paraphrase reference.

From these results it is difficult to draw any hard conclusions on the relative performance of the different training regimes. However we feel confident in claiming that we have achieved our goal of training a probabilistic model on millions of sparse features which obtains performance competitive with the current state-of-the-art training algorithm.

5 Conclusion

In this paper we have shown that statistical machine translation can be effectively modelled as a well posed machine learning task. In doing so we have described a model capable of estimating a probability distribution over translations using sparse complex features, and achieving performance comparable to the state-of-the-art on standard metrics. With further work on scaling these models to large data sets, and engineering high performance features, we believe this research has the potential to provide significant increases in translation quality.

Abstract

Minimum-error-rate training (MERT) is a bottleneck for current development in statistical machine translation because it is limited in the number of weights it can reliably optimize. Building on the work of Watanabe et al., we explore the use of the MIRA algorithm of Crammer et al. as an alternative to MERT. We first show that by parallel processing and exploiting more of the parse forest, we can obtain results using MIRA that match or surpass MERT in terms of both translation quality and computational cost. We then test the method on two classes of features that address deficiencies in the Hiero hierarchical phrase-based model: first, we simultaneously train a large number of Marton and Resnik's soft syntactic constraints, and, second, we introduce a novel structural distortion model. In both cases we obtain significant improvements in translation performance. Optimizing them in combination, for a total of 56 feature weights, we improve performance by 2.6 Bleu on a subset of the NIST 2006 Arabic-English evaluation data.

1 Introduction

Since its introduction by Och (2003), minimum error rate training (MERT) has been widely adopted for training statistical machine translation (MT) systems. However, MERT is limited in the number of feature weights that it can optimize reliably, with folk estimates of the limit ranging from 15 to 30 features.

One recent example of this limitation is a series of experiments by Marton and Resnik (2008), in which they added syntactic features to Hiero (Chiang, 2005; Chiang, 2007), which ordinarily uses no linguistically motivated syntactic information. Each of their new features rewards or punishes a derivation depending on how similar or dissimilar it is to a syntactic parse of the input sentence. They found that in order to obtain the greatest improvement, these features had to be specialized for particular syntactic categories and weighted independently. Not being able to optimize them all at once using MERT, they resorted to running MERT many times in order to test different combinations of features. But it would have been preferable to use a training method that can optimize the features all at once.

There has been much work on improving MERT's performance (Duh and Kirchoff, 2008; Smith and Eisner, 2006; Cer et al., 2008), or on replacing MERT wholesale (Turian et al., 2007; Blunsom et al., 2008). This paper continues a line of research on online discriminative training (Tillmann and Zhang, 2006; Liang et al., 2006; Arun and Koehn, 2007), extending that of Watanabe et al. (2007), who use the Margin Infused Relaxed Algorithm (MIRA) due to Crammer et al. (2003; 2006). Our guiding principle is practicality: like Watanabe et al., we train on a small tuning set comparable in size to that used by MERT, but by parallel processing and exploiting more of the parse forest, we obtain results using MIRA that match or surpass MERT in terms of both translation quality and computational cost on a large-scale translation task.

Taking this further, we test MIRA on two classes of features that make use of syntactic information and hierarchical structure. First, we generalize Marton and Resnik's (2008) soft syntactic constraints by training all of them simultaneously; and, second, we introduce a novel structural distortion model. We obtain significant improvements in both cases, and further large improvements when the two feature sets are combined.

The paper proceeds as follows. We describe our training algorithm in section 2; our generalization of Marton and Resnik's soft syntactic constraints in section 3; our novel structural distortion features in section 4; and experimental results in section 5.

2 Learning algorithm

The translation model is a standard linear model (Och and Ney, 2002), which we train using MIRA (Crammer and Singer, 2003; Crammer et al., 2006), following Watanabe et al. (2007). We describe the basic algorithm first and then progressively refine it.

2.1 Basic algorithm

Let $\mathbf{e}$, by abuse of notation, stand for both output strings and their derivations. We represent the feature vector for derivation $\mathbf{e}$ as $\mathbf{h}(\mathbf{e})$. Initialize the feature weights $\mathbf{w}$. Then, repeatedly:

- Select a batch of input sentences $\mathbf{f}_1, \ldots, \mathbf{f}_m$.
- Decode each $\mathbf{f}_i$ to obtain a set of hypothesis translations $\mathbf{e}_{i1}, \ldots, \mathbf{e}_{in}$.
- For each i, select one of the $\mathbf{e}_{ij}$ to be the *oracle translation* $\mathbf{e}_i^*$, by a criterion described below. Let $\Delta\mathbf{h}_{ij} = \mathbf{h}(\mathbf{e}_i^*) - \mathbf{h}(\mathbf{e}_{ij})$.
- For each $\mathbf{e}_{ij}$, compute the *loss* ℓ_{ij}, which is some measure of how bad it would be to guess $\mathbf{e}_{ij}$ instead of $\mathbf{e}_i^*$.
- Update $\mathbf{w}$ to the value of $\mathbf{w}'$ that minimizes:

$$\frac{1}{2}\|\mathbf{w}' - \mathbf{w}\|^2 + C\sum_{i=1}^{m} \max_{1\leq j\leq n}(\ell_{ij} - \Delta\mathbf{h}_{ij} \cdot \mathbf{w}') \quad (1)$$

  where we set $C = 0.01$. The first term means that we want $\mathbf{w}'$ to be close to $\mathbf{w}$, and second term (the *generalized hinge loss*) means that we want $\mathbf{w}'$ to score $\mathbf{e}_i^*$ higher than each $\mathbf{e}_{ij}$ by a margin at least as wide as the loss ℓ_{ij}.

When training is finished, the weight vectors from all iterations are averaged together. (If multiple passes through the training data are made, we only average the weight vectors from the last pass.) The technique of averaging was introduced in the context of perceptrons as an approximation to taking a vote among all the models traversed during training, and has been shown to work well in practice (Freund and Schapire, 1999; Collins, 2002). We follow McDonald et al. (2005) in applying this technique to MIRA.

Note that the objective (1) is not the same as that used by Watanabe et al.; rather, it is the same as that used by Crammer and Singer (2003) and related to that of Taskar et al. (2005). We solve this optimization problem using a variant of sequential minimal optimization (Platt, 1998): for each i, initialize $\alpha_{ij} = C$ for a single value of j such that $\mathbf{e}_{ij} = \mathbf{e}_i^*$, and initialize $\alpha_{ij} = 0$ for all other values of j. Then, repeatedly choose a sentence i and a pair of hypotheses j, j', and let

$$\mathbf{w}' \leftarrow \mathbf{w}' + \delta(\Delta\mathbf{h}_{ij} - \Delta\mathbf{h}_{ij'}) \quad (2)$$

$$\alpha_{ij} \leftarrow \alpha_{ij} + \delta \quad (3)$$

$$\alpha_{ij'} \leftarrow \alpha_{ij'} - \delta \quad (4)$$

where

$$\delta = \underset{[-\alpha_{ij},\alpha_{ij'}]}{\text{clip}} \frac{(\ell_{ij} - \ell_{ij'}) - (\Delta\mathbf{h}_{ij} - \Delta\mathbf{h}_{ij'}) \cdot \mathbf{w}'}{\|\Delta\mathbf{h}_{ij} - \Delta\mathbf{h}_{ij'}\|^2} \quad (5)$$

where the function $\text{clip}_{[x,y]}(z)$ gives the closest number to z in the interval $[x, y]$.

2.2 Loss function

Assuming Bleu as the evaluation criterion, the loss ℓ_{ij} of $\mathbf{e}_{ij}$ relative to $\mathbf{e}_i^*$ should be related somehow to the difference between their Bleu scores. However, Bleu was not designed to be used on individual sentences; in general, the highest-Bleu translation of a sentence depends on what the other sentences in the test set are. Sentence-level approximations to Bleu exist (Lin and Och, 2004; Liang et al., 2006), but we found it most effective to perform Bleu computations in the context of a set O of previously-translated sentences, following Watanabe et al. (2007). However, we don't try to accumulate translations for the entire dataset, but simply maintain an exponentially-weighted moving average of previous translations.

More precisely: For an input sentence $\mathbf{f}$, let $\mathbf{e}$ be some hypothesis translation and let $\{\mathbf{r}_k\}$ be the set of reference translations for $\mathbf{f}$. Let $\mathbf{c}(\mathbf{e}; \{\mathbf{r}_k\})$, or simply $\mathbf{c}(\mathbf{e})$ for short, be the vector of the following counts: $|\mathbf{e}|$, the effective reference length $\min_k |\mathbf{r}_k|$, and, for $1 \leq n \leq 4$, the number of n-grams in $\mathbf{e}$, and the number of n-gram matches between $\mathbf{e}$ and $\{\mathbf{r}_k\}$. These counts are sufficient to calculate a Bleu score, which we write as $\text{Bleu}(\mathbf{c}(\mathbf{e}))$. The pseudo-document O is an exponentially-weighted moving average of these vectors. That is, for each training sentence, let $\hat{\mathbf{e}}$ be the 1-best translation; after processing the sentence, we update O, and its input length O_f:

$$O \leftarrow 0.9(O + \mathbf{c}(\hat{\mathbf{e}})) \tag{6}$$

$$O_f \leftarrow 0.9(O_f + |\mathbf{f}|) \tag{7}$$

We can then calculate the Bleu score of hypotheses $\mathbf{e}$ in the context of O. But the larger O is, the smaller the impact the current sentence will have on the Bleu score. To correct for this, and to bring the loss function roughly into the same range as typical margins, we scale the Bleu score by the size of the input:

$$B(\mathbf{e}; \mathbf{f}, \{\mathbf{r}_k\}) = (O_f + |\mathbf{f}|) \times \text{Bleu}(O + \mathbf{c}(\mathbf{e}; \{\mathbf{r}_k\})) \tag{8}$$

which we also simply write as $B(\mathbf{e})$. Finally, the loss function is defined to be:

$$\ell_{ij} = B(\mathbf{e}_i^*) - B(\mathbf{e}_{ij}) \tag{9}$$

2.3 Oracle translations

We now describe the selection of $\mathbf{e}^*$. We know of three approaches in previous work. The first is to force the decoder to output the reference sentence exactly, and select the derivation with the highest model score, which Liang et al. (2006) call *bold updating*. The second uses the decoder to search for the highest-Bleu translation (Tillmann and Zhang, 2006), which Arun and Koehn (2007) call *max*-Bleu *updating*. Liang et al. and Arun and Koehn experiment with these methods and both opt for a third method, which Liang et al. call *local updating*: generate an n-best list of translations and select the highest-Bleu translation from it. The intuition is that due to noise in the training data or reference translations, a high-Bleu translation may actually use peculiar rules which it would be undesirable to encourage the model to use. Hence, in local updating, the search for the highest-Bleu translation is limited to the n translations with the highest model score, where n must be determined experimentally.

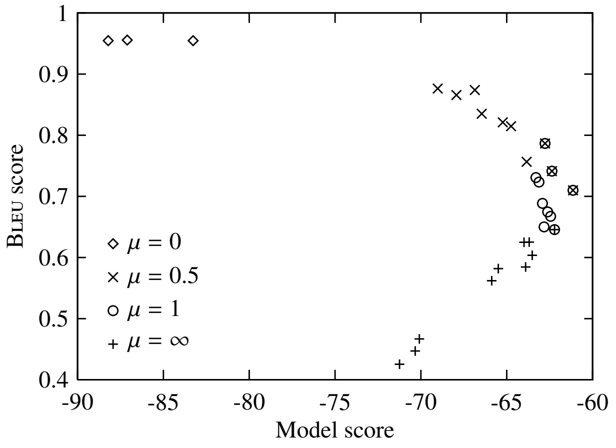

Figure 1: Scatter plot of 10-best unique translations of a single sentence obtained by forest rescoring using various values of μ in equation (11).

Here, we introduce a new oracle-translation selection method, formulating the intuition behind local updating as an optimization problem:

$$\mathbf{e}^* = \arg\max_{\mathbf{e}} (B(\mathbf{e}) + \mathbf{h}(\mathbf{e}) \cdot \mathbf{w}) \tag{10}$$

Instead of choosing the highest-Bleu translation from an n-best list, we choose the translation that maximizes a combination of (approximate) Bleu and the model.

We can also interpret (10) in the following way: we want $\mathbf{e}^*$ to be the max-Bleu translation, but we also want to minimize (1). So we balance these two criteria against each other:

$$\mathbf{e}^* = \arg\max_{\mathbf{e}} (B(\mathbf{e}) - \mu(B(\mathbf{e}) - \mathbf{h}(\mathbf{e}) \cdot \mathbf{w})) \tag{11}$$

where $(B(\mathbf{e}) - \mathbf{h}(\mathbf{e}) \cdot \mathbf{w})$ is that part of (1) that depends on $\mathbf{e}^*$, and μ is a parameter that controls how much we are willing to allow some translations to have higher Bleu than $\mathbf{e}^*$ if we can better minimize (1). Setting $\mu = 0$ would reduce to max-Bleu updating; setting $\mu = \infty$ would never update $\mathbf{w}$ at all. Setting $\mu = 0.5$ reduces to equation (10).

Figure 1 shows the 10-best unique translations for a single input sentence according to equation (11) under various settings of μ. The points at far right are the translations that are scored highest according to the model. The $\mu = 0$ points in the upper-left corner are typical of oracle translations that would be selected under the max-BLEU policy: they indeed have a very high BLEU score, but are far removed from the translations preferred by the model; thus they would cause violent updates to $\mathbf{w}$. Local updating would select the topmost point labeled $\mu = 1$. Our scheme would select one of the $\mu = 0.5$ points, which have BLEU scores almost as high as the max-BLEU translations, yet are not very far from the translations preferred by the model.

2.4 Selecting hypothesis translations

What is the set $\{\mathbf{e}_{ij}\}$ of translation hypotheses? Ideally we would let it be the set of all possible translations, and let the objective function (1) take all of them into account. This is the approach taken by Taskar et al. (2004), but their approach assumes that the loss function can be decomposed into local loss functions. Since our loss function cannot be so decomposed, we select:

- the 10-best translations according to the model;

we then rescore the forest to obtain

- the 10-best translations according to equation (11) with $\mu = 0.5$, the first of which is the oracle translation, and
- the 10-best translations with $\mu = \infty$, to serve as negative examples.

The last case is what Crammer et al. (2006) call *max-loss updating* (where "loss" refers to the generalized hinge loss) and Taskar et al. (2005) call *loss-augmented inference*. The rationale here is that since the objective (1) tries to minimize $\max_j(\ell_{ij} - \Delta\mathbf{h}_{ij} \cdot \mathbf{w}')$, we should include the translations that have the highest $(\ell_{ij} - \Delta\mathbf{h}_{ij} \cdot \mathbf{w})$ in order to approximate the effect of using the whole forest.

See Figure 1 again for an illustration of the hypotheses selected for a single sentence. The max-BLEU points in the upper left are not included (and would have no effect even if they were included). The $\mu = \infty$ points in the lower-right are the negative examples: they are poor translations that are scored too high by the model, and the learning algorithm attempts to shift them to the left.

To perform the forest rescoring, we need to use several approximations, since an exact search for BLEU-optimal translations is NP-hard (Leusch et al., 2008). For every derivation $\mathbf{e}$ in the forest, we calculate a vector $\mathbf{c}(\mathbf{e})$ of counts as in Section 2.2 except using *unclipped* counts of n-gram matches (Dreyer et al., 2007), that is, the number of matches for an n-gram can be greater than the number of occurrences of the n-gram in any reference translation. This can be done efficiently by calculating $\mathbf{c}$ for every hyperedge (rule application) in the forest:

- the number of output words generated by the rule
- the effective reference length scaled by the fraction of the input sentence consumed by the rule
- the number of n-grams formed by the application of the rule ($1 \leq n \leq 4$)
- the (unclipped) number of n-gram matches formed by the application of the rule ($1 \leq n \leq 4$)

We keep track of n-grams using the same scheme used to incorporate an n-gram language model into the decoder (Wu, 1996; Chiang, 2007).

To find the best derivation in the forest, we traverse it bottom-up as usual, and for every set of alternative subtranslations, we select the one with the highest score. But here a rough approximation lurks, because we need to calculate B on the nodes of the forest, but B does not have the optimal substructure property, i.e., the optimal score of a parent node cannot necessarily be calculated from the optimal scores of its children. Nevertheless, we find that this rescoring method is good enough for generating high-BLEU oracle translations and low-BLEU negative examples.

2.5 Parallelization

One convenient property of MERT is that it is embarrassingly parallel: we decode the entire tuning set sending different sentences to different processors, and during optimization of feature weights, different random restarts can be sent to different processors. In order to make MIRA comparable in efficiency to MERT, we must parallelize it. But with an online learning algorithm, parallelization requires a little more coordination. We run MIRA on each processor simultaneously, with each maintaining its own weight vector. A master process distributes different sentences from the tuning set to each of the processors; when each processor finishes decoding a sentence, it transmits the resulting hypotheses, with their losses, to all the other processors and receives any hypotheses waiting from other processors. Those hypotheses were generated from different weight vectors, but can still provide useful information. The sets of hypotheses thus collected are then processed as one batch. When the whole training process is finished, we simply average all the weight vectors from all the processors.

Having described our training algorithm, which includes several practical improvements to Watanabe et al.'s usage of MIRA, we proceed in the remainder of the paper to demonstrate the utility of the our training algorithm on models with large numbers of structurally sensitive features.

3 Soft syntactic constraints

The first features we explore are based on a line of research introduced by Chiang (2005) and improved on by Marton and Resnik (2008). A hierarchical phrase-based translation model is based on synchronous context-free grammar, but does not normally use any syntactic information derived from linguistic knowledge or treebank data: it uses translation rules that span any string of words in the input sentence, without regard for parser-defined syntactic constituency boundaries. Chiang (2005) experimented with a constituency feature that rewarded rules whose source language side exactly spans a syntactic constituent according to the output of an external source-language parser. This feature can be viewed as a *soft syntactic constraint*: it biases the model toward translations that respect syntactic structure, but does not force it to use them. However, this more syntactically aware model, when tested in Chinese-English translation, did not improve translation performance.

Recently, Marton and Resnik (2008) revisited the idea of constituency features, and succeeded in showing that finer-grained soft syntactic constraints yield substantial improvements in BLEU score for both Chinese-English and Arabic-English translation. In addition to adding separate features for different syntactic nonterminals, they introduced a new type of constraint that penalizes rules when the source language side *crosses* the boundaries of a source syntactic constituent, as opposed to simply rewarding rules when they are consistent with the source-language parse tree.

Marton and Resnik optimized their features' weights using MERT. But since MERT does not scale well to large numbers of feature weights, they were forced to test individual features and manually selected feature combinations each in a separate model. Although they showed gains in translation performance for several such models, many larger, potentially better feature combinations remained unexplored. Moreover, the best-performing feature subset was different for the two language pairs, suggesting that this labor-intensive feature selection process would have to be repeated for each new language pair.

Here, we use MIRA to optimize Marton and Resnik's finer-grained single-category features all at once. We define below two sets of features, a coarse-grained class that combines several constituency categories, and a fine-grained class that puts different categories into different features. Both kinds of features were used by Marton and Resnik, but only a few at a time. Crucially, our training algorithm provides the ability to train all the fine-grained features, a total of 34 feature weights, simultaneously.

Coarse-grained features As the basis for coarse-grained syntactic features, we selected the following nonterminal labels based on their frequency in the tuning data, whether they frequently cover a span of more than one word, and whether they represent linguistically relevant constituents: NP, PP, S, VP, SBAR, ADJP, ADVP, and QP. We define two new features, one which fires when a rule's source side span in the input sentence matches any of the above-mentioned labels in the input parse, and another which fires when a rule's source side span crosses a boundary of one of these labels (e.g., its source side span only partially covers the words in a VP subtree, and it also covers some or all or the words outside the VP subtree). These two features are equivalent to Marton and Resnik's $\mathrm{XP}^{=}$ and XP^{+} feature combinations, respectively.

Fine-grained features We selected the following nonterminal labels that appear more than 100 times in the tuning data: NP, PP, S, VP, SBAR, ADJP, WHNP, PRT, ADVP, PRN, and QP. The labels that were excluded were parts of speech, nonconstituent labels like FRAG, or labels that occurred only two or three times. For each of these labels X, we added a separate feature that fires when a rule's source side span in the input sentence matches X, and a second feature that fires when a span crosses a boundary of X. These features are similar to Marton and Resnik's $X^{=}$ and X^{+}, except that our set includes features for WHNP, PRT, and PRN.

4 Structural distortion features

In addition to parser-based syntactic constraints, which were introduced in prior work, we introduce a completely new set of features aimed at improving the modeling of reordering within Hiero. Again, the feature definition gives rise to a larger number of features than one would expect to train successfully using MERT.

In a phrase-based model, reordering is performed both within phrase pairs and by the phrase-reordering model. Both mechanisms are able to learn that longer-distance reorderings are more costly than shorter-distance reorderings: phrase pairs, because phrases that involve more extreme reorderings will (presumably) have a lower count in the data, and phrase reordering, because models are usually explicitly dependent on distance.

By contrast, in a hierarchical model, all reordering is performed by a single mechanism, the rules of the grammar. In some cases, the model will be able to learn a preference for shorter-distance reorderings, as in a phrase-based system, but in the case of a word being reordered across a nonterminal, or two nonterminals being reordered, there is no dependence in the model on the size of the nonterminal or nonterminals involved in reordering.

So, for example, if we have rules

$$X \rightarrow \langle \text{il dit } X_1, \text{he said } X_1 \rangle \tag{12}$$

$$X \rightarrow \langle \text{il dit } X_1, X_1 \text{ he said} \rangle \tag{13}$$

we might expect that rule (12) is more common in general, but that rule (13) becomes more and more rare as X_1 gets larger. The default Hiero features have no way to learn this.

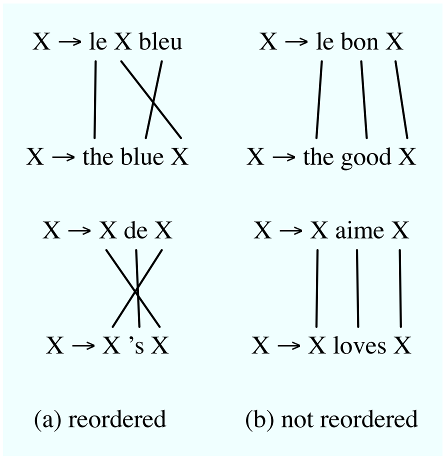

Figure 2: Classifying nonterminal occurrences for the structural distortion model.

To address this defect, we can classify every nonterminal pair occurring on the right-hand side of each grammar rule as "reordered" or "not reordered", that is, whether it intersects any other word alignment link or nonterminal pair (see Figure 2). We then define coarse- and fine-grained versions of the structural distortion model.

Coarse-grained features Let R be a binary-valued random variable that indicates whether a nonterminal occurrence is reordered, and let S be an integer-valued random variable that indicates how many source words are spanned by the nonterminal occurrence. We can estimate $P(R \mid S)$ via relative-frequency estimation from the rules as they are extracted from the parallel text, and incorporate this probability as a new feature of the model.

Fine-grained features A difficulty with the coarse-grained reordering features is that the grammar extraction process finds overlapping rules in the training data and might not give a sensible probability estimate; moreover, reordering statistics from the training data might not carry over perfectly into the translation task (in particular, the training data may have some very freely-reordering translations that one might want to avoid replicating in translation). As an alternative, we introduce a fine-grained version of our distortion model that can be trained directly in the translation task as follows: define a separate binary feature for each value of (R, S), where R is as above and $S \in \{\star, 1, \ldots, 9, \geq 10\}$ and $\star$ means any size. For example, if a nonterminal with span 11 has its contents reordered, then the features (true, $\geq$10) and (true, $\star$) would both fire. Grouping all sizes of 10 or more into a single feature is designed to avoid overfitting.

Again, using MIRA makes it practical to train with the full fine-grained feature set—coincidentally also a total of 34 features.

5 Experiment and results

We now describe our experiments to test MIRA and our features, the soft-syntactic constraints and the structural distortion features, on an Arabic-English translation task. It is worth noting that this experimentation is on a larger scale than Watanabe et al.'s (2007), and considerably larger than Marton and Resnik's (2008).

5.1 Experimental setup

The baseline model was Hiero with the following baseline features (Chiang, 2005; Chiang, 2007):

- two language models
- phrase translation probabilities $p(f \mid e)$ and $p(e \mid f)$
- lexical weighting in both directions (Koehn et al., 2003)
- word penalty
- penalties for:
  - automatically extracted rules
  - identity rules (translating a word into itself)
  - two classes of number/name translation rules
  - glue rules

The probability features are base-100 log-probabilities.

The rules were extracted from all the allowable parallel text from the NIST 2008 evaluation (152+175 million words of Arabic+English), aligned by IBM Model 4 using GIZA++ (union of both directions). Hierarchical rules were extracted from the most in-domain corpora (4.2+5.4 million words) and phrases were extracted from the remainder. We trained the coarse-grained distortion model on 10,000 sentences of the training data.

Two language models were trained, one on data similar to the English side of the parallel text and one on 2 billion words of English. Both were 5-gram models with modified Kneser-Ney smoothing, lossily compressed using a perfect-hashing scheme similar to that of Talbot and Brants (2008) but using minimal perfect hashing (Botelho et al., 2005).

We partitioned the documents of the NIST 2004 (newswire) and 2005 Arabic-English evaluation data into a tuning set (1178 sentences) and a development set (1298 sentences). The test data was the NIST 2006 Arabic-English evaluation data (NIST part, newswire and newsgroups, 1529 sentences).

To obtain syntactic parses for this data, we tokenized it according to the Arabic Treebank standard using AMIRA (Diab et al., 2004), parsed it with the Stanford parser (Klein and Manning, 2003), and then forced the trees back into the MT system's tokenization.[1]

We ran both MERT and MIRA on the tuning set using 20 parallel processors. We stopped MERT when the score on the tuning set stopped increasing, as is common practice, and for MIRA, we used the development set to decide when to stop training.[2] In our runs, MERT took an average of 9 passes through the tuning set and MIRA took an average of 8 passes. (For comparison, Watanabe et al. report decoding their tuning data of 663 sentences 80 times.)

5.2 Results

Table 1 shows the results of our experiments with the training methods and features described above. All significance testing was performed against the first line (MERT baseline) using paired bootstrap resampling (Koehn, 2004).

First of all, we find that MIRA is competitive with MERT when both use the baseline feature set. In-

[1]The only notable consequence this had for our experimentation is that proclitic Arabic prepositions were fused onto the first word of their NP object, so that the PP and NP brackets were coextensive.

[2]We chose this policy for MIRA to avoid overfitting. However, we could have used the tuning set for this purpose, just as with MERT: in none of our runs would this change have made more than a 0.2 BLEU difference on the development set.

			Dev	NIST 06 (NIST part)		
Train	Features	#	nw	nw	ng	nw+ng
MERT	baseline	12	52.0	50.5	32.4	44.6
	syntax (coarse)	14	52.2	50.9	33.0^{+}	45.0^{+}
	syntax (fine)	34	52.1	50.4	33.5^{++}	44.8
	distortion (coarse)	13	52.3	51.3^{+}	34.3^{++}	45.8^{++}
	distortion (fine)	34	52.0	50.9	34.5^{++}	45.5^{++}
MIRA	baseline	12	52.0	49.8^{-}	34.2^{++}	45.3^{++}
	syntax (fine)	34	53.1^{++}	51.3^{+}	34.5^{++}	46.4^{++}
	distortion (fine)	34	53.3^{++}	51.5^{++}	34.7^{++}	46.7^{++}
	distortion+syntax (fine)	56	53.6^{++}	52.0^{++}	35.0^{++}	47.2^{++}

Table 1: Comparison of MERT and MIRA on various feature sets. Key: # = number of features; nw = newswire, ng = newsgroups; + or ++ = significantly better than MERT baseline ($p < 0.05$ or $p < 0.01$, respectively), − = significantly worse than MERT baseline ($p < 0.05$).

deed, the MIRA system scores significantly higher on the test set; but if we break the test set down by genre, we see that the MIRA system does slightly worse on newswire and better on newsgroups. (This is largely attributable to the fact that the MIRA translations tend to be longer than the MERT translations, and the newsgroup references are also relatively longer than the newswire references.)

When we add more features to the model, the two training methods diverge more sharply. When training with MERT, the coarse-grained pair of syntax features yields a small improvement, but the fine-grained syntax features do not yield any further improvement. By contrast, when the fine-grained features are trained using MIRA, they yield substantial improvements. We observe similar behavior for the structural distortion features: MERT is not able to take advantage of the finer-grained features, but MIRA is. Finally, using MIRA to combine both classes of features, 56 in all, produces the largest improvement, 2.6 Bleu points over the MERT baseline on the full test set.

We also tested some of the differences between our training method and Watanabe et al.'s (2007); the results are shown in Table 2. Compared with local updating (line 2), our method of selecting the oracle translation and negative examples does better by 0.5 Bleu points on the development data. Using loss-augmented inference to add negative examples to local updating (line 3) does not appear to help. Nevertheless, the negative examples are important: for if we use our method for selecting the oracle translation without the additional negative examples (line 4), the algorithm fails, generating very long translations and unable to find a weight setting to shorten them. It appears, then, that the additional negative examples enable the algorithm to reliably learn from the enhanced oracle translations.

Setting	Dev
full	53.6
local updating, no LAI	53.1^{-}
local updating, LAI	53.0^{--}
$\mu = 0.5$ oracle, no LAI	failed
no sharing of updates	53.1^{--}

Table 2: Effect of removing various improvements in learning method. Key: − or −− = significantly worse than full system ($p < 0.05$ or $p < 0.01$, respectively); LAI = loss-augmented inference for additional negative examples.

Finally, we compared our parallelization method against a simpler method in which all processors learn independently and their weight vectors are all averaged together (line 5). We see that sharing information among the processors makes a significant difference.

6 Conclusions

In this paper, we have brought together two existing lines of work: the training method of Watanabe et al. (2007), and the models of Chiang (2005) and Marton and Resnik (2008). Watanabe et al.'s work showed that large-margin training with MIRA can be made feasible for state-of-the-art MT systems by using a manageable tuning set; we have demonstrated that parallel processing and exploiting more of the parse forest improves MIRA's performance and that, even using the same set of features, MIRA's performance compares favorably to MERT in terms of both translation quality and computational cost.

Marton and Resnik (2008) showed that it is possible to improve translation in a data-driven framework by incorporating source-side syntactic analysis in the form of soft syntactic constraints. This work joins a growing body of work demonstrating the utility of syntactic information in statistical MT. In the area of source-side syntax, recent research has continued to improve tree-to-string translation models, soften the constraints of the input tree in various ways (Mi et al., 2008; Zhang et al., 2008), and extend phrase-based translation with source-side soft syntactic constraints (Cherry, 2008). All this work shows strong promise, but Marton and Resnik's soft syntactic constraint approach is particularly appealing because it can be used unobtrusively with any hierarchically-structured translation model. Here, we have shown that using MIRA to weight all the constraints at once removes the crucial drawback of the approach, the problem of feature selection.

Finally, we have introduced novel structural distortion features to fill a notable gap in the hierarchical phrase-based approach. By capturing how reordering depends on constituent length, these features improve translation quality significantly. In sum, we have shown that removing the bottleneck of MERT opens the door to many possibilities for better translation.

A noisy-channel model of rational human sentence comprehension under uncertain input

Abstract

Language comprehension, as with all other cases of the extraction of meaningful structure from perceptual input, takes places under noisy conditions. If human language comprehension is a rational process in the sense of making use of all available information sources, then we might expect uncertainty at the level of word-level input to affect sentence-level comprehension. However, nearly all contemporary models of sentence comprehension assume *clean* input—that is, that the input to the sentence-level comprehension mechanism is a perfectly-formed, completely certain sequence of input tokens (words). This article presents a simple model of rational human sentence comprehension under noisy input, and uses the model to investigate some outstanding problems in the psycholinguistic literature for theories of rational human sentence comprehension. We argue that by explicitly accounting for input-level noise in sentence processing, our model provides solutions for these outstanding problems and broadens the scope of theories of human sentence comprehension as rational probabilistic inference.

[*] Part of this work has benefited from presentation at the 21st annual meeting of the CUNY Sentence Processing Conference in Chapel Hill, NC, 14 March 2008, and at a seminar at the Center for Research on Language, UC San Diego. I am grateful to Klinton Bicknell, Andy Kehler, and three anonymous reviewers for comments and suggestions, Cyril Allauzen for guidance regarding the OpenFST library, and to Mark Johnson, Mark-Jan Nederhof, and Noah Smith for discussion of renormalizing weighted CFGs.

1 Introduction

Considering the adversity of the conditions under which linguistic communication takes place in everyday life—ambiguity of the signal, environmental competition for our attention, speaker error, and so forth—it is perhaps remarkable that we are as successful at it as we are. Perhaps the leading explanation of this success is that (a) the linguistic signal is redundant, and (b) diverse information sources are generally available that can help us obtain infer the intended message (or something close enough) when comprehending an utterance (Tanenhaus et al., 1995; Altmann and Kamide, 1999; Genzel and Charniak, 2002, 2003; Aylett and Turk, 2004; Keller, 2004; Levy and Jaeger, 2007). Given the difficulty of this task coupled with the availability of redundancy and useful information sources, it would seem rational for all available information to be used to its fullest in sentence comprehension. This idea is either implicit or explicit in several interactivist theories of probabilistic language comprehension (Jurafsky, 1996; Hale, 2001; Narayanan and Jurafsky, 2002; Levy, 2008). However, these theories have implicitly assumed a partitioning of interactivity that distinguishes the *word* as a fundamental level of linguistic information processing: word recognition is an evidential process whose output is nonetheless a specific "winner-takes-all" sequence of words, which is in turn the input to an evidential sentence-comprehension process. It is theoretically possible that this partition is real and is an optimal solution to the problem of language comprehension under gross architectural constraints that favor modularity

(Fodor, 1983). On the other hand, it is also possible that this partition has been a theoretical convenience but that, in fact, evidence at the sub-word level plays an important role in sentence processing, and that sentence-level information can in turn affect word recognition. If the latter is the case, then the question arises of how we might model this type of information flow, and what consequences it might have for our understanding of human language comprehension. This article employs the well-understood formalisms of probabilistic context-free grammars (PCFGs) and weighted finite-state automata (wFSAs) to propose a novel yet simple noisy-channel probabilistic model of sentence comprehension under circumstances where there is uncertainty about word-level representations. Section 2 introduces this model. We use this new model to investigate two outstanding problems for the theory of rational sentence comprehension: one involving *global inference*—the beliefs that a human comprehender arrives at regarding the meaning of a sentence after reading it in its entirety (Section 3)—and one involving *incremental inference*—the beliefs that a comprehender forms and updates moment by moment while reading each part of it (Section 4). The common challenge posed by each of these problems is an apparent failure on the part of the comprehender to use information made available in one part of a sentence to rule out an interpretation of another part of the sentence that is inconsistent with this information. In each case, we will see that the introduction of uncertainty into the input representation, coupled with noisy-channel inference, provides a unified solution within a theory of rational comprehension.

2 Sentence comprehension under uncertain input

The use of generative probabilistic grammars for parsing is well understood (e.g., Charniak, 1997; Collins, 1999). The problem of using a probabilistic grammar G to find the "best parse" T for a known input string $\mathbf{w}$ is formulated as[1]

$$\arg\max_T P_G(T|\mathbf{w}) \qquad \text{(I)}$$

but a *generative* grammar directly defines the joint distribution $P_G(T, \mathbf{w})$ rather than the conditional distribution. In this case, Bayes' rule is used to find the posterior:

$$P_G(T|\mathbf{w}) = \frac{P(T,\mathbf{w})}{P(\mathbf{w})} \qquad \text{(II)}$$

$$\propto P(T,\mathbf{w}) \qquad \text{(III)}$$

If the input string is unknown, the problem changes. Suppose we have some noisy evidence I that determines a probability distribution over input strings $P(\mathbf{w}|I)$. We can still use Bayes' rule to obtain the posterior:

$$P_G(T|I) = \frac{P(T,I)}{P(I)} \qquad \text{(IV)}$$

$$\propto \sum_{\mathbf{w}} P(I|T,\mathbf{w})P(\mathbf{w}|T)P(T) \qquad \text{(V)}$$

Likewise, if we are focused on inferring which words were seen given an uncertain input, we have

$$P_G(\mathbf{w}|I) \propto \sum_T P(I|T,\mathbf{w})P(\mathbf{w}|T)P(T) \qquad \text{(VI)}$$

2.1 Uncertainty for a Known Input

This paper considers situations such as controlled psycholinguistic experiments where we (the researchers) know the sentence $\mathbf{w}^*$ presented to a comprehender, but do not know the specific input I that the comprehender obtains. In this case, if we are, for example, interested in the expected inferences of a rational comprehender about what word string she was exposed to, the probability distribution of interest is

$$P(\mathbf{w}|\mathbf{w}^*) = \int_I P_C(\mathbf{w}|I,\mathbf{w}^*)P_T(I|\mathbf{w}^*)\,dI \quad \text{(VII)}$$

where P_C is the probability distribution used by the comprehender to process perceived input, and P_T is the "true" probability distribution over the inputs

[1]By assumption, G is defined such that its complete productions T completely specify the string, such that $P(\mathbf{w}|T)$ is non-zero for only one value of $\mathbf{w}$.

that might actually be perceived given the true sentence. Since the comprehender does not observe $\mathbf{w}^*$ we must have conditional independence between $\mathbf{w}$ and $\mathbf{w}^*$ given I. We can then apply Bayes' rule to (VII) to obtain

$$P(\mathbf{w}|\mathbf{w}^*) = \int_I \frac{P_C(I|\mathbf{w})P_C(\mathbf{w})}{P_C(I)} P_T(I|\mathbf{w}^*)\, dI \tag{VIII}$$

$$= P_C(\mathbf{w}) \int_I \frac{P_C(I|\mathbf{w})P_T(I|\mathbf{w}^*)}{P_C(I)}\, dI \tag{IX}$$

$$\propto P_C(\mathbf{w})Q(\mathbf{w},\mathbf{w}^*) \tag{X}$$

where $Q(\mathbf{w},\mathbf{w}^*)$ is proportional to the integral term in Equation (IX). The term $P_C(\mathbf{w})$ corresponds to the comprehender's prior beliefs; the integral term is the effect of input uncertainty. If comprehenders model noise rationally, then we should have $P_C(I|\mathbf{w}) = P_T(I|\mathbf{w})$, and thus $Q(\mathbf{w},\mathbf{w}^*)$ becomes a symmetric, non-negative function of $\mathbf{w}$ and $\mathbf{w}^*$; hence the effect of input uncertainty can be modeled by a *kernel function* on input string pairs. (Similar conclusions result when the posterior distribution of interest is over structures T.) It is an open question which kernel functions might best model the inferences made in human sentence comprehension. Most obviously the kernel function should account for noise (environmental, perceptual, and attentional) introduced into the signal en route to the neural stage of abstract sentence processing. In addition, this kernel function might also be a natural means of accounting for modeling error such as disfluencies (Johnson and Charniak, 2004), word/phrase swaps, and even well-formed utterances that the speaker did not intend. For purposes of this paper, we limit ourselves to a simple kernel based on the Levenshtein distance $LD(w,w')$ between words and constructed in the form of a weighted finite-state automaton (Mohri, 1997).

2.2 The Levenshtein-distance kernel

Suppose that the input word string $\mathbf{w}^*$ consists of words $w_{1\ldots n}$. We define the Levenshtein-distance kernel as follows. Start with a weighted finite-state automaton in the log semiring over the vocabulary Σ with states $0\ldots n$, state 0 being the start state

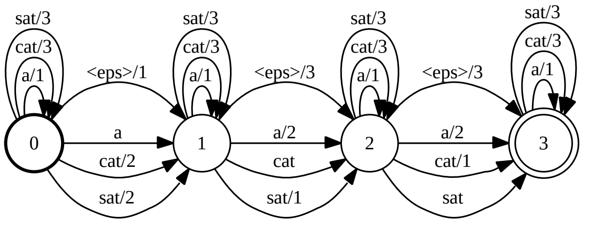

Figure 1: The Levenshtein-distance kernel for multi-word string edits. $K_{LD}(\mathbf{w}^*)$ is shown for $\Sigma = \{\text{cat,sat,a}\}$, $\mathbf{w}^* = (\text{a cat sat})$, and $\lambda = 1$. State 0 is the start state, and State 3 is the lone (zero-cost) final state.

and n the (zero-cost) final state. We add two types of arcs to this automaton: (a) substitution/deletion arcs $(i-1,w') \to i$, $i \in 1,\ldots,n$, each with cost $\lambda\, LD(w_i,w')$, for all $w' \in \Sigma \cup \{\epsilon\}$; and (b) insertion loop arcs $(j,w') \to j$, $j \in 0,\ldots,n$, each with cost $\lambda\, LD(\epsilon,w')$, for all $w' \in \Sigma$.[2] The resulting wFSA $K_{LD}(\mathbf{w}^*)$ defines a function over $\mathbf{w}$ such that the summed weight of paths through the wFSA accepting $\mathbf{w}$ is $\log Q(\mathbf{w},\mathbf{w}^*)$. This kernel allows for the possibility of word *substitutions* (represented by the transition arcs with labels that are neither w_i nor ϵ), word *deletions* (represented by the transition arcs with ϵ labels), and even word *insertions* (represented by the loop arcs). The unnormalized probability of each type of operation is exponential in the Levenshtein distance of the change induced by the operation. The term λ is a free parameter, with smaller values corresponding to noisier input. Figure 1 gives an example of the Levenshtein-distance kernel for a simple vocabulary and sentence.[3]

[2]For purposes of computing the Levenshtein distance between words, the epsilon label ϵ is considered to be a zero-length letter string.

[3]The Levenshtein-distance kernel can be seen to be symmetric in $\mathbf{w},\mathbf{w}^*$ as follows. Any path accepting $\mathbf{w}$ in the wFSA generated from $\mathbf{w}^*$ involves the following non-zero-cost transitions: insertions $w'^{I}_{1\ldots i}$, deletions $w^{D}_{1\ldots j}$, and substitutions $(w \to w')^{S}_{1\ldots k}$. For each such path P, there will be exactly one path P' in the wFSA generated from $\mathbf{w}$ that accepts $\mathbf{w}^*$ with insertions $w^{D}_{1\ldots j}$, deletions $w'^{I}_{1\ldots i}$, and substitutions $(w' \to w)^{S}_{1\ldots k}$. Due to the symmetry of the Levenshtein distance, the paths P and P' will have identical costs. Therefore the kernel is indeed symmetric.

2.3 Efficient computation of posterior beliefs

The problem of finding structures or strings with high posterior probability given a particular input string $\mathbf{w}^*$ is quite similar to the problem faced in the parsing of speech, where the acoustic input I to a parser can be represented as a lattice of possible word sequences, and the edges of the lattice have weights determined by a model of acoustic realization of words, $P(I|\mathbf{w})$ (Collins et al., 2004; Hall and Johnson, 2003, 2004). The two major differences between lattice parsing and our problem are (a) we have integrated out the expected effect of noise, which is thus implicit in our choice of kernel; and (b) the loops in the Levenshtein-distance kernel mean that the input to parsing is no longer a lattice. This latter difference means that some of the techniques applicable to string parsing and lattice parsing – notably the computation of inside probabilities – are no longer possible using exact methods. We return to this difference in Sections 3 and 4.

3 Global inference

One clear prediction of the uncertain-input model of (VII)–(X) is that under appropriate circumstances, the prior expectations $P_C(\mathbf{w})$ of the comprehender should in principle be able to override the linguistic input actually presented, so that a sentence is interpreted as meaning—and perhaps even *being*—something other than it actually meant or was. At one level, it is totally clear that comprehenders do this on a regular basis: the ability to do this is required for someone to act as a copy editor—that is, to notice and (crucially) correct mistakes on the printed page. In many cases, these types of correction happen at a level that may be below consciousness—thus we sometimes miss a typo but interpret the sentences as it was intended, or ignore the disfluency of a speaker. What has not been previously proposed in a formal model, however, is that this can happen *even when an input is a completely grammatical sentence*. Here, we argue that an effect demonstrated by Christianson et al. (2001) (see also Ferreira et al., 2002) is an example of expectations overriding input. When presented sentences of the forms in (1) using methods that did not permit rereading, and asked questions of the type *Did the man hunt the deer?*, experimental participants gave affirmative responses significantly more often for sentences of type (1a), in which the substring *the man hunted the deer* appears, than for either (1b) or (1c).

(1) a. While the man hunted the deer ran into the woods. (GARDENPATH)
    b. While the man hunted the pheasant the deer ran into the woods. (TRANSITIVE)
    c. While the man hunted, the deer ran into the woods. (COMMA)

This result was interpreted by Christianson et al. (2001) and Ferreira et al. (2002) as reflecting (i) the fact that there is a syntactic garden path in (1a)—after reading the first six words of the sentence, the preferred interpretation of the substring *the man hunted the deer* is as a simple clause indicating that the deer was hunted by the man—and (ii) that readers were not always successful at revising away this interpretation when they saw the disambiguating verb *ran*, which signals that *the deer* is actually the subject of the main clause, and that *hunted* must therefore be intransitive. Furthermore (and crucially), for (1a) participants also responded affirmatively most of the time to questions of the type *Did the deer run into the woods?* This result is a puzzle for existing models of sentence comprehension because no grammatical analysis exists of any substring of (1a) for which *the deer* is both the object of *hunted* and the subject of *ran*. In fact, no formal model has yet been proposed to account for this effect.

The uncertain-input model gives us a means of accounting for these results, because there are near neighbors of (1a) for which there *is* a global grammatical analysis in which either *the deer* or a coreferent NP is in fact the object of the subordinate-clause verb *hunted*. In particular, inserting the word *it* either before or after *the deer* creates such a near neighbor:

(2) a. While the man hunted the deer it ran into the woods.
    b. While the man hunted it the deer ran into the woods.

We formalize this intuition within our model by using the wFSA representation of the Levenshtein-

distance kernel. A probabilistic context-free grammar (PCFG) representing the comprehender's grammatical knowledge can be intersected with that wFSA using well-understood techniques, generating a new weighted CFG (Bar-Hillel et al., 1964; Nederhof and Satta, 2003). This intersection thus represents the unnormalized posterior $P_C(T, \mathbf{w}|\mathbf{w}^*)$. Because there are loops in the wFSA generated by the Levenshtein-distance kernel, exact normalization of the posterior is not tractable (though see Nederhof and Satta, 2003; Chi, 1999; Smith and Johnson, 2007 for possible approaches to approximating the normalization constant). We can, however, use the lazy k-best algorithm of Huang and Chiang (2005; Algorithm 3) to obtain the word-string/parse-tree pairs with highest posterior probability.

3.1 Experimental Verification

To test our account of the rational noisy-channel interpretation of sentences such as (1), we defined a small PCFG using the phrasal rules listed in Figure 2, with rule probabilities estimated from the parsed Brown corpus.[4] Lexical rewrite probabilities were determined using relative-frequency estimation over the entire parsed Brown corpus. For each of the sentence sets like (1) used in Experiments 1a, 1b, and 2 of Christianson et al. (2001) that have complete lexical coverage in the parsed Brown corpus (22 sets in total), a noisy-input wFSA was constructed using K_{LD}, permitting all words occurring more than 2500 times in the parsed Brown corpus as possible edit/insertion targets.[5] Figure 3 shows the average proportion of parse trees among the 100 best parses in the intersection between this PCFG and the wFSA for each sentence for which an interpretation is available such that *the deer* or a coreferent NP is the direct object of *hunted*.[6] The Levenshtein distance penalty λ is a free parameter in the model, but the results are consistent for a wide range of λ: interpretations of type (2) are more prevalent both in terms of number mass for (1a) than for either (1b) or (1c). Furthermore, across 9 noise values for 22 sentence sets, there were never more interpretations of type (2) for COMMA sentences than for the corresponding GARDENPATH sentences, and in only one case were there more such interpretations for a TRANSITIVE sentence than for the corresponding GARDENPATH sentence.

4 Incremental comprehension and error identification

We begin taking up the role of input uncertainty for incremental comprehension by posing a question:

[4]Counts of these rules were obtained using `tgrep2/Tregex` tree-matching patterns (Rohde, 2005; Levy and Andrew, 2006), available online at `http://idiom.ucsd.edu/~rlevy/papers/emnlp2008/tregex_patterns`. We have also investigated the use of broad-coverage PCFGs estimated using standard treebank-based techniques, but found that the computational cost of inference with treebank-sized grammars was prohibitive.

[5]The word-frequency cutoff was introduced for computational speed; we have obtained qualitatively similar results with lower word-frequency cutoffs.

[6]We took a parse tree to satisfy this criterion if the NP *the deer* appeared either as the matrix-clause subject or the embedded-clause object, and a pronoun appeared in the other position. In a finer-grained grammatical model, number/gender agreement would be enforced between such a pronoun and the NP in the posterior, so that the probability mass for these parses would be concentrated on cases where the pronoun is *it*.

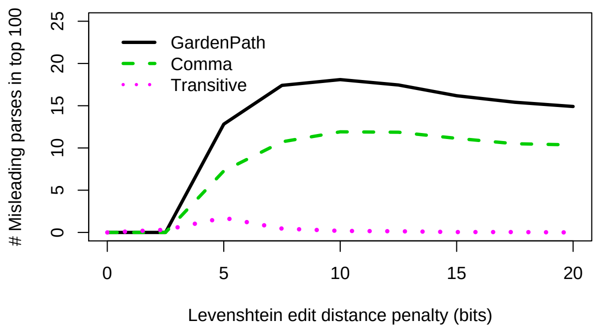

Figure 3: Results for 100-best global inference, as a function of the Levenshtein distance penalty λ (in bits).

what is the optimal way to read a sentence on a page (Legge et al., 1997)? Presumably, the goal of reading is to find a good compromise between scanning the contents of the sentence as quickly as possible while achieving an accurate understanding of the sentence's meaning. To a first approximation, humans solve this problem by reading each sentence in a document from beginning to end, regardless of the actual layout; whether this general solution is best understood in terms of optimality or rather as parasitic on spoken language comprehension is an open question beyond the immediate scope of the present paper. However, about 10–15% of eye movements in reading are regressive (Rayner, 1998), and we may usefully refine our question to when a *regressive* eye movement might be a good decision. In traditional models of sentence comprehension, the optimal answer would certainly be "never", since past observations are known with certainty. But once uncertainty about the past is accounted for, it is clear that there may in principle be situations in which regressive saccades may be the best choice.

What are these situations? One possible answer would be: when the uncertainty (e.g., measured by entropy) about an earlier part of the sentence is high. There are some cases in which this is probably the correct answer: many regressive eye movements are very small and the consensus in the eye-movement literature is that they represent corrections for motor error at the saccadic level. That is, the eyes overshoot the intended target and regress to obtain information about what was missed. However, motor error can account only for short, isolated regressions, and about one-sixth of regressions are part of a longer series back into the sentence, into a much earlier part of the text which has already been read. We propose that these regressive saccades might be the best choice *when the most recent observed input significantly changes the comprehender's beliefs about the earlier parts of the sentence*. To make the discussion more concrete, we turn to another recent result in the psycholinguistic literature that has been argued to be problematic for rational theories of sentence comprehension.

It has been shown (Tabor et al., 2004) that sentences such as (3) below induce considerable processing difficulty at the word *tossed*, as measured in word-by-word reading times:

(3) The coach smiled at the player tossed a frisbee. (LOCALLY COHERENT)

Both intuition and controlled experiments reveal that this difficulty seems due at least in part to the category ambiguity of the word *tossed*, which is occasionally used as a participial verb but is much more frequently used as a simple-past verb. Although *tossed* in (3) is actually a participial verb introducing a reduced relative clause (and *the player* is hence its recipient), most native English speakers find it extremely difficult not to interpret *tossed* as a main verb and *the player* as its agent—far more difficult than for corresponding sentences in which the critical participial verb is morphologically distinct from the simple past form ((4a), (4c); c.f. *threw*) or in which the relative clause is unreduced and thus clearly marked ((4b), (4c)).

(4) a. The coach smiled at the player thrown a frisbee. (LOCALLY INCOHERENT)
b. The coach smiled at the player who was tossed a frisbee.
c. The coach smiled at the player who was thrown a frisbee.

The puzzle here for rational approaches to sentence comprehension is that the preceding top-down context provided by *The coach smiled at...* should completely rule out the possibility of seeing a main verb immediately after *player*, hence a rational comprehender should not be distracted by the part-of-speech ambiguity.[7]

4.1 An uncertain-input solution

The solution we pursue to this puzzle lies in the fact that (3) has many near-neighbor sentences in which the word *tossed* is in fact a simple-past tense verb. Several possibilities are listed below in (5):

(5)
a. The coach **who** smiled at the player tossed a frisbee.
b. The coach smiled **as** the player tossed a frisbee.
c. The coach smiled **and** the player tossed a frisbee.
d. The coach smiled at the player **who** tossed a frisbee.
e. The coach smiled at the player **that** tossed a frisbee.
f. The coach smiled at the player **and** tossed a frisbee.

The basic intuition we follow is that simple-past verb *tossed* is much more probable where it appears in any of (5a)-(5f) than participial *tossed* is in (3). Therefore, seeing this word causes the comprehender to shift her probability distribution about the earlier part of the sentence away from (3), where it had been peaked, toward its near neighbors such as the examples in (5). This change in beliefs about the past is treated as an error identification signal (EIS). In reading, a sensible response to an EIS would be a slowdown or a regressive saccade; in spoken language comprehension, a sensible response would be to allocate more working memory resources to the comprehension task.

4.2 Quantifying the Error Identification Signal

We quantify our proposed error identification signal as follows. Consider the probability distribution over the input up to, but not including, a position j in a sentence $\mathbf{w}$:

7This preceding context sharply distinguishes (3) from better-known, traditional garden-path sentences such as *The horse raced past the barn fell*, in which preceding context cannot be used to correctly disambiguate the part of speech of the ambiguous verb *raced*.

$$P(w_{[0,j)}) \qquad \text{(XI)}$$

We use the subscripting $[0, j)$ to illustrate that this interval is “closed” through to include the beginning of the string, but “open” at position j—that is, it includes all material before position j but does not include anything at that position or beyond. Let us then define the posterior distribution after seeing all input up through and including word i as $P_i(w_{[0,j)})$. We define the EIS induced by reading a word w_i as follows:

$$D\left(P_i(w_{[0,i)})||P_{i-1}(w_{[0,i)})\right) \qquad \text{(XII)}$$

$$\equiv \sum_{w \in \{w_{[0,i)}\}} P_i(w) \log \frac{P_i(w)}{P_{i-1}(w)} \qquad \text{(XIII)}$$

where $D(q||p)$ is the Kullback-Leibler divergence, or relative entropy, from p to q, a natural way of quantifying the distance between probability distributions (Cover and Thomas, 1991) which has also been argued for previously in modeling attention and surprise in both visual and linguistic cognition (Itti and Baldi, 2005; Levy, 2008).

4.3 Experimental Verification

As in Section 3, we use a small probabilistic grammar covering the relevant structures in the problem domain to represent the comprehender's knowledge, and a wFSA based on the Levenshtein-distance kernel to represent noisy input. We are interested in comparing the EIS at the word *tossed* in (3) versus the EIS at the word *thrown* in (4a). In this case, the interval $w_{[0,j)}$ contains all the material that could possibly have come before the word *tossed/thrown*, but does not contain material at or after the position introduced by the word itself. Loops in the probabilistic grammar and the Levenshtein-distance kernel pose a challenge, however, to evaluating the EIS, because the normalization constant of the resulting grammar/input intersection is essential to evaluating Equation (XIII). To circumvent this problem, we eliminate loops from the kernel by allowing only one insertion per inter-word space.[8] (See Section 5 for a possible alternative).

[8]Technically, this involves the following transformation of a Levenshtein-distance wFSA. First, eliminate all loop arcs.

Figure 4: The grammar used for the incremental-inference experiment of Section 4. Rule weights given as negative log-probabilities in bits.

Figure 4 shows the (finite-state) probabilistic grammar used for the study, with rule probabilities once again determined from the parsed Brown corpus using relative frequency estimation. To calculate the distribution over strings after exposure to the i-th word in the sentence, we "cut" the input wFSA such that all transitions and arcs after state $2i+2$ were removed and replaced with a sequence of states $j = 2i+3, \ldots, m$, with zero-cost transitions $(j-1, w') \rightarrow j$ for all $w' \in \Sigma \cup \{\epsilon\}$, and each new j being a zero-cost final state.[9] Because the intersection between this "cut" wFSA and the probabilistic grammar is loop-free, it can be renormalized, and the EIS can be calculated without difficulty. All the computations in this section were carried out using the OpenFST library (Allauzen et al., 2007).

Next, map every state i onto a state pair in a new wFSA $(2i, 2i+1)$, with all incoming arcs in i being incoming into $2i$, all outgoing arcs from i being outgoing from $2i+1$, and new transition arcs $(2i, w') \rightarrow 2i+1$ for each $w' \in \Sigma \cup \{\epsilon\}$ with cost $LD(\epsilon, w')$. Finally, add initial state 0 to the new wFSA with transition arcs to state 1 for all $w' \in \Sigma \cup \{\epsilon\}$ with cost $LD(\epsilon, w')$. A final state i in the old wFSA corresponds to a final state $2i+1$ in the new wFSA.

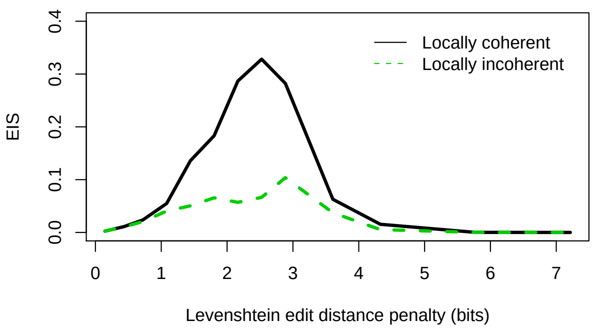

Figure 5: The Error Identification Signal (EIS) for (3) and (4a), as a function of the Levenshtein distance penalty λ (in bits)

Figure 5 shows the average magnitude of the EIS for sentences (3) versus (4a) at the critical word position *tossed/thrown*. Once again, the Levenshtein-distance penalty λ is a free parameter in the model, so we show model behavior as a function of λ, for the eight sentence pairs in Experiment 1 of Tabor et al. with complete lexical and syntactic coverage for the grammar of Figure 4. For values of λ where the EIS is non-negligible, it is consistently larger at the critical word (*tossed* in (3), *thrown* in (4a)) in the COHERENT condition than in the INCOHERENT condition. Across a range of eight noise levels, 67% of sentence pairs had a higher EIS in the COHERENT condition than in the INCOHERENT condition. Furthermore, the cases where the INCOHERENT condition had a larger EIS occurred only for noise levels below 1.1 and above 3.6, and the maximum such EIS was quite small, at 0.067. Overall, the model's behavior is consistent with the experimental results of Tabor et al. (2004), and can be explained through the intuition described at the end of Section 4.1.

[9]The number of states added had little effect on results, so long as at least as many states were added as words remained in the sentence.

5 Conclusion

In this paper we have outlined a simple model of rational sentence comprehension under uncertain input and explored some of the consequences for outstanding problems in the psycholinguistic literature. The model proposed here will require further empirical investigation in order to distinguish it from other proposals that have been made in the literature, but if our proposal turns out to be correct it has important consequences for both the theory of language processing and cognition more generally. Most notably, it furthers the case for rationality in sentence processing; and it eliminates one of the longest-standing modularity hypotheses implicit in work on the cognitive science of language: a partition between systems of word recognition and sentence comprehension (Fodor, 1983). Unlike the pessimistic picture originally painted by Fodor, however, the interactivist picture resulting from our model's joint inference over possible word strings and structures points to many rich details that still need to be filled in. These include questions such as what kernel functions best account for human comprehenders' modeling of noise in linguistic input, and what kinds of algorithms might allow representations with uncertain input to be computed incrementally.

The present work could also be extended in several more technical directions. Perhaps most notable is the problem of the normalization constant for the posterior distribution over word strings and structures; this problem was circumvented via a k-best approach in Section 3 and by removing loops from the Levenshtein-distance kernel in Section 4. We believe, however, that a more satisfactory solution may exist via sampling from the posterior distribution over trees and strings. This may be possible either by estimating normalizing constants for the posterior grammar using iterative weight propagation and using them to obtain proper production rule probabilities (Chi, 1999; Smith and Johnson, 2007), or by using reversible-jump Markov-chain Monte Carlo (MCMC) techniques to sample from the posterior (Green, 1995), and estimating the normalizing constant with annealing-based techniques (Gelman and Meng, 1998) or nested sampling (Skilling, 2004). Scaling the model up for use with treebank-size grammars is another area for technical improvement.

Finally, we note that the model here could potentially find practical application in grammar correction. Although the noisy channel has been in use for many years in spelling correction, our model could be used more generally for grammar corrections, including insertions, deletions, and (with new noise functions) potentially changes in word order.

Incorporating Temporal and Semantic Information with Eye Gaze for Automatic Word Acquisition in Multimodal Conversational Systems

Abstract

One major bottleneck in conversational systems is their incapability in interpreting unexpected user language inputs such as out-of-vocabulary words. To overcome this problem, conversational systems must be able to learn new words automatically during human machine conversation. Motivated by psycholinguistic findings on eye gaze and human language processing, we are developing techniques to incorporate human eye gaze for automatic word acquisition in multimodal conversational systems. This paper investigates the use of temporal alignment between speech and eye gaze and the use of domain knowledge in word acquisition. Our experiment results indicate that eye gaze provides a potential channel for automatically acquiring new words. The use of extra temporal and domain knowledge can significantly improve acquisition performance.

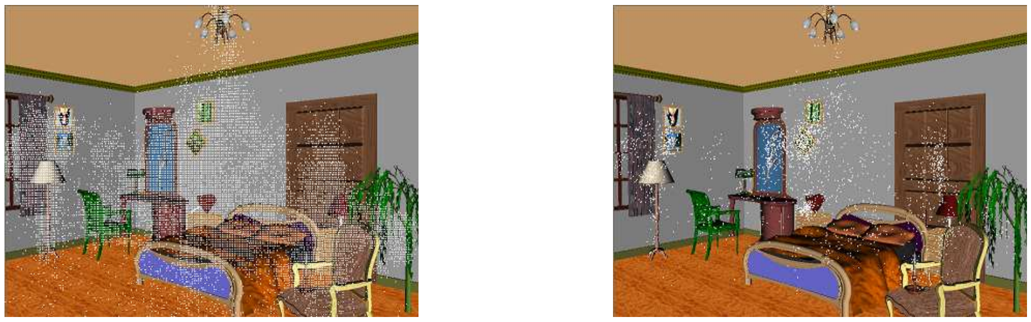
1 Introduction

Interpreting human language is a challenging problem in human machine conversational systems due to the flexibility of human language behavior. When the encountered vocabulary is outside of the system's knowledge, conversational systems tend to fail. It is desirable that conversational systems can learn new words automatically during human machine conversation. While automatic word acquisition in general is quite challenging, multimodal conversational systems offer an unique opportunity to explore word acquisition. In a multimodal conversational system where users can talk and interact with a graphical display, users' eye gaze, which occurs naturally with speech production, provides a potential channel for the system to learn new words automatically during human machine conversation.

Psycholinguistic studies have shown that eye gaze is tightly linked to human language processing. Eye gaze is one of the reliable indicators of what a person is "thinking about" (Henderson and Ferreira, 2004). The direction of eye gaze carries information about the focus of the user's attention (Just and Carpenter, 1976). The perceived visual context influences spoken word recognition and mediates syntactic processing of spoken sentences (Tanenhaus et al., 1995). In addition, directly before speaking a word, the eyes move to the mentioned object (Griffin and Bock, 2000).

Motivated by these psycholinguistic findings, we are investigating the use of eye gaze for automatic word acquisition in multimodal conversation. Particulary, this paper investigates the use of temporal information about speech and eye gaze and domain semantic relatedness for automatic word acquisition. The domain semantic and temporal information are incorporated in statistical translation models for word acquisition. Our experiments show that the use of domain semantic and temporal information significantly improves word acquisition performance.

In the following sections, we first describe the basic translation models for word acquisition. Then, we describe the enhanced models that incorporate temporal and semantic information about speech and eye gaze for word acquisition. Finally, we present the results of empirical evaluation.



(a) Raw gaze points (b) Processed gaze fixations

2 Related Work

Word acquisition by grounding words to visual entities has been studied in many language grounding systems. For example, given speech paired with video images of single objects, mutual information between audio and visual signals was used to acquire words by associating acoustic phone sequences with the visual prototypes (e.g., color, size, shape) of objects (Roy and Pentland, 2002). Generative models were used to acquire words by associating words with image regions given parallel data of pictures and description text (Barnard et al., 2003). Different from these works, in our work, the visual attention foci accompanying speech are indicated by eye gaze. Eye gaze is an implicit and subconscious input, which brings additional challenges in word acquisition.

Eye gaze has been explored for word acquisition in previous work. In (Yu and Ballard, 2004), given speech paired with eye gaze information and video images, a translation model was used to acquire words by associating acoustic phone sequences with visual representations of objects and actions. A recent investigation on word acquisition from transcribed speech and eye gaze in human machine conversation was reported in (Liu et al., 2007). In this work, a translation model was developed to associate words with visual objects on a graphical display. Different from these previous works, here we investigate the incorporation of extra knowledge, specifically speech-gaze temporal information and domain knowledge, with eye gaze to facilitate word acquisition.

3 Data Collection

We recruited users to interact with a simplified multimodal conversational system to collect speech and eye gaze data.

3.1 Domain

We are working on a 3D room decoration domain. Figure 1 shows the 3D room scene that was shown to the user in the experiments. There are 28 3D objects (bed, chairs, paintings, lamp, etc.) in the room scene. During the human machine conversation, the system verbally asked the user a question (e.g., "*what do you dislike about the arrangement of the room*?") or issued a request (e.g., "*describe the left wall*") about the room. The user provided responses by speaking to the system.

During the experiments, users' speech was recorded through an open microphone and users' eye gaze was captured by an Eye Link II eye tracker. Eye gaze data consists of the screen coordinates of each gaze point that was captured by the eye tracker at a sampling rate of 250hz.

3.2 Data Preprocessing

As for speech data, we collected 357 spoken utterances from 7 users' experiments. The vocabulary size is 480, among which 227 words are nouns and adjectives. We manually transcribed the collected speech.

As for gaze data, the first step is to identify gaze fixation from raw gaze points. As shown in Figure 1(a), the collected raw gaze points are very noisy. They can not be used directly for identifying gaze fixated entities in the scene. We processed the raw gaze data to eliminate invalid and saccadic gaze points. Invalid gaze points occur when users look off the screen. Saccadic gaze points occur during ballistic eye movements between gaze fixations. Vision studies have shown that no visual processing occurs in the human mind during saccades (i.e., saccadic suppression) (Matin, 1974). Since eyes do not stay still but rather make small, frequent jerky movements, we average nearby gaze points to better identify gaze fixations. The processed eye gaze fixations are shown in Figure 1(b).

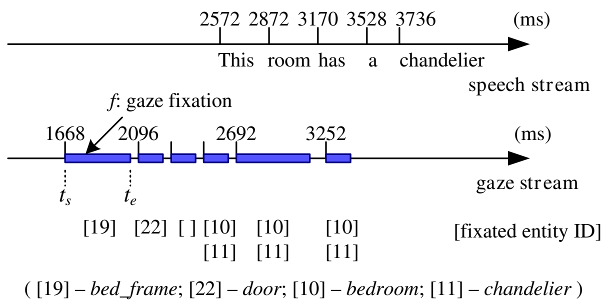

Figure 2: Parallel speech and gaze streams

Figure 2 shows an excerpt of the collected speech and gaze fixation in one experiment. In the speech stream, each word starts at a particular timestamp. In the gaze stream, each gaze fixation has a starting timestamp t_s and an ending timestamp t_e. Each gaze fixation also has a list of fixated entities (3D objects). An entity e on the graphical display is fixated by gaze fixation f if the area of e contains fixation point of f.

Given the collected speech and gaze fixations, we build parallel speech-gaze data set as follows. For each spoken utterance and its accompanying gaze fixations, we construct a pair of word sequence and entity sequence $(\mathbf{w}, \mathbf{e})$. The word sequence $\mathbf{w}$ consists of only nouns and adjectives in the utterance. Each gaze fixation results in a fixated entity in the entity sequence $\mathbf{e}$. When multiple entities are fixated by one gaze fixation due to the overlapping of the entities, the forefront one is chosen. Also, we merge the neighboring gaze fixations that contain the same fixated entities. For the parallel speech and gaze streams shown in Figure 2, the resulting word sequence is $\mathbf{w}$ = [room chandelier] and the entity sequence is $\mathbf{e}$ = [*bed_frame door chandelier*].

4 Translation Models for Automatic Word Acquisition

Since we are working on conversational systems where users interact with a visual scene, we consider the task of word acquisition as associating words with visual entities in the domain. Given the parallel speech and gaze fixated entities $\{(\mathbf{w}, \mathbf{e})\}$, we formulate word acquisition as a translation problem and use translation models to estimate word-entity association probabilities $p(w|e)$. The words with the highest association probabilities are chosen as acquired words for entity e.

4.1 Base Model I

Using the translation model I (Brown et al., 1993), where each word is equally likely to be aligned with each entity, we have

$$p(\mathbf{w}|\mathbf{e}) = \frac{1}{(l+1)^m} \prod_{j=1}^{m} \sum_{i=0}^{l} p(w_j|e_i) \qquad (1)$$

where l and m are the lengths of entity and word sequences respectively. This is the model used in (Liu et al., 2007) and (Yu and Ballard, 2004). We refer to this model as **Model-1** throughout the rest of this paper.

4.2 Base Model II

Using the translation model II (Brown et al., 1993), where alignments are dependent on word/entity positions and word/entity sequence lengths, we have

$$p(\mathbf{w}|\mathbf{e}) = \prod_{j=1}^{m} \sum_{i=0}^{l} p(a_j = i|j, m, l) p(w_j|e_i) \qquad (2)$$

where $a_j = i$ means that w_j is aligned with e_i. When $a_j = 0$, w_j is not aligned with any entity (e_0 represents a *null* entity). We refer to this model as **Model-2**.

Compared to Model-1, Model-2 considers the ordering of words and entities in word acquisition. EM algorithms are used to estimate the probabilities $p(w|e)$ in the translation models.

5 Using Speech-Gaze Temporal Information for Word Acquisition

In Model-2, word-entity alignments are estimated from co-occurring word and entity sequences in an unsupervised way. The estimated alignments are dependent on where the words/entities appear in the word/entity sequences, not on when those words and gaze fixated entities actually occur. Motivated by the finding that users move their eyes to the mentioned object directly before speaking a word (Griffin and Bock, 2000), we make the word-entity alignments dependent on their temporal relation in a new model (referred as **Model-2t**):

$$p(\mathbf{w}|\mathbf{e}) = \prod_{j=1}^{m} \sum_{i=0}^{l} p_t(a_j = i|j, \mathbf{e}, \mathbf{w}) p(w_j|e_i) \quad (3)$$

where $p_t(a_j = i|j, \mathbf{e}, \mathbf{w})$ is the temporal alignment probability computed based on the temporal distance between entity e_i and word w_j.

We define the temporal distance between e_i and w_j as

$$d(e_i, w_j) = \begin{cases} 0 & t_s(e_i) \leq t_s(w_j) \leq t_e(e_i) \\ t_e(e_i) - t_s(w_j) & t_s(w_j) > t_e(e_i) \\ t_s(e_i) - t_s(w_j) & t_s(w_j) < t_s(e_i) \end{cases} \quad (4)$$

where $t_s(w_j)$ is the starting timestamp (ms) of word w_j, $t_s(e_i)$ and $t_e(e_i)$ are the starting and ending timestamps (ms) of gaze fixation on entity e_i.

The alignment of word w_j and entity e_i is decided by their temporal distance $d(e_i, w_j)$. Based on the psycholinguistic finding that eye gaze happens before a spoken word, w_j is not allowed to be aligned with e_i when w_j happens earlier than e_i (i.e., $d(e_i, w_j) > 0$). When w_j happens no earlier than e_i (i.e., $d(e_i, w_j) \leq 0$), the closer they are, the more likely they are aligned. Specifically, the temporal alignment probability of w_j and e_i in each co-occurring instance $(\mathbf{w}, \mathbf{e})$ is computed as

$$p_t(a_j = i|j, \mathbf{e}, \mathbf{w}) = \begin{cases} 0 & d(e_i, w_j) > 0 \\ \frac{\exp[\alpha \cdot d(e_i, w_j)]}{\Sigma_i \exp[\alpha \cdot d(e_i, w_j)]} & d(e_i, w_j) \leq 0 \end{cases} \quad (5)$$

where α is a constant for scaling $d(e_i, w_j)$. In our experiments, α is set to 0.005.

An EM algorithm is used to estimate probabilities $p(w|e)$ in Model-2t.

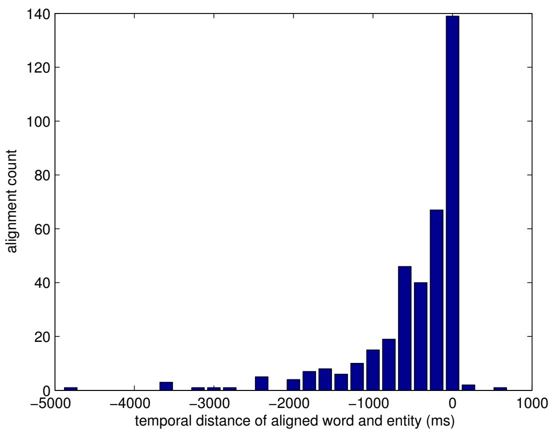

Figure 3: Histogram of truly aligned word and entity pairs over temporal distance (bin width = 200ms)

For the purpose of evaluation, we manually annotated the truly aligned word and entity pairs. Figure 3 shows the histogram of those truly aligned word and entity pairs over the temporal distance of aligned word and entity. We can observe in the figure that 1) almost no eye gaze happens after a spoken word, and 2) the number of word-entity pairs with closer temporal distance is generally larger than the number of those with farther temporal distance. This is consistent with our modeling of the temporal alignment probability of word and entity (Equation (5)).

6 Using Domain Semantic Relatedness for Word Acquisition

Speech-gaze temporal alignment and occurrence statistics sometimes are not sufficient to associate words to an entity correctly. For example, suppose a user says "*there is a lamp on the dresser*" while looking at a lamp object on a table object. Due to their co-occurring with the lamp object, words *dresser* and *lamp* are both likely to be associated with the lamp object in the translation models. As a result, word *dresser* is likely to be incorrectly acquired for the lamp object. For the same reason, the word *lamp* could be acquired incorrectly for the table object. To solve this type of association problem, the semantic knowledge about the domain and words can be helpful. For example, the knowledge that the word *lamp* is more semantically related to the object lamp can help the system avoid associating the word *dresser* to the lamp object. Therefore, we are interested in investigating the use of semantic knowledge in word acquisition.

On one hand, each conversational system has a *domain model*, which is the knowledge representation about its domain such as the types of objects and their properties and relations. On the other hand, there are available resources about domain independent lexical knowledge (e.g., WordNet (Fellbaum, 1998)). The question is whether we can utilize the domain model and external lexical knowledge resource to improve word acquisition. To address this question, we link the domain concepts in the domain model with WordNet concepts, and define semantic relatedness of word and entity to help the system acquire domain semantically compatible words.

In the following sections, we first describe our domain modeling, then define the semantic relatedness of word and entity based on domain modeling and WordNet semantic lexicon, and finally describe different ways of using the semantic relatedness of word and entity to help word acquisition.

6.1 Domain Modeling

We model the 3D room decoration domain as shown in Figure 4. The domain model contains all domain related semantic concepts. These concepts are linked to the WordNet concepts (i.e., synsets in the format of "word#part-of-speech#sense-id"). Each of the entities in the domain has one or more properties (e.g., semantic type, color, size) that are denoted by domain concepts. For example, the entity *dresser_1* has domain concepts *SEM_DRESSER* and *COLOR*. These domain concepts are linked to "dresser#n#4" and "color#n#1" in WordNet.

Note that in the domain model, the domain concepts are not specific to a certain entity, they are general concepts for a certain type of entity. Multiple entities of the same type have the same properties and share the same set of domain concepts.

6.2 Semantic Relatedness of Word and Entity

We compute the semantic relatedness of a word w and an entity e based on the semantic similarity between w and the properties of e. Specifically, semantic relatedness $SR(e, w)$ is defined as

$$SR(e, w) = \max_{i,j} sim(s(c_e^i), s_j(w)) \tag{6}$$

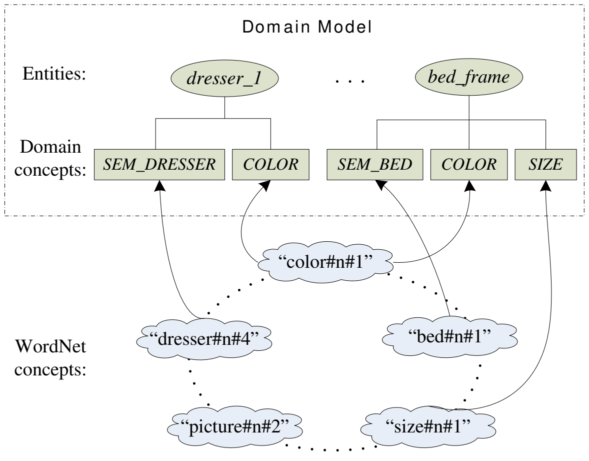

Figure 4: Domain model with domain concepts linked to WordNet synsets

where c_e^i is the i-th property of entity e, $s(c_e^i)$ is the synset of property c_e^i as designed in domain model, $s_j(w)$ is the j-th synset of word w as defined in WordNet, and $sim(\cdot, \cdot)$ is the similarity score of two synsets.

We computed the similarity score of two synsets based on the path length between them. The similarity score is inversely proportional to the number of nodes along the shortest path between the synsets as defined in WordNet. When the two synsets are the same, they have the maximal similarity score of 1. The WordNet-Similarity tool (Pedersen et al., 2004) was used for the synset similarity computation.

6.3 Word Acquisition with Word-Entity Semantic Relatedness

We can use the semantic relatedness of word and entity to help the system acquire semantically compatible words for each entity, and therefore improve word acquisition performance. The semantic relatedness can be applied for word acquisition in two ways: post process learned word-entity association probabilities by rescoring them with semantic relatedness, or directly affect the learning of word-entity associations by constraining the alignment of word and entity in the translation models.

6.3.1 Rescoring with semantic relatedness

In the acquired word list for an entity e_i, each word w_j has an association probability $p(w_j|e_i)$ that is learned from a translation model. We use the semantic relatedness $SR(e_i, w_j)$ to redistribute the probability mass for each w_j. The new association probability is given by:

$$p'(w_j|e_i) = \frac{p(w_j|e_i)SR(e_i, w_j)}{\sum_j p(w_j|e_i)SR(e_i, w_j)} \tag{7}$$

6.3.2 Semantic alignment constraint in translation model

When used to constrain the word-entity alignment in the translation model, semantic relatedness can be used alone or used together with speech-gaze temporal information to decide the alignment probability of word and entity.

- Using only semantic relatedness to constrain word-entity alignments in **Model-2s**, we have

$$p(\mathbf{w}|\mathbf{e}) = \prod_{j=1}^{m} \sum_{i=0}^{l} p_s(a_j = i|j, \mathbf{e}, \mathbf{w}) p(w_j|e_i) \tag{8}$$

  where $p_s(a_j = i|j, \mathbf{e}, \mathbf{w})$ is the alignment probability based on semantic relatedness,

$$p_s(a_j = i|j, \mathbf{e}, \mathbf{w}) = \frac{SR(e_i, w_j)}{\sum_i SR(e_i, w_j)} \tag{9}$$

- Using semantic relatedness and temporal information to constrain word-entity alignments in **Model-2ts**, we have

$$p(\mathbf{w}|\mathbf{e}) = \prod_{j=1}^{m} \sum_{i=0}^{l} p_{ts}(a_j = i|j, \mathbf{e}, \mathbf{w}) p(w_j|e_i) \tag{10}$$

  where $p_{ts}(a_j = i|j, \mathbf{e}, \mathbf{w})$ is the alignment probability that is decided by both temporal relation and semantic relatedness of e_i and w_j,

$$p_{ts}(a_j = i|j, \mathbf{e}, \mathbf{w}) = \frac{p_s(a_j = i|j, \mathbf{e}, \mathbf{w}) p_t(a_j = i|j, \mathbf{e}, \mathbf{w})}{\sum_i p_s(a_j = i|j, \mathbf{e}, \mathbf{w}) p_t(a_j = i|j, \mathbf{e}, \mathbf{w})} \tag{11}$$

  where $p_s(a_j = i|j, \mathbf{e}, \mathbf{w})$ is the semantic alignment probability in Equation (9), and $p_t(a_j = i|j, \mathbf{e}, \mathbf{w})$ is the temporal alignment probability given in Equation (5).

EM algorithms are used to estimate $p(w|e)$ in Model-2s and Model-2ts.

7 Grounding Words to Domain Concepts

As discussed above, based on translation models, we can incorporate temporal and domain semantic information to obtain $p(w|e)$. This probability only provides a means to ground words to entities. In conversational systems, the ultimate goal of word acquisition is to make the system understand the semantic meaning of new words. Word acquisition by grounding words to objects is not always sufficient for identifying their semantic meanings. Suppose the word *green* is grounded to a green chair object, so is the word *chair*. Although the system is aware that *green* is some word describing the green chair, it does not know that word *green* refers to the chair's color while the word *chair* refers to the chair's semantic type. Thus, after learning the word-entity associations $p(w|e)$ by the translation models, we need to further ground words to domain concepts of entity properties.

We further apply WordNet to ground words to domain concepts. For each entity e, based on association probabilities $p(w|e)$, we can choose the n-best words as acquired words for e. Those n-best words have the n highest association probabilities. For each word w acquired for e, the grounded concept c_e^* for w is chosen as the one that has the highest semantic relatedness with w:

$$c_e^* = \arg\max_i \big[\max_j sim(s(c_e^i), s_j(w))\big] \tag{12}$$

where $sim(s(c_e^i), s_j(w))$ is the semantic similarity score defined in Equation (6).

8 Evaluation

We evaluate word acquisition performance of different models on the data collected from our user studies (see Section 3).

8.1 Evaluation Metrics

The following metrics are used to evaluate the words acquired for domain concepts (i.e., entity properties) $\{c_e^i\}$.

- Precision

$$\frac{\sum_e \sum_i \text{\# words correctly acquired for } c_e^i}{\sum_e \sum_i \text{\# words acquired for } c_e^i}$$

- Recall

$$\frac{\sum_e \sum_i \text{\# words correctly acquired for } c_e^i}{\sum_e \sum_i \text{\# ground-truth}^1 \text{ words of } c_e^i}$$

- F-measure

$$\frac{2 \times precision \times recall}{precision + recall}$$

The metrics of precision, recall, and F-measure are based on the n-best words acquired for the entity properties. Therefore, we have different precision, recall, and F-measure when n changes.

The metrics of precision, recall, and F-measure only provide evaluation on the top n candidate words. To measure the acquisition performance on the entire ranked list of candidate words, we define a new metric as follows:

- Mean Reciprocal Rank Rate (MRRR)

$$\text{MRRR} = \frac{\sum_e \frac{\sum_{i=1}^{N_e} \frac{1}{index(w_e^i)}}{\sum_{i=1}^{N_e} \frac{1}{i}}}{\#e}$$

  where N_e is the number of all ground-truth words $\{w_e^i\}$ for entity e, $index(w_e^i)$ is the index of word w_e^i in the ranked list of candidate words for entity e.

Entities may have a different number of ground-truth words. For each entity e, we calculate a Reciprocal Rank Rate (RRR), which measures how close the ranks of the ground-truth words in the candidate word list is to the best scenario where the top N_e words are the ground-truth words for e. RRR is in the range of $(0, 1]$. The higher the RRR, the better is the word acquisition performance. The average of RRRs across all entities gives the Mean Reciprocal Rank Rate (MRRR).

Note that MRRR is directly based on the learned word-entity associations $p(w|e)$, it is in fact a measure of grounding words to entities.

[1]The ground-truth words were compiled and agreed upon by two human judges.

8.2 Evaluation Results

To compare the effects of different speech-gaze alignments on word acquisition, we evaluate the following models:

- Model-1 – base model I without word-entity alignment (Equation (1)).
- Model-2 – base model II with positional alignment (Equation (2)).
- Model-2t – enhanced model with temporal alignment (Equation (3)).
- Model-2s – enhanced model with semantic alignment (Equation (8)).
- Model-2ts – enhanced model with both temporal and semantic alignment (Equation (10)).

To compare the different ways of incorporating semantic relatedness in word acquisition as discussed in Section 6.3.1, we also evaluate the following models:

- Model-1-r – Model-1 with semantic relatedness rescoring of word-entity association.
- Model-2t-r – Model-2t with semantic relatedness rescoring of word-entity association.

Figure 5 shows the results of models with different speech-gaze alignments. Figure 6 shows the results of models with semantic relatedness rescoring. In Figure 5 & 6, *n-best* means the top *n* word candidates are chosen as acquired words for each entity. The Mean Reciprocal Rank Rates of all models are compared in Figure 7.

8.2.1 Results of using different speech-gaze alignments

As shown in Figure 5, Model-2 does not show a consistent improvement compared to Model-1 when a different number of n-best words are chosen as acquired words. This result shows that it is not very helpful to consider the index-based positional alignment of word and entity for word acquisition.

Figure 5 also shows that models considering temporal or/and semantic information (Model-2t, Model-2s, Model-2ts) consistently perform better than the models considering neither temporal nor

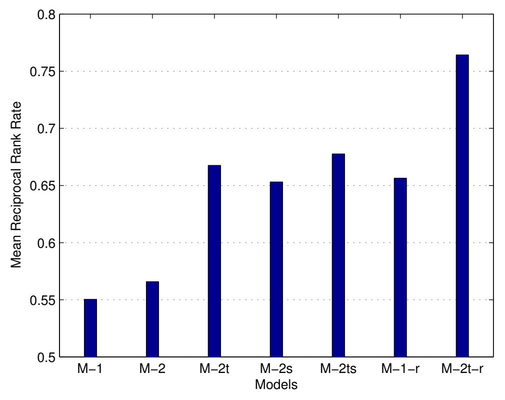

Figure 7: MRRRs achieved by different models

semantic information (Model-1, Model-2). Among Model-2t, Model-2s, and Model-2ts, it is found that they do not make consistent differences.

As shown in Figure 7, the MRRRs of different models are consistent with their performances on F-measure. A t-test has shown that the difference between the MRRRs of Model-1 and Model-2 is not statistically significant. Compared to Model-1, t-tests have confirmed that MRRR is significantly improved by Model-2t ($t = 2.27, p < 0.02$), Model-2s ($t = 3.40, p < 0.01$), and Model-2ts($t = 2.60, p < 0.01$). T-tests have shown no significant differences among Model-2t, Model-2s, and Model-2ts.

8.2.2 Results of applying semantic relatedness rescoring

Figure 6 shows that semantic relatedness rescoring improves word acquisition. After semantic relatedness rescoring of the word-entity associations learned by Model-1, Model-1-r improves the F-measure consistently when a different number of n-best words are chosen as acquired words. Compared to Model-2t, Model-2t-r also improves the F-measure consistently.

Comparing the two ways of using semantic relatedness for word acquisition, it is found that rescoring word-entity association with semantic relatedness works better. When semantic relatedness is used together with temporal information to constrain word-entity alignments in Model-2ts, word acqui-

Model	Rank 1	Rank 2	Rank 3	Rank 4	Rank 5
M-1	**table**(0.173)	**dresser**(0.067)	area(0.058)	picture(0.053)	dressing(0.041)
M-2t	**table**(0.146)	**dresser**(0.125)	dressing(0.061)	**vanity**(0.051)	fact(0.050)
M-2t-r	**table**(0.312)	**dresser**(0.241)	**vanity**(0.149)	**desk**(0.047)	area(0.026)

Table 1: N-best candidate words acquired for the entity *dresser_1* by different models

sition performance is not improved compared to Model-2t. However, using semantic relatedness to rescore word-entity association learned by Model-2t, Model-2t-r further improves word acquisition.

As shown in Figure 7, the MRRRs of Model-1-r and Model-2t-r are consistent with their performances on F-measure. Compared to Model-2t, Model-2t-r improves MRRR. A t-test has confirmed that this is a significant improvement ($t = 1.97, p < 0.03$). Compared to Model-1, Model-1-r significantly improves MRRR ($t = 2.33, p < 0.02$). There is no significant difference between Model-1-r and Model-2t/Model-2s/Model-2ts.

In Figures 5&6, we also notice that the recall of the acquired words is still comparably low even when 10 best word candidates are chosen for each entity. This is mainly due to the scarcity of those words that are not acquired in the data. Many of the words that are not acquired appear less than 3 times in the data, which makes them unlikely to be associated with any entity by the translation models. When more data is available, we expect to see higher recall.

8.3 An Example

Table 1 shows the 5-best words acquired by different models for the entity *dresser_1* in the 3d room scene (see Figure 1). In the table, each word is followed by its word-entity association probability $p(w|e)$. The correctly acquired words are shown in bold font.

As shown in the example, the baseline Model-1 learned 2 correct words in the 5-best list. Considering speech-gaze temporal information, Model-2t learned one more correct word *vanity* in the 5-best list. With semantic relatedness rescoring, Model-2t-r further acquired word *desk* in the 5-best list because of the high semantic relatedness of word *desk* and the type of entity *dresser_1*. Although neither Model-1 nor Model-2t successfully acquired the word *desk* in the 5-best list, the rank (=7) of the word *desk* in Model-2t's n-best list is much higher than the rank (=21) in Model-1's n-best list.

9 Conclusion

Motivated by the psycholinguistic findings, we investigate the use of eye gaze for automatic word acquisition in multimodal conversational systems. Particularly, we investigate the use of speech-gaze temporal information and word-entity semantic relatedness to facilitate word acquisition. Our experiments show that word acquisition is significantly improved when temporal information is considered, which is consistent with the previous psycholinguistic findings about speech and eye gaze. Moreover, using temporal information together with semantic relatedness rescoring further improves word acquisition.

Eye tracking systems are no longer bulky systems that prevent natural human machine communication. Display mounted gaze tracking systems (e.g., Tobii) are completely non-intrusive, can tolerate head motion, and provide high tracking quality. Integrating eye tracking with conversational interfaces is no longer beyond reach. Recent works have shown that eye gaze can facilitate spoken language processing in conversational systems (Qu and Chai, 2007; Prasov and Chai, 2008). Incorporating eye gaze with automatic word acquisition provides another potential approach to improve the robustness of human machine conversation.

Abstract

Human linguistic annotation is crucial for many natural language processing tasks but can be expensive and time-consuming. We explore the use of Amazon's Mechanical Turk system, a significantly cheaper and faster method for collecting annotations from a broad base of paid non-expert contributors over the Web. We investigate five tasks: affect recognition, word similarity, recognizing textual entailment, event temporal ordering, and word sense disambiguation. For all five, we show high agreement between Mechanical Turk non-expert annotations and existing gold standard labels provided by expert labelers. For the task of affect recognition, we also show that using non-expert labels for training machine learning algorithms can be as effective as using gold standard annotations from experts. We propose a technique for bias correction that significantly improves annotation quality on two tasks. We conclude that many large labeling tasks can be effectively designed and carried out in this method at a fraction of the usual expense.

1 Introduction

Large scale annotation projects such as TreeBank (Marcus et al., 1993), PropBank (Palmer et al., 2005), TimeBank (Pustejovsky et al., 2003), FrameNet (Baker et al., 1998), SemCor (Miller et al., 1993), and others play an important role in natural language processing research, encouraging the development of novel ideas, tasks, and algorithms. The construction of these datasets, however, is extremely expensive in both annotator-hours and financial cost. Since the performance of many natural language processing tasks is limited by the amount and quality of data available to them (Banko and Brill, 2001), one promising alternative for some tasks is the collection of non-expert annotations.

In this work we explore the use of Amazon Mechanical Turk[1] (AMT) to determine whether non-expert labelers can provide reliable natural language annotations. We chose five natural language understanding tasks that we felt would be sufficiently natural and learnable for non-experts, and for which we had gold standard labels from expert labelers, as well as (in some cases) expert labeler agreement information. The tasks are: affect recognition, word similarity, recognizing textual entailment, event temporal ordering, and word sense disambiguation. For each task, we used AMT to annotate data and measured the quality of the annotations by comparing them with the gold standard (expert) labels on the same data. Further, we compare machine learning classifiers trained on expert annotations vs. non-expert annotations.

In the next sections of the paper we introduce the five tasks and the evaluation metrics, and offer methodological insights, including a technique for bias correction that improves annotation quality.[2]

2 Related Work

The idea of collecting annotations from volunteer contributors has been used for a variety of tasks. Luis von Ahn pioneered the collection of data via online annotation tasks in the form of games, including the ESPGame for labeling images (von Ahn and Dabbish, 2004) and Verbosity for annotating word relations (von Ahn et al., 2006). The Open Mind Initiative (Stork, 1999) has taken a similar approach, attempting to make such tasks as annotating word sense (Chklovski and Mihalcea, 2002) and commonsense word relations (Singh, 2002) sufficiently "easy and fun" to entice users into freely labeling data.

There have been an increasing number of experiments using Mechanical Turk for annotation. In (Su et al., 2007) workers provided annotations for the tasks of hotel name entity resolution and attribute extraction of age, product brand, and product model, and were found to have high accuracy compared to gold-standard labels. Kittur et al. (2008) compared AMT evaluations of Wikipedia article quality against experts, finding validation tests were important to ensure good results. Zaenen (Submitted) studied the agreement of annotators on the problem of recognizing textual entailment (a similar task and dataset is explained in more detail in Section 4).

At least several studies have already used AMT without external gold standard comparisons. In (Nakov, 2008) workers generated paraphrases of 250 noun-noun compounds which were then used as the gold standard dataset for evaluating an automatic method of noun compound paraphrasing. Kaisser and Lowe (2008) use AMT to help build a dataset for question answering, annotating the answers to 8107 questions with the *sentence* containing the answer. Kaisser et al. (2008) examines the task of customizing the summary length of QA output; non-experts from AMT chose a summary length that suited their information needs for varying query types. Dakka and Ipeirotis (2008) evaluate a document facet generation system against AMT-supplied facets, and also use workers for user studies of the system. Sorokin and Forsyth (2008) collect data for machine vision tasks and report speed and costs similar to our findings; their summaries of worker behavior also corroborate with what we have found.

In general, volunteer-supplied or AMT-supplied data is more plentiful but noisier than expert data. It is powerful because independent annotations can be aggregated to achieve high reliability. Sheng et al. (2008) explore several methods for using many noisy labels to create labeled data, how to choose which examples should get more labels, and how to include labels' uncertainty information when training classifiers. Since we focus on empirically validating AMT as a data source, we tend to stick to simple aggregation methods.

3 Task Design

In this section we describe Amazon Mechanical Turk and the general design of our experiments.

3.1 Amazon Mechanical Turk

We employ the Amazon Mechanical Turk system in order to elicit annotations from non-expert labelers. AMT is an online labor market where workers are paid small amounts of money to complete small tasks. The design of the system is as follows: one is required to have an Amazon account to either submit tasks for annotations or to annotate submitted tasks. These Amazon accounts are anonymous, but are referenced by a unique Amazon ID. A *Requester* can create a *group* of *Human Intelligence Tasks* (or *HIT*s), each of which is a form composed of an arbitrary number of questions. The user requesting annotations for the group of HITs can specify the number of unique annotations per HIT they are willing to pay for, as well as the reward payment for each individual HIT. While this does not guarantee that unique people will annotate the task (since a single person could conceivably annotate tasks using multiple accounts, in violation of the user agreement), this does guarantee that annotations will be collected from unique accounts. AMT also allows a requester to restrict which workers are allowed to annotate a task by requiring that all workers have a particular set of qualifications, such as sufficient accuracy on a small test set or a minimum percentage of previously accepted submissions. Annotators (variously referred to as *Workers* or *Turkers*) may then annotate the tasks of their choosing. Finally, after each HIT has been annotated, the Requester has the option of approving the work and optionally giving a bonus to individual workers. There is a two-way communication channel between the task designer and the workers mediated by Amazon, and Amazon handles all financial transactions.

3.2 Task Design

In general we follow a few simple design principles: we attempt to keep our task descriptions as succinct as possible, and we attempt to give demonstrative examples for each class wherever possible. We have published the full experimental design and the data we have collected for each task online[3]. We have restricted our study to tasks where we require only a multiple-choice response or numeric input within a fixed range. For every task we collect ten independent annotations for each unique item; this redundancy allows us to perform an in-depth study of how data quality improves with the number of independent annotations.

4 Annotation Tasks

We analyze the quality of non-expert annotations on five tasks: affect recognition, word similarity, recognizing textual entailment, temporal event recognition, and word sense disambiguation. In this section we define each annotation task and the parameters of the annotations we request using AMT. Additionally we give an initial analysis of the task results, and summarize the cost of the experiments.

4.1 Affective Text Analysis

This experiment is based on the affective text annotation task proposed in Strapparava and Mihalcea (2007), wherein each annotator is presented with a list of short headlines, and is asked to give numeric judgments in the interval [0,100] rating the headline for six emotions: anger, disgust, fear, joy, sadness, and surprise, and a single numeric rating in the interval [-100,100] to denote the overall positive or negative *valence* of the emotional content of the headline, as in this sample headline-annotation pair:

Outcry at N Korea 'nuclear test'

$(Anger, 30), (Disgust,30), (Fear,30), (Joy,0),$
$(Sadness,20), (Surprise,40), (Valence,-50).$

[3]All tasks and collected data are available at `http://ai.stanford.edu/~rion/annotations/`.

For our experiment we select a 100-headline sample from the original SemEval test set, and collect 10 affect annotations for each of the seven label types, for a total of 7000 affect labels.

We then performed two comparisons to evaluate the quality of the AMT annotations. First, we asked how well the non-experts agreed with the experts. We did this by comparing the interannotator agreement (ITA) of individual expert annotations to that of single non-expert and averaged non-expert annotations. In the original experiment ITA is measured by calculating the Pearson correlation of one annotator's labels with the average of the labels of the other five annotators. For each expert labeler, we computed this ITA score of the expert against the other five; we then average these ITA scores across all expert annotators to compute the average expert ITA (reported in Table 1 as "E vs. E". We then do the same for individual non-expert annotations, averaging Pearson correlation across all sets of the five expert labelers ("NE vs. E"). We then calculate the ITA for each expert vs. the averaged labels from all other experts and non-experts (marked as "E vs. All") and for each non-expert vs. the pool of other non-experts and all experts ("NE vs. All"). We compute these ITA scores for each emotion task separately, averaging the six emotion tasks as "Avg. Emo" and the average of all tasks as "Avg. All".

Emotion	E vs. E	E vs. All	NE vs. E	NE vs. All
Anger	0.459	0.503	0.444	0.573
Disgust	0.583	0.594	0.537	0.647
Fear	0.711	0.683	0.418	0.498
Joy	0.596	0.585	0.340	0.421
Sadness	0.645	0.650	0.563	0.651
Surprise	0.464	0.463	0.201	0.225
Valence	0.759	0.767	0.530	0.554
Avg. Emo	0.576	0.603	0.417	0.503
Avg. All	0.580	0.607	0.433	0.510

Table 1: Average expert and non-expert ITA on test-set

The results in Table 1 conform to the expectation that experts are better labelers: experts agree with experts more than non-experts agree with experts, although the ITAs are in many cases quite close. But we also found that adding non-experts to the gold standard ("E vs. All") improves agreement, suggesting that non-expert annotations are good enough to increase the overall quality of the gold labels. Our first comparison showed that individual experts were better than individual non-experts. In our next comparison we ask how many averaged non-experts it would take to rival the performance of a single expert. We did this by averaging the labels of each possible subset of n non-expert annotations, for value of n in $\{1, 2, \ldots, 10\}$. We then treat this average as though it is the output of a single 'meta-labeler', and compute the ITA with respect to each subset of five of the six expert annotators. We then average the results of these studies across each subset size; the results of this experiment are given in Table 2 and in Figure 1. In addition to the single meta-labeler, we ask: what is the minimum number of non-expert annotations k from which we can create a meta-labeler that has equal or better ITA than an expert annotator? In Table 2 we give the minimum k for each emotion, and the averaged ITA for that meta-labeler consisting of k non-experts (marked "k-NE"). In Figure 1 we plot the expert ITA correlation as the horizontal dashed line.

Emotion	1-Expert	10-NE	k	k-NE
Anger	0.459	0.675	2	0.536
Disgust	0.583	0.746	2	0.627
Fear	0.711	0.689	–	–
Joy	0.596	0.632	7	0.600
Sadness	0.645	0.776	2	0.656
Surprise	0.464	0.496	9	0.481
Valence	0.759	0.844	5	0.803
Avg. Emo.	0.576	0.669	4	0.589
Avg. All	0.603	0.694	4	0.613

Table 2: Average expert and averaged correlation over 10 non-experts on test-set. k is the minimum number of non-experts needed to beat an average expert.

These results show that for all tasks except "Fear" we are able to achieve expert-level ITA with the held-out set of experts within 9 labelers, and frequently within only 2 labelers. Pooling judgments across all 7 tasks we find that on average it requires only 4 non-expert annotations per example to achieve the equivalent ITA as a single expert annotator. Given that we paid US\$2.00 in order to collect the 7000 non-expert annotations, we may interpret our rate of 3500 non-expert labels per USD as at least 875 expert-equivalent labels per USD.

4.2 Word Similarity

This task replicates the word similarity task used in (Miller and Charles, 1991), following a previous

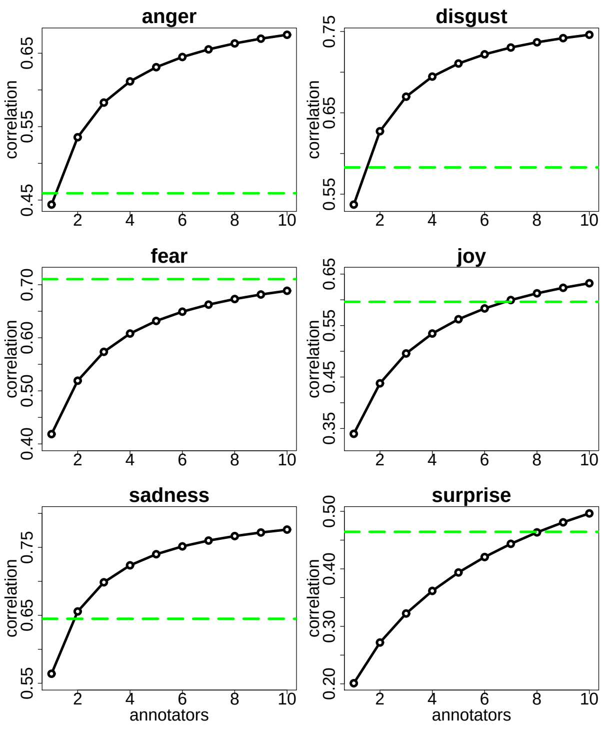

Figure 1: Non-expert correlation for affect recognition

task initially proposed by (Rubenstein and Goodenough, 1965). Specifically, we ask for numeric judgments of word similarity for 30 word pairs on a scale of [0,10], allowing fractional responses[4]. These word pairs range from highly similar (e.g., {*boy, lad*}), to unrelated (e.g., {*noon, string*}). Numerous expert and non-expert studies have shown that this task typically yields very high interannotator agreement as measured by Pearson correlation; (Miller and Charles, 1991) found a 0.97 correlation of the annotations of 38 subjects with the annotations given by 51 subjects in (Rubenstein and Goodenough, 1965), and a following study (Resnik, 1999) with 10 subjects found a 0.958 correlation with (Miller and Charles, 1991).

In our experiment we ask for 10 annotations each of the full 30 word pairs, at an offered price of \$0.02 for each set of 30 annotations (or, equivalently, at the rate of 1500 annotations per USD). The most surprising aspect of this study was the speed with which it was completed; the task of 300 annotations was completed by 10 annotators in less than 11 min-

[4](Miller and Charles, 1991) and others originally used a numerical score of [0,4].

utes from the time of submission of our task to AMT, at the rate of 1724 annotations / hour.

As in the previous task we evaluate our non-expert annotations by averaging the numeric responses from each possible subset of n annotators and computing the interannotator agreement with respect to the gold scores reported in (Miller and Charles, 1991). Our results are displayed in Figure 2, with Resnik's 0.958 correlation plotted as the horizontal line; we find that at 10 annotators we achieve a correlation of 0.952, well within the range of other studies of expert and non-expert annotations.

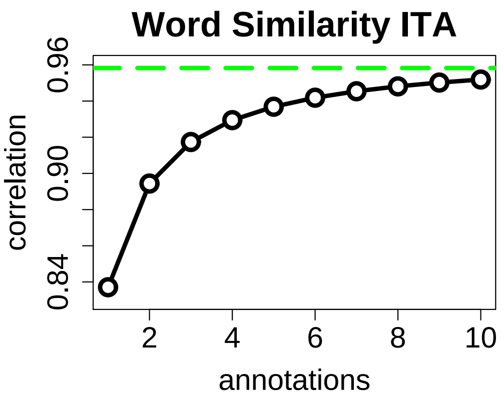

Figure 2: ITA for word similarity experiment

4.3 Recognizing Textual Entailment

This task replicates the recognizing textual entailment task originally proposed in the PASCAL Recognizing Textual Entailment task (Dagan et al., 2006); here for each question the annotator is presented with two sentences and given a binary choice of whether the second *hypothesis* sentence can be inferred from the first. For example, the hypothesis sentence "*Oil prices drop*" would constitute a *true entailment* from the text "*Crude Oil Prices Slump*", but a *false entailment* from "*The government announced last week that it plans to raise oil prices*".

We gather 10 annotations each for all 800 sentence pairs in the PASCAL RTE-1 dataset. For this dataset expert interannotator agreement studies have been reported as achieving 91% and 96% agreement over various subsections of the corpus. When considering multiple non-expert annotations for a sentence pair we use simple majority voting, breaking ties randomly and averaging performance over all possible ways to break ties. We collect 10 annotations for each of 100 RTE sentence pairs; as displayed in Figure 3, we achieve a maximum accuracy of 89.7%, averaging over the annotations of 10 workers[5].

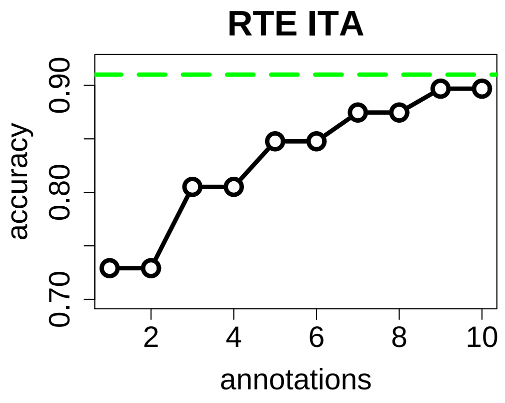

Figure 3: Inter-annotator agreement for RTE experiment

4.4 Event Annotation

This task is inspired by the TimeBank corpus (Pustejovsky et al., 2003), which includes among its annotations a label for event-pairs that represents the temporal relation between them, from a set of fourteen relations (*before*, *after*, *during*, *includes*, etc.). We implement *temporal ordering* as a simplified version of the TimeBank event temporal annotation task: rather than annotating all fourteen event types, we restrict our consideration to the two simplest labels: "strictly before" and "strictly after". Furthermore, rather than marking both nouns and verbs in the text as possible events, we only consider possible verb events. We extract the 462 verb event pairs labeled as "strictly before" or "strictly after" in the TimeBank corpus, and we present these pairs to annotators with a forced binary choice on whether the event described by the first verb occurs *before* or *after* the second. For example, in a dialogue about a plane explosion, we have the utterance: "*It just blew up in the air, and then we saw two fireballs go down to the,*

[5]It might seem pointless to consider an even number of annotations in this circumstance, since the majority voting mechanism and tie-breaking yields identical performance for $2n + 1$ and $2n + 2$ annotators; however, in Section 5 we will consider methods that can make use of the even annotations.

to the water, and there was a big small, ah, smoke, from ah, coming up from that". Here for each annotation we highlight the specific verb pair of interest (e.g., *go*/*coming*, or *blew*/*saw*) and ask which event occurs first (here, *go* and *blew*, respectively).

The results of this task are presented in Figure 4. We achieve high agreement for this task, at a rate of 0.94 with simple voting over 10 annotators (4620 total annotations). While an expert ITA of 0.77 was reported for the more general task involving all fourteen labels on both noun and verb events, no expert ITA numbers have been reported for this simplified temporal ordering task.

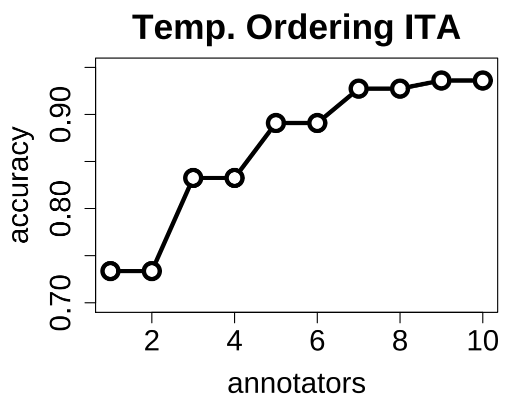

Figure 4: ITA for temporal ordering experiment

4.5 Word Sense Disambiguation

In this task we consider a simple problem on which machine learning algorithms have been shown to produce extremely good results; here we annotate part of the SemEval Word Sense Disambiguation Lexical Sample task (Pradhan et al., 2007); specifically, we present the labeler with a paragraph of text containing the word "president" (e.g., a paragraph containing "*Robert E. Lyons III...was appointed president and chief operating officer...*") and ask the labeler which one of the following three sense labels is most appropriate:

1) *executive officer of a firm, corporation, or university*
2) *head of a country (other than the U.S.)*
3) *head of the U.S., President of the United States*

We collect 10 annotations for each of 177 examples of the noun "president" for the three senses given in SemEval. As shown in Figure 5, performing simple majority voting (with random tie-breaking) over annotators results in a rapid accuracy plateau at a very high rate of 0.994 accuracy. In fact, further analysis reveals that there was only a single disagreement between the averaged non-expert vote and the gold standard; on inspection it was observed that the annotators voted strongly against the original gold label (9-to-1 against), and that it was in fact found to be an error in the original gold standard annotation.[6] After correcting this error, the non-expert accuracy rate is 100% on the 177 examples in this task. This is a specific example where non-expert annotations can be used to correct expert annotations.

Since expert ITA was not reported per word on this dataset, we compare instead to the performance of the best automatic system performance for disambiguating "president" in SemEval Task 17 (Cai et al., 2007), with an accuracy of 0.98.

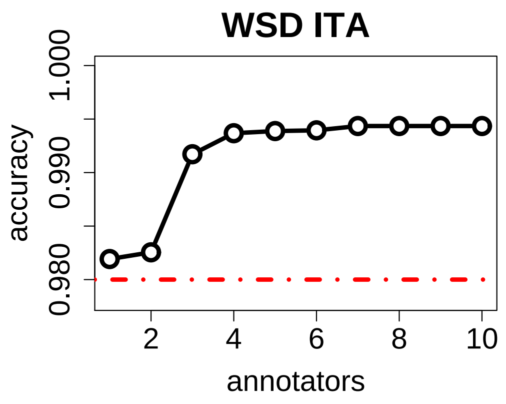

Figure 5: Inter-annotator agreement for WSD experiment

4.6 Summary

Task	Labels	Cost (USD)	Time (hrs)	Labels per USD	Labels per hr
Affect	7000	$2.00	5.93	3500	1180.4
WSim	300	$0.20	0.174	1500	1724.1
RTE	8000	$8.00	89.3	1000	89.59
Event	4620	$13.86	39.9	333.3	115.85
WSD	1770	$1.76	8.59	1005.7	206.1
Total	21690	25.82	143.9	840.0	150.7

Table 3: Summary of costs for non-expert labels

[6]The example sentence began "*The Egyptian president said he would visit Libya today...*" and was mistakenly marked as the "head of a company" sense in the gold annotation (example id 24:0@24@wsj/23/wsj_2381@wsj@en@on).

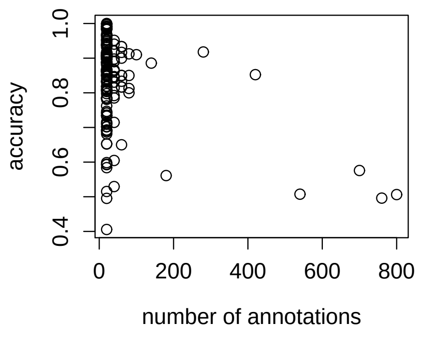

Figure 6: Worker accuracies on the RTE task. Each point is one worker. Vertical jitter has been added to points on the left to show the large number of workers who did the minimum amount of work (20 examples).

In Table 3 we give a summary of the costs associated with obtaining the non-expert annotations for each of our 5 tasks. Here *Time* is given as the total amount of time in hours elapsed from submitting the group of HITs to AMT until the last assignment is submitted by the last worker.

5 Bias correction for non-expert annotators

The reliability of individual workers varies. Some are very accurate, while others are more careless and make mistakes; and a small few give very noisy responses. Furthermore, for most AMT data collection experiments, a relatively small number of workers do a large portion of the task, since workers may do as much or as little as they please. Figure 6 shows accuracy rates for individual workers on one task. Both the overall variability, as well as the prospect of identifying high-volume but low-quality workers, suggest that controlling for individual worker quality could yield higher quality overall judgments.

In general, there are at least three ways to enhance quality in the face of worker error. More workers can be used, as described in previous sections. Another method is to use Amazon's compensation mechanisms to give monetary bonuses to highly-performing workers and deny payments to unreliable ones; this is useful, but beyond the scope of this paper. In this section we explore a third alternative, to model the reliability and biases of individual workers and correct for them.

A wide number of methods have been explored to correct for the bias of annotators. Dawid and Skene (1979) are the first to consider the case of having multiple annotators per example but unknown true labels. They introduce an EM algorithm to simultaneously estimate annotator biases and latent label classes. Wiebe et al. (1999) analyze linguistic annotator agreement statistics to find bias, and use a similar model to correct labels. A large literature in biostatistics addresses this same problem for medical diagnosis. Albert and Dodd (2004) review several related models, but argue they have various shortcomings and emphasize instead the importance of having a gold standard.

Here we take an approach based on gold standard labels, using a small amount of expert-labeled training data in order to correct for the individual biases of different non-expert annotators. The idea is to recalibrate worker's responses to more closely match expert behavior. We focus on categorical examples, though a similar method can be used with numeric data.

5.1 Bias correction in categorical data

Following Dawid and Skene, we model labels and workers with a multinomial model similar to Naive Bayes. Every example i has a true label x_i. For simplicity, assume two labels $\{Y, N\}$. Several different workers give labels $y_{i1}, y_{i2}, \dots y_{iW}$. A worker's conditional probability of response is modeled as multinomial, and we model each worker's judgment as conditionally independent of other workers given the true label x_i, i.e.:

$$P(y_{i1}, \dots, y_{iW}, x_i) = \left(\prod_w P(y_{iw}|x_i) \right) p(x_i)$$

To infer the posterior probability of the true label for a new example, worker judgments are integrated via Bayes rule, yielding the posterior log-odds:

$$\begin{aligned} & \log \frac{P(x_i = Y|y_{i1} \dots y_{iW})}{P(x_i = N|y_{i1} \dots y_{iW})} \\ = \quad & \sum_w \log \frac{P(y_{iw}|x_i = Y)}{P(y_{iw}|x_i = N)} + \log \frac{P(x_i = Y)}{P(x_i = N)} \end{aligned}$$

The worker response likelihoods $P(y_w|x = Y)$ and $P(y_w|x = N)$ can be directly estimated from frequencies of worker performance on gold standard examples. (If we used maximum likelihood estimation with no Laplace smoothing, then each $y_w|x$ is just the worker's empirical confusion matrix.) For MAP label estimation, the above equation describes a weighted voting rule: each worker's vote is weighted by their log likelihood ratio for their given response. Intuitively, workers who are more than 50% accurate have positive votes; workers whose judgments are pure noise have zero votes; and anticorrelated workers have negative votes. (A simpler form of the model only considers accuracy rates, thus weighting worker votes by $\log \frac{\text{acc}_w}{1-\text{acc}_w}$. But we use the full unconstrained multinomial model here.)

5.1.1 Example tasks: RTE-1 and event annotation

We used this model to improve accuracy on the RTE-1 and event annotation tasks. (The other categorical task, word sense disambiguation, could not be improved because it already had maximum accuracy.) First we took a sample of annotations giving k responses per example. Within this sample, we trained and tested via 20-fold cross-validation across examples. Worker models were fit using Laplace smoothing of 1 pseudocount; label priors were uniform, which was reasonably similar to the empirical distribution for both tasks.

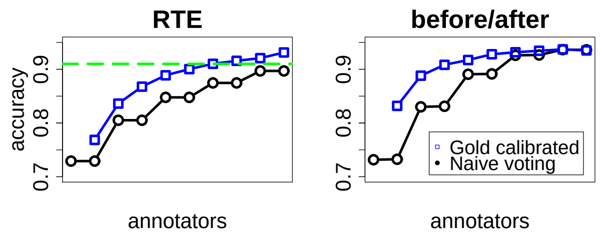

Figure 7: Gold-calibrated labels versus raw labels

Figure 7 shows improved accuracy at different numbers of annotators. The lowest line is for the naive 50% majority voting rule. (This is equivalent to the model under uniform priors and equal accuracies across workers and labels.) Each point is the data set's accuracy against the gold labels, averaged across resamplings each of which obtains k annotations per example. RTE has an average +4.0% accuracy increase, averaged across 2 through 10 annotators. We find a +3.4% gain on event annotation. Finally, we experimented with a similar calibration method for numeric data, using a Gaussian noise model for each worker: $y_w|x \sim N(x + \mu_w, \sigma_w)$. On the affect task, this yielded a small but consistent increases in Pearson correlation at all numbers of annotators, averaging a +0.6% gain.

6 Training a system with non-expert annotations

In this section we train a supervised affect recognition system with expert vs. non-expert annotations.

6.1 Experimental Design

For the purpose of this experiment we create a simple bag-of-words unigram model for predicting affect and valence, similar to the SWAT system (Katz et al., 2007), one of the top-performing systems on the SemEval Affective Text task.[7] For each token t in our training set, we assign t a weight for each emotion e equal to the average emotion score observed in each headline H that t participates in. i.e., if $\mathbf{H}_t$ is the set of headlines containing the token t, then:

$$Score(e,t) = \frac{\sum_{H \in \mathbf{H}_t} Score(e,H)}{|\mathbf{H}_t|}$$

With these weights of the individual tokens we may then compute the score for an emotion e of a new headline H as the average score over the set of tokens $t \in H$ that we've observed in the training set (ignoring those tokens not in the training set), i.e.:

$$Score(e,H) = \sum_{t \in H} \frac{Score(e,t)}{|H|}$$

Where $|H|$ is simply the number of tokens in headline H, ignoring tokens not observed in the training set.

[7] Unlike the SWAT system we perform no lemmatization, synonym expansion, or any other preprocessing of the tokens; we simply use whitespace-separated tokens within each headline.

6.2 Experiments

We use 100 headlines as a training set (examples 500-599 from the test set of SemEval Task 14), and we use the remaining 900 headlines as our test set. Since we are fortunate to have the six separate expert annotations in this task, we can perform an extended systematic comparison of the performance of the classifier trained with expert vs. non-expert data.

Emotion	1-Expert	10-NE	k	k-NE
Anger	0.084	0.233	1	0.172
Disgust	0.130	0.231	1	0.185
Fear	0.159	0.247	1	0.176
Joy	0.130	0.125	–	–
Sadness	0.127	0.174	1	0.141
Surprise	0.060	0.101	1	0.061
Valence	0.159	0.229	2	0.146
Avg. Emo	0.116	0.185	1	0.135
Avg. All	0.122	0.191	1	0.137

Table 4: Performance of expert-trained and non-expert-trained classifiers on test-set. k is the minimum number of non-experts needed to beat an average expert.

For this evaluation we compare the performance of systems trained on expert and non-expert annotations. For each expert annotator we train a system using only the judgments provided by that annotator, and then create a gold standard test set using the average of the responses of the remaining five labelers on that set. In this way we create six independent expert-trained systems and compute the average across their performance, calculated as Pearson correlation to the gold standard; this is reported in the “1-Expert” column of Table 4.

Next we train systems using non-expert labels; for each possible subset of n annotators, for $n \in \{1, 2, \ldots, 10\}$ we train a system, and evaluate by calculating Pearson correlation with the same set of gold standard datasets used in the expert-trained system evaluation. Averaging the results of these studies yields the results in Table 4.

As in Table 2 we calculate the minimum number of non-expert annotations per example k required on average to achieve similar performance to the expert annotations; surprisingly we find that for five of the seven tasks, the average system trained with a single set of non-expert annotations outperforms the average system trained with the labels from a single expert. One possible hypothesis for the cause of this non-intuitive result is that individual labelers (including experts) tend to have a strong bias, and since multiple non-expert labelers may contribute to a single set of non-expert annotations, the annotator diversity within the single set of labels may have the effect of reducing annotator bias and thus increasing system performance.

7 Conclusion

We demonstrate the effectiveness of using Amazon Mechanical Turk for a variety of natural language annotation tasks. Our evaluation of non-expert labeler data vs. expert annotations for five tasks found that for many tasks only a small number of non-expert annotations per item are necessary to equal the performance of an expert annotator. In a detailed study of expert and non-expert agreement for an affect recognition task we find that we require an average of 4 non-expert labels per item in order to emulate expert-level label quality. Finally, we demonstrate significant improvement by controlling for labeler bias.

Abstract

Compared to the telephone, email based customer care is increasingly becoming the preferred channel of communication for corporations and customers. Most email-based customer care management systems provide a method to include template texts in order to reduce the handling time for a customer's email. The text in a template is suitably modified into a response by a customer care agent. In this paper, we present two techniques to improve the effectiveness of a template by providing tools for the template authors. First, we present a tool to track and visualize the edits made by agents to a template which serves as a vital feedback to the template authors. Second, we present a novel method that automatically extracts potential templates from responses authored by agents. These methods are investigated in the context of an email customer care analysis tool that handles over a million emails a year.

1 Introduction

Email based customer care is increasingly becoming the preferred channel of communication for corporations and customers compared to the conventional telephone-based customer care. For customers, email channel offers several advantages – there are no tedious menus to navigate, there is no waiting time to reach an operator, the request can be formulated at the customer's pace and additional material supporting the case can be attached to the email. There is also a record of the service request for the customer unlike the telephone-based customer care. However, there are also limitations of the email channel. The most significant one is that the customer-agent interaction could be drawn out over successive emails spanning over several days as opposed to being resolved in one or two telephone calls. For corporations, the asynchronous nature of email-based customer care offers significant opportunities to reduce operations cost by effective load balancing compared to telephone-based customer care. It is quite common for an email customer care agent to work on several cases simultaneously over a period of a few hours. Email channel also offers higher bandwidth for corporations to send additional information in the form of web links, images and video or audio instructions.

The effectiveness of customer care in the email channel is measured using two competing metrics: Average Handling Time (AHT) and Customer Experience Evaluation (CEE). AHT measures the time taken from when a customer email is opened to the time when the response is sent out. This time is typically averaged over a period of a week or a month for reporting purposes. CEE measures customer satisfaction through a survey of a random subset of customers who have interacted with the email customer care center. These surveys typically involve qualitative and quantitative questions and measure the quality of the interactions along a number of different dimensions. As is the case in many surveys the population responding to such questionnaires is typically small and very often quite biased. We do not use the CEE metric for the work we report in this paper.

As is evident from the definitions of AHT and CEE, it is in the interest of a corporation to minimize AHT while maximizing CEE. In order to reduce AHT, most email customer care systems (Kana, 2008; Genesys, 2008) provide a mechanism for an agent to respond to a customer's email by selecting a predefined template text that can be quickly customized to serve as the response. The template text is usually associated with a problem category it is intended to address and might even be suggested to the agent automatically using classification techniques applied to the customer's email. Once the template is selected, the agent edits the template text to personalize as well as add case specific details as part of composing a response. Each of the text edits contributes to the handling time of the email. Hence, it is in the interest of the template designer to minimize the number of edits of the template in order to lower AHT.

Although most email management systems provide a mechanism to author the template text, there is typically no mechanism to monitor and track how these templates are modified by the agents when they compose a response. This information is vital to the template authors when creating new versions of the templates that reduce the number of edits and consequently reduce AHT.

In this paper, we present two methods for improving the templates in a principled manner. After describing the related work in Section 2, we present a brief description of the email tracking tool we have developed in Section 3. In Section 4, we present a tool called HotSpots that helps visualize the edits being made by the customer care agents to the templates. This tool provides a visual feedback to the template authors and suggests means of improving the template text based on the edits made by agents. In Section 5, we present a new approach to automatically identify emerging templates – texts that are repeatedly created by agents and are similar to each other but distinct from the current template text. We use AHT as the metric to minimize for automatic identification of emerging templates. We discuss some of the issues concerning this work in Section 6 and conclude in Section 7.

2 Related Work

There are few threads of research that are relevant to the work presented in this paper. First, the topic of email response generation in the context of customer care has been investigated by (Coch, 1996; Lapalme and Kosseim, 2003; Zukerman and Marom, 2007). In (Coch, 1996), the authors model multi-sentence generation of response letters to customer complaints in French. The generation model is carefully crafted for the domain using domain-specific rules for conceptual planning, rhetorical relations and surface word order operators. They show that their approach performs better than predefined templates and slightly worse than human generated responses. In (Lapalme and Kosseim, 2003), the authors explore three different approaches based on classification, case-based reasoning and question-answering to compose responses to queries in an email customer care application for the telecommunication industry. The case-based reasoning approach is the most similar to the template approach we follow. In (Zukerman and Marom, 2007), the authors investigate an approach to assembling a response by first predicting the clusters of sentences to be included in the response text and then applying multi-document summarization techniques to collate the representative sentences into a single response. In contrast, in this paper, due to constraints from the deployment environment, we rely on a template-based approach to response generation. We focus on providing tools for investigating how the templates are modified and suggest techniques for evolving more effective templates based on quantitative criteria.

Another thread of relevant research are methods for visualizing texts. There are several methods that have been proposed to provide a visual map of a set of text documents with the focus of illustrating the relatedness of these texts (Card et al., 1999). Using a metric for comparing texts (e.g. n-gram overlap) , the texts are clustered and the resulting clusters are visualized as two or three dimensional color maps. These approaches are useful to depict similarities in a static repository of documents or the return results of a search query. These maps are primarily designed for exploration and navigation through the document space. While the underlying algorithm we use to illustrate the text edits is similar to the one used in text map visualizations, our focus in this paper is to provide a mechanism for template designers to quickly identify the variants of a template sentence created by the agents.

A third thread is in the context of human-assisted machine translation, where a human translator post-edits the output of a machine translation system (Foster et al., 1997; Foster et al., 2002; Och et al., 2003). In order to improve the efficiency of a human translator, the k-best output of a translation system could be displayed as word or phrase choices which are color coded based on the confidence value assigned by the translation model. While the approach we follow is partly motivated by the post-editing paradigm, there are significant differences in the context we apply this approach. In the context of this paper, the template designer is presented a summary of the set of variants created by each agent for each sentence of the template. The task of the template designer is to use this tool to select (or construct) a new variant for the template sentence with the aim of minimizing the need for editing that sentence in future uses of the template.

3 Email Customer Care

Typically, a large email customer care management center receives over 100,000 emails a month. These centers typically use a customer care management system that offer not only logging and tracking of emails but also tools for improving the efficiency of agents responding to emails. Usually, an incoming customer email is categorized into a set of few topics/issues. The categorization might be done automatically based on regular expressions involving keywords in the email or using weighted classifiers that are trained on data. In order for an agent to respond to an incoming email, these systems provide a text box which allows the agent to author a response from scratch. However, most email customer care systems offer the ability to store a prefabricated response (also called *templates*), instead of agents having to author a response from scratch. These templates are typically associated with a problem category or an issue that they are intended to address.

A template helps an agent compose a well-formed response quickly. It contains hints for information that the agent should enter as well as indications of where that information should be entered in the template. The template might also contain helpful information to the customer in addition to legal verbiage that the customer needs to be aware of.

An agent receives a customer email and after comprehending the issues and consulting the customer records in the database, selects one of the predefined set of templates that best addresses the issues raised in the email. Less frequently, she might even select more than one template to compose the response. She then proceeds to edit and personalize the chosen templates to better suit the customer's email. An example of a 'generic' template – not associated with a specific problem category is shown in Figure 1.

Greetings Contact.FirstName,
Thank you for your email in regard to XXXXXXXX.
I will be happy to assist you with your inquiry.
XXX BODY XXX
If I can be of any further assistance,
please reply directly to this email.
Thank you for using our company.
We appreciate your business and continued loyalty.
Regards,
Agent.FirstName

Figure 1: An example of a generic template

The process of selecting an appropriate template that addresses the customer's inquiries could be quite tedious when there are hundreds of templates. Email management systems offer tools that suggest appropriate template to use based on the content of the customer's email. These tools are trained using classification techniques on previous email interactions.

As mentioned earlier, there are two metrics that are typically used to measure the effectiveness and efficiency of email responses. Customers are surveyed after their email interaction to assess their level of satisfaction for the service they received. This is usually called the Customer Experience Evaluation (CEE) and includes an evaluation of the customer's total interaction experience with the corporation, not just the last email interaction. A small subset of customers who had an interaction with the email center is randomly chosen (typically in the order of about 10% of customers) and are invited to take part in the follow-up survey. Typically, only a small percent (about 10%) of the customers who receive these invitations respond to the survey; effectively about 1% of the total emails have customer survey scores.

A second metric that is also used to measure the efficiency of an operation is called the average handling time (AHT) which measures the average of times taken by agents to respond to emails. The handling time includes the time to comprehend the email, the time for database lookup and the time for response composition. It is in the interest of the email customer care operation to minimize AHT and maximize CEE scores.

3.1 Email Customer Care Analysis Tool

We have designed and developed an Email Customer Care Analysis Tool (ECAT) to help analyze the operations of the email care center. It provides an end-to-end view from the activities involved in answering emails to the results of subsequent customer care surveys. In addition, ECAT also provides insights into how the agents are editing templates as well as guides template authors in designing more effective templates.

ECAT is a web-based tool and offers a birds-eye summary of the operations aggregated by region, the template used, and the customer satisfaction survey results. Using this tool, analysts can drill down through a series of views until they are eventually presented with the results of a single survey or a single email interaction.

One of the most useful functions of the tool is that it shows the extent to which agents edit the templates in the process of creating responses to customer emails. The degree to which a template is edited is based on Levenshtein string edit distance metric (Levenshtein, 1966). This metric measures the number of edits (substitution, deletion and insertions) of words that are needed to transform a template into a response. The number of edits is normalized by the number of words in the template. These morphing scores can be viewed for a single email or averaged per agent or per template used. The scores range from 100 to 0, with 100 representing a template which hadn't been edited at all.

The tool also allows the morphing score to be viewed alongside the handling time for an email, in other words the amount of time that the agent spends gathering data and actually composing a response. Handling time is an important metric since it is directly related to cost of operating the email customer care center. The more editing an agent does, the more time they take to respond to a customer. So, the number of templates, their precise wording and the ease with which agents can distinguish them obviously have significant influences on overall handling time.

Beyond the confines of the email centers themselves, the CEE is the most important elements in gauging the effectiveness of the agent. The survey asks customers to rate their overall satisfaction with the email reply to their question. Five is the highest score which equates with 'Extremely Satisfied' while a one equals 'Extremely Dissatisfied.' Customers are also asked to rank the email in terms of it's content, clarity, professionalism and the length of time it took to receive a reply. The customer is also allowed to enter some free text so that they can say how satisfied they were, or not, with how an inquiry or problem was dealt with. Customers can also say whether they called the company using a telephone channel before turning to the email channel.

The survey files, all of which can be accessed in their entirety from within the ECAT tool, also contain information on what templates were used when replying to the customer. They also tell the analyst who the replying agent was and whether this was the first or a subsequent email in communications between the customer and the company.

The ECAT tool juxtaposes this CEE score with the template morphing score to show correlations between customer satisfaction and the degree to which the template had been edited. This data is graphed so that the analyst can immediately see if heavy editing of a template is leading to higher CEE. Heavy editing with a low customer rating could mean that the template is not helping the agent to respond correctly to the customer.

4 HotSpots

We designed the HotSpots tool that provides insights to the template authors on how templates are being edited by the agents when creating responses. It suggests methods for improving the next version of the template so as to reduce edits by agents and hence reduce the handling time for an email. In this section, we discuss the algorithm and the visualization of the information that aids template authors in improving the efficacy of the templates.

The HotSpots algorithm proceeds in two steps as shown in Algorithm 1. The first step creates an alignment between the template string and the re-

Algorithm 1 Compute HotSpots for a template T given a response set $\mathcal{R}$

```
1: $EdEv = \phi$
2: $T = s_1 s_2 \dots s_n$
3: $T_s = \{s_i | 1 \le i \le n\}$
4: $R_s = \{r_i^j | R_j \in \mathcal{R}, R_j = r_1^j r_2^j \dots r_{m_j}^j, 1 \le i \le m_j\}$
5: $Index : \{T_s \cup R_s\} \rightarrow \mathbb{I}$
6: $T_{in} = Index(s_1) Index(s_2) \dots Index(s_n)$
7: for all $R \in \mathcal{R}$ do
8:    $R = r_1 r_2 \dots r_{n_R}$
9:    $R_{in} = Index(r_1) Index(r_2) \dots Index(r_{n_R})$
      // compute distance with sentences as tokens and return the alignment and score
10:   $(alignment, score) = IndDist(T_{in}, R_{in})$
      // for each of the sentences in T, update its map
11:   for all $s_i \in T$ do
12:      $in = Index(s_i)$
13:      if $(s_i, \epsilon) \in alignment$ then
14:         $EdEv[in].map = EdEv[in].map \cup \{*delete*\}$
15:      else // $(s_i, r_j) \in alignment$
16:         $EdEv[in].map = EdEv[in].map \cup \{r_j\}$
17:      end if
18:   end for
19: end for
    // Cluster the response sentences aligned for each template sentence
20: for all $s_i \in T$ do
21:    $in = Index(s_i)$
22:    $Cl = KmedianCl(EdEv[in].map, ncl)$
23: end for
```

Algorithm 2 KmedianCl: Compute k centroids for a set of strings S using k-median clustering algorithm

```
1: $c_s = \phi$ // centroid of string $s$'s cluster
2: $ce_i = \phi$ // centroid of cluster $i$
3: $numcl = 0$ // number of cluster created so far
4: $Cl_i = \phi$ // members of cluster $i$
5: while $(numcl \le k) \wedge (numcl \le |S|)$ do
6:    if $numcl = 0$ then
7:       $ce_0 = \underset{c \in S}{argmin} \sum_{s \in S} Dist(c, s)$
8:    else // select the string ($s$) that is farthest from its centroid ($c_s$)
9:       $ce_{numcl} = \underset{s \in S}{argmax}\, Dist(c_s, s)$
10:   end if
      // Move strings to the closest cluster and compute centroids until the set of centroids don't change
11:   repeat
12:      for all $s \in S$ do
13:         $i^* = \underset{0 \le i \le numcl}{argmin}\, Dist(ce_i, s)$
14:         $c_s = ce_{i^*}$
15:         $Cl_{i^*} = Cl_{i^*} \cup \{s\}$
            // Computed the closest cluster centroid $ce_i$ to $s$.
16:      end for
         // Recompute the cluster centroids $ce_i$
17:      for all $i$ such that $0 \le i \le numcl$ do
18:         $ce_i = \underset{c \in Cl_i}{argmin} \sum_{s \in Cl_i} Dist(c, s)$
19:      end for
20:   until set of centroids does not change
21:   $numcl = numcl + 1$ // new cluster added
22: end while
```

sponse string. For the purposes of this paper, we consider the alignments between the template text and the response text with sentences as tokens instead of a word-based alignment. The rationale for this tokenization is that for template developers the visualization of the edits is expected to be more meaningful when aggregated at the sentence level rather than at the word level. In the second step, using the sentence-level alignment we compute the edit events (insertion, deletion and substitution) of the template sentences in order to create the response. All the edits events associated with a template sentence are then clustered into k clusters and the centroids of the k clusters are displayed as the potential changes to that sentence. We next describe these two steps in detail as illustrated in Algorithm 1 and Algorithm 2.

Given a set of responses $\mathcal{R}$ that agents create using a template T, Algorithm 1 proceeds as follows. Each of the sentences in the template and the set of responses are mapped into an integer index (Line 1). The template T and each of the responses in R are split into sentences and mapped into index sequences (Line 6 and Line 9). The alignment between the two index strings is computed in Line 10. This is a dynamic programming algorithm similar to computing Levenshtein distance between two strings, except the cost function used to compute the match between tokens is as shown below.

From the alignment that maps s_i to r_j, we collect the set of response sentences associated with each template sentence (Line 13-16). These sentences are then clustered using k-median clustering method (illustrated in Algorithm 2) in Line 22.

In Algorithm 2, we illustrate the method of clustering we use to summarize the set of sentences we have collected for each template sentence after the alignment step. The algorithm is similar to the k-means algorithm (Duda et al., 2001), however, given that we are clustering strings instead of real numbers (as is typical in applications of k-means), we restrict the centroid of a cluster to be one of the members of the set being clustered, hence the name k-median algorithm (Martnez-Hinarejos et al., 2003). The distance function to measure the closeness of two strings is instantiated to be an n-gram overlap between the two strings.[1]

The algorithm iterates over three steps until the data is partitioned into k clusters (Line 5). The first step (Lines 6-10) is the initialization of a centroid for a new cluster. Initially when the data is not partitioned into any cluster, the median string of the data set is used as the initial centroid. For subsequent iterations, the farthest point from all the centroids computed thus far is used as the centroid for the new cluster. In the second step (Lines 11-16), each member of the data set is assigned to the nearest cluster based on its distance to that cluster's centroid. Finally, in the third step (Lines 17-20), the cluster centroids are recomputed based on the new cluster memberships. Steps two and three are repeated until there are no changes in the cluster memberships and cluster centroids. This completes the introduction of a new cluster for the data.

For the purposes of our task, we use up to a four-gram overlap to measure distance between two strings and use $k = 5$ for clustering the data.

4.1 Visualizing the HotSpots

The HotSpots page was created within the ECAT tool to surgically dissect the way in which templates were being morphed. For a given template, as shown in Figure 2, the analyst is presented with a copy of the texts from the current and previous versions of that template. Each sentence in the two versions of the template are color coded to show how frequently the agents have changed that sentence. This involved running the HotSpots algorithm against approximately 1,000 emails per template version. A sentence that is colored red is one that was changed in over 50% of the emails that were responded to using that template. An orange sentence is one that was edited in between 30% and 50%, green is between 10% to 30% and blue is between 0% and 10%. The more often a sentence is edited the 'hotter' the color.

The analyst can see the typical substitutions for a sentence by hovering the mouse over that sentence. The typical sentences computed as the centroids of the clusters created using Algorithm 2 are themselves color coded using the same identification sys-

[1]We have also experimented with a symmetric version of Levenshtein distance, but we prefer the n-gram overlap score due to its linear run time complexity.

tem. A typical sentence that occurred in over 50% of the emails is colored red. A typical sentence that occurred in 30% to 50% of the emails was orange and so on.

In seeing the two versions side by side, the analyst can visually inspect the agents' edits on the current version of a template relative to the previous version. If the previous version of the template is a 'hotter' document (with more red sentences), it means that the changes made to the template by the author had led to less editing by agents thus speeding up the process of creating a customer response. If the current template looks hotter, it suggests that the changes made to the template were increasing the agents' edits and probably the email handling time.

5 Automatic Extraction of Potential Templates

The goal of the template author is to minimize the number of edits done to a template and thus indirectly lowering the handling time for an email. In the preceding section, we discussed a tool that aids the template authors to identify sentences where changes are most often made by agents to a template. This information could be used by the template authors to create a new version of the template that achieve the goal.

In this section, we investigate a technique that automatically identifies a possible template with the potential of directly minimizing the average handling time for an email. We use the set of responses created by the agents using a given template and select one of the responses to be generalized and stored as a new template. The response to be converted into a template is chosen so as to directly minimize the average handling time. In essence, we seek to partition the set of responses R generated from template T into two clusters R_1 and R_2. These clusters have centroids T (current template) and T' (new template) such that constraint shown in 1 holds.

$$\begin{aligned}(\forall_{r \in R_1} AHT(T,r) < AHT(T',r)) \wedge \\ (\forall_{r \in R_2} AHT(T',r) < AHT(T,r))\end{aligned} \qquad (1)$$

Now, the quantity $AHT(T,r)$ is logged as part of the email management system and corresponds to the time taken to respond to a customer's email.[2]

[2]Although typically this time includes the time to look up a

2	206	GREETINGSPHR, Thank you for letting me know that you've been unable to send an online order to upgrade your NAMEDENTITY service. Please accept my apologies for any problems this issue may have caused you. You're a highly valued customer. I understand your concerns and I'll be happy to address them. I am investigating this issue. I have already made a personal commitment to email you tomorrow, with the resolution. Thank you for your patience and for choosing the company. We appreciate your business and continued loyalty. Sincerely, Agent.FirstName

Table 1: Result of clustering responses using the AHT model as the distance metric.

However, we do not have access to $AHT(T', r)$ for any $T' \neq T$. We propose a model to estimate this in the next section.

5.1 Modeling Average Handling Time

We model AHT as a linear combination of several factors which we believe would influence the handling time for an email. These factors include the length in words of the customer's input email ($inplen$), the length in words of the template ($templatelen$), the length in words of the response ($resplen$), the total number of edits between the template and the response ($edit$), the normalized edit score ($nedit$), the number of individual events of the edit distance – substitution (sub), insertion (ins), deletion (del) and identity (id), the number of block (contiguous) substitution ($blksub$), block insertion ($blkins$) and block deletion ($blkdel$). Using these independent variables, we fit a linear regression model using the AHT values for 6175 responses created from one particular template (say G). The result of the regression fit is shown in Equation 2 and the data and error statistics are shown in Table 2. It must be noted that the coefficients for the variables are not necessarily reflective of the importance of the variables, since they compensate for the different ranges in variable values. We have also tried several different regression fits with fewer variables, but find that this fit gives us the best correlation with the data.

$$\begin{aligned} \hat{AHT} = {} & 0.5314 * inplen - 2.7648 * templatelen \\ & +1.9982 * resplen - 0.5822 * edit \\ & +2900.5242 * nedit \\ & +4.7499 * id - 1.6647 * del \\ & -1.6021 * ins + 26.6704 * blksub \\ & -15.239 * blkins + 24.3931 * blkdel \\ & -261.6627 \end{aligned} \quad (2)$$

Mean AHT	675.74 seconds
Median AHT	543 seconds
Mode AHT	366 seconds
Standard Deviation	487.72 seconds
Correlation coefficient	0.3822
Mean absolute error	320.2 seconds
Root mean squared error	450.64 seconds
Total Number of Instances	6175

Table 2: Data statistics and the goodness of the regression model for 6175 AHT data points.

Based on the goodness statistics of the regression fit, it is clear the AHT model could be improved further. However, we acknowledge that AHT does not depend solely on the editing of a template to a

the customer's account etc., we assume that time is quite similar for all responses created from the same template.

response but involves several other components including the user interface, the complexity of customer's email, the database retrieval to access the customer's account and so forth.

Nevertheless, we use this model to cluster a new set of 2005 responses originating from the same template (G), as shown in Equation 1. Using the k-median clustering as described earlier, we partition the responses into two clusters. We restrict the first cluster centroid to be the template and search for the best centroid for the second cluster. The results are shown in Table 1. The centroid for cluster 1 with 1799 members is the template itself while the centroid for cluster 2 with 206 members is a response that could be suitably generalized to serve as a template. The overall AHT for the 2005 responses using the template was 989.2 seconds, while the average AHT for the members of cluster 1 and 2 was 971.9 seconds and 1140 seconds, indicating that the template had to be edited considerably to create the members of cluster 2.

6 Discussion

For the purposes of this paper, it is assumed that AHT is the same as or correlates well with the time to compose a response for an email. However, in most cases the email care agent might have to perform several verification, validation, and problem resolution phases by consulting the specifics of a customer account before formulating and composing a response. The time taken for each of these phases typically varies depending on the customer's account and the problem category. Nevertheless, we assume that the times for these phases is mostly a constant for a given problem category, and hence the results presented in this paper need to be interpreted on a per problem category basis.

A second limitation of the approach presented in this paper is that the metric used to measure the similarity between strings (n-gram overlap) is only a crude approximation of an ideal semantic similarity metric. There are however other similarity metrics (e.g. BLEU (Papineni et al., 2002)) which could be used equally well. The purpose of this paper is to illustrate the possibility of analysis of responses using one particular instantiation of the similarity metric.

In spite of the several directions that this work can be improved, the system and algorithms described in this paper have been deployed in an operational customer care center. The qualitative feedback we have received are extremely positive and analysts have greatly improved the efficiency of the operation using this tool.

7 Conclusions

In this paper, we have presented two approaches that help template authors in designing effective templates for email customer care agents. In the first approach, we have presented details of a graphical tool that provides vital feedback to the template authors on how their templates are being modified by agents when creating responses. The template authors can accommodate this information when designing the next version of the template. We also presented a novel technique for identifying responses that can potentially serve as templates and reduce AHT. Towards this end, we discussed a method to model AHT based on the characteristics of the customer's email, the template text and the response text.

8 Acknowledgments

We would like to thanks Mazin Gilbert, Junlan Feng, Narendra Gupta and Wenling Hsu for the discussions during the course of this work. We also thank the members who generously offered to their support to provide us with data used in this study without which this work would not have been possible. We thank the anonymous reviewers for their useful suggestions in improving the quality of this paper.

Abstract

This paper describes a language-independent, scalable system for both challenges of cross-document co-reference: name variation and entity disambiguation. We provide system results from the ACE 2008 evaluation in both English and Arabic. Our English system's accuracy is 8.4% relative better than an exact match baseline (and 14.2% relative better over entities mentioned in more than one document). Unlike previous evaluations, ACE 2008 evaluated both name variation and entity disambiguation over naturally occurring named mentions. An information extraction engine finds document entities in text. We describe how our architecture designed for the 10K document ACE task is scalable to an even larger corpus. Our cross-document approach uses the names of entities to find an initial set of document entities that could refer to the same real world entity and then uses an agglomerative clustering algorithm to disambiguate the potentially co-referent document entities. We analyze how different aspects of our system affect performance using ablation studies over the English evaluation set. In addition to evaluating cross-document co-reference performance, we used the results of the cross-document system to improve the accuracy of within-document extraction, and measured the impact in the ACE 2008 within-document evaluation.

1 Introduction

Cross-document entity co-reference is the problem of identifying whether mentions from different documents refer to the same or distinct entities. There are two principal challenges: the same entity can be referred to by more than one name string (e.g. Mahmoud Abbas and Abu Mazen) and the same name string can be shared by more than one entity (e.g. John Smith). Algorithms for solving the cross-document co-reference problem are necessary for systems that build knowledge bases from text, question answering systems, and watch list applications.

There are several challenges in evaluating and developing systems for the cross-document co-reference task. (1) The annotation process required for evaluation and for training is expensive; an annotator must cluster a large number of entities across a large number of documents. The annotator must read the context around each instance of an entity to make reliable judgments. (2) On randomly selected text, a baseline of exact string match will do quite well, making it difficult to evaluate progress. (3) For a machine, there can easily be a scalability challenge since the system must cluster a large number of entities.

Because of the annotation challenges, many previous studies in cross-document co-reference have focused on only the entity disambiguation problem (where one can use string retrieval to collect many documents that contain same name); or have used artificially ambiguated data.

Section 2 describes related work; section 3 introduces ACE, where the work was evaluated; section 4 describes the underlying information extraction engine; sections 5 and 6 address the challenges of coping with name variation and disambiguating entities; sections 7, 8, and 9 present empirical results, improvement of entity extraction within documents using cross-document coreference, and a difference in performance on person versus organization entities. Section 10 discusses the scalability challenge. Section 11 concludes.

2 Related Work

Person disambiguation given a person name string. Bagga and Baldwin (1998b) produced one of the first works in cross-document co-reference. Their work presented a vector space model for the problem of entity disambiguation, clustering 197 articles that contained the name 'John Smith'.

Participants in the 2007 Sem-Eval Web People Search(WEPS) task clustered 100-document sets based on which person a name string of interest referenced. WEPS document sets were collected by selecting the top 100 web search results to queries about a name string (Artiles, et al., 2007).

Mann and Yarowsky (2003) and Gooi and Allan (2004) used artificially ambiguous data to allow for much larger experiments in clustering documents around a known person of interest.

Clustering different variants of the same name. Lloyd et. al (2006) use a combination of 'morphological similarity' and 'contextual similarity' to cluster name variants that refer to the same entity.

Clustering and disambiguation. The John Hopkins 2007 Summer Workshop produced a cross-document annotated version of the ACE 2005 corpus (18K document entities, 599 documents) consisting of 5 entity types (Day, et. al, 2007). There was little ambiguity or variation in the corpus. Participants demonstrated that disambiguation improvements could be achieved with a Metropolis-Hastings clustering algorithm. The study assumed human markup of document-level entities.

Our work. The work reported in this paper addresses both entity clustering and name variation for both persons and organizations in a corpus of 10K naturally occurring documents selected to be far richer than the ACE 2005 data by NIST and LDC. We investigated a new approach in both English and Arabic, and evaluated on document-level entities detected by information extraction.

3 ACE Evaluation

NIST's ACE evaluation measures system performance on a predetermined set of entities, relations, and events. For the 2008 global entity detection and recognition task (GEDR)[1], system performance was measured on named instances of person and organization entities. The GEDR task was run over both English and Arabic documents. Participants processed over 10K documents for each language. References were produced for about 400 documents per language (NIST, 2008). The evaluation set included documents from several genres over a 10 year time period. Document counts are provided in Table 1. This evaluation differed from previous community cross-document coreference evaluations in that it (a) covered both organizations and people; (b) required processing a relatively large data set; (c) evaluated entity disambiguation and name variation simultaneously; and (d) measured cross-document co-reference over system-detected document-level entities and mentions.

	English	**Arabic**
broadcast conversation	8	38
broadcast news	72	19
meeting	18	---
newswire	237	314
telephone	18	12
usenet	15	15
weblog	47	14

Table 1: Documents per genre in ACE2008 test set

The evaluation set was selected to include interesting cases for cross-document co-reference (e.g cases with spelling variation and entities with shared names). This is necessary because annotation is difficult to produce and naturally sampled data has a high percentage of entities resolvable with string match. The selection techniques were unknown to ACE participants.

4 Extraction System Overview

Our cross-document co-reference system relies on SERIF, a state-of-the-art information extraction (IE) system (Ramshaw, et. al, 2001) for document-level information extraction. The IE system uses statistically trained models to detect and classify mentions, link mentions into entities, and detect and classify relations and events. English and Arabic SERIF share the same general models, although there are differences in the specific features used by the models. Arabic SERIF does not perform event detection. While Arabic SERIF does

[1] NIST's evaluation of cross-document co-reference.

make use of some morphological features, the cross-document co-reference system, which focused specifically on entity names, does not use these features.

Figure 1 and Figure 2 illustrate the architecture and algorithms of the cross-document co-reference system respectively. Our system separately addresses two aspects of the cross-document co-reference problem: name variation (Section 5) and entity disambiguation (Section 6). This leads to a scalable solution as described in Section 10.

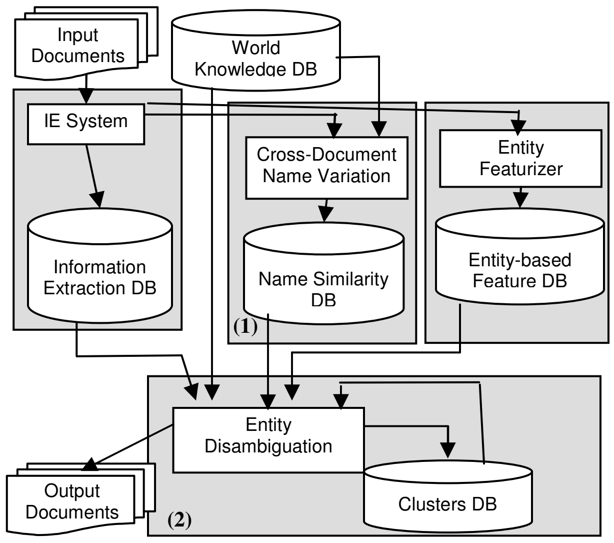

Figure 1: Cross-document Co-reference Architechure

The features used by the cross-document co-reference system can be divided into four classes: World Knowledge (W), String Similarity (S), Predictions about Document Context (C), and Metadata (M). Name variation (V) features operate over unique corpus name strings. Entity disambiguation features (D) operate over document-level entity instances. During disambiguation, the agglomerative clustering algorithm merges two clusters when conditions based on the features are met. For example, two clusters are merged when they share at least half the frequently occurring nouns that describe an entity (e.g. president). As shown in Table 2, features from the same class were often used in both variation and disambiguation. All classes of features were used in both English and Arabic. Because very little training data was available, both the name variation system and the disambiguation system use manually tuned heuristics to combine the features. Tuning was done using the ACE2008 pilot data (LDC, 2008b), documents from the SemEval WEPS task (Artiles, et al., 2007), and some internally annotated documents. Internal annotation was similar in style to the WEPS annotation and did not include full ACE annotation. Annotators simply clustered documents based on potentially confusing entities. Internal annotation was done for ~100 names in both English and Arabic.

Feature Class	**Stage**	**Class**
Wikipedia knowledge	D, V	W
Web-mined aliases	V	W
Word-based similarity	D, V	S
Character-based similarity	V	S
Translation dictionaries	V	S
Corpus Mined Aliases	D, V	C
SERIF extraction	D,V	C
Predicted Document Topics	D	C
Metadata (source, date, etc.)	D	M

Table 2: Features for Cross-Document Co-Reference

5 Name Variation

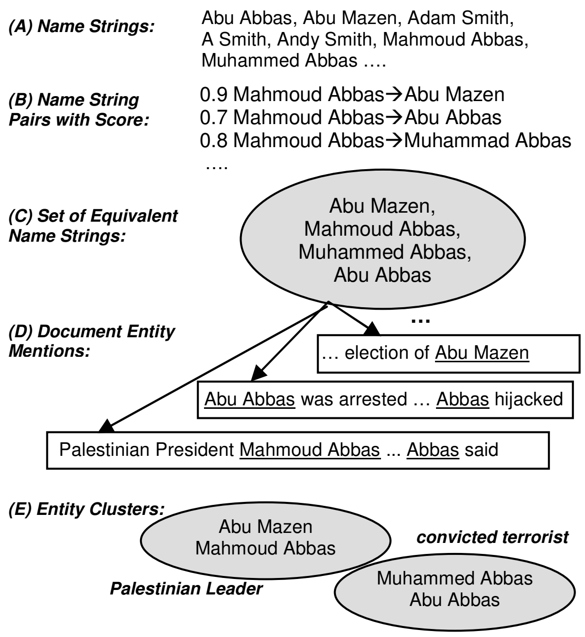
The name variation component (Block 1 of Figure 1) collects all name strings that appear in the document set and provides a measure of similarity between each pair of name strings.[2] Regions (A) and (B) of Figure 2 illustrate the input and output of the name variation component.

This component was initially developed for question answering applications, where when asked the question *'Who is George Bush?'* relevant answers can refer to both George W and George HW (the question is ambiguous). However when asked '*Who leads al Qaeda?'* the QA system must be able to identify spelling variants for the name al Qaeda. For the cross-document co-reference problem, separating the name variation component from the disambiguation component improves the scalability of the system (described in Section 10).

The name variation component makes use of a variety of features including web-mined alias lists, aliases mined from the corpus (e.g *'John aka J'*), statistics about the relations and co-reference decisions predicted by SERIF, character-based edit distance, and token subset trees. The token subset trees algorithm measures similarity using word overlap by building tree-like structures from the unique corpus names based on overlapping tokens. Translation dictionaries (pulled from machine

[2] For the majority of pairs, this similarity score will be 0.

translation training and cross-language links in Wikipedia) account for names that have a canonical form in one language but may appear in many forms in another language.



(A) Name Strings:
Abu Abbas, Abu Mazen, Adam Smith, A Smith, Andy Smith, Mahmoud Abbas, Muhammed Abbas ….
(B) Name String Pairs with Score:
0.9 Mahmoud Abbas→Abu Mazen
0.7 Mahmoud Abbas→Abu Abbas
0.8 Mahmoud Abbas→Muhammad Abbas
….
(C) Set of Equivalent Name Strings:
Abu Mazen, Mahmoud Abbas, Muhammed Abbas, Abu Abbas
(D) Document Entity Mentions:
…
… election of Abu Mazen
Abu Abbas was arrested … Abbas hijacked
Palestinian President Mahmoud Abbas ... Abbas said
(E) Entity Clusters:
Abu Mazen Mahmoud Abbas
Palestinian Leader
convicted terrorist
Muhammed Abbas Abu Abbas

Figure 2: Cross-document Co-reference Process

The features are combined with hand-tuned weights resulting in a unidirectional similarity score for each pair of names. The similarity between two name strings is also influenced by the similarity between the contexts in which the two names appear (for example the modifiers or titles that precede a name). This information allows the system to be more lenient with edit distance when the strings appear in a highly similar context, for example increasing the similarity score between *'Iranian President Ahmadinejad'* and *'Iranian President Nejad.'*

6 Entity Disambiguation

We use a complete link agglomerative clustering algorithm for entity disambiguation. To make agglomerative clustering feasible over a 10K document corpus, rather than clustering all document-level entities together, we run agglomerative clustering over subsets of the corpus entities. For each name string, we select the set of names that the variation component chose as valid variants. In Figure 2 region C, we have selected Mahmoud Abbas and 3 variants.

We then run a three stage agglomerative clustering algorithm over the set of document entities that include any of the name string variants or the original name. Figure 2 region D illustrates three document-level entities.

The name variation links are not transitive, and therefore a name string can be associated with more than one clustering instance. Furthermore document-level entities can include more than one name string. However once a document-level entity has been clustered, it remains linked to entities that were a part of that initial clustering. Because of this, the order in which the algorithm selects name strings is important. We sort the name strings so that those names about which we have the most information and believe are less likely to be ambiguous are clustered first. Name strings that are more ambiguous or about which less information is available are clustered later.

The clustering procedure starts by initializing singleton clusters for each document entity, except those document entities that have already participated in an agglomerative clustering process. For those entities that have already been clustered, the clustering algorithm retrieves the existing clusters.

The merging decisions are based on the similarity between two clusters as calculated through feature matches. Many features are designed to capture the context of the document in which entities appear. These features include the document topics (as predicted by the unsupervised topic detection system (Sista, et al., 2002), the publication date and source of a document, and the other names that appear in the document (as predicted by SERIF). Other features are designed to provide information about the specific context in which an entity appears for example: the noun phrases that refer to an entity and the relationships and events in which an entity participates (as predicted by SERIF). Finally some features, such as the uniqueness of a name in Wikipedia are designed to provide the disambiguation component with world knowledge about the entity. Since each cluster represents a global entity, as clusters grow through merges, the features associated with the clusters expand. For example, the set of associated document topics the global entity participates in grows.

While we have experimented with statistically learning the threshold for merging, because of the small amount of available training data, this threshold was set manually for the evaluation.

Clustering over these subsets of similar strings has the additional benefit of limiting the number of global decisions that are affected by a mistake in the within-document entity linking. For example, if in one document, the system linked *Hillary Clinton* to *Bill Clinton*; assuming that the two names are not chosen as similar variants, we are likely to end up with a cluster made largely of mentions of *Hillary* with one spurious mention of *Bill* and a separate cluster that contains all other mentions of *Bill.* In this situation, an agglomerative clustering algorithm that linked over the full set of document-level entities is more likely to be led astray and create a single *'Bill and Hillary'* entity.

7 Experimental Results

Table 3 and Table 4 include preliminary ACE results[3] for the highest, lowest, and average system in the local and cross-document tasks respectively. While a single participant could submit more than one entry, these numbers reflect only the primary submissions. The ACE scorer maps system produced entities to reference entities and produces several metrics. For the within-document task, metrics include ACE Value, B3, and a variant of B3 weighted to reflect ACE value weightings. For the cross-document task, the B3 metric is replaced with F (NIST, 2008). ACE value has traditionally been the official metric of the ACE evaluation. It puts a higher cost on certain classes of entities (e.g. people are more important than facilities), certain classes of mentions (e.g. names are more important than pronouns), and penalizes systems for mistakes in type and subtype detection as well as linking mistakes. Assigning a mention to the wrong entity is very costly in terms of value score. If the mention is a name, a system is penalized 1.0 for the missed mention and an additional 0.75 for a mention false alarm. We will report ACE Value and value weighted B3/F. Scores on the local task are not directly comparable to scores on the global task. The local entity detection and recognition task (LEDR) includes entity detection for five (rather than two) classes of entities and includes pronoun and nominal (e.g. 'the group') mentions in addition to names.

[3] Results in this paper use v2.1 of the references and v17 of the ACE scorer. Final results will be posted to http://www.nist.gov/speech/tests/ace/2008/

BBN-B-med-fix[5]	61.7	77	31.4	60.1

Table 4: ACE 2008 Cross-Document Results (GEDR)

Our cross-document co-reference system used BBN-A-edropt as input. BBN-B-st-mg is the result of using cross-document co-reference to improve local results (Section 9). For cross-document co-reference, our primary submission, BBN-B-med, was slightly outperformed by an alternate system BBN-B-low. The two submissions differed only in a parameter setting for the topic detection system (BBN-B-low requires more documents to predict a 'topic'). BBN-A-st-mg-fix and BBN-B-med-fix are the result of post-processing the BBN output to account for a discrepancy between the training and evaluation material.[5]

In addition to releasing results, NIST also released the references. Table 5 includes the ACE score for our submitted English system and the score when the system was run over only the 415 documents with references. The system performs slightly better when operating over the full document set. This suggests that the system is using information from the corpus even when it is not directly scored.

[4] There was a swap in rank between metrics, so the low numbers reflect two different systems.

[5] There were discrepancies between the ACE evaluation and training material with respect to the portions of text that should be processed. Therefore our initial system included a number of spurious entities. NIST has accepted revised output that removes these entities. Experiments in this paper reflect the corrected system.

10K documents processed (415 scored) (BBN-B-med-fix)	77
Only 415 documents processed	76.3

Table 5: Full English System ACE Evaluation Results

We have run a series of ablation experiments over the 415 files in the English test set to evaluate the effectiveness of different feature classes. These experiments were run using only the annotated files (and not the full 10K document set). We ran two simple baselines. The first baseline ('No Link') does not perform any cross-document co-reference, all document entities are independent global entities. The second baseline ('Exact Match') links document-level entities using exact string match. We ran 6 variations of our system:

- Configuration 1 is the most limited system. It uses topics and IE system output for disambiguation, and aliases mined from the documents for the name variation component.
- Configuration 2 includes Configuration 1 features with the addition of string similarity (edit distance, token subset trees) algorithms for the name variation stage.
- Configuration 3 includes Configuration 2 features and adds context-based features (e.g. titles and premodifiers) for name variation.
- Configuration 4 adds information from document metadata to the disambiguation component.
- Configuration 5 adds web-mined information (alias lists, Wikipedia, etc.) to both the variation and disambiguation components. This is the configuration that was used for our NIST submission.
- Configuration 5a is identical to Configuration 5 except that the string-based edit distance was removed from the name variation component.

As noted previously, the ACE collection was selected to include challenging entities. The selection criteria of the corpus (which are not known by ACE participants) can affect the importance of features. For example, a corpus that included very few transliterated names would make less use of features based on edit distance.

Figure 3 and Figure 4 show performance (with value weighted F) on the eight conditions over system predicted within-document extraction and reference within-document extraction respectively. Figure 3 also includes configuration 5 run over all 10K documents. We provide two sets of results. The first evaluates system performance over all entities. The relatively high score of the 'No Link' baseline indicates that a high percentage of the document-level entities in the corpus are only mentioned in one document. The second set of numbers measures system performance on those entities appearing in more than one reference document. While this metric does not give a complete picture of the cross-document co-reference task (sometimes a singleton entity must be disambiguated from a large entity that shares the same name); it does provide useful insights given the frequency of singleton entities.

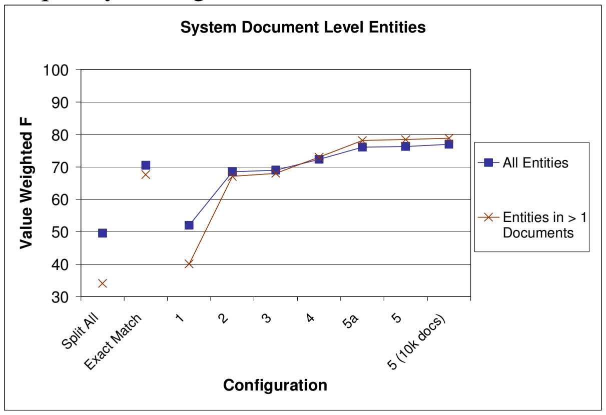

Figure 3: Performance on System Document Entities

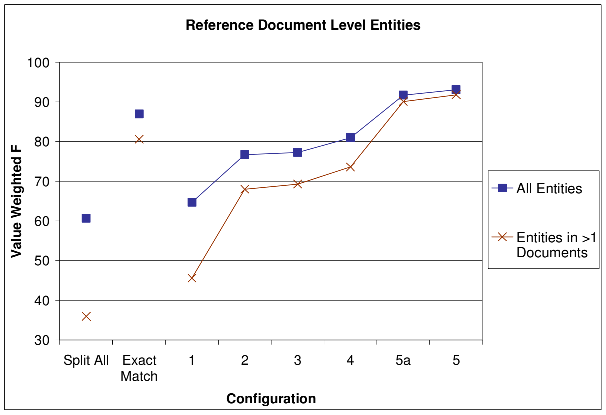

Figure 4: Performance on Perfect Document Entities

Overall system performance improved as features were added. Configuration 1, which disambiguated entities with a small set of features, performed worse than a more aggressive exact string match strategy. The nature of our agglomerative clustering algorithm leads to entity merges only when there is sufficient evidence for the merge. The relatively high performance of the exact match strategy suggests that in the ACE corpus, most entities that shared a name string referred to the same entity, and therefore aggressive merging leads to better performance. As additional features are added, our system becomes more confident and merges more document-level entities.

With the addition of string similarity measures (Configuration 2) our system outperforms the exact match baseline. The submitted results on system entities (Configuration 5) provide a 8.4% relative reduction in error over the exact match baseline. If scored only on entities that occur in more than one document, Configuration 5 gives a 14.2% relative redution in error over the exact match baseline.

The context based features (Configuration 3) allow for more aggressive edit-distance-based name variation when two name strings frequently occur in the same context. In Configuration 3, *'Sheik Hassan Nasrallah'* was a valid variant of *'Hassan Nasrallah'* because both name strings were commonly preceded by '*Hezbollah leader*'. Similarly, *'Dick Cheney'* became a valid variant of '*Richard Bruce Cheney'* because both names were preceded by '*vice president*'. In Configuration 2 the entities included in both sets of name strings had remained unmerged because the strings were not considered valid variants. With the addition of contextual information (Configuration 3), the clustering algorithm created a single global entity. For the '*Dick Cheney'* cluster, this was correct. *'Sheik Hassan Nassrallah'* was a more complex instance, in some cases linking was correct, in others it was not.

The impact of the metadata features (Configuration 4) was both positive and negative. An article about the '*Arab League Secretary General Amru Moussa'* was published on the same day in the same source as an article about '*Intifada Fatah movement leader Abu Moussa*'. With the addition of metadata features, these two distinct global entities were merged. However, the addition of metadata features correctly led to the merging of three instances of the name '*Peter'* in ABC news text (all referring ABC's Peter Jennings).

Web-mined information (Configuration 5) provides several variation and disambiguation features. As we observed, the exact match baseline has fairly high accuracy but is obviously also too aggressive of a strategy. However, for certain very famous global entities, any reference to the name (especially in corpora made of primarily news text) is likely to be a reference to a single global entity. Because these people/organizations are famous, and commonly mentioned, many of the topic and extraction based features will provide insufficient evidence for merging. The same famous person will be mentioned in many different contexts. We use Wikipedia as a resource for such entities. If a name is unambiguous in Wikipedia, then we merge all instances of this name string. In the evaluation corpus, this led to the merging of many different instances of '*Osama Bin Laden'* into a single entity. Web-mined information is also a resource for aliases and acronyms. These alias lists, allowed us to merge '*Abu Muktar'* with '*Khadafi Montanio'* and '*National Liberation Army'* with *'ELN'*.

Interestingly, removing the string edit distance algorithm (System 5a), is a slight improvement over System 5. Initial error analysis has shown that while the string edit distance algorithm did improve accuracy on some entities (e.g linking '*Sam Alito'* with *'Sam Elito'* and linking '*Andres Pastrana'* with '*Andreas Pastrana*'*);* in other cases, the algorithm *allowed* the system to overlink two entities, for example linking *'Megawati Soekarnoputri'* and her sister '*Rachmawati Sukarnoputri'*.

8 Improving Document-Level Extraction with Global Information

In addition to evaluating the cross-document system performance on the GEDR task, we ran a preliminary set of experiments using the cross-document co-reference system to improve within-document extraction. Global output modified within-document extraction in two ways.

First, the cross-document co-reference system was used to modify the within-document system's subtype classification. In addition to evaluating entity links and type classification, the ACE task measures subtype classification. For example, for organization entities, systems distinguish between Media and Entertainment organizations. The IE system uses all mentions in a given entity to assign a subtype. The cross-document co-reference system has merged several document-level entities, and therefore has even more information with which to assign subtypes. The cross-document system also has access to a set of manual labels that have been assigned to Wikipedia categories.

Secondly, we used the cross-document co-reference system's linking decisions to merge within-document entities. If the cross-document co-reference system merged two entities in the same document, then those entities were merged in the within-document output.

Table 6 includes results for our within-document IE system, the IE system with improved subtypes, and the IE system with improved subtypes and merged entities.

	B3Val	Val
Local	77.3	56.7
+ Subtypes	77.3	56.9
+ Merge	77.4	57.2

Table 6: Within-document Results

While these preliminary experiments yield relatively small improvements in accuracy, an analysis of the system's output suggests that the merging approach is quite promising. The output that has been corrected with global merges includes the linking entities with 'World Knowledge' acronyms (e.g. linking *'FARC'* with *'Armed Revolutionary Forces of Colombia');* linking entities despite document-level extraction mistakes (e.g. '*Lady Thatcher*' with '*Margaret Thatcher');* and linking entities despite spelling mistakes in a document (e.g linking *'Avenajado'* with *'Robert Aventajado').* However, as we have already seen, the cross-document co-reference system does make mistakes and these mistakes can propagate to the within-document output.

In particular, we have noticed that the cross-document system has a tendency to link person names with the same last name when both names appear in a single document. As we think about the set of features used for entity disambiguation, we can see why this would be true. These names may have enough similarity to be considered equivalent names. Because they appear in the same document, they will have the same publication date, document source, and document topics. Adjusting the cross-document system to either use a slightly different approach to cluster document-level entities from the same document or at the very least to be more conservative in applying merges that are the result primarily of document metadata and context to the within-document output could improve accuracy.

9 Effect of LEDR on GEDR

Unlike previous evaluations of cross-document co-reference performance, the ACE 2008 evaluation included both person and organization entities. We have noticed that the performance of the cross-document co-reference system on organizations lags behind the performance of the system on people. In contrast, for LEDR, the extraction system's performance is quite similar between the two entity classes. Furthermore, the difference between global organization and person accuracy in the GEDR is smaller when the GEDR task performed with perfect document-level extraction. Scores are shown in Table 7. These differences suggest that part of the reason for the low performance on organizations in GEDR is within-document accuracy.

	LEDR		GEDR-System		GEDR-Perfect	
	B3Val	Val	FVal	Val	FVal	Val
Org	75.1	51.7	67.8	45.9	91.5	84.0
Per	76.2	52.9	83.2	71.4	94.3	89.5

Table 7: Performance on ORG and PER Entities

The LEDR task evaluates names, nominals, and pronouns. GEDR, however only evaluates over name strings. To see if this was a part of the difference in accuracy, we removed all pronoun and nominal mentions from both the IE system's local output and the reference set. As shown in Table 8, the gap in performance between organizations and people is much larger in this setting.

	LEDR- Name Only	
	B3Val	Val
ORG	82.6	83.0
PER	90.1	90.4

Table 8: Local Performance on Name Only Task

Because the GEDR task focuses exclusively on names and excludes nominals and pronouns, mistakes in mention type labeling (e.g. labeling a name as a nominal) become misses and false alarms rather than type substitutions. As the task is currently defined, type substitutions are much less costly than a missing or false alarm entity.

Intuitively, correctly labeling the name of a person as a name and not a nominal is simple. The distinction for organizations may be fuzzier. For example the string 'the US Department of Justice' could conceivably contain one name, two names, or a name and a nominal. The ACE guidelines (LDC, 2008a) suggest that this distinction can be difficult to make, and in fact have a lengthy set of rules for classifying such cases. However, these rules can seem unintuitive, and may be difficult for machines to learn. For example 'Justice Department' is not a name but 'Department of Justice' is. In some sense, this is an artificial distinction enforced by the task definition, but the accuracy numbers suggest that the distinction has a negative effect on system evaluation.

10 Scalability

One of the challenges for systems participating in the ACE task was the need to process a relatively large document set (10K documents). In question answering applications, our name variation algorithms have been applied to even larger corpora (up to 1M documents). There are two factors that make our solution scalable.

First, much of the name variation work is highly parallelizable. Most of the time spent in this algorithm is spent in the name string edit distance calculation. This is also the only algorithm in the name variation component that scales quadratically with the number of name strings. However, each calculation is independent, and could be done simultaneously (with enough machines). For the 10K document set, we ran this algorithm on one machine, but when working with larger document sets, these computations were run in parallel.

Second, the disambiguation algorithm clusters subsets of document-level entities, rather than running the clustering over all entities in the document set. In the English ACE corpus, the IE system found more than 135K document-level entities that were candidates for global entity resolution. There were 62,516 unique name strings each of which was used to initialize an agglomerative clustering instance. As described in Section 6, a document entity is only clustered one time. Consequently, 36% of these clustering instances are 'skipped' because they contain only already clustered document entities. Even the largest clustering instance contained only 1.4% of the document-level entities.

The vast majority of agglomerative clustering instances disambiguated a small number of document-level entities and ran quickly. 99.7% of the agglomerative clustering runs took less than 1 second. 99.9% took 90 seconds or less.

A small number of clustering instances included a large number of document entities, and took significant time. The largest clustering instance, initialized with the name string '*Xinhua,*' contained 1848 document-level entities (1.4% of the document-level entities in the corpus). This instance took 2.6 hours (27% of the total time spent running agglomerative clustering). Another frequent entity '*George Bush*' took 1.2 hours.

As described in Section 6, the clustering procedure can combine unresolved document-level entities into existing global entities. For large cluster sets (e.g entities referred to by the string '*Xinhua*'), speed would be improved by running many smaller clustering instances on subsets of the document-level entities and then merging the results.

11 Conclusions and Future Work

We have presented a cross-document co-reference clustering algorithm for linking entities across a corpus of documents that

- addresses both the challenges of name variation and entity disambiguation.
- is language-independent,
- is scalable

As measured in ACE 2008, for English our system produced an .8.4% relative reduction in error over a baseline that used exact match of name strings. When measured on only entities that appeared in more than one document, the system gave a 14.2% relative reduction in error. For the Arabic task, our system produced a 7% reduction in error over exact match (12.4% when scored over entities that appear in more than one document). We have shown how a variety of features are important for addressing different aspects of the cross-document co-reference problem. Our current features are merged with hand-tuned weights. As additional development data becomes available, we believe it would be feasible to statistically learn the weights. With statistically learned weights, a larger feature set could improve accuracy even further.

Global information from the cross-document co-reference system improved within-document information extraction. This suggests both that a document-level IE system operating over a large corpus text can improve its accuracy with information that it learns from the corpus; and also that integrating an IE system more closely with a source of world knowledge (e.g. a knowledge base) could improve extraction accuracy.

Abstract

The Named Entity Recognition (NER) task has been garnering significant attention in NLP as it helps improve the performance of many natural language processing applications. In this paper, we investigate the impact of using different sets of features in two discriminative machine learning frameworks, namely, Support Vector Machines and Conditional Random Fields using Arabic data. We explore lexical, contextual and morphological features on eight standardized data-sets of different genres. We measure the impact of the different features in isolation, rank them according to their impact for each named entity class and incrementally combine them in order to infer the optimal machine learning approach and feature set. Our system yields a performance of $F_{\beta=1}$-measure=83.5 on ACE 2003 Broadcast News data.

1 Introduction

Named Entity Recognition (NER) is the process by which named entities are identified and classified in an open-domain text. NER is one of the most important sub-tasks in Information Extraction. Thanks to standard evaluation test beds such as the Automatic Content Extraction (ACE)[1], the task of NER has garnered significant attention within the natural language processing (NLP) community. ACE has facilitated evaluation for different languages creating standardized test sets and evaluation metrics. NER systems are typically enabling sub-tasks within large NLP systems. The quality of the NER system has a direct impact on the quality of the overall NLP system. Evidence abound in the literature in areas such as Question Answering, Machine Translation, and Information Retrieval (Babych and Hartley, 2003; Ferrández et al., 2004; Toda and Kataoka, 2005). The most prominent NER systems approach the problem as a classification task: identifying the named entities (NE) in the text and then classifying them according to a set of designed features into one of a predefined set of classes (Bender et al., 2003). The number of classes differ depending on the data set. To our knowledge, to date, the approach is always to model the problem with a single set of features for all the classes simultaneously. This research, diverges from this view. We recognize that different classes are sensitive to differing features. Hence, in this study, we aspire to discover the optimum feature set per NE class. We approach the NER task from a multi-classification perspective. We create a classifier for each NE class independently based on an optimal feature set, then combine the different classifiers for a global NER system. For creating the different classifiers per class, we adopt two discriminative approaches: Support Vector Machines (SVM)(Vapnik, 1995), and Conditional Random Fields (CRF)(Lafferty et al., 2001). We comprehensively investigate many sets of features for each class of NEs: contextual, lexical, morphological and shallow syntactic features. We explore the feature sets in isolation first. Then, we employ the Fuzzy Borda Voting Scheme (FBVS) (García Lapresta and Martínez Panero, 2002) in order to rank the features according to their perfor-

[1]http://www.nist.gov/speech/tests/ace/2004/doc/ace04-evalplan-v7.pdf

mance per class. The incremental approach to feature selection leads to an interpretable system where we have a better understanding of the resulting errors. The paper is structured as follows: Section 2 gives a general overview of the state-of-the-art NER approaches with a particular emphasis on Arabic NER; Section 3 describes relevant characteristics of the Arabic language illustrating the challenges posed to NER; in Section 4.1 we describe the Support Vector Machines and Conditional Random Fields Modeling approaches. We discuss details about our feature-set in 4.2 and describe the Fuzzy Borda Voting Scheme in Section 4.3. Section 5 describes the experiments and shows the results obtained; Withing Section 5, Section 5.1 gives details about the data-sets which we use; finally, we discuss the results and some of our insights in Section 6 and draw some conclusions in 7.

2 Related Work

To date, the most successful language independent approaches to English NER are systems that employ Maximum Entropy (ME) techniques in a supervised setting (Bender et al., 2003).

(Tran et al., 2007) show that using a Support Vector Machine (SVM) approach outperforms ($F_{\beta=1}$=87.75) using CRF ($F_{\beta=1}$=86.48) on the NER task in Vietnamese. For Arabic NER, (Benajiba et al., 2007) show that using a basic ME approach yields $F_{\beta=1}$=55.23. Then they followed up with further work in (Benajiba and Rosso, 2007), where they model the problem as a two step classification approach applying ME, separating the NE boundary detection from the NE classification. That modification showed an improvement in performance yielding an $F_{\beta=1}$=65.91. None of these studies included Arabic specific features, all the features used were language independent. In a later study, (Benajiba and Rosso, 2008) report using lexical and morphological features in a single step model using CRF which resulted in significant improvement over state of the art to date for Arabic NER, yielding $F_{\beta=1}$=79.21. However, the data that was used in these evaluation sets were not standard sets. Most recently, (Farber et al., 2004) have explored using a structured perceptron based model that employs Arabic morphological features. Their system benefits from the basic POS tag (15 tags) information and the corresponding capitalization information on the gloss corresponding to the Arabic word. Exploiting this information yields a significant improvement in recall of 7% and an overall $F_{\beta=1}$=69.6 on the ACE2005 data set. The authors note the lack of improvement in the system's performance when using other Arabic morphological information.

3 Arabic in the context of NER

The Arabic language is a language of significant interest in the NLP community mainly due to its political and economic significance, but also due to its interesting characteristics. Arabic is a Semitic language. It is known for its templatic morphology where words are made up of roots, patterns, and affixes. Clitics agglutinate to words. For instance, the surface word وبحسناتهم *wbHsnAthm*[2] 'and by their virtues[fem.]', can be split into the conjunction *w* 'and', preposition *b* 'by', the stem *HsnAt* 'virtues [fem.]', and possessive pronoun *hm* 'their'.

With respect to the NER task, Arabic poses several major challenges:

Absence of capital letters in the orthography: English like many other Latin script based languages has a specific marker in the orthography, namely capitalization of the initial letter, indicating that a word or sequence of words is a named entity. Arabic has no such special signal rendering the detection of NEs more challenging.

Absence of short vowels: The absence of short vowels renders the lexical items a lot more ambiguous than in other languages exacerbating the homography problem. The average polysemy for surface unvowelized words in Arabic is 12 possible vowelized forms and when the inflections are removed the average is 4 possible vowelized forms.[3] For instance, words such as براد *brAd* can be read both as 'refrigerator' or 'Brad',respectively, where the former is a common noun and the latter is an NE.

[2]We use the Buckwalter transliteration scheme to show romanized Arabic (Buckwalter, 2002).

[3]It is worth noting that each vowelized form could still be ambiguous as in the English homograph/homophone 'bank' case.

The Arabic language is highly inflectional: As we mentioned earlier, Arabic language uses an agglutinative strategy to form surface tokens. As seen in the example above, a surface Arabic word may be translated as a phrase in English. Consequently, the Arabic data in its raw surface form (from a statistical viewpoint) is much more sparse which decreases the efficiency of training significantly.

4 Our Approach

We approach the problem of NER from a per NE class based perspective. The intuition is that features that are discriminative for one NE class might not be for another class. In the process, we decide on an optimal set of features for each NE class. Finally we combine the different classifiers to create a global NER system. Hence, we identify a set of features for NER and proceed to investigate them individually. Then we use an automatic ranking system to pick the optimal set of features per NE class. To that end, we use the Fuzzy Borda Voting Scheme (FBVS). We employ two discriminative classification techniques: Support Vector Machines (SVM) and Conditional Random Fields (CRF). Even though some previous studies seem to point to the superiority of SVM over CRF for NER (Tran et al., 2007), it is hard to draw a definitive conclusion since their assessment was based on comparing the average F-measure.[4] Moreover, the best system to date on Arabic NER reports results using CRF (Benajiba and Rosso, 2008). We adopt an IOB2 annotation scheme for classification. For each NE class, we have two types of class labels: B-Class, marking the beginning of a Class chunk, and I-Class marking the inside of a class chunk. Finally, we mark words not participating in an NE as O, meaning they are outside some NE class label.

4.1 SVM and CRF

SVM approach is based on Neural Networks (Vapnik, 1995). The goal is to find, in the training phase, the best decision function which allows us to obtain the class c for each set of features f. SVM are robust to noise and have powerful generalization ability, especially in the presence of a large number of features. Moreover, SVM have been used successfully in many NLP areas of research in general (Diab et al., 2007), and for the NER task in particular (Tran et al., 2007). We use a sequence model *Yamcha toolkit*,[5] which is defined over SVM.

CRF are a generalization of Hidden Markov Models oriented toward segmenting and labeling sequence data (Lafferty et al., 2001). CRF are undirected graphical models. During the training phase the conditional likelihood of the classes are maximized. The training is discriminative. They have been used successfully for Arabic NER (see section 2). We have used *CRF++*[6] for our experiments.

4.2 Our Feature Sets

One of the most challenging aspects in machine learning approaches to NLP problems is deciding on the optimal feature sets. In this work, we investigate a large space of features which are characterized as follows:

Contextual (CXT): defined as a window of $+/-$ n tokens from the NE of interest

Lexical (LEX_i): defined as the lexical orthographic nature of the tokens in the text. It is a representation of the character n-grams in a token. We define the lexical features focusing on the first three and last three character n-grams in a token. Accordingly, for a token $C_1C_2C_3...C_{n-1}Cn$, then the lexical features for this token are LEX_1=C_1, LEX_2=C_1C_2, LEX_3=$C_1C_2C_3$, $LEX4$=C_n, $LEX_5 = C_{n-1}C_n$, $LEX_6 = C_{n-2}C_{n-1}C_n$.

Gazetteers (GAZ): These include hand-crafted dictionaries/gazetteers listing predefined NEs. We use three gazetteers for person names, locations and organization names.[7] We semi-automatically enriched the location gazetteer using the Arabic Wikipedia[8] as well as other web sources. This enrichment consisted of: (i) taking the page labeled "*Countries of the world*" (دول العالم, dwl AlEAlm) as a starting point to crawl into Wikipedia and retrieve location names; (ii) we automatically filter the data removing stop words; (iii) finally, the resulting

[4]The authors did not report any per class comparison between SVM and CRF.

[5]http://chasen.org/∼taku/software/yamcha/

[6]http://crfpp.sourceforge.net/

[7]http://www.dsic.upv.es/∼ybenajiba

[8]http://ar.wikipedia.org

list goes through a manual validation step to ensure quality. On the training and test data, we tag only the entities which exist entirely in the gazetteer, e.g. if the entity ‘United States of America’ exists in our gazetteer, we would not tag ‘United States’ on the data as a location. Exception is made for person names. We augment our dictionary by converting the multiword names to their singleton counterparts in addition to keeping the multiword names in the list. We tag them on the evaluation data separately. Accordingly, the name ‘Bill Clinton’ and ‘Michael Johnson’ as two entries in our dictionary, are further broken down to ‘Bill’, ‘Clinton’, ‘Michael’, ‘Johnson’. The intuition is that the system will be able to identify names such as ‘Bill Johnson’ and ‘Clinton’ as person names. This is always true for person names, however this assumption does not hold for location or organization names.

Part-Of-Speech (POS) tags and Base Phrase Chunks (BPC): To derive part of speech tags (POS) and base phrase chunks (BPC) for Arabic, we employ the AMIRA-1.0 system[9] described in (Diab et al., 2007). The POS tagger has a reported accuracy of 96.2% (25 tags) and the BPC system performs at a reported $F_{\beta=1}$=96.33%, assuming gold tokenization and POS tagging.

Nationality (NAT): The input is checked against a manually created list of nationalities.

Morphological features (MORPH): This feature set is based on exploiting the characteristic rich morphological features of the Arabic language. We rely on the MADA system for morphological disambiguation (Habash and Rambow, 2005), to extract relevant morphological information. MADA disambiguates words along 14 different morphological dimensions. It typically operates on untokenized texts (surface words as they naturally occur), hence, several of the features indicate whether there are clitics of different types. We use MADA for the preprocessing step of clitic tokenization (which addresses one of the challenges we note in Section 3, namely the impact different morphological surface forms have on sparseness). Recognizing the varying importance of the different morphological features and heeding the reported MADA performance per feature, we carefully engineered the choice of the relevant morphological features and their associated value representations. We selected 5 morphological features to include in this study.

[9]http://www1.cs.columbia.edu/∼mdiab/

1. Aspect (M_{ASP}) : In Arabic, a verb maybe imperfective, perfective or imperative. However since none of the NEs is verbal, we decided to turn this feature into a binary feature, namely indicating if a token is marked for Aspect (APP, for applicable) or not (NA, for not applicable).

2. Person (M_{PER}) : In Arabic, verbs, nouns, and pronouns typically indicate person information. The possible values are *first, second* or *third* person. Again, similar to *aspect*, the applicability of this feature to the NEs is more relevant than the actual value of *first* versus *second*, etc. Hence, we converted the values to APP and NA, where APP applies if the person feature is rendered as *first, second* or *third*.

3. Definiteness (M_{DEF}) : MADA indicates whether a token is definite or not. All the NEs by definition are definite. The possible values are DEF, INDEF or NA.

4. Gender (M_{GEN}) : All nominals in Arabic bear *gender* information. According to MADA, the possible values for this feature are masculine (MASC), feminine (FEM), and neuter (or not applicable NA), which is the case where gender is not applicable for instance in some of the closed class tokens such as prepositions, or in the case of verbs. We use the three possible values MASC, FEM and NA, for this feature. The intuition is that since we are using a sequence model, we are likely to see agreement in *gender* information in participants in the same NE.

5. Number (M_{NUM}) : For almost all the tokens categories (verbs, nouns, adjectives, etc.) MADA provides the grammatical *number*. In Arabic, the possible values are singular (SG), dual (DU) and plural (PL). The correlation of the SG value with most of the NEs classes is very high. Heeding the underlying agreement of words in Arabic when they are part of the same NE, the values for this feature are SG, DU, PL and NA (for cases where number is not applicable such as closed class function words).

Corresponding English Capitalization (CAP): MADA provides the English translation for the words it morphologically disambiguates as it is based on an underlying bilingual lexicon. The intuition is that if the translation begins with a capital letter, then it is most probably a NE. This feature is an attempt to overcome the lack of capitalization for NEs in Arabic (see Section 3). This is similar to the *GlossCAP* feature used in (Farber et al., 2004).

4.3 Fuzzy Borda Voting Scheme

Fuzzy Borda Voting Scheme (FBVS) is useful when several possible candidates (c_n) are ranked by different experts (e_m) and we need to infer a single ranking (García Lapresta and Martínez Panero, 2002). It is based on the Borda count method which was introduced by Jean-Charles de Borda in 1770. In FBVS, each expert provides the ranking of the candidates with a weight[10] (w_n^m) assigned to each of them. Thereafter, for each expert e_i, we generate a square matrix such as $e_i = (r_{1,1}^i \dots r_{n,n}^i)$ where:

$$r_{j,k}^i = \frac{w_j^i}{w_j^i + w_k^i} \tag{1}$$

Given each expert matrix, we calculate for each row $r'^i_j = \sum_k r_{j,k}^i;\ r_{j,k}^i > \alpha$ where α is a certain threshold. Accordingly, for each candidate, we sum up the weights obtained from the different experts in order to obtain a final weight for each candidate ($r''^j = \sum_i r'^i_j$). Finally, we rank them according to r''^j. In our experiments, the candidates we rank are the features. The FBVS ranking is calculated per ML technique and class of NEs across all the data sets according to the features' performances $\mathrm{F}_{\beta=1}$, i.e. the weights. The $\mathrm{F}_{\beta=1}$ ranges from $0-1$. We use $\alpha = 0.5$, thereby taking into consideration only the features which have shown a significant difference in performance.

5 Experiments and Results

5.1 Data

We report the results of our experiments on the standard sets of ACE 2003, ACE 2004 and ACE 2005 data sets.[11] The ACE data (see Table 1) is annotated for many tasks: Entity Detection and Tracking (EDT), Relation Detection and Recognition (RDR), Event Detection and Recognition (EDR). All the data sets comprise *Broadcast News* (BN) and *Newswire* (NW) genres. ACE 2004 includes an additional NW data set from the Arabic TreeBank (ATB). ACE 2005 includes a different genre of *Weblogs* (WL).

$Corpus$	$genre$	$Size_{train}$	$Size_{dev}$	$Size_{test}$
ACE 2003	BN	12.41k	4.12k	5.63k
	NW	23.85k	9.5k	9.1k
ACE 2004	BN	45.68k	14.44k	14.81k
	NW	45.66k	15.2k	16.9k
	ATB	19.04k	6.16k	6.08k
ACE 2005	BN	18.54k	5k	8.4k
	NW	40.26k	12.5k	13.83k
	WL	13.7k	6.2k	6.4

Table 1: Statistics of ACE 2003, 2004 and 2005 data

We create a dev, test and train set for each of the collections. Table 1 gives the relevant statistics. It is worth noting that the standard training sets have 4 folds that are typically used for training. We used one of the folds as dev data for tuning purposes, rendering our training data less for our experiments. For data preprocessing, we remove all annotations which are not oriented to the EDR task. Also, we remove all the 'nominal' and 'pronominal' mentions of the entities and keep only the 'named' ones. Hence, all the listed characteristics for this corpus pertain to the portions of the data that are relevant to NER only. The ACE 2003 data defines four different NE classes: Person (e.g. Albert Einstein), Geographical and Political Entities (GPE) (e.g. Kazakhistan), Organization (e.g. Google Co.) and Facility (e.g. the White House). Whereas in ACE 2004 and 2005, two NE classes are added to the ACE 2003 tag-set: Vehicles (e.g. Rotterdam Ship) and Weapons (e.g. Kalashnikof). In order to overcome the sparseness issues resulting , we clitic tokenize the text using the MADA system. We use the ATB style clitic tokenization standard. Finally, we convert the data from the ACE format into the IOB2 annotation scheme (Tjong Kim Sang and De Meudler, 2003).

5.2 Experimentation

Our objective is to find the optimum set of features per NE class and then combine the outcome in a

[10]weights are not required for classical Borda count.
[11]http://www.nist.gov/speech/tests/ace/

global NER system for Arabic. We set the context window to be of size $-1/+1$ for all the experiments, as it empirically yields the best performance. We use the CoNLL evaluation metrics of precision, recall, and $F_{\beta=1}$ measures. The CoNLL metrics are geared to the chunk level yielding results as they pertain to the entire NE (Tjong Kim Sang and De Meudler, 2003). Our experiments are presented as follows:

1. Training per individual NE class: We train for an individual class by turning off the other annotations for the other classes in the training set. We experimented with two settings: 1. Setting all the other NE classes to O, similar to non-NE words, thereby yielding a 3-way classification, namely, B-NE and I-NE for the class of interest, and O for the rest including the rest of the NEs and other words and punctuation; 2. The second setting discriminated between the other NE classes that are not of interest and the rest of the words. The intuition in this case is that NE class words will naturally behave differently than the rest of the words in the data. Thereby, this setting yields a 4-way classification: B-NE and I-NE for class of interest, NE for the other NE classes, and O for the other words and punctuation in the data. In order to contrast the 3-way vs the 4-way classification, we run experiments and evaluate using the ACE 2003 data set with no features apart from 'CXT' and 'current word' using SVM. Table 2 illustrates the yielded results. For all

Class	*Num(classes)*	*BN genre*	*NW genre*
GPE	3	76.72	79.88
	4	**76.88**	**80.99**
PER	3	64.34	42.93
	4	**67.56**	**44.43**
ORG	3	41.73	25.24
	4	**46.02**	**37.97**
FAC	3	**23.33**	15.3
	4	**23.33**	**18.12**

Table 2: $F_{\beta=1}$ Results using 3-way vs. 4-way class annotations using SVM

the NE classes we note that the 4-way classification yields the best results. Moreover, we counted the number of 'conflicts' obtained for each NE classification. A 'conflict' arises when the same token is classified as a different NE class by more than one classification system. Our findings are summarized as follows:

(i). 3 classes: 16 conflicts (8 conflicts in BN and 8 in NW). 10 of these conflicts are between GPE and PER, and 6 of them are between GPE and ORG.

(ii). 4 classes: 10 conflicts (3 conflicts in BN and 7 in NW). 9 of these conflicts are between GPE and ORG, and only one of them is between GPE and FAC.

An example of a conflict observed using the 3-way classification that disappeared when we apply the 4-way classification is in the following sentence: نشرت صحيفة واشنطن تايمس تقريرا *n$rt SHyfp WA$nTn tAyms tqryrA*, which is translated as 'The Washington Times newspaper published a report'. When trained using a 3-way classifier, 'Washington' is assigned the tag GPE by the GPE classifier system and as an ORG by the ORG classifier system. However, when trained using the 4-way classifier, this conflict is resolved as an ORG in the ORG classifier system and an NE in the GPE classifier system. Thereby confirming our intuition that a 4-way classification is better suited for the individual NE classification systems. Accordingly, for the rest of the experiments in this paper reporting on individual NE classifiers systems, we use a 4-way classification approach.

2. Measuring the impact of Individual features per class : An experiment is run for each fold of the data. We train on data annotated for one NE class, one Machine Learning (ML) method (i.e. SVM or CRF), and one feature. For each experiment we use the tuning set for evaluation, i.e. obtaining the $F_{\beta=1}$ performance value.

3. FBVS Ranking : After obtaining the F-measures for all the individual features on all the data genres and using the two ML techniques, we rank the features (in a decreasing order) according to their impact (F-measure obtained) using FBVS (see 4.3). This results in a ranked list of features for each ML approach and data genre per class. Once the features are ranked, we incrementally experiment with the features in the order of the ranking, i.e. train with the first feature and measure the performance on the tuning data, then train with the second together with the first feature, i.e. the first two features and measure performance, then the first three features and so on.

M_{NUM}	6	10	14	14	13
CAP	2	1	8	1	2

Table 3: Ranked features according to FBVS using SVM for each NE class

4. Feature set/class generalization : Finally, we pick the first *n* features that yield the best converging performance (after which additional features do not impact performance or cause it to deteriorate). We use the top *n* features to tag the test data and compare the results against the system when it is trained on the whole feature set.

5.3 Individual Features Experiments

After running experiments using each feature individually, each result is considered an expert (the obtained F-measure is the weight in this framework).

Our goal is to find a general ranking of the features for each ML approach and each class. Table 3 shows the obtained rankings of the features for each class using SVM. It is worth noting that the obtained CRF rankings are very similar to those yielded by using SVM. We note that there are no specific features that have proven to be useless for all classes and ML approaches.

5.4 Feature set/class Experiments

We combine the features per NE class incrementally. Since the total number of features is 16, each ML classifier is trained and evaluated on the tuning data 16 times for each genre. A best number of features per class per genre per ML technique is determined based on the highest yielded $F_{\beta=1}$. Finally, the last step is combining the outputs of the different classifiers for all the classes. In case of conflicts, where the same token is tagged as two different NE classes, we use a simple heuristic based on the classifier precision for that specific tag, favoring the tag with the highest precision.

Table 4 illustrates the obtained results. For each data set and each genre it shows the F-measure obtained using the best feature set and ML approach. We show results for both the dev and test data using the optimal number of features **Best Feat-Set/ML** contrasted against the system when using all 16 features per class **All Feats/ML**. The table also illustrates three baseline results on the test data only. **FreqBaseline**: For this baseline, we assign a test token the most frequent tag observed for it in the training data, if a test token is not observed in the training data, it is assigned the most frequent tag which is the O tag. **MLBaseline**: In this baseline setting, we train an NER system with the full 16 features for all the NE classes at once. We use the two different ML approaches yielding two baselines: **MLBaseline**$_{SVM}$ and **MLBaseline**$_{CRF}$.
It is important to note the difference between the **All Feats/ML** setting and the **MLBaseline** setting. In the former, **All Feats/ML**, all 16 features are used per class in a 4-way classifier system and then the classifications are combined and the conflicts are resolved using our simple heuristic while in the latter case of **MLBaseline** the classes are trained together with all 16 features for all classes in one system. Since different feature-sets and different ML approaches are used and combined for each experiment, it is not possible to present the number of features used in each experiment in Table 4. However, Table 5 shows the number of features and the ML approach used for each genre and NE class.

6 Discussion and Error Analysis

As illustrated in Table 5, SVM outperformed CRF on most of the classes. Interestingly, CRF tends to model the ORG and FAC entities better than SVM. Hence, it is not possible to give a final word on the superiority of SVM or CRF in the NER task, and it is necessary to conduct a per class study, as the one we present in this paper, in order to determine the right ML approach and features to use for each class. Therefore, our best global NER system combined

Weapon	3	SVM	3	SVM	3	SVM	3	SVM

Table 5: Number of features and ML approach used to obtain the best results

the results obtained from both ML approaches.

Table 4, shows that our **Best Feat-set/ML** setting outperforms the baselines and the **All Feats** {**SVM/CRF**} settings for all the data genres and sets forthe test data. Moreover, the **Best Feat-set/ML** setting outperforms both **All Feats** {**SVM/CRF**} settings for the dev data for all genres except for ACE2003 NW, where the difference is very small.

The results yielded from the ML baselines are comparable across all the data genres and the two ML approaches.

Comparing the global ML baseline systems against the All Feature Setting, we see that the **All Feats** setting consistently outperforms the **MLBaseline** settings except for ACE2005 NW data set. This suggests that training separate systems for the different NEs has some benefit over training in one global system.

Comparing the performance per genre across the different data sets. We note better performance across the board for BN data over NW per year. The worst results are yielded for ACE 2004 data for both BN and NW genres. There is no definitive conclusion that a specific ML approach is better suited for a specific data genre. We observe slightly better performance for the CRF ML approach in the **MLBaseline**$_{CRF}$ condition for both BN and NW.

The worst performance is yielded for the WL data. This may be attributed to the small amount of training data available for this genre. Moreover the quality of the performance of the different feature extraction tools such as AMIRA (for POS tagging and BPC) and MADA (for the morphological features) are optimized for NW data genres, thereby yielding suboptimal performance on the WL genre, leading to more noise than signal for training. However, comparing relative performance on this genre, we see a significant jump from the most frequent baseline **FreqBaseline** ($F_{\beta=1}$=27.66) to the best baseline **MLBaseline**$_{CRF}$ ($F_{\beta=1}$=55.32). We see a further significant improvement when the **Best Feat-set/ML** setting is applied yielding an $F_{\beta=1}$=57.3. Interestingly, however the **MLBaseline**$_{CRF}$ yields a much better performance ($F_{\beta=1}$=55.32) than **All Feats CRF** with an $F_{\beta=1}$=27.36. This may indicate that a global system that trains all classes at once using CRF for sparse data is better than training separate classifiers and then combining the outputs. It is worth noting the difference between **MLBaseline**$_{SVM}$ and **All Feats SVM**, F$_{\beta=1}$=54.68 and F$_{\beta=1}$=55.58, respectively. This result suggests that SVM are more robust to less training data as illustrated in the case of the individual classifiers in the latter setting.

Comparing dev and test performance, we note that the overall results on the dev data are better than those obtained on the test data, which is expected given that the weights for the FBVS ranking are derived based on the dev data used as a tuning set. The only counter example for this trend is with the WL data genre, where the test data yields a significantly higher performance for all the conditions except for **All Feats CRF**.

As observed in Table 3, the ranking of the individual features could be very different for two NE classes. For instance, the BPC is ranked 4th for the PER class and is ranked 13th for GPE and ORG classes. The disparity in ranking for the same individual features strongly suggests that using the same features for all the classes cannot lead to a global optimal classifier. With regards to morphological features, we note in Table 3, that Definiteness, M_{DEF}, is helpful for all the NE classification systems, by virtue of being included for all optimal systems for all NE classification systems. Aspect, M_{ASP}, is useful for all classes except PER. Moreover, M_{GEN} and M_{NUM}, corresponding to Gender and Number, respectively, contributed significantly to the increase in recall for PER and GPE classes. Finally, the Person feature, M_{PER} contributed mostly to improving the classification of ORG and FAC classes. Accordingly, observing these results, contrary to previous results by (Farber et al., 2004), our results strongly suggest the significant impact morphological features have on Arabic NER, if applied at the right level of granularity.

Inconsistencies in the data lead to many of the observed errors. The problem is that the ACE data is annotated primarily for a mention detection task which leads to the same exact words not being annotated consistently. For instance, the word 'Palestinians' would sometimes be annotated as a GPE class while in similar other contexts it is not annotated as a named entity at all. Since we did not manually correct these cases, the classifiers are left with mixed signals. The VEH and WEA classes both exhibit a uniform ranking for all the features and yield a very low performance. This is mainly attributed to the fact that they appear very rarely in the training data. For instance, in the ACE 2005, BN genre, there are 1707 instances of the class PER, 1777 of GPE, 103 of ORG, 106 of FAC and only 4 for WEA and 24 for VEH.

7 Conclusions and Future Directions

We described the performance yielded using language-dependent and language independent features in SVM and CRF for the NER task on different standard Arabic data-sets comprising different genres. We have measured the impact of each feature individually on each class, we ranked them according to their impact using the Fuzzy Borda Voting Scheme, and then performed an incremental features' selection considering each time the N best features.

We reported the importance of each feature for each class and then the performance obtained when the best feature-set is used. Our experiments yield state of the art performance significantly outperforming the baseline. Our best results achieve an F$_{\beta=1}$ score of 83.5 for the ACE 2003 BN data. Our ACE2005 results are state of the art when compared to the best system to date. It is worth noting that these obtained results are trained on less data since we train only on 3 folds vs the standard 4 folds. Our results show that the SVM and CRF have very similar behaviors. However, SVM showed more robust performance in our system using data with very random contexts, namely for the WL data, i.e. Weblogs. We definitively illustrate that correctly exploiting morphological features for languages with rich morphological structures yields state of the art performance. For future work, we intend to investigate the use of automatic feature selection methods on the same data.

Understanding the Value of Features for Coreference Resolution

Eric Bengtson **Dan Roth**

{ebengt2,danr}@illinois.edu

Abstract

In recent years there has been substantial work on the important problem of coreference resolution, most of which has concentrated on the development of new models and algorithmic techniques. These works often show that complex models improve over a weak pairwise baseline. However, less attention has been given to the importance of selecting strong features to support learning a coreference model.

This paper describes a rather simple pairwise classification model for coreference resolution, developed with a well-designed set of features. We show that this produces a state-of-the-art system that outperforms systems built with complex models. We suggest that our system can be used as a baseline for the development of more complex models – which may have less impact when a more robust set of features is used. The paper also presents an ablation study and discusses the relative contributions of various features.

1 Introduction

Coreference resolution is the task of grouping all the mentions of entities[1] in a document into equivalence classes so that all the mentions in a given class refer to the same discourse entity. For example, given the sentence (where the head noun of each mention is subscripted)

> *An American$_1$ official$_2$ announced that American$_1$ President$_3$ Bill Clinton$_3$ met his$_3$ Russian$_4$ counterpart$_5$, Vladimir Putin$_5$, today.*

the task is to group the mentions so that those referring to the same entity are placed together into an equivalence class.

Many NLP tasks detect attributes, actions, and relations between discourse entities. In order to discover all information about a given entity, textual mentions of that entity must be grouped together. Thus coreference is an important prerequisite to such tasks as textual entailment and information extraction, among others.

Although coreference resolution has received much attention, that attention has not focused on the relative impact of high-quality features. Thus, while many structural innovations in the modeling approach have been made, those innovations have generally been tested on systems with features whose strength has not been established, and compared to weak pairwise baselines. As a result, it is possible that some modeling innovations may have less impact or applicability when applied to a stronger baseline system.

This paper introduces a rather simple but state-of-the-art system, which we intend to be used as a strong baseline to evaluate the impact of structural innovations. To this end, we combine an effective coreference classification model with a strong set of features, and present an ablation study to show the relative impact of a variety of features.

As we show, this combination of a pairwise model and strong features produces a 1.5 percent-

[1]We follow the ACE (NIST, 2004) terminology: A noun phrase referring to a discourse entity is called a *mention*, and an equivalence class is called an *entity*.

age point increase in B-Cubed F-Score over a complex model in the state-of-the-art system by Culotta et al. (2007), although their system uses a complex, non-pairwise model, computing features over partial clusters of mentions.

2 A Pairwise Coreference Model

Given a document and a set of mentions, coreference resolution is the task of grouping the mentions into equivalence classes, so that each equivalence class contains exactly those mentions that refer to the same discourse entity. The number of equivalence classes is not specified in advance, but is bounded by the number of mentions.

In this paper, we view coreference resolution as a graph problem: Given a set of mentions and their context as nodes, generate a set of edges such that any two mentions that belong in the same equivalence class are connected by some path in the graph. We construct this entity-mention graph by learning to decide for each mention which preceding mention, if any, belongs in the same equivalence class; this approach is commonly called the pairwise coreference model (Soon et al., 2001). To decide whether two mentions should be linked in the graph, we learn a pairwise coreference function *pc* that produces a value indicating the probability that the two mentions should be placed in the same equivalence class.

The remainder of this section first discusses how this function is used as part of a document-level coreference decision model and then describes how we learn the *pc* function.

2.1 Document-Level Decision Model

Given a document d and a pairwise coreference scoring function pc that maps an ordered pair of mentions to a value indicating the probability that they are coreferential (see Section 2.2), we generate a coreference graph G_d according to the Best-Link decision model (Ng and Cardie, 2002b) as follows:

For each mention m in document d, let B_m be the set of mentions appearing before m in d. Let a be the highest scoring antecedent:

$$a = \underset{b \in B_m}{\operatorname{argmax}}(pc(b, m)).$$

If $pc(a, m)$ is above a threshold chosen as described in Section 4.4, we add the edge (a, m) to the coreference graph G_d.

The resulting graph contains connected components, each representing one equivalence class, with all the mentions in the component referring to the same entity. This technique permits us to learn to detect some links between mentions while being agnostic about whether other mentions are linked, and yet via the transitive closure of all links we can still determine the equivalence classes.

We also require that no non-pronoun can refer back to a pronoun: If m is not a pronoun, we do not consider pronouns as candidate antecedents.

2.1.1 Related Models

For pairwise models, it is common to choose the best antecedent for a given mention (thereby imposing the constraint that each mention has at most one antecedent); however, the method of deciding which is the best antecedent varies.

Soon et al. (2001) use the Closest-Link method: They select as an antecedent the closest preceding mention that is predicted coreferential by a pairwise coreference module; this is equivalent to choosing the closest mention whose pc value is above a threshold. Best-Link was shown to outperform Closest-Link in an experiment by Ng and Cardie (2002b). Our model differs from that of Ng and Cardie in that we impose the constraint that non-pronouns cannot refer back to pronouns, and in that we use as training examples all ordered pairs of mentions, subject to the constraint above.

Culotta et al. (2007) introduced a model that predicts whether a pair of equivalence classes should be merged, using features computed over all the mentions in both classes. Since the number of possible classes is exponential in the number of mentions, they use heuristics to select training examples. Our method does not require determining which equivalence classes should be considered as examples.

2.2 Pairwise Coreference Function

Learning the pairwise scoring function pc is a crucial issue for the pairwise coreference model. We apply machine learning techniques to learn from examples a function pc that takes as input an ordered pair of mentions (a, m) such that a precedes m in the document, and produces as output a value that is interpreted as the conditional probability that m and a belong in the same equivalence class.

2.2.1 Training Example Selection

The ACE training data provides the equivalence classes for mentions. However, for some pairs of mentions from an equivalence class, there is little or no direct evidence in the text that the mentions are coreferential. Therefore, training *pc* on all pairs of mentions within an equivalence class may not lead to a good predictor. Thus, for each mention m we select from m's equivalence class the closest preceding mention a and present the pair (a, m) as a positive training example, under the assumption that there is more direct evidence in the text for the existence of this edge than for other edges. This is similar to the technique of Ng and Cardie (2002b). For each m, we generate negative examples (a, m) for all mentions a that precede m and are not in the same equivalence class. Note that in doing so we generate more negative examples than positive ones.

Since we never apply *pc* to a pair where the first mention is a pronoun and the second is not a pronoun, we do not train on examples of this form.

2.2.2 Learning Pairwise Coreference Scoring Model

We learn the pairwise coreference function using an averaged perceptron learning algorithm (Freund and Schapire, 1998) – we use the regularized version in Learning Based Java[2] (Rizzolo and Roth, 2007).

3 Features

The performance of the document-level coreference model depends on the quality of the pairwise coreference function *pc*. Beyond the training paradigm described earlier, the quality of *pc* depends on the features used.

We divide the features into categories, based on their function. A full list of features and their categories is given in Table 2. In addition to these boolean features, we also use the conjunctions of all pairs of features.[3]

[2]LBJ code is available at `http://L2R.cs.uiuc.edu/~cogcomp/asoftware.php?skey=LBJ`

[3]The package of all features used is available at `http://L2R.cs.uiuc.edu/~cogcomp/asoftware.php?skey=LBJ#features`.

In the following description, the term *head* means the head noun phrase of a mention; the *extent* is the largest noun phrase headed by the head noun phrase.

3.1 Mention Types

The type of a mention indicates whether it is a proper noun, a common noun, or a pronoun. This feature, when conjoined with others, allows us to give different weight to a feature depending on whether it is being applied to a proper name or a pronoun. For our experiments in Section 5, we use gold mention types as is done by Culotta et al. (2007) and Luo and Zitouni (2005).

Note that in the experiments described in Section 6 we predict the mention types as described there and do not use any gold data. The mention type feature is used in all experiments.

3.2 String Relation Features

String relation features indicate whether two strings share some property, such as one being the substring of another or both sharing a modifier word. Features are listed in Table 1. Modifiers are limited to those occurring before the head.

Feature	Definition
Head match	$head_i == head_j$
Extent match	$extent_i == extent_j$
Substring	$head_i$ substring of $head_j$
Modifiers Match	$mod_i ==$ ($head_j$ or mod_j)
Alias	$acronym(head_i) == head_j$ or $lastname_i == lastname_j$

Table 1: String Relation Features

3.3 Semantic Features

Another class of features captures the semantic relation between two words. Specifically, we check whether gender or number match, or whether the mentions are synonyms, antonyms, or hypernyms. We also check the relationship of modifiers that share a hypernym. Descriptions of the methods for computing these features are described next.

Gender Match We determine the gender (male, female, or neuter) of the two phrases, and report whether they match (true, false, or unknown). For

Category	Feature	Source
Mention Types	Mention Type Pair	Annotation and tokens
String Relations	Head Match	Tokens
	Extent Match	Tokens
	Substring	Tokens
	Modifiers Match	Tokens
	Alias	Tokens and lists
Semantic	Gender Match	WordNet and lists
	Number Match	WordNet and lists
	Synonyms	WordNet
	Antonyms	WordNet
	Hypernyms	WordNet
	Both Speak	Context
Relative Location	Apposition	Positions and context
	Relative Pronoun	Positions and tokens
	Distances	Positions
Learned	Anaphoricity	Learned
	Name Modifiers Predicted Match	Learned
Aligned Modifiers	Aligned Modifiers Relation	WordNet and lists
Memorization	Last Words	Tokens
Predicted Entity Types	Entity Types Match	Annotation and tokens
	Entity Type Pair	WordNet and tokens

Table 2: Features by Category

a proper name, gender is determined by the existence of *mr*, *ms*, *mrs*, or the gender of the first name. If only a last name is found, the phrase is considered to refer to a person. If the name is found in a comprehensive list of cities or countries, or ends with an organization ending such as *inc*, then the gender is neuter. In the case of a common noun phrase, the phrase is looked up in WordNet (Fellbaum, 1998), and it is assigned a gender according to whether *male*, *female*, *person*, *artifact*, *location*, or *group* (the last three correspond to neuter) is found in the hypernym tree. The gender of a pronoun is looked up in a table.

Number Match Number is determined as follows: Phrases starting with the words *a*, *an*, or *this* are singular; *those*, *these*, or *some* indicate plural. Names not containing *and* are singular. Common nouns are checked against extensive lists of singular and plural nouns – words found in neither or both lists have unknown number. Finally, if the number is unknown yet the two mentions have the same spelling, they are assumed to have the same number.

WordNet Features We check whether any sense of one head noun phrase is a synonym, antonym, or hypernym of any sense of the other. We also check whether any sense of the phrases share a hypernym, after dropping *entity*, *abstraction*, *physical entity*, *object*, *whole*, *artifact*, and *group* from the senses, since they are close to the root of the hypernym tree.

Modifiers Match Determines whether the text before the head of a mention matches the head or the text before the head of the other mention.

Both Mentions Speak True if both mentions appear within two words of a verb meaning *to say*. Being in a window of size two is an approximation to being a syntactic subject of such a verb. This feature is a proxy for having similar semantic types.

3.4 Relative Location Features

Additional evidence is derived from the relative location of the two mentions. We thus measure distance (quantized as multiple boolean features of the form [$distance \geq i$]) for all i up to the distance and less than some maximum, using units of compatible mentions, and whether the mentions are in the same sentence. We also detect apposition (mentions separated by a comma). For details, see Table 3.

Feature	Definition
Distance	In same sentence # compatible mentions
Apposition	m_1, m_2 found
Relative Pronoun	Apposition and m_2 is PRO

Table 3: Location Features. Compatible mentions are those having the same gender and number.

3.5 Learned Features

Modifier Names If the mentions are both modified by other proper names, use a basic coreference classifier to determine whether the modifiers are coreferential. This basic classifier is trained using Mention Types, String Relations, Semantic Features, Apposition, Relative Pronoun, and Both Speak. For each mention m, examples are generated with the closest antecedent a to form a positive example, and every mention between a and m to form negative examples.

Anaphoricity Ng and Cardie (2002a) and Denis and Baldridge (2007) show that when used effectively, explicitly predicting anaphoricity can be helpful. Thus, we learn a separate classifier to detect whether a mention is anaphoric (that is, whether it is not the first mention in its equivalence class), and use that classifier's output as a feature for the coreference model. Features for the anaphoricity classifier include the mention type, whether the mention appears in a quotation, the text of the first word of the extent, the text of the first word after the head (if that word is part of the extent), whether there is a longer mention preceding this mention and having the same head text, whether any preceding mention has the same extent text, and whether any preceding mention has the same text from beginning of the extent to end of the head. Conjunctions of all pairs of these features are also used. This classifier predicts anaphoricity with about 82% accuracy.

3.6 Aligned Modifiers

We determine the relationship of any pair of modifiers that share a hypernym. Each aligned pair may have one of the following relations: match, substring, synonyms, hypernyms, antonyms, or mismatch. Mismatch is defined as none of the above. We restrict modifiers to single nouns and adjectives occurring before the head noun phrase.

3.7 Memorization Features

We allow our system to learn which pairs of nouns tend to be used to mention the same entity. For example, *President* and *he* often refer to *Bush* but *she* and *Prime Minister* rarely do, if ever. To enable the system to learn such patterns, we treat the presence or absence of each pair of final head nouns, one from each mention of an example, as a feature.

3.8 Predicted Entity Type

We predict the entity type (*person*, *organization*, *geo-political entity*, *location*, *facility*, *weapon*, or *vehicle*) as follows: If a proper name, we check a list of personal first names, and a short list of honorary titles (e.g. *mr*) to determine if the mention is a person. Otherwise we look in lists of personal last names drawn from US census data, and in lists of cities, states, countries, organizations, corporations, sports teams, universities, political parties, and organization endings (e.g. *inc* or *corp*). If found in exactly one list, we return the appropriate type. We return *unknown* if found in multiple lists because the lists are quite comprehensive and may have significant overlap.

For common nouns, we look at the hypernym tree for one of the following: *person*, *political unit*, *location*, *organization*, *weapon*, *vehicle*, *industrial plant*, and *facility*. If any is found, we return the appropriate type. If multiple are found, we sort as in the above list.

For personal pronouns, we recognize the entity as a person; otherwise we specify unknown.

This computation is used as part of the following two features.

Entity Type Match This feature checks to see whether the predicted entity types match. The result is true if the types are identical, false if they are different, and unknown if at least one type is unknown.

Entity Type Conjunctions This feature indicates the presence of the pair of predicted entity types for the two mentions, except that if either word is a pronoun, the word token replaces the type in the pair. Since we do this replacement for entity types, we also add a similar feature for mention types here. These features are boolean: For any given pair, a feature is active if that pair describes the example.

3.9 Related Work

Many of our features are similar to those described in Culotta et al. (2007). This includes Mention Types, String Relation Features, Gender and Number Match, WordNet Features, Alias, Apposition, Relative Pronoun, and Both Mentions Speak. The implementations of those features may vary from those of other systems. Anaphoricity has been proposed as a part of the model in several systems, including Ng and Cardie (2002a), but we are not aware of it being used as a feature for a learning algorithm. Distances have been used in e.g. Luo et al. (2004). However, we are not aware of any system using the number of compatible mentions as a distance.

4 Experimental Study

4.1 Corpus

We use the official ACE 2004 English training data (NIST, 2004). Much work has been done on coreference in several languages, but for this work we focus on English text. We split the corpus into three sets: Train, Dev, and Test. Our test set contains the same 107 documents as Culotta et al. (2007). Our training set is a random 80% of the 336 documents in their training set and our Dev set is the remaining 20%.

For our ablation study, we further randomly split our development set into two evenly sized parts, Dev-Tune and Dev-Eval. For each experiment, we set the parameters of our algorithm to optimize B-Cubed F-Score using Dev-Tune, and use those parameters to evaluate on the Dev-Eval data.

4.2 Preprocessing

For the experiments in Section 5, following Culotta et al. (2007), to make experiments more comparable across systems, we assume that perfect mention boundaries and mention type labels are given. We do not use any other gold annotated input at evaluation time. In Section 6 experiments we do not use any gold annotated input and do not assume mention types or boundaries are given. In all experiments we automatically split words and sentences using our preprocessing tools.[4]

4.3 Evaluation Scores

B-Cubed F-Score We evaluate over the commonly used B-Cubed F-Score (Bagga and Baldwin, 1998), which is a measure of the overlap of predicted clusters and true clusters. It is computed as the harmonic mean of precision (P),

$$P = \frac{1}{N} \sum_{d \in D} \left(\sum_{m \in d} \left(\frac{c_m}{p_m} \right) \right), \qquad (1)$$

and recall (R),

$$R = \frac{1}{N} \sum_{d \in D} \left(\sum_{m \in d} \left(\frac{c_m}{t_m} \right) \right), \qquad (2)$$

where c_m is the number of mentions appearing both in m's predicted cluster and in m's true cluster, p_m is the size of the predicted cluster containing m, and t_m is the size of m's true cluster. Finally, d represents a document from the set D, and N is the total number of mentions in D.

B-Cubed F-Score has the advantage of being able to measure the impact of singleton entities, and of giving more weight to the splitting or merging of larger entities. It also gives equal weight to all types of entities and mentions. For these reasons, we report our results using B-Cubed F-Score.

MUC F-Score We also provide results using the official MUC scoring algorithm (Vilain et al., 1995). The MUC F-score is also the harmonic mean of precision and recall. However, the MUC precision counts precision errors by computing the minimum number of links that must be added to ensure that all mentions referring to a given entity are connected in the graph. Recall errors are the number of links that must be removed to ensure that no two mentions referring to different entities are connected in the graph.

[4]The code is available at `http://L2R.cs.uiuc.edu/~cogcomp/tools.php`

4.4 Learning Algorithm Details

We train a regularized average perceptron using examples selected as described in Section 2.2.1. The learning rate is 0.1 and the regularization parameter (separator thickness) is 3.5. At training time, we use a threshold of 0.0, but when evaluating, we select parameters to optimize B-Cubed F-Score on a held-out development set. We sample all even integer thresholds from -16 to 8. We choose the number of rounds of training similarly, allowing any number from one to twenty.

5 Results

	Precision	Recall	B^3 F
Culotta et al.	86.7	73.2	79.3
Current Work	88.3	74.5	**80.8**

Table 4: Evaluation on unseen Test Data using B^3 score. Shows that our system outperforms the advanced system of Culotta et al. The improvement is statistically significant at the $p = 0.05$ level according to a non-parametric bootstrapping percentile test.

In Table 4, we compare our performance against a system that is comparable to ours: Both use gold mention boundaries and types, evaluate using B-Cubed F-Score, and have the same training and test data split. Culotta et al. (2007) is the best comparable system of which we are aware.

Our results show that a pairwise model with strong features outperforms a state-of-the-art system with a more complex model.

MUC Score We evaluate the performance of our system using the official MUC score in Table 5.

MUC Precision	MUC Recall	MUC F
82.7	69.9	75.8

Table 5: Evaluation of our system on unseen Test Data using MUC score.

5.1 Analysis of Feature Contributions

In Table 6 we show the relative impact of various features. We report data on Dev-Eval, to avoid the possibility of overfitting by feature selection. The parameters of the algorithm are chosen to maximize the BCubed F-Score on the Dev-Tune data. Note that since we report results on Dev-Eval, the results in Table 6 are not directly comparable with Culotta et al. (2007). For comparable results, see Table 4 and the discussion above.

Our ablation study shows the impact of various classes of features, indicating that almost all the features help, although some more than others. It also illustrates that some features contribute more to precision, others more to recall. For example, aligned modifiers contribute primarily to precision, whereas our learned features and our apposition features contribute to recall. This information can be useful when designing a coreference system in an application where recall is more important than precision, or vice versa.

We examine the effect of some important features, selecting those that provide a substantial improvement in precision, recall, or both. For each such feature we examine the rate of coreference amongst mention pairs for which the feature is active, compared with the overall rate of coreference. We also show examples on which the coreference systems differ depending on the presence or absence of a feature.

Apposition This feature checks whether two mentions are separated by only a comma, and it increases B-Cubed F-Score by about one percentage point. We hypothesize that proper names and common noun phrases link primarily through apposition, and that apposition is thus a significant feature for good coreference resolution.

When this feature is active 36% of the examples are coreferential, whereas only 6% of all examples are coreferential. Looking at some examples our system begins to get right when apposition is added, we find the phrase

> *Israel's Deputy Defense Minister, Ephraim Sneh.*

Upon adding apposition, our system begins to correctly associate *Israel's Deputy Defense Minister* with *Ephraim Sneh*. Likewise in the phrase

> *The court president, Ronald Sutherland*,

the system correctly associates *The court president* with *Ronald Sutherland* when they appear in an appositive relation in the text. In addition, our system

	Precision	Recall	B-Cubed F
String Similarity	86.88	67.17	75.76
+ Semantic Features	85.34	69.30	**76.49**
+ Apposition	89.77	67.53	77.07
+ Relative Pronoun	88.76	68.97	77.62
+ Distances	89.62	71.93	79.81
+ Learned Features	87.37	74.51	**80.43**
+ Aligned Modifiers	88.70	74.30	80.86
+ Memorization	86.57	75.59	80.71
+ Predicted Entity Types	87.92	76.46	81.79

Table 6: Contribution of Features as evaluated on a development set. Bold results are significantly better than the previous line at the $p = 0.05$ level according to a paired non-parametric bootstrapping percentile test. These results show the importance of Distance, Entity Type, and Apposition features.

begins correctly associating relative pronouns such as *who* with their referents in phrases like

Sheikh Abbad, who died 500 years ago.

although an explicit relative pronoun feature is added only later.

Although this feature may lead the system to link comma separated lists of entities due to misinterpretation of the comma, for example *Wyoming* and *western South Dakota* in a list of locations, we believe this can be avoided by refining the apposition feature to ignore lists.

Relative Pronoun Next we investigate the relative pronoun feature. With this feature active, 93% of examples were positive, indicating the precision of this feature. Looking to examples, we find *who* in

the official, who wished to remain anonymous

is properly linked, as is *that* in

nuclear warheads that can be fitted to missiles.

Distances Our distance features measure separation of two mentions in number of compatible mentions (quantized), and whether the mentions are in the same sentence. Distance features are important for a system that makes links based on the best pairwise coreference value rather than implicitly incorporating distance by linking only the closest pair whose score is above a threshold, as done by e.g. Soon et al. (2001).

Looking at examples, we find that adding distances allows the system to associate the pronoun *it* with *this missile* not separated by any mentions, rather than *Tehran*, which is separated from *it* by many mentions.

Predicted Entity Types Since no two mentions can have different entity types (person, organization, geo-political entity, etc.) and be coreferential, this feature has strong discriminative power. When the entity types match, 13% of examples are positive compared to only 6% of examples in general. Qualitatively, the entity type prediction correctly recognizes *the Gulf region* as a geo-political entity, and *He* as a person, and thus prevents linking the two. Likewise, the system discerns *Baghdad* from *ambassador* due to the entity type. However, in some cases an identity type match can cause the system to be overly confident in a bad match, as in the case of a *palestinian state* identified with *holy Jerusalem* on the basis of proximity and shared entity type. This type of example may require some additional world knowledge or deeper comprehension of the document.

6 End-to-End Coreference

The ultimate goal for a coreference system is to process unannotated text. We use the term *end-to-end coreference* for a system capable of determining coreference on plain text. We describe the challenges associated with an end-to-end system, describe our approach, and report results below.

6.1 Challenges

Developing an end-to-end system requires detecting and classifying mentions, which may degrade coreference results. One challenge in detecting mentions is that they are often heavily nested. Additionally, there are issues with evaluating an end-to-end system against a gold standard corpus, resulting from the possibility of mismatches in mention boundaries, missing mentions, and additional mentions detected, along with the need to align detected mentions to their counterparts in the annotated data.

6.2 Approach

We resolve coreference on unannotated text as follows: First we detect mention heads following a state of the art chunking approach (Punyakanok and Roth, 2001) using standard features. This results in a 90% F_1 head detector. Next, we detect the extent boundaries for each head using a learned classifier. This is followed by determining whether a mention is a proper name, common noun phrase, prenominal modifier, or pronoun using a learned mention type classifier that. Finally, we apply our coreference algorithm described above.

6.3 Evaluation and Results

To evaluate, we align the heads of the detected mentions to the gold standard heads greedily based on number of overlapping words. We choose not to impute errors to the coreference system for mentions that were not detected or for spuriously detected mentions (following Ji et al. (2005) and others). Although this evaluation is lenient, given that the mention detection component performs at over 90% F_1, we believe it provides a realistic measure for the performance of the end-to-end system and focuses the evaluation on the coreference component. The results of our end-to-end coreference system are shown in Table 7.

	Precision	Recall	B^3 F
End-to-End System	84.91	72.53	78.24

Table 7: Coreference results using detected mentions on unseen Test Data.

7 Conclusion

We described and evaluated a state-of-the-art coreference system based on a pairwise model and strong features. While previous work showed the impact of complex models on a weak pairwise baseline, the applicability and impact of such models on a strong baseline system such as ours remains uncertain. We also studied and demonstrated the relative value of various types of features, showing in particular the importance of distance and apposition features, and showing which features impact precision or recall more. Finally, we showed an end-to-end system capable of determining coreference in a plain text document.

Acknowledgments

We would like to thank Ming-Wei Chang, Michael Connor, Alexandre Klementiev, Nick Rizzolo, Kevin Small, and the anonymous reviewers for their insightful comments. This work is partly supported by NSF grant SoD-HCER-0613885 and a grant from Boeing.

Abstract

Complex questions that require inferencing and synthesizing information from multiple documents can be seen as a kind of topic-oriented, informative multi-document summarization. In this paper, we have experimented with one empirical and two unsupervised statistical machine learning techniques: k-means and Expectation Maximization (EM), for computing relative importance of the sentences. However, the performance of these approaches depends entirely on the feature set used and the weighting of these features. We extracted different kinds of features (i.e. lexical, lexical semantic, cosine similarity, basic element, tree kernel based syntactic and shallow-semantic) for each of the document sentences in order to measure its importance and relevancy to the user query. We used a local search technique to learn the weights of the features. For all our methods of generating summaries, we have shown the effects of syntactic and shallow-semantic features over the bag of words (BOW) features.

1 Introduction

After having made substantial headway in factoid and list questions, researchers have turned their attention to more complex information needs that cannot be answered by simply extracting named entities (persons, organizations, locations, dates, etc.) from documents. For example, the question: *"Describe the after-effects of cyclone Sidr-Nov 2007 in Bangladesh"* requires inferencing and synthesizing information from multiple documents. This information synthesis in NLP can be seen as a kind of topic-oriented, informative multi-document summarization, where the goal is to produce a single text as a compressed version of a set of documents with a minimum loss of relevant information.

In this paper, we experimented with one empirical and two well-known unsupervised statistical machine learning techniques: k-means and EM and evaluated their performance in generating topic-oriented summaries. However, the performance of these approaches depends entirely on the feature set used and the weighting of these features. We extracted different kinds of features (i.e. lexical, lexical semantic, cosine similarity, basic element, tree kernel based syntactic and shallow-semantic) for each of the document sentences in order to measure its importance and relevancy to the user query. We have used a gradient descent local search technique to learn the weights of the features. Traditionally, information extraction techniques are based on the BOW approach augmented by language modeling. But when the task requires the use of more complex semantics, the approaches based on only BOW are often inadequate to perform fine-level textual analysis. Some improvements on BOW are given by the use of dependency trees and syntactic parse trees (Hirao et al., 2004), (Punyakanok et al., 2004), (Zhang and Lee, 2003), but these, too are not adequate when dealing with complex questions whose answers are expressed by long and articulated sentences or even paragraphs. Shallow semantic representations, bearing a more compact information, could prevent the sparseness of deep structural approaches and the weakness of BOW models (Moschitti et al., 2007). Attempting an application of syntactic and semantic information to complex QA hence seems natural, as pinpointing the answer to a question relies on a deep understanding of the semantics of both. In more complex tasks such as computing the relatedness between the query sentences and the document sentences in order to generate query-focused summaries (or answers to complex questions), to our knowledge no study uses tree kernel functions to encode syntactic/semantic information. For all our methods of generating summaries (i.e. empirical, k-means and EM), we have shown the effects of syntactic and shallow-semantic features over the BOW features.

This paper is organized as follows: Section 2 focuses on the related work, Section 3 describes how the features are extracted, Section 4 discusses the scoring approaches, Section 5 discusses how we remove the redundant sentences before adding them to the summary, Section 6 describes our experimental study. We conclude and give future directions in Section 7.

2 Related Work

Researchers all over the world working on query-based summarization are trying different directions to see which methods provide the best results. The *LexRank* method addressed in (Erkan and Radev, 2004) was very successful in generic multi-document summarization. A topic-sensitive LexRank is proposed in (Otterbacher et al., 2005). As in LexRank, the set of sentences in a document cluster is represented as a graph, where nodes are sentences and links between the nodes are induced by a similarity relation between the sentences. Then the system ranked the sentences according to a random walk model defined in terms of both the inter-sentence similarities and the similarities of the sentences to the topic description or question.

The summarization methods based on lexical chain first extract the nouns, compound nouns and named entities as candidate words (Li et al., 2007). Then using WordNet, the systems find the semantic similarity between the nouns and compound nouns. After that, lexical chains are built in two steps: 1) Building single document strong chains while disambiguating the senses of the words and, 2) building multi-chain by merging the strongest chains of the single documents into one chain. The systems rank sentences using a formula that involves a) the lexical chain, b) keywords from query and c) named entities.

(Harabagiu et al., 2006) introduce a new paradigm for processing complex questions that relies on a combination of (a) question decompositions; (b) factoid QA techniques; and (c) Multi-Document Summarization (MDS) techniques. The question decomposition procedure operates on a Marcov chain, by following a random walk with mixture model on a bipartite graph of relations established between concepts related to the topic of a complex question and subquestions derived from topic-relevant passages that manifest these relations. Decomposed questions are then submitted to a state-of-the-art QA system in order to retrieve a set of passages that can later be merged into a comprehensive answer by a MDS system. They show that question decompositions using this method can significantly enhance the relevance and comprehensiveness of summary-length answers to complex questions.

There are approaches that are based on probabilistic models (Pingali et al., 2007) (Toutanova et al., 2007). (Pingali et al., 2007) rank the sentences based on a mixture model where each component of the model is a statistical model:

$$Score(s) = \alpha \times QIScore(s) + (1-\alpha) \times QFocus(s, Q)$$

Where, Score(s) is the score for sentence s. Query-independent score (QIScore) and query-dependent score (QFocus) are calculated based on probabilistic models. (Toutanova et al., 2007) learns a log-linear sentence ranking model by maximizing three metrics of sentence goodness: (a) ROUGE oracle, (b) Pyramid-derived, and (c) Model Frequency. The scoring function is learned by fitting weights for a set of feature functions of sentences in the document set and is trained to optimize a sentence pair-wise ranking criterion. The scoring function is further adapted to apply to summaries rather than sentences and to take into account redundancy among sentences.

There are approaches in "Recognizing Textual Entailment", "Sentence Alignment" and "Question Answering" that use syntactic and/or semantic information in order to measure the similarity between two textual units. (MacCartney et al., 2006) use typed dependency graphs (same as dependency trees) to represent the text and the hypothesis. Then they try to find a good partial alignment between the typed dependency graphs representing the hypothesis and the text in a search space of $O((m + 1)n)$

where hypothesis graph contains n nodes and a text graph contains m nodes. (Hirao et al., 2004) represent the sentences using Dependency Tree Path (DTP) to incorporate syntactic information. They apply String Subsequence Kernel (SSK) to measure the similarity between the DTPs of two sentences. They also introduce Extended String Subsequence Kernel (ESK) to incorporate semantics in DTPs. (Kouylekov and Magnini, 2005) use the tree edit distance algorithms on the dependency trees of the text and the hypothesis to recognize the textual entailment. According to this approach, a text T entails a hypothesis H if there exists a sequence of transformations (i.e. deletion, insertion and substitution) applied to T such that we can obtain H with an overall cost below a certain threshold. (Punyakanok et al., 2004) represent the question and the sentence containing answer with their dependency trees. They add semantic information (i.e. named entity, synonyms and other related words) in the dependency trees. They apply the approximate tree matching in order to decide how similar any given pair of trees are. They also use the edit distance as the matching criteria in the approximate tree matching. All these methods show the improvement over the BOW scoring methods.

Our Basic Element (BE)-based feature used the dependency tree to extract the BEs (i.e. head-modifier-relation) and ranked the BEs based on their log-likelihood ratios. For syntactic feature, we extracted the syntactic trees for the sentence as well as for the query using the Charniak parser and measured the similarity between the two trees using the tree kernel function. We used the ASSERT semantic role labeler system to parse the sentence as well as the query semantically and used the shallow semantic tree kernel to measure the similarity between the two shallow-semantic trees.

3 Feature Extraction

The sentences in the document collection are analyzed in various levels and each of the document-sentences is represented as a vector of feature-values. The features can be divided into several categories:

3.1 Lexical Features

3.1.1 N-gram Overlap

N-gram overlap measures the overlapping word sequences between the candidate sentence and the query sentence. With the view to measure the N-gram (N=1,2,3,4) overlap scores, a *query pool* and a *sentence pool* are created. In order to create the query (or sentence) pool, we took the query (or document) sentence and created a set of related sentences by replacing its important words[1] by their first-sense synonyms. For example given a stemmed document-sentence: "John write a poem", the sentence pool contains: "John compose a poem", "John write a verse form" along with the given sentence. We measured the recall based n-gram scores for a sentence P using the following formula:

n-gramScore(P) = $max_i(max_j$ N-gram$(s_i, q_j))$

$$\text{N-gram(S,Q)} = \frac{\sum_{gram_n \in S} Count_{match}(gram_n)}{\sum_{gram_n \in S} Count(gram_n)}$$

Where, n stands for the length of the n-gram $(n = 1, 2, 3, 4)$ and $Count_{match}\,(gram_n)$ is the number of n-grams co-occurring in the query and the candidate sentence, q_j is the j^{th} sentence in the query pool and s_i is the i^{th} sentence in the sentence pool of sentence P.

3.1.2 LCS, WLCS and Skip-Bigram

A sequence $W = [w_1, w_2, ..., w_n]$ is a subsequence of another sequence $X = [x_1, x_2, ..., x_m]$, if there exists a strict increasing sequence $[i_1, i_2, ..., i_k]$ of indices of X such that for all $j = 1, 2, ..., k$ we have $x_{i_j} = w_j$. Given two sequences, S_1 *and* S_2, the Longest Common Subsequence (LCS) of S_1 *and* S_2 is a common subsequence with maximum length. The longer the LCS of two sentences is, the more similar the two sentences are.

The basic LCS has a problem that it does not differentiate LCSes of different spatial relations within their embedding sequences (Lin, 2004). To improve the basic LCS method, we can remember the length of consecutive matches encountered so far to a regular two dimensional dynamic program table computing LCS. We call this weighted LCS (WLCS) and use k to indicate the length of the current consecutive matches ending at words x_i and y_j. Given two sentences X and Y, the WLCS score of X and Y can be computed using the similar dynamic programming procedure as stated in (Lin, 2004). We computed the LCS and WLCS-based F-measure following (Lin, 2004) using both the query pool and the sentence pool as in the previous section.

Skip-bigram is any pair of words in their sentence order, allowing for arbitrary gaps. Skip-bigram measures the overlap of skip-bigrams between a candidate sentence and a query sentence. Following (Lin, 2004), we computed the skip bi-gram score using both the sentence pool and the query pool.

[1]hence forth important words are the nouns, verbs, adverbs and adjectives

3.1.3 Head and Head Related-words Overlap

The number of head words common in between two sentences can indicate how much they are relevant to each other. In order to extract the heads from the sentence (or query), the sentence (or query) is parsed by Minipar [2] and from the dependency tree we extract the heads which we call exact head words. For example, the head word of the sentence: "John eats rice" is "eat".

We take the synonyms, hyponyms and hypernyms[3] of both the query-head words and the sentence-head words and form a set of words which we call head-related words. We measured the exact head score and the head-related score as follows:

$$\text{ExactHeadScore} = \frac{\sum_{w_1 \in HeadSet} Count_{match}(w_1)}{\sum_{w_1 \in HeadSet} Count(w_1)}$$

$$\text{HeadRelatedScore} = \frac{\sum_{w_1 \in HeadRelSet} Count_{match}(w_1)}{\sum_{w_1 \in HeadRelSet} Count(w_1)}$$

Where HeadSet is the set of head words in the sentence and $Count_{match}$ is the number of matches between the HeadSet of the query and the sentence. HeadRelSet is the set of synonyms, hyponyms and hypernyms of head words in the sentence and $Count_{match}$ is the number of matches between the head-related words of the query and the sentence.

3.2 Lexical Semantic Features

We form a set of words which we call *QueryRelatedWords* by taking the important words from the query, their first-sense synonyms, the nouns' hypernyms/hyponyms and important words from the nouns' gloss definitions.

Synonym overlap measure is the overlap between the list of synonyms of the important words extracted from the candidate sentence and the *QueryRelatedWords*. *Hypernym/hyponym overlap* measure is the overlap between the list of hypernyms and hyponyms of the nouns extracted from the sentence and the *QueryRelatedWords*, and *gloss overlap* measure is the overlap between the list of important words that are extracted from the gloss definitions of the nouns of the sentence and the *QueryRelatedWords*.

[2]http://www.cs.ualberta.ca/ lindek/minipar.htm

[3]hypernym and hyponym levels are restricted to 2 and 3 respectively

3.3 Statistical Similarity Measures

Statistical similarity measures are based on the co-occurance of similar words in a corpus. We have used two statistical similarity measures: *1. Dependency-based similarity measure* and *2. Proximity-based similarity measure*.

Dependency-based similarity measure uses the dependency relations among words in order to measure the similarity. It extracts the dependency triples then uses statistical approach to measure the similarity. *Proximity-based similarity measure* is computed based on the linear proximity relationship between words only. It uses the information theoretic definition of similarity to measure the similarity.

We used the data provided by Dr. Dekang Lin[4]. Using the data, one can retrieve most similar words for a given word. The similar words are grouped into clusters. Note that, for a word there can be more than one cluster. Each cluster represents the sense of the word and its similar words for that sense.

For each query word, we extract all of its clusters from the data. Now, in order to determine the right cluster for a query word, we measure the overlap score between the *QueryRelatedWords* and the *clusters of words*. The hypothesis is that, the cluster that has more words common with the *QueryRelatedWords* is the right cluster. We chose the cluster for a word which has the highest overlap score.

Once we get the clusters for the query words, we measured the overlap between the cluster words and the sentence words as follows:

$$\text{Measure} = \frac{\sum_{w_1 \in SenWords} Count_{match}(w_1)}{\sum_{w_1 \in SenWords} Count(w_1)}$$

Where, SenWords is the set of important words extracted from the sentence and $Count_{match}$ is the number of matches between the sentence words and the clusters of similar words of the query words.

3.4 Graph-based Similarity Measure

In LexRank (Erkan and Radev, 2004), the concept of graph-based centrality is used to rank a set of sentences, in producing generic multi-document summaries. A similarity graph is produced for the sentences in the document collection. In the graph, each node represents a sentence. The edges between the nodes measure the cosine similarity between the respective pair of sentences. The degree of a given node is an indication of how much important the sentence is. Once the similarity graph is

[4]http://www.cs.ualberta.ca/ lindek/downloads.htm

constructed, the sentences are then ranked according to their eigenvector centrality. To apply LexRank to query-focused context, a topic-sensitive version of LexRank is proposed in (Otterbacher et al., 2005). We followed a similar approach in order to calculate this feature. The score of a sentence is determined by a mixture model of the relevance of the sentence to the query and the similarity of the sentence to other high-scoring sentences.

3.5 Syntactic and Semantic Features:

So far, we have included the features of type Bag of Words (BOW). The task like *query-based summarization* that requires the use of more complex syntactic and semantics, the approaches with only BOW are often inadequate to perform fine-level textual analysis. We extracted three features that incorporate syntactic/semantic information.

3.5.1 Basic Element (BE) Overlap Measure

The "head-modifier-relation" triples, extracted from the dependency trees are considered as BEs in our experiment. The triples encode some syntactic/semantic information and one can quite easily decide whether any two units match or not- considerably more easily than with longer units (Zhou et al., 2005). We used the BE package distributed by ISI[5] to extract the BEs for the sentences.

Once we get the BEs for a sentence, we computed the Likelihood Ratio (LR) for each BE following (Zhou et al., 2005). Sorting BEs according to their LR scores produced a BE-ranked list. Our goal is to generate a summary that will answer the user questions. The ranked list of BEs in this way contains important BEs at the top which may or may not be relevant to the user questions. We filter those BEs by checking whether they contain any word which is a *query word* or a *QueryRelatedWords* (defined in Section 3.2). The score of a sentence is the sum of its BE scores divided by the number of BEs in the sentence.

3.5.2 Syntactic Feature

Encoding syntactic structure is easier and straight forward. Given a sentence (or query), we first parse it into a syntactic tree using a syntactic parser (i.e. Charniak parser) and then we calculate the similarity between the two trees using the *tree kernel* defined in (Collins and Duffy, 2001).

3.5.3 Shallow-semantic Feature

Though introducing BE and syntactic information gives an improvement on BOW by the use of dependency/syntactic parses, but these, too are not adequate when dealing with complex questions whose answers are expressed by long and articulated sentences or even paragraphs. Shallow semantic representations, bearing a more compact information, could prevent the sparseness of deep structural approaches and the weakness of BOW models (Moschitti et al., 2007).

[5]BE website:http://www.isi.edu/ cyl/BE

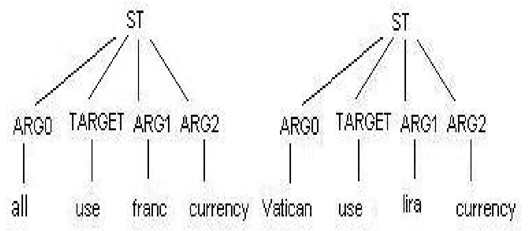

Figure 1: Example of semantic trees

Initiatives such as PropBank (PB) (Kingsbury and Palmer, 2002) have made possible the design of accurate automatic Semantic Role Labeling (SRL) systems like ASSERT (Hacioglu et al., 2003). For example, consider the PB annotation:

[ARG0 all][TARGET use][ARG1 the french franc][ARG2 as their currency]

Such annotation can be used to design a shallow semantic representation that can be matched against other semantically similar sentences, e.g.

[ARG0 the Vatican][TARGET use][ARG1 the Italian lira][ARG2 as their currency]

In order to calculate the semantic similarity between the sentences, we first represent the annotated sentence using the tree structures like Figure 1 which we call Semantic Tree (ST). In the semantic tree, arguments are replaced with the most important word-often referred to as the semantic head.

The sentences may contain one or more subordinate clauses. For example the sentence, "the Vatican, located wholly within Italy uses the Italian lira as their currency." gives the STs as in Figure 2. As we can see in Figure 2(A), when an argument node corresponds to an entire subordinate clause, we label its leaf with ST, e.g. the leaf of ARG0. Such ST node is actually the root of the subordinate clause in Figure 2(B). If taken separately, such STs do not express the whole meaning of the sentence, hence it is more accurate to define a single structure encoding the dependency between the two predicates as in Figure 2(C). We refer to this kind of nested STs as STNs.

Note that, the tree kernel (TK) function defined in (Collins and Duffy, 2001) computes the number of common subtrees between two trees. Such subtrees are subject to the constraint that their nodes are taken with all or none of the children they have in the original tree.

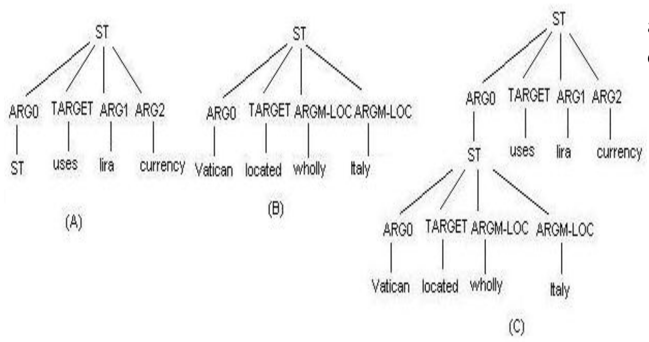

Figure 2: Two STs composing a STN

Though, this definition of subtrees makes the TK function appropriate for syntactic trees but at the same time makes it not well suited for the semantic trees (ST) defined above. For instance, although the two STs of Figure 1 share most of the subtrees rooted in the *ST* node, the kernel defined above computes only one match (ST ARG0 TARGET ARG1 ARG2) which is not useful.

The critical aspect of the TK function is that the productions of two evaluated nodes have to be identical to allow the match of further descendants. This means that common substructures cannot be composed by a node with only some of its children as an effective ST representation would require. (Moschitti et al., 2007) solve this problem by designing the Shallow Semantic Tree Kernel (SSTK) which allows to match portions of a ST. We followed the similar approach to compute the SSTK.

4 Ranking Sentences

In this section, we describe the scoring techniques in detail.

4.1 Learning Feature-weights: A Local Search Strategy

In order to fine-tune the weights of the features, we used a local search technique with simulated annealing to find the global maximum. Initially, we set all the feature-weights, $w_1, \cdots, w_n$, as equal values (i.e. 0.5) (see Algorithm 1). Based on the current weights we score the sentences and generate summaries accordingly. We evaluate the summaries using the automatic evaluation tool ROUGE (Lin, 2004) (described in Section 6) and the ROUGE value works as the feedback to our learning loop. Our learning system tries to maximize the ROUGE score in every step by changing the weights individually by a specific step size (i.e. 0.01). That means, to learn weight w_i, we change the value of w_i keeping all other weight values ($w_j \forall_{j \neq i}$) stagnant. For each weight w_i, the algorithm achieves the local maximum of ROUGE value. In order to find the global maximum we ran this algorithm multiple times with different random choices of initial values (i.e. simulated annealing).

```
**Input**: Stepsize $l$, Weight Initial Value $v$
**Output**: A vector $\vec{w}$ of learned weights
Initialize the weight values $w_i$ to $v$.
**for** $i \leftarrow 1 \; to \; n$ **do**
    $rg1 = rg2 = prev = 0$
    **while** *(true)* **do**
        scoreSentences($\vec{w}$)
        generateSummaries()
        $rg2$ = evaluateROUGE()
        **if** $rg1 \leq rg2$ **then**
            prev = $w_i$
            $w_i + = l$
            $rg1 = rg2$
        **else**
            break
        **end**
    **end**
**end**
return $\vec{w}$
```

Algorithm 1: Tuning weights using Local Search technique

Once we have learned the feature-weights, our *empirical* method computes the final scores for the sentences using the formula:

$$score_i = \vec{x_i}.\vec{w} \quad (1)$$

Where, $\vec{x_i}$ is the feature vector for i-th sentence, $\vec{w}$ is the weight vector and $score_i$ is the score of i-th sentence.

4.2 K-means Learning

We start with a set of initial cluster centers and go through several iterations of assigning each object to the cluster whose center is closest. After all objects have been assigned, we recompute the center of each cluster as the centroid or mean (μ) of its members.

Once we have learned the means of the clusters using the k-means algorithm, our next task is to rank the sentences according to a probability model. We have used Bayesian model in order to do so. Bayes' law says:

$$P(q_k|\vec{x}, \Theta) = \frac{p(\vec{x}|q_k, \Theta)P(q_k|\Theta)}{\sum_{k=1}^{K} p(\vec{x}|q_k, \Theta)p(q_k|\Theta)} \quad (2)$$

where q_k is a class, $\vec{x}$ is a feature vector representing a sentence and Θ is the parameter set of all class models. We set the weights of the clusters as equiprobable (i.e. $P(q_k|\Theta) = 1/K$). We calculated

$p(x|q_k, \Theta)$ using the gaussian probability distribution. The gaussian probability density function (pdf) for the d-dimensional random variable $\vec{x}$ is given by:

$$p_{(\mu,\Sigma)}(\vec{x}) = \frac{e^{\frac{-1}{2}(\vec{x}-\mu)^T \Sigma^{-1}(\vec{x}-\mu)}}{\sqrt{2\pi}^d \sqrt{det(\Sigma)}} \quad (3)$$

where μ, the mean vector and Σ, the covariance matrix are the parameters of the gaussian distribution. We get the means (μ) from the k-means algorithm and we calculate the covariance matrix using the unbiased covariance estimation:

$$\hat{\Sigma} = \frac{1}{N-1} \sum_{i=1}^{N} (x_j - \mu_j)(x_i - \mu_i)^T \quad (4)$$

4.3 EM Learning

EM is an iterative two step procedure: 1. Expectation-step and 2. Maximization-step. In the expectation step, we compute expected values for the hidden variables $h_{i,j}$ which are cluster membership probabilities. Given the current parameters, we compute how likely an object belongs to any of the clusters. The maximization step computes the most likely parameters of the model given the cluster membership probabilities. The data-points are considered to be generated by a mixture model of k-gaussians of the form:

$$P(\vec{x}) = \sum_{i=1}^{k} P(C=i) P(\vec{x}|\mu_i, \Sigma_i) \quad (5)$$

Where the total likelihood of model Θ with k components given the observed data points, $X = x_1, \cdots, x_n$ is:

$$\begin{aligned} L(\Theta|X) &= \prod_{i=1}^{n} \sum_{j=1}^{k} P(C=j) P(x_i|\Theta_j) \\ &= \prod_{i=1}^{n} \sum_{j=1}^{k} w_j P(x_i|\mu_j, \Sigma_j) \\ &\Leftrightarrow \sum_{i=1}^{n} log \sum_{j=1}^{k} w_j P(x_i|\mu_j, \Sigma_j) \end{aligned}$$

where P is the probability density function (i.e. eq 3). μ_j and Σ_j are the mean and covariance matrix of component j, respectively. Each component contributes a proportion, w_j, of the total population, such that: $\sum_{j=1}^{K} w_j = 1$.

However, a significant problem with the EM algorithm is that it converges to a local maximum of the likelihood function and hence the quality of the result depends on the initialization. In order to get good results from using random starting values, we can run the EM algorithm several times and choose the initial configuration for which we get the maximum log likelihood among all configurations. Choosing the best one among several runs is very computer intensive process. So, to improve the outcome of the EM algorithm on gaussian mixture models it is necessary to find a better method of estimating initial means for the components. To achieve this aim we explored the widely used "k-means" algorithm as a cluster (means) finding method. That means, the means found by k-means clustering above will be utilized as the initial means for EM and we calculate the initial covariance matrices using the unbiased covariance estimation procedure (eq:4).

Once the sentences are clustered by EM algorithm, we filter out the sentences which are not query-relevant by checking their probabilities, $P(q_r|x_i, \Theta)$ where, q_r denotes the cluster "query-relevant". If for a sentence x_i, $P(q_r|x_i, \Theta) > 0.5$ then x_i is considered to be query-relevant.

Our next task is to rank the query-relevant sentences in order to include them in the summary. This can be done easily by multiplying the feature vector $\vec{x_i}$ with the weight vector $\vec{w}$ that we learned by the local search technique (eq:1).

5 Redundancy Checking

When many of the competing sentences are included in the summary, the issue of information overlap between parts of the output comes up, and a mechanism for addressing redundancy is needed. Therefore, our summarization systems employ a final level of analysis: before being added to the final output, the sentences deemed to be important are compared to each other and only those that are not too similar to other candidates are included in the final answer or summary. Following (Zhou et al., 2005), we modeled this by BE overlap between an intermediate summary and a to-be-added candidate summary sentence. We call this overlap ratio R, where R is between 0 and 1 inclusively. Setting $R = 0.7$ means that a candidate summary sentence, s, can be added to an intermediate summary, S, if the sentence has a BE overlap ratio less than or equal to 0.7.

6 Experimental Evaluation

6.1 Evaluation Setup

We used the main task of Document Understanding Conference (DUC) 2007 for evaluation. The task was: *"Given a complex question (topic description) and a collection of relevant documents, the task is to synthesize a fluent, well-organized 250-word summary of the documents that answers the question(s) in the topic."*

NIST assessors developed topics of interest to them and choose a set of 25 documents relevant (document cluster) to each topic. Each topic and its document cluster were given to 4 different NIST assessors. The assessor created a 250-word summary of the document cluster that satisfies the information need expressed in the topic statement. These multiple "reference summaries" are used in the evaluation of summary content.

We carried out automatic evaluation of our summaries using ROUGE (Lin, 2004) toolkit, which has been widely adopted by DUC for automatic summarization evaluation. It measures summary quality by counting overlapping units such as the n-grams (ROUGE-N), word sequences (ROUGE-L and ROUGE-W) and word pairs (ROUGE-S and ROUGE-SU) between the candidate summary and the reference summary. ROUGE parameters were set as the same as DUC 2007 evaluation setup.

One purpose of our experiments is to study the impact of different features for complex question answering task. To accomplish this, we generated summaries for the topics of DUC 2007 by each of our seven systems defined as below:

The **LEX** system generates summaries based on only lexical features: n-gram (n=1,2,3,4), LCS, WLCS, skip bi-gram, head, head synonym. The **LSEM** system considers only lexical semantic features: synonym, hypernym/hyponym, gloss, dependency-based and proximity-based similarity. The **COS** system generates summary based on the graph-based method. The **SYS1** system considers all the features except the BE, syntactic and semantic features. The **SYS2** system considers all the features except the syntactic and semantic features. The **SYS3** considers all the features except the semantic and the **ALL**[6] system generates summaries taking all the features into account.

6.2 Evaluation Results

Table 1[7] to Table 3, Table 4 to Table 6 and Table 7 to Table 9 show the evaluation measures for k-means, EM and empirical approaches respectively. As Table 1 shows, in k-means, SYS2 gets 0-21%, SYS3 gets 4-32% and ALL gets 3-36% improvement in *ROUGE-2* scores over the SYS1 system. We get best *ROUGE-W* (Table 2) scores for SYS2 (i.e. including BE) but SYS3 and ALL do not perform well in this case. SYS2 improves the ROUGE-W F-score by 1% over SYS1. We do not get any improvement in *ROUGE-SU* (Table 3) scores when we include any kind of syntactic/semantic structures.

The case is different for EM and empirical approaches. Here, in every case we get a significant amount of improvement when we include the syntactic and/or semantic features. For EM (Table 4 to Table 6), the ratio of improvement in F-scores over SYS1 is: 1-3% for SYS2, 3-15% for SYS3 and 2-24% for ALL. In our empirical approach (Table 7 to Table 9), SYS2, SYS3 and ALL improve the F-scores by 3-11%, 7-15% and 8-19% over SYS1 respectively. These results clearly indicate the positive impact of the syntactic/semantic features for complex question answering task.

Table 9: ROUGE-SU in empirical approach

ates summaries by returning all the leading sentences (up to 250 words) in the $\langle TEXT \rangle$ field of the most recent document(s). It shows that the empirical approach outperforms the other two learning techniques and EM performs better than k-means algorithm. EM improves the F-scores over k-means by 0.7-22.5%. Empirical approach improves the F-scores over k-means and EM by 5.9-20.2% and 3.5-6.5% respectively. Comparing with the DUC 2007 participants our systems achieve top scores and for some ROUGE measures there is no statistically significant difference between our system and the best DUC 2007 system.

Empirical	0.413	0.107	0.148	0.170

Table 10: F-measures for different systems

7 Conclusion and Future Work

Our experiments show the following: (a) our approaches achieve promising results, (b) empirical approach outperforms the other two learning and EM performs better than the k-means algorithm for this particular task, and (c) our systems achieve better results when we include BE, syntactic and semantic features.

In future, we have the plan to decompose the complex questions into several simple questions before measuring the similarity between the document sentence and the query sentence. We expect that by decomposing complex questions into the sets of subquestions that they entail, systems can improve the average quality of answers returned and achieve better coverage for the question as a whole.

Sampling Alignment Structure under a Bayesian Translation Model

John DeNero, Alexandre Bouchard-Côté and Dan Klein

Abstract

We describe the first tractable Gibbs sampling procedure for estimating phrase pair frequencies under a probabilistic model of phrase alignment. We propose and evaluate two nonparametric priors that successfully avoid the degenerate behavior noted in previous work, where overly large phrases memorize the training data. Phrase table weights learned under our model yield an increase in BLEU score over the word-alignment based heuristic estimates used regularly in phrase-based translation systems.

1 Introduction

In phrase-based translation, statistical knowledge of translation equivalence is primarily captured by counts of how frequently various phrase pairs occur in training bitexts. Since bitexts do not come segmented and aligned into phrase pairs, these counts are typically gathered by fixing a word alignment and applying phrase extraction heuristics to this word-aligned training corpus. Alternatively, phrase pair frequencies can be learned via a probabilistic model of phrase alignment, but this approach has presented several practical challenges.

In this paper, we address the two most significant challenges in phrase alignment modeling. The first challenge is with inference: computing alignment expectations under general phrase models is #P-hard (DeNero and Klein, 2008). Previous phrase alignment work has sacrificed consistency for efficiency, employing greedy hill-climbing algorithms and constraining inference with word alignments (Marcu and Wong, 2002; DeNero et al., 2006; Birch et al., 2006). We describe a Gibbs sampler that consistently and efficiently approximates expectations, using only polynomial-time computable operators. Despite the combinatorial complexity of the phrase alignment space, our sampled phrase pair expectations are guaranteed to converge to the true posterior distributions under the model (in theory) and do converge to effective values (in practice).

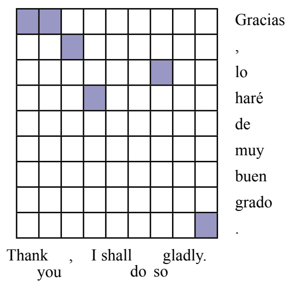
The second challenge in learning phrase alignments is avoiding a degenerate behavior of the general model class: as with many models which can choose between large and small structures, the larger structures win out in maximum likelihood estimation. Indeed, the maximum likelihood estimate of a joint phrase alignment model analyzes each sentence pair as one large phrase with no internal structure (Marcu and Wong, 2002). We describe two nonparametric priors that empirically avoid this degenerate solution.

Fixed word alignments are used in virtually every statistical machine translation system, if not to extract phrase pairs or rules directly, then at least to constrain the inference procedure for higher-level models. We estimate phrase translation features consistently using an inference procedure that is not constrained by word alignments, or any other heuristic. Despite this substantial change in approach, we report translation improvements over the standard word-alignment-based heuristic estimates of phrase table weights. We view this result as an important step toward building fully model-based translation systems that rely on fewer procedural heuristics.

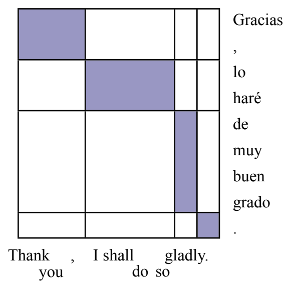
2 Phrase Alignment Model

While state-of-the-art phrase-based translation systems include an increasing number of features, translation behavior is largely driven by the phrase pair count ratios $\phi(e|f)$ and $\phi(f|e)$. These features are typically estimated heuristically using the counts $c(\langle e, f\rangle)$ of all phrase pairs in a training corpus that are licensed by word alignments:

$$\phi(e|f) = \frac{c(\langle e, f\rangle)}{\sum_{e'} c(\langle e', f\rangle)} \quad .$$



(a) example word alignment



(b) example phrase alignment

Figure 1: In this corpus example, the phrase alignment model found the non-literal translation pair $\langle$*gladly, de muy buen grado*$\rangle$ while heuristically-combined word alignment models did not. (a) is a *grow-diag-final-and* combined IBM Model 4 word alignment; (b) is a phrase alignment under our model.

In contrast, a generative model that explicitly aligns pairs of phrases $\langle e, f\rangle$ gives us well-founded alternatives for estimating phrase pair scores. For instance, we could use the model's parameters as translation features. In this paper, we compute the expected counts of phrase pairs in the training data according to our model, and derive features from these expected counts. This approach endows phrase pair scores with well-defined semantics relative to a probabilistic model. Practically, phrase models can discover high-quality phrase pairs that often elude heuristics, as in Figure 1. In addition, the model-based approach fits neatly into the framework of statistical learning theory for unsupervised problems.

2.1 Generative Model Description

We first describe the symmetric joint model of Marcu and Wong (2002), which we will extend. A two-step generative process constructs an ordered set of English phrases $e_{1:m}$, an ordered set of foreign phrases $f_{1:n}$, and a phrase-to-phrase alignment between them, $\mathbf{a} = \{(j, k)\}$ indicating that $\langle e_j, f_k\rangle$ is an aligned pair.

1. Choose a number of components ℓ and generate each of ℓ phrase pairs independently.

2. Choose an ordering for the phrases in the foreign language; the ordering for English is fixed by the generation order.[1]

[1]We choose the foreign to reorder without loss of generality.

In this process, $m = n = |\mathbf{a}|$; all phrases in both sentences are aligned one-to-one.

We parameterize the choice of ℓ using a geometric distribution, denoted P_{G}, with stop parameter $p_{\$}$:

$$P(\ell) = P_{\text{G}}(\ell; p_{\$}) = p_{\$} \cdot (1 - p_{\$})^{\ell-1} \ .$$

Each aligned phrase pair $\langle e, f\rangle$ is drawn from a multinomial distribution θ_{J} which is unknown. We fix a simple distortion model, setting the probability of a permutation of the foreign phrases proportional to the product of position-based distortion penalties for each phrase:

$$\begin{aligned} P(\mathbf{a}|\{\langle e, f\rangle\}) &\propto \prod_{a \in \mathbf{a}} \delta(a) \\ \delta(a = (j, k)) &= b^{|pos(e_j) - pos(f_k) \cdot s|} \ , \end{aligned}$$

where $pos(\cdot)$ denotes the word position of the start of a phrase, and s the ratio of the length of the English to the length of the foreign sentence. This positional distortion model was deemed to work best by Marcu and Wong (2002).

We can now state the joint probability for a phrase-aligned sentence consisting of ℓ phrase pairs:

$$P(\{\langle e, f\rangle\}, \mathbf{a}) = P_{\text{G}}(\ell; p_{\$}) P(\mathbf{a}|\{\langle e, f\rangle\}) \prod_{\langle e, f\rangle} \theta_{\text{J}}(\langle e, f\rangle) \ .$$

While this model has several free parameters in addition to θ_{J}, we fix them to reasonable values to focus learning on the phrase pair distribution.[2]

2.2 Unaligned Phrases

Sentence pairs do not always contain equal information on both sides, and so we revise the generative story to include unaligned phrases in both sentences. When generating each component of a sentence pair, we first decide whether to generate an aligned phrase pair or, with probability $p_{\o}$, an unaligned phrase.[3] Then, we either generate an aligned phrase pair from θ_{J} or an unaligned phrase from θ_{N}, where θ_{N} is a multinomial over phrases. Now, when generating $e_{1:m}$, $f_{1:n}$ and alignment $\mathbf{a}$, the number of phrases $m + n$ can be greater than $2 \cdot |\mathbf{a}|$.

[2]Parameters were chosen by hand during development on a small training corpus. $p_{\$} = 0.1, b = 0.85$ in experiments.

[3]We strongly discouraged unaligned phrases in order to align as much of the corpus as possible: $p_{\o} = 10^{-10}$ in experiments.

To unify notation, we denote unaligned phrases as phrase pairs with one side equal to *null*: $\langle e, null\rangle$ or $\langle null, f\rangle$. Then, the revised model takes the form:

$$\begin{aligned} P(\{\langle e,f\rangle\},\mathbf{a}) &= P_{\mathrm{G}}(\ell; p_{\$})P(\mathbf{a}|\{\langle e,f\rangle\})\prod_{\langle e,f\rangle} P_{\mathrm{M}}(\langle e,f\rangle) \\ P_{\mathrm{M}}(\langle e,f\rangle) &= p_{\o}\theta_{\mathrm{N}}(\langle e,f\rangle) + (1-p_{\o})\theta_{\mathrm{J}}(\langle e,f\rangle)\,. \end{aligned}$$

In this definition, the distribution θ_{N} gives non-zero weight only to unaligned phrases of the form $\langle e, null\rangle$ or $\langle null, f\rangle$, while θ_{J} gives non-zero weight only to aligned phrase pairs.

3 Model Training and Expectations

Our model involves observed sentence pairs, which in aggregate we can call x, latent phrase segmentations and alignments, which we can call z, and parameters θ_{J} and θ_{N}, which together we can call θ. A model such as ours could be used either for the learning of the key phrase pair parameters in θ, or to compute expected counts of phrase pairs in our data. These two uses are very closely related, but we focus on the computation of phrase pair expectations. For exposition purposes, we describe a Gibbs sampling algorithm for computing expected counts of phrases under $P(z|x, \theta)$ for fixed θ. Such expectations would be used, for example, to compute maximum likelihood estimates in the E-step of EM. In Section 4, we instead compute expectations under $P(z|x)$, with θ marginalized out entirely.

In a Gibbs sampler, we start with a *complete* phrase segmentation and alignment, state z_0, which sets all latent variables to some initial configuration. We then produce a sequence of sample states z_i, each of which differs from the last by some small local change. The samples z_i are guaranteed (in the limit) to consistently approximate the conditional distribution $P(z|x, \theta)$ (or $P(z|x)$ later). Therefore, the average counts of phrase pairs in the samples converge to expected counts under the model. Normalizing these expected counts yields estimates for the features $\phi(e|f)$ and $\phi(f|e)$.

Gibbs sampling is not new to the natural language processing community (Teh, 2006; Johnson et al., 2007). However, it is usually used as a search procedure akin to simulated annealing, rather than for approximating expectations (Goldwater et al., 2006; Finkel et al., 2007). Our application is also atypical for an NLP application in that we use an approximate sampler not only to include Bayesian prior information (section 4), but also because computing phrase alignment expectations exactly is a #P-hard problem (DeNero and Klein, 2008). That is, we could not run EM exactly, even if we wanted maximum likelihood estimates.

3.1 Related Work

Expected phrase pair counts under $P(z|x, \theta)$ have been approximated before in order to run EM. Marcu and Wong (2002) employed local search from a heuristic initialization and collected alignment counts during a hill climb through the alignment space. DeNero et al. (2006) instead proposed an exponential-time dynamic program pruned using word alignments. Subsequent work has relied heavily on word alignments to constrain inference, even under reordering models that admit polynomial-time E-steps (Cherry and Lin, 2007; Zhang et al., 2008).

None of these approximations are consistent, and they offer no method of measuring their biases. Gibbs sampling is not only consistent in the limit, but also allows us to add Bayesian priors conveniently (section 4). Of course, sampling has liabilities as well: we do not know in advance how long we need to run the sampler to approximate the desired expectations "closely enough."

Snyder and Barzilay (2008) describe a Gibbs sampler for a bilingual morphology model very similar in structure to ours. However, the basic sampling step they propose – resampling all segmentations and alignments for a sequence at once – requires a #P-hard computation. While this asymptotic complexity was apparently not prohibitive in the case of morphological alignment, where the sequences are short, it is prohibitive in phrase alignment, where the sentences are often very long.

3.2 Sampling with the SWAP Operator

Our Gibbs sampler repeatedly applies each of five operators to each position in each training sentence pair. Each operator freezes all of the current state z_i except a small local region, determines all the ways that region can be reconfigured, and then chooses a (possibly) slightly different z_{i+1} from among those outcomes according to the conditional probability of each, given the frozen remainder of the state. This frozen region of the state is called a *Markov blanket* (denoted m), and plays a critical role in proving the correctness of the sampler.

The first operator we consider is SWAP, which changes alignments but not segmentations. It freezes the set of phrases, then picks two English phrases e_1 and e_2 (or two foreign phrases, but we focus on the English case). All alignments are frozen except the phrase pairs $\langle e_1, f_1\rangle$ and $\langle e_2, f_2\rangle$. SWAP chooses between keeping $\langle e_1, f_1\rangle$ and $\langle e_2, f_2\rangle$ aligned as they are (outcome o_0), or swapping their alignments to create $\langle e_1, f_2\rangle$ and $\langle e_2, f_1\rangle$ (outcome o_1).

SWAP chooses stochastically in proportion to each outcome's posterior probability: $P(o_0|m, x, \theta)$ and $P(o_1|m, x, \theta)$. Each phrase pair in each outcome contributes to these posteriors the probability of adding a new pair, deciding whether it is null, and generating the phrase pair along with its contribution to the distortion probability. This is all captured in a succinct potential function $\psi(\langle e, f\rangle) =$

$$\begin{cases} (1-p_\$)\,(1-p_\varnothing)\,\theta_\mathrm{J}(\langle e, f\rangle)\,\delta(\langle e, f\rangle) & e \,\&\, f \text{ non-}\mathit{null} \\ (1-p_\$)\cdot p_\varnothing \cdot \theta_\mathrm{N}(\langle e, f\rangle) & \text{otherwise} \end{cases}$$

.

Thus, outcome o_0 is chosen with probability $P(o_0|m, x, \theta) =$

$$\frac{\psi(\langle e_1, f_1\rangle)\psi(\langle e_2, f_2\rangle)}{\psi(\langle e_1, f_1\rangle)\psi(\langle e_2, f_2\rangle) + \psi(\langle e_1, f_2\rangle)\psi(\langle e_2, f_1\rangle)}.$$

Operators in a Gibbs sampler require certain conditions to guarantee the correctness of the sampler. First, they must choose among *all possible configurations* of the unfrozen local state. Second, immediately re-applying the operator from any outcome must yield the same set of outcome options as before.[4] If these conditions are not met, the sampler may no longer be guaranteed to yield consistent approximations of the posterior distribution.

A subtle issue arises with SWAP as defined: should it also consider an outcome o_2 of $\langle e_1, \mathit{null}\rangle$ and $\langle e_2, \mathit{null}\rangle$ that removes alignments? No part of the frozen state is changed by removing these alignments, so the first Gibbs condition dictates that we must include o_2. However, after choosing o_2, when we reapply the operator to positions e_1 and e_2, we freeze all alignments except $\langle e_1, \mathit{null}\rangle$ and $\langle e_2, \mathit{null}\rangle$, which prevents us from returning to o_0. Thus, we fail to satisfy the second condition. This point is worth emphasizing because some prior work has treated Gibbs sampling as randomized search and, intentionally or otherwise, proposed inconsistent operators.

[4]These are two sufficient conditions to guarantee that the Metropolis-Hastings acceptance ratio of the sampling step is 1.

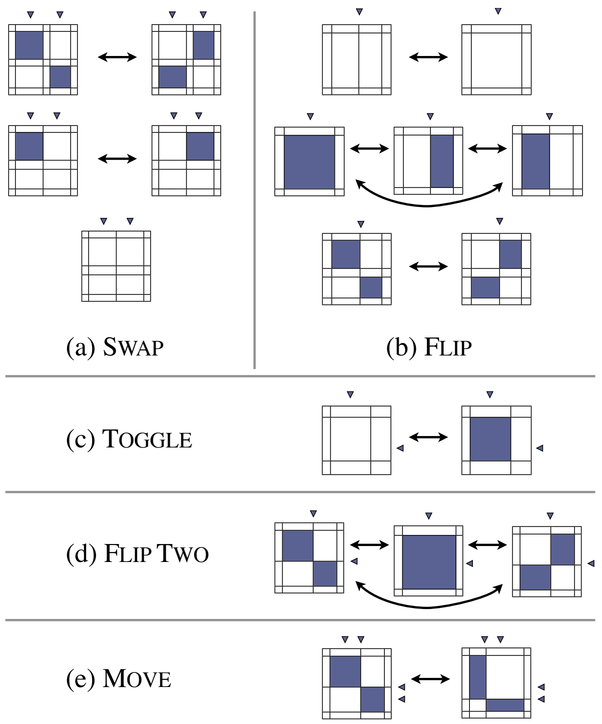


Figure 2: Each local operator manipulates a small portion of a single alignment. Relevant phrases are exaggerated for clarity. The outcome sets (depicted by arrows) of each possible configuration are fully connected. Certain configurations cannot be altered by certain operators, such as the final configuration in SWAP. Unalterable configurations for TOGGLE have been omitted for space.

Luckily, the problem is not with SWAP, but with our justification of it: we can salvage SWAP by augmenting its Markov blanket. Given that we have selected $\langle e_1, f_1\rangle$ and $\langle e_2, f_2\rangle$, we not only freeze all other alignments and phrase boundaries, but also the number of aligned phrase pairs. With this count held invariant, o_2 is not among the possible outcomes of SWAP given m. Moreover, regardless of the outcome chosen, SWAP can immediately be reapplied at the same location with the same set of outcomes.

All the possible starting configurations and outcome sets for SWAP appear in Figure 2(a).

Figure 3: The three steps involved in applying the FLIP operator. The Markov blanket freezes all segmentations except English position 1 and all alignments except those for *Ellos* and *The boys*. The blanket also freezes the number of alignments, which disallows the lower right outcome.

3.3 The FLIP operator

SWAP can arbitrarily shuffle alignments, but we need a second operator to change the actual phrase boundaries. The FLIP operator changes the status of a single *segmentation position*[5] to be either a phrase boundary or not. In this sense FLIP is a bilingual analog of the segmentation boundary flipping operator of Goldwater et al. (2006).

Figure 3 diagrams the operator and its Markov blanket. First, FLIP chooses any between-word position in either sentence. The outcome sets for FLIP vary based on the current segmentation and adjacent alignments, and are depicted in Figure 2.

Again, for FLIP to satisfy the Gibbs conditions, we must augment its Markov blanket to freeze not only all other segmentation points and alignments, but also the number of aligned phrase pairs. Otherwise, we end up allowing outcomes from which we cannot return to the original state by reapplying FLIP. Consequently, when a position is already segmented and both adjacent phrases are currently aligned, FLIP cannot unsegment the point because it can't create two aligned phrase pairs with the one larger phrase that results (see bottom of Figure 2(b)).

[5]A segmentation position is a position between two words that is also potentially a boundary between two phrases in an aligned sentence pair.

3.4 The TOGGLE operator

Both SWAP and FLIP freeze the number of alignments in a sentence. The TOGGLE operator, on the other hand, can add or remove individual alignment links. In TOGGLE, we first choose an e_1 and f_1. If $\langle e_1, f_1 \rangle \in \mathbf{a}$ or both e_1 and f_1 are *null*, we freeze all segmentations and the rest of the alignments, and choose between including $\langle e_1, f_1 \rangle$ in the alignment or leaving both e_1 and f_1 unaligned. If only one of e_1 and f_1 are aligned, or they are not aligned to each other, then TOGGLE does nothing.

3.5 A Complete Sampler

Together, FLIP, SWAP and TOGGLE constitute a complete Gibbs sampler that consistently samples from the posterior $P(z|x, \theta)$. Not only are these operators valid Gibbs steps, but they also can form a path of positive probability from any source state to any target state in the space of phrase alignments (formally, the induced Markov chain is *irreducible*). Such a path can at worst be constructed by unaligning all phrases in the source state with TOGGLE, composing applications of FLIP to match the target phrase boundaries, then applying TOGGLE to match the target alignments.

We include two more local operators to speed up the rate at which the sampler explores the hypothesis space. In short, FLIP TWO simultaneously flips an English and a foreign segmentation point (to make a large phrase out of two smaller ones or vice versa), while MOVE shifts an aligned phrase boundary to the left or right. We omit details for lack of space.

3.6 Phrase Pair Count Estimation

With our sampling procedure in place, we can now estimate the expected number of times a given phrase pair occurs in our data, for fixed θ, using a Monte-Carlo average,

$$\frac{1}{N} \sum_{i=1}^{N} \text{count}_{\langle e,f \rangle}(x, z_i) \xrightarrow{a.s.} \mathbb{E}\left[\text{count}_{\langle e,f \rangle}(x, \cdot)\right] \quad .$$

The left hand side is simple to compute; we count aligned phrase pairs in each sample we generate. In practice, we only count phrase pairs after applying every operator to every position in every sentence (one iteration).[6] Appropriate normalizations of these expected counts can be used either in an M-step as maximum likelihood estimates, or to compute values for features $\phi(f|e)$ and $\phi(e|f)$.

4 Nonparametric Bayesian Priors

The Gibbs sampler we presented addresses the inference challenges of learning phrase alignment models. With slight modifications, it also enables us to include prior information into the model. In this section, we treat θ as a random variable and shape its prior distribution in order to correct the well-known degenerate behavior of the model.

4.1 Model Degeneracy

The structure of our joint model penalizes explanations that use many small phrase pairs. Each phrase pair token incurs the additional expense of generation and distortion. In fact, the maximum likelihood estimate of the model puts mass on $\langle e, f\rangle$ pairs that span entire sentences, explaining the training corpus with one phrase pair per sentence.

Previous phrase alignment work has primarily mitigated this tendency by constraining the *inference procedure*, for example with word alignments and linguistic features (Birch et al., 2006), or by disallowing large phrase pairs using a non-compositional constraint (Cherry and Lin, 2007; Zhang et al., 2008). However, the problem lies with the model, and therefore should be corrected in the model, rather than the inference procedure.

Model-based solutions appear in the literature as well, though typically combined with word alignment constraints on inference. A sparse Dirichlet prior coupled with variational EM was explored by Zhang et al. (2008), but it did not avoid the degenerate solution. Moore and Quirk (2007) proposed a new conditional model structure that does not cause large and small phrases to compete for probability mass. May and Knight (2007) added additional model terms to balance the cost of long and short derivations in a syntactic alignment model.

[6]For experiments, we ran the sampler for 100 iterations.

4.2 A Dirichlet Process Prior

We control this degenerate behavior by placing a Dirichlet process (DP) prior over θ_{J}, the distribution over aligned phrase pairs (Ferguson, 1973).

If we were to assume a maximum number K of phrase pair types, a (finite) Dirichlet distribution would be an appropriate prior. A draw from a K-dimensional Dirichlet distribution is a list of K real numbers in $[0, 1]$ that sum to one, which can be interpreted as a distribution over K phrase pair types.

However, since the event space of possible phrase pairs is in principle unbounded, we instead use a Dirichlet process. A draw from a DP is a *countably infinite* list of real numbers in $[0, 1]$ that sum to one, which we interpret as a distribution over a countably infinite list of phrase pair types.[7]

The Dirichlet distribution and the DP distribution have similar parameterizations. A K-dimensional Dirichlet can be parameterized with a *concentration parameter* $\alpha > 0$ and a *base distribution* $M_0 = (\mu_1, \ldots, \mu_{K-1})$, with $\mu_i \in (0, 1)$.[8] This parameterization has an intuitive interpretation: under these parameters, the average of independent samples from the Dirichlet will converge to M_0. That is, the average of the ith element of the samples will converge to μ_i. Hence, the base distribution M_0 characterizes the sample mean. The concentration parameter α only affects the variance of the draws.

Similarly, we can parameterize the Dirichlet process with a concentration parameter α (that affects only the variance) and a base distribution M_0 that determines the mean of the samples. Just as in the finite Dirichlet case, M_0 is simply a probability distribution, but now with countably infinite support: all possible phrase pairs in our case. In practice, we can use an unnormalized M_0 (a base measure) by appropriately rescaling α.

In our model, we select a base measure that strongly prefers shorter phrases, encouraging the model to use large phrases only when it has sufficient evidence for them. We continue the model:

[7]Technical note: to simplify exposition, we restrict the discussion to settings such as ours where the base measure of the DP has countable support.

[8]This parametrization is equivalent to the standard pseudo-counts parametrization of K positive real numbers. The bijection is given by $\alpha = \sum_{i=1}^{K} \tilde{\alpha}_i$ and $\mu_i = \tilde{\alpha}_i/\alpha$, where $(\tilde{\alpha}_1, \ldots, \tilde{\alpha}_K)$ are the pseudo-counts.

$$\begin{aligned}
\theta_{\mathrm{J}} &\sim DP(M_0, \alpha) \\
M_0(\langle e, f\rangle) &= [P_f(f) P_{\mathrm{WA}}(e|f) \cdot P_e(e) P_{\mathrm{WA}}(f|e)]^{\frac{1}{2}} \\
P_f(f) &= P_{\mathrm{G}}(|f|; p_s) \cdot \left(\frac{1}{n_f}\right)^{|f|} \\
P_e(e) &= P_{\mathrm{G}}(|e|; p_s) \cdot \left(\frac{1}{n_e}\right)^{|e|} .
\end{aligned}$$

.

P_{WA} is the IBM model 1 likelihood of one phrase conditioned on the other (Brown et al., 1994). P_f and P_e are uniform over types for each phrase length: the constants n_f and n_e denote the vocabulary size of the foreign and English languages, respectively, and P_{G} is a geometric distribution.

Above, θ_{J} is drawn from a DP centered on the geometric mean of two joint distributions over phrase pairs, each of which is composed of a monolingual unigram model and a lexical translation component. This prior has two advantages. First, we pressure the model to use smaller phrases by increasing p_s ($p_s = 0.8$ in experiments). Second, we encourage good phrase pairs by incorporating IBM Model 1 distributions. This use of word alignment distributions is notably different from lexical weighting or word alignment constraints: we are supplying prior knowledge that phrases will generally follow word alignments, though with enough corpus evidence they need not (and often do not) do so in the posterior samples. The model proved largely insensitive to changes in the sparsity parameter α, which we set to 100 for experiments.

4.3 Unaligned phrases and the DP Prior

Introducing unaligned phrases invites further degenerate megaphrase behavior: a sentence pair can be generated cheaply as two unaligned phrases that each span an entire sentence. We attempted to place a similar DP prior over θ_{N}, but surprisingly, this modeling choice invoked yet another degenerate behavior. The DP prior imposes a *rich-get-richer* property over the phrase pair distribution, strongly encouraging the model to reuse existing pairs rather than generate new ones. As a result, common words consistently aligned to *null*, even while suitable translations were present, simply because each null alignment reinforced the next. For instance, *the* was always unaligned.

Instead, we fix θ_{N} to a simple unigram model that is uniform over word types. This way, we discourage unaligned phrases while focusing learning on θ_{J}. For simplicity, we reuse $P_f(f)$ and $P_e(e)$ from the prior over θ_{J}.

$$\theta_{\mathrm{N}}(\langle e, f\rangle) = \begin{cases} \frac{1}{2} \cdot P_e(e) & \text{if } f = \mathit{null} \\ \frac{1}{2} \cdot P_f(f) & \text{if } e = \mathit{null} \end{cases} .$$

The $\frac{1}{2}$ represents a choice of whether the aligned phrase is in the foreign or English sentence.

4.4 Collapsed Sampling with a DP Prior

Our entire model now has the general form $P(x, z, \theta_{\mathrm{J}})$; all other model parameters have been fixed. Instead of searching for a suitable θ_{J},[9] we sample from the posterior distribution $P(z|x)$ with θ_{J} marginalized out.

To this end, we convert our Gibbs sampler into a collapsed Gibbs sampler[10] using the Chinese Restaurant Process (CRP) representation of the DP (Aldous, 1985). With the CRP, we avoid the problem of explicitely representing samples from the DP. CRP-based samplers have served the community well in related language tasks, such as word segmentation and coreference resolution (Goldwater et al., 2006; Haghighi and Klein, 2007).

Under this representation, the probability of each sampling outcome is a simple expression in terms of the state of the rest of the training corpus (the Markov blanket), rather than explicitly using θ_{J}.

Let z_m be the set of aligned phrase pair tokens observed in the rest of the corpus. Then, when $\langle e, f\rangle$ is aligned (that is, neither e nor f are *null*), the conditional probability for a pair $\langle e, f\rangle$ takes the form:

$$\tau(\langle e, f\rangle | z_m) = \frac{\mathrm{count}_{\langle e,f\rangle}(z_m) + \alpha \cdot M_0(\langle e, f\rangle)}{|z_m| + \alpha},$$

where $\mathrm{count}_{\langle e,f\rangle}(z_m)$ is the number of times that $\langle e, f\rangle$ appears in z_m. We can write this expression thanks to the exchangeability of the model. For further exposition of this collapsed sampler posterior,

[9] For instance, using approximate MAP EM.

[10] A collapsed sampler is simply one in which the model parameters have been marginalized out.

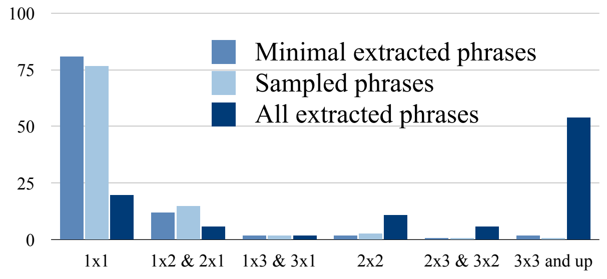

Figure 4: The distribution of phrase pair sizes (denoted *English length* x *foreign length*) favors small phrases under the model.

see Goldwater et al. (2006).[11]

The sampler remains exactly the same as described in Section 3, except that the posterior conditional probability of each outcome uses a revised potential function $\psi_{\text{DP}}(\langle e, f\rangle) =$

$$\begin{cases} (1-p_\$)\ (1-p_\emptyset)\ \tau(\langle e,f\rangle)\ \delta(\langle e,f\rangle) & e\ \&\ f \text{ non-}null \\ (1-p_\$)\cdot p_\emptyset \cdot \theta_{\text{N}}(\langle e,f\rangle) & \text{otherwise} \ . \end{cases}$$

ψ_{DP} is like ψ, but the fixed θ_{J} is replaced with the constantly-updated τ function.

4.5 Degeneracy Analysis

Figure 4 shows a histogram of phrase pair sizes in the distribution of expected counts under the model. As reference, we show the size distribution of both *minimal* and *all* phrase pairs extracted from word alignments using the standard heuristic. Our model tends to select minimal phrases, only using larger phrases when well motivated.[12]

This result alone is important: a model-based solution with no inference constraint has yielded a non-degenerate distribution over phrase lengths. Note that our sampler does find the degenerate solution quickly under a uniform prior, confirming that the model, and not the inference procedure, is selecting these small phrases.

[11]Note that the expression for τ changes slightly under conditions where two phrase pairs being changed simultaneously coincidentally share the same lexical content. Details of these fringe conditions have been omitted for space, but were included in our implementation.

[12]The largest phrase pair found was 13 English words by 7 Spanish words.

4.6 A Hierarchical Dirichlet Process Prior

We also evaluate a hierarchical Dirichlet process (HDP) prior over θ_{J}, which draws monolingual distributions θ_{E} and θ_{F} from a DP and θ_{J} from their cross-product:

$$\begin{aligned} \theta_{\text{J}} &\sim DP(M_0', \alpha) \\ M_0'(\langle e,f\rangle) &= [\theta_{\text{F}}(f) P_{\text{WA}}(e|f)\cdot \theta_{\text{E}}(e) P_{\text{WA}}(f|e)]^{\frac{1}{2}} \\ \theta_{\text{F}} &\sim DP(P_f, \alpha') \\ \theta_{\text{E}} &\sim DP(P_e, \alpha')\ . \end{aligned}$$

This prior encourages novel phrase pairs to be composed of phrases that have been used before. In the sampler, we approximate table counts for θ_{E} and θ_{F} with their expectations, which can be computed from phrase pair counts (see the appendix of Goldwater et al. (2006) for details). The HDP prior gives a similar distribution over phrase sizes.

5 Translation Results

We evaluate our new estimates using the baseline translation pipeline from the 2007 Statistical Machine Translation Workshop shared task.

5.1 Baseline System

We trained Moses on all Spanish-English Europarl sentences up to length 20 (177k sentences) using GIZA++ Model 4 word alignments and the *grow-diag-final-and* combination heuristic (Koehn et al., 2007; Och and Ney, 2003; Koehn, 2002), which performed better than any alternative combination heuristic.[13] The baseline estimates (*Heuristic*) come from extracting phrases up to length 7 from the word alignment. We used a bidirectional lexicalized distortion model that conditions on both foreign and English phrases, along with their orientations. Our 5-gram language model was trained on 38.3 million words of Europarl using Kneser-Ney smoothing. We report results with and without lexical weighting, denoted *lex*.

We tuned and tested on development corpora for the 2006 translation workshop. The parameters for each phrase table were tuned separately using minimum error rate training (Och, 2003). Results are

[13]Sampling iteration time scales quadratically with sentence length. Short sentences were chosen to speed up our experiment cycle.

Estimate	Phrase Pair Count	NIST BLEU	Exact Match METEOR
Heuristic	4.4M	29.8	52.4
DP	0.6M	28.8	51.7
HDP	0.3M	29.1	52.0
DP-composed	3.7M	30.1	52.7
HDP-composed	3.1M	30.1	52.6
DP-smooth	4.8M	30.1	52.5
HDP-smooth	4.6M	**30.2**	**52.7**
Heuristic + lex	4.4M	30.5	52.9
DP-smooth + lex	4.8M	30.4	53.0
HDP-smooth + lex	4.6M	**30.7**	**53.2**

Table 1: BLEU results for learned distributions improve over a heuristic baseline. Estimate labels are described fully in section 5.3. The label *lex* indicates the addition of a lexical weighting feature.

scored with lowercased, tokenized NIST BLEU, and exact match METEOR (Papineni et al., 2002; Lavie and Agarwal, 2007).

The baseline system gives a BLEU score of 29.8, which increases to 30.5 with *lex*, as shown in Table 1. For reference, training on all sentences of length less than 40 (the shared task baseline default) gives 32.4 BLEU with *lex*.

5.2 Learned Distribution Performance

We *initialized* the sampler with a configuration derived from the word alignments generated by the baseline. We greedily constructed a phrase alignment from the word alignment by identifying minimal phrase pairs consistent with the word alignment in each region of the sentence. We then ran the sampler for 100 iterations through the training data. Each iteration required 12 minutes under the DP prior, and 30 minutes under the HDP prior. Total running time for the HDP model neared two days on an eight-processor machine with 16 Gb of RAM.

Estimating phrase counts under the DP prior decreases BLEU to 28.8, or 29.1 under the HDP prior. This gap is not surprising: heuristic extraction discovers many more phrase pairs than sampling. Note that sacrificing only 0.7 BLEU while shrinking the phrase table by 92% is an appealing trade-off in resource-constrained settings.

5.3 Increasing Phrase Pair Coverage

The estimates *DP-composed* and *HDP-composed* in Table 1 take expectations of a more liberal count function. While sampling, we count not only aligned phrase pairs, but also larger ones composed of two or more contiguous aligned pairs. This count function is similar to the phrase pair extraction heuristic, but never includes unaligned phrases in any way. Expectations of these composite phrases still have a probabilistic interpretation, but they are not the structures we are directly modeling. Notably, these estimates outperform the baseline by 0.3 BLEU without ever extracting phrases from word alignments, and performance increases despite a reduction in table size.

We can instead increase coverage by smoothing the learned estimates with the heuristic counts. The estimates *DP-smooth* and *HDP-smooth* add counts extracted from word alignments to the sampler's running totals, which improves performance by 0.4 BLEU over the baseline. This smoothing balances the lower-bias sampler counts with the lower-variance heuristics ones.

6 Conclusion

Our novel Gibbs sampler and nonparametric priors together address two open problems in learning phrase alignment models, approximating inference consistently and efficiently while avoiding degenerate solutions. While improvements are modest relative to the highly developed word-alignment-centered baseline, we show for the first time competitive results from a system that uses word alignments only for model initialization and smoothing, rather than inference and estimation. We view this milestone as critical to eventually developing a clean probabilistic approach to machine translation that unifies model structure across both estimation and decoding, and decreases the use of heuristics.

Abstract

In recent years, with the development of Chinese semantically annotated corpus, such as Chinese Proposition Bank and Normalization Bank, the Chinese semantic role labeling (SRL) task has been boosted. Similar to English, the Chinese SRL can be divided into two tasks: semantic role identification (SRI) and classification (SRC). Many features were introduced into these tasks and promising results were achieved. In this paper, we mainly focus on the second task: SRC. After exploiting the linguistic discrepancy between numbered arguments and ARGMs, we built a semantic role classifier based on a hierarchical feature selection strategy. Different from the previous SRC systems, we divided SRC into three sub tasks in sequence and trained models for each sub task. Under the hierarchical architecture, each argument should first be determined whether it is a numbered argument or an ARGM, and then be classified into fine-gained categories. Finally, we integrated the idea of exploiting argument interdependence into our system and further improved the performance. With the novel method, the classification precision of our system is 94.68%, which outperforms the strong baseline significantly. It is also the state-of-the-art on Chinese SRC.

1 Introduction

Semantic Role labeling (SRL) was first defined in Gildea and Jurafsky (2002). The purpose of SRL task is to identify and classify the semantic roles of each predicate in a sentence. The semantic roles are marked and each of them is assigned a tag which indicates the type of the semantic relation with the related predicate. Typical tags include Agent, Patient, Source, etc. and some adjuncts such as Temporal, Manner, Extent, etc. Since the arguments can provide useful semantic information, the SRL is crucial to many natural language processing tasks, such as Question and Answering (Narayanan and Harabagiu 2004), Information Extraction (Surdeanu et al. 2003), and Machine Translation(Boas 2002). With the efforts of many researchers (Carreras and Màrquez 2004, 2005, Moschitti 2004, Pradhan et al 2005, Zhang et al 2007), different machine learning methods and linguistics resources are applied in this task, which has made SRL task progress fast.

Compared to the research on English, the research on Chinese SRL is still in its infancy stage. Previous work on Chinese SRL mainly focused on how to transplant the machine learning methods which has been successful with English, such as Sun and Jurafsky (2004), Xue and Palmer (2005) and Xue (2008). Sun and Jurafsky (2004) did the preliminary work on Chinese SRL without any large semantically annotated corpus of Chinese. They just labeled the predicate-argument structures of ten specified verbs to a small collection of Chinese sentences, and used Support Vector Machines to identify and classify the arguments. This paper made the first attempt on Chinese SRL and produced promising results. After the PropBank (Xue and Palmer 2003) was built, Xue and Palmer (2005) and Xue (2008) have produced more complete and systematic research on Chinese SRL.

Moschitti et al. (2005) has made some preliminary attempt on the idea of hierarchical semantic role labeling. However, without considerations on how to utilize the characteristics of linguistically similar semantic roles, the purpose of the hierarchical system is to simplify the classification process to make it less time consuming. So the hierarchical system in their paper performs a little worse than the traditional SRL systems, although it is more efficient.

Xue and Palmer (2004) did very encouraging work on the feature calibration of semantic role labeling. They found out that different features suited for different sub tasks of SRL, i.e. semantic role identification and classification. For semantic analysis, developing features that capture the right kind of information is crucial. Experiments on Chinese SRL (Xue and Palmer 2005, Xue 2008) reassured these findings.

In this paper, we mainly focus on the semantic role classification (SRC) process. With the findings about the linguistic discrepancy of different semantic role groups, we try to build a 2-step semantic role classifier with hierarchical feature selection strategy. That means, for different sub tasks, different models will be trained with different features. The purpose of this strategy is to capture the right kind of information of different semantic role groups. It is hard to do manual selection of features since there are too many feature templates which has been proven to be useful in SRC; so, we designed a simple feature selection algorithm to select useful features automatically from a large set of feature templates. With this hierarchical feature selection architecture, our system can outperform previous systems. The selected feature templates for each process of SRC can in turn reassure the existence of the linguistic discrepancy. At last, we also integrate the idea of exploiting argument interdependence to make our system perform better.

The rest of the paper is organized as follows. In section 2, the semantically annotated corpus - Chinese Propbank is discussed. The architecture of our method is described in section 3. The feature selection strategy is discussed in section 4. The settings of experiments can be found in section 5. The results of the experiments can be found in section 6, where we will try to make some linguistic explanations of the selected features. Section 7 is conclusions and future work.

Figure 1. an example from PropBank

2 The Chinese PropBank

The Chinese PropBank has labeled the predicate-argument structures of sentences from the Chinese TreeBank (Xue et al. 2005). It is constituted of two parts. One is the labeled data, which indicates the positions of the predicates and its arguments in the Chinese Treebank. The other is a dictionary which lists the frames of all the labeled predicates. Figure 1 is an example from the PropBank[1]. We put the word-by-word translation and the translation of the whole sentence below the example.

It is quite a complex sentence, as there are many semantic roles in it. In this sentence, all the semantic roles of the verb 提供 (provide) are presented in the syntactic tree. We can separate the semantic roles into two groups.

The first group of semantic roles can be called the core arguments, which capture the core relations. In this sentence, there are three arguments of verb 提供 (provide) in this sentence. 保险公司 (the insurance company) is labeled as ARG0, which is the proto-agent of the verb. Specifically to the verb 提供 (provide), it is the provider. 保险服务 (insurance services) is the direct object of the verb, and it is the proto-patient, which is labeled as ARG1. Specifically to the verb 提供 (provide), it represents things provided. 为三峡工程 (for the Sanxia Project) is another kind of argument, which is labeled as ARG1, and it represents the receiver.

The other group of semantic roles is called adjuncts. They are always used to reveal the peripheral information. There are two adjuncts of the target verb in this sentence: 截止目前 (until recently) and 已 (has), both of which are labeled as ARGM. However, the two ARGMs reveal information of different aspects. Besides the ARGM tags, the secondary tags "TMP" and "ADV" are assigned to the two semantic roles respectively. "TMP" indicates that 截止目前 (until recently) is a modifier representing the temporal information, and "ADV" indicates that 已 (has) is an adverbial modifier.

In the Chinese PropBank, the difference of the two groups is obvious. The core arguments are all labeled with numbers, and they are also called the numbered arguments. The numbers range from 0 to 4 in Chinese PropBank. The adjuncts are labeled with "ARGM".

3 Building a Hierarchical Semantic Role Classifier

In this section, we will discuss the linguistic fundaments of the construction of a hierarchical semantic role classifier. We use "hierarchical" to distinguish our classifier from the previous "flat" ones.

3.1 Linguistic Discrepancy of Different Semantic Role Groups

The purpose of the SRC task is to assign a tag to all the semantic roles which have been identified. The tags include ARG0-4, and 17 kinds of ARGMs (with functional tags). Previous SRC systems treat all the tags equally, and view the SRC as a multi-category classification task. However, we have different opinions of the traditional architecture.

Due to the discussions in section 2, we noticed that the semantic roles can be divided into two groups naturally according to the different kinds of semantic information represented by them. Here we will make some linguistic analysis of the two semantic role groups. Conversely to the process of the syntactic realization of semantic roles, we want to find out what linguistic features make a constituent ARG0 instead of ARG1, or another constituent ARGM-TMP instead of ARGM-ADV, i.e. what features capture the most crucial information of the two groups.

As what we have assumed, the linguistic features which made a syntactic constituent labeled as either one of the core arguments or one of the adjuncts varies greatly. Take the sentence in section 2 as an example, even if the only information we have about the phrase 截止目前 (until now) is that it is an adjunct of the verb, we can almost confirm, no matter where this node takes place in the parsing tree, this constituent will be labeled as ARGM-TMP. 已 (has) is also the same. According to its meaning, the only category can be assigned to it is ARGM-ADV. But, things are quite different to the core argument. In the same sentence, 保险公司 (the insurance company) is a good example. If we limit our observation to the phrase itself, we can hardly assert that it is the ARG0 of the target verb. Only when we extend our observation to the syntactic structure level, find out it is the subject of this sentence, and the voice of the sentence is active, the semantic type of 保险公司 (the insurance company) is finally confirmed. If we have another sentence in which 保险公司 (the insurance company) is not the subject, but rather the object, and the target verb is 开办 (set up), then it will probably be labeled as ARG1.

[1] This sentence is extracted from chtb_082.fid of Chinese PropBank 1.0, and we made some simplifications on it.

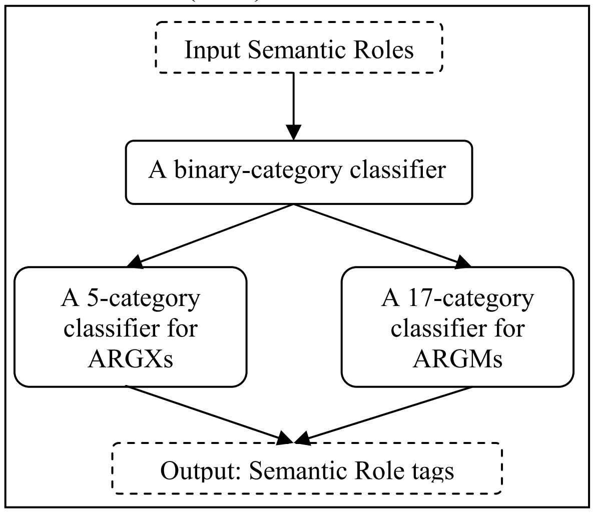
Due to the analysis above, we can conclude the linguistic discrepancy of the two semantic role groups as follows. Core arguments and adjuncts share different kinds of inner linguistic consistency respectively. For the core arguments, the specific type cannot be determined with the information of the arguments only. At this level, the core arguments are dependent on other information except the information about themselves. For example, the information of syntactic structures is crucial to the determination of the types of core arguments, and trivial differences of the syntactic structures will lead to the different output. Because of this, we can say that the core arguments are sensitive to the syntactic structures. Compared to the core arguments, adjuncts are the opposite. They are relatively independent on other information, since most of the adjuncts can be easily classified just based on the information about themselves[2]. And although the positions of the adjuncts in the syntactic structure can vary, the types of the adjuncts are fixed. In this sense, the adjuncts are insensitive to the syntactic structures.

After we made the linguistic discrepancy of the two semantic role groups, we can make a bold assumption that the differences of the two groups can be reflected in the capability of different kinds of features to capture the crucial information for the two groups. For example, the "voice" features seems to be crucial to the core arguments but useless to the adjuncts. This assumption provided us with the idea of a hierarchical feature selection system.

In this system, we first classify the constituents into two classes: core arguments and adjuncts. And then, the system classifies core arguments and adjuncts separately. For different subtasks we only select the most useful features and discard the less pertinent ones. We hope to take utilization of the most crucial features to improve semantic role classification.

3.2 System Architecture

Previous semantic role classifiers always did the classification problem in one-step. However, in this paper, we did SRC in two steps. The architectures of hierarchical semantic role classifiers can be found in figure 2, which is similar with that in Moschitti et al. (2005).



Input Semantic Roles
A binary-category classifier
A 5-category classifier for ARGXs
A 17-category classifier for ARGMs
Output: Semantic Role tags

Figure 2. The architecture of our hierarchical SRC system

As what has been shown in figure 2, a semantic role will first be determined whether it is a numbered argument or an ARGM by a binary-category classifier. And, then if the semantic role is a numbered argument, it will be determined by a 5-category classifier designed for ARGX, i.e. the numbered arguments. If it is an ARGM, the functional tag will be assigned by a 17-category classifier built for ARGMs. Accordingly, with this hierarchical architecture, the SRC problem is divided into 3 sub tasks, each of which has an independent classifier.

3.3 Integrating the Idea of Exploiting Argument Interdependence

Jiang et al. (2005) has built a semantic role classifier exploiting the interdependence of semantic roles. It has turned the single point classification problem into the sequence labeling problem with the introduction of semantic context features. Semantic context features indicates the features extracted from the arguments around the current one. We can use window size to represent the scope of the context. Window size [-m, n] means that, in the sequence that all the arguments has constructed, the features of previous m and following n arguments will be utilized for the classification of current semantic role. There are two kinds of argument sequences in Jiang et al. (2005), and we only test the linear sequence. Take the sentence in figure 1 as an example. The linear sequence of the arguments in this sentence is: 截止目前(until then),

[2] Extra features e.g. predicate may be still useful because that the information, provided by the high-level description of self-descriptive features, e.g. phrase type, are limited.

保险公司 (the insurance company), 已 (has), 为三峡工程 (for the Sanxia Project), 保险服务 (insurance services). For the argument 已 (has), if the semantic context window size is [-1,2], the semantic context features e.g. headword, phrase type and etc. of 保险公司 (the insurance company), 为三峡工程 (for the Sanxia Project) and 保险服务 (insurance services) will be utilized to serve the classification task of 已 (has).

While their paper has improved the SRC performance on English, it also has one potential disadvantage, which is that they didn't separate the core arguments and ARGMs. The influence and explanations of this defect are presented in Section 6. But in our hierarchical system, this problem can be solved. Since in the first step, we have separated the numbered arguments and ARGMs. We suppose that with the separation of the two semantic role groups, the system performance will be further improved.

4 Feature Selection Strategy

Due to what we have discussed in the section 3.1, we need to select different features for the three sub task of SRC. In this paper, we did not make the selection manually; however, we make a simple greedy strategy for feature selection to do it automatically. Although the best solution may not be found, automatic selection of features can try far more combinations of feature templates than manual selection. Because of this, this strategy possibly can produce a better local optional solution.

First, we built a pool of feature templates which has proven to be useful on the SRC. Most of the feature templates are standard, so only the new ones will be explained. The candidate feature templates include:

Voice from Sun and Jurafsky (2004).

Head word POS, Head Word of Prepositional Phrases, Constituent tree distance, from Pradhan etc. (2004).

Position, subcat frame, phrase type, first word, last word, subcat frame+, predicate, path, head word and its POS, predicate + head word, predicate + phrase type, path to BA and BEI, verb class[3]*, verb class + head word, verb class + phrase type,* from Xue (2008).

predicate POS, first word + last word, phrase type of the sibling to the left, phrase type of the sibling to the right, verb + subcate frame+, verb POS + subcat frame+, the amount of VPs in path, phrase type + phrase type of parent node, which can be easily understood by name.

voice position, indicates whether the voice marker (BA, BEI) is before or after the constituent in focus.

subcat frame,* the rule that expands the parent node of the constituent in focus.

subcat frame@, the rule that expands the constituent in focus.

layer of the constituent in focus, the number of constituents in the ascending part of the path subtracted by the number of those in the descending part of path, e.g. if the path is PP-BNF ↑ VP ↓ VP ↓ VV, the feature extracted by this template will be -1.

SemCat (semantic category) of predicate, SemCat of first word, SemCat of head word, SemCat of last word, SemCat of predicate + SemCat of first word, SemCat of predicate + SemCat of last word, predicate + SemCat of head word, SemCat of predicate + head word. The semantic categories of verbs and other words are extracted from the Semantic Knowledge-base of Contemporary Chinese (Wang et al. 2003).

verb AllFrameSets, the combination of all the framesets of a predicate.

verb class + verb AllFrameSets, verb AllFrameSets + head word, verb AllFrameSets + phrase type.

There are more than 40 feature templates, and it is quite difficult to traverse all the possible combinations and get the best one. So we use a greedy algorithm to get an approximate optimal solution.

The feature selection algorithm is as follows. Each time we choose one of the feature templates and add it into the system. The one, after which is added, the performance is the highest, will be chosen. Then we continue to choose feature templates until there are no one left. In the end, there are a series of feature sets, which recorded the process of feature selection. Then we choose the feature set which can perform the best on development set. The code of feature selection algorithm is designed in Figure 3.

[3] It is a bit different from Xue (2008), since we didn't use the syntactic alternation information.

```
1. add all feature templates to set $\mathbf{S}$, the set of
   selected feature templates $\mathbf{C_0}$ is null
2. for i = 0 to n-1, n is the number of elements
   in $\mathbf{S}$
3.     $\mathbf{P_i}$ = 0
4.     for each feature template $ft_j$ in set $\mathbf{S}$
5.         $\mathbf{C'_i} = \mathbf{C_i} + ft_j$
6.         train a model with features extracted
             by $\mathbf{C'_i}$ and test on development set
7.         if the result $\mathbf{P'} > \mathbf{P_i}$
8.             $\mathbf{P_i} = \mathbf{P'}$, k= j
9.     end for
10.    $\mathbf{C_{i+1}} = \mathbf{C_i} + ft_k$
11.    $\mathbf{S} = \mathbf{S} - ft_k$
12. end for
13. the set $\mathbf{C_m}$ correspondent to $\mathbf{P_m}$, which is
    the highest, will be chosen.
```

Figure 3. the greedy feature selection algorithm

To make a comparison, we also built a traditional 1-step semantic role classifier based on this feature selection strategy. We will take this classifier as the baseline system.

5 Experiment Settings

5.1 Classifier

In our SRL system, we use a Maximum Entropy toolkit with tunable Gaussian Prior and L-BFGS parameter estimation, which is implemented by Zhang Le. This toolkit is available at `http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html`. It can well handle the multi-category classification problem and it is quite efficient.

5.2 Data

We use Chinese PropBank 1.0 (LDC number: LDC2005T23) in our experiments. PropBank 1.0 includes the annotations for files chtb_001.fid to chtb_931.fid, or the first 250K words of the Chinese TreeBank 5.1. For the experiments, the data of PropBank is divided into three parts. 648 files (from chtb_081 to chtb_899.fid) are used as the training set. The development set includes 40 files, from chtb_041.fid to chtb_080.fid. The test set includes 72 files, which are chtb_001 to chtb_041, and chtb_900 to chtb_931. We use the same data setting with Xue (2008), however a bit different from Xue and Palmer (2005).

6 Results and Discussion

The results of the feature selection are presented in table1. In this table, "Baseline" indicates the 1-step architecture, and "Hierarchical" indicates the "hierarchical feature selection architecture" implemented in this paper. "X_M", "ARGX" and "ARGM" indicate the three sub-procedures of the hierarchical architecture, which are "ARGX and ARGM separation", "ARGX classification", "ARGM classification" respectively. "Y" in the table indicates that the feature template has been selected for the sub task.

According to table 1, we can find some interesting facts, which in turn prove what we found about semantic role groups in section 3.1.

In table 1, feature templates related to the syntactic structure includes: voice-related group (voice, voice information, path to BA and BEI), frame-related group (verb class, verb class + head word, verb class + phrase type, all frames of verb, verb class + all frames of verb), the layer of argument, position and 4 kinds of subcat frames. As we assumed before, these features are crucial to core arguments but of little use to adjuncts. The results have proven this assumption. Of the entire 14 syntactic structure-related feature templates, 8 were selected by the ARGX process but only 2 was selected by the ARGM process. The two exceptions should be viewed as the result of random impact, which cannot be avoided in automatic feature selection.

Compared with the different features selected by these tasks, we can find other interesting results. Few of the features selected by the X_M process also have related with the verb or the syntactic structures, which is quite similar with the ARGM process. This is probably because most of ARGMs are easy to be identified without syntactic structure information, which makes the opposite of ARGMs, i.e. the ARGXs easy to be filtered. Besides, the features selected by the baseline system have much in common with those selected by the ARGX process. This can be explained by the fact that both in the development and test set, the amount of core arguments outperforms that of adjuncts. The proportions between core arguments and adjuncts are 1.79:1 on the development set, and 1.63:1 on the test set. Because of the bias, the baseline system will tend to choose more syntactic structure-related features to label core arguments precisely.

Baseline	Hierarchical			Feature Name
	X_M	ARGX	ARGM	
		Y		predicate
Y		Y		predicate POS
	Y		Y	first word
			Y	first word + last word
Y		Y		head word
Y				head word POS
Y	Y			phrase type
	Y		Y	phrase type + phrase type of parent node
			Y	phrase type of the sibling to the left
Y		Y		phrase type of the sibling to the right
Y	Y			position
		Y		voice
Y				voice position
Y		Y		path to BA and BEI
Y	Y	Y		verb class
			Y	verb class + head word
Y	Y			verb class + phrase type
Y		Y		verb AllFrameSets
Y		Y		verb class + verb AllFrameSets
		Y		subcat frame
	Y			subcat frame*
		Y		subcate frame@
			Y	subcat frame+
Y		Y		layer of the constituent in focus
	Y	Y	Y	predicate + head word
Y	Y	Y	Y	predicate + phrase type
Y	Y	Y		SemCat of predicate
Y				SemCat of first word
Y		Y		SemCat of last word
			Y	SemCat of predicate + SemCat of last word
Y		Y		SemCat of head word

Table 1. Feature selection results for the baseline and the hierarchical system

	Baseline	Hierarchical
DEV	95.15%	**95.94%**
TEST	93.38%	**94.31%**

Table 2. Comparison of the performance between the baseline and hierarchical system

With this new architecture, we have achieved improvement on the performance of the semantic role classification, which can be found in table 2. Our classifier performs better both on the development and the test set. The labeled precision on the development set is from 95.15% to 95.94%, and the test set is from 93.38% to 94.31%, with an ERR (error reduction rate) of 14.05%. Both of the improvements are statistically significant ($\chi 2$ test with p= 0.05). The errors of SRC have three origins, which are correspondent to the three sub tasks of the hierarchical architecture. Detailed information of the comparison between the two systems can be found in table 3, which can tell us where the improvements come from.

	Baseline	Hierarchical
ARGX/ARGM errors	1.66%	1.75%
inner ARGX errors	3.59%	2.75%
inner ARGM errors	1.37%	1.19%
TOTAL	6.62%	5.69%

Table 3 Error rate analysis on the test set

In table 3, the percentages are calculated the way that the number of the errors was divided by the number of the arguments in the test set. ARGX/ARGM errors represent the errors that the semantic roles are classified into wrong group, e.g. ARGXs are labeled as ARGMs and vice versa. The inner errors represent the errors in a group, e.g. ARG0 are labeled as ARG1. From this table, we can find that ARGX is the most difficult task. X-M and ARGM are less challenging. Besides the relatively little error reduction in the ARGM process, the greatest part of improvement comes from the process of the most difficult sub task: the ARGX sub task. It is a bit surprising that the first step of the X_M in the hierarchical system process did not perform better than that in the baseline system.

	Baseline	Hierarchical	Sum
ARG0	96.14%	96.58%	2046
ARG1	92.75%	94.60%	2428
ARG2	78.46%	78.85%	260
ARG3	60.00%	76.00%	25
ARG4	40.00%	100.00%	5
ARGM-ADV	96.64%	96.85%	1490
ARGM-ASP	100.00%	0.00%	1
ARGM-BNF	91.30%	86.96%	23
ARGM-CND	77.78%	77.78%	9
ARGM-CRD	N/A	N/A	0
ARGM-DGR	N/A	N/A	0
ARGM-DIR	54.84%	58.06%	31
ARGM-DIS	79.38%	79.38%	97
ARGM-EXT	50.00%	25.00%	8
ARGM-FRQ	N/A	N/A	0
ARGM-LOC	90.91%	92.21%	308
ARGM-MNR	89.92%	91.13%	248
ARGM-PRD	N/A	N/A	0
ARGM-PRP	97.83%	97.83%	46
ARGM-TMP	95.41%	96.30%	675
ARGM-TPC	33.33%	8.33%	12
TBERR[4]	0.00%	0.00%	2

Table 4 Detailed labeled precision on the test set

Table 4 presented the labeled precision of each type of semantic role. It demonstrates that with respect to ARGMs and ARGXs, the hierarchical system outperforms the baseline system. Furthermore, the improvement on ARGXs is greater than that of ARGMs. All types of numbered arguments get improvement in the hierarchical architecture, especially ARG1, ARG4 and ARG3. Although the performances of some types of the ARGMs decreased, the performances of all types of the ARGMs which occurs more than 100 times increased, including ADV (adverbials), LOC (locatives), MNR (manner markers) and TMP (temporal markers).

After the hierarchical system was built, we tried to integrate the idea of exploiting argument interdependence into our system. We extract the semantic context features in a linear order, with the window size from [0,0] to [-3,3]. Larger window sizes are of little value since too few arguments have more than 6 other arguments in context. The results are presented in table 5.

	Baseline	Hierarchical
Base	93.38%	94.31%
+window selection	93.38%	**94.68%**

Table 5 integrating window selection into our system

"Base" stands for the hierarchical system built above, without semantic context features. "+window selection" indicates the new system which has utilized the idea of exploiting argument interdependence. The best window sizes for the baseline system, ARGX and ARGM processes in the hierarchical system are [0,0], [-1,1], [0,0] respectively, which were determined by testing on the development set. We can find that only for the ARGX process, the semantic context features are useful. For the baseline system and the ARGM process, exploiting argument interdependence does not help improve the performance. This conclusion is different from Jiang et al. (2004), but it can be explained in the following way.

In fact, the interdependence only exists among core arguments. For ARGMs, it is a different thing. An ARGM cannot provide any information about the type of the arguments close to it and the semantic context features does not help the classification of ARGMs. Also, take the sentence in section 2 as an example, the fact that 截止目前 (until now) is ARGM-TMP cannot raise the probability that 保险公司 (the insurance company) is ARG0 or 已 (has) is ARGM-ADV and vice versa. However, if we know that 保险公司 (the insurance company) is ARG0, at least the phrase 保险服务 (insurance services) can never be ARG0. The semantic context features extracted from or for ARGMs will do

[4] From the name, TBERR possibly indicates the labeled errors in Chinese PropBank. However, we did not find any explanations, so we just put it here and group it to ARGM.

harm to the improvement of the system, since they are irrelative information. Because of the same reason, the performance of base system also decreased when semantic context features were extracted, since the core arguments and the ARGMs are mixed together in the baseline system.

But for the ARGX sub task of our hierarchical system, since we have separated the numbered arguments and ARGMs first, the influences of ARGMs can be eliminated. This made the interdependence of core arguments can be directly explored from the extraction of semantic context features. So the ARGX sub task is improved.

To prove that our method is effective, we also make a comparison between the performances of our system and Xue and Palmer (2005), Xue (2008). Xue (2008) is the best SRL system until now and it has the same data setting with ours. The results are presented in Table 6.

X & P (2005)	Xue(2008)	Ours
93.9%	94.1%	**94.68%**

Table 6. Comparison with previous systems

We have to point out that all the three systems are based on Gold standard parsing. From the table 6, we can find that our system is better than both of the related systems. Our system has outperformed Xue (2008) with a relative error reduction rate of 9.8%.

7 Conclusions and Future Work

In this paper, we have divided all the semantic roles into two groups according to their semantic relations with the verb. After the grouping of the semantic roles was made, we designed a hierarchical semantic role classifier. To capture the accurate information of different semantic role groups, we designed a simple feature selection algorithm to calibrate features for each sub task of SRC. It was very encouraging that the hierarchical SRC system outperformed the strong baseline built with traditional methods. And the selected features could be explained, which in turn proves that the linguistic discrepancy of semantic role groups not only exists but also can be captured. Then we integrated the idea of exploiting argument interdependence to further improve the performance of our system and explained linguistically why the results of our system were different from the ones in previous research.

Although we make discriminations of arguments and adjuncts, the analysis is still coarse-grained. Yi et al. (2007) has made the first attempt working on the single semantic role level to make further improvement. However, the impact of this idea is limited due to that the amount of the research target, ARG2, is few in PropBank. What if we could extend the idea of hierarchical architecture to the single semantic role level? Would that help the improvement of SRC?

Abstract

This paper describes a novel Bayesian approach to unsupervised topic segmentation. Unsupervised systems for this task are driven by *lexical cohesion*: the tendency of well-formed segments to induce a compact and consistent lexical distribution. We show that lexical cohesion can be placed in a Bayesian context by modeling the words in each topic segment as draws from a multinomial language model associated with the segment; maximizing the observation likelihood in such a model yields a lexically-cohesive segmentation. This contrasts with previous approaches, which relied on hand-crafted cohesion metrics. The Bayesian framework provides a principled way to incorporate additional features such as cue phrases, a powerful indicator of discourse structure that has not been previously used in unsupervised segmentation systems. Our model yields consistent improvements over an array of state-of-the-art systems on both text and speech datasets. We also show that both an entropy-based analysis and a well-known previous technique can be derived as special cases of the Bayesian framework.[1]

1 Introduction

Topic segmentation is one of the fundamental problems in discourse analysis, where the task is to divide a text into a linear sequence of topically-coherent segments. Hearst's TEXTTILING (1994) introduced the idea that unsupervised segmentation can be driven by *lexical cohesion*, as high-quality segmentations feature homogeneous lexical distributions within each topic segment. Lexical cohesion has provided the inspiration for several successful systems (e.g., Utiyama and Isahara, 2001; Galley et al.2003; Malioutov and Barzilay, 2006), and is currently the dominant approach to unsupervised topic segmentation.

But despite the effectiveness of lexical cohesion for unsupervised topic segmentation, it is clear that there are other important indicators that are ignored by the current generation of unsupervised systems. For example, consider *cue phrases*, which are explicit discourse markers such as "now" or "however" (Grosz and Sidner, 1986; Hirschberg and Litman, 1993; Knott, 1996). Cue phrases have been shown to be a useful feature for supervised topic segmentation (Passonneau and Litman, 1993; Galley et al., 2003), but cannot be incorporated by current unsupervised models. One reason for this is that existing unsupervised methods use arbitrary, hand-crafted metrics for quantifying lexical cohesion, such as weighted cosine similarity (Hearst, 1994; Malioutov and Barzilay, 2006). Without supervision, it is not possible to combine such metrics with additional sources of information. Moreover, such hand-crafted metrics may not generalize well across multiple datasets, and often include parameters which must be tuned on development sets (Malioutov and Barzilay, 2006; Galley et al., 2003).

In this paper, we situate lexical cohesion in a Bayesian framework, allowing other sources of information to be incorporated without the need for labeled data. We formalize lexical cohesion in a generative model in which the text for each seg-

[1]Code and materials for this work are available at `http://groups.csail.mit.edu/rbg/code/bayesseg/`.

ment is produced by a distinct lexical distribution. Lexically-consistent segments are favored by this model because probability mass is conserved for a narrow subset of words. Thus, lexical cohesion arises naturally through the generative process, and other sources of information – such as cue words – can easily be incorporated as emissions from the segment boundaries.

More formally, we treat the words in each sentence as draws from a language model associated with the topic segment. This is related to topic-modeling methods such as latent Dirichlet allocation (LDA; Blei et al. 2003), but here the induced topics are tied to a linear discourse structure. This property enables a dynamic programming solution to find the exact maximum-likelihood segmentation. We consider two approaches to handling the language models: estimating them explicitly, and integrating them out, using the Dirichlet Compound Multinomial distribution (also known as the multivariate Polya distribution).

We model cue phrases as generated from a separate multinomial that is shared across all topics and documents in the dataset; a high-likelihood model will obtain a compact set of cue phrases. The addition of cue phrases renders our dynamic programming-based inference inapplicable, so we design a sampling-based inference technique. This algorithm can learn in a completely unsupervised fashion, but it also provides a principled mechanism to improve search through the addition of declarative linguistic knowledge. This is achieved by biasing the selection of samples towards boundaries with known cue phrases; this does not change the underlying probabilistic model, but guides search in the direction of linguistically-plausible segmentations.

We evaluate our algorithm on corpora of spoken and written language, including the benchmark ICSI meeting dataset (Janin et al., 2003) and a new textual corpus constructed from the contents of a medical textbook. In both cases our model achieves performance surpassing multiple state-of-the-art baselines. Moreover, we demonstrate that the addition of cue phrases can further improve segmentation performance over cohesion-based methods.

In addition to the practical advantages demonstrated by these experimental results, our model reveals interesting theoretical properties. Other researchers have observed relationships between discourse structure and entropy (e.g., Genzel and Charniak, 2002). We show that in a special case of our model, the segmentation objective is equal to a weighted sum of the negative entropies for each topic segment. This finding demonstrates that a relationship between discourse segmentation and entropy is a natural consequence of modeling topic structure in a generative Bayesian framework. In addition, we show that the benchmark segmentation system of Utiyama and Isahara (2001) can be viewed as another special case of our Bayesian model.

2 Related Work

Existing unsupervised cohesion-based approaches can be characterized in terms of the metric used to quantify cohesion and the search technique. Galley et al. (2003) characterize cohesion in terms of lexical chains – repetitions of a given lexical item over some fixed-length window of sentences. In their unsupervised model, inference is performed by selecting segmentation points at the local maxima of the cohesion function. Malioutov and Barzilay (2006) optimize a normalized minimum-cut criteria based on a variation of the cosine similarity between sentences. Most similar to our work is the approach of Utiyama and Isahara (2001), who search for segmentations with compact language models; as shown in Section 3.1.1, this can be viewed as a special case of our model. Both of these last two systems use dynamic programming to search the space of segmentations.

An alternative Bayesian approach to segmentation was proposed by Purver et al. (2006). They assume a set of documents that is characterized by some number of hidden topics that are shared across multiple documents. They then build a linear segmentation by adding a switching variable to indicate whether the topic distribution for each sentence is identical to that of its predecessor. Unlike Purver et al., we do not assume a dataset in which topics are shared across multiple documents; indeed, our model can be applied to single documents individually. Additionally, the inference procedure of Purver et al. requires sampling multiple layers of hidden variables. In contrast, our inference procedure leverages the nature of linear segmentation to search only in the space of segmentation points.

The relationship between discourse structure and cue phrases has been studied extensively; for an early example of computational work on this topic, see (Grosz, 1977). Passonneau and Litman (1993) were the first to investigate the relationship between cue phrases and linear segmentation. More recently, cue phrases have been applied to topic segmentation in the supervised setting. In a supervised system that is distinct from the unsupervised model described above, Galley et al. (2003) automatically identify candidate cue phrases by mining labeled data for words that are especially likely to appear at segment boundaries; the presence of cue phrases is then used as a feature in a rule-based classifier for linear topic segmentation. Elsner and Charniak (2008) specify a list of cue phrases by hand; the cue phrases are used as a feature in a maximum-entropy classifier for conversation disentanglement. Unlike these approaches, we identify candidate cue phrases automatically from unlabeled data and incorporate them in the topic segmentation task without supervision.

3 Lexical Cohesion in a Bayesian Framework

The core idea of lexical cohesion is that topically-coherent segments demonstrate compact and consistent lexical distributions (Halliday and Hasan, 1976). Lexical cohesion can be placed in a probabilistic context by modeling the words in each topic segment as draws from a multinomial language model associated with the segment. Formally, if sentence t is in segment j, then the bag of words $\mathbf{x}_t$ is drawn from the multinomial language model θ_j. This is similar in spirit to hidden topic models such as latent Dirichlet allocation (Blei et al., 2003), but rather than assigning a hidden topic to each word, we constrain the topics to yield a linear segmentation of the document.

We will assume that topic breaks occur at sentence boundaries, and write z_t to indicate the topic assignment for sentence t. The observation likelihood is,

$$p(\mathbf{X}|\mathbf{z},\Theta) = \prod_{t}^{T} p(\mathbf{x}_t|\theta_{z_t}), \tag{1}$$

where $\mathbf{X}$ is the set of all T sentences, $\mathbf{z}$ is the vector of segment assignments for each sentence, and Θ is the set of all K language models.[2] A linear segmentation is ensured by the additional constraint that z_t must be equal to either z_{t-1} (the previous sentence's segment) or $z_{t-1}+1$ (the next segment).

To obtain a high likelihood, the language models associated with each segment should concentrate their probability mass on a compact subset of words. Language models that spread their probability mass over a broad set of words will induce a lower likelihood. This is consistent with the principle of lexical cohesion.

Thus far, we have described a segmentation in terms of two parameters: the segment indices $\mathbf{z}$, and the set of language models Θ. For the task of segmenting documents, we are interested only in the segment indices, and would prefer not to have to search in the space of language models as well. We consider two alternatives: taking point estimates of the language models (Section 3.1), and analytically marginalizing them out (Section 3.2).

3.1 Setting the language model to the posterior expectation

One way to handle the language models is to choose a single point estimate for each set of segmentation points $\mathbf{z}$. Suppose that each language model is drawn from a symmetric Dirichlet prior: $\theta_j \sim \text{Dir}(\theta_0)$. Let $\mathbf{n}_j$ be a vector in which each element is the sum of the lexical counts over all the sentences in segment j: $n_{j,i} = \sum_{\{t:z_t=j\}} m_{t,i}$, where $m_{t,i}$ is the count of word i in sentence t. Assuming that each $\mathbf{x}_t \sim \theta_j$, then the posterior distribution for θ_j is Dirichlet with vector parameter $\mathbf{n}_j + \theta_0$ (Bernardo and Smith, 2000). The expected value of this distribution is the multinomial distribution $\hat{\theta}_j$, where,

$$\hat{\theta}_{j,i} = \frac{n_{j,i} + \theta_0}{\sum_i^W n_{j,i} + W\theta_0}. \tag{2}$$

In this equation, W indicates the number of words in the vocabulary. Having obtained an estimate for the language model $\hat{\theta}_j$, the observed data likelihood for segment j is a product over each sentence in the segment,

[2]Our experiments will assume that the number of topics K is known. This is common practice for this task, as the desired number of segments may be determined by the user (Malioutov and Barzilay, 2006).

$$p(\{\mathbf{x}_t : z_t = j\}|\hat{\theta}_j) = \prod_{\{t:z_t=j\}} \prod_{i \in \mathbf{x}_t} \hat{\theta}_{j,i} \quad (3)$$

$$= \prod_{\{t:z_t=j\}} \prod_{i}^{W} \hat{\theta}_{j,i}^{m_{t,i}} \quad (4)$$

$$= \prod_{i}^{W} \hat{\theta}_{j,i}^{n_{j,i}}. \quad (5)$$

By viewing the likelihood as a product over all terms in the vocabulary, we observe interesting connections with prior work on segmentation and information theory.

3.1.1 Connection to previous work

In this section, we explain how our model generalizes the well-known method of Utiyama and Isahara (2001; hereafter U&I). As in our work, Utiyama and Isahara propose a probabilistic framework based on maximizing the compactness of the language models induced for each segment. Their likelihood equation is identical to our equations 3-5. They then define the language models for each segment as $\hat{\theta}_{j,i} = \frac{n_{j,i}+1}{W+\sum_i^W n_{j,i}}$, without rigorous justification. This form is equivalent to Laplacian smoothing (Manning and Schütze, 1999), and is a special case of our equation 2, with $\theta_0 = 1$. Thus, the language models in U&I can be viewed as the expectation of the posterior distribution $p(\theta_j|\{\mathbf{x}_t : z_t = j\}, \theta_0)$, in the special case that $\theta_0 = 1$. Our approach generalizes U&I and provides a Bayesian justification for the language models that they apply. The remainder of the paper further extends this work by marginalizing out the language model, and by adding cue phrases. We empirically demonstrate that these extensions substantially improve performance.

3.1.2 Connection to entropy

Our model also has a connection to entropy, and situates entropy-based segmentation within a Bayesian framework. Equation 1 defines the objective function as a product across sentences; using equations 3-5 we can decompose this across segments instead. Working in logarithms,

$$\log p(\mathbf{X}|\mathbf{z}, \hat{\Theta}) = \sum_{t}^{T} \log p(\mathbf{x}_t|\hat{\theta}_{z_t})$$

$$= \sum_{j}^{K} \sum_{\{t:z_t=j\}} \log p(\mathbf{x}_t|\hat{\theta}_j)$$

$$= \sum_{j}^{K} \sum_{i}^{W} n_{j,i} \log \hat{\theta}_{j,i} \quad (6)$$

The last line substitutes in the logarithm of equation 5. Setting $\theta_0 = 0$ and rearranging equation 2, we obtain $n_{j,i} = N_j \hat{\theta}_{j,i}$, with $N_j = \sum_i^W n_{j,i}$, the total number of words in segment j. Substituting this into equation 6, we obtain

$$\log p(\mathbf{X}|\mathbf{z}, \hat{\Theta}) = \sum_{j}^{K} N_j \sum_{i} \hat{\theta}_{j,i} \log \hat{\theta}_{j,i}$$

$$= \sum_{j}^{K} N_j H(\hat{\theta}_j),$$

where $H(\hat{\theta}_j)$ is the negative entropy of the multinomial $\hat{\theta}_j$. Thus, with $\theta_0 = 0$, the log conditional probability in equation 6 is optimized by a segmentation that minimizes the weighted sum of entropies per segment, where the weights are equal to the segment lengths. This result suggests intriguing connections with prior work on the relationship between entropy and discourse structure (e.g., Genzel and Charniak, 2002; Sporleder and Lapata, 2006).

3.2 Marginalizing the language model

The previous subsection uses point estimates of the language models to reveal connections to entropy and prior work on segmentation. However, point estimates are theoretically unsatisfying from a Bayesian perspective, and better performance may be obtained by marginalizing over all possible language models:

$$
\begin{aligned}
p(\mathbf{X}|\mathbf{z},\theta_0) &= \prod_j^K \prod_{\{t:z_t=j\}} p(\mathbf{x}_t|\theta_0) \\
&= \prod_j^K \int d\theta_j \prod_{\{t:z_t=j\}} p(x_t|\theta_j)p(\theta_j|\theta_0) \\
&= \prod_j^K p_{dcm}(\{\mathbf{x}_t : z_t = j\}|\theta_0), \qquad (7)
\end{aligned}
$$

where p_{dcm} refers to the Dirichlet compound multinomial distribution (DCM), also known as the multivariate Polya distribution (Johnson et al., 1997). The DCM distribution expresses the expectation over all multinomial language models, when conditioning on the Dirichlet prior θ_0. When θ_0 is a symmetric Dirichlet prior,

$$
\begin{aligned}
&p_{dcm}(\{\mathbf{x}_t : z_t = j\}|\theta_0) \\
&\quad = \frac{\Gamma(W\theta_0)}{\Gamma(N_j + W\theta_0)} \prod_i^W \frac{\Gamma(n_{j,i} + W\theta_0)}{\Gamma(\theta_0)},
\end{aligned}
$$

where $n_{j,i}$ is the count of word i in segment j, and $N_j = \sum_i^W n_{j,i}$, the total number of words in the segment. The symbol Γ refers to the Gamma function, an extension of the factorial function to real numbers. Using the DCM distribution, we can compute the data likelihood for each segment from the lexical counts over the entire segment. The overall observation likelihood is a product across the likelihoods for each segment.

3.3 Objective function and inference

The optimal segmentation maximizes the joint probability,

$$p(\mathbf{X},\mathbf{z}|\theta_0) = p(\mathbf{X}|\mathbf{z},\theta_0)p(\mathbf{z}).$$

We assume that $p(\mathbf{z})$ is a uniform distribution over valid segmentations, and assigns no probability mass to invalid segmentations. The data likelihood is defined for point estimate language models in equation 5 and for marginalized language models in equation 7. Note that equation 7 is written as a product over segments. The point estimates for the language models depend only on the counts within each segment, so the overall likelihood for the point-estimate version also decomposes across segments.

Any objective function that can be decomposed into a product across segments can be maximized using dynamic programming. We define $B(t)$ as the value of the objective function for the optimal segmentation up to sentence t. The contribution to the objective function from a single segment between sentences t' and t is written,

$$b(t',t) = p(\{\mathbf{x}_{t'} \ldots \mathbf{x}_t\}|\mathbf{z}_{t' \ldots t} = j)$$

The maximum value of the objective function is then given by the recurrence relation, $B(t) = \max_{t'<t} B(t')b(t'+1,t)$, with the base case $B(0) = 1$. These values can be stored in a table of size T (equal to the number of sentences); this admits a dynamic program that performs inference in polynomial time.[3] If the number of segments is specified in advance, the dynamic program is slightly more complex, with a table of size TK.

3.4 Priors

The Dirichlet compound multinomial integrates over language models, but we must still set the prior θ_0. We can re-estimate this prior based on the observed data by interleaving gradient-based search in a Viterbi expectation-maximization framework (Gauvain and Lee, 1994). In the E-step, we estimate a segmentation $\hat{\mathbf{z}}$ of the dataset, as described in Section 3.3. In the M-step, we maximize $p(\theta_0|\mathbf{X},\hat{\mathbf{z}}) \propto p(\mathbf{X}|\theta_0,\hat{\mathbf{z}})p(\theta_0)$. Assuming a non-informative hyperprior $p(\theta_0)$, we maximize the likelihood in Equation 7 across all documents. The maximization is performed using a gradient-based search; the gradients are dervied by Minka (2003). This procedure is iterated until convergence or a maximum of twenty iterations.

4 Cue Phrases

One of the key advantages of a Bayesian framework for topic segmentation is that it permits the principled combination of multiple data sources, even

[3]This assumes that the objective function for individual segments can also be computed efficiently. In our case, we need only keep vectors of counts for each segment, and evaluate probability density functions over the counts.

without labeled data. We are especially interested in cue phrases, which are explicit markers for discourse structure, such as "now" or "first" (Grosz and Sidner, 1986; Hirschberg and Litman, 1993; Knott, 1996). Cue phrases have previously been used in supervised topic segmentation (e.g., Galley et al. 2003); we show how they can be used in an unsupervised setting.

The previous section modeled lexical cohesion by treating the bag of words in each sentence as a series of draws from a multinomial language model indexed by the topic segment. To incorporate cue phrases, this generative model is modified to reflect the idea that some of the text will be topic-specific, but other terms will be topic-neutral cue phrases that express discourse structure. This idea is implemented by drawing the text at each topic boundary from a special language model ϕ, which is shared across all topics and all documents in the dataset.

For sentences that are not at segment boundaries, the likelihood is as before: $p(\mathbf{x}_t|\mathbf{z}, \Theta, \phi) = \prod_{i \in \mathbf{x}_t} \theta_{z_t,i}$. For sentences that immediately follow segment boundaries, we draw the first ℓ words from ϕ instead. Writing $\mathbf{x}_t^{(\ell)}$ for the ℓ cue words in $\mathbf{x}_t$, and $\tilde{\mathbf{x}}_t$ for the remaining words, the likelihood for a segment-initial sentence is,

$$p(\mathbf{x}_t|z_t \neq z_{t-1}, \Theta, \phi) = \prod_{i \in \mathbf{x}_t^{(\ell)}} \phi_i \prod_{i \in \tilde{\mathbf{x}}_t} \theta_{z_t,i}.$$

We draw ϕ from a symmetric Dirichlet prior ϕ_0. Following prior work (Galley et al., 2003; Litman and Passonneau, 1995), we consider only the first word of each sentence as a potential cue phrase; thus, we set $\ell = 1$ in all experiments.

4.1 Inference

To estimate or marginalize the language models Θ and ϕ, it is necessary to maintain lexical counts for each segment and for the segment boundaries. The counts for ϕ are summed across every segment in the entire dataset, so shifting a boundary will affect the probability of every segment, not only the adjacent segments as before. Thus, the factorization that enabled dynamic programming inference in Section 3.3 is no longer applicable. Instead, we must resort to approximate inference.

Sampling-based inference is frequently used in related Bayesian models. Such approaches build a stationary Markov chain by repeatedly sampling among the hidden variables in the model. The most commonly-used sampling-based technique is Gibbs sampling, which iteratively samples from the conditional distribution of each hidden variable (Bishop, 2006). However, Gibbs sampling is slow to converge to a stationary distribution when the hidden variables are tightly coupled. This is the case in linear topic segmentation, due to the constraint that $z_t \in \{z_{t-1}, z_{t-1}+1\}$ (see Section 3).

For this reason, we apply the more general Metropolis-Hastings algorithm, which permits sampling arbitrary transformations of the latent variables. In our framework, such transformations correspond to moves through the space of possible segmentations. A new segmentation $\mathbf{z}'$ is drawn from the previous hypothesized segmentation $\mathbf{z}$ based on a *proposal distribution* $q(\mathbf{z}'|\mathbf{z})$.[4] The probability of accepting a proposed transformation depends on the ratio of the joint probabilities and a correction term for asymmetries in the proposal distribution:

$$p_{\text{accept}}(\mathbf{z} \rightarrow \mathbf{z}') = \min\left\{1, \frac{p(\mathbf{X}, \mathbf{z}'|\theta_0, \phi_0)}{p(\mathbf{X}, \mathbf{z}|\theta_0, \phi_0)} \frac{q(\mathbf{z}|\mathbf{z}')}{q(\mathbf{z}'|\mathbf{z})}\right\}.$$

The Metropolis-Hastings algorithm guarantees that by accepting samples at this ratio, our sampling procedure will converge to the stationary distribution for the hidden variables $\mathbf{z}$. When cue phrases are included, the observation likelihood is written:

$$p(\mathbf{X}|\mathbf{z}, \Theta, \phi) = \prod_{\{t: z_t \neq z_{t-1}\}} \prod_{i \in \mathbf{x}_t^{(\ell)}} \phi_i \prod_{i \in \tilde{\mathbf{x}}_t} \theta_{z_t,i} \times \prod_{\{t: z_t = z_{t-1}\}} \prod_{i \in \mathbf{x}_t} \theta_{z_t,i}.$$

As in Section 3.2, we can marginalize over the language models. We obtain a product of DCM distributions: one for each segment, and one for all cue phrases in the dataset.

4.2 Proposal distribution

Metropolis-Hastings requires a proposal distribution to sample new configurations. The proposal distri-

[4]Because the cue phrase language model ϕ is used across the entire dataset, transformations affect the likelihood of all documents in the corpus. For clarity, our exposition will focus on the single-document case.

bution does not affect the underlying probabilistic model – Metropolis-Hastings will converge to the same underlying distribution for any non-degenerate proposal. However, a well-chosen proposal distribution can substantially speed convergence.

Our basic proposal distribution selects an existing segmentation point with uniform probability, and considers a set of local moves. The proposal is constructed so that no probability mass is allocated to moves that change the order of segment boundaries, or merge two segments; one consequence of this restriction is that moves cannot add or remove segments.[5] We set the proposal distribution to decrease exponentially with the move distance, thus favoring incremental transformations to the segmentation.

More formally, let $d(\mathbf{z} \rightarrow \mathbf{z}') > 0$ equal the distance that the selected segmentation point is moved when we transform the segmentation from $\mathbf{z}$ to $\mathbf{z}'$. We can write the proposal distribution $q(\mathbf{z}' \mid \mathbf{z}) \propto c(\mathbf{z} \rightarrow \mathbf{z}')d(\mathbf{z} \rightarrow \mathbf{z}')^{\lambda}$, where $\lambda < 0$ sets the rate of exponential decay and c is an indicator function enforcing the constraint that the moves do not reach or cross existing segmentation points.[6]

We can also incorporate declarative linguistic knowledge by biasing the proposal distribution in favor of moves that place boundaries near known cue phrase markers. We multiply the unnormalized chance of proposing a move to location $\mathbf{z} \rightarrow \mathbf{z}'$ by a term equal to one plus the number of candidate cue phrases in the segment-initial sentences in the new configuration $\mathbf{z}'$, written $\textsf{num-cue}(\mathbf{z}')$. Formally, $q_{\text{ling}}(\mathbf{z}' \mid \mathbf{z}') \propto (1 + \textsf{num-cue}(\mathbf{z}'))q(\mathbf{z}' \mid \mathbf{z})$. We use a list of cue phrases identified by Hirschberg and Litman (1993). We evaluate our model with both the basic and linguistically-enhanced proposal distributions.

4.3 Priors

As in section 3.4, we set the priors θ_0 and ϕ_0 using gradient-based search. In this case, we perform gradient-based optimization after epochs of 1000 Metropolis-Hasting steps. Interleaving sampling-based inference with direct optimization of parameters can be considered a form of Monte Carlo Expectation-Maximization (MCEM; Wei and Tanner, 1990).

5 Experimental Setup

Corpora We evaluate our approach on corpora from two different domains: transcribed meetings and written text.

For multi-speaker meetings, we use the ICSI corpus of meeting transcripts (Janin et al., 2003), which is becoming a standard for speech segmentation (e.g., Galley et al. 2003; Purver et al. 2006). This dataset includes transcripts of 75 multi-party meetings, of which 25 are annotated for segment boundaries.

For text, we introduce a dataset in which each document is a chapter selected from a medical textbook (Walker et al., 1990).[7] The task is to divide each chapter into the sections indicated by the author. This dataset contains 227 chapters, with 1136 sections (an average of 5.00 per chapter). Each chapter contains an average of 140 sentences, giving an average of 28 sentences per segment.

Metrics All experiments are evaluated in terms of the commonly-used P_k (Beeferman et al., 1999) and WindowDiff (WD) (Pevzner and Hearst, 2002) scores. Both metrics pass a window through the document, and assess whether the sentences on the edges of the window are properly segmented with respect to each other. WindowDiff is stricter in that it requires that the number of intervening segments between the two sentences be identical in the hypothesized and the reference segmentations, while P_k only asks whether the two sentences are in the same segment or not. P_k and WindowDiff are penalties, so lower values indicate better segmentations. We use the evaluation source code provided by Malioutov and Barzilay (2006).

System configuration We evaluate our Bayesian approach both with and without cue phrases. Without cue phrases, we use the dynamic programming inference described in section 3.3. This system is referred to as BAYESSEG in Table 1. When adding

[5]Permitting moves to change the number of segments would substantially complicate inference.

[6]We set $\lambda = -\frac{1}{\textsf{max-move}}$, where $\textsf{max-move}$ is the maximum move-length, set to 5 in our experiments. These parameters affect the rate of convergence but are unrelated to the underlying probability model. In the limit of enough samples, all non-pathological settings will yield the same segmentation results.

[7]The full text of this book is available for free download at http://onlinebooks.library.upenn.edu.

cue phrases, we use the Metropolis-Hastings model described in 4.1. Both basic and linguistically-motivated proposal distributions are evaluated (see Section 4.2); these are referred to as BAYESSEG-CUE and BAYESSEG-CUE-PROP in the table.

For the sampling-based systems, results are averaged over five runs. The initial configuration is obtained from the dynamic programming inference, and then 100,000 sampling iterations are performed. The final segmentation is obtained by annealing the last 25,000 iterations to a temperature of zero. The use of annealing to obtain a maximum *a posteriori* (MAP) configuration from sampling-based inference is common (e.g., Finkel 2005; Goldwater 2007). The total running time of our system is on the order of three minutes per document. Due to memory constraints, we divide the textbook dataset into ten parts, and perform inference in each part separately. We may achieve better results by performing inference over the entire dataset simultaneously, due to pooling counts for cue phrases across all documents.

Baselines We compare against three competitive alternative systems from the literature: U&I (Utiyama and Isahara, 2001); LCSEG (Galley et al., 2003); MCS (Malioutov and Barzilay, 2006). All three systems are described in the related work (Section 2). In all cases, we use the publicly available executables provided by the authors.

Parameter settings For LCSEG, we use the parameter values specified in the paper (Galley et al., 2003). MCS requires parameter settings to be tuned on a development set. Our corpora do not include development sets, so tuning was performed using the lecture transcript corpus described by Malioutov and Barzilay (2006). Our system does not require parameter tuning; priors are re-estimated as described in Sections 3.4 and 4.3. U&I requires no parameter tuning, and is used "out of the box." In all experiments, we assume that the number of desired segments is provided.

Preprocessing Standard preprocessing techniques are applied to the text for all comparisons. The Porter (1980) stemming algorithm is applied to group equivalent lexical items. A set of stop-words is also removed, using the same list originally employed by several competitive systems (Choi, 2000; Utiyama and Isahara, 2001; Malioutov and Barzilay, 2006).

Table 1: Comparison of segmentation algorithms. Both metrics are penalties, so lower scores indicate better performance. BAYESSEG is the cohesion-only Bayesian system with marginalized language models. BAYESSEG-CUE is the Bayesian system with cue phrases. BAYESSEG-CUE-PROP adds the linguistically-motivated proposal distribution.

6 Results

Table 1 presents the performance results for three instantiations of our Bayesian framework and three competitive alternative systems. As shown in the table, the Bayesian models achieve the best results on both metrics for both corpora. On the medical textbook corpus, the Bayesian systems achieve a raw performance gain of 2-3% with respect to all baselines on both metrics. On the ICSI meeting corpus, the Bayesian systems perform 4-5% better than the best baseline on the P_k metric, and achieve smaller improvement on the WindowDiff metric. The results on the meeting corpus also compare favorably with the topic-modeling method of Purver et al. (2006), who report a P_k of .289 and a WindowDiff of .329.

Another observation from Table 1 is that the contribution of cue phrases depends on the dataset. Cue phrases improve performance on the meeting corpus, but not on the textbook corpus. The effectiveness of cue phrases as a feature depends on whether the writer or speaker uses them consistently. At the

Table 2: Cue phrases selected by our unsupervised model, sorted by chi-squared. Boldface indicates that the chi-squared value is significant at the level of $p < .01$. Asterisks indicate cue phrases that were extracted by the supervised procedure of Galley et al. (2003).

same time, the addition of cue phrases prevents the use of exact inference techniques, which may explain the decline in results for the meetings dataset.

To investigate the quality of the cue phrases that our model extracts, we list its top ten cue phrases for each dataset in Table 2. Cue phrases are ranked by their chi-squared value, which is computed based on the number of occurrences for each word at the beginning of a hypothesized segment, as compared to the expectation. For cue phrases listed in bold, the chi-squared value is statistically significant at the level of $p < .01$, indicating that the frequency with which the cue phrase appears at the beginning of segments is unlikely to be a chance phenomenon.

As shown in the left column of the table, our model has identified several strong cue phrases from the meeting dataset which appear to be linguistically plausible. Galley et al. (2003) performed a similar chi-squared analysis, but used the true segment boundaries in the labeled data; this can be thought of as a sort of ground truth. Four of the ten cue phrases identified by our system overlap with their analysis; these are indicated with asterisks. In contrast to our model's success at extracting cue phrases from the meeting dataset, only very common words are selected for the textbook dataset. This may help to explain why cue phrases improve performance for meeting transcripts, but not for the textbook.

7 Conclusions

This paper presents a novel Bayesian approach to unsupervised topic segmentation. Our algorithm is capable of incorporating both lexical cohesion and cue phrase features in a principled manner, and outperforms state-of-the-art baselines on text and transcribed speech corpora. We have developed exact and sampling-based inference techniques, both of which search only over the space of segmentations and marginalize out the associated language models. Finally, we have shown that our model provides a theoretical framework with connections to information theory, while also generalizing and justifying prior work. In the future, we hope to explore the use of similar Bayesian techniques for hierarchical segmentation, and to incorporate additional features such as prosody and speaker change information.

Abstract

There is growing interest in applying Bayesian techniques to NLP problems. There are a number of different estimators for Bayesian models, and it is useful to know what kinds of tasks each does well on. This paper compares a variety of different Bayesian estimators for Hidden Markov Model POS taggers with various numbers of hidden states on data sets of different sizes. Recent papers have given contradictory results when comparing Bayesian estimators to Expectation Maximization (EM) for unsupervised HMM POS tagging, and we show that the difference in reported results is largely due to differences in the size of the training data and the number of states in the HMM. We invesigate a variety of samplers for HMMs, including some that these earlier papers did not study. We find that all of Gibbs samplers do well with small data sets and few states, and that Variational Bayes does well on large data sets and is competitive with the Gibbs samplers. In terms of times of convergence, we find that Variational Bayes was the fastest of all the estimators, especially on large data sets, and that explicit Gibbs sampler (both pointwise and sentence-blocked) were generally faster than their collapsed counterparts on large data sets.

1 Introduction

Probabilistic models now play a central role in computational linguistics. These models define a probability distribution $\mathrm{P}(\boldsymbol{x})$ over structures or analyses $\boldsymbol{x}$. For example, in the part-of-speech (POS) tagging application described in this paper, which involves predicting the part-of-speech tag t_i of each word w_i in the sentence $\boldsymbol{w} = (w_1, \ldots, w_n)$, the structure $\boldsymbol{x} = (\boldsymbol{w}, \boldsymbol{t})$ consists of the words $\boldsymbol{w}$ in a sentence together with their corresponding parts-of-speech $\boldsymbol{t} = (t_1, \ldots, t_n)$.

In general the probabilistic models used in computational linguistics have adjustable parameters $\boldsymbol{\theta}$ which determine the distribution $\mathrm{P}(\boldsymbol{x} \mid \boldsymbol{\theta})$. In this paper we focus on bitag Hidden Markov Models (HMMs). Since our goal here is to compare algorithms rather than achieve the best performance, we keep the models simple by ignoring morphology and capitalization (two very strong cues in English) and treat each word as an atomic entity. This means that the model parameters $\boldsymbol{\theta}$ consist of the HMM state-to-state transition probabilities and the state-to-word emission probabilities.

In virtually all statistical approaches the parameters $\boldsymbol{\theta}$ are chosen or *estimated* on the basis of training data $\boldsymbol{d}$. This paper studies unsupervised estimation, so $\boldsymbol{d} = \boldsymbol{w} = (w_1, \ldots, w_n)$ consists of a sequence of words w_i containing all of the words of training corpus appended into a single string, as explained below.

Maximum Likelihood (ML) is the most common estimation method in computational linguistics. A Maximum Likelihood estimator sets the parameters to the value $\hat{\boldsymbol{\theta}}$ that makes the likelihood $L_{\boldsymbol{d}}$ of the data $\boldsymbol{d}$ as large as possible:

$$\begin{aligned} L_{\boldsymbol{d}}(\boldsymbol{\theta}) &= \mathrm{P}(\boldsymbol{d} \mid \boldsymbol{\theta}) \\ \hat{\boldsymbol{\theta}} &= \arg\max_{\theta} L_{\boldsymbol{d}}(\boldsymbol{\theta}) \end{aligned}$$

In this paper we use the Inside-Outside algorithm, which is a specialized form of Expectation-

Maximization, to find HMM parameters which (at least locally) maximize the likelihood function $L_{\boldsymbol{d}}$.

Recently there is increasing interest in Bayesian methods in computational linguistics, and the primary goal of this paper is to compare the performance of various Bayesian estimators with each other and with EM.

A Bayesian approach uses Bayes theorem to factorize the *posterior distribution* $\mathrm{P}(\boldsymbol{\theta} \mid \boldsymbol{d})$ into the *likelihood* $\mathrm{P}(\boldsymbol{d} \mid \boldsymbol{\theta})$ and the *prior* $\mathrm{P}(\boldsymbol{\theta})$.

$$\mathrm{P}(\boldsymbol{\theta} \mid \boldsymbol{d}) \quad \propto \quad \mathrm{P}(\boldsymbol{d} \mid \boldsymbol{\theta})\, \mathrm{P}(\boldsymbol{\theta})$$

Priors can be useful because they can express preferences for certain types of models. To take an example from our POS-tagging application, most words belong to relatively few parts-of-speech (e.g., most words belong to a single POS, and while there are some words which are both nouns and verbs, very few are prepositions and adjectives as well). One might express this using a prior which prefers HMMs in which the state-to-word emissions are *sparse*, i.e., each state emits few words. An appropriate Dirichlet prior can express this preference.

While it is possible to use Bayesian inference to find a single model, such as the Maximum A Posteriori or MAP value of $\boldsymbol{\theta}$ which maximizes the posterior $\mathrm{P}(\boldsymbol{\theta} \mid \boldsymbol{d})$, this is not necessarily the best approach (Bishop, 2006; MacKay, 2003). Instead, rather than commiting to a single value for the parameters $\boldsymbol{\theta}$ many Bayesians often prefer to work with the full posterior distribution $\mathrm{P}(\boldsymbol{\theta} \mid \boldsymbol{d})$, as this naturally reflects the uncertainty in $\boldsymbol{\theta}$'s value.

In all but the simplest models there is no known closed form for the posterior distribution. However, the Bayesian literature describes a number of methods for approximating the posterior $\mathrm{P}(\boldsymbol{\theta} \mid \boldsymbol{d})$. Monte Carlo sampling methods and Variational Bayes are two kinds of approximate inference methods that have been applied to Bayesian inference of unsupervised HMM POS taggers (Goldwater and Griffiths, 2007; Johnson, 2007). These methods can also be used to approximate other distributions that are important to us, such as the conditional distribution $\mathrm{P}(\boldsymbol{t} \mid \boldsymbol{w})$ of POS tags (i.e., HMM hidden states) $\boldsymbol{t}$ given words $\boldsymbol{w}$.

This recent literature reports contradictory results about these Bayesian inference methods. Johnson (2007) compared two Bayesian inference algorithms, Variational Bayes and what we call here a point-wise collapsed Gibbs sampler, and found that Variational Bayes produced the best solution, and that the Gibbs sampler was extremely slow to converge and produced a worse solution than EM. On the other hand, Goldwater and Griffiths (2007) reported that the same kind of Gibbs sampler produced much better results than EM on their unsupervised POS tagging task. One of the primary motivations for this paper was to understand and resolve the difference in these results. We replicate the results of both papers and show that the difference in their results stems from differences in the sizes of the training data and numbers of states in their models.

It turns out that the Gibbs sampler used in these earlier papers is not the only kind of sampler for HMMs. This paper compares the performance of four different kinds of Gibbs samplers, Variational Bayes and Expectation Maximization on unsupervised POS tagging problems of various sizes. Our goal here is to try to learn how the performance of these different estimators varies as we change the number of hidden states in the HMMs and the size of the training data.

In theory, the Gibbs samplers produce streams of samples that eventually converge on the true posterior distribution, while the Variational Bayes (VB) estimator only produces an approximation to the posterior. However, as the size of the training data distribution increases the likelihood function and therefore the posterior distribution becomes increasingly peaked, so one would expect this variational approximation to become increasingly accurate. Further the Gibbs samplers used in this paper should exhibit reduced mobility as the size of training data increases, so as the size of the training data increases eventually the Variational Bayes estimator should prove to be superior.

However the two point-wise Gibbs samplers investigated here, which resample the label of each word conditioned on the labels of its neighbours (amongst other things) only require $O(m)$ steps per sample (where m is the number of HMM states), while EM, VB and the sentence-blocked Gibbs samplers require $O(m^2)$ steps per sample. Thus for HMMs with many states it is possible to perform one or two orders of magnitude more iterations of the point-wise Gibbs samplers in the same run-time as the other samplers, so it is plausible that they would yield better results.

2 Inference for HMMs

There are a number of excellent textbook presentations of Hidden Markov Models (Jelinek, 1997; Manning and Schütze, 1999), so we do not present them in detail here. Conceptually, a Hidden Markov Model uses a Markov model to generate the sequence of states $\boldsymbol{t} = (t_1, \ldots, t_n)$ (which will be interpreted as POS tags), and then generates each word w_i conditioned on the corresponding state t_i.

We insert endmarkers at the beginning and end of the corpus and between sentence boundaries, and constrain the estimators to associate endmarkers with a special HMM state that never appears elsewhere in the corpus (we ignore these endmarkers during evaluation). This means that we can formally treat the training corpus as one long string, yet each sentence can be processed independently by a first-order HMM.

In more detail, the HMM is specified by a pair of multinomials $\boldsymbol{\theta}_t$ and $\boldsymbol{\phi}_t$ associated with each state t, where $\boldsymbol{\theta}_t$ specifies the distribution over states t' following t and $\boldsymbol{\phi}_t$ specifies the distribution over words w given state t.

$$\begin{array}{rcccl} t_i & \mid & t_{i-1} = t & \sim & \mathrm{Multi}(\boldsymbol{\theta}_t) \\ w_i & \mid & t_i = t & \sim & \mathrm{Multi}(\boldsymbol{\phi}_t) \end{array} \quad (1)$$

The Bayesian model we consider here puts a fixed uniform Dirichlet prior on these multinomials. Because Dirichlets are conjugate to multinomials, this greatly simplifies inference.

$$\begin{array}{rccl} \boldsymbol{\theta}_t & \mid \ \alpha & \sim & \mathrm{Dir}(\boldsymbol{\alpha}) \\ \boldsymbol{\phi}_t & \mid \ \alpha' & \sim & \mathrm{Dir}(\boldsymbol{\alpha}') \end{array}$$

A multinomial $\boldsymbol{\theta}$ is distributed according to the Dirichlet distribution $\mathrm{Dir}(\boldsymbol{\alpha})$ iff:

$$\mathrm{P}(\boldsymbol{\theta} \mid \boldsymbol{\alpha}) \ \propto \ \prod_{j=1}^{m} \theta_j^{\alpha_j - 1}$$

In our experiments we set $\boldsymbol{\alpha}$ and $\boldsymbol{\alpha}'$ to the uniform values (i.e., all components have the same value α or α'), but it is possible to estimate these as well (Goldwater and Griffiths, 2007). Informally, α controls the sparsity of the state-to-state transition probabilities while α' controls the sparsity of the state-to-word emission probabilities. As α' approaches zero the prior strongly prefers models in which each state emits as few words as possible, capturing the intuition that most word types only belong to one POS mentioned earlier.

2.1 Expectation Maximization

Expectation-Maximization is a procedure that iteratively re-estimates the model parameters $(\boldsymbol{\theta}, \boldsymbol{\phi})$, converging on a local maximum of the likelihood. Specifically, if the parameter estimate at iteration ℓ is $(\boldsymbol{\theta}^{(\ell)}, \boldsymbol{\phi}^{(\ell)})$, then the re-estimated parameters at iteration $\ell + 1$ are:

$$\begin{array}{rcl} \theta^{(\ell+1)}_{t'|t} & = & \mathrm{E}[n_{t',t}]/\mathrm{E}[n_t] \\ \phi^{(\ell+1)}_{w|t} & = & \mathrm{E}[n'_{w,t}]/\mathrm{E}[n_t] \end{array} \quad (2)$$

where $n'_{w,t}$ is the number of times word w occurs with state t, $n_{t',t}$ is the number of times state t' follows t and n_t is the number of occurences of state t; all expectations are taken with respect to the model $(\boldsymbol{\theta}^{(\ell)}, \boldsymbol{\phi}^{(\ell)})$.

The experiments below used the Forward-Backward algorithm (Jelinek, 1997), which is a dynamic programming algorithm for calculating the likelihood and the expectations in (2) in $O(nm^2)$ time, where n is the number of words in the training corpus and m is the number of HMM states.

2.2 Variational Bayes

Variational Bayesian inference attempts to find a function $Q(\boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi})$ that minimizes an upper bound (3) to the negative log likelihood.

$$\begin{array}{rl} & -\log \mathrm{P}(\boldsymbol{w}) \\ = & -\log \displaystyle\int Q(\boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi}) \frac{\mathrm{P}(\boldsymbol{w}, \boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi})}{Q(\boldsymbol{t}, \theta, \phi)} \, d\boldsymbol{t} \, d\boldsymbol{\theta} \, d\boldsymbol{\phi} \\ \leq & -\displaystyle\int Q(\boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi}) \log \frac{\mathrm{P}(\boldsymbol{w}, \boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi})}{Q(\boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi})} \, d\boldsymbol{t} \, d\boldsymbol{\theta} \, d\boldsymbol{\phi} \quad (3) \end{array}$$

The upper bound (3) is called the *Variational Free Energy*. We make a "mean-field" assumption that the posterior can be well approximated by a factorized model Q in which the state sequence $\boldsymbol{t}$ does not covary with the model parameters $\boldsymbol{\theta}, \boldsymbol{\phi}$:

$$\mathrm{P}(\boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi} \mid \boldsymbol{w}) \ \approx \ Q(\boldsymbol{t}, \boldsymbol{\theta}, \boldsymbol{\phi}) \ = \ Q_1(\boldsymbol{t}) Q_2(\boldsymbol{\theta}, \boldsymbol{\phi})$$

$$\mathrm{P}(t_i|\boldsymbol{w}, \boldsymbol{t}_{-i}, \alpha, \alpha') \quad \propto \quad \left(\frac{n'_{w_i,t_i} + \alpha'}{n_{t_i} + m'\alpha'}\right) \left(\frac{n_{t_i,t_{i-1}} + \alpha}{n_{t_{i-1}} + m\alpha}\right) \left(\frac{n_{t_{i+1},t_i} + \mathrm{I}(t_{i-1} = t_i = t_{i+1}) + \alpha}{n_{t_i} + \mathrm{I}(t_{i-1} = t_i) + m\alpha}\right)$$

Figure 1: The conditional distribution for state t_i used in the pointwise collapsed Gibbs sampler, which conditions on all states $\boldsymbol{t}_{-i}$ *except* t_i (i.e., the counts n do not include t_i). Here m' is the size of the vocabulary, m is the number of HMM states and $\mathrm{I}(\cdot)$ is the indicator function (i.e., equal to one if its argument is true and zero otherwise),

The calculus of variations is used to minimize the KL divergence between the desired posterior distribution and the factorized approximation. It turns out that if the likelihood and conjugate prior belong to exponential families then the optimal Q_1 and Q_2 do too, and there is an EM-like iterative procedure that finds locally-optimal model parameters (Bishop, 2006).

This procedure is especially attractive for HMM inference, since it involves only a minor modification to the M-step of the Forward-Backward algorithm. MacKay (1997) and Beal (2003) describe Variational Bayesian (VB) inference for HMMs. In general, the E-step for VB inference for HMMs is the same as in EM, while the M-step is as follows:

$$\begin{aligned} \tilde{\theta}^{(\ell+1)}_{t'|t} &= f(\mathrm{E}[n_{t',t}] + \alpha)/f(\mathrm{E}[n_t] + m\alpha) \qquad (4) \\ \tilde{\phi}^{(\ell+1)}_{w|t} &= f(\mathrm{E}[n'_{w,t}] + \alpha')/f(\mathrm{E}[n_t] + m'\alpha') \\ f(v) &= \exp(\Psi(v)) \end{aligned}$$

where m' and m are the number of word types and states respectively, Ψ is the digamma function and the remaining quantities are as in (2). This means that a single iteration can be performed in $O(nm^2)$ time, just as for the EM algorithm.

2.3 MCMC sampling algorithms

The goal of Markov Chain Monte Carlo (MCMC) algorithms is to produce a stream of samples from the posterior distribution $\mathrm{P}(\boldsymbol{t} \mid \boldsymbol{w}, \boldsymbol{\alpha})$. Besag (2004) provides a tutorial on MCMC techniques for HMM inference.

A Gibbs sampler is a simple kind of MCMC algorithm that is well-suited to sampling high-dimensional spaces. A Gibbs sampler for $\mathrm{P}(\boldsymbol{z})$ where $\boldsymbol{z} = (z_1, \ldots, z_n)$ proceeds by sampling and updating each z_i in turn from $\mathrm{P}(z_i \mid \boldsymbol{z}_{-i})$, where $\boldsymbol{z}_{-i} = (z_1, \ldots, z_{i-1}, z_{i+1}, \ldots, z_n)$, i.e., all of the z *except* z_i (Geman and Geman, 1984; Robert and Casella, 2004).

We evaluate four different Gibbs samplers in this paper, which vary along two dimensions. First, the sampler can either be *pointwise* or *blocked*. A pointwise sampler resamples a single state t_i (labeling a single word w_i) at each step, while a blocked sampler resamples the labels for all of the words in a sentence at a single step using a dynamic programming algorithm based on the Forward-Backward algorithm. (In principle it is possible to use block sizes other than the sentence, but we did not explore this here). A pointwise sampler requires $O(nm)$ time per iteration, while a blocked sampler requires $O(nm^2)$ time per iteration, where m is the number of HMM states and n is the length of the training corpus.

Second, the sampler can either be *explicit* or *collapsed*. An explicit sampler represents and samples the HMM parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ in addition to the states $\boldsymbol{t}$, while in a collapsed sampler the HMM parameters are integrated out, and only the states $\boldsymbol{t}$ are sampled. The difference between explicit and collapsed samplers corresponds exactly to the difference between the two PCFG sampling algorithms presented in Johnson et al. (2007).

An iteration of the pointwise explicit Gibbs sampler consists of resampling $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ given the state-to-state transition counts $\boldsymbol{n}$ and state-to-word emission counts $\boldsymbol{n}'$ using (5), and then resampling each state t_i given the corresponding word w_i and the neighboring states t_{i-1} and t_{i+1} using (6).

$$\begin{aligned} \boldsymbol{\theta}_t \mid \boldsymbol{n}_t, \boldsymbol{\alpha} &\sim \mathrm{Dir}(\boldsymbol{n}_t + \boldsymbol{\alpha}) \\ \boldsymbol{\phi}_t \mid \boldsymbol{n}'_t, \boldsymbol{\alpha}' &\sim \mathrm{Dir}(\boldsymbol{n}'_t + \boldsymbol{\alpha}') \end{aligned} \qquad (5)$$

$$\mathrm{P}(t_i \mid w_i, \boldsymbol{t}_{-i}, \boldsymbol{\theta}, \boldsymbol{\phi}) \propto \theta_{t_i|t_{i-1}} \phi_{w_i|t_i} \theta_{t_{i+1}|t_i} \qquad (6)$$

The Dirichlet distributions in (5) are non-uniform; $\boldsymbol{n}_t$ is the vector of state-to-state transition counts in $\boldsymbol{t}$ leaving state t in the current state vector $\boldsymbol{t}$, while

$\boldsymbol{n}'_t$ is the vector of state-to-word emission counts for state t. See Johnson et al. (2007) for a more detailed explanation, as well as an algorithm for sampling from the Dirichlet distributions in (5).

The samplers that Goldwater and Griffiths (2007) and Johnson (2007) describe are pointwise collapsed Gibbs samplers. Figure 1 gives the sampling distribution for this sampler. As Johnson et al. (2007) explains, samples of the HMM parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ can be obtained using (5) if required.

The blocked Gibbs samplers differ from the pointwise Gibbs samplers in that they resample the POS tags for an entire sentence at a time. Besag (2004) describes the well-known dynamic programming algorithm (based on the Forward-Backward algorithm) for sampling a state sequence $\boldsymbol{t}$ given the words $\boldsymbol{w}$ and the transition and emission probabilities $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$.

At each iteration the explicit blocked Gibbs sampler resamples $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ using (5), just as the explicit pointwise sampler does. Then it uses the new HMM parameters to resample the states $\boldsymbol{t}$ for the training corpus using the algorithm just mentioned. This can be done in parallel for each sentence in the training corpus.

The collapsed blocked Gibbs sampler is a straight-forward application of the Metropolis-within-Gibbs approach proposed by Johnson et al. (2007) for PCFGs, so we only sketch it here. We iterate through the sentences of the training data, resampling the states for each sentence conditioned on the state-to-state transition counts $\boldsymbol{n}$ and state-to-word emission counts $\boldsymbol{n}'$ for the other sentences in the corpus. This is done by first computing the parameters $\boldsymbol{\theta}^\star$ and $\boldsymbol{\phi}^\star$ of a *proposal HMM* using (7).

$$\begin{aligned} \theta^\star_{t'|t} &= \frac{n_{t',t}+\alpha}{n_t+m\alpha} \\ \phi^\star_{w|t} &= \frac{n'_{w,t}+\alpha'}{n_t+m'\alpha} \end{aligned} \qquad (7)$$

Then we use the dynamic programming sampler described above to produce a *proposal state sequence* $\boldsymbol{t}^\star$ for the words in the sentence. Finally, we use a Metropolis-Hastings accept-reject step to decide whether to update the current state sequence for the sentence with the proposal $\boldsymbol{t}^\star$, or whether to keep the current state sequence. In practice, with all but the very smallest training corpora the acceptance rate is very high; the acceptance rate for all of our collapsed blocked Gibbs samplers was over 99%.

3 Evaluation

The previous section described six different unsupervised estimators for HMMs. In this section we compare their performance for English part-of-speech tagging. One of the difficulties in evaluating unsupervised taggers such as these is mapping the system's states to the gold-standard parts-of-speech. Goldwater and Griffiths (2007) proposed an information-theoretic measure known as the *Variation of Information* (VI) described by Meilă (2003) as an evaluation of an unsupervised tagging. However as Goldwater (p.c.) points out, this may not be an ideal evaluation measure; e.g., a tagger which assigns all words the same single part-of-speech tag does disturbingly well under Variation of Information, suggesting that a poor tagger may score well under VI.

In order to avoid this problem we focus here on evaluation measures that construct an explicit mapping between the gold-standard part-of-speech tags and the HMM's states. Perhaps the most straight-forward approach is to map each HMM state to the part-of-speech tag it co-occurs with most frequently, and use this mapping to map each HMM state sequence $\boldsymbol{t}$ to a sequence of part-of-speech tags. But as Clark (2003) observes, this approach has several defects. If a system is permitted to posit an unbounded number of states (which is not the case here) it can achieve a perfect score on by assigning each word token its own unique state.

We can partially address this by cross-validation. We divide the corpus into two equal parts, and from the first part we extract a mapping from HMM states to the parts-of-speech they co-occur with most frequently, and use that mapping to map the states of the second part of the corpus to parts-of-speech. We call the accuracy of the resulting tagging the *cross-validation accuracy*.

Finally, following Haghighi and Klein (2006) and Johnson (2007) we can instead insist that at most one HMM state can be mapped to any part-of-speech tag. Following these authors, we used a greedy algorithm to associate states with POS tags; the accuracy of the resulting tagging is called the *greedy 1-to-1*

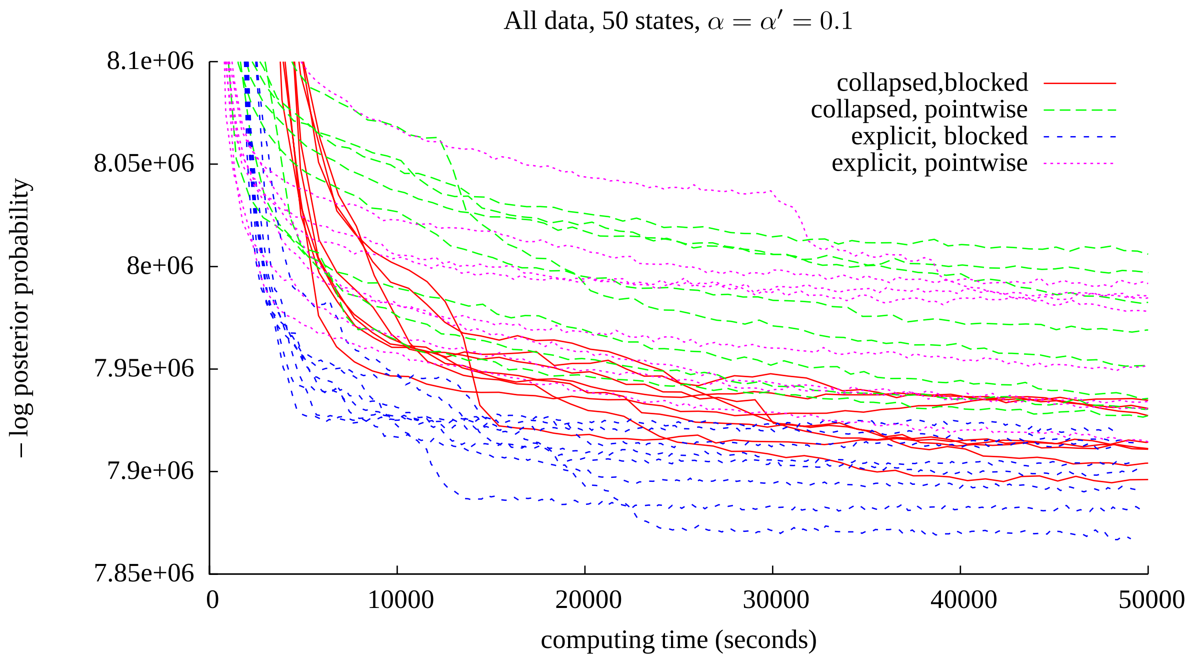
Figure 5: Average number of iterations until the negative logarithm of the posterior probability (or likelihood) changes by less than 0.5% (smaller is better) per at least 2,000 iterations. No annealing was used.



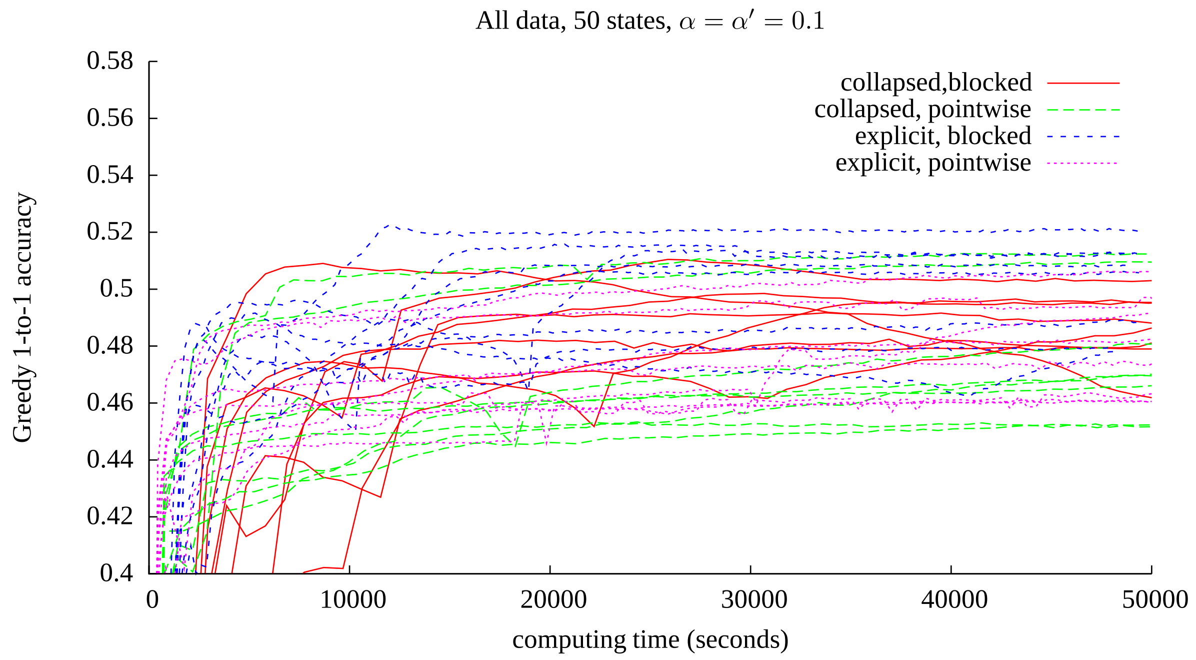


Figure 6: Variation in (a) negative log likelihood and (b) 1-to-1 accuracy as a function of running time on a 3GHz dual quad-core Pentium for the four different Gibbs samplers on all data and 50 hidden states. Each iteration took approximately 96 sec. for the collapsed blocked sampler, 7.5 sec. for the collapsed pointwise sampler, 25 sec. for the explicit blocked sampler and 4.4 sec. for the explicit pointwise sampler.

accuracy.

The studies presented by Goldwater and Griffiths (2007) and Johnson (2007) differed in the number of states that they used. Goldwater and Griffiths (2007) evaluated against the reduced tag set of 17 tags developed by Smith and Eisner (2005), while Johnson (2007) evaluated against the full Penn Treebank tag set. We ran all our estimators in both conditions here (thanks to Noah Smith for supplying us with his tag set).

Also, the studies differed in the size of the corpora used. The largest corpus that Goldwater and Griffiths (2007) studied contained 96,000 words, while Johnson (2007) used all of the 1,173,766 words in the full Penn WSJ treebank. For that reason we ran all our estimators on corpora containing 24,000 words and 120,000 words as well as the full treebank.

We ran each estimator with the eight different combinations of values for the hyperparameters α and α' listed below, which include the optimal values for the hyperparameters found by Johnson (2007), and report results for the best combination for each estimator below [1].

α	α'
1	1
1	0.5
0.5	1
0.5	0.5
0.1	0.1
0.1	0.0001
0.0001	0.1
0.0001	0.0001

Further, we ran each setting of each estimator at least 10 times (from randomly jittered initial starting points) for at least 1,000 iterations, as Johnson (2007) showed that some estimators require many iterations to converge. The results of our experiments are summarized in Figures 2–5.

[1]We found that on some data sets the results are sensitive to the values of the hyperparameters. So, there is a bit uncertainty in our comparison results because it is possible that the values we tried were good for one estimator and bad for others. Unfortunately, we do not know any efficient way of searching the optimal hyperparameters in a much wider and more fine-grained space. We leave it to future work.

4 Conclusion and future work

As might be expected, our evaluation measures disagree somewhat, but the following broad tendancies seem clear. On small data sets all of the Bayesian estimators strongly outperform EM (and, to a lesser extent, VB) with respect to all of our evaluation measures, confirming the results reported in Goldwater and Griffiths (2007). This is perhaps not too surprising, as the Bayesian prior plays a comparatively stronger role with a smaller training corpus (which makes the likelihood term smaller) and the approximation used by Variational Bayes is likely to be less accurate on smaller data sets.

But on larger data sets, which Goldwater et al did not study, the results are much less clear, and depend on which evaluation measure is used. Expectation Maximization does surprisingly well on larger data sets and is competitive with the Bayesian estimators at least in terms of cross-validation accuracy, confirming the results reported by Johnson (2007).

Variational Bayes converges faster than all of the other estimators we examined here. We found that the speed of convergence of our samplers depends to a large degree upon the values of the hyperparameters α and α', with larger values leading to much faster convergence. This is not surprising, as the α and α' specify how likely the samplers are to consider novel tags, and therefore directly influence the sampler's mobility. However, in our experiments the best results are obtained in most settings with small values for α and α', usually between 0.1 and 0.0001.

In terms of time to convergence, on larger data sets we found that the blocked samplers were generally faster than the pointwise samplers, and that the explicit samplers (which represented and sampled $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$) were faster than the collapsed samplers, largely because the time saved in not computing probabilities on the fly overwhelmed the time spent resampling the parameters.

Of course these experiments only scratch the surface of what is possible. Figure 6 shows that pointwise-samplers initially converge faster, but are overtaken later by the blocked samplers. Inspired by this, one can devise hybrid strategies that interleave blocked and pointwise sampling; these might perform better than both the blocked and pointwise samplers described here.

Abstract

This paper introduces a new method for identifying named-entity (NE) transliterations in bilingual corpora. Recent works have shown the advantage of discriminative approaches to transliteration: given two strings (w_s, w_t) in the source and target language, a classifier is trained to determine if w_t is the transliteration of w_s. This paper shows that the transliteration problem can be formulated as a constrained optimization problem and thus take into account contextual dependencies and constraints among character bi-grams in the two strings. We further explore several methods for learning the objective function of the optimization problem and show the advantage of learning it discriminately. Our experiments show that the new framework results in over 50% improvement in translating English NEs to Hebrew.

1 Introduction

Named entity (NE) transliteration is the process of transcribing a NE from a source language to some target language based on phonetic similarity between the entities. Identifying transliteration pairs is an important component in many linguistic applications which require identifying out-of-vocabulary words, such as machine translation and multilingual information retrieval (Klementiev and Roth, 2006b; Hermjakob et al., 2008).

It may appear at first glance that identifying the phonetic correlation between names based on an orthographic analysis is a simple, straight-forward task; however in many cases a consistent deterministic mapping between characters does not exist; rather, the mapping depends on the context the characters appear in and on transliteration conventions which may change across domains. Figure 1 exhibits two examples of NE transliterations in English and Hebrew, with the correct mapping across the two scripts. Although the two Hebrew names share a common prefix[1], this prefix can be mapped into a single English character or into two different characters depending on the context it appears in. Similarly, depending on the context it appears in, the English character a can be mapped into different characters or to an "empty" character.

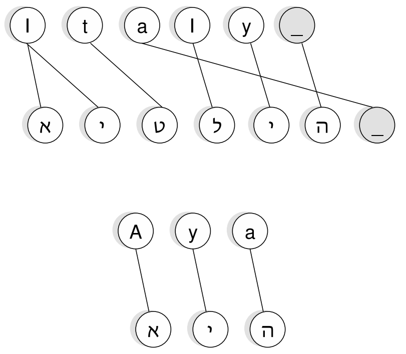

Figure 1: Named entities transliteration pairs in English and Hebrew and the character level mapping between the two names. The Hebrew names can be romanized as *ee-ta-l-ya* and *a-ya*

[1]In all our example the Hebrew script is shown left-to-right to simplify the visualization of the transliteration mapping.

In recent years, as it became clear that solutions that are based on linguistics rules are not satisfactory, machine learning approaches have been developed to address this problem. The common approach adopted is therefore to view this problem as a classification problem (Klementiev and Roth, 2006a; Tao et al., 2006) and train a discriminative classifier. That is, given two strings, one in the source and the other in the target language, extract pairwise features, and train a classifier that determines if one is a transliteration of the other. Several papers have followed up on this basic approach and focused on semi-supervised approaches to this problem or on extracting better features for the discriminative classifier (Klementiev and Roth, 2006b; Bergsma and Kondrak, 2007; Goldwasser and Roth, 2008). While it has been clear that the relevancy of pairwise features is context sensitive and that there are contextual constraints among them, the hope was that a discriminative approach will be sufficient to account for those by weighing features appropriately. This has been shown to be difficult for language pairs which are very different, such as English and Hebrew (Goldwasser and Roth, 2008).

In this paper, we address these difficulties by proposing to view the transliteration decision as a globally phrased constrained optimization problem. We formalize it as an optimization problem over a set of local pairwise features – character n-gram matches across the two string – and subject to legitimacy constraints.

We use a discriminatively trained classifier as a way to learn the objective function for the global constrained optimization problem. Our technical approach follows a large body of work developed over the last few years, following (Roth and Yih, 2004) that has formalized global decisions problems in NLP as constrained optimization problems and solved these optimization problems using Integer Linear Programming (ILP) or other methods (Punyakanok et al., 2005; Barzilay and Lapata, 2006; Clarke and Lapata, ; Marciniak and Strube, 2005).

We investigate several ways to train our objective function, which is represented as a dot product between a set of features chosen to represent a pair (w_s, w_t), and a vector of initial weights. Our first baseline makes use of all features extracted from a pair, along with a simple counting method to determine initial weights. We then use a method similar to (Klementiev and Roth, 2006a; Goldwasser and Roth, 2008) in order to discriminatively train a better weight vector for the objective function.

Our key contribution is that we use a constrained optimization approach also to determine a better feature representation for a given pair. (Bergsma and Kondrak, 2007) attempted a related approach to restricting the set of features representing a transliteration candidate. However, rather than directly aligning the two strings as done there, we exploit the expressiveness of the ILP formulation and constraints to generate a better representation of a pair. This is the representation we then use to discriminatively learn a better weight vector for the objective function used in our final model.

Our experiments focus on Hebrew-English transliteration, which were shown to be very difficult in a previous work (Goldwasser and Roth, 2008). We show very significant improvements over existing work with the same data set, proving the advantage of viewing the transliteration decision as a global inference problem. Furthermore, we show the importance of using a discriminatively trained objective function.

The rest of the paper is organized as follows. The main algorithmic contribution of this paper is described in Sec. 2. Our experimental study is describes in Sec. 3 and Sec. 4 concludes.

2 Using inference for transliteration

In this section we present our transliteration decision framework, which is based on solving a constrained optimization problem with an objective function that is discriminatively learned. Our framework consists of three key elements:

1. **Decision Model** When presented with a NE in the source language w_s and a set of candidates $\{w_t\}_1^k$ in the target language, the decision model ranks the candidate pairs (w_s, w_t) and selects the "best" candidate pair. This is framed as an optimization problem

$$w_t^* = argmax_i\{w \cdot F(w_s, w_t^i)\}, \qquad (1)$$

where F is a feature vector *representation* of the pair (w_s, w_t^i) and w is a vector of *weights* assigned to each feature.

2. **Representation** A pair $s = (w_s, w_t)$ of source and target NEs is represented as a vector of *features*, each of which is a pair of character n-grams, from w_s and w_t, resp. Starting with a baseline representation introduced in (Klementiev and Roth, 2006a), denoted here $AF(s)$, we refine this representation to take into account dependencies among the individual n-gram pairs. This refinement process is framed as a constrained optimization problem:

$$F(s)^* = argmax_{F \subseteq AF}\{w \cdot AF(s)\}, \quad (2)$$

subject to a set C of linear constraints. Here AF is the initial representation (All$-$Features), w is a vector of *weights* assigned to each feature and C is a set of constraints accounting for interdependencies among features.

3. **Weight Vector** Each pairwise n-gram feature is associated with a weight; this weigh vector is used in both optimization formulations above. The weight vector is determined by considering the whole training corpus. The initial weight vector is obtained generatively, by counting the relative occurrence of substring pairs in positive examples. The representation is refined by discriminatively training a classifier to maximize transliteration performance on the training data. In doing that, each example is represented using the feature vector representation described above.

The three key operations described above are being used in several stages, with different parameters (weight vectors and representations) as described in Alg. 1. In each stage a different element is refined. The input to this process is a training corpus Tr=(D_S,D_T) consisting of NE transliteration pairs $s = (w_s, w_t)$, where w_s, w_t are NEs in the source and target language, respectively. Each such sample point is initially represented as a feature vector $AF(s)$ (for All$-$Features), where features are pairs of substrings from the two words (following (Klementiev and Roth, 2006a)).

Given the set of feature vectors generated by applying AF to Tr, we assign initial weights W to the features ((1) in Alg. 1). These weights form the initial objective function used to construct a new feature based representation, Informative$-$Features, $IF_W(s)$ ((2) in Alg. 1). Specifically, for an instance s, $IF_W(s)$ is the solution of the optimization problem in Eq. 2, with W as the weight vector, $AF(s)$ as the representation, and a set of constraints ensuring the "legitimacy" of the selected set of features (Sec. 2.2.1).

```
Input: Training Corpora Tr=($D_S$,$D_T$)
Output: Transliteration model $\mathcal{M}$

1. Initial Representation and Weights
    For each sample s ∈ Tr, use AF to generate a feature vector
    $\{(f_s, f_t)^1, (f_s, f_t)^2, \ldots, (f_s, f_t)^n\} \in \{0,1\}^n$.
    Define $W{:}f \rightarrow \mathcal{R}$ s.t. foreach feature $f=(f_s, f_t)$
        $W(f) = \frac{\#(f_s,f_t)}{\#(f_s)} \times \frac{\#(f_s,f_t)}{\#(f_t)}$
2. Inferring Informative Representation ($W$)
    Modify the initial representation by solving the following constrained optimization problem:
    $IF_W(s)^* = argmax_{IF(s) \subseteq (AF(s))} W \cdot AF(s)$,
    subject to constraints C.
3. Discriminative Training
    Train a discriminative model on Tr, using $\{IF(s)\}_{s \in Tr}$.
    Let $W_D$ be the new weight vector obtained by discriminative training.
4. Inferring Informative Representation ($W_D$)
    Modify the initial representation by solving the following constrained optimization problem. This time, the objective function is determined by the discriminatively trained weight vector $W_D$.
    $IF_{W_D}(s)^* = argmax_{IF(s) \subseteq (AF(s))} W_D \cdot AF(s)$,
    subject to constraints C.
5. Decision Model
    Given a word $w_s$ and a list of candidates $w_t^1, w_t^2, \ldots w_t^k$, the chosen transliteration is $w_{t^*}$, determined by:
        $t^* = argmax_i\{W_D \cdot IF_{W_D}((w_s, w_t^i))\}$
```

Algorithm 1: Transliteration Framework.

The new feature extraction operator $IF_W(s)$ is now used to construct a new representation of the training corpus. With this representation, we train discriminately a new weight vector W_D. This weight vector, now defines a new objective function for the optimization problem in Eq. 2; W_D is the weight vector and $AF(s)$ the representation. We denote by $IF_{W_D}(s)$ the solution of this optimization problem for an instance s.

Given a representation and a weight vector, the optimization problem in Eq. 1 is used to find the transliteration of w_s. Our best decision model makes use of Eq. 1 using W_D as the feature vector and $IF_{W_D}(s)$ as the feature representation of s.

The rest of this section provides details on the operations and how we use them in different stages.

2.1 Initial Representation and Weights

The feature space we consider consists of n potential features, each feature $f = (f_s, f_t)$ represents a pairing of character level n-grams, where $f_s \in \{$*Source-Language* $\cup$ *empty-string* $\}$ and $f_t \in \{$*Target-Language* $\cup$ *empty-string*$\}$. A given sample (w_s, w_t) consisting of a pair of NEs is represented as a features vector $s \in \{0,1\}^n$. We say that a feature f^i is active if $f^i = 1$ and that $s_1 \subset s_2, \iff \{f^i\}_{\{f^i=\,1\ in\ s_1\}} \subset \{f^i\}_{\{f^i=1\ in\ s_2\}}$. We represent the active features corresponding to a pair as a bipartite graph $G = (V, E)$, in which each vertex $v \in V$ either represents the empty string, a single character or a bi-gram. V^S, V^T denote the vertices representing source and target language n-grams respectively. Each of these sets is composed of two disjoint subsets: $V_S = V^S_U \cup V^S_B$, $V_T = V^T_U \cup V^T_B$ consisting of vertices representing the uni-gram and bi-gram strings. Given a vertex v, *degree(*v, V'*)*denotes the degree of v in a subgraph of G, consisting only of $V' \subset V$; *index(v)* is the index of the substring represented by v in the original string.

Edges in the bipartite graph represent active features. The only deviation is that the vertex representing the empty string can be connected to any other (non-empty) vertex.

Our initial feature extraction method follows the one presented in (Klementiev and Roth, 2006a), in which the feature space consists of n-gram pairs from the two languages. Given a pair, each word is decomposed into a set of character substrings of up to a given length (including the empty string). Features are generated by pairing substrings from the two sets whose relative positions in the original words differ by k or less places, or formally:

$$E = \{e = (v_i, v_j) \mid (v_i \in V_S \wedge v_j \in V_T) \Rightarrow (index(v_j) + k \geq index(v_i) \geq index(v_j) - k) \wedge (v_i \neq v_{empty-string} \vee v_j \neq v_{empty-string})\}.$$

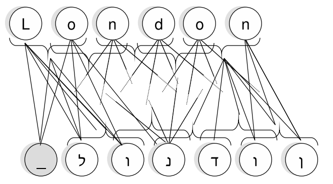

Figure 2: All possible unigram and bigram pairs generated by the AF operator. The Hebrew name can be romanized as *lo-n-do-n*

In our experiments we used *k*=1 which tested empirically, achieved the best performance.

Figure 2 exhibits the active features in the example using the graph representation. We refer to this feature extraction method as $All\text{-}Features$ (AF), and define it formally as an operator $AF : s \rightarrow \{(f_s, f_t)^i\}$ that maps a sample point $s = (w_s, w_t)$ to a set of active features.

The initial sample representation generates features by coupling substrings from the two terms without considering the dependencies between the possible consistent combinations. Ideally, given a positive sample, it is desirable that paired substrings would encode phonetic similarity or a distinctive context in which the two substrings correlate. However, AF simply pairs substrings from the two words, resulting in a noisy representation of the sample point. Given enough positive samples, we assume that features appearing with distinctive frequency will encode the desired relation. We use this observation, and construct a weight vector, associating each feature with a positive number indicating its relative occurrence frequency in the training data representation formed by AF. This weight is computed as follows:

Definition 1 (Initial Feature Weights Vector) *Let* W*:*f $\rightarrow \mathcal{R}$ *s.t. for each feature* f=$\{f_s, f_t\}$,

$$W(\text{f}) = \frac{\#(f_s, f_t)}{\#(f_s)} \times \frac{\#(f_s, f_t)}{\#(f_t)},$$

where $\#(f_s, f_t)$ *is the number of occurrences of that feature in the positive sample set, and* $\#(f_L), L = \{s, t\}$ *is the number of occurrences of an individual substring, in any of the features extracted from positive samples in the training set.*

These weights transform every example into a weighted graph, where each edge is associated by W with the weight assigned to the feature it represents. As we empirically tested, this initialization assigns high weights to features that preserve the phonetic correlation between the two languages. The top part of figure 5 presents several examples of weights assigned by W to features composed of different English and Hebrew substrings combinations. It can be observed that combination which are phonetically similar are associated with a higher weight. However, as it turns out, transliteration mappings do not consist of "clean" and consistent mappings of phonetically similar substrings. In the following section we explain how to use these weights to generate a more compact representation of samples.

2.2 Inferring Informative Representations

In this section we suggest a new feature extraction method for determining the representation of a given word pair. We use the strength of the active features computed above, along with legitimacy constraints on mappings between source and target strings to find an optimal set of consistent active features that represents a pair. This problem can be naturally encoded as a linear optimization problem, which seeks to maximize a linear objective function determined by W, over a set of variables representing the active features selection, subject to a set of linear constraints representing the dependencies between selections. We follow the formulation given by (Roth and Yih, 2004), and define it as an Integer Linear Programming (ILP) optimization problem, in which each integer variable $a_{(j,k)}$, defined over $\{0,1\}$, represents whether a feature pairing an n-gram $j \in S$ with an n-gram $k \in T$, is active. Although using ILP is in general NP-hard, it has been used efficiently in many natural language (see section 1). Our experience as well has been that this process is very efficient due to the sparsity of the constraints used.

2.2.1 Constraining Feature Dependencies

To limit the selection of active features in each sample we require that each element in the decomposition of w_s into bi-grams should be paired with an element in w_t, and the vice-versa. We restrict the possible pairs by allowing only a single n-gram to be matched to any other n-gram, with one exception - we allow every bi-gram to be mapped into an empty string. Viewed as a bipartite graph, we allow each node (with the exception of the empty string) to have only one connected edge. These constraints, given the right objective function, should enforce an alignment of bi-grams according to phonetic similarity; for example, the word pairs described in Figure 1, depicts a character level alignment between the words, where in some cases a bi-gram is mapped into a single character and in other cases single characters are mapped to each other, based on phonetic similarity encoded by the two scripts. However, imposing these constraints over the entire set of candidate features would be too restrictive; it is unlikely that one can consistently represent a single "correct" phonetic mapping. We wish to represent both the character level and bi-gram mapping between names as both represent informative features on the correspondence between the names over the two scripts. To allow this, we decompose the problem into two disjoint sets of constraints imposing 1-1 mappings, one over the set of single character substrings and the other over the bi-gram substrings. Given the bipartite graph generated by *AF*, we impose the following constraints:

Definition 2 (Transliteration Constraints) *Let C be the set of constraints, consisting of the following predicates:*

$$\forall v \in V^S,\ \text{degree}(v, V^S \cup V_U^T) \leq 1 \wedge$$
$$\forall v \in V^S,\ \text{degree}(v, V^S \cup V_B^T) \leq 1 \wedge$$
$$\forall v \in V^T,\ \text{degree}(v, V^T \cup V_U^S) \leq 1 \wedge$$
$$\forall v \in V^T,\ \text{degree}(v, V^T \cup V_B^S) \leq 1$$

For example, Figure 2 shows the graph of all possible candidates produced by AF. In Figure 3, the graph is decomposed into two graphs, each depicting possible matches between the character level uni-gram or bi-gram substrings. the ILP constraints ensure that in each graph, every node (with the exception of the empty string) has a degree of one . Figure 4 gives the results of the ILP process – a unified graph in which every node has only a single edge associated with it.

Definition 3 (Informative Feature Extraction (IF)) *We define the Informative-Features(IF) feature extraction operator, $IF : s \rightarrow \{(f_s, f_t)^i\}$ as the solution to the ILP problem in Eq. 2. Namely,*

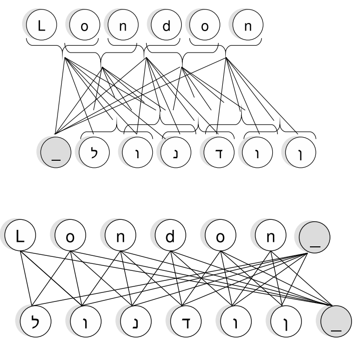

Figure 3: Find informative features by solving an ILP problem. Dependencies between matching decisions are modeled by allowing every node to be connected to a single edge (except the node representing the empty-string).

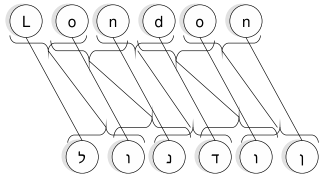

Figure 4: The result of applying the IF operator by solving an ILP problem, represented as a pruned graph.

$$IF(s)^{*} = argmax_{IF(s)\subseteq(AF(s))} w \cdot AF(s),$$

subject to constraints ***C***.

We will use this operator with $w = W$, defined above, and denote it IF_W, and also use it with a different weight vector, trained discriminatively, as described next.

2.3 Discriminative Training

Using the IF_W operator, we generate a better representation of the training data, which is now used to train a discriminative model. We use a linear classifier trained with a regularized average perceptron update rule (Grove and Roth, 2001) as implemented in SNoW, (Roth, 1998). This learning algorithm provides a simple and general linear classifier that has been demonstrated to work well in other NLP classification tasks, e.g. (Punyakanok et al., 2005), and allows us to incorporate extensions such as strength of features naturally into the training algorithm. We augment each sample in the training data with feature weights; given a sample, the learner is presented with a real-valued feature vector instead of a binary vector. This can be viewed as providing a better starting point for the learner, which improves the learning rate (Golding and Roth, 1999; Ng and Jordan, 2001).

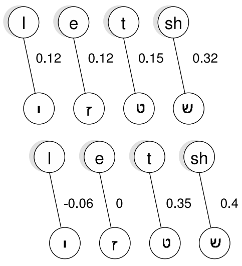

Figure 5: Several examples of weights assigned to features generated by coupling English and Hebrew substrings. Top figure: initial weights. Bottom figure: Discriminatively learned weights. The Hebrew characters, ordered left to right, can be romanized as *y,z,t,sh*

The weight vector learned by the discriminative training is denoted W_D. Given the new weight vector, we can define a new feature extraction operator, that we get by applying the objective function in Eq. 2 with W_D instead of W. Given a sample s, the feature representation generated by this new information extraction operator is denoted $IF_{W_D}(s)$. The key difference between W and W_D is that the latter was trained over a corpora containing both negative and positive examples, and as a result W_D contains negative weights. To increase the impact of training we multiplied the negative weights by 2.

Figure 5 presents some examples of the benefit of discriminately learning the objective function; the weighted edges in the top figure show the values assigned to features by W, while the bottom figure shows the weights assigned by W_D. In all cases, phonetically similar characters were assigned higher scores by W_D, and character pairs not phonetically similar were typically assigned negative weights. It is also interesting to note a special phenomena occurring in English-Hebrew transliterations. The English vowels will be paired to almost any Hebrew character when generating pairs using AF, since vowels in most cases are omitted in Hebrew, there is no distinctive context in which English vowels appear. We can see for example, in the top graph presented in Figure 5 an edge matching a vowel to a Hebrew character with a high weight, the bottom graph showing the results of the discriminative training process show that this edge is associated with a zero weight score.

2.4 Decision Models

This section defines several transliteration decision models given a word w_s and a list of candidates $w_t^1, w_t^2, \dots w_t^k$. The models are used to identify the correct transliteration pair from the set of candidates $\{s_i = (w_s, w_t^i)\}_{i=1\dots k}$.

In all cases, the decision is formulated as in Eq. 1, where different models differ by the representations and weight vectors used.

Decision Model 1 *Ranking the transliteration candidates is done by evaluating*

$$s^* = argmax_i \; W \cdot AF(s_i),$$

which selects the transliteration pair which maximizes the objective function based on the generatively computed weight vector.

Decision Model 2 *Ranking the transliteration candidates is done by evaluating:*

$$s^* = argmax_i \; W_D \cdot AF(s_i)).$$

This decision model is essentially equivalent to the transliteration models used in (Klementiev and Roth, 2006a; Goldwasser and Roth, 2008), in which a linear transliteration model was trained using a feature extraction method equivalent to *AF*.

Decision Model 3 *Ranking the transliteration candidates is done by evaluating:*

$$s^* = argmax_i \; W \cdot IF_W(s_i),$$

which maximizes the objective function with the generatively computed weight vector and the informative feature representation derived based on it.

Decision Model 4 *Ranking the transliteration candidates is done by evaluating:*

$$s^* = argmax_i \; W_D \cdot IF_W(s_i)),$$

which conceptually resembles the transliteration model presented in (Bergsma and Kondrak, 2007), in that a discriminative classifier was trained and used over a pruned feature set.

Decision Model 5 *Ranking the transliteration candidates is done by evaluating:*

$$s^* = argmax_i \; W_D \cdot IF_{W_D}(s_i),$$

which maximize the objective function with the discriminately derived weight vector and the informative features inferred based on it. This decision model is the only model that incorporates discriminative weights as part of the feature extraction process; W_D is used as the objective function used when inferring IF_{W_D}.

3 Evaluation

We evaluated our approach over a corpus of 300 English-Hebrew transliteration pairs, and used another 250 different samples for training the models. We constructed the test set by pairing each English name with all Hebrew names in the corpus. The system was evaluated on its ability to correctly identify the 300 transliteration pairs out of all the possible transliteration candidates. We measured performance using the *Mean Reciprocal Rank* (MRR) measure. This measure, originally introduced in the field of information retrieval, is used to evaluate systems that rank several options according to their probability of correctness. MRR is a natural measure in our settings and has been used previously for evaluating transliteration systems, for example by (Tao et al., 2006).

Given a set Q of queries and their respective responses ranked according to the system's confidence, we denote the rank of the correct response to a query $q_i \in Q$ as $rank(q_i)$. MRR is then defined as the average of the multiplicative inverse of the rank of the correct answer, that is:

$$MRR = \frac{1}{|Q|} \sum_{i=1\dots|Q|} \frac{1}{rank(q_i)}.$$

In our experiments we solved an ILP problem for every transliteration candidate pairs, and computed MRR with respect to the confidence of our decision model across the candidates. Although this required solving thousands of ILP instances, it posed no computational burden as these instances typically contained a small number of variables and constraints. The entire test set is solved in less than 20 minutes using the publicly available GLPK package (`http://www.gnu.org/software/glpk/`).

The performance of the different models is summarized in table 1, these results are based on a training set of 250 samples used to train the discriminative transliteration models and also to construct the initial weight vector W. Figure 6 shows performance over different number of training examples. Our evaluation is concerns with the core transliteration and decision models presented here and does not consider any data set optimizations that were introduced in previous works, which we view as orthogonal additions, hence the difference with the results published in (Goldwasser and Roth, 2008).

The results clearly show that our final model, model 5, outperform other models. Interestingly, model 1, a simplistic model, significantly outperforms the discriminative model presented in (Klementiev and Roth, 2006b). We believe that this is due to two reasons. It shows that discriminative training over the representation obtained using AF is not efficient; moreover, this phenomenon is accentuated given that we train over a very small data set, which favors generative estimation of weights. This is also clear when comparing the performance of model 1 to model 4, which shows that learning over the representation obtained using constrained optimization (IF) results in a very significant performance improvement.

The improvement of using IF_W is not automatic. Model 3, which uses IF_W, and model 1, which uses AF, converge to nearly the same result. Both these models use generative weights to make the transliteration decision, and this highlights the importance of discriminative training. Both model 4 and model 5 use discriminatively trained weights and significantly outperform model 3. These results indicate that using constraint optimization to generate the examples' representation in itself may not help; the objective function used in this inference has a significant role in improved performance.

The benefit of discriminatively training the objective function becomes even clearer when comparing the performance of model 5 to that of model 4, which uses the original weight vector when inferring the sample representation.

It can be assumed that this algorithm can benefit from further iterations – generating a new feature representations, training a model on it, and using the resulting model as a new objective function. However, it turns out that after a single round, improved weights due to additional training do not change the feature representation; the inference process does not yield a different outcome.

Decision Model	MRR
Baseline model, used in (KR'06,GR'08)	
Model 2	0.51
Models presented in this paper	
Model 1	0.713
Model 3	0.715
Model 4	0.832
Model 5	0.848

Table 1: Results of the different transliteration models, trained using 250 samples. To facilitate readability (Klementiev and Roth, 2006b; Goldwasser and Roth, 2008) are referenced as KR'06 and GR'08 respectively.

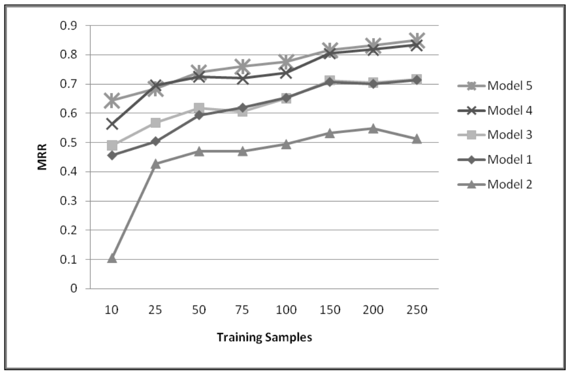

Figure 6: Results of the different constraint optimization transliteration models. Performance is compared relative to the number of samples used for training.

3.1 Normalized Objective Function

Formulating the transliteration decision as an optimization problem also allows us to naturally encode other considerations into our objective function. in this case we give preference to matching short words. We encode this preference as a normalization factor for the objective function. When evaluating on pair (w_s, w_t), we divide the weight vector length of the shorter word; our decision model now becomes:

Decision Model 6 (Model 5 - LengthNormalization)

Decision Model	MRR
Model 5	0.848
Model 5 - LN	0.894

Table 2: Results of using model 5 with and without a normalized objective function. Both models were trained using 250 samples. The LN suffix in the model's name indicate that the objective function used length normalization.

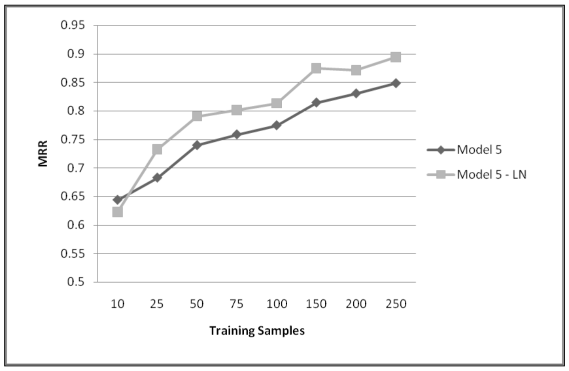

Figure 7: Results of using model 5 with and without a normalized objective function. Performance is compared relative to the number of samples used for training.

Ranking the transliteration candidates is done by evaluating:

$$s^* = argmax_i \ W_D \cdot IF_{W_D}(s_i)/min(|w_s|, |w_t|)$$

As described in table 2 and figure 7, using length normalization significantly improves the results. This can be attributed to the fact that typically Hebrew names are shorter and therefore every pair (w_s, w_t) considered by our model will be effected differently by this normalization factor.

4 Discussion

We introduced a new approach for identifying NE transliteration, viewing the transliteration decision as a global inference problem. We explored several methods for combining discriminative learning in a global constraint optimization framework and showed that discriminatively learning the objective function improves performance significantly.

From an algorithmic perspective, our key contribution is the introduction of a new method, in which learning and inference are used in an integrated way. We use learning to generate an objective function for the inference process; use the inference process to generate a better representation for the learning process, and iterate these stages.

From the transliteration perspective, our key contribution is in deriving and showing the significance of a good representation for a pair of NEs. Our representation captures both phonetic similarity and distinctive occurrence patterns across character level matchings of the two input strings, while enforcing the constraints induced by the interdependencies of the individual matchings. As we show, this representation serves to improve the ability of a discriminative learning algorithm to weigh features appropriately and results in significantly better transliteration models. This representation can be viewed as a compromise between models that do not consider dependencies between local decisions and those that try to align the two strings. Achieving this compromise is one of the advantages of the flexibility allowed by the constrained optimization framework we use. We plan to investigate using more constraints within this framework, such as soft constraints which can penalize unlikely local decisions while not completely eliminating the entire solution.

Acknowledgments

We wish to thank Alex Klementiev and the anonymous reviewers for their insightful comments. This work is partly supported by NSF grant SoD-HCER-0613885 and DARPA funding under the Bootstrap Learning Program.

Abstract

How can the development of ideas in a scientific field be studied over time? We apply unsupervised topic modeling to the ACL Anthology to analyze historical trends in the field of Computational Linguistics from 1978 to 2006. We induce topic clusters using Latent Dirichlet Allocation, and examine the strength of each topic over time. Our methods find trends in the field including the rise of probabilistic methods starting in 1988, a steady increase in applications, and a sharp decline of research in semantics and understanding between 1978 and 2001, possibly rising again after 2001. We also introduce a model of the diversity of ideas, *topic entropy*, using it to show that COLING is a more diverse conference than ACL, but that both conferences as well as EMNLP are becoming broader over time. Finally, we apply Jensen-Shannon divergence of topic distributions to show that all three conferences are converging in the topics they cover.

1 Introduction

How can we identify and study the exploration of ideas in a scientific field over time, noting periods of gradual development, major ruptures, and the waxing and waning of both topic areas and connections with applied topics and nearby fields? One important method is to make use of citation graphs (Garfield, 1955). This enables the use of graph-based algorithms like PageRank for determining researcher or paper centrality, and examining whether their influence grows or diminishes over time.

However, because we are particularly interested in the change of *ideas* in a field over time, we have chosen a different method, following Kuhn (1962). In Kuhn's model of scientific change, science proceeds by shifting from one paradigm to another. Because researchers' ideas and vocabulary are constrained by their paradigm, successive incommensurate paradigms will naturally have different vocabulary and framing.

Kuhn's model is intended to apply only to very large shifts in scientific thought rather than at the micro level of trends in research foci. Nonetheless, we propose to apply Kuhn's insight that vocabulary and vocabulary shift is a crucial indicator of ideas and shifts in ideas. Our operationalization of this insight is based on the unsupervised topic model Latent Dirichlet Allocation (LDA; Blei et al. (2003)).

For many fields, doing this kind of historical study would be very difficult. Computational linguistics has an advantage, however: the ACL Anthology, a public repository of all papers in the *Computational Linguistics* journal and the conferences and workshops associated with the ACL, COLING, EMNLP, and so on. The ACL Anthology (Bird, 2008), and comprises over 14,000 documents from conferences and the journal, beginning as early as 1965 through 2008, indexed by conference and year. This resource has already been the basis of citation analysis work, for example, in the ACL Anthology Network of Joseph and Radev (2007). We apply LDA to the text of the papers in the ACL Anthology to induce topics, and use the trends in these topics over time and over conference venues to address questions about the development of the field.

Venue	# Papers	Years	Frequency
Journal	1291	1974–Present	Quarterly

Table 1: Data in the ACL Anthology

Despite the relative youth of our field, computational linguistics has witnessed a number of research trends and shifts in focus. While some trends are obvious (such as the rise in machine learning methods), others may be more subtle. Has the field gotten more theoretical over the years or has there been an increase in applications? What topics have declined over the years, and which ones have remained roughly constant? How have fields like Dialogue or Machine Translation changed over the years? Are there differences among the conferences, for example between COLING and ACL, in their interests and breadth of focus? As our field matures, it is important to go beyond anecdotal description to give grounded answers to these questions. Such answers could also help give formal metrics to model the differences between the many conferences and venues in our field, which could influence how we think about reviewing, about choosing conference topics, and about long range planning in our field.

2 Methodology

2.1 Data

The analyses in this paper are based on a text-only version of the Anthology that comprises some 12,500 papers. The distribution of the Anthology data is shown in Table 1.

2.2 Topic Modeling

Our experiments employ Latent Dirichlet Allocation (LDA; Blei et al. (2003)), a generative latent variable model that treats documents as bags of words generated by one or more topics. Each document is characterized by a multinomial distribution over topics, and each topic is in turn characterized by a multinomial distribution over words. We perform parameter estimation using collapsed Gibbs sampling (Griffiths and Steyvers, 2004).

Possible extensions to this model would be to integrate topic modelling with citations (e.g., Dietz et al. (2007), Mann et al. (2006), and Jo et al. (2007)). Another option is the use of more fine-grained or hierarchical model (e.g., Blei et al. (2004), and Li and McCallum (2006)).

All our studies measure change in various aspects of the ACL Anthology over time. LDA, however, does not explicitly model temporal relationships. One way to model temporal relationships is to employ an extension to LDA. The Dynamic Topic Model (Blei and Lafferty, 2006), for example, represents each year's documents as generated from a normal distribution centroid over topics, with the following year's centroid generated from the preceding year's. The Topics over Time Model (Wang and McCallum, 2006) assumes that each document chooses its own time stamp based on a topic-specific beta distribution.

Both of these models, however, impose constraints on the time periods. The Dynamic Topic Model penalizes large changes from year to year while the beta distributions in Topics over Time are relatively inflexible. We chose instead to perform *post hoc* calculations based on the observed probability of each topic given the current year. We define $\hat{p}(z|y)$ as the empirical probability that an arbitrary paper d written in year y was about topic z:

$$\begin{aligned}\hat{p}(z|y) &= \sum_{d:t_d=y} \hat{p}(z|d)\hat{p}(d|y) \\ &= \frac{1}{C}\sum_{d:t_d=y} \hat{p}(z|d) \\ &= \frac{1}{C}\sum_{d:t_d=y}\sum_{z'_i\in d} I(z'_i = z)\end{aligned} \quad (1)$$

where I is the indicator function, t_d is the date document d was written, $\hat{p}(d|y)$ is set to a constant $1/C$.

3 Summary of Topics

We first ran LDA with 100 topics, and took 36 that we found to be relevant. We then hand-selected seed

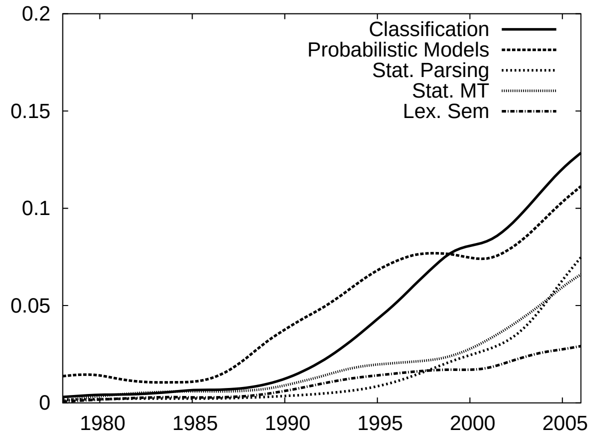

Figure 1: Topics in the ACL Anthology that show a strong recent increase in strength.

words for 10 more topics to improve coverage of the field. These 46 topics were then used as priors to a new 100-topic run. The top ten most frequent words for 43 of the topics along with hand-assigned labels are listed in Table 2. Topics deriving from manual seeds are marked with an asterisk.

4 Historical Trends in Computational Linguistics

Given the space of possible topics defined in the previous section, we now examine the history of these in the entire ACL Anthology from 1978 until 2006. To visualize some trends, we show the probability mass associated with various topics over time, plotted as (a smoothed version of) $\hat{p}(z|y)$.

4.1 Topics Becoming More Prominent

Figure 1 shows topics that have become more prominent more recently.

Of these new topics, the rise in *probabilistic models* and *classification/tagging* is unsurprising. In order to distinguish these two topics, we show 20 of the strongly weighted words:

Probabilistic Models: *model word probability set data number algorithm language corpus method figure probabilities table test statistical distribution function al values performance*

Classification/Tagging: *features data corpus set feature table word tag al test accuracy pos classification performance tags tagging text task information class*

Some of the papers with the highest weights for the *probabilistic models* class include:

N04-1039	Goodman, Joshua. Exponential Priors For Maximum Entropy Models (HLT-NAACL, 2004)
W97-0309	Saul, Lawrence, Pereira, Fernando C. N. Aggregate And Mixed-Order Markov Models For Statistical Language Processing (EMNLP, 1997)
P96-1041	Chen, Stanley F., Goodman, Joshua. An Empirical Study Of Smoothing Techniques For Language Modeling (ACL, 1996)
H89-2013	Church, Kenneth Ward, Gale, William A. Enhanced Good-Turing And CatCal: Two New Methods For Estimating Probabilities Of English Bigrams (Workshop On Speech And Natural Language, 1989)
P02-1023	Gao, Jianfeng, Zhang, Min Improving Language Model Size Reduction Using Better Pruning Criteria (ACL, 2002)
P94-1038	Dagan, Ido, Pereira, Fernando C. N. Similarity-Based Estimation Of Word Cooccurrence Probabilities (ACL, 1994)

Some of the papers with the highest weights for the *classification/tagging* class include:

W00-0713	Van Den Bosch, Antal Using Induced Rules As Complex Features In Memory-Based Language Learning (CoNLL, 2000)
W01-0709	Estabrooks, Andrew, Japkowicz, Nathalie A Mixture-Of-Experts Framework For Text Classification (Workshop On Computational Natural Language Learning CoNLL, 2001)
A00-2035	Mikheev, Andrei. Tagging Sentence Boundaries (ANLP-NAACL, 2000)
H92-1022	Brill, Eric. A Simple Rule-Based Part Of Speech Tagger (Workshop On Speech And Natural Language, 1992)

As Figure 1 shows, *probabilistic models* seem to have arrived significantly before *classifiers*. The probabilistic model topic increases around 1988, which seems to have been an important year for probabilistic models, including high-impact papers like A88-1019 and C88-1016 below. The ten papers from 1988 with the highest weights for the *probabilistic model* and *classifier* topics were the following:

C88-1071	Kuhn, Roland. Speech Recognition and the Frequency of Recently Used Words (COLING)
J88-1003	DeRose, Steven. Grammatical Category Disambiguation by Statistical Optimization. (CL Journal)
C88-2133	Su, Keh-Yi, and Chang, Jing-Shin. Semantic and Syntactic Aspects of Score Function. (COLING)
A88-1019	Church, Kenneth Ward. A Stochastic Parts Program and Noun Phrase Parser for Unrestricted Text. (ANLP)
C88-2134	Sukhotin, B.V. Optimization Algorithms of Deciphering as the Elements of a Linguistic Theory. (COLING)
P88-1013	Haigh, Robin, Sampson, Geoffrey, and Atwell, Eric. Project APRIL: a progress report. (ACL)

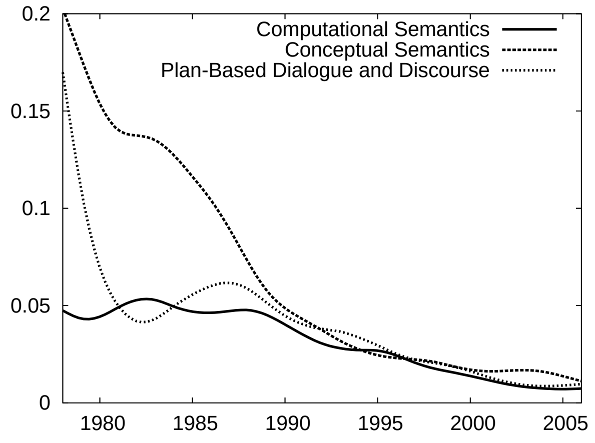

Figure 2: Topics in the ACL Anthology that show a strong decline from 1978 to 2006.

probabilistic models and classifiers entered the field? First, not surprisingly, we note that the vast majority (9 of 10) of the papers appeared in conference proceedings rather than the journal, confirming that in general new ideas appear in conferences. Second, of the 9 conference papers, most of them appeared in the COLING conference (5) or the ANLP workshop (3) compared to only 1 in the ACL conference. This suggests that COLING may have been more receptive than ACL to new ideas at the time, a point we return to in Section 6. Finally, we examined the background of the authors of these papers. Six of the 10 papers either focus on speech (C88-1010, A88-1028, C88-1071) or were written by authors who had previously published on speech recognition topics, including the influential IBM (Brown *et al.*) and AT&T (Church) labs (C88-1016, A88-1005, A88-1019). Speech recognition is historically an electrical engineering field which made quite early use of probabilistic and statistical methodologies. This suggests that researchers working on spoken language processing were an important conduit for the borrowing of statistical methodologies into computational linguistics.

4.2 Topics That Have Declined

Figure 2 shows several topics that were more prominent at the beginning of the ACL but which have shown the most precipitous decline. Papers strongly associated with the *plan-based dialogue* topic include:

J99-1001	Carberry, Sandra, Lambert, Lynn. A Process Model For Recognizing Communicative Acts And Modeling Negotiation Subdialogues (CL, 1999)
J95-4001	McRoy, Susan W., Hirst, Graeme. The Repair Of Speech Act Misunderstandings By Abductive Inference (CL, 1995)
P93-1039	Chu, Jennifer. Responding To User Queries In A Collaborative Environment (ACL, 1993)
P86-1032	Pollack, Martha E. A Model Of Plan Inference That Distinguishes Between The Beliefs Of Actors And Observers (ACL, 1986)
T78-1017	Perrault, Raymond C., Allen, James F. Speech Acts As A Basis For Understanding Dialogue Coherence (Theoretical Issues In Natural Language Processing, 1978)
P84-1063	Litman, Diane J., Allen, James F. A Plan Recognition Model For Clarification Subdialogues (COLING-ACL, 1984)

Papers strongly associated with the *computational semantics* topic include:

J90-4002	Haas, Andrew R. Sentential Semantics For Propositional Attitudes (CL, 1990)
P83-1009	Hobbs, Jerry R. An Improper Treatment Of Quantification In Ordinary English (ACL, 1983)
J87-1005	Hobbs, Jerry R., Shieber, Stuart M. An Algorithm For Generating Quantifier Scopings (CL, 1987)
C90-1003	Johnson, Mark, Kay, Martin. Semantic Abstraction And Anaphora (COLING, 1990)
P89-1004	Alshawi, Hiyan, Van Eijck, Jan. Logical Forms In The Core Language Engine (ACL, 1989)

Papers strongly associated with the *conceptual semantics/story understanding* topic include:

C80-1022	Ogawa, Hitoshi, Nishi, Junichiro, Tanaka, Kokichi. The Knowledge Representation For A Story Understanding And Simulation System (COLING, 1980)
A83-1012	Pazzani, Michael J., Engelman, Carl. Knowledge Based Question Answering (ANLP, 1983)
P82-1029	McCoy, Kathleen F. Augmenting A Database Knowledge Representation For Natural Language Generation (ACL, 1982)
H86-1010	Ksiezyk, Tomasz, Grishman, Ralph An Equipment Model And Its Role In The Interpretation Of Nominal Compounds (Workshop On Strategic Computing - Natural Language, 1986)
P80-1030	Wilensky, Robert, Arens, Yigal. PHRAN - A Knowledge-Based Natural Language Understander (ACL, 1980)
A83-1013	Boguraev, Branimir K., Sparck Jones, Karen. How To Drive A Database Front End Using General Semantic Information (ANLP, 1983)
P79-1003	Small, Steven L. Word Expert Parsing (ACL, 1979)

The declines in both computational semantics and *conceptual semantics/story understanding* suggests that it is possible that the entire field of natural language understanding and computational semantics broadly construed has fallen out of favor. To see if this was in fact the case we created a metatopic called *semantics* in which we combined various semantics topics (not including pragmatic topics like anaphora resolution or discourse coherence) including: *lexical semantics, conceptual semantics/story*

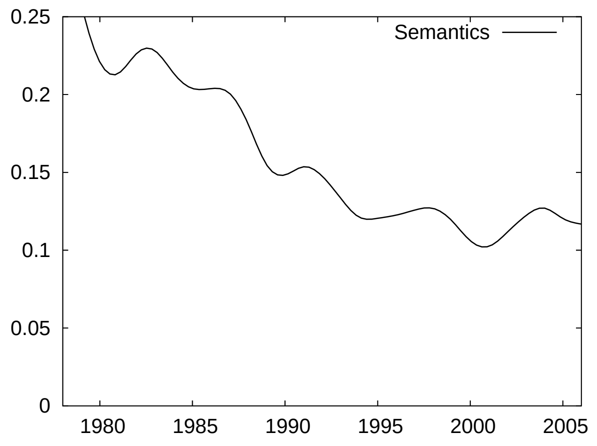

Figure 3: Semantics over time

understanding, computational semantics, WordNet, word sense disambiguation, semantic role labeling, RTE and paraphrase, MUC information extraction, and *events/temporal*. We then plotted $\hat{p}(z \in S|y)$, the sum of the proportions per year for these topics, as shown in Figure 3. The steep decrease in semantics is readily apparent. The last few years has shown a levelling off of the decline, and possibly a revival of this topic; this possibility will need to be confirmed as we add data from 2007 and 2008.

We next chose two fields, Dialogue and Machine Translation, in which it seemed to us that the topics discovered by LDA suggested a shift in paradigms in these fields. Figure 4 shows the shift in translation, while Figure 5 shows the change in dialogue.

The shift toward statistical machine translation is well known, at least anecdotally. The shift in dialogue seems to be a move toward more applied, speech-oriented, or commercial dialogue systems and away from more theoretical models.

Finally, Figure 6 shows the history of several topics that peaked at intermediate points throughout the history of the field. We can see the peak of *unification* around 1990, of *syntactic structure* around 1985 of *automata* in 1985 and again in 1997, and of *word sense disambiguation* around 1998.

5 Is Computational Linguistics Becoming More Applied?

We don't know whether our field is becoming more applied, or whether perhaps there is a trend towards new but unapplied theories. We therefore

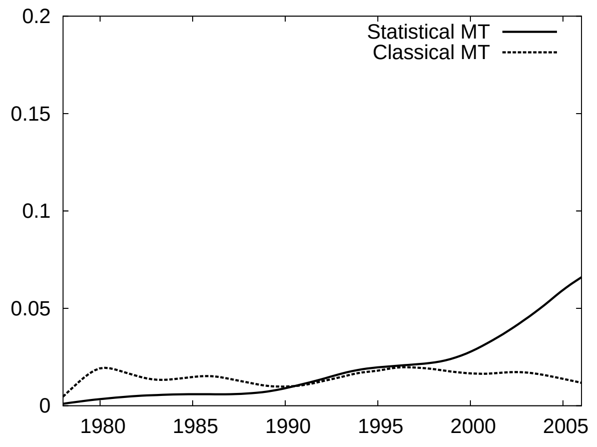

Figure 4: Translation over time

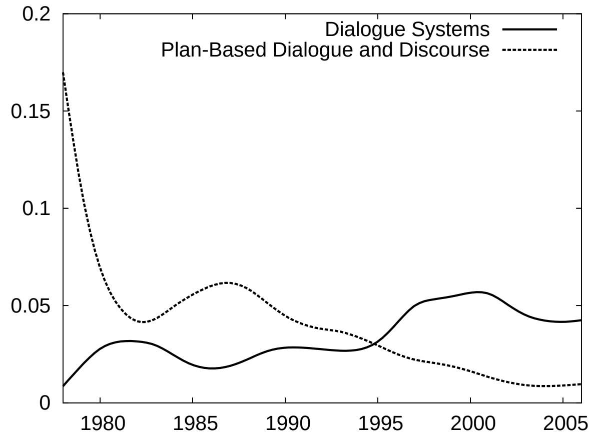

Figure 5: Dialogue over time

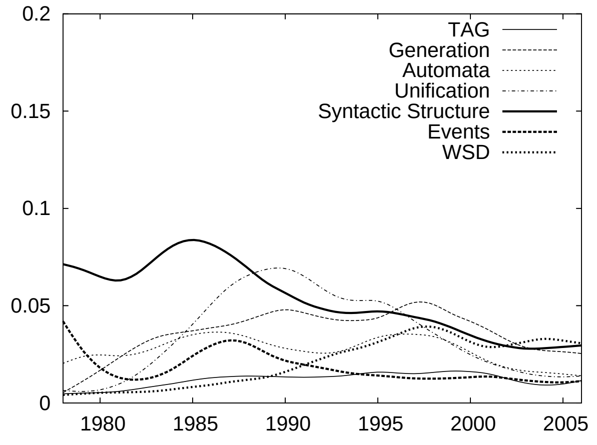

Figure 6: Peaked topics

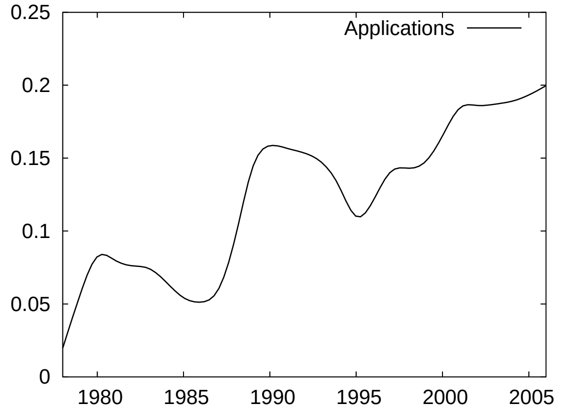

Figure 7: Applications over time

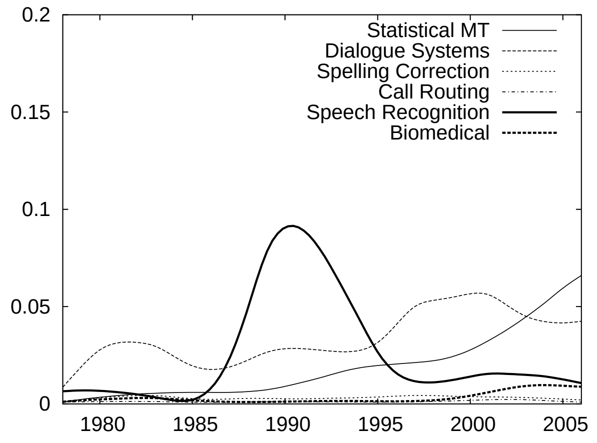

Figure 8: Six applied topics over time

looked at trends over time for the following applications: *Machine Translation*, *Spelling Correction*, *Dialogue Systems*, *Information Retrieval*, *Call Routing*, *Speech Recognition*, and *Biomedical* applications.

Figure 7 shows a clear trend toward an increase in applications over time. The figure also shows an interesting bump near 1990. Why was there such a sharp temporary increase in applications at that time? Figure 8 shows details for each application, making it clear that the bump is caused by a temporary spike in the *Speech Recognition* topic.

In order to understand why we see this temporary spike, Figure 9 shows the unsmoothed values of the *Speech Recognition* topic prominence over time.

Figure 9 clearly shows a huge spike for the years 1989–1994. These years correspond exactly to the DARPA Speech and Natural Language Workshop,

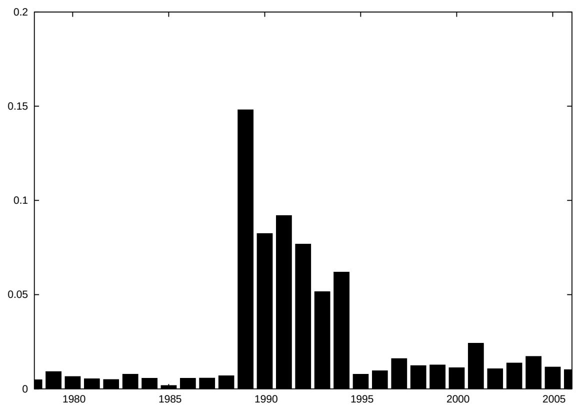

Figure 9: Speech recognition over time

held at different locations from 1989–1994. That workshop contained a significant amount of speech until its last year (1994), and then it was revived in 2001 as the Human Language Technology workshop with a much smaller emphasis on speech processing. It is clear from Figure 9 that there is still some speech research appearing in the Anthology after 1995, certainly more than the period before 1989, but it's equally clear that speech recognition is not an application that the ACL community has been successful at attracting.

6 Differences and Similarities Among COLING, ACL, and EMNLP

The computational linguistics community has two distinct conferences, COLING and ACL, with different histories, organizing bodies, and philosophies. Traditionally, COLING was larger, with parallel sessions and presumably a wide variety of topics, while ACL had single sessions and a more narrow scope. In recent years, however, ACL has moved to parallel sessions, and the conferences are of similar size. Has the distinction in breadth of topics also been blurred? What are the differences and similarities in topics and trends between these two conferences?

More recently, the EMNLP conference grew out of the Workshop on Very Large Corpora, sponsored by the Special Interest Group on Linguistic Data and corpus-based approaches to NLP (SIGDAT). EMNLP started as a much smaller and narrower conference but more recently, while still smaller than both COLING and ACL, it has grown large enough to be considered with them. How does the breadth of its topics compare with the others?

Our hypothesis, based on our intuitions as conference attendees, is that ACL is still more narrow in scope than COLING, but has broadened considerably. Similarly, our hypothesis is that EMNLP has begun to broaden considerably as well, although not to the extent of the other two.

In addition, we're interested in whether the topics of these conferences are converging or not. Are the probabilistic and machine learning trends that are dominant in ACL becoming dominant in COLING as well? Is EMNLP adopting some of the topics that are popular at COLING?

To investigate both of these questions, we need a model of the topic distribution for each conference. We define the empirical distribution of a topic z at a conference c, denoted by $\hat{p}(z|c)$ by:

$$\begin{aligned}\hat{p}(z|c) &= \sum_{d:c_d=c} \hat{p}(z|d)\hat{p}(d|c) \\ &= \frac{1}{C}\sum_{d:c_d=c} \hat{p}(z|d) \\ &= \frac{1}{C}\sum_{d:c_d=c}\sum_{z_i'\in d} I(z_i' = z)\end{aligned} \tag{2}$$

We also condition on the year for each conference, giving us $\hat{p}(z|y,c)$.

We propose to measure the breadth of a conference by using what we call *topic entropy*: the conditional entropy of this conference topic distribution. Entropy measures the average amount of information expressed by each assignment to a random variable. If a conference has higher topic entropy, then it more evenly divides its probability mass across the generated topics. If it has lower, it has a far more narrow focus on just a couple of topics. We therefore measured *topic entropy*:

$$H(z|c,y) = -\sum_{i=1}^{K} \hat{p}(z_i|c,y)\log \hat{p}(z_i|c,y) \tag{3}$$

Figure 10 shows the conditional topic entropy of each conference over time. We removed from the ACL and COLING lines the years when ACL and COLING are colocated (1984, 1998, 2006), and marked those colocated years as points separate from either plot. As expected, COLING has been historically the broadest of the three conferences, though perhaps slightly less so in recent years. ACL started with a fairly narrow focus, but became nearly as broad as COLING during the 1990's. However, in the past 8 years it has become more narrow again, with a steeper decline in breadth than COLING. EMNLP, true to its status as a "Special Interest" conference, began as a very narrowly focused conference, but now it seems to be catching up to at least ACL in terms of the breadth of its focus.

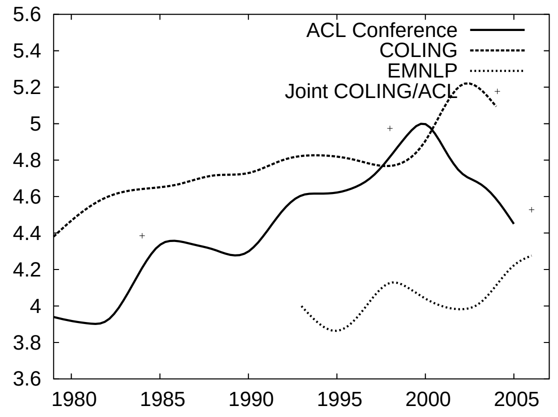

Figure 10: Entropy of the three major conferences per year

Since the three major conferences seem to be converging in terms of breadth, we investigated whether or not the topic distributions of the conferences were also converging. To do this, we plotted the Jensen-Shannon (JS) divergence between each pair of conferences. The Jensen-Shannon divergence is a symmetric measure of the similarity of two pairs of distributions. The measure is 0 only for identical distributions and approaches infinity as the two differ more and more. Formally, it is defined as the average of the KL divergence of each distribution to the average of the two distributions:

$$\begin{aligned}\mathrm{D}_{\mathrm{JS}}(P||Q) &= \frac{1}{2}\mathrm{D}_{\mathrm{KL}}(P||R) + \frac{1}{2}\mathrm{D}_{\mathrm{KL}}(Q||R) \\ R &= \frac{1}{2}(P+Q)\end{aligned} \tag{4}$$

Figure 11 shows the JS divergence between each pair of conferences over time. Note that EMNLP

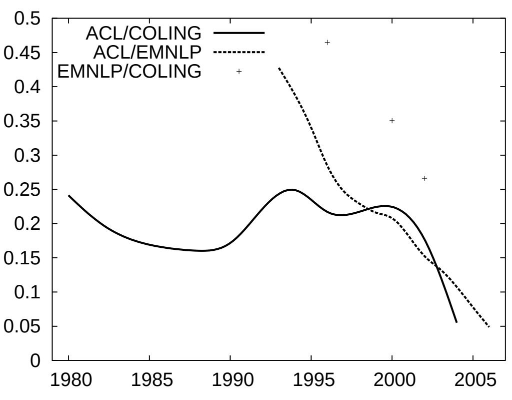

Figure 11: JS Divergence between the three major conferences

and COLING have historically met very infrequently in the same year, so those similarity scores are plotted as points and not smoothed. The trend across all three conferences is clear: each conference is not only increasing in breadth, but also in similarity. In particular, EMNLP and ACL's differences, once significant, are nearly erased.

7 Conclusion

Our method discovers a number of trends in the field, such as the general increase in applications, the steady decline in semantics, and its possible reversal. We also showed a convergence over time in topic coverage of ACL, COLING, and EMNLP as well an expansion of topic diversity. This growth and convergence of the three conferences, perhaps influenced by the need to increase recall (Church, 2005) seems to be leading toward a tripartite realization of a single new "latent" conference.

Acknowledgments

Many thanks to Bryan Gibson and Dragomir Radev for providing us with the data behind the ACL Anthology Network. Also to Sharon Goldwater and the other members of the Stanford NLP Group as well as project Mimir for helpful advice. Finally, many thanks to the Office of the President, Stanford University, for partial funding.

Abstract

This paper describes a lexical trigger model for statistical machine translation. We present various methods using triplets incorporating long-distance dependencies that can go beyond the local context of phrases or n-gram based language models. We evaluate the presented methods on two translation tasks in a reranking framework and compare it to the related IBM model 1. We show slightly improved translation quality in terms of BLEU and TER and address various constraints to speed up the training based on Expectation-Maximization and to lower the overall number of triplets without loss in translation performance.

1 Introduction

Data-driven methods have been applied very successfully within the machine translation domain since the early 90s. Starting from single-word-based translation approaches, significant improvements have been made through advances in modeling, availability of larger corpora and more powerful computers. Thus, substantial progress made in the past enables today's MT systems to achieve acceptable results in terms of translation quality for specific language pairs such as Arabic-English. If sufficient amounts of parallel data are available, statistical MT systems can be trained on millions of

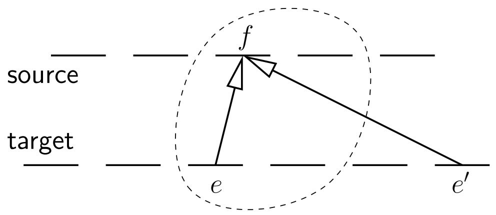

Figure 1: Triplet example: a source word f is triggered by two target words e and e', where one of the words is within and the other outside the considered phrase pair (indicated by the dashed line).

sentence pairs and use an extended level of context based on bilingual groups of words which denote the building blocks of state-of-the-art phrase-based SMT systems.

Due to data sparseness, statistical models are often trained on local context only. Language models are derived from n-grams with $n \leq 5$ and bilingual phrase pairs are extracted with lengths up to 10 words on the target side. This captures the local dependencies of the data in detail and is responsible for the success of data-driven phrase-based approaches.

In this work, we will introduce a new statistical model based on lexicalized triplets (f, e, e') which we will also refer to as cross-lingual triggers of the form $(e, e' \rightarrow f)$. This can be understood as two words in one language triggering one word in another language. These triplets, modeled by $p(f|e, e')$, are closely related to lexical translation probabilities based on the IBM model 1, i.e. $p(f|e)$. Several constraints and setups will be described later on in more detail, but as an introduction one can

[*]The work was carried out while the author was at the Human Language Technology and Pattern Recognition group at RWTH Aachen University and partly supported by the Valencian *Conselleria d'Empresa, Universitat i Ciència* under grants CTBPRA/2005/ and BEFPI/2007/014.

think of the following interpretation which is depicted in Figure 1: Using a phrase-based MT approach, a source word f is triggered by its translation e which is part of the phrase being considered, whereas another target word e' outside this phrase serves as an additional trigger in order to allow for more fine-grained distinction of a specific word sense. Thus, this cross-lingual trigger model can be seen as a combination of a lexicon model (i.e. f and e) and a model similar to monolingual long-range (i.e. distant bigram) trigger models (i.e. e and e', although these dependencies are reflected indirectly via $e' \rightarrow f$) which uses both local (in-phrase) and global (in-sentence) information for the scoring. The motivation behind this approach is to get non-local information outside the current context (i.e. the currently considered bilingual phrase pair) into the translation process. The triplets are trained via the EM algorithm, as will be shown later in more detail.

2 Related Work

In the past, a significant number of methods has been presented that try to capture long-distance dependencies, i.e. use dependencies in the data that reach beyond the local context of n-grams or phrase pairs. In language modeling, monolingual trigger approaches have been presented (Rosenfeld, 1996; Tillmann and Ney, 1997) as well as syntactical methods that parse the input and model long-range dependencies on the syntactic level by conditioning on the predecessing words and their corresponding parent nodes (Chelba and Jelinek, 2000; Roark, 2001). The latter approach was shown to reduce perplexities and improve the WER in speech recognition systems. One drawback is that the parsing process might slow down the system significantly and the approach is complicated to be integrated directly in the search process. Thus, the effect is often shown offline in reranking experiments using n-best lists.

One of the simplest models that can be seen in the context of lexical triggers is the IBM model 1 (Brown et al., 1993) which captures lexical dependencies between source and target words. It can be seen as a lexicon containing correspondents of translations of source and target words in a very broad sense since the pairs are trained on the full sentence level. The model presented in this work is very close to the initial IBM model 1 and can be seen as taking another word into the conditioning part, i.e. the triggering items.[1] Furthermore, since the second trigger can come from any part of the sentence, we also have a link to long-range monolingual triggers as presented above.

A long-range trigram model is presented in (Della Pietra et al., 1994) where it is shown how to derive a probabilistic link grammar in order to capture long-range dependencies in English using the EM algorithm. Expectation-Maximization is used in the presented triplet model as well which is described in more detail in Section 3. Instead of deriving a grammar automatically (based on POS tags of the words), we rely on a fully lexicalized approach, i.e. the training is taking place at the word level.

Related work in the context of fine-tuning language models by using cross-lingual lexical triggers is presented in (Kim and Khudanpur, 2003). The authors show how to use cross-lingual triggers on a document level in order to extract translation lexicons and domain-specific language models using a mutual information criterion.

Recently, word-sense disambiguation (WSD) methods have been shown to improve translation quality (Chan et al., 2007; Carpuat and Wu, 2007). Chan et al. (2007) use an SVM based classifier for disambiguating word senses which are directly incorporated in the decoder through additional features that are part of the log-linear combination of models. They use local collocations based on surrounding words left and right of an ambiguous word including the corresponding parts-of-speech. Although no long-range dependencies are modeled, the approach yields an improvement of +0.6% BLEU on the NIST Chinese-English task. In Carpuat and Wu (2007), another state-of-the-art WSD engine (a combination of naive Bayes, maximum entropy, boosting and Kernel PCA models) is used to dynamically determine the score of a phrase pair under consideration and, thus, let the phrase selection adapt to the context of the sentence. Although the baseline is significantly lower than in the work of Chan et al., this setup reaches an improvement of 0.5% BLEU on the NIST CE task and up to 1.1% BLEU on the

[1]Thus, instead of $p(f|e)$ we model $p(f|e, e')$ with different additional constraints as explained later on.

IWSLT'06 test sets.

The work in this paper tries to complement the WSD approaches by using long-range dependencies. If triggers from a local context determine different lexical choice for the word being triggered, the setting is comparable to the mentioned WSD approaches (although local dependencies might already be reflected sufficiently in the phrase models). A distant second trigger, however, might have a beneficial effect for specific languages, e.g. by capturing word splits (as it is the case in German for verbs with separable prefixes) or, as already mentioned, allowing for a more fine-grained lexical choice of the word being triggered, namely based on another word which is not part of the current local, i.e. phrasal, context.

The basic idea of triplets of the form $(e, f' \rightarrow f)$, called multi-word extensions, is also mentioned in (Tillmann, 2001) but neither evaluated nor investigated in further detail.

In the following sections, we will describe the model proposed in this work. In Section 3, a detailed introduction is given, as well as the EM training and variations of the model. The different settings will be evaluated in Section 4, where we show experiments on the IWSLT Chinese-English and TC-STAR EPPS English-Spanish/Spanish-English tracks. A discussion of the results and further examples are given in Section 5. Final remarks and future work are addressed in Section 6.

3 Model

As an extension to commonly used lexical word pair probabilities $p(f|e)$ as introduced in (Brown et al., 1993), we define our model to operate on word triplets. A triplet (f, e, e') is assigned a value $\alpha(f|e, e') \geq 0$ with the constraint such that

$$\forall e, e' : \sum_{f} \alpha(f|e, e') = 1.$$

Throughout this paper, e and e' will be referred to as the *first* and the *second trigger*, respectively. In view of its triggers f will be termed the *effect*.

For a given bilingual sentence pair (f_1^J, e_1^I), the probability of a source word f_j given the whole target sentence e_1^I for the triplet model is defined as:

$$p_{all}(f_j|e_1^I) = \frac{1}{Z} \sum_{i=1}^{I} \sum_{k=i+1}^{I} \alpha(f_j|e_i, e_k), \qquad (1)$$

where Z denotes a normalization factor based on the corresponding target sentence length, i.e.

$$Z = \frac{I(I-1)}{2}. \qquad (2)$$

The introduction of a second trigger (i.e. e_k in Eq. 1) enables the model to combine local (i.e. word or phrase level) and global (i.e. sentence level) information.

In the following, we will describe the training procedure of the model via maximum likelihood estimation for the unconstrained case.

3.1 Training

The goal of the training procedure is to maximize the log-likelihood F_{all} of the triplet model for a given bilingual training corpus $\{(f_1^J, e_1^I)\}_1^N$ consisting of N sentence pairs:

$$F_{all} := \sum_{n=1}^{N} \sum_{j=1}^{J_n} \log p_{all}(f_j|e_1^{I_n}),$$

where J_n and I_n are the lengths of the nth source and target sentences, respectively. As there is no closed form solution for the maximum likelihood estimate, we resort to iterative training via the EM algorithm (Dempster et al., 1977). We define the auxiliary function $Q(\mu; \bar{\mu})$ based on F_{all} where $\bar{\mu}$ is the new estimate within an iteration which is to be derived from the current estimate μ. Here, μ stands for the entire set of model parameters to be estimated, i.e. the set of all $\{\alpha(f|e, e')\}$. Thus, we obtain

$$Q\big(\{\alpha(f|e,e')\}; \{\bar{\alpha}(f|e,e')\}\big) = \sum_{n=1}^{N} \sum_{j=1}^{J_n} \sum_{i=1}^{I_n} \sum_{k=i+1}^{I_n} \left[\frac{Z_n^{-1} \alpha(f_j|e_i, e_k)}{p_{all}(f_j|e_1^{I_n})} \cdot \log\big(Z_n^{-1} \bar{\alpha}(f_j|e_i, e_k)\big) \right], \qquad (3)$$

where Z_n is defined as in Eq. 2. Using the method of Lagrangian multipliers for the normalization constraint, we take the derivative with respect to

$\bar{\alpha}(f|e,e')$ and obtain:

$$\bar{\alpha}(f|e,e') = \frac{A(f,e,e')}{\sum_{f'} A(f',e,e')} \tag{4}$$

where $A(f,e,e')$ is a relative weight accumulator over the parallel corpus:

$$A(f,e,e') = \sum_{n=1}^{N} \sum_{j=1}^{J_n} \delta(f,f_j) \frac{Z_n^{-1}\alpha(f|e,e')}{p_{all}(f_j|e_1^{I_n})} C_n(e,e') \tag{5}$$

and

$$C_n(e,e') = \sum_{i=1}^{I_n} \sum_{k=i+1}^{I_n} \delta(e,e_i)\delta(e',e_k).$$

The function $\delta(\cdot,\cdot)$ denotes the Kronecker delta. The resulting training procedure is analogous to the one presented in (Brown et al., 1993) and (Tillmann and Ney, 1997).

The next section presents variants of the basic unconstrained model by putting restrictions on the valid regions of triggers (in-phrase vs. out-of-phrase) and using alignments obtained from either GIZA++ training or forced alignments in order to reduce the model size and to incorporate knowledge already obtained in previous training steps.

3.2 Model variations

Based on the unconstrained triplet model presented in Section 3, we introduce additional constraints, namely the *phrase-bounded* and the *path-aligned* triplet model in the following. The former reduces the number of possible triplets by posing constraints on the position of where valid triggers may originate from. In order to obtain phrase boundaries on the training data, we use forced alignments, i.e. translate the whole training data by constraining the translation hypotheses to the target sentences of the training corpus.

Path-aligned triplets use an alignment constraint from the word alignments that are trained with GIZA++. Here, we restrict the first trigger pair (f, e) to the alignment path as based on the alignment matrix produced by IBM model 4.

These variants require information in addition to the bilingual sentence pair (f_1^J, e_1^I), namely a corresponding phrase segmentation $\Pi = \{\pi_{ij}\}$ with

$$\pi_{ij} = \begin{cases} 1 & \exists \text{ a phrase pair that covers } e_i \text{ and } f_j \\ 0 & \text{otherwise} \end{cases}$$

for the phrase-bounded method and, similarly, a word alignment $A = \{a_{ij}\}$ where

$$a_{ij} = \begin{cases} 1 & \text{if } e_i \text{ is aligned to } f_j \\ 0 & \text{otherwise} \end{cases} .$$

3.2.1 Phrase-bounded triplets

The phrase-bounded triplet model (referred to as p_{phr} in the following), restricts the first trigger e to the same phrase as f, whereas the second trigger e' is set outside the phrase, resulting in

$$p_{phr}(f_j|e_1^I,\Pi) = \frac{1}{Z_j} \sum_{i=1}^{I} \sum_{k=1}^{I} \pi_{ij}(1-\pi_{kj})\alpha(f_j|e_i,e_k). \tag{6}$$

3.2.2 Path-aligned triplet

The path-aligned triplet model (denoted by p_{align} in the following), restricts the scope of e to words aligned to f by A, yielding:

$$p_{align}(f_j|e_1^I,A) = \frac{1}{Z_j} \sum_{i=1}^{I} \sum_{k=1}^{I} a_{ij}\alpha(f_j|e_i,e_k) \tag{7}$$

where the Z_j are, again, the appropriate normalization terms.

Also, to account for non-aligned words (analogously to the IBM models), the empty word e_0 is considered in all three model variations. We show the effect of the empty word in the experiments (Section 4). Furthermore, we can train the presented models in the inverse direction, i.e. $p(e|f,f')$, and combine the two directions in the rescoring framework. The next section presents a set of experiments that evaluate the performance of the presented triplet model and its variations.

4 Experiments

In this section, we describe the system setup used in this work, including the translation tasks and the corresponding training corpora. The experiments are based on an n-best list reranking framework.

4.1 System

The experiments were carried out using a state-of-the-art phrase-based SMT system. The dynamic programming beam search decoder uses several models during decoding by combining them log-linearly. We incorporate phrase translation and word lexicon models in both directions, a language model, as well as phrase and word penalties including a distortion model for the reordering. While generating the hypotheses, a word graph is created which compactly represents the most likely translation hypotheses. Out of this word graph, we generate n-best lists and use them to test the different setups as described in Section 3.

In the experiments, we use 10,000-best lists containing unique translation hypotheses, i.e. duplicates generated due to different phrase segmentations are reduced to one single entry. The advantage of this reranking approach is that we can directly test the obtained models since we already have fully generated translations. Thus, we can apply the triplet lexicon model based on $p(f|e, e')$ and its inverse counterpart $p(e|f, f')$ directly. During decoding, since e' could be from anywhere outside the current phrase, i.e. even from a part which lies beyond the current context which has not yet been generated, we would have to apply additional constraints during training (i.e. make further restrictions such as $i' < i$ for a trigger pair $(e_i, e_{i'})$).

Optimization of the model scaling factors is carried out using minimum error rate training (MERT) on the development sets. The optimization criterion is 100-BLEU since we want to maximize the BLEU score.

4.2 Tasks

4.2.1 IWSLT

For the first part of the experiments, we use the corpora that were released for the IWSLT'07 evaluation campaign. The training corpus consists of approximately 43K Chinese-English sentence pairs, mainly coming from the BTEC corpus (Basic Travel Expression Corpus). This is a multilingual speech corpus which contains tourism-related material, such as transcribed conversations about making reservations, asking for directions or conversations as taking place in restaurants. For the experiments, we use the clean data track, i.e. transcriptions of read speech. As the development set which is used for tuning the parameters of the baseline system and the reranking framework, we use the IWSLT'04 evaluation set (500 sentence pairs). The two blind test sets which are used to evaluate the final performance of the models are the official evaluation sets from IWSLT'05 (506 sentences) and IWSLT'07 (489 sentences).

The average sentence length of the training corpus is 10 words. Thus, the task is somewhat limited and very domain-specific. One of the advantages of this setting is that preliminary experiments can be carried out quickly in order to analyze the effects of the different models in detail. This and the small vocabulary size (12K entries) makes the corpus ideal for first "rapid application development"-style setups without having to care about possible constraints due to memory requirements or CPU time restrictions.

4.2.2 EPPS

Furthermore, additional experiments are based on the EPPS corpus (European Parliament Plenary Sessions) as used within the FTE (Final Text Edition) track of the TC-STAR evaluations. The corpus contains speeches held by politicians at plenary sessions of the European Parliament that have been transcribed, "corrected" to make up valid written texts and translated into several target languages. The language pairs considered in the experiments here are Spanish-English and English-Spanish.

The training corpus consists of roughly 1.3M sentence pairs with 35.5M running words on the English side. The vocabulary sizes are considerably larger than for the IWSLT task, namely around 170K on the target side. As development set, we use the development data issued for the 2006 evaluation (1122 sentences), whereas the two blind test sets are the official evaluation data from 2006 (TC-Star'06, 1117 sentences) and 2007 (TC-Star'07, 1130 sentences).

4.3 Results

4.3.1 IWSLT experiments

One of the first questions that arises is how many EM iterations should be carried out during training of the triplet model. Since the IWSLT task is small,

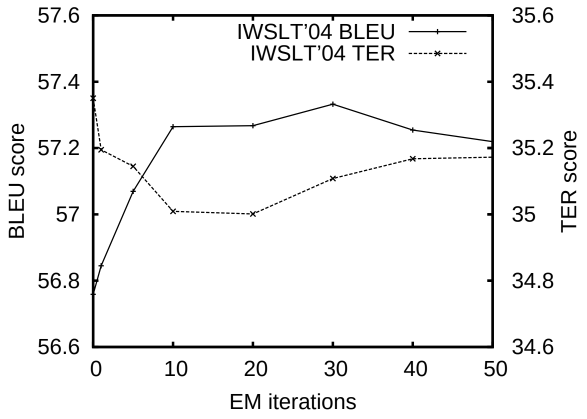

Figure 2: Effect of EM iterations on IWSLT'04, left axis shows BLEU (higher numbers better), right axis (dashed graph) shows TER score (lower numbers better).

	IWSLT'04		IWSLT'05	
	BLEU	TER	BLEU	TER
baseline	56.7	35.49	61.1	30.59
$p_{all}(e\|f,f')$	57.1	35.03	61.3	30.55
w/ singletons	57.3	35.04	61.3	30.61
w/ empties	57.3	35.00	61.2	30.65
+ $p_{all}(f\|e,e')$	**57.5**	**34.69**	**61.7**	**30.24**

Table 1: Different setups showing the effect of singletons and empty words for IWSLT CE IWSLT'04 (dev) and IWSLT'05 (test) sets, p_{all} triplets, 20 EM iterations.

	IWSLT'05		IWSLT'07	
	BLEU	TER	BLEU	TER
baseline	61.1	30.59	38.9	45.60
IBM model 1	61.5	30.29	39.4	45.31
trip fe+ef p_{all}	**61.7**	**30.24**	**39.7**	45.24
trip fe+ef p_{phr}	61.5	30.32	39.1	45.36
trip fe+ef p_{align}	61.2	30.60	**39.7**	**45.02**

Table 2: Comparison of triplet variants on IWSLT CE test sets, 20 EM iterations, with singletons and empty words.

we can quickly run the experiments on a full unconstrained triplet model without any cutoff or further constraints. Figure 2 shows the rescoring performance for different numbers of EM iterations. The first 10 iterations significantly improve the triplet model performance for the IWSLT task. After that, there are no big changes. The performance even degrades a little bit after 30 iterations. For the IWSLT task, we therefore set a fixed number of 20 EM iterations for the following experiments since it shows a good performance in terms of both BLEU and TER score. The oracle TER scores of the 10k-best lists are 14.18% for IWSLT'04, 11.36% for IWSLT'05 and 18.85% for IWSLT'07, respectively.

The next chain of experiments on the IWSLT task investigates the impact of changes to the setup of training an unconstrained triplet model, such as the addition of the empty word and the inclusion of singletons (i.e. triplets that were only seen once in the training data). This might show the importance of rare events in order to derive strategies when moving to larger tasks where it is not feasible to train all possible triplets, such as e.g. on the EPPS task (as shown later) or the Chinese-English NIST task. The results for the unconstrained model are shown in Table 1, beginning with a full triplet model in reverse direction, $p_{all}(e|f, f')$, that contains no singletons and no empty words for the triggering side. In this setting, singletons seem to help on dev but there is no clear improvement on one of the test sets, whereas empty words do not make a significant difference but can be used since they do not harm either. The baseline can be improved by +0.6% BLEU and around -0.5% in TER on the IWSLT'04 set. For the various setups, there are no big differences in the TER score which might be an effect of optimization on BLEU. Therefore, for further experiments using the constraints from Section 3.2, we use both singletons and empty words as the default.

Adding the other direction $p(f|e, e')$ results in another increase, with a total of +0.8% BLEU and -0.8% TER, which shows that the combination of both directions helps overall translation quality. The results on the two test sets are shown in Table 2. As can be seen, we arrive at similar improvements, namely +0.6% BLEU and -0.3% TER on IWSLT'05 and +0.8% BLEU and -0.4% TER on IWSLT'07, respectively. The constrained models, i.e. the phrase-bounded (p_{phr}) and path-aligned (p_{align}) triplets are outperformed by the full unconstrained case, although on IWSLT'07 both unconstrained and path-aligned models are close.

For a fair comparison, we added a classical IBM model 1 in the rescoring framework. It can be seen that the presented triplet models slightly outperform

	TC-Star'06		TC-Star'07

baseline	52.3	34.57	50.4	36.46
trip fe+ef p_{all}	52.9	34.32	50.6	36.34
+ max dist 10	52.9	34.20	50.8	36.22

Table 3: Effect of using maximum distance constraint for p_{all} on EPPS Spanish-English test sets, occ_3, 4 EM iterations due to time constraints.

the simple IBM model 1. Note that IBM model 1 is a special case of the triplet lexicon model if the second trigger is the empty word.

4.3.2 EPPS experiments

Since EPPS is a considerably harder task (larger vocabulary and longer sentences), the training of a full unconstrained triplet model cannot be done due to memory restrictions. One possibility to reduce the number of extracted triplets is to apply a maximum distance constraint in the training procedure, i.e. only trigger pairs are considered where the distance between first and second trigger is below or equal to the specified maximum.

Table 3 shows the effect of a maximum distance constraint for the Spanish-English direction. Due to the large amount of triplets (we extract roughly two billion triplets[2] for the EPPS data), we drop all triplets that occur less than 3 times which results in 640 million triplets. Also, due to time restrictions[3], we only train 4 iterations and compare it to 4 iterations of the same setting with the maximum distance set to 10. The training with the maximum distance constraints ends with a total of 380 million triplets. As can be seen (Table 3), the performance is comparable while cutting down the computation time from 9.2 to 3.1 hours. The experiments were carried out on a 2.2GHz Opteron machine with 16 GB of memory. The overall gain is +0.4–0.6% BLEU and up to -0.4% in TER. We even observe a slight increase in BLEU for the TC-Star'07 set which might be a random effect due to optimization on the development set where the behavior is the same as for TC-Star'06.

[2]Extraction can be easily done in parallel by splitting the corpus and merging identical triplets iteratively in a separate step for two chunks at a time.

[3]One iteration needs more than 12 hours for the unconstrained case.

	TC-Star'06		TC-Star'07	
	BLEU	TER	BLEU	TER
baseline	49.5	37.65	51.0	36.03
trip fe+ef p_{phr}	50.2	37.01	51.5	35.38
+ occ_2	50.2	37.06	51.8	35.32

Table 4: Results on EPPS, English-Spanish, p_{phr} combined, occ_3, 10 EM iterations.

	TC-Star'06		TC-Star'07	
	BLEU	TER	BLEU	TER
baseline	49.5	37.65	51.0	36.03
using FA	50.0	37.18	51.7	35.52
using IBM4	50.0	37.12	51.7	35.43
+ occ_2	50.2	36.84	52.0	35.10
+ max dist 1	50.0	37.10	51.7	35.51

Table 5: Results on EPPS, English-Spanish, maximum approximation, p_{align} combined, occ_3, 10 EM iterations.

Results on EPPS English-Spanish for the phrase-bounded triplet model are presented in Table 4. Since the number of triplets is less than for the unconstrained model, we can lower the cutoff from 3 to 2 (denoted in the table by occ_3 and occ_2, respectively). There is a small additional gain on the TC-Star'07 test set by this step, with a total of +0.7% BLEU for TC-Star'06 and +0.8% BLEU for TC-Star'07.

Table 5 shows results for a variation of the path-aligned triplet model p_{align} that restricts the first trigger to the best aligned word as estimated in the IBM model 1, thus using a maximum-approximation of the given word alignment. The model was trained on two word alignments, firstly the one contained in the forced alignments on the training data, and secondly on an IBM-4 word alignment generated using GIZA++. For this second model we also demonstrate the improvement obtained when increasing the triplet lexicon size by using less trimming.

Another experiment was carried out to investigate the effect of immediate neighboring words used as triggers within the p_{align} setting. This is equivalent to using a "maximum distance of 1" constraint. We obtained worse results, namely a 0.2-0.3% drop in BLEU and a 0.3-0.4% raise in TER (cf. Table 5, last row), although the training is significantly faster with this setup, namely roughly 30 minutes per it-

	TC-Star'06		TC-Star'07

baseline	49.5	37.65	51.0	36.03
IBM model 1	50.0	37.12	51.8	35.51
p_{all}, occ_3	50.0	37.17	51.8	35.43
p_{phr}, occ_2	50.2	37.06	51.8	35.32
p_{align}, occ_2	**50.2**	**36.84**	**52.0**	**35.10**

Table 6: Final results on EPPS English-Spanish, constrained triplet models, 10 EM iterations, compared to standard IBM model 1.

f	e	e'	$\alpha(f\|e,e')$
pagar	taxpayer	bill	0.76
factura	taxpayer	bill	0.11
contribuyente	taxpayer	bill	0.10
f	e	–	$p_{ibm1}(f\|e)$
contribuyente	taxpayer		0.40
contribuyentes	taxpayer		0.18
europeo	taxpayer		0.08
factura	bill		0.19
ley	bill		0.18
proyecto	bill		0.11

Table 7: Example of triplets and related IBM model 1 lexical probabilities. The triggers "taxpayer" and "bill" have a new effect ("pagar"), previously not seen in the top ranks of the lexicon.

eration using less than 2 GB of memory. However, this shows that triggers outside the immediate context help overall translation quality. Additionally, it supports the claim that the presented methods are a complementary alternative to the WSD approaches mentioned in Section 2 which only consider the immediate context of a single word.

Finally, we compare the constrained models to an unconstrained setting and, again, to a standard IBM model 1. Table 6 shows that the p_{align} model constrained on using the IBM-4 word alignments yields +0.7% in BLEU on TC-Star'06 which is +0.2% more than with a standard IBM model 1. TER decreases by -0.3% when compared to model 1. For the TC-Star'07 set, the observations are similar.

The oracle TER scores of the development n-best list are 25.16% for English-Spanish and 27.0% for Spanish-English, respectively.

5 Discussion

From the results of our reranking experiments, we can conclude that the presented triplet lexicon model outperforms the baseline single-best hypotheses of the decoder. When comparing to a standard IBM model 1, the improvements are significantly smaller though measurable. So far, since IBM model 1 is considered one of the stronger rescoring models, these results look promising. An unconstrained triplet model has the best performance if training is feasible since it also needs the most memory and time to be trained, at least for larger tasks.

In order to cut down computational requirements, we can apply phrase-bounded and path-aligned training constraints that restrict the possibilities of selecting triplet candidates (in addition to simple thresholding). Although no clear effect could be observed for adding empty words on the triggering side, it does not harm and, thus, we get a similar functionality to IBM model 1 being "integrated" in the triplet lexicon model. The phrase-bounded training variant uses forced alignments computed on the whole training data (i.e. search constrained to producing the target sentences of the bilingual corpus) but could not outperform the path-aligned model which reuses the alignment path information obtained in regular GIZA++ training.

Additionally, we observe a positive impact from triggers lying outside the immediate context of one predecessor or successor word.

5.1 Examples

Table 7 shows an excerpt of the top entries for $(e, e') = (taxpayer, bill)$ and compares it to the top entries of a lexicon based on IBM model 1. We observe a triggering effect since the Spanish word *pagar* (*to pay*) is triggered at top position by the two English words *taxpayer* and *bill*. The average distance of *taxpayer* and *bill* is 5.4 words. The models presented in this work try to capture this property and apply it in the scoring of hypotheses in order to allow for better lexical choice in specific contexts.

In Table 8, we show an example translation where rescoring with the triplet model achieves higher n-gram coverage on the reference translation than the variant based on IBM model 1 rescoring. The differing phrases are highlighted.

Source sentence	…respecto de la Posición Común del Consejo con vistas a la adopción del Reglamento del Parlamento Europeo y del Consejo relativo al …
IBM-1 rescoring	…on the Council common position with a view to the adoption of the Rules of Procedure of the European Parliament and of the Council …
Triplet rescoring	…on the common position of the Council with a view to the adoption of the regulation of the European Parliament and of the Council …
Reference translation	…as regards the Common Position of the Council with a view to the adoption of a European Parliament and Council Regulation as regards the …

Table 8: A translation example on TC-Star'07 Spanish-English comparing the effect of the triplet model to a standard IBM-1 model.

6 Outlook

We have presented a new lexicon model based on triplets extracted on a sentence level and trained iteratively using the EM algorithm. The motivation of this approach is to add an additional second trigger to a translation lexicon component which can come from a more global context (on a sentence level) and allow for a more fine-grained lexical choice given a specific context. Thus, the method is related to word sense disambiguation approaches.

We showed improvements by rescoring n-best lists of the IWSLT Chinese-English and EPPS Spanish-English/English-Spanish task. In total, we achieve up to +1% BLEU for some of the test sets in comparison to the decoder baseline and up to +0.3% BLEU compared to IBM model 1.

Future work will address an integration into the decoder since the performance of the current rescoring framework is limited by the quality of the n-best lists. For the inverse model, $p(e|f, f')$, an integration into the search is directly possible. Further experiments will be conducted, especially on large tasks such as the NIST Chinese-English and Arabic-English task. Training on these huge databases will only be possible with an appropriate selection of promising triplets.

Abstract

In this paper we present a textual dialogue system that uses word associations retrieved from the Web to create propositions. We also show experiment results for the role of modality generation. The proposed system automatically extracts sets of words related to a conversation topic set freely by a user. After the extraction process, it generates an utterance, adds a modality and verifies the semantic reliability of the proposed sentence. We evaluate word associations extracted form the Web, and the results of adding modality. Over 80% of the extracted word associations were evaluated as correct. Adding modality improved the system significantly for all evaluation criteria. We also show how our system can be used as a simple and expandable platform for almost any kind of experiment with human-computer textual conversation in Japanese. Two examples with affect analysis and humor generation are given.

1 Introduction

Many task-oriented dialogue systems (Liu et al., 2003; Reitter et al., 2006) have been developped. Research on non-task-oriented dialogue systems like casual conversation dialogue systems (”chatbots”) is on the other hand not very common, perhaps due to the many amateurs who try to build naturally talking systems using sometimes very clever, but rather unscientific methods although there are systems with chatting abilities as (Bickmore and Cassell, 2001) but concentrate on applying strategies to casual conversation rather than their automatic generation of those conversations. However, we believe that the main reason is that an unrestricted domain is disproportionately difficult compared to the possible use such a system could have. It is for example very hard to predict the contents and topics of user utterances, and therefore it is almost impossible to prepare conversational scenarios. Furthermore, scenarios need more or less specific goals to be useful. However in our opinion, sooner or later non-task-oriented dialogue systems will have to be combined with task oriented systems and used after recognizing that the user's utterance does not belong to a given task. This would lead to more natural interfaces for e.g. information kiosks or automatic guides placed in public places where anyone can talk to them about anything (Gustafson and Bell, 2000; Kopp et al., 2005) regardless of the role the developers intended. For this reason we have also started implementing emotiveness recognition and joke generation modules that are presented later in the paper.

Well-known examples of non-task-oriented dialogue systems are ELIZA (Weizenbaum, 1966) and A.L.I.C.E [1], though the former was built to parody a Rogerian therapist which can be regarded as a task. Both systems and their countless imitators [2] use a lot of rules coded by hand. ELIZA is able to make a response to any input, but these responses are only information requests without providing any new information to the user. In the case of A.L.I.C.E,

[1]Wallace, R. The Anatomy of A.L.I.C.E. http://www.alicebot.org/anatomy.html.

[2]Many of them have been quite successful in the Loebner Prize and the Chatterbox Challenge (competitions only for English-speaking bots) but explanations of their algorithms are not available.

the knowledge resource is limited to the existing database. Creating such databases is costly and a programmer must learn the AIML mark-up language to build it. Although there have been attempts at updating AIML databases automatically (Pietro et al., 2005), the scale was rather limited.

As mentioned above, these examples and many other ”chatbots” need hand-crafted rules, and are thus often ignored by computer scientists and rarely become a research topic. However, they have proved to be useful for e-learning (Pietro et al., 2005) and machine learning (Araki and Kuroda, 2006) support.

Building a system using automatic methods, like we do, seems to be the most realistic way for unrestricted domains. Considering the large cost of developing a program that can talk about any topic, it is appealing to turn to the huge and cheap textual source that is the Internet.

In this very moment millions of people (Kumar et al, 2003) are updating their blogs and writing articles on every possible topic. These are available on the Web which we can access any time, and in a faster and faster manner, the search engines grow more and more efficient. Thus, the Web is well suited to extracting word associations triggered by words from user utterances made in a topic-free dialogue system.. We present a system making use of this type of information. It automatically extracts word association lists using all keywords in a given utterance without choosing a specific one (which most other systems that ignore the context do) then generates a reply using the only one strongest association from the nouns, verbs and adjectives association groups. Modality is then added to the reply, and then it is output.

Our system is built upon the idea that human utterances consist of a proposition and a modality (Nitta et al., 1989). In this paper we present an algorithm for extracting word associations from the Web and a method for adding modality to statements. We evaluate both the word associations and the use of modality. We also suggest some future possible extensions of the system and show a small experiment with adding humor to the system.

In this paper, the system described works for Japanese and uses text as input and output. Though the final goal of our research is to help developing freely talking car navigation systems that by their chatting abilities can help to avoid drowsiness while driving and so on. in this part of the development we concentrate on proposition generation and modality processing. Therefore, we work only with text now. We plan to combine this project with research on in car voice recognition and generation.

2 Extracting Word Associations

In this chapter, we present a method for automatic extraction of word associations based on keywords from user utterances. We use the Google[3] search engine snippets to extract word associations in real time without using earlier prepared resources, such as off-line databases.

2.1 Extracting Word Associations from the Web

In the first step, the system analyzed user utterances using the morphological analyzer MeCab[4] in order to spot query keywords for extracting word associations lists. We define nouns, verbs, adjectives, and unknown words as query keywords. The reason we chose these word classes is that these word classes can be treated as important and, to some extent, describe the context. We define a noun as the longest set of nouns in a compound noun. For example, the compound noun *shizen gengo shori*[5] (natural language processing) is treated by MeCab as three words: (*shizen* - natural), (*gengo* - language) and (*shori* - processing). Our system, however, threats it as one noun.

In the next step, the system uses these keywords as query words for the Google search engine. The system extracts the nouns from the search results and sorts them in frequency order. This process is based on the idea that words which co-occur frequently with the input words are of high relevance to them. The number of extracted snippets is 500. This value was set experimentally, taking the processing time and output quality into account. The top ten words of a list are treated as word associations, see Table 1 for an example.

[5]All Japanese transcriptions will be written in italics.

Table 1: Examples of noun associations triggered by a user utterance

Sapporo wa samui. (Sapporo city is cold.)		
Association frequency ranking:		
1	*yuki* (snow)	52
2	*fuyu* (winter)	50
3	*kion* (temperature)	16
4	*jiki* (season)	12
5	*Tokyo* (Tokyo)	12
6	*tenki* (weather)	11
7	*chiiki* (area)	10
8	*heya* (room)	10

2.2 Evaluation

We asked volunteers to use our system and to evaluate the correctness of word lists generated by the system. First, a participant freely inputs an utterance, for which the system retrieves ten association words. Next, a participant rated these words using a scale of one to three with 3 meaning ”perfectly correct”, 2 -”partially correct” and 1 - ”incorrect”. In this experiment we consider words that receive a 2 or 3 as usable. The reason associations rated 2 or 3 are considered as usable is that the definition of what makes a good word association here is difficult to specify. When it comes to topic-free conversations we have observed that associations have an effect on a certain context. Three volunteers repeated the experiment ten times, so the final amount of evaluated words was 300. Table 2 shows the results of the top 10 words, sorted by the frequency of appearance. Table 3 shows the results of the top 5 words.

What constitutes a correct word association was left to each volunteer to decide subjectively since in a casual conversation setting associations are hard to define strictly.

Table 2: Top 10 word associations

score	participant(A，B，C)	total
3	40，52，57	149
2	37，17，27	81
1	23，31，16	70
usability (%)	77，69，84	77

As shown in Table 2 approximately 77% of the word associations were judged as usable but there were individual differences between the evaluators. This shows that the definition of word associations is different for each participant. Table 3 shows that approximately 80% of the word associations were judged as usable. It is thus highly likely that the top words from the frequency lists are correct associations. The results show that automatic extracting of word associations using a Web search engine is feasible. The main reason for extracting word associations from the Web is that thanks to this method, the system can handle new information, proper names, technical terms and so on. by using only the snippets from the search engine. The word association extraction takes no more than few seconds. For the evaluation we used only nouns but we expect although verbs and adjectives are often more abstract than nouns, the word associations for them will improve the results.

Table 3: Top 5 word associations

score	participant（A，B，C）	total
3	20，29，36	85
2	17，9，10	36
1	13，12，4	29
usability (%)	74，76，92	81

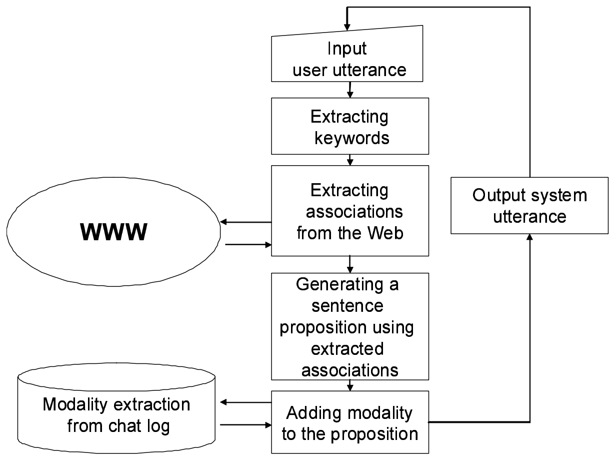
3 General Description of the System

The system generates replies in the following way:

- extraction of keywords from user utterance
- extraction of word associations from the Web
- generation of sentence proposition using the extracted associations
- addition of modality to the sentence proposition

3.1 Extraction of Keywords from User Utterances

The system applies morphological analysis to the use utterances in the same way as described in section **2.1** and extracts keywords based on part of speech.



Input user utterance
Extracting keywords
Extracting associations from the Web
WWW
Output system utterance
Generating a sentence proposition using extracted associations
Modality extraction from chat log
Adding modality to the proposition

Figure 1: System flow

3.2 Extraction of Words Association from the Web

The system performs a Google search using the extracted keywords as a query. The system sorts the results obtained from the query by their frequency as in section **2.1**. In section **2.1** only nouns were extracted but here we also extract verbs and adjectives. After sorting all words in adjective, verb and noun lists the system uses the ones with the highest frequency as word associations.

3.3 Generation of Proposition Using Word Associations

Using the associations, the system generates the proposition of a sentence to be used as a reply to the user input. A proposition is an expression representing an objective statement. The proposition is generated by applying associations to a proposition template like [(noun) (topic indicating particle *wa*) (adjective)]. We prepared 8 proposition templates manually (see Table 4). The templates were chosen subjectively after examining statistics from IRC [6] chat logs. Our criteria for choosing templates from the chat logs was that they should belong to the 20 most frequent modality patterns and to be flexible enough to fit a range of grammatical constructions, for example in English, ”isn’t it” cannot follow verbs while ”I guess” can follow nouns, adjectives, and verbs. The proposition templates are applied in a predetermined order: for example, first a template ”(noun) *(wa)* (adjective)” is used; next a template ”(noun) *(ga)* (adjective)” is used. However, since the generated proposition is not always a natural statement, the system uses exact matching searches of the whole phrases in a search engine to check the naturalness of each proposition. If the frequency of occurrence of the proposition is low, it is defined as unnatural and deleted. This processing is based on the idea that the phrases existing on the Web in large numbers are most probably correct grammatically and semantically. If an unnatural proposition is generated, the system generates another proposition in the same way. In this experiment the system used propositions for which the hit number exceeded 1,000 hits using Google. Thus, the processing proceeds as follows. The system first selects the top noun, top verb, and top adjective word associations. These are applied to the templates in a predetermined order. If a generated proposition is judged as valid (using Google, occurrence on the web indicates validity), it is used. If not, another template is tried until a valid proposition is found. The reason for not trying every possible combination of associated words is prohibitively long processing time.

(noun) *(wa)* (adjective)
(noun) *(ga)* (adjective)
(noun) *(ga)* (verb)
(noun) *(wa)* (verb)
(so-re) *(wa)* (verb)
(noun)
(adjective)
(verb)

3.4 Adding Modality to the Propositions

Finally, the system adds modality to the generated proposition. By modality we mean a set of grammatical and pragmatic rules to express subjective judgments and attitudes. In our system, modality is realized through adverbs at the end of a sentence which is common in Japanese (Nitta et al., 1989). In our system, a pair of sentence head and sentence end auxiliary verb are defined as ”modality”.

3.4.1 Extracting Modality

There is no standard definition of what constitutes modality in Japanese. In this paper modality of casual conversation is classified into questions and informative expressions. Questions are expressions that request information from the user. Informative expressions are expressions that transmit information to the user. Patterns for these modalities are extracted automatically from IRC chat logs (100,000 utterances) in advance. Modality patterns are extracted in these ways:

- pairs of grammatical particles and an auxiliary verbs placed at the end of sentences are defined as ending patterns
- sentences with question marks are defined as questions
- adverbs, emotive words, and connectives at the beginning of sentences are defined as informative expressions
- candidate patterns thus obtained are sorted by frequency

First the system extracts sentence ending patterns from IRC chat logs. If an expression contains question marks, it is classified as a question. Next, the system extracts adverbs, emotive words, and connectives from the beginning and end of sentences from the IRC logs. These pairs (beginning and end) of expressions are classified as ”informative expressions”. For example question expression ”desu-ka?” is extracted from a human utterance like ”*Kyou-wa samui desu-ka?*” (Is it cold today?). An informative expression ”*maa *** kedo*” is extracted from a human utterance as ”*Maa sore-wa ureshii kedo*” (Well, I’m glad, but you know...).

685 patterns were obtained for informative expressions. 550 of these informative expression patterns were considered by authors as correct (80%). For questions 396 patterns were obtained, and 292 patterns (73%) were evaluated as correct. We sorted these candidates in frequency order. The words appearing at the top of the list were correct, but even the ones appearing only once were still deemed as usable. For example, the question expression ”*janakatta deshita-kke?*” is a correct expression, but appeared only once in the 100,000 utterances. Hence, we confirmed that chat logs include various modality expressions, and only a few of them are incorrect. Tables 5 and 6 show some examples of modality patterns.

Table 5: Examples of informative expression modality

informative expression	frequency
maa - kedo (Well , it can be said - but -)	21
maa - dana (Well , it can be said -)	16
maa - desu-ga (Well , it appears that -)	16
soko-de - desu-yo (Here , it is said that -)	15
maa - da-ga (Well , it can be said - but -)	14
maa - desu-yo (Well , it is that -)	12

Table 6: Examples of question modality sentence endings

question	freqency
...desuka? (Is it that ... ?)	232
...kana? (Maybe ... ?)	90
...da-kke? (Is it right that ... ?)	87
...masu-ka? (Is it that ... ?)	69
...nano? (Is it that ... ?)	68
...toka? (... , isn’t it ?)	55

3.4.2 Adding Modality

The system adds the modality from section **3.4.1** to the proposition from section **3.3** to generate the system output. This process is based on the idea that human utterance consists of proposition and modality. A modality pattern is selected randomly. For example, if the system generates the proposition ”*fuyu wa samui* (Winter is cold.)” and selects the modality ”*iyaa ... desu-yo* (Ooh ... isn’t it?)”, the generated output will be ”*iyaa, fuyu-wa samui desu-yo* (Winter is cold, you know)”. However, there is a possibility that the system generates unnatural output like ”*fuyu-wa samui dayo-ne* (Winter is cold, arent't it?)”, depending on the pair of proposition and modality. To this problem, the system uses the Google search engine to filter out unnatural output. The system performs a phrase search on the end of the sentence. If the number of search hits is higher than threshold, the output is judged as correct. If the number of a search hits is lower than the threshold, the output is judged as incorrect and discarded, and a new reply is generated. Here, we experimentally set the threshold to 100 hits.

4 Experimental Results

We used system α, generating only the proposition, and system β, generating both proposition and modality. 5 participants used each systems for conversations of 10 turns and evaluated the conversations on a 5-point scale. Evaluation criteria were ”will to continue the conversation” (A), ”grammatical naturalness of dialogues” (B), ”semantical naturalness of dialogues” (C), ”vocabulary richness” (D), ”knowledge richness” (E), and ”humanity of the system” (F). Table 7 shows average scores for the evaluations of each system. System β that uses modality scored much higher than system α. Table 8 shows examples of actual dialogue. In the evaluation, the participants expressed the opinion that an utterance like *(xx ha yy)* is unnatural and using a modality like *(maa)*(”well”), *(moo)*(”anyway”) is very natural. Thus we can say that the modality expressions make the utterances of the system seem more natural.

Table 8: Examples of dialogues with system β

user:	*Nanika suki-na tabemono aru?* (What food do you like ?)
system:	*Maa, tabemono-wa oishii desu.* (Well, food tastes good.)
user:	*Saikin-wa osake-mo suki-ni natte-kita-n-da.* (Recently, I begin to like alcohol, too.)
system:	*Demo, sake-wa yowai-no-yo-ne.* (But, I can't drink much.)
user:	*Yowai-n-da... Sugu yochau-no?* (Really...? Do you get drunk quickly?)
system:	*Maa, sore-wa sugoi-wa-ne.* (Whow, that's amazing.)
user:	*Boku-wa wari-to osake-wa tsuyoi hou-nan-da.* (I have a rather high tolerance for alcohol.)
system:	*Iya, sore-wa tsuyoi-n-de.* (Well, it is strong, I can say.)

user:	*Kyou-wa sukoshi hadazamui-yo-ne. Natsu-nanoni.* (It is a little cold today. Even though it is summer.)
system:	*Asa-wa hadazamui-toka ?* (Isn't it chilly in morning?)
user:	*Asa-kara hadazamukatta-ne.* (It was chilly since morning.)
system:	*Aa kyou-wa hayai-na.* (Ah, it's early.)

5 The System as a Platform

The simplicity, real-time processing capabilities and promising results showing that users do not get bored so quickly encouraged us to perform trials with other ongoing projects and experiment with the system working as a platform for adding various modules and algorithms. By using our system it is possible to perform tests to see if a new idea will support or improve human-computer interaction or not. Here we will briefly describe two such trials - one on guessing emotive values of utterances and one on improving the system's overall evaluation by adding a pun generator.

5.1 Testing Affect Analysis

Ptaszynski et al.(Ptaszynski et al., 2008) have developed a method for affect analysis of Japanese text. Their method is based on cross-referencing lexical emotive elements with emotive expressions appearing in text. In the process of analysis first a general emotive context is determined and then the specific types of emotional states conveyed in an utterance are extracted. They support this method with a

Table 7: Evaluation Results

	System α (proposition)						system β (proposition + modality)					
Evaluation criteria	A	B	C	D	E	F	A	B	C	D	E	F
Participant a	1	3	2	2	4	2	4	4	3	4	3	5
Participant b	1	3	1	2	1	1	4	4	4	5	4	3
Participant c	1	2	1	2	1	1	1	2	1	2	1	1
Participant d	1	3	1	3	1	2	4	3	1	3	3	4
Oarticipant e	1	4	1	1	2	1	3	2	2	4	5	4
Average	1.0	3.0	1.2	2.0	1.8	1.4	3.2	3.0	2.2	3.6	3.2	3.4

Web-mining technique to improve the performance of the emotional state type extraction. A system constructed on the basis of their method achieved human level performance in determining the emotiveness of utterances, and 65% of human level performance in extracting the specific types of emotions. Also, the supporting Web mining technique improved the performance of the emotional state type extraction to 85% of the human level (Shi et al, 2008). As these are very promising figures we are currently in the phase of implementing their ideas in our system and testing how emotion recognition can influence speech act analysis and the automatic choice of proper modality.

5.2 Improving the System Using Humor

In this trial, an experiment showing that humor can improve a non-task oriented conversational system's overall performance was conducted.

5.2.1 Implementing PUNDA system

By using a simplified version of Dybala's PUNDA system (Dybala et al., 2008), a pun-generation was added to our baseline system. The PUNDA algorithm consists of two parts: A Candidate Selection Algorithm and a Sentence Integration Engine. The former generates a candidate for a pun analyzing an input utterance and selects words or phrases that could be transformed into a pun by one of four generation patterns: homophony, initial mora addition, internal mora addition or final mora addition. The latter part generates a sentence including the candidate extracted in the previous step. To make the system's response more related to the user's input, each sentence that included a joke started with the pattern "[base phrase] *to ieba*" ("Speaking of [base phrase]"). The remaining part of the sentence was extracted from the Web and the candidate was used as a query word and the list of sentences including this word was retrieved. Then the shortest sentence with an exclamation mark is selected as most jokes convey some emotions. When the candidate list was empty, the system selected one random pun from a pun database.

5.2.2 Experiment results

In the first experiment, 5 participants were asked to perform a 10-turn dialogue with two systems. After using both systems (baseline and humor-equipped), users were asked to evaluate both systems's performances by answering the following questions: A) Do you want to continue the dialogue?; B) Was the system's utterances grammatically natural?; C) Was the system's utterances semantically natural?; D) Was the system's vocabulary rich?; E) Did you get an impression that the system possesses any knowledge?; F) Did you get an impression that the system was human-like?; G) Do you think the system tried to make the dialogue more funny and interesting? and H) Did you find the system's utterances interesting and funny? Answers were given on a 5-point scale and the results are shown in Table 9.

A third-person evaluation experiment was also performed and again the humor-equipped system scored higher than the non-humor one. The question asked in this evaluation was: "Which dialogue do you find most interesting and funny?". Evaluators could choose between 3 options: Dialogue 1 (Baseline system first 3 turns), Dialogue 2 (Humor-equipped system, first 3 turns with system's third response replaced by pun generator's output) and Dia-

Table 9: Results of humor experiments

Evaluation Criteria	A	B	C	D	E	F	G	H
Baseline System	3.0	2.2	2.4	2.4	2.0	2.8	2.2	2.8
With pun generator	3.2	3.0	2.8	2.8	2.2	3.0	3.4	3.6

logue 3 (the first 3 turns of the baseline system with joking ability). Dialogue 1 and Dialogue 2 have the same input. Among 25 evaluators, only 5 (20%) responded that Dialogue 1 was most interesting and funny. 10 chose Dialogue 2 and the other 10 chose Dialogue 3 (40% respectively). This means that each of humor equipped dialogues received evaluations two times higher than non-humor dialogue.

5.3 A Toolkit for Conversation-Related Experiments

Our system can be also disassembled into a set of flexible tools which help students to experiment with dialogue processing. By using simple web-mining techniques we described, this dialogue engine is capable of automatic retrieval of associations which can be used to produce a whole range of utterances - for example by using the bottom, not the top of the associations list, one can examine how interesting or provocative the dialogue becomes. As the system has a cgi interface, the experiments are easy and any new feature (for instance a speech act choice menu) can be easily added. Such toolkit gives students an opportunity to experiment on a given aspect of dialogue processing without the need of building a conversation system from the scratch. There is also no need of laborious knowledge input and, as such open-domain oriented system generates new ”on topic” utterances, experiment subjects do not get bored quickly, which is always a problem while collecting conversation logs of human-machine interaction. A programmer also can freely choose between thousands of IRC logs utterances and Internet resources for the statistical trials, grammar patterns retrieval, speech acts analysis.

6 Conclusion and Future Work

In this research we investigated if word associations extracted automatically from the Web are reasonable (semantically on topic) and if they can be successfully used in non-task-oriented dialogue systems. We also implemented such a system extraction module. It is able to automatically generate in real-time responses to user utterances by generating a proposition and adding modality retrieved from IRC chat logs. We conducted evaluation experiments on the overall influence of the modality usage and it improved the system. Therefore we showed that it is possible to construct a dialogue system that automatically generates understandable on-topic utterances without the need of creating vast amounts of rules and data beforehand. We also confirmed that our system can be used as a experimental platform which can be easily used by other researchers to test their algorithms with a more unpredictible (and less boring) ”chatbot”, an important factor for long tiring sessions of human-computer conversation. Currently there are several projects which use the system described here as a platform for experiments and we introduced two of them - on joke generation and affect analysis.

There is still a lot of work left to be done. It is necessary for a non-task-oriented dialogue system to obtain not only word associations, but also different kinds of knowledge - of user’s preferences or of dialogue itself - for example conversational strategies. At this moment the system generates utterances by applying word associations to the proposition templates and adding modality. We also need to more deeply consider semantics, speech acts and context to create a more advanced system. Finally, the system needs to recognize not only keywords, but also user’s modality. We assume that the affect recognition mentioned above will help us to achieve this goal in near future and this is our next step. By opening the system’s code and giving others the opportunity of adding their own modules and changes we hope to solve remaining problems. In this paper we focus on the impact of adding modality to a system. Comparing the system to Japanese versions of ELIZA (already available) and ALICE (not available in Japanese yet) is also one of our next steps.

Abstract

Foreign name translations typically include multiple spelling variants. These variants cause data sparseness problems, increase Out-of-Vocabulary (OOV) rate, and present challenges for machine translation, information extraction and other NLP tasks. This paper aims to identify name spelling variants in the target language using the source name as an anchor. Based on word-to-word translation and transliteration probabilities, as well as the string edit distance metric, target name translations with similar spellings are clustered. With this approach tens of thousands of high precision name translation spelling variants are extracted from sentence-aligned bilingual corpora. When these name spelling variants are applied to Machine Translation and Information Extraction tasks, improvements over strong baseline systems are observed in both cases.

1 Introduction

Foreign names typically have multiple spelling variants after translation, as seen in the following examples:

```
He confirmed that "al-Kharroub
province is at the top of our
priorities."
…for the Socialist Progressive
Party in upper Shuf and the Al-
Kharrub region,…
…during his tour of a number of
villages in the region of Al-
Kharub,…
…Beirut and its suburbs and
Iqlim al-Khurub,…
```

Such name spelling variants also frequently appear in other languages, such as 布什(bushi) / 布殊(bushu) / 布希(buxi) (for Bush) in Chinese, and سبرنغفيلد (sbrngfyld) /سبرينغفيلد (sbryngfyld) / سبرينجفيلد (sbrynjfyld) (for Springfield) in Arabic.

These spelling variants present challenges for many NLP tasks, increasing vocabulary size and OOV rate, exacerbating the data sparseness problem and reducing the readability of MT output when different spelling variants are generated for the same name in one document. We address this problem by replacing each spelling variant with its corresponding canonical form. Such text normalization could potentially benefit many NLP tasks including information retrieval, information extraction, question answering, speech recognition and machine translation.

Research on name spelling variants has been studied mostly in Information Retrieval research, especially in query expansion and cross-lingual IR. Baghat and Hovy (2007) proposed two approaches for spelling variants generation, based on the letters-to-phonemes mapping and Soundex algorithm (Knuth 1973). Raghaven and Allan (2005) proposed several techniques to group names in ASR output and evaluated their effectiveness in spoken document retrieval (SDR). Both approaches use a named entity extraction system to automatically identify names. For multi-lingual name spelling variants, Linden (2005) proposed to use a general edit distance metric with a weighted FST to find technical term translations (which were referred to as "cross-lingual spelling variants"). These variants are typically translated words with similar stems in another language. Toivonen and colleagues (2005) proposed a two-step fuzzy translation technique to solve similar problems. Al-Onaizan and Knight (2002), Huang (2003) and Ji and Grishman (2007) investigated the general name entity translation problem, especially in the context of machine translation.

This paper aims to identify mono-lingual name spelling variants using cross-lingual information. Instead of using a named entity tagger to identify name spelling variants, we treat names in one language as the anchor of spelling variants in another language. From sentence-aligned bilingual corpora we collect word co-occurrence statistics and calculate word translation[1] probabilities. For each source word, we group its target translations into clusters according to string edit distances, then calculate the transliteration cost between the source word and each target translation cluster. Word pairs with small transliteration costs are considered as name translations, and the target cluster contains multiple spelling variants corresponding to the source name.

We apply this approach to extract name transliteration spelling variants from bilingual corpora. We obtained tens of thousands of high precision name translation pairs. We further apply these spelling variants to Machine Translation (MT) and Information Extraction (IE) tasks, and observed statistically significant improvement on the IE task, and close to oracle improvement on the MT task.

The rest of the paper is organized as follows. In section 2 we describe the technique to identify name spelling variants from bilingual data. In section 3 and 4 we address their application to MT and IE respectively. We present our experiment results and detailed analysis in section 5. Section 6 concludes this paper with future work.

2 Finding Name Translation Variants

[1] In this paper, the translation cost measures the semantic difference between source and target names, which are estimated from their co-occurrence statistics. The transliteration cost measures their phonetic distance and are estimated based on a character transliteration model.

Starting from sentence-aligned parallel data, we run HMM alignment (Vogel et. al. 1996 & Ge 2004) to obtain a word translation model. For each source word this model generates target candidate translations as well as their translation probabilities. A typical entry is shown in Table 1. It can be observed that the Arabic name's translations include several English words with similar spellings, all of which are correct translations. However, because the lexical translation probabilities are distributed among these variants, none of them has the highest probability. As a result, the incorrect translation, *iqlim*, is assigned the highest probability and often selected in MT output. To fix this problem, it is desirable to identify and group these target spelling variants, convert them into a canonical form and merge their translation probabilities.

الخروب | Alxrwb

iqlim [0.22]	al-kharrub [0.16]	al-kharub [0.11]	overflew [0.09]
junbulat [0.05]	al-khurub [0.05]	hours [0.04]	al-kharroub [0.03]

Table 1. English translations of a Romanized Arabic name *Alxrwb* with translation probabilities.

For each source word in the word translation model, we cluster its target translations based on string edit distances using group average agglomerative clustering algorithm (Manning and Schütze, 2000). Initially each target word is a single word cluster. We calculate the average editing distance between any two clusters, and merge them if the distance is smaller than a certain threshold. This process repeats until the minimum distance between any two clusters is above a threshold. In the above example, *al-kharrub, al-kharub, al-khurub* and *al-kharroub* are grouped into a single cluster, and each of the ungrouped words remains in its single word cluster. Note that the source word may not be a name while its translations may still have similar spellings. An example is the Arabic word اعلم which is aligned to English words *brief, briefing, briefed* and *briefings*. To detect whether a source word is a name, we calculate the transliteration cost between the source word and its target translation cluster, which is defined as the average transliteration cost between the source word and each target word in the cluster. As many names are translated based on their pronunciations, the source and target names have similar phonetic features and lower transliteration costs. Word pairs whose transliteration cost is lower than an empirically selected threshold are considered as name translations.

2.1 Name Transliteration Cost

The transliteration cost measures the phonetic similarity between a source word and a target word. It is calculated based on the character transliteration model, which can be trained from bilingual name translation pairs. We segment the source and target names into characters, then run monotone[2] HMM alignment on the source and target character pairs. After the training, character transliteration probabilities can be estimated from the relevant frequencies of character alignments.

Suppose the source word f contains m characters, $f_1, f_2, \ldots, f_m$, and the target word e contains n characters, $e_1, e_2, \ldots, e_n$. For j=1, 2,…, n, letter e_j is aligned to character f_{a_j} according to the HMM aligner. Under the assumption that character alignments are independent, the word transliteration probability is calculated as

$$P(e \mid f) = \prod_{j=1}^{n} p(e_j \mid f_{a_j}) \qquad (2.1)$$

where $p(e_j \mid f_{a_j})$ is the character transliteration probability. Note that in the above configuration one target character can be aligned to only one source character, and one source character can be aligned to multiple target characters.

An example of the trained A-E character transliteration model is shown in Figure 1. The Arabic character خ is aligned with high probabilities to English letters with similar pronunciation. Because Arabic words typically omit vowels, English vowels are also aligned to Arabic characters. Given this model, the characters within a Romanized Arabic name and its English translation are aligned as shown in Figure 1.

[2] As name are typically phonetically translated, the character alignment are often monotone. There is no cross-link in character alignments.

2.2 Transliteration Unit Selection

The transliteration units are typically characters. The Arabic alphabet includes 32 characters, and the English alphbet includes 56 letters[3]. However, Chinese has about 4000 frequent characters. The imbalance of Chinese and English vocabulary sizes results in suboptimal transliteration model estimation. Each Chinese character also has a pinyin, the Romanized representation of its pronunciation. Segmenting the Chinese pinyin into sequence of Roman letters, we now have comparable vocabulary sizes for both Chinese and English. We build a pinyin transliteration model using Chinese-English name translation pairs, and compare its performance with a character transliteration model in Experiment section 5.1.

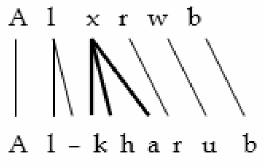

Figure 1. Example of the learned A-E character transliteration model with probabilities, and its application in the alignment between an Romanized Arabic name and an English translation.

3 Application to Machine Translation

We applied the extracted name translation spelling variants to the machine translation task. Given the name spelling variants, we updated both the translation and the language model, adding variants' probabilities to the canonical form.

Our baseline MT decoder is a phrase-based decoder as described in (Al-Onaizan and Papineni 2006). Given a source sentence, the decoder tries to find the translation hypothesis with minimum translation cost, which is defined as the log-linear combination of different feature functions, such as translation model cost, language model cost, distortion cost and

[3]Uppercase and lowercase letters plus some special symbols such as '_', '-".

sentence length cost. The translation cost includes word translation probability and phrase translation probability.

3.1 Updating The Translation Model

Given target name spelling variants $\{t_1, t_2, ..., t_m\}$ for a source name *s*, here $t_1, t_2, ..., t_m$ are sorted based on their lexical translation probabilities, $p(t_1 \mid s) \geq p(t_2 \mid s) \geq ... \geq p(t_m \mid s)$.

We select t_1 as the canonical spelling, and merge other spellings' translation probabilities with this one:

$$p(t_1 \mid s) = \sum_{j=1}^{m} p(t_m \mid s).$$

Other spelling variants get zero probability. Table 2 shows the updated word translation probabilities for "الخروب|Alxwrb". Compared with Figure 1, the translation probabilities from several spelling variants are merged with the canonical form, *al-kharrub*, which now has the highest probability in the new model.

الخروب | Alxwrb

al-kharrub [0.35]	iqlim [0.22]	al-kharub [0.0]	overflew [0.09]
junbulat [0.05]	al-khurub [0.0]	hours [0.04]	al-kharroub [0.0]

Table 2. English translations of an Arabic name الخروب|*Alxrwb* with the updated word translation model.

The phrase translation table includes source phrases, their target phrase translations and the frequencies of the bilingual phrase pair alignment. The phrase translation probabilities are calculated based on their alignment frequencies, which are collected from word aligned parallel data. To update the phrase translation table, for each phrase pair including a source name and its spelling variant in the target phrase, we replace the target name with its canonical spelling. After the mapping, two target phrases differing only in target names may end up with the identical target phrase, and their alignment frequencies are added. Phrase translation probabilities are re-estimated with the updated frequencies.

3.2 Updating The Language Model

The machine translation decoder uses a language model as a measure of a well-formedness of the output sentence. Since the updated translation model can produce only the canonical form of a group of spelling variants, the language model should be updated in that all *m*-grams ($1 \leq m \leq N$) that are spelling variants of each other are merged (and their counts added), resulting in the canonical form of the *m*-gram. Two *m*-grams are considered spelling variants of each other if they contain words t_1^i, t_2^i ($t_1^i \neq t_2^i$) at the same position *i* in the *m*-gram, and that t_1^i and t_2^i belong to the same spelling variant group.

An easy way to achieve this update is to replace every spelling variant in the original language model training data with its corresponding canonical form, and then build the language model again. However, since we do not want to replace words that are not names we need to have a mechanism for detecting names. For simplicity, in our experiments we assumed a word is a name if it is capitalized, and we replaced spelling variants with their canonical forms only for words that start with a capital letter.

4 Applying to Information Extraction

Information extraction is a crucial step toward understanding a text, as it identifies the important conceptual objects in a discourse. We address here one important and basic task of information extraction: *mention detection*[4]: we call instances of textual references to objects *mentions*, which can be either named (e.g. John Smith), nominal (the president) or pronominal (e.g. he, she). For instance, in the sentence

- President <u>*John Smith*</u> said <u>*he*</u> has no comments.

there are two mentions: *John Smith* and *he*. Similar to many classical NLP tasks, we formulate the mention detection problem as a classification problem, by assigning to each token in the text a label, indicating whether it starts a specific mention, is inside a specific mention, or is outside any mentions. Good

[4]We adopt here the ACE (NIST 2007) nomenclature.

performance in many natural language processing tasks has been shown to depend heavily on integrating many sources of information (Florian et al. 2007). We select an exponential classifier, the Maximum Entropy (MaxEnt henceforth) classifier that can integrate arbitrary types of information and make a classification decision by aggregating all information available for a given classification (Berger et al. 1996). In this paper, the MaxEnt model is trained using the *sequential conditional generalized iterative scaling* (SCGIS) technique (Goodman, 2002), and it uses a *Gaussian prior* for regularization (Chen and Rosenfeld, 2000).

In ACE, there are seven possible mention types: person, organization, location, facility, geopolitical entity (GPE), weapon, and vehicle. Experiments are run on Arabic and English. Our baseline system achieved very competitive result among systems participating in the ACE 2007 evaluation. It uses a large range of features, including lexical, syntactic, and the output of other information extraction models. These features were described in (Zitouni and Florian, 2008 & Florian et al. 2007), and are not discussed here. In this paper we focus on examining the effectiveness of name spelling variants in improving mention detection systems. We add a new feature that for each token x_i to process we fire its canonical form (class label) $C(x_i)$, representative of name spelling variants of x_i. This name spelling variant feature is also used in *conjunction* with the lexical (e.g., words and morphs in a 3-word window, prefixes and suffixes of length up to 4, stems in a 4-word window for Arabic) and syntactic (POS tags, text chunks) features.

5 Experiments

5.1 Evaluating the precision of name spelling variants

We extracted Arabic-English and English-Arabic name translation variants from sentence-aligned parallel corpora released by LDC. The accuracy of the extracted name translation spelling variants are judged by proficient Arabic and Chinese speakers.

The Arabic-English parallel corpora include 5.6M sentence pairs, 845K unique Arabic words and 403K unique English words. We trained a word translation model by running HMM alignment on the parallel data, grouped target translation with similar spellings and computed the average transliteration cost between the Arabic word and each English word in the translation clusters according to Formula 2.1. We sorted the name translation groups according to their transliteration costs, and selected 300 samples at different ranking position for evaluation (20 samples at each ranking position). The quality of the name translation variants are judged as follows: for each candidate name translation group $\{t_1, t_2, ..., t_m \mid s\}$, if the source word *s* is a name and all the target spelling variants are correct translations, it gets a credit of 1. If *s* is not a name, the credit is 0. If *s* is a name but only part of the target spelling variants are correct, it gets partial credit *n/m*, where *n* is the number of correct target translations. We evaluate only the precision of the extracted spelling variants[5]. As seen in Figure 2, the precision of the top 22K A-E name translations is 96.9%. Among them 98.5% of the Arabic words are names. The precision gets lower and lower when more non-name Arabic words are included. On average, each Arabic name has 2.47 English spelling variants, although there are some names with more than 10 spelling variants.

Switching the source and target languages, we obtained English-Arabic name spelling variants, i.e., one English name with multiple Arabic spellings. As seen in Figure 3, top 20K E-A name pairs are obtained with a precision above 87.9%, and each English name has 3.3 Arabic spellings on average. Table 3 shows some A-E and E-A name spelling variants, where Arabic words are represented in their Romanized form.

We conduct a similar experiment on the Chinese-English language pair, extracting Chinese-English and English-Chinese name spelling variants from 8.7M Chinese-English sentence pairs. After word segmentation, the Chinese vocabulary size is 1.5M words, and English vocabulary size is 1.4M words. With the

[5] Evaluating recall requires one to manually look through the space of all possible transliterations (hundreds of thousands of entries), which is impractical.

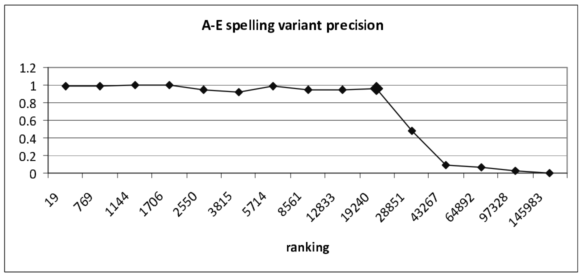

Figure 2. Arabic-English name spelling variants precision curve (Precision of evaluation sample at different ranking positions. The larger square indicates the cutoff point).

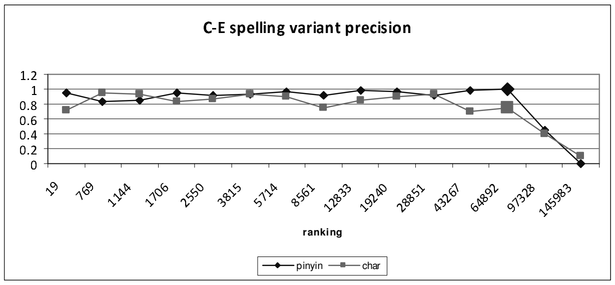

Figure 4. Chinese-English name spelling variants precision curve.

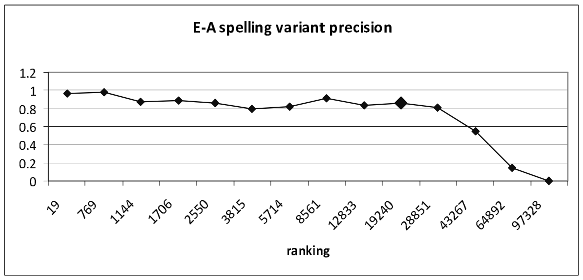

Figure 3. English-Arabic name spelling variants precision curve.

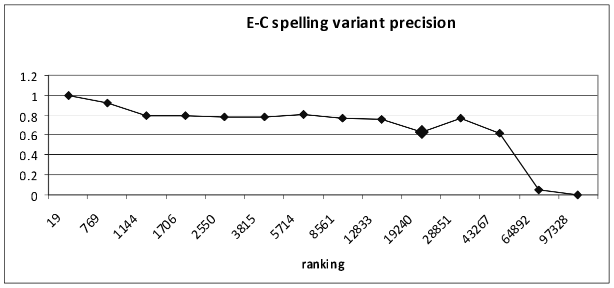

Figure 5. English-Chinese name spelling variants precision curve.

Chinese pinyin transliteration model, we extract 64K C-E name spelling variants with 93.6% precision. Figure 4 also shows the precision curve of the Chinese character transliteration model. On average the pinyin transliteration model has about 6% higher precision than the character transliteration model. The pinyin transliteration model is particularly better on the tail of the curve, extracting more C-E transliteration variants. Figure 5 shows the precision curve for E-C name spelling variants, where 20K name pairs are extracted using letter-to-character transliteration model, and obtaining a precision of 74.3%.

Table 4 shows some C-E and E-C name spelling variants. We observed errors due to word segmentation. For example, the last two Chinese words corresponding to “drenica” have additional Chinese characters, meaning “drenica region” and “drenica river”. Similarly for tenet, the last two Chinese words also have segmentation errors due to missing or spurious characters. Note that in the C-E spelling variants, the source word “韦尔曼” has 14 spelling variants. Judge solely from the spelling, it is hard to tell whether they are the same person name with different spellings.

5.2 Experiments on Machine Translation

We apply the Arabic-English name spelling variants on the machine translation task. Our baseline system is trained with 5.6M Arabic-English sentence pairs, the same training data used to extract A-E spelling variants. The language model is a modified Kneser-Ney 5-gram model trained on roughly 3.5 billion words. After pruning (using count cutoffs), it contains a total of 935 million *N*-grams. We updated the translation models and the language model with the name spelling variant class.

Table 5 shows a Romanized Arabic sentence, the translation output from the baseline system and the output from the updated models. In the baseline system output, the Arabic name “Alxrwb” was incorrectly translated into “regional”. This error was fixed in the updated model, where both translation and language models assign higher probabilities to the correct translation “al-kharroub” after spelling variant normalization.

Lang. Pair	Source Name	Target Spelling Variants

Baseline+ULM+UTM	0.2718	51.46
Ref. Normalization	0.2724	51.40

Table 6. MT scores with updated TM and LM

We also evaluated the updated MT models on a MT test set. The test set includes 70 documents selected from GALE 2007 Development set. It contains 42 newswire documents and 28 weblog and newsgroup documents. There are 669 sentences with 16.3K Arabic words in the test data. MT results are evaluated against one reference human translation using BLEU (Papineni et. al. 2001) and TER (Snover et. al. 2006) scores. The results using the baseline decoder and the updated models are shown in Table 6. Applying the updated language model (ULM) and the translation model (UTM) lead to a small reduction in TER. After we apply similar name spelling normalization on the reference translation, we observed some additional improvements. Overall, the BLEU score is increased by 0.1 BLEU point and TER is reduced by 0.26.

Although the significance of correct name translation can not be fully represented by

BLEU and TER scores[6], we still want to understand the reason of the relatively small improvement. After some error analysis, we found that in the testset only 2.5% of Arabic words are names with English spelling variants. Among them, 73% name spelling errors can be corrected with the translation spelling variants obtained in section 5.1. Because the MT system is trained on the same bilingual data from which the name spelling variants are extracted, some of these Arabic names are already correctly translated in the baseline system. So the room of improvement is small. We did an oracle experiment, manually correcting the name translation errors in the first 10 documents (89 sentences with 2545 words). With only 6 name translation errors corrected, this reduced the TER from 48.83 to 48.65.

5.2 Experiments on Information Extraction

Mention detection system experiments are conducted on the ACE 2007 data sets in Arabic and English. Since the evaluation test set is not publicly available, we have split the publicly available training corpus into an 85%/15% data split. To facilitate future comparisons with work presented here, and to simulate a realistic scenario, the splits are created based on article dates: the test data is selected as the latest 15% of the data in chronological order. This way, the documents in the training and test data sets do not overlap in time, and the content of the test data is more recent than the training data. For English we use 499 documents for training and 100 documents for testing, while for Arabic we use 323 documents for training and 56 documents for testing. English and Arabic mention detection systems are using a large range of features, including lexical (e.g., words and morphs in a 3-word window, prefixes and suffixes of length up to 4, stems in a 4-word window for Arabic), syntactic (POS tags, text chunks), and the output of other information extraction models. These features were described in (Zitouni and Florian, 2008 & Florian et al. 2007) with more details. Our goal here is to investigate the effectiveness of name spelling variants information in improving mention detection system performance.

	Baseline			**Baseline+NSV**		
	P	**R**	**F**	**P**	**R**	**F**
English	84.4	80.6	**82.4**	84.6	80.9	**82.7**
Arabic	84.3	79.0	**81.6**	84.4	79.1	**81.7**

Table 7: Performance of English and Arabic mention detection systems without (Baseline) and with (Baseline+NSV) the use of name spelling variants. Performance is presented in terms of Precision (P), Recall (R), and F-measure (F).

Results in Table 7 show that the use of name spelling variants (**NSV**) improves mention detection systems performance, especially for English; an interesting improvement is obtained in recall – which is to be expected, given the method –, but also in precision, leading to systems with better performance in terms of F-measure (82.4 vs. 82.7). This improvement in performance is statistically significant according to the stratified bootstrap re-sampling approach (Noreen 1989). This approach is used in the named entity recognition shared task of CoNLL-2002[7]. However, the small improvement obtained for Arabic is not statistically significant based on the approach described earlier. One hypothesis is that Arabic name spelling variants are not rich enough and that a better tuning of the alignment score is required to improve precision.

6 Conclusion

We proposed a cross-lingual name spelling variants extraction technique. We extracted tens of thousands of high precision bilingual name translation spelling variants. We applied the spelling variants to the IE task, observing statistically significant improvements over a strong baseline system. We also applied the spelling variants to MT task and even though the overall improvement is relatively small, it achieves performance close to the one observed in an oracle experiment.

[6] These scores treat information bearing words, like names, the same as any other words, like punctuations.

Abstract

This paper introduces a new kernel which computes similarity between two natural language sentences as the number of paths shared by their dependency trees. The paper gives a very efficient algorithm to compute it. This kernel is also an improvement over the word subsequence kernel because it only counts linguistically meaningful word subsequences which are based on word dependencies. It overcomes some of the difficulties encountered by syntactic tree kernels as well. Experimental results demonstrate the advantage of this kernel over word subsequence and syntactic tree kernels.

1 Introduction

Kernel-based learning methods (Vapnik, 1998) are becoming increasingly popular in natural language processing (NLP) because they allow one to work with potentially infinite number of features without explicitly constructing or manipulating them. In most NLP problems, the data is present in structured forms, like strings or trees, and this structural information can be effectively passed to a kernel-based learning algorithm using an appropriate kernel, like a string kernel (Lodhi et al., 2002) or a tree kernel (Collins and Duffy, 2001). In contrast, feature-based methods require reducing the data to a pre-defined set of features often leading to some loss of the useful structural information present in the data.

A kernel is a measure of similarity between every pair of examples in the data and a kernel-based machine learning algorithm accesses the data only through these kernel values. For example, the string kernel (Lodhi et al., 2002; Cancedda et al., 2003) computes the similarity between two natural language strings as the number of common word subsequences between them. A subsequence allows gaps between the common words which are penalized according to a parameter. Each word subsequence hence becomes an implicit feature used by the kernel-based machine learning algorithm. A problem with this kernel is that many of these word subsequences common between two strings may not be semantically expressive or linguistically meaningful[1]. Another problem with this kernel is that if there are long-range dependencies between the words in a common word subsequence, then they will unfairly get heavily penalized because of the presence of word gaps.

The syntactic tree kernel presented in (Collins and Duffy, 2001) captures the structural similarity between two syntactic trees as the number of syntactic subtrees common between them. However, often syntactic parse trees may share syntactic subtrees which correspond to very different semantics based on what words they represent in the sentence. On the other hand, some subtrees may differ syntactically but may represent similar underlying semantics. These differences can become particularly problematic if the tree kernel is to be used for tasks which require semantic processing.

This paper presents a new kernel which computes similarity between two sentences as the the number of paths common between their dependency trees.

[1](Lodhi et al., 2002) use character subsequences instead of word subsequences which are even less meaningful.

(a) *A fat cat was chased by a dog.*
(b) *A cat with a red collar was chased two days ago by a fat dog.*

Figure 1: Two natural language sentences.

It improves over the word subsequence kernel because it only counts the word subsequences which are linked by dependencies. It also circumvents some of the difficulties encountered with the syntactic tree kernel when applied for semantic processing tasks.

Although several dependency-tree-based kernels and modifications to syntactic tree kernels have been proposed which we briefly discuss in the Related Work section, to our best knowledge no previous work has presented a kernel based on dependency paths which offers some unique advantages. We also give a very efficient algorithm to compute this kernel. We present experimental results on the task of domain-specific semantic parsing demonstrating the advantage of this kernel over word subsequence and syntactic tree kernels.

The following section gives some background on string and tree kernels. Section 3 then introduces the dependency-based word subsequence kernel and gives an efficient algorithm to compute it. Some of the related work is discussed next, followed by experiments, future work and conclusions.

2 String and Tree Kernels

2.1 Word-Subsequence Kernel

A kernel between two sentences measures the similarity between them. Lodhi et al. (2002) presented a string kernel which measures the similarity between two sentences, or two documents in general, as the number of character subsequences shared between them. This was extended by Cancedda et al. (2003) to the number of common word subsequences between them. We will refer to this kernel as the *word subsequence kernel*.

Consider the two sentences shown in Figure 1. Some common word subsequences between them are "a cat", "was chased by", "by a dog", "a cat chased by a dog", etc. Note that the subsequence "was chased by" is present in the second sentence but it requires skipping the words "two days ago" or has a gap of three words present in it. The kernel downweights the presence of gaps by a decay factor $\lambda \epsilon (0, 1]$. If g_1 and g_2 are the sum totals of gaps for a subsequence present in the two sentences respectively, then the contribution of this subsequence towards the kernel value will be $\lambda^{g_1+g_2}$. The kernel can be normalized to have values in the range of $[0, 1]$ to remove any bias due to different sentence lengths. Lodhi et al. (2002) give a dynamic programming algorithm to compute string subsequence kernels in $O(nst)$ time where s and t are the lengths of the two input strings and n is the maximum length of common subsequences one wants to consider. Rousu and Shawe-Taylor (2005) present an improved algorithm which works faster when the vocabulary size is large. Subsequence kernels have been used with success in NLP for text classification (Lodhi et al., 2002; Cancedda et al., 2003), information extraction (Bunescu and Mooney, 2005b) and semantic parsing (Kate and Mooney, 2006).

There are, however, some shortcomings of this word subsequence kernel as a measure of similarity between two sentences. Firstly, since it considers all possible common subsequences, it is not sensitive to whether the subsequence is linguistically meaningful or not. For example, the meaningless subsequences "cat was by" and "a was a" will also be considered common between the two sentences by this kernel. Since these subsequences will be used as implicit features by the kernel-based machine learning algorithm, their presence can only hurt the performance. Secondly, if there are long distance dependencies between the words of the subsequence present in a sentence then the subsequence will get unfairly penalized. For example, the most important word subsequence shared between the two sentences shown in Figure 1 is "a cat was chased by a dog" which will get penalized by total gap of eight words coming from the second sentence and a gap of one word from the first sentence. Finally, the kernel is not sensitive to the relations between the words, for example, the kernel will consider "a fat dog" as a common subsequence although in the first sentence "a fat" relates to the cat and not to the dog.

2.2 Syntactic Tree Kernel

Syntactic tree kernels were first introduced by Collins and Duffy (2001) and were also used by

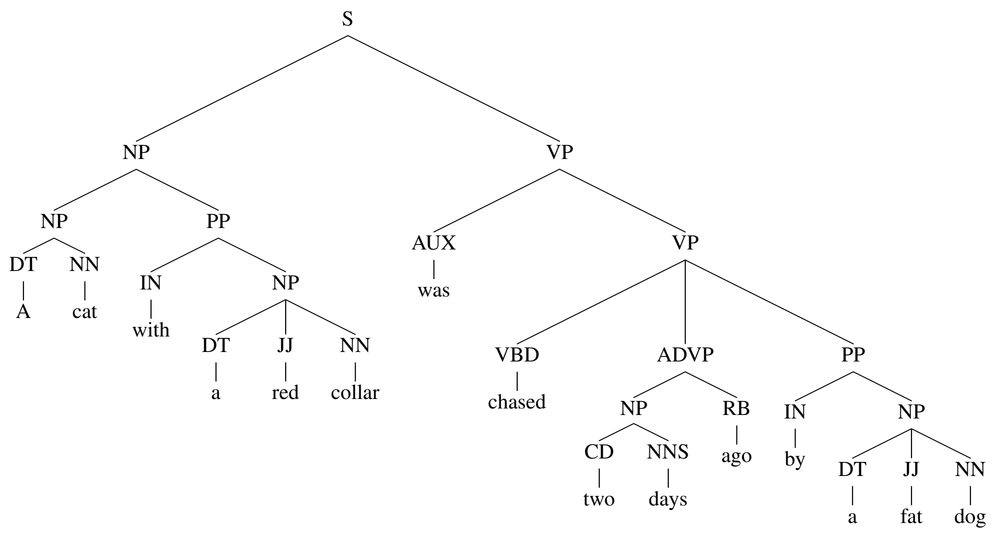

Figure 3: Syntactic parse tree of the sentence shown in Figure 1 (b).

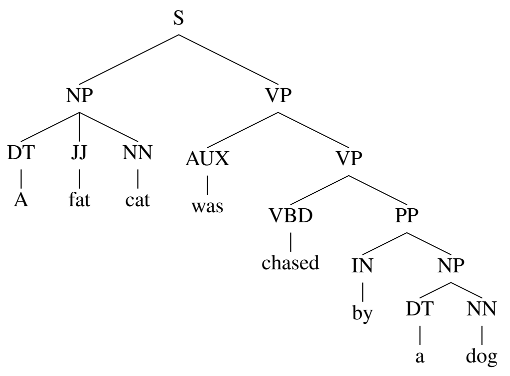

Figure 2: Syntactic parse tree of the sentence shown in Figure 1 (a).

Collins (2002) for the task of re-ranking syntactic parse trees. They define a kernel between two trees as the number of subtrees shared between them. A subtree is defined as any subgraph of the tree which includes more than one node, with the restriction that entire productions must be included at every node. The kernel defined this way captures most of the structural information present in the syntactic parse trees in the form of tree fragments which the kernelized learning algorithms can then implicitly use as features. The kernel can be computed in $O(|N_1||N_2|)$ time, where $|N_1|$ and $|N_2|$ are the number of nodes of the two trees. An efficient algorithm to compute tree kernels was given by Moschitti (2006a) which runs in close to linear time in the size of the input trees.

One drawback of this tree kernel, though, particularly when used for any task requiring semantic processing, is that it may match syntactic subtrees between two trees even though they represent very dissimilar things in the sentence. For example, between the syntactic parse trees shown in Figures 2 and 3 for the two sentences shown in Figure 1, the syntactic tree kernel will find (NP (DT a) JJ NN) as a common subtree but in the first sentence it represents "cat" while in the second it represents "collar" and "dog". It will also find "(NP (DT a) (JJ fat) NN)" as a common subtree which again refers to "cat" in the first sentence and "dog" in the second sentence. As another example, consider two simple sentences: (S (NP Chip) (VP (V saw) (NP Dale))) and (S (NP Mary) (VP (V heard) (NP Sally))). Even though semantically nothing is similar between them, the syntactic tree kernel will still find common subtrees (S NP VP), (VP N NP) and (S NP (VP V NP)). The underlying problem is that the syntactic tree kernel tends to overlook the words of the sentences which, in fact, carry the essential semantics. On the other hand, although (NP (DT a) (NN cat)) and (NP (DT a) (JJ fat) (NN cat)) represent very similar concepts but the kernel will not capture this high level similarity between the two constituents, and will only find (DT a) and (NN cat) as the common substructures. Finally, the most important similarity between the two sentences is "a cat was chased by a dog" which will not be captured by this kernel because

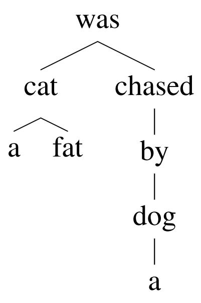

Figure 4: Dependency tree of the sentence shown in Figure 1 (a).

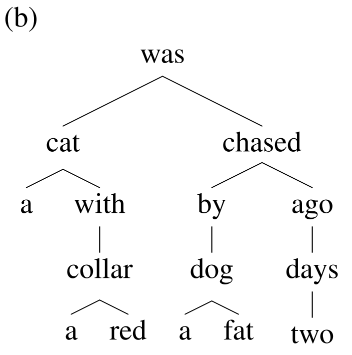

Figure 5: Dependency tree of the sentence shown in Figure 1 (b).

there is no common subtree which covers it. The Related Work section discusses some modifications that have been proposed to the syntactic tree kernel.

3 A Dependency-based Word Subsequence Kernel

A dependency tree encodes functional relationships between the words in a sentence (Hudson, 1984). The words of the sentence are the nodes and if a word complements or modifies another word then there is a child to parent edge from the first word to the second word. Every word in a dependency tree has exactly one parent except for the root word. Figures 4 and 5 show dependency trees for the two sentences shown in Figure 1. There has been a lot of progress in learning dependency tree parsers (McDonald et al., 2005; Koo et al., 2008; Wang et al., 2008). They can also be obtained indirectly from syntactic parse trees utilizing the head words of the constituents.

We introduce a new kernel which takes the words into account like the word-subsequence kernel and also takes the syntactic relations between them into account like the syntactic tree kernel, however, it does not have the shortcomings of the two kernels pointed out in the previous section. This kernel counts the number of common paths between the dependency trees of the two sentences. Another way to look at this kernel is that it counts all the common word subsequences which are linked by dependencies. Hence we will call it a *dependency-based word subsequence kernel*. Since the implicit features it uses are dependency paths which are enumerable, it is a well defined kernel. In other words, an example gets implicitly mapped to the feature space in which each dependency path is a dimension.

The dependency-based word subsequence kernel will find the common paths 'a $\rightarrow$ cat', 'cat $\rightarrow$ was $\leftarrow$ chased', 'chased $\leftarrow$ by $\leftarrow$ dog' among many others between the dependency trees shown in Figures 4 and 5. The arrows are always shown from child node to the parent node. A common path takes into account the direction between the words as well. Also note that it will find the important subsequence 'a $\rightarrow$ cat $\rightarrow$ was $\leftarrow$ chased $\leftarrow$ by $\leftarrow$ dog $\leftarrow$ a' as a common path.

It can be seen that the word subsequences this kernel considers as common paths are linguistically meaningful. It is also not affected by long-range dependencies between words because those words are always directly linked in a dependency tree. There is no need to allow gaps in this kernel either because related words are always linked. It also won't find 'a fat' as a common path because in the first tree "cat" is between the two words and in the second sentence "dog" is between them. Thus it does not have the shortcomings of the word subsequence kernel. It also avoids the shortcomings of the syntactic tree kernel because the common paths are words themselves and syntactic labels do not interfere in capturing the similarity between the two sentences. It will not find anything common between dependency trees for the sentences "Chip saw Dale" and "Mary heard Sally". But it will find 'a $\rightarrow$ cat' as a common path between "a cat" and "a fat cat". We however note that this kernel does not use general syntactic categories, unlike the syntactic tree kernel, which will limit its applicability to the tasks which depend on the syntactic categories, like re-ranking syntactic parse trees.

We now give an efficient algorithm to compute all the common paths between two trees. To our best knowledge, no previous work has considered this problem. The key observation for this algorithm is that a path in a tree always has a structure in which nodes (possibly none) go up to a highest node followed by nodes (possibly none) coming down. Based on this observation we compute two quantities for every pair of nodes between the two trees. We call the first quantity *common downward paths* (CDP) between two nodes, one from each tree, and it counts the number of common paths between the two trees which originate from those two nodes and *which always go downward*. For example, the common downward paths between the 'chased' node of the tree in Figure 4 and the 'chased' node of the tree in Figure 5 are 'chased $\leftarrow$ by', 'chased $\leftarrow$ by $\leftarrow$ dog' and 'chased $\leftarrow$ by $\leftarrow$ dog $\leftarrow$ a'. Hence $CDP(chased, chased)$ = 3. A word may occur multiple times in a sentence so the CDP values will be computed separately for each occurrence. We will shortly give a fast recursive algorithm to compute CDP values.

Once these CDP values are known, using these the second quantity is computed which we call *common peak paths* (CPP) between every two nodes, one from each tree. This counts the number of common paths between the two trees which *peak* at those two nodes, i.e. these nodes are the highest nodes in those paths. For example, 'was' is the peak for the path 'a $\rightarrow$ cat $\rightarrow$ was $\leftarrow$ chased'. Since every common path between the two trees has a unique highest node, once these CPP values have been computed, the number of common paths between the two trees is simply the sum of all these CPP values.

We now describe how all these values are efficiently computed. The CDP values between every two nodes n_1 and n_2 of the trees T_1 and T_2 respectively, is recursively computed as follows:

$$CDP(n_1, n_2) = 0 \; if \; n_1.w \neq n_2.w$$

otherwise,

$$CDP(n_1, n_2) = \sum_{\substack{c_1 \epsilon C(n_1)\\ c_2 \epsilon C(n_2)\\ c_1.w = c_2.w}} (1 + CDP(c_1, c_2))$$

In the first equation, $n.w$ stands for the word at the node n. If the words are not equal then there cannot be any common downward paths originating from the nodes. In the second equation, $C(n)$ represents the set of children nodes of the node n in a tree. If the words at two children nodes are the same, then the number of common downward paths from the parent will include all the common downward paths at the two children nodes incremented with the link from the parent to the children. In addition the path from parent to the child node is also a common downward path. For example, in the trees shown in Figures 4 and 5, the nodes with word 'was' have 'chased' as a common child. Hence all the common downward paths originating from 'chased' (namely 'chased $\leftarrow$ by', 'chased $\leftarrow$ by $\leftarrow$ dog' and 'chased $\leftarrow$ by $\leftarrow$ dog $\leftarrow$ a') when incremented with 'was $\leftarrow$ chased' become common downward paths originating from 'was'. In addition, the path 'was $\leftarrow$ chased' itself is a common downward path. Since 'cat' is also a common child at 'was', it's common downward paths will also be added.

The CDP values thus computed are then used to compute the CPP values as follows:

$$CPP(n_1, n_2) = 0 \; if \; n_1.w \neq n_2.w$$

otherwise,

$$CPP(n_1, n_2) = CDP(n_1, n_2) + \sum_{\substack{c_1, \hat{c_1} \epsilon C(n_1)\\ c_2, \hat{c_2} \epsilon C(n_2)\\ c_1.w = c_2.w\\ \hat{c_1}.w = \hat{c_2}.w}} \left(\begin{array}{c} 1 + CDP(c_1, c2) + CDP(\hat{c_1}, \hat{c_2}) + \\ CDP(c_1, c_2) * CDP(\hat{c_1}, \hat{c_2}) \end{array} \right)$$

If the two nodes are not equal then the number of common paths that peak at them will be zero. If the nodes are equal, then all the common downward paths between them will also be the paths that peak at them, hence it is the first term in the above equation. Next, the remaining paths that peak at them can be counted by considering every pair of common children nodes represented by c_1 & c_2 and $\hat{c_1}$ & $\hat{c_2}$. For example, for the common node 'was' in Figures 4 and 5, the children nodes 'cat' and 'chased' are common. The path 'cat $\rightarrow$ was $\leftarrow$ chased' is a path that peaks at 'was', hence 1 is added in the second term. All the downward paths from ‘cat’ when incremented up to ‘was’ and down to ‘chased’ are also the paths that peak at ‘was’ (namely ‘a → cat → was ← chased’). Similarly, all the downward paths from ‘chased’ when incremented up to ‘was’ and down to ‘cat’ are also paths that peak at ‘was’ (‘cat → was ← chased ← by’, ‘cat → was ← chased ← by ← dog’, etc.). Hence the next two terms are present in the equation. Finally, all the downward paths from ‘cat’ when incremented up to ‘was’ and down to every downward path from ‘chased’ are also the paths that peak at ‘was’ (‘a → cat → was ← chased ← by’, ‘a → cat → was ← chased ← by ← dog’ etc.). Hence there is the product term present in the equation. It is important not to re-count a path from the opposite direction hence the two pairs of common children are considered only once (i.e. not reconsidered symmetrically).

The dependency word subsequence kernel between two dependency trees T_1 and T_2 is then simply:

$$K(T_1, T_2) = \sum_{\substack{n_1 \epsilon T_1 \\ n_2 \epsilon T_2 \\ n_1.w = n_2.w}} (1 + CPP(n_1, n_2))$$

We also want to count the number of common words between the two trees in addition to the number of common paths, hence 1 is added in the equation. The kernel is normalized to remove any bias due to different tree sizes:

$$K_{normalized}(T_1, T_2) = \frac{K(T_1, T_2)}{\sqrt{K(T_1, T_1) * K(T_2, T_2)}}$$

Since for any long path common between two trees, there will be many shorter paths within it which will be also common between the two trees, it is reasonable to downweight the contribution of long paths. We do this by introducing a parameter $\alpha \epsilon (0, 1]$ and by downweighting a path of length l by α^l. A similar mechanism was also used in the syntactic tree kernel (Collins and Duffy, 2001).

The equations for computing CDP and CPP are accordingly modified as follows to accommodate this downweighting.

$$CDP(n_1, n_2) = 0 \; if \; n_1.w \neq n_2.w$$

otherwise,

$$CDP(n_1, n_2) = \sum_{\substack{c_1 \epsilon C(n_1) \\ c_2 \epsilon C(n_2) \\ c_1.w = c_2.w}} (\alpha + \alpha * CDP(c_1, c_2))$$

$$CPP(n_1, n_2) = 0 \; if \; n_1.w \neq n_2.w$$

otherwise,

$$CPP(n_1, n_2) = CDP(n_1, n_2) + \sum_{\substack{c_1, \hat{c_1} \epsilon C(n_1) \\ c_2, \hat{c_2} \epsilon C(n_2) \\ c_1.w = c_2.w \\ \hat{c_1}.w = \hat{c_2}.w}} \left(\begin{array}{c} \alpha^2 + \alpha * CDP(c_1, c2) + \\ \alpha * CDP(\hat{c_1}, \hat{c_2}) + \\ \alpha^2 * CDP(c_1, c_2) * CDP(\hat{c_1}, \hat{c_2}) \end{array} \right)$$

This algorithm to compute all the common paths between two trees has worst time complexity of $O(|T_1||T_2|)$, where $|T_1|$ and $|T_2|$ are the number of nodes of the two trees T_1 and T_2 respectively. This is because CDP computations are needed for every pairs of nodes between the two trees and is recursively computed. Using dynamic programming their recomputations can be easily avoided. The CPP computations then simply add the CDP values[2]. If the nodes common between the two trees are sparse then the algorithm will run much faster. Since the algorithm only needs to store the CDP values, its space complexity is $O(|T_1||T_2|)$. Also note that this algorithm computes the number of common paths of *all* lengths unlike the word subsequence kernel in which the maximum subsequence length needs to be specified and the time complexity then depends on this length.

4 Related Work

Several modifications to the syntactic tree kernels have been proposed to overcome the type of problems pointed out in Subsection 2.2. Zhang et al. (2007) proposed a grammar-driven syntactic tree kernel which allows soft matching between the subtrees of the trees if that is deemed appropriate by the grammar. For example, their kernel will be able

[2]This analysis uses the fact that any node in a tree on average has $O(1)$ number of children.

to match the subtrees (NP (DT a) (NN cat)) and (NP (DT a) (JJ fat) (NN cat)) with some penalty. Moschitti (2006b) proposed a partial tree kernel which can partially match subtrees. Moschitti et al. (2007) proposed a tree kernel over predicate-argument structures of sentences based on the PropBank labels. Che et al. (2006) presented a hybrid tree kernel which combines a constituent and a path kernel. We however note that the paths in this kernel link predicates and their arguments and are very different from general paths in a tree that our dependency-based word subsequence kernel uses. Shen et al. (2003) proposed a lexicalized syntactic tree kernel which utilizes LTAG-based features. Toutanova et al. (2004) compute similarity between two HPSG parse trees by finding similarity between the leaf projection paths using string kernels.

A few kernels based on dependency trees have also been proposed. Zelenko et al. (2003) proposed a tree kernel over shallow parse tree representations of sentences. This tree kernel was slightly generalized by Culotta and Sorensen (2004) to compute similarity between two dependency trees. In addition to the words, this kernel also incorporates word classes into the kernel. The kernel is based on counting matching subsequences of children of matching nodes. But as was also noted in (Bunescu and Mooney, 2005a), this kernel is *opaque* i.e. it is not obvious what the implicit features are and the authors do not describe it either. In contrast, our dependency-based word subsequence kernel, which also computes similarity between two dependency trees, is very transparent with the implicit features being simply the dependency paths. Their kernel is also very time consuming and in their more general sparse setting it requires $O(mn^3)$ time and $O(mn^2)$ space, where m and n are the number of nodes of the two trees ($m >= n$) (Zelenko et al., 2003).

Bunescu and Mooney (2005a) give a shortest path dependency kernel for relation extraction. Their kernel, however, does not find similarity between two sentences but between the shortest dependency paths connecting the two entities of interests in the sentences. This kernel uses general dependency graphs but if the graph is a tree then the shortest path is the only path between the entities. Their kernel also uses word classes in addition to the words themselves.

5 Experiments

We show that the new dependency-based word subsequence kernel performs better than word subsequence kernel and syntactic tree kernel on the task of domain-specific semantic parsing.

5.1 Semantic Parsing

Semantic parsing is the task of converting natural language sentences into their domain-specific complete formal meaning representations which an application can execute, for example, to answer database queries or to control a robot. A learning system for semantic parsing induces a semantic parser from the training data of natural language sentences paired with their respective meaning representations. KRISP (Kate and Mooney, 2006) is a semantic parser learning system which uses word subsequence kernel based SVM (Cristianini and Shawe-Taylor, 2000) classifiers and was shown to be robust to noise compared to other semantic parser learners. The system learns an SVM classifier for every production of the meaning representation grammar which tells the probability with which a substring of the sentence represents the semantic concept of the production. Using these classifiers a complete meaning representation of an input sentence is obtained by finding the most probable parse which covers the whole sentence. For details please refer to (Kate and Mooney, 2006).

The key operation in KRISP is to find the similarity between any two substrings of two natural language sentences. Word subsequence kernel was employed in (Kate and Mooney, 2006) to compute the similarity between two substrings. We modified KRISP so that the similarity between two substrings can also be computed using the syntactic tree kernel and the dependency-based word subsequence kernel. For applying the syntactic tree kernel, the syntactic subtree over a substring of a sentence is determined from the syntactic tree of the sentence by finding the lowest common ancestor of the words in this substring and then considering the smallest subtree rooted at this node which includes all the words of the substring. For applying the dependency-based word subsequence kernel to two substrings of a sentence, the kernel computation was suitably modified so that the common paths between the two dependency trees always begin and end with the words present in the substrings. This is achieved by including only those downward paths in computations of CDP which end with words within the given substrings. These paths relate the words within the substrings perhaps using words outside of these substrings.

5.2 Methodology

We measure the performance of KRISP obtained using the three types of kernels on the GEOQUERY corpus which has been used previously by several semantic parsing learning systems. It contains 880 natural language questions about the US geography paired with their executable meaning representations in a functional query language (Kate et al., 2005). Since the purpose of the experiments is to compare different kernels and not different semantic parsers, we do not compare the performance with other semantic parser learning systems. The training and testing was done using standard 10-fold cross-validation and the performance was measured in terms of precision (the percentage of generated meaning representations that were correct) and recall (the percentage of all sentences for which correct meaning representations were obtained). Since KRISP assigns confidences to the meaning representations it outputs, an entire range of precision-recall trade-off can be obtained. We measure the best F-measure (harmonic mean of precision and recall) obtained when the system is trained using increasing amounts of training data.

Since we were not interested in the accuracy of dependency trees or syntactic trees but in the comparison between various kernels, we worked with gold-standard syntactic trees. We did not have gold-standard dependency trees available for this corpus so we obtained them indirectly from the gold-standard syntactic trees using the head-rules from (Collins, 1999). We however note that accurate syntactic trees can be obtained by training a syntactic parser on WSJ treebank and gold-standard parse trees of some domain-specific sentences (Kate et al., 2005).

In the experiments, the α parameter of the dependency-based word subsequence kernel was set to 0.25, the λ parameter of the word subsequence kernel was fixed to 0.75 and the downweighting parameter for the syntactic tree kernel was fixed to 0.4. These were determined through pilot experiments with a smaller portion of the data set. The maximum length of subsequences required by the word subsequence kernel was fixed to 3, a longer length was not found to improve the performance and was only increasing the running time.

Examples	Dependency	Word	Syntactic
40	**25.62**	21.51	23.65
80	**45.30**	42.77	43.14
160	**63.78**	61.22	59.66
320	**72.44**	70.36	67.05
640	77.32	77.82	74.26
792	79.79	79.09	76.62

Table 1: Results on the semantic parsing task with increasing number of training examples using dependency-based word subsequence kernel, word subsequence kernel and syntactic tree kernel.

5.3 Results

Table 1 shows the results. The dependency-based word subsequence kernel always performs better than the syntactic tree kernel. All the numbers under the dependency kernel were found statistically significant ($p < 0.05$) over the corresponding numbers under the syntactic tree kernel based on paired t-tests. The improvement of the dependency-based word subsequence kernel over the word subsequence kernel is greater with less training data, showing that the dependency information is more useful when the training data is limited. The performance converges with higher amounts of training data. The numbers shown in bold were found statistically significant over the corresponding numbers under the word subsequence kernel.

It may be noted that syntactic tree kernel is mostly doing worse than the word subsequence kernel. We believe this is because of the shortcomings of the syntactic tree kernel pointed out in Subsection 2.2. Since this is a semantic processing task, the words play an important role and the generalized syntactic categories are not very helpful.

6 Future Work

In future, the dependency-based word subsequence kernel could be extended to incorporate word classes like the kernels presented in (Bunescu and Mooney, 2005a; Zelenko et al., 2003). It should be possible to achieve this by incorporating matches between word classes in addition to the exact word matches in the kernel computations similar to the way in which the word subsequence kernel was extended to incorporate word classes in (Bunescu and Mooney, 2005b). This will generalize the kernel and make it more robust to data sparsity.

The dependency-based word subsequence kernel could be tested on other tasks which require computing similarity between sentences or texts, like text classification, paraphrasing, summarization etc. We believe this kernel will help improve performance on those tasks.

7 Conclusions

We introduced a new kernel which finds similarity between two sentences as the number of common paths shared between their dependency trees. This kernel can also be looked upon as an improved word subsequence kernels which only counts the common word subsequences which are related by dependencies. We also gave an efficient algorithm to compute this kernel. The kernel was shown to out-perform the word subsequence kernel and the syntactic tree kernel on the task of semantic parsing.

Abstract

Lexical gaps between queries and questions (documents) have been a major issue in question retrieval on large online question and answer (Q&A) collections. Previous studies address the issue by *implicitly* expanding queries with the help of translation models pre-constructed using statistical techniques. However, since it is possible for *unimportant* words (e.g., non-topical words, common words) to be included in the translation models, a lack of noise control on the models can cause degradation of retrieval performance. This paper investigates a number of empirical methods for eliminating unimportant words in order to construct *compact translation models* for retrieval purposes. Experiments conducted on a real world Q&A collection show that substantial improvements in retrieval performance can be achieved by using compact translation models.

1 Introduction

Community-driven question answering services, such as Yahoo! Answers[1] and Live Search QnA[2], have been rapidly gaining popularity among Web users interested in sharing information online. By inducing users to collaboratively submit questions and answer questions posed by other users, large amounts of information have been collected in the form of question and answer (Q&A) pairs in recent years. This user-generated information is a valuable resource for many information seekers, because users can acquire information straightforwardly by searching through answered questions that satisfy their information need.

[1]http://answers.yahoo.com/
[2]http://qna.live.com/

Retrieval models for such Q&A collections should manage to handle the lexical gaps or word mismatches between user questions (queries) and answered questions in the collection. Consider the two following examples of questions that are semantically similar to each other:

- *"Where can I get cheap airplane tickets?"*
- *"Any travel website for low airfares?"*

Conventional word-based retrieval models would fail to capture the similarity between the two, because they have no words in common. To bridge the query-question gap, prior work on Q&A retrieval by Jeon et al. (2005) implicitly expands queries with the use of pre-constructed translation models, which lets you generate query words not in a question by translation to alternate words that are related. In practice, these translation models are often constructed using statistical machine translation techniques that primarily rely on word co-occurrence statistics obtained from parallel strings (e.g., question-answer pairs).

A critical issue of the translation-based approaches is the quality of translation models constructed in advance. If no noise control is conducted during the construction, it is possible for translation models to contain "unnecessary" translations (i.e., translating a word into an unimportant word, such as a non-topical or common word). In the query expansion viewpoint, an attempt to identify and decrease the proportion of unnecessary translations in a translation model may produce an effect of "selective" implicit query expansion and result in improved retrieval. However, prior work on translation-based Q&A retrieval does not recognize this issue and uses the translation model as it is; essentially no attention seems to have been paid to improving the performance of the translation-based approach by enhancing the quality of translation models.

In this paper, we explore a number of empirical methods for selecting and eliminating unimportant words from parallel strings to avoid unnecessary translations from being learned in translation models built for retrieval purposes. We use the term *compact translation models* to refer to the resulting models, since the total number of parameters for modeling translations would be minimized naturally. We also present experiments in which compact translation models are used in Q&A retrieval. The main goal of our study is to investigate if and how compact translation models can improve the performance of Q&A retrieval.

The rest of this paper is organized as follows. The next section introduces a translation-based retrieval model and accompanying techniques used to retrieve query-relevant questions. Section 3 presents a number of empirical ways to select and eliminate unimportant words from parallel strings for training compact translation models. Section 4 summarizes the compact translation models we built for retrieval experiments. Section 5 presents and discusses the results of retrieval experiments. Section 6 presents related works. Finally, the last section concludes the paper and discusses future directions.

2 Translation-based Retrieval Model

This section introduces the translation-based language modeling approach to retrieval that has been used to bridge the lexical gap between queries and already-answered questions in this paper.

In the basic language modeling framework for retrieval (Ponte and Croft, 1998), the similarity between a query Q and a document D for ranking may be modeled as the probability of the document language model M_D built from D generating Q:

$$sim(Q, D) \approx P(Q|M_D) \tag{1}$$

Assuming that query words occur independently given a particular document language model, the query-likelihood $P(Q|M_D)$ is calculated as:

$$P(Q|M_D) = \prod_{q \in Q} P(q|M_D) \tag{2}$$

where q represents a query word.

To avoid zero probabilities in document language models, a mixture between a document-specific multinomial distribution and a multinomial distribution estimated from the entire document collection is widely used in practice:

$$\begin{aligned} P(Q|M_D) \;\; = \;\; & \prod_{q \in Q} \Big[(1-\lambda) \cdot P(q|M_D) \\ & + \lambda \cdot P(q|M_C)\Big] \end{aligned} \tag{3}$$

where $0 < \lambda < 1$ and M_C represents a language model built from the entire collection. The probabilities $P(w|M_D)$ and $P(w|M_C)$ are calculated using maximum likelihood estimation.

The basic language modeling framework does not address the issue of lexical gaps between queries and question. Berger and Lafferty (1999) viewed information retrieval as statistical document-query translation and introduced translation models to map query words to document words. Assuming that a translation model can be represented by a conditional probability distribution of translation $T(\cdot|\cdot)$ between words, we can model $P(q|M_D)$ in Equation 3 as:

$$P(q|M_D) = \sum_{w \in D} T(q|w) P(w|M_D) \tag{4}$$

where w represents a document word.[3]

The translation probability $T(q|w)$ virtually represents the degree of relationship between query word q and document word w captured in a different, machine translation setting. Then, in the traditional information retrieval viewpoint, the use of translation models produce an implicit query expansion effect, since query words not in a document are mapped to related words in the document. This implies that translation-based retrieval models would make positive contributions to retrieval performance only when the pre-constructed translation models have reliable translation probability distributions.

[3]The formulation of our retrieval model is basically equivalent to the approach of Jeon et al. (2005).

2.1 IBM Translation Model 1

Obviously, we need to build a translation model in advance. Usually the IBM Model 1, developed in the statistical machine translation field (Brown et al., 1993), is used to construct translation models for retrieval purposes in practice. Specifically, given a number of parallel strings, the IBM Model 1 learns the translation probability from a source word s to a target word t as:

$$T(t|s) = \lambda_s^{-1} \sum_i^N c(t|s; J_i) \qquad (5)$$

where λ_s is a normalization factor to make the sum of translation probabilities for the word s equal to 1, N is the number of parallel string pairs, and J_i is the ith parallel string pair. $c(t|s; J_i)$ is calculated as:

$$\begin{aligned} c(t|s; J_i) &= \left(\frac{P(t|s)}{P(t|s_1) + \cdots + P(t|s_n)}\right) \\ &\quad \times freq_{t,J_i} \times freq_{s,J_i} \qquad (6) \end{aligned}$$

where $\{s_1, \ldots, s_n\}$ are words in the source text in J^i. $freq_{t,J^i}$ and $freq_{s,J^i}$ are the number of times that t and s occur in J_i, respectively.

Given the initial values of $T(t|s)$, Equations (5) and (6) are used to update $T(t|s)$ repeatedly until the probabilities converge, in an EM-based manner.

Note that the IBM Model 1 solely relies on word co-occurrence statistics obtained from parallel strings in order to learn translation probabilities. This implies that if parallel strings have unimportant words, a resulted translation model based on IBM Model 1 may contain unimportant words with non-zero translation probabilities.

We alleviate this drawback by eliminating unimportant words from parallel strings, avoiding them from being included in the conditional translation probability distribution. This naturally induces the construction of compact translation models.

2.2 Gathering Parallel Strings from Q&A Collections

The construction of statistical translation models previously discussed requires a corpus consisting of parallel strings. Since monolingual parallel texts are generally not available in real world, one must artificially generate a "synthetic" parallel corpus.

Question and answer as parallel pairs: The simplest approach is to directly employ questions and their answers in the collections by setting either as source strings and the other as target strings, with the assumption that a question and its corresponding answer are naturally parallel to each other. Formally, if we have a Q&A collection as $C = \{D_1, D_2, \ldots, D_n\}$, where D_i refers to an ith Q&A data consisting of a question q_i and its answer a_i, we can construct a parallel corpus C' as $\{(q_1, a_1), \ldots, (q_n, a_n)\} \cup \{(a_1, q_1), \ldots, (a_n, q_n)\} = C'$ where each element (s, t) refers to a parallel pair consisting of source string s and target string t. The number of parallel string samples would eventually be twice the size of the collections.

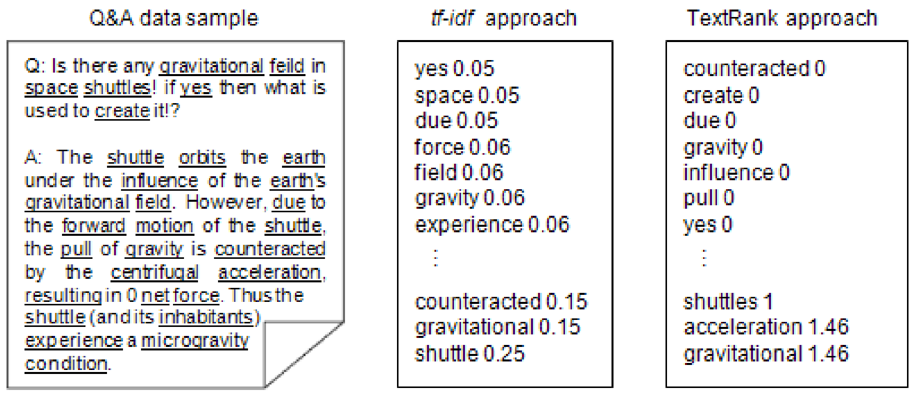
Similar questions as parallel pairs: Jeon et al. (2005) proposed an alternative way of automatically collecting a relatively larger set of parallel strings from Q&A collections. Motivated by the observation that many semantically identical questions can be found in typical Q&A collections, they used similarities between answers calculated by conventional word-based retrieval models to automatically group questions in a Q&A collection as pairs. Formally, two question strings q_i and q_j would be included in a parallel corpus C' as $\{(q_i, q_j), (q_j, q_i)\} \subset C'$ only if their answer strings a_i and a_j have a similarity higher than a pre-defined threshold value. The similarity is calculated as the reverse of the harmonic mean of ranks as $sim(a_i, a_j) = \frac{1}{2}(\frac{1}{r_j} + \frac{1}{r_i})$, where r_j and r_i refer to the rank of the a_j and a_i when a_i and a_j are given as queries, respectively. This approach may artificially produce much more parallel string pairs for training the IBM Model 1 than the former approach, depending on the threshold value.[4]

To our knowledge, there has not been any study comparing the effectiveness of the two approaches yet. In this paper, we try both approaches and compare the effectiveness in retrieval performance.

3 Eliminating Unimportant Words

We adopt a term weight ranking approach to identify and eliminate unimportant words from parallel strings, assuming that a word in a string is unim-

[4]We have empirically set the threshold (0.05) for our experiments.



Q&A data sample

Q: Is there any gravitational feild in space shuttles! if yes then what is used to create it!?

A: The shuttle orbits the earth under the influence of the earth's gravitational field. However, due to the forward motion of the shuttle, the pull of gravity is counteracted by the centrifugal acceleration, resulting in 0 net force. Thus the shuttle (and its inhabitants) experience a microgravity condition.

portant if it holds a relatively low significance in the document (Q&A pair) of which the string is originally taken from. Some issues may arise:

- How to assign a weight to each word in a document for term ranking?
- How much to remove as unimportant words from the ranked list?

The following subsections discuss strategies we use to handle each of the issues above.

3.1 Assigning Term Weights

In this section, the two different term weighting strategies are introduced.

tf-idf: The use of *tf-idf* weighting on evaluating how unimportant a word is to a document seems to be a good idea to begin with. We have used the following formulas to calculate the weight of word w in document D:

$$tf\text{-}idf_{w,D} = tf_{w,D} \times idf_w \tag{7}$$

$$tf_{w,D} = \frac{freq_{w,D}}{|D|}, \quad idf_w = \log \frac{|C|}{df_w}$$

where $freq_{w,D}$ refers to the number of times w occurs in D, $|D|$ refers to the size of D (in words), $|C|$ refers to the size of the document collection, and df_w refers to the number of documents where w appears. Eventually, words with low *tf-idf* weights may be considered as unimportant.

TextRank: The task of term weighting, in fact, has been often applied to the keyword extraction task in natural language processing studies. As an alternative term weighting approach, we have used a variant of Mihalcea and Tarau (2004)'s TextRank, a graph-based ranking model for keyword extraction which achieves state-of-the-art accuracy without the need of deep linguistic knowledge or domain-specific corpora.

Specifically, the ranking algorithm proceeds as follows. First, words in a given document are added as vertices in a graph G. Then, edges are added between words (vertices) if the words co-occur in a fixed-sized window. The number of co-occurrences becomes the weight of an edge. When the graph is constructed, the score of each vertex is initialized as 1, and the PageRank-based ranking algorithm is run on the graph iteratively until convergence. The TextRank score of a word w in document D at kth iteration is defined as follows:

$$R^k_{w,D} = (1-d) + d \cdot \sum_{\forall j:(i,j)\in G} \frac{e_{i,j}}{\sum_{\forall l:(j,l)\in G} e_{j,l}} R^{k-1}_{w,D} \tag{8}$$

where d is a damping factor usually set to 0.85, and $e_{i,j}$ is an edge weight between i and j.

The assumption behind the use of the variant of TextRank is that a word is likely to be an important word in a document if it co-occurs frequently with other important words in the document. Eventually, words with low TextRank scores may be considered as unimportant. The main differences of TextRank compared to *tf-idf* is that it utilizes the context information of words to assign term weights.

Figure 1 demonstrates that term weighting results of TextRank and *tf-idf* are greatly different. Notice that TextRank assigns low scores to words that co-

Corpus: (Q‖A)	Vocabulary Size (%chg)		Average Translations (%chg)	
	tf-idf	*TextRank*	*tf-idf*	*TextRank*
Initial	90,441		73	
25%Removal	90,326 (∇0.1%)	73,021 (∇19.3%)	73 (∇0.0%)	44 (∇39.7%)
50%Removal	90,230 (∇0.2%)	72,225 (∇20.1%)	72 (∇1.4%)	43 (∇41.1%)
75%Removal	88,763 (∇1.9%)	65,268 (∇27.8%)	53 (∇27.4%)	38 (∇47.9%)
Avg.Score	66,412 (∇26.6%)	31,849 (∇64.8%)	14 (∇80.8%)	18 (∇75.3%)

Table 1: Impact of various word elimination strategies on translation model construction using (Q‖A) corpus.

Corpus: (Q‖Q)	Vocabulary Size (%chg)		Average Translations (%chg)	
	tf-idf	*TextRank*	*tf-idf*	*TextRank*
Initial	34,485		442	
25%Removal	34,374 (∇0.3%)	26,900 (∇22.0%)	437 (∇1.1%)	282 (∇36.2%)
50%Removal	34,262 (∇0.6%)	26,421 (∇23.4%)	423 (∇4.3%)	274 (∇38.0%)
75%Removal	32,813 (∇4.8%)	23,354 (∇32.3%)	288 (∇34.8%)	213 (∇51.8%)
Avg.Score	28,613 (∇17.0%)	16,492 (∇52.2%)	163 (∇63.1%)	164 (∇62.9%)

Table 2: Impact of various word elimination strategies on translation model construction using (Q‖Q) corpus.

occur only with stopwords. This implies that TextRank weighs terms more "strictly" than the *tf-idf* approach, with use of contexts of words.

3.2 Deciding the Quantity to be Removed from Ranked List

Once a final score (either *tf-idf* or TextRank score) is obtained for each word, we create a list of words ranked in decreasing order of their scores and eliminate the ones at lower ranks as unimportant words. The question here is how to decide the proportion or quantity to be removed from the ranked list.

Removing a fixed proportion: The first approach we have used is to decide the number of unimportant words based on the size of the original string. For our experiments, we manually vary the proportion to be removed as 25%, 50%, and 75%. For instance, if the proportion is set to 50% and an original string consists of ten words, at most five words would be remained as important words.

Using average score as threshold: We also have used an alternate approach to deciding the quantity. Instead of eliminating a *fixed* proportion, words are removed if their score is lower than the average score of all words in a document. This approach decides the proportion to be removed more flexibly than the former approach.

4 Building Compact Translation Models

We have initially built two parallel corpora from a Q&A collection[5], denoted as (Q‖A) corpus and (Q‖Q) corpus henceforth, by varying the methods in which parallel strings are gathered (described in Section 2.2). The (Q‖A) corpus consists of 85,938 parallel string pairs, and the (Q‖Q) corpus contains 575,649 parallel string pairs.

In order to build compact translation models, we have preprocessed the parallel corpus using different word elimination strategies so that unimportant words would be removed from parallel strings. We have also used a stoplist[6] consisting of 429 words to remove stopwords. The out-of-the-box GIZA++[7] (Och and Ney, 2004) has been used to learn translation models using the pre-processed parallel corpus for our retrieval experiments. We have also trained initial translation models, using a parallel corpus from which only the stopwords are removed, to compare with the compact translation models.

Eventually, the number of parameters needed for modeling translations would be minimized if unimportant words are eliminated with different ap-

[5]Details on this data will be introduced in the next section.

[7]http://www.fjoch.com/GIZA++.html

proaches. Table 1 and 2 shows the impact of various word elimination strategies on the construction of compact translation models using the (Q||A) corpus and the (Q||Q) corpus, respectively. The two tables report the size of the vocabulary contained and the average number of translations per word in the resulting compact translation models, along with percentage decreases with respect to the initial translation models in which only stopwords are removed. We make these observations:

- The translation models learned from the (Q||Q) corpus have *less* vocabularies but *more* average translations per word than the ones learned from the (Q||A) corpus. This result implies that a large amount of noise may have been created inevitably when a large number of parallel strings (pairs of similar questions) were artificially gathered from the Q&A collection.
- The TextRank strategy tends to eliminate larger sets of words as unimportant words than the *tf-idf* strategy when a fixed proportion is removed, regardless of the corpus type. Recall that the TextRank approach assigns weights to words more strictly by using contexts of words.
- The approach to remove words according to the average weight of a document (denoted as *Avg.Score*) tends to eliminate relatively larger portions of words as unimportant words than any of the fixed-proportion strategies, regardless of either the corpus type or the ranking strategy.

5 Retrieval Experiments

Experiments have been conducted on a real world Q&A collection to demonstrate the effectiveness of compact translation models on Q&A retrieval.

5.1 Experimental Settings

In this section, four experimental settings for the Q&A retrieval experiments are described in detail.

Data: For the experiments, Q&A data have been collected from the *Science* domain of Yahoo! Answers, one of the most popular community-based question answering service on the Web. We have obtained a total of 43,001 questions with a best answer (selected either by the questioner or by votes of other users) by recursively traversing subcategories of the *Science* domain, with up to 1,000 question pages retrieved.[8]

Among the obtained Q&A pairs, 32 Q&A pairs have been randomly selected as the test set, and the remaining 42,969 questions have been the reference set to be retrieved. Each Q&A pair has three text fields: question title, question content, and answer.[9] The fields of each Q&A pair in the test set are considered as various test queries; the question title, the question content, and the answer are regarded as a short query, a long query, and a supplementary query, respectively. We have used long queries and supplementary queries only in the relevance judgment procedure. All retrieval experiments have been conducted using short queries only.

Relevance judgments: To find relevant Q&A pairs given a short query, we have employed a pooling technique used in the TREC conference series. We have pooled the top 40 Q&A pairs from each retrieval results generated by varying the retrieval algorithms, the search field, and the query type. Popular word-based models, including the Okapi BM25, query-likelihood language model, and previous translation-based models (Jeon et al., 2005), have been used.[10]

Relevance judgments have been done by two student volunteers (both fluent in English). Since many community-based question answering services present their search results in a hierarchical fashion (*i.e.* a list of relevant questions is shown first, and then the user chooses a specific question from the list to see its answers), a Q&A pair has been judged as relevant if its question is semantically similar to the query; neither quality nor rightness of the answer has not been considered. When a disagreement has been made between two volunteers, one of the authors has made the final judgment. As a result, 177 relevant Q&A pairs have been found in total for the 32 short queries.

Baseline retrieval models: The proposed ap-

[8]Yahoo! Answers did not expose additional question pages to external requests at the time of collecting the data.

[9]When collecting parallel strings from the Q&A collection, we have put together the question title and the question content as one question string.

[10]The retrieval model using compact translation models has not been used in the pooling procedure.

proach to Q&A retrieval using compact translation models (denoted as CTLM henceforth) is compared to three baselines:

QLM: Query-likelihood language model for retrieval (equivalent to Equation 3, without use of translation models). This model represents word-based retrieval models widely used in practice.

TLM(Q||Q): Translation-based language model for question retrieval (Jeon et al., 2005). This model uses IBM Model 1 learned from the (Q||Q) corpus of which stopwords are removed.

TLM(Q||A): A variant of the translation-based approach. This model uses IBM model 1 learned from the (Q||A) corpus.

Evaluation metrics: We have reported the retrieval performance in terms of Mean Average Precision (MAP) and Mean R-Precision (R-Prec).

Average Precision can be computed based on the precision at each relevant document in the ranking. Mean Average Precision is defined as the mean of the Average Precision values across the set of all queries:

$$MAP(Q) = \frac{1}{|Q|}\sum_{q \in Q}\frac{1}{m_q}\sum_{k=1}^{m_q} Precision(R_k) \quad (9)$$

where Q is the set of test queries, m_q is the number of relevant documents for a query q, R_k is the set of ranked retrieval results from the top until rank position k, and $Precision(R_k)$ is the fraction of relevant documents in R_k (Manning et al., 2008).

R-Precision is defined as the precision after R documents have been retrieved where R is the number of relevant documents for the current query (Buckley and Voorhees, 2000). Mean R-Precision is the mean of the R-Precisions across the set of all queries.

We take MAP as our primary evaluation metric.

5.2 Experimental Results

Preliminary retrieval experiments have been conducted using the baseline QLM and different fields of Q&A data as retrieval unit. Table 3 shows the effectiveness of each field.

The results imply that the question title field is the most important field in our Yahoo! Answers collection; this also supports the observation presented by

Retrieval unit	**MAP**	**R-Prec**
Question title	**0.1031**	**0.2396**
Question content	0.0422	0.0999
Answer	0.0566	0.1062

Table 3: Preliminary retrieval results.

Model	**MAP (%chg)**	**R-Prec (%chg)**
QLM	0.1031	0.2396
TLM(Q||Q)*	0.1121 (△9%)	0.2251 (∇6%)
CTLM(Q||Q)	**0.1415** (△37%)	**0.2425** (△1%)
TLM(Q||A)	0.1935 (△88%)	0.3135 (△31%)
CTLM(Q||A)	**0.2095** (△103%)	**0.3585** (△50%)

Table 4: Comparisons with three baseline retrieval models. * indicates that it is equivalent to Jeon et al. (2005)'s approach. MAP improvements of CTLMs have been tested to be statistically significant using paired t-test.

Jeon et al. (2005). Based on the preliminary observations, all retrieval models tested in this paper have ranked Q&A pairs according to the similarity scores between queries and question titles.

Table 4 presents the comparison results of three baseline retrieval models and the proposed CTLMs. For each method, the best performance after empirical λ parameter tuning according to MAP is presented.

Notice that both the TLMs and CTLMs have outperformed the word-based QLM. This implies that word-based models that do not address the issue of lexical gaps between queries and questions often fail to retrieve relevant Q&A data that have little word overlap with queries, as noted by Jeon et al. (2005).

Moreover, notice that the proposed CTLMs have achieved significantly better performances in all evaluation metrics than both QLM and TLMs, regardless of the parallel corpus in which the incorporated translation models are trained from. This is a clear indication that the use of compact translation models built with appropriate word elimination strategies is effective in closing the query-question lexical gaps

(Q‖Q)	MAP (%chg)	
	tf-idf	*TextRank*
Initial	0.1121	
25%Rmv	0.1141 (△1.8)	0.1308 (△16.7)
50%Rmv	0.1261 (△12.5)	0.1334 (△19.00)
75%Rmv	0.1115 (▽0.5)	0.1160 (△3.5)
Avg.Score	0.1056 (▽5.8)	**0.1415 (△26.2)**

Table 5: Contributions of various word elimination strategies on MAP performance of `CTLM(Q‖Q)`.

(Q‖A)	MAP (%chg)	
	tf-idf	*TextRank*
Initial	0.1935	
25%Rmv	**0.2095 (△8.3)**	0.1733 (▽10.4)
50%Rmv	0.2085 (△7.8)	0.1623 (▽16.1)
75%Rmv	0.1449 (▽25.1)	0.1515 (▽21.7)
Avg.Score	0.1168 (▽39.6)	0.1124 (▽41.9)

Table 6: Contributions of various word elimination strategies on MAP performance of `CTLM(Q‖A)`.

for improving the performance of question retrieval in the context of language modeling framework.

Note that the retrieval performance varies by the type of training corpus; `CTLM(Q‖A)` has outperformed `CTLM(Q‖Q)` significantly. This proves the statement we made earlier that the (Q‖Q) corpus would contain much noise since the translation models learned from the (Q‖Q) corpus tend to have smaller vocabulary sizes but significantly more average translations per word than the ones learned from the (Q‖A) corpus.

Table 5 and 6 show the effect of various word elimination strategies on the retrieval performance of `CTLM`s in which the incorporated compact translation models are trained from the (Q‖Q) corpus and the (Q‖A) corpus, respectively. It is interesting to note that the importance of modifications in word elimination strategies also varies by the type of training corpus.

The retrieval results indicate that when the translation model is trained from the “less noisy” (Q‖A) corpus, eliminating a relatively large proportions of words may hurt the retrieval performance of `CTLM`. In the case when the translation model is trained from the “noisy” (Q‖Q) corpus, a better retrieval performance may be achieved if words are eliminated appropriately to a certain extent.

In terms of weighting scheme, the TextRank approach, which is more “strict” than *tf-idf* in eliminating unimportant words, has led comparatively higher retrieval performances on all levels of removal quantity when the translation model has been trained from the “noisy” (Q‖Q) corpus. On the contrary, the “less strict” *tf-idf* approach has led better performances when the translation model has been trained from the “less noisy” (Q‖A) corpus.

In summary, the results imply that the performance of translation-based retrieval models can be significantly improved when strategies for building of compact translation models are chosen properly, regarding the expected noise level of the parallel corpus for training the translation models. In a case where a noisy parallel corpus is given for training of translation models, it is better to get rid of noise as much as possible by using “strict” term weighting algorithms; when a less noisy parallel corpus is given for building the translation models, a tolerant approach would yield better retrieval performance.

6 Related Works

Our work is most closely related to Jeon et al. (2005)’s work, which addresses the issue of word mismatch between queries and questions in large online Q&A collections by using translation-based methods. Apart from their work, there have been some related works on applying translation-based methods for retrieving FAQ data. Berger et al. (2000) report some of the earliest work on FAQ retrieval using statistical retrieval models, including translation-based approaches, with a small set of FAQ data. Soricut and Brill (2004) present an answer passage retrieval system that is trained from 1 million FAQs collected from the Web using translation methods. Riezler et al. (2007) demonstrate the advantages of translation-based approach to answer retrieval by utilizing a more complex translation model also trained from a large amount of data extracted from FAQs on the Web. Although all of these translation-based approaches are based on the statistical translation models, including the IBM Model 1, none of them focus on addressing the noise issues in translation models.

7 Conclusion and Future Work

Bridging the query-question gap has been a major issue in retrieval models for large online Q&A collections. In this paper, we have shown that the performance of translation-based retrieval on real online Q&A collections can be significantly improved by using compact translation models of which the noise (unimportant word translations) is properly reduced. We have also observed that the performance enhancement may be achieved by choosing the appropriate strategies regarding the strictness of various term weighting algorithms and the expected noise level of the parallel data for learning such translation models.

Future work will focus on testing the effectiveness of the proposed method on a larger set of Q&A collections with broader domains. Since the proposed approach cannot handle many-to-one or one-to-many word transformations, we also plan to investigate the effectiveness of phrase-based translation models in closing gaps between queries and questions for further enhancement of Q&A retrieval.

Scalable Language Processing Algorithms for the Masses: A Case Study in Computing Word Co-occurrence Matrices with MapReduce

Jimmy Lin

National Center for Biotechnology Information, National Library of Medicine
jimmylin@umd.edu

Abstract

This paper explores the challenge of scaling up language processing algorithms to increasingly large datasets. While cluster computing has been available in commercial environments for several years, academic researchers have fallen behind in their ability to work on large datasets. I discuss two barriers contributing to this problem: lack of a suitable programming model for managing concurrency and difficulty in obtaining access to hardware. Hadoop, an open-source implementation of Google's MapReduce framework, provides a compelling solution to both issues. Its simple programming model hides system-level details from the developer, and its ability to run on commodity hardware puts cluster computing within the reach of many academic research groups. This paper illustrates these points with a case study in building word co-occurrence matrices from large corpora. I conclude with an analysis of an alternative computing model based on renting instead of buying computer clusters.

1 Introduction

Over the past couple of decades, the field of computational linguistics (and more broadly, human language technologies) has seen the emergence and later dominance of empirical techniques and data-driven research. Concomitant with this trend is a coherent research thread that focuses on exploiting increasingly-large datasets. Banko and Brill (2001) were among the first to demonstrate the importance of dataset size as a significant factor governing prediction accuracy in a supervised machine learning task. In fact, they argued that size of training set was perhaps more important than the choice of machine learning algorithm itself. Similarly, experiments in question answering have shown the effectiveness of simple pattern-matching techniques when applied to large quantities of data (Brill et al., 2001; Dumais et al., 2002). More recently, this line of argumentation has been echoed in experiments with Web-scale language models. Brants et al. (2007) showed that for statistical machine translation, a simple smoothing technique (dubbed *Stupid Backoff*) approaches the quality of the Kneser-Ney algorithm as the amount of training data increases, and with the simple method one can process significantly more data.

Challenges in scaling algorithms to increasingly-large datasets have become a serious issue for researchers. It is clear that datasets readily available today and the types of analyses that researchers wish to conduct have outgrown the capabilities of individual computers. The only practical recourse is to distribute the computation across multiple cores, processors, or machines. The consequences of failing to scale include misleading generalizations on artificially small datasets and limited practical applicability in real-world contexts, both undesirable.

This paper focuses on two barriers to developing scalable language processing algorithms: challenges associated with parallel programming and access to hardware. Google's MapReduce framework (Dean and Ghemawat, 2004) provides an attractive programming model for developing scalable algorithms, and with the release of Hadoop, an open-source implementation of MapReduce lead by Yahoo, cost-effective cluster computing is within the reach of most academic research groups. It is emphasized that this work focuses on large-data algorithms from the perspective of academia—colleagues in commercial environments have long enjoyed the advantages of cluster computing. However, it is only recently that such capabilities have become *practical* for academic research groups. These points are illustrated by a case study in building large word co-occurrence matrices, a simple task that underlies many NLP algorithms.

The remainder of the paper is organized as follows: the next section overviews the MapReduce framework and why it provides a compelling solution to the issues sketched above. Section 3 introduces the task of building word co-occurrence matrices, which provides an illustrative case study. Two separate algorithms are presented in Section 4. The experimental setup is described in Section 5, followed by presentation of results in Section 6. Implications and generalizations are discussed following that. Before concluding, I explore an alternative model of computing based on renting instead of buying hardware, which makes cluster computing practical for *everyone*.

2 MapReduce

The only practical solution to large-data challenges today is to distribute the computation across multiple cores, processors, or machines. The development of parallel algorithms involves a number of tradeoffs. First is that of cost: a decision must be made between "exotic" hardware (e.g., large shared memory machines, InfiniBand interconnect) and commodity hardware. There is significant evidence (Barroso et al., 2003) that solutions based on the latter are more cost effective—and for resource-constrained academic NLP groups, commodity hardware is often the only practical route.

Given appropriate hardware, researchers must still contend with the challenge of developing software. Quite simply, parallel programming is difficult. Due to communication and synchronization issues, concurrent operations are notoriously challenging to reason about. Reliability and fault tolerance become important design considerations on clusters containing large numbers of unreliable commodity parts. With traditional parallel programming models (e.g., MPI), the developer shoulders the burden of explicitly managing concurrency. As a result, a significant amount of the programmer's attention is devoted to system-level details, leaving less time for focusing on the actual problem.

Recently, MapReduce (Dean and Ghemawat, 2004) has emerged as an attractive alternative to existing parallel programming models. The MapReduce abstraction shields the programmer from having to explicitly worry about system-level issues such as synchronization, inter-process communication, and fault tolerance. The runtime is able to transparently distribute computations across large clusters of commodity hardware with good scaling characteristics. This frees the programmer to focus on solving the problem at hand.

MapReduce builds on the observation that many information processing tasks have the same basic structure: a computation is applied over a large number of records (e.g., Web pages, bitext pairs, or nodes in a graph) to generate partial results, which are then aggregated in some fashion. Naturally, the per-record computation and aggregation function vary according to task, but the basic structure remains fixed. Taking inspiration from higher-order functions in functional programming, MapReduce provides an abstraction at the point of these two operations. Specifically, the programmer defines a "mapper" and a "reducer" with the following signatures:

map: $(k_1, v_1) \rightarrow [(k_2, v_2)]$
reduce: $(k_2, [v_2]) \rightarrow [(k_3, v_3)]$

Key-value pairs form the basic data structure in MapReduce. The mapper is applied to every input key-value pair to generate an arbitrary number of intermediate key-value pairs ([...] is used to denote a list). The reducer is applied to all values associated with the same intermediate key to generate output key-value pairs. This two-stage processing structure is illustrated in Figure 1.

Under the framework, a programmer needs only to provide implementations of the mapper and reducer. On top of a distributed file system (Ghemawat et al., 2003), the runtime transparently handles all other aspects of execution, on clusters ranging from a few to a few thousand nodes. The runtime is responsible for scheduling map and reduce

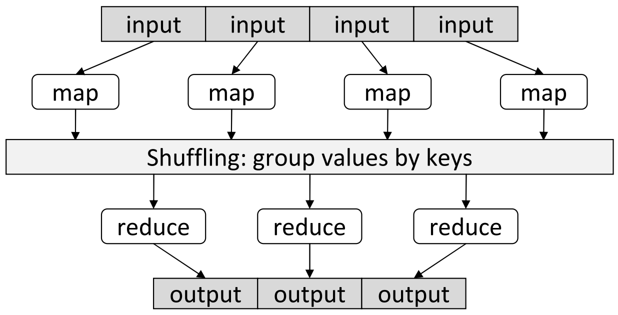

Figure 1: Illustration of the MapReduce framework: the "mapper" is applied to all input records, which generates results that are aggregated by the "reducer". The runtime groups together values by keys.

workers on commodity hardware assumed to be unreliable, and thus is tolerant to various faults through a number of error recovery mechanisms. In the distributed file system, data blocks are stored on the local disks of machines in the cluster—the MapReduce runtime handles the scheduling of mappers on machines where the necessary data resides. It also manages the potentially very large sorting problem between the map and reduce phases whereby intermediate key-value pairs must be grouped by key.

As an optimization, MapReduce supports the use of "combiners", which are similar to reducers except that they operate directly on the output of mappers (in memory, before intermediate output is written to disk). Combiners operate in isolation on each node in the cluster and cannot use partial results from other nodes. Since the output of mappers (i.e., the key-value pairs) must ultimately be shuffled to the appropriate reducer over a network, combiners allow a programmer to aggregate partial results, thus reducing network traffic. In cases where an operation is both associative and commutative, reducers can directly serve as combiners.

Google's proprietary implementation of MapReduce is in C++ and not available to the public. However, the existence of Hadoop, an open-source implementation in Java spearheaded by Yahoo, allows anyone to take advantage of MapReduce. The growing popularity of this technology has stimulated a flurry of recent work, on applications in machine learning (Chu et al., 2006), machine translation (Dyer et al., 2008), and document retrieval (Elsayed et al., 2008).

3 Word Co-occurrence Matrices

To illustrate the arguments outlined above, I present a case study using MapReduce to build word co-occurrence matrices from large corpora, a common task in natural language processing. Formally, the co-occurrence matrix of a corpus is a square $N \times N$ matrix where N corresponds to the number of unique words in the corpus. A cell m_{ij} contains the number of times word w_i co-occurs with word w_j within a specific context—a natural unit such as a sentence or a certain window of m words (where m is an application-dependent parameter). Note that the upper and lower triangles of the matrix are identical since co-occurrence is a symmetric relation.

This task is quite common in corpus linguistics and provides the starting point to many other algorithms, e.g., for computing statistics such as pointwise mutual information (Church and Hanks, 1990), for unsupervised sense clustering (Schütze, 1998), and more generally, a large body of work in lexical semantics based on distributional profiles, dating back to Firth (1957) and Harris (1968). The task also has applications in information retrieval, e.g., (Schütze and Pedersen, 1998; Xu and Croft, 1998), and other related fields as well. More generally, this problem relates to the task of estimating distributions of discrete events from a large number of observations (more on this in Section 7).

It is obvious that the space requirement for this problem is $O(N^2)$, where N is the size of the vocabulary, which for real-world English corpora can be hundreds of thousands of words. The computation of the word co-occurrence matrix is quite simple if the entire matrix fits into memory—however, in the case where the matrix is too big to fit in memory, a naive implementation can be very slow as memory is paged to disk. For large corpora, one needs to optimize disk access and avoid costly seeks. As illustrated in the next section, MapReduce handles exactly these issues transparently, allowing the programmer to express the algorithm in a straightforward manner.

A bit more discussion of the task before moving on: in many applications, researchers have discovered that building the complete word co-occurrence matrix may not be necessary. For example, Schütze (1998) discusses feature selection techniques in defining context vectors; Mohammad and Hirst (2006) present evidence that conceptual distance is better captured via distributional profiles mediated by thesaurus categories. These objections, however, miss the point—the focus of this paper is on practical cluster computing for academic researchers; this particular task serves merely as an illustrative example. In addition, for rapid prototyping, it may be useful to start with the complete co-occurrence matrix (especially if it can be built efficiently), and then explore how algorithms can be optimized for specific applications and tasks.

4 MapReduce Implementation

This section presents two MapReduce algorithms for building word co-occurrence matrices for large corpora. The goal is to illustrate how the problem can be concisely captured in the MapReduce programming model, and how the runtime hides many of the system-level details associated with distributed computing.

Pseudo-code for the first, more straightforward, algorithm is shown in Figure 2. Unique document ids and the corresponding texts make up the input key-value pairs. The mapper takes each input document and emits intermediate key-value pairs with each co-occurring word pair as the key and the integer one as the value. In the pseudo-code, EMIT denotes the creation of an intermediate key-value pair that is collected (and appropriately sorted) by the MapReduce runtime. The reducer simply sums up all the values associated with the same co-occurring word pair, arriving at the absolute counts of the joint event in the corpus (corresponding to each cell in the co-occurrence matrix).

For convenience, I refer to this algorithm as the "pairs" approach. Since co-occurrence is a symmetric relation, it suffices to compute half of the matrix. However, for conceptual clarity and to generalize to instances where the relation may not be symmetric, the algorithm computes the entire matrix.

The Java implementation of this algorithm is quite concise—less than fifty lines long. Notice the MapReduce runtime guarantees that all values associated with the same key will be gathered together at the reduce stage. Thus, the programmer does not need to explicitly manage the collection and distribution of partial results across a cluster. In addition, the programmer does not need to explicitly partition the input data and schedule workers. This example shows the extent to which distributed processing can be dominated by system issues, and how an appropriate abstraction can significantly simplify development.

```
1: procedure MAP_1($n, d$)
2:     for all $w \in d$ do
3:         for all $u \in$ NEIGHBORS($w$) do
4:             EMIT(($w, u$), 1)
1: procedure REDUCE_1($p, [v_1, v_2, \ldots]$)
2:     for all $v \in [v_1, v_2, \ldots]$ do
3:         $sum \leftarrow sum + v$
4:     EMIT($p, sum$)
```

Figure 2: Pseudo-code for the "pairs" approach for computing word co-occurrence matrices.

```
1: procedure MAP_2($n, d$)
2:     INITIALIZE($H$)
3:     for all $w \in d$ do
4:         for all $u \in$ NEIGHBORS($w$) do
5:             $H\{u\} \leftarrow H\{u\} + 1$
6:     EMIT($w, H$)
1: procedure REDUCE_2($w, [H_1, H_2, H_3, \ldots]$)
2:     INITIALIZE($H_f$)
3:     for all $H \in [H_1, H_2, H_3, \ldots]$ do
4:         MERGE($H_f, H$)
5:     EMIT($w, H_f$)
```

Figure 3: Pseudo-code for the "stripes" approach for computing word co-occurrence matrices.

It is immediately obvious that Algorithm 1 generates an immense number of key-value pairs. Although this can be mitigated with the use of a combiner (since addition is commutative and associative), the approach still results in a large amount of network traffic. An alternative approach is presented in Figure 3, first reported in Dyer et al. (2008). The major difference is that counts of co-occurring words are first stored in an associative array (H). The output of the mapper is a number of key-value pairs with words as keys and the corresponding associative arrays as the values. The reducer performs an element-wise sum of all associative arrays with the same key (denoted by the function MERGE), thus accumulating counts that correspond to the same cell in the co-occurrence matrix. Once again, a combiner can be used to cut down on the network traffic by merging partial results. In the final output, each key-value pair corresponds to a row in the word co-occurrence matrix. For convenience, I refer to this as the "stripes" approach.

Compared to the "pairs" approach, the "stripes" approach results in far fewer intermediate key-value pairs, although each is significantly larger (and there is overhead in serializing and deserializing associative arrays). A critical assumption of the "stripes" approach is that at any point in time, each associative array is small enough to fit into memory (otherwise, memory paging may result in a serious loss of efficiency). This is true for most corpora, since the size of the associative array is bounded by the vocabulary size. Section 6 compares the efficiency of both algorithms.[1]

5 Experimental Setup

Work reported in this paper used the English Gigaword corpus (version 3),[2] which consists of newswire documents from six separate sources, totaling 7.15 million documents (6.8 GB compressed, 19.4 GB uncompressed). Some experiments used only documents from the Associated Press Worldstream (APW), which contains 2.27 million documents (1.8 GB compressed, 5.7 GB uncompressed). By LDC's count, the entire collection contains approximately 2.97 billion words.

Prior to working with Hadoop, the corpus was first preprocessed. All XML markup was removed, followed by tokenization and stopword removal using standard tools from the Lucene search engine. All tokens were replaced with unique integers for a more efficient encoding. The data was then packed into a Hadoop-specific binary file format. The entire Gigaword corpus took up 4.69 GB in this format; the APW sub-corpus, 1.32 GB.

Initial experiments used Hadoop version 0.16.0 running on a 20-machine cluster (1 master, 19 slaves). This cluster was made available to the University of Maryland as part of the Google/IBM Academic Cloud Computing Initiative. Each machine has two single-core processors (running at either 2.4 GHz or 2.8 GHz), 4 GB memory. The cluster has an aggregate storage capacity of 1.7 TB. Hadoop ran on top of a virtualization layer, which has a small but measurable impact on performance; see (Barham et al., 2003). Section 6 reports experimental results using this cluster; Section 8 explores an alternative model of computing based on "renting cycles".

[1]Implementations of both algorithms are included in Cloud[9], an open source Hadoop library that I have been developing to support research and education, available from my homepage.

[2]LDC catalog number LDC2007T07

6 Results

First, I compared the running time of the "pairs" and "stripes" approaches discussed in Section 4. Running times on the 20-machine cluster are shown in Figure 4 for the APW section of the Gigaword corpus: the *x*-axis shows different percentages of the sub-corpus (arbitrarily selected) and the *y*-axis shows running time in seconds. For these experiments, the co-occurrence window was set to two, i.e., w_i is said to co-occur with w_j if they are no more than two words apart (after tokenization and stopword removal).

Results demonstrate that the stripes approach is far more efficient than the pairs approach: 666 seconds (11m 6s) compared to 3758 seconds (62m 38s) for the entire APW sub-corpus (improvement by a factor of 5.7). On the entire sub-corpus, the mappers in the pairs approach generated 2.6 billion intermediate key-value pairs totally 31.2 GB. After the combiners, this was reduced to 1.1 billion key-value pairs, which roughly quantifies the amount of data involved in the shuffling and sorting of the keys. On the other hand, the mappers in the stripes approach generated 653 million intermediate key-value pairs totally 48.1 GB; after the combiners, only 28.8 million key-value pairs were left. The stripes approach provides more opportunities for combiners to aggregate intermediate results, thus greatly reducing network traffic in the sort and shuffle phase.

Figure 4 also shows that both algorithms exhibit highly desirable scaling characteristics—linear in the corpus size. This is confirmed by a linear regression applied to the running time data, which yields R^2 values close to one. Given that the stripes algorithm is more efficient, it is used in the remainder of the experiments.

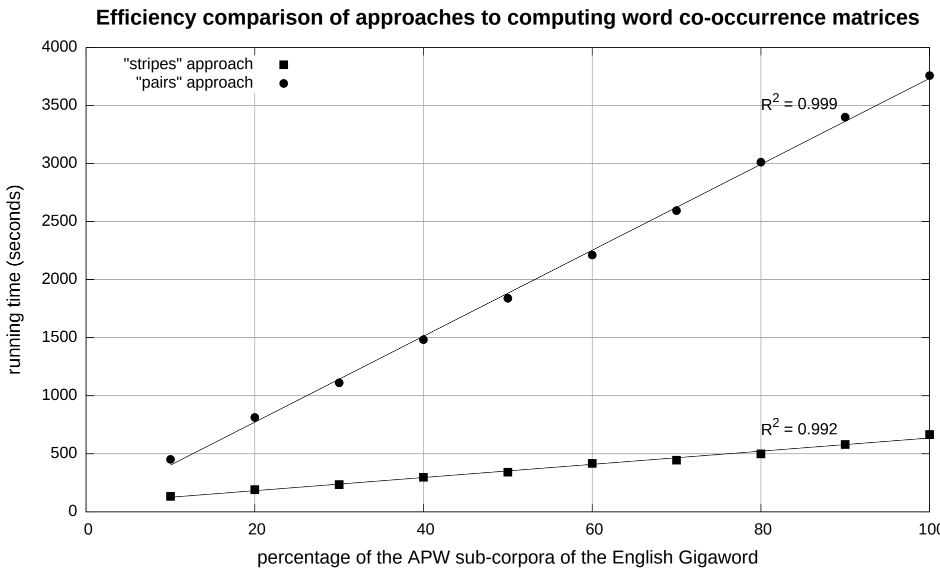

Figure 4: Running time of the two algorithms ("stripes" vs. "pairs") for computing word co-occurrence matrices on the APW section of the Gigaword corpus. The cluster used for this experiment contains 20 machines, each with two single-core processors.

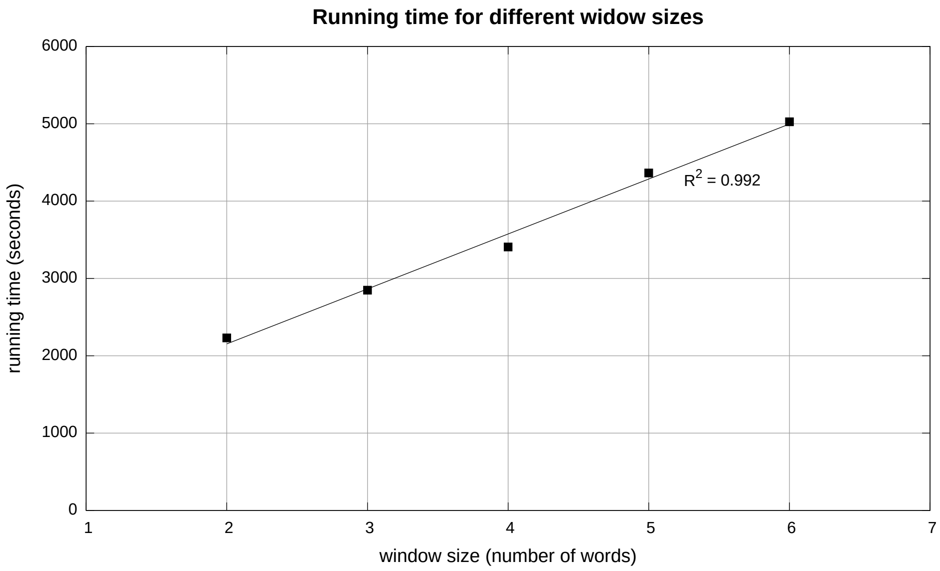

Figure 5: Running times for computing word co-occurrence matrices from the entire Gigaword corpus with varying window sizes. The cluster used for this experiment contains 20 machines, each with two single-core processors.

With a window size of two, computing the word co-occurrence matrix for the entire Gigaword corpus (7.15 million documents) takes 37m 11s on the 20-machine cluster. Figure 5 shows the running time as a function of window size. With a window of six words, running time on the complete Gigaword corpus rises to 1h 23m 45s. Once again, the stripes algorithm exhibits the highly desirable characteristic of linear scaling in terms of window size, as confirmed by the linear regression with an R^2 value very close to one.

7 Discussion

The elegance of the programming model and good scaling characteristics of resulting implementations make MapReduce a compelling tool for a variety of natural language processing tasks. In fact, MapReduce excels at a large class of problems in NLP that involves estimating probability distributions of discrete events from a large number of observations according to the maximum likelihood criterion:

$$P_{MLE}(B|A) = \frac{c(A,B)}{c(A)} = \frac{c(A,B)}{\sum_{B'} c(A,B')} \quad (1)$$

In practice, it matters little whether these events are words, syntactic categories, word alignment links, or any construct of interest to researchers. Absolute counts in the stripes algorithm presented in Section 4 can be easily converted into conditional probabilities by a final normalization step. Recently, Dyer et al. (2008) used this approach for word alignment and phrase extraction in statistical machine translation. Of course, many applications require smoothing of the estimated distributions—this problem also has known solutions in MapReduce (Brants et al., 2007).

Synchronization is perhaps the single largest bottleneck in distributed computing. In MapReduce, this is handled in the shuffling and sorting of key-value pairs between the map and reduce phases. Development of efficient MapReduce algorithms critically depends on careful control of intermediate output. Since the network link between different nodes in a cluster is by far the component with the largest latency, any reduction in the size of intermediate output or a reduction in the number of key-value pairs will have significant impact on efficiency.

8 Computing on Demand

The central theme of this paper is practical cluster computing for NLP researchers in the academic environment. I have identified two key aspects of what it means to be "practical": the first is an appropriate programming model for simplifying concurrency management; the second is access to hardware resources. The Hadoop implementation of MapReduce addresses the first point and to a large extent the second point as well. The cluster used for experiments in Section 6 is modest by today's standards and within the capabilities of many academic research groups. It is not even a requirement for the computers to be rack-mounted units in a machine room (although that is clearly preferable); there are plenty of descriptions on the Web about Hadoop clusters built from a handful of desktop machines connected by gigabit Ethernet.

Even without access to hardware, cluster computing remains within the reach of resource-constrained academics. "Utility computing" is an emerging concept whereby anyone can provision clusters on demand from a third-party provider. Instead of upfront capital investment to acquire a cluster and reoccurring maintenance and administration costs, one could "rent" computing cycles as they are needed—this is not a new idea (Rappa, 2004). One such service is provided by Amazon, called Elastic Compute Cloud (EC2).[3] With EC2, researchers could dynamically create a Hadoop cluster on-the-fly and tear down the cluster once experiments are complete. To demonstrate the use of this technology, I replicated some of the previous experiments on EC2 to provide a case study of this emerging model of computing.

Virtualized computation units in EC2 are called instances. At the time of these experiments, the basic instance offers, according to Amazon, 1.7 GB of memory, 1 EC2 Compute Unit (1 virtual core with 1 EC2 Compute Unit), and 160 GB of instance storage. Each instance-hour costs \$0.10 (all prices given in USD). Computational resources are simply charged by the instance-hour, so that a ten-instance cluster for ten hours costs the same as a hundred-instance cluster for one hour (both \$10)—the Amazon infrastructure allows one to dynamically provision and release resources as necessary. This is at-

[3]http://www.amazon.com/ec2

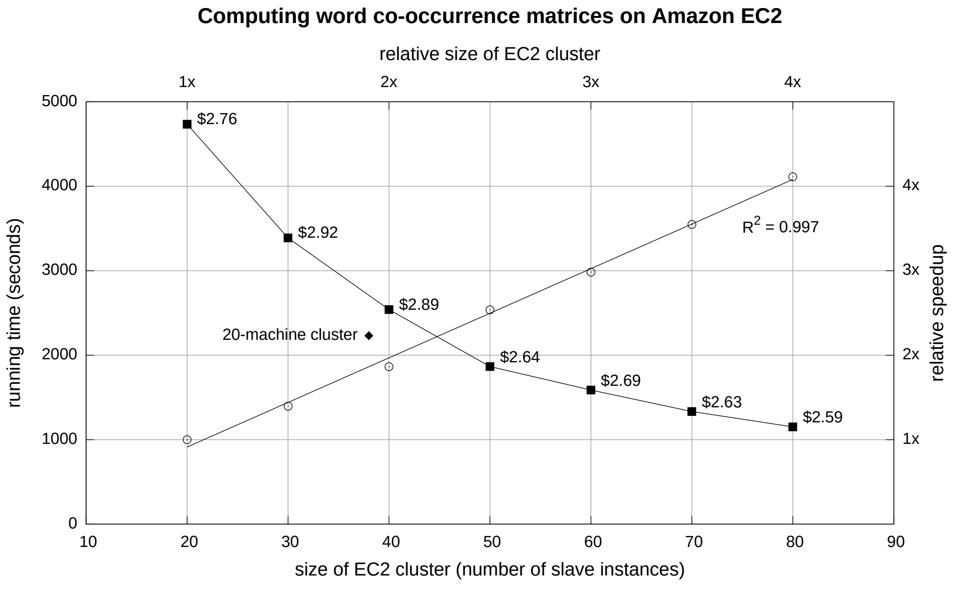

Figure 6: Running time analysis on Amazon EC2 with various cluster sizes; solid squares are annotated with the cost of each experiment. Alternate axes (circles) plot scaling characteristics in terms increasing cluster size.

tractive for researchers, who could on a limited basis allocate clusters much larger than they could otherwise afford if forced to purchase the hardware outright. Through virtualization technology, Amazon is able to parcel out allotments of processor cycles while maintaining high overall utilization across a data center and exploiting economies of scale.

Using EC2, I built word co-occurrence matrices from the entire English Gigaword corpus (window of two) on clusters of various sizes, ranging from 20 slave instances all the way up to 80 slave instances. The entire cluster consists of the slave instances plus a master controller instance that serves as the job submission queue; the clusters ran Hadoop version 0.17.0 (the latest release at the time these experiments were conducted). Running times are shown in Figure 6 (solid squares), with varying cluster sizes on the *x*-axis. Each data point is annotated with the cost of running the complete experiment.[4] Results show that computing the complete word co-occurrence matrix costs, quite literally, a couple of dollars—certainly affordable by any academic researcher without access to hardware. For reference, Figure 6 also plots the running time of the same experiment on the 20-machine cluster used in Section 6 (which contains 38 worker cores, each roughly comparable to an instance).

The alternate set of axes in Figure 6 shows the scaling characteristics of various cluster sizes. The circles plot the relative size and speedup of the EC2 experiments, with respect to the 20-slave cluster. The results show highly desirable linear scaling characteristics.

The above figures include only the cost of running the instances. One must additionally pay for bandwidth when transferring data in and out of EC2. At the time these experiments were conducted, Amazon charged \$0.10 per GB for data transferred in and \$0.17 per GB for data transferred out. To complement EC2, Amazon offers persistent storage via the Simple Storage Service (S3),[5] at a cost of \$0.15 per GB per month. There is no charge for data transfers between EC2 and S3. The availability of this service means that one can choose between paying for data transfer or paying for persistent storage on a cyclic basis—the tradeoff naturally depends on the amount of data and its permanence.

The cost analysis presented above assumes optimally-efficient use of Amazon's services; end-to-end cost might better quantify real-world usage conditions. In total, the experiments reported in this

[4]Note that Amazon bills in whole instance-hour increments; these figures assume fractional accounting.

[5]http://www.amazon.com/s3

section resulted in a bill of approximately thirty dollars. The figure includes all costs associated with instance usage and data transfer costs. It also includes time taken to learn the Amazon tools (I previously had no experience with either EC2 or S3) and to run preliminary experiments on smaller datasets (before scaling up to the complete corpus). The lack of fractional accounting on instance-hours contributed to the larger-than-expected costs, but such wastage would naturally be reduced with more experiments and higher sustained use. Overall, these cost appear to be very reasonable, considering that the largest cluster in these experiments (1 master + 80 slave instances) might be too expensive for most academic research groups to own and maintain.

Consider another example that illustrates the possibilities of utility computing. Brants et al. (2007) described experiments on building language models with increasingly-large corpora using MapReduce. Their paper reported experiments on a corpus containing 31 billion tokens (about an order of magnitude larger than the English Gigaword): on 400 machines, the model estimation took 8 hours.[6] With EC2, such an experiment would cost a few hundred dollars—sufficiently affordable that availability of data becomes the limiting factor, not computational resources themselves.

The availability of "computing-on-demand" services and Hadoop make cluster computing practical for academic researchers. Although Amazon is currently the most prominent provider of such services, they are not the sole player in an emerging market—in the future there will be a vibrant market with many competing providers. Considering the tradeoffs between "buying" and "renting", I would recommend the following model for an academic research group: purchase a modest cluster for development and for running smaller experiments; use a computing-on-demand service for scaling up and for running larger experiments (since it would be more difficult to economically justify a large cluster if it does not receive high sustained utilization).

If the concept of utility computing takes hold, it would have a significant impact on computer science research in general: the natural implication is that algorithms should not only be analyzed in traditional terms such as asymptotic complexity, but also in terms of monetary costs, in relationship to dataset and cluster size. One can argue that cost is a more direct and practical measure of algorithmic efficiency.

9 Conclusion

This paper address two challenges faced by academic research groups in scaling up natural language processing algorithms to large corpora: the lack of an appropriate programming model for expressing the problem and the difficulty in getting access to hardware. With this case study in building word co-occurrence matrices from large corpora, I demonstrate that MapReduce, via the open source Hadoop implementation, provides a compelling solution. A large class of algorithms in computational linguistics can be readily expressed in MapReduce, and the resulting code can be transparently distributed across commodity clusters. Finally, the "cycle-renting" model of computing makes access to large clusters affordable to researchers with limited resources. Together, these developments dramatically lower the entry barrier for academic researchers who wish to explore large-data issues.

Abstract

We propose a novel lexicon acquirer that works in concert with the morphological analyzer and has the ability to run in online mode. Every time a sentence is analyzed, it detects unknown morphemes, enumerates candidates and selects the best candidates by comparing multiple examples kept in the storage. When a morpheme is unambiguously selected, the lexicon acquirer updates the dictionary of the analyzer, and it will be used in subsequent analysis. We use the constraints of Japanese morphology and effectively reduce the number of examples required to acquire a morpheme. Experiments show that unknown morphemes were acquired with high accuracy and improved the quality of morphological analysis.

1 Introduction

Morphological analysis is the first step for most natural language processing applications. In Japanese morphological analysis, segmentation is processed simultaneously with the assignment of a part of speech (POS) tag to each morpheme. Segmentation is a nontrivial task in Japanese because it does not delimit words by white-space.

Japanese morphological analysis has successfully adopted dictionary-based approaches (Kurohashi et al., 1994; Asahara and Matsumoto, 2000; Kudo et al., 2004). In these approaches, a sentence is transformed into a lattice of morphemes by searching a pre-defined dictionary, and an optimal path in the lattice is selected.

This area of research may be considered almost completed, as previous studies reported the F-score of nearly 99% (Kudo et al., 2004). When applied to web texts, however, more errors are made due to unknown morphemes. In previous studies, experiments were performed on newspaper articles, but web texts include slang words, informal spelling alternates (Nishimura, 2003) and technical terms. For example, the verb "ググる" (*gugu-ru*, to google) is erroneously segmented into "ググ" (*gugu*) and "る" (*ru*).

One solution to this problem is to augment the lexicon of the morphological analyzer by extracting unknown morphemes from texts (Mori and Nagao, 1996). In the previous method, a morpheme extraction module worked independently of the morphological analyzer and ran in off-line (batch) mode. It is inefficient because almost all high-frequency morphemes have already been registered to the predefined dictionary. Moreover, it is inconvenient when applied to web texts because the web corpus is huge and diverse compared to newspaper corpora. It is not necessarily easy to build subcorpora before lexicon acquisition. Suppose that we want to analyze whaling-related documents. It is unnecessary and probably harmful to acquire morphemes that are irrelevant to the topic. A whaling-related subcorpus should be extracted from the whole corpus but it is not clear how large it must be.

We propose a novel lexicon acquirer that works in concert with the morphological analyzer and has the ability to run in online mode. As shown in Figure 1, every time a sentence is analyzed, the lexicon acquirer detects unknown morphemes, enumerates

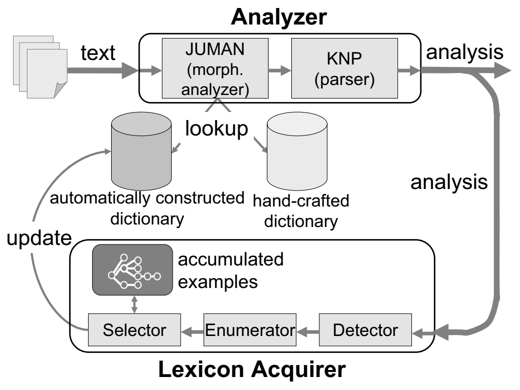

Figure 1: System architecture

candidates and selects the best candidates by comparing multiple examples kept in the storage. When a morpheme is unambiguously selected, the lexicon acquirer updates the automatically constructed dictionary, and it will be used in subsequent analysis. The proposed method is flexible and gives the system more control over the process. We do not have to limit the target corpus beforehand and the system can stop whenever appropriate.

We use the constraints of Japanese morphology that have already been coded in the morphological analyzer. These constraints effectively reduce the number of examples required to acquire an unknown morpheme. Experiments show that unknown morphemes were acquired with high accuracy and improved the quality of morphological analysis.

2 Japanese Morphology

In order to understand the task of lexicon acquisition, we briefly describe the Japanese morphological analyzer JUMAN.[1] We explain Japanese morphemes in Section 2.1, morphological constraints in Section 2.2, and unknown morpheme processing in Section 2.3.

2.1 Morpheme

In JUMAN, the POS tagset consists of four elements: class, subclass, conjugation type and conjugation form. The classes are noun, verb, adjective and others. Noun has subclasses such as common noun, *sa*-group noun, proper noun, organization, place, personal name. Verb and adjective have no subclasses.

Verbs and adjectives among others change their form according to the morphemes that occur after them, which is called conjugation. Conjugable morphemes are grouped by conjugation types such as vowel verb, *ra*-row verb, *i*-type adjective and *na*-type adjective. Each conjugable morpheme takes one of conjugation forms in texts. It has an invariant stem and an ending which changes according to conjugation type and conjugation form.

In this paper, the tuple of class, subclass and conjugation type is referred to as a POS tag. For simplicity, POS tags for nouns are called by their subclasses and those for verbs and adjectives by their conjugation types.

There are two types of morphemes: abstract dictionary entries, and examples or actual occurrences in texts. An entry consists of a stem and a POS tag while an example consists of a stem, a POS tag and a conjugation form. For example, the entry of the *ra*-row verb “走る” (*hashi-ru*, to run) can be represented as

(“走” (*hashi*), *ra*-row verb),

and their examples “走ら” (*hashi-ra*) and “走り” (*hashi-ri*) as

(“走” (*hashi*), *ra*-row verb, imperfective),

and

(“走” (*hashi*), *ra*-row verb, plain continuative)

respectively. As nouns do not conjugate, the entry of the *sa*-group noun “希望” (*kibou*, hope) can be represented as

(“希望” (*kibou*), *sa*-group noun)

and its sole example form is

(“希望” (*kibou*), *sa*-group noun, NIL).

2.2 Morphological Constraints

Japanese is an agglutinative language. Depending on its grammatical roles, a morpheme is followed by a sequence of grammatical suffixes, auxiliary verbs and particles, and the connectivity of these elements is bound by morphological constraints. For example, the particle “を” (*wo*, accusative case) can follow a verb with the conjugation form of plain continuative, as in “走りを” (*hashi-ri-wo*, running-ACC),

[1]`http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman.html`

but it cannot follow an imperfective verb ("*走らを" (*hashi-ra-wo*)).

These constraints are used by JUMAN to reduce the ambiguity. They can be also used in lexicon acquisition.

2.3 Unknown Morpheme Processing

Given a sentence, JUMAN builds a lattice of morphemes by searching a pre-defined dictionary, and then selects an optimal path in the lattice. To handle morphemes that cannot be found in the dictionary, JUMAN enumerates unknown morpheme candidates using character type-based heuristics, and adds them to the morpheme lattice. Unknown morphemes are given the special POS tag "undefined," which is treated as noun.

Character type-based heuristics are based on the fact that Japanese is written with several different character types such as kanji, hiragana and katakana, and that the choice of character types gives some clues on morpheme boundaries. For example, a sequence of katakana characters are considered as an unknown morpheme candidate, as in "グーグル" (*gûguru*, Google) out of "グーグルが" (*gûguru-ga*, Google-NOM). Kanji characters are segmented per character, which is sometimes wrong but prevents error propagation.

These heuristics are simple and effective, but far from perfect. They cannot identify mixed-character morphemes, verbs and adjectives correctly. For example, the verb "ググる" (*gugu-ru*, to google) is wrongly divided into the katakana unknown morpheme " ググ" (*gugu*) and the hiragana suffix "る" (*ru*).

3 Lexicon Acquisition

3.1 Task

The task of lexicon acquisition is to generate dictionary entries inductively from their examples in texts. Since the morphological analyzer provides a basic lexicon, the morphemes to be acquired are limited to those unknown to the analyzer.

In order to generate an entry, its stem and POS tag need to be identified. Determining the stem of an example is to draw the front and rear boundaries in a character sequence in texts which corresponds to the stem. The POS tag is selected from the tagset given by the morphological analyzer.

3.2 System Architecture

Figure 1 shows the system architecture. Each sentence in texts is processed by the morphological analyzer JUMAN and the dependency parser KNP.[2] JUMAN consults a hand-crafted dictionary and an automatically constructed dictionary. KNP is used to form a phrasal unit called *bunsetsu* by chunking morphemes.

Every time a sentence is analyzed, the lexicon acquirer receives the analysis. It detects examples of unknown morphemes and keeps them in storage. When an entry is unambiguously selected, the lexicon acquirer updates the automatically constructed dictionary, and it will be used in subsequent analysis.

3.3 Algorithm Overview

The process of lexicon acquisition has four phases: detection, candidate enumeration, aggregation and selection. First the analysis is scanned to detect examples of unknown morphemes. For each example, one or more candidates for dictionary entries are enumerated. It is added to the storage, and multiple examples in the storage that share the candidates are aggregated. They are compared and the best candidate is selected from it.

Take the *ra*-row verb "ググる" (*gugu-ru*) for example. Its example "ググってみた。" (*gugu-tte-mi-ta*, to have tried to google) can be interpreted in many ways as shown in Figure 2. Similarly, multiple candidates are enumerated for another example "ググるのは" (*gugu-ru-no-ha*, to google-TOPIC). If these examples are compared, we can see that the *ra*-row verb "ググる" (*gugu-ru*) can explain them.

3.4 Suffixes

Morphological constraints are used for candidate enumeration. Since they are coded in JUMAN, we first transform them into a set of strings called suffixes. A suffix is created by concatenating the ending of a morpheme (if any) and subsequent ancillary morphemes. Each POS tag is associated with a set of suffixes, as shown in Table 1. This means that a stem can be followed by one of the suffixes specified

[2]http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp.html

Table 1: Examples of suffixes

POS tag	base form	stem	ending	conjugation form[1]	suffixes
ra-row verb	*hashi-ru*	*hashi*	*ra*	imperfective	*razu*, *ranaide*
			ri	plain continuative	*riwo*, *riwomo*
			ru	plain	*ru*, *rukawo*
vowel verb	*akogare-ru*	*akogare*	ϕ	imperfective	*zu*, *naide*
			ϕ	plain continuative	*wo*, *womo*
			ru	plain	*ru*, *rukawo*
sa-group noun	*kibou*	*kibou*	NIL	*wo*	*wo*, *womo*
			NIL	*suru*	*suru*, *shitara*

[1] The conjugation form of a noun is substituted with the base form of its immediate ancillary morpheme because nouns do not conjugate.

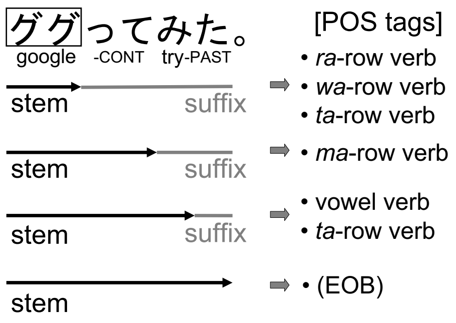

Figure 2: Candidate enumeration

by its POS tag and cannot be followed by any other suffix.

In preparation for lexicon acquisition, suffixes are acquired from a corpus. We used a web corpus that was compiled through the procedures proposed by Kawahara and Kurohashi (2006). Suffixes were extracted from examples of registered morphemes and were aggregated per POS tag.

We found that the number of suffixes did not converge even in this large-scale corpus. It was because ancillary morphemes included the wide variety of auxiliary verbs and formal nouns. Alternatively, we used the first five characters as a suffix. In the experiments, we obtained 500 thousand unique suffixes from 100 million pages. The number of POS tags that corresponded to a suffix was 1.33 on average.

3.5 Unknown Morpheme Detection

The first step of lexicon acquisition is unknown morpheme detection. Every time the analysis of a sentence was given, the sequence of morphemes are scanned, and suspicious points that probably represent unknown morphemes are detected.

Currently, we use the POS tag "undefined" to detect unknown morphemes. For example, the example "ググってみた。" is detected because "ググ" is given "undefined." This simple method cannot detect unknown morphemes if they are falsely segmented into combinations of registered morphemes. We leave the comprehensive detection of unknown morphemes to future work.

3.6 Candidate Enumeration

For each example, one or more candidates for the dictionary entry are enumerated. Each candidate is represented by a combination of a front boundary and the pair of a rear boundary and a POS tag.

The search range for enumeration is based on *bunsetsu* phrases, which is created by chunking morphemes. The range is at most the corresponding *bunsetsu* and the two immediately preceding and succeeding *bunsetsu*, which we found wide enough to contain correct candidates.

The candidates for the rear boundary and the POS tag are enumerated by string matching of suffixes as shown in Figure 2. If a suffix matches, the starting position of the suffix becomes a candidate for the rear boundary and the suffix is mapped to one or more corresponding POS tags.

In addition, the candidates for the front and rear boundaries are enumerated by scanning the sequence of morphemes. The boundary markers we use are

- punctuations,
- grammatical prefixes such as "御" (*go*-, honorific prefix), for front boundaries,

- grammatical suffixes such as “様” (*-sama*, honorific title), for rear boundaries, and
- *bunsetsu* boundaries given by KNP.

Each rear boundary candidate whose corresponding POS tag is not decided is given the special tag “EOB” (*end-of-bunsetsu*). This means that no suffix is attached to the candidate. Since nouns, vowel verbs and *na*-type adjectives can appear in isolation, it will be expanded to these POS tags when selecting the best POS tag.

3.7 Aggregation of Examples

Selection of the best candidate is done by comparing multiple examples. Each example is added to the storage, and then examples that possibly represent the same entry with it are extracted from the storage. Examples aggregated at this phase share the front boundary but may be unrelated to the example in question. They are pruned in the next phase.

In order to manage examples efficiently, we implement a trie. The example is added to the trie for each front boundary candidate. The key is the character sequence determined by the front boundary and the leftmost rear boundary. To retrieve examples that share the front boundary with it, we check every node in the path from the root to the node where it is stored, and collect examples stored in each node.

3.8 Selection

The best candidate is selected by identifying the front boundary, the rear boundary and the POS tag in this order. Starting from the rightmost front boundary candidate, multiple rear boundary candidates that share the front boundary are compared and some are dropped. Then starting from the leftmost surviving rear boundary candidate, the best POS tag is selected from the examples that share the stem. If the selected candidate satisfies simple termination conditions, it is added to the dictionary and the examples are removed from the storage.

For each front boundary candidate, some inappropriate rear boundary candidates are dropped by examining the inclusion relation between the examples of a pair of candidates. The assumption behind this is that an appropriate candidate can interpret more examples than incorrect ones. Let p and q be a pair of the candidates for the rear boundary, and R_p and R_q be the sets of examples for which p and q are enumerated. If p is a prefix of q and p is the correct stem, then R_q must be contained in R_p. In practice we loosen this condition, considering possible errors in candidate enumeration

For each stem candidate, the appropriate POS tag is identified. Similarly to rear boundary identification, POS identification is done by checking inclusion relation.

If the POS tag is successfully disambiguated, simple termination conditions is checked to prevent the accidental acquisition of erroneous candidates. The first condition is that the number of unique conjugation forms that appear in the examples should be 3 or more. If the candidate is a noun, it is substituted with the number of the unique base forms of their immediate ancillary morphemes. The second condition is that the front boundaries of some examples are decided by clear boundary markers such as punctuations and the beginning of sentence. This prevents oversegmentation. For example, the stem candidate “*撰組” (**sengumi*) is always enumerated for examples of “新撰組” (*Shingengumi*, a historical organization) since “新” (*shin-*, new) is a prefix. This candidate is not acquired because “*撰組” (**sengumi*) does not occur alone and is always accompanied by “新” (*shin-*). Thresholds are chosen empirically.

3.9 Decompositionality

Since a morpheme is extracted from a small number of examples, it is inherently possible that the acquired morpheme actually consists of two or more morphemes. For example, the noun phrase “顆粒タイプ” (*karyuu-taipu*, granular type) may be acquired as a morpheme before “顆粒” (*karyuu*, granule) is extracted. To handle this phenomenon, it is checked at the time of acquisition whether the new morpheme (*kairyuu*) can decompose registered morphemes (*kairyuu-taipu*). If found, a composite “morpheme” is removed from the dictionary.

Currently we leave the decompositionality check to the morphological analyzer. Possible compounds are enumerated by string matching and temporarily removed from the dictionary. Each candidate is analyzed by the morphological analyzer and it is checked whether the candidate is divided into a combination of registered morphemes. If not, the candidate is restored to the dictionary.

Table 2: Statistical information per query

query	number of sentences	number of affected sentences (ratio)	number of acquired morphs	number of correct morphs (precision)	number of examples[1]
捕鯨問題 (whaling issue)	135,379	2,444 (1.81%)	293	290 (99.0%)	4
赤ちゃんポスト (baby hatch)	74,572	775 (1.04%)	107	105 (98.1%)	4
ジャスラック (JASRAC)	195,928	6,259 (3.19%)	913	907 (99.3%)	4
ツンデレ (tsundere)	77,962	12,012 (15.4%)	243	238 (97.4%)	5
アガリクス (agaricus)	78,922	3,037 (3.85%)	114	107 (93.9%)	9

[1] The median number of examples used for acquisition.

4 Experiments

4.1 Experimental Design

We used the default dictionary of the morphological analyzer JUMAN as the initial lexicon. It contained 30 thousand basic morphemes. If spelling variants were expanded and proper nouns were counted, the total number of morphemes was 120 thousands.

We used domain-specific corpora as target texts because efficient acquisition was expected. If target texts shared a topic, relevant unknown morphemes were used frequently. In the experiments, we used search engine TSUBAKI (Shinzato et al., 2008) and casted the search results as domain-specific corpora. For each query, our system sequentially read pages from the top of the result and acquired morphemes. We terminated the acquisition at the 1000th page and analyzed the same 1000 pages with the augmented lexicon. The queries used were "捕鯨問題" (whaling issue), "赤ちゃんポスト" (baby hatch), "ジャスラック" (JASRAC, a copyright collective), "ツンデレ" (tsundere, a slang word) and "アガリクス" (agaricus).

4.2 Evaluation Measures

The proposed method is evaluated by measuring the accuracy of acquired morphemes and their contribution to the improvement of morphological analysis. A morpheme is considered accurate if both segmentation and the POS tag are correct. Note that segmentation is a nontrivial problem for evaluation. In fact, the disagreement over segmentation criteria was considered one of the main reasons for reported errors by Nagata (1999) and Uchimoto et al. (2001). It is difficult to judge whether a compound term should be divided because there is no definite standard for morpheme boundaries in Japanese. For example, "ミンク鯨" (*minku-kujira*, minke whale) can be extracted as a single morpheme or decomposed into "ミンク" and "鯨." While segmentation is an open question in Japanese morphological analysis, "correct" segmentation is not necessarily important for applications using morphological analysis. Even if a noun is split into two or more morphemes in morphological analysis, they are chunked to form a phrasal unit called *bunsetsu* in dependency parsing, and to extract a keyword (Nakagawa and Mori, 2002).

To avoid the decompositionality problem, we adopted manual evaluation. We analyzed the target texts with both the initial lexicon and the augmented lexicon. Then we checked differences between the two analyses and extracted sentences that were affected by the augmentation. Among these sentences, we evaluated randomly selected 50 sentences per query. We checked the accuracy of segmentation and POS tagging of each "diff" block, which is illustrated in Figure 3. The segmentation of a block was judged correct unless morpheme boundaries were clearly wrong.

In the evaluation of POS tagging, we did not distinguish subclasses of noun[3] such as common noun

[3]In the experiments, we regarded demonstrative pronouns as

Table 3: Examples of acquired morphemes

query	examples
whaling issue	モラトリアム (moratorium), ツチクジラ (giant beaked whale), 混獲 (bycatch)
baby hatch	ダンナ (husband), 助産師 (midwife), 棄てる (to abandon), 訊く (to inquire)
JASRAC	ソフ倫 (an organization), シャ乱 Q (a pop-rock band), ヲタ (geek)
tsundere	アキバ (abbr. of Akihabara), 腐女子 (*fujoshi*, a slang word), モテる (to be popular)
agaricus	サプリ (abbr. of suppliment), アロマ (aroma), 食効 (enhanced nutritional function)

Table 4: Evaluation of "diff" blocks

	segmentation				POS tagging

> ググる    verb - ra-row verb
```

Figure 3: A "diff" block in a sentence

and proper noun. The special POS tag "undefined" given by JUMAN was treated as noun.

4.3 Results

Table 2 summarizes statistical information per query. The number of sentences affected by the augmentation varied considerably (1.04%–15.4%). The initial lexicon of the morphological analyzer lacked morphemes that appeared frequently in some corpora because morphological analysis had been tested mainly with newspaper articles.

The precision of acquired morphemes was high (97.4%–99.3%), and the number of examples used for acquisition was as little as 4–9. These results are astonishing considering that Mori and Nagao (1996) ignored candidates that appeared less than 10 times (because they were unreliable).

nouns because their morphological behaviors were the same as those of nouns. Although demonstrative nouns are closed class morphemes, their katakana forms such as "コレ" (this) were acquired as nouns. The morphological analyzer assumed that demonstrative pronouns were written in hiragana, e.g., "これ," as they always are in a newspaper.

Table 3 shows some acquired morphemes. As expected, the overwhelming majority were nouns (93.0%–100%) and katakana morphemes (80.7%–91.6%). Some were mixed-character morphemes ("ソフ倫" and "シャ乱 Q"), which cannot be recognized by character-type based heuristics, and slang words ("腐女子," "ヲタ," etc.) which did not appear in newspaper articles. Some morphemes were spelling variants of those in the pre-defined dictionary. Uncommon kanji characters were used in basic words ("棄てる" for "捨てる" and "訊く" for "聞く") and katakana was used to change nuances ("モテる" for "もてる" and "ダンナ" for "旦那").

Table 4 shows the results of manual evaluation of "diff" blocks. The overwhelming majority of blocks were correctly analyzed with the augmented lexicon (E → C and C → C). On the other hand, adverse effects were observed only in a few blocks (C → E). In conclusion, acquired morphemes improve the quality of morphological analysis.

4.4 Error Analysis

Some short katakana morphemes oversegmented other katakana nouns. For example, "サーバー" (*sâbâ*, server) was wrongly segmented by newly-acquired "サー" (sâ, sir) and preregistered "バー" (*bâ*, bar). Neither the morphological analyzer and the lexicon acquirer could detect this semantic mismatch. Curiously, one example of "サー" (sâ) was actuallly part of "サーバー" (*sâbâ*), which was erro-

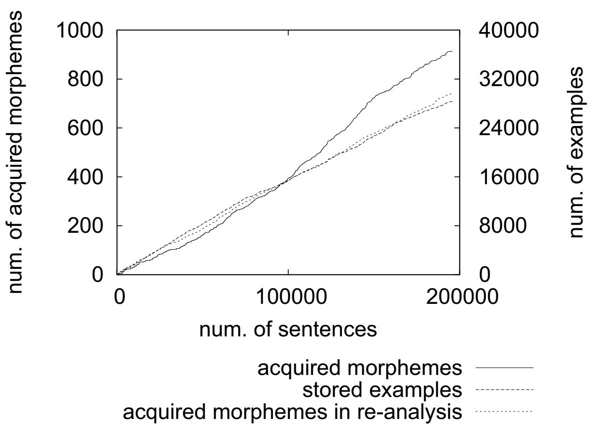

Figure 4: Process of online acquisition

neously segmented when extracting sentences from HTML.

The katakana adjective "イイ" (*i-i*, good), a spelling variant of the basic morpheme "いい," was falsely identified as a noun because its ending "イ" was written in katakana. The morphological analyzer, and hence the lexicon acquirer, assume that the ending of a verb or adjective is written in hiragana. This assumption is reasonable for standard Japanese, but does not always hold when we analyze web texts. In order to recognize unconventional spellings that are widely used in web texts (Nishimura, 2003), more flexible analysis is needed.

4.5 Discussion

It is too costly or impractical to calculate the recall of acquisition, or the ratio of the number of acquired morphemes against the total number of unknown morphemes because it requires human judges to find *undetected* unknown morphemes from a large amount of raw texts.

Alternatively, we examined the ratio against the number of *detected* unknown morphemes. Figure 4 shows the process of online acquisition for the query "JASRAC." The monotonic increase of the numbers of acquired morphemes and stored examples suggests that the vocabulary size did not converge. The number of occurrences of acquired morphemes in re-analysis was approximately the same with the number of examples kept in the storage during acquisition. This means that, in terms of frequency of occurrence, about half of unknown morphemes were acquired. Most unknown morphemes belong to the "long tail" and the proposed method seems to have seized a "head" of the long tail.

Although some previous studies emphasized correct identification of low frequency terms (Nagata, 1999; Asahara and Matsumoto, 2004), it is no longer necessary because very large scale web texts are available today. If a small set of texts needs to be analyzed with high accuracy, we can incorporate similar texts retrieved from the web, to increase the number of examples of unknown morphemes. The proposed method can be modified to check if unknown morphemes detected in the initial set are acquired and to terminate whenever sufficient acquisition coverage is achieved.

5 Related Work

Since most languages delimit words by white-space, morphological analysis in these languages is to segment words into morphemes. For example, Morpho Challenge 2007 (Kurimo et al., 2007) was evaluations of unsupervised segmentation for English, Finnish, German and Turkish.

While Japanese is an agglutinative language, other non-segmented languages such as Chinese and Thai are analytic languages. Among them, Chinese has been a subject of intensive research. Peng et al. (2004) integrated new word detection into word segmentation. They detected new words by computing segment confidence and re-analyzed the inputs with detected words as features.

The Japanese language is unique in that it is written with several different character types. Heuristics widely used in unknown morpheme processing are based on character types. They were also used as important clues in statistical methods. Nagata (1999) integrated a probabilistic unknown word models into the word segmentation model. Uchimoto et al. (2001) incorporated them as feature functions of a Maximum Entropy-based morphological analyzer. Asahara and Matsumoto (2004) used them as a feature of character-based chunking of unknown words using Support Vector Machines.

Mori (1996) extracted words from texts and estimated their POSs using distributional analysis. The appropriateness of a word candidate was measured by the distance between probability distributions of the candidate and a model. In this method, morphological constraints were indirectly represented by distributions.

Nakagawa and Matsumoto (2006) presented a method for guessing POS tags of pre-segmented unknown words that took into consideration all the occurrences of each unknown word in a document. This setting is impractical in Japanese because POS tagging is inseparable from segmentation.

6 Conclusion

We propose a novel method that augments the lexicon of a Japanese morphological analyzer by acquiring unknown morphemes from texts in online mode. Unknown morphemes are acquired with high accuracy and improve the quality of morphological analysis.

Unknown morphemes are one of the main sources of error in morphological analysis when we analyze web texts. The proposed method has the potential to overcome the unknown morpheme problem, but it cannot be achieved without recognizing or being robust over various phenomena such as unconventional spellings and typos. These phenomena are not observed in newspaper articles but cannot be ignored in web texts. In the future, we will work on these phenomena.

Morphological analysis is now very mature. It is widely applied as preprocessing for NLP applications such as parsing and information retrieval. Hence in the future, we aim to use the proposed method to improve the quality of these applications.

Legal Docket-Entry Classification: Where Machine Learning stumbles

Ramesh Nallapati and Christopher D. Manning

{nmramesh,manning}@cs.stanford.edu

Abstract

We investigate the problem of binary text classification in the domain of legal docket entries. This work presents an illustrative instance of a domain-specific problem where the state-of-the-art Machine Learning (ML) classifiers such as SVMs are inadequate. Our investigation into the reasons for the failure of these classifiers revealed two types of prominent errors which we call conjunctive and disjunctive errors. We developed simple heuristics to address one of these error types and improve the performance of the SVMs. Based on the intuition gained from our experiments, we also developed a simple propositional logic based classifier using hand-labeled features, that addresses both types of errors simultaneously. We show that this new, but simple, approach outperforms all existing state-of-the-art ML models, with statistically significant gains. We hope this work serves as a motivating example of the need to build more expressive classifiers beyond the standard model classes, and to address text classification problems in such non-traditional domains.

1 Introduction

Text Classification is a widely researched area, with publications spanning more than a decade (Yang and Liu, 1999). Although earlier models used logic based rules (Apté et al., 1994) and decision trees (Lewis and Ringuette, 1994), recently the emphasis has been on statistical classifiers such as the naive Bayes model (McCallum and Nigam, 1998), logistic regression (Zhang and Oles, 2001) and support vector machines (Joachims, 1998). Although several complex features were considered for classification, eventually researchers have settled down to simple bag-of-words features such as unigrams and some times bigrams (Dumais et al., 1998), thereby completely ignoring the grammar and other semantic information in the text. Despite this fact, the state-of-the-art performance is close to or above 90% on F1 scores on most standard test collections such as Reuters, 20 newsgroups, *etc.* (Bekkerman et al., 2003). As such, most researchers and practitioners believe text classification technology has reached a mature state, where it is suitable for deployment in real life applications.

In this work, we present a text classification problem from the legal domain which challenges some of our understanding of text classification problems. In the new domain, we found that the standard ML approaches using bag-of-words features perform relatively poorly. Not only that, we noticed that the linear form (or even polynomial form) used by these classifiers is inadequate to capture the semantics of the text. Our investigation into the shortcomings of the traditional models such as SVMs, lead us to build a simple propositional logic based classifier using hand-labeled features that outperforms these strong baselines.

Although the new model by itself is interesting, the main objective of our work is to present the text classification community with an interesting problem where the current models are found inadequate. Our hope is that the new problem will encourage researchers to continue to build more sophisticated models to solve classification problems in diverse, non-traditional domains.

The rest of the paper is organized as follows. In section 2, we introduce the problem of legal docket entry classification and describe the data with some representative examples. In section 3, we describe the experiments performed with SVMs and several of its variants. We also identify the shortcomings of the current classifiers in this section. In section 3.2, we present results from using human selected features for the classification problem and motivate their application for the docket entry classification using propositional logic in subsection 3.3. We also show that simple propositional logic using human selected features and their labels outperforms the state-of-the-art classifiers. We conclude the discussion in section 4, where we argue the case for more sophisticated classifiers for specialized domains.

2 Docket Entry Classification

In this section, we introduce the problem of legal docket entry classification.

In any US district court of law, information on the chronological events in a case is usually entered in a document called the *case docket*. Each entry in a docket lists an event that occured on a specific date such as pleading, appeal, order, jury trial, judgment, etc. The entries are brief descriptions of the events in natural language. Sometimes, a single docket entry can list multiple events that take place on the same day. Table 1 displays a sample docket for a case.

Identifying various events in a court case is a crucial first step to automatically understanding the progression of a case and also in gathering aggregate statistics of court cases for further analysis. While some events such as "Complaint" may be easy to identify using regular expressions, others are much more complex and may require sophisticated modeling.

In this work, we are primarily interested in identifying one such complex event called "Order re: Summary Judgment". Summary Judgment is a legal term which means that a court has made a determination (a judgment) without a full trial.[1] Such a judgment may be issued as to the merits of an entire case, or of specific issues in that case. Typically, one of the parties (plaintiff or defendant) involved in the case moves a motion for summary judgment, (usually) in an attempt to eliminate the risk of losing a trial. In an "Order re: Summary Judgment" event, the court may grant or deny a motion for summary judgment upon inspecting all the evidence and facts in the case. The task then, is to identify all docket entries in a set of cases that list occurrences of "Order re: Summary Judgment" events. We will call them OSJ events in short.

A few typical positive and negative docket entries for the OSJ event from various cases are shown in table 2. The examples require some explanation. Firstly, all orders granting, denying or amending motions for full or partial summary judgment are considered OSJs. However, if the motion is denied as moot or denied without prejudice, it is not an OSJ event, as shown in the negative examples 1 and 2 in table 2. This is because in such cases, no decision was made on substantive issues of the case. Also, there are other kinds of orders that are issued with reference to a summary judgment motion that do not fall into the category of OSJ, such as negative examples 3 through 9. To elaborate further, negative example 3 is about amending the deadline for filing a summary judgment motion, but not a summary judgment motion itself. Likewise, in negative example 4, the judge denies a motion to shorten time on a motion to vacate the order on summary judgment, but not the motion on summary judgment itself. The other negative examples are very similar in spirit and we leave it as an exercise to the reader to interpret why they are negatively labeled.

On first glance, it appears that a standard classifier may do a good job on this data, since the classification seems to depend mostly on certain key words such as 'granting', 'denying', 'moot', etc. Also notice that some of the docket entries contain multiple events, but as long as it contains the 'order re: summary judgment' event, it falls into the positive class. This seems very similar to the standard case, where a document may belong to multiple topics, but it is still identified as on-topic by a binary classifier on the corresponding topic.

Hence, as a first step, we attempted using a standard SVM classifier.

Table 1: An example (incomplete) docket: each row in the table corresponds to a docket-entry

2.1 Data

We have collected 5,595 docket entries from several court cases on intellectual property litigation, that are related to orders pertaining to summary judgment, and hand labeled them into OSJ or not OSJ categories.[2] The hand-labeling was done by a single legal expert, who practised law for a number of years. In all, 1,848 of these docket entries fall into the OSJ category.

In all our experiments, we split the entire data randomly into 20 disjoint subsets, where each set has the same proportion of positive-to-negative examples as the original complete set. For all the classifiers we used in this work, we performed 20-fold cross validation. We compute F1 scores on the held-out data of each run and report overall F1 score as the single point performance measure. We also perform statistical significance tests using the results from the 20 cross-validation runs.

2.2 Preprocessing

Before we ran our classifiers, we removed all punctuation, did casefolding, removed stopwords and stemmed the words using the Porter stemmer. We used unigrams and bigrams as our basic features.[3] We considered all the words and bigrams as binary features and did not use any TF-IDF weighting. Our justification for this decision is as follows: the docket text is typically very short and it is usually rare to see the same feature occurring multiple times in a docket entry. In addition, unlike in standard text classification, some of the features that are highly frequent across docket entries such as 'denying','granting', etc., are also the ones that are highly discriminative. In such a case, down-weighting these features using IDF weights might actually hurt performance. Besides (Dumais et al., 1998) found that using binary features works as well as using TF-IDF weights.

In addition, we also built a domain specific sentence boundary detector using regular expressions.[4] For constructing the features of a docket entry, we only consider those sentences in the entry that contain the phrase "summary judgment" and its variants.[5] Our preliminary experiments found that this helps the classifier focus on the relevant features, helping it to improve precision while not altering its recall noticeably.

3 Experiments and results

3.1 Basic SVM

First we implemented the standard linear SVM[6] on this problem with only word-based features (unigrams and bigrams) as the input. Quite surprisingly, the model achieves an F1 score of only 79.44% as shown in entry 1 of table 5. On inspection, we no-

[2]The data can be made available free of cost upon request. Please email the first author for more information.

[3]In our preliminary experiments, we found that a combination of unigrams and bigrams works better than unigrams alone.

[4]It works well in most cases but is far from perfect, due to the noisy nature of the data.

[5]The variants include "sum jgm", "S/J", "summary adjudication", "summary jgm", etc.

[6]All our SVM experiments were performed using the libsvm implementation downloadable from http://www.csie.ntu.edu.tw/∼cjlin/libsvm/

REPRESENTATIVE POSITIVE EXAMPLES

1. ORDER denying [36-1] motion for summary judgment on dfts Ranbaxy invalidity defenses by pltfs. (signed by Judge Garrett E. Brown, Jr.)
2. ORDER GRANTING IN PART AND DENYING IN PART DEFENDANTS' MOTION FOR SUMMARY JUDGMENT
3. ORDER re 78 MOTION to Amend/Correct Motion for Summary Judgment and supporting documents, filed by Defendant Synergetics USA, Inc. ; ORDERED GRANTED.
4. MEMORANDUM AND ORDER re: 495 Third MOTION for Partial Summary Judgment Dismissing Monsanto's Defenses Related to Dr. Barnes filed by Bayer BioScience N.V., motion is GRANTED IN PART AND DENIED IN PART.
5. ORDER GRANTING IN PART PLTF S/J MOT; GRANTING IN PART PLTF MOT/CLARIFY; GRANTING DEFT MOT/CLARIFY; PRTL S/J STAYED.
6. ORDER by Chief Judge Joe B. McDade. Court is granting in part and denying in part Deere's motion for reconsideration and clarification [42-2]; granting Toro's motion for summary judgment of non-infringement [45-1]; denying Deere's motion for summary judgment [58-1];
7. ORDER GRANTING DEFT. MOTION FOR S/J AND DENYING PLTF. MOTIONS FOR S/J AND TO SUPPLEMENT.

REPRESENTATIVE NEGATIVE EXAMPLES

1. ORDER - denying w/out prejudice 17 Motion for Summary Judgment, denying w/out prejudice 49 Motion to Amend/Correct . Signed by Judge Kent A. Jordan on 1/23/06.
2. Order denying as moot motion for summary judgment.
3. Order granting 53 Motion to Amend/Correct the deadline for filing summary jgm motions will be moved 12/1/03 to 12/8/03
4. ORDER by Judge Claudia Wilken denying plaintiff's motion to shorten time on motion to vacate portions of Court's order on cross-motion for summary judgment on patent issues [695-1] [697-1]
5. MEMORANDUM AND ORDER: by Honorable E. Richard Webber, IT IS HEREBY ORDERED that Defendant Aventis shall have 10 days from the date of this order to demonstrate why the Court should not grant summary judgment to Monsanto of non-infringement of claims 1-8 and 12 of the '565 patent and claim 4 of the '372 patent.
6. ORDER by Judge Claudia Wilken DENYING motion for an order certifying for immediate appeal portions of the courts' 2/6/03 order granting in part plaintiff's motion for partial summary judgment [370-1]
7. ORDER by Judge William Alsup denying in part 12 Motion to Consolidate Cases except as to one issue, granting in part for collateral estoppel 20 Motion for Summary Judgment
8. ORDER (Chief Mag. Judge Jonathan G. Lebedoff / 9/11/02) that the court grants Andersen's motion and orders that Andersen be allowed to bring its motions for summary judgment
9. ORDER by Judge Susan J. Dlott denying motion to strike declaration of H Bradley Hammond attached to memorandum in opposition to motion for partial summary judgment as to liability on the patent infringement and validity claims [40-1] [47-1] [48-1]

Table 2: Order: re Summary Judgment: positive and negative docket entries. The entries are reproduced as they are.

ticed that the SVM assigns high weights to many spurious features owing to their strong correlation with the class.

As a natural solution to this problem, we selected the top 100 features[7] using the standard information gain metric (Yang and Pedersen, 1997) and ran the SVM on the pruned feature set. As one would expect, the performance of the SVM improved significantly to reach an F1 score of 83.08% as shown in entry 2 of the same table. However, it is still a far cry from the typical results on standard test beds where the performance is above 90% F1. We suspected that training data was probably insufficient, but a learning curve plotting performance of the SVM as a function of the amount of training data reached a plateau with the amount of training data we had, so this problem was ruled out.

To understand the reasons for its inferior performance, we studied the features that are assigned the highest weights by the classifier. Although the SVM is able to assign high weights to several discriminative features such as ‘denied’, and ‘granted’, it also assigns high weights to features such as ‘opinion’, ‘memorandum’, ‘order’, ‘judgment’, etc., which have high co-occurrence rates with the positive class, but are not very discriminative in terms of the actual classification.

This is indicative of the problems associated with standard feature selection algorithms such as information gain in these domains, where high correlation with the label does not necessarily imply high discriminative power of the feature. Traditional classification tasks usually fall into what we call the ‘topical classification’ domain, where the distribution of words in the documents is a highly discriminative feature. On such tasks, feature selection algorithms based on feature-class correlation have been very successful. In contrast, in the current problem, which we call ‘semantic classification’, there seem to be a fixed number of domain specific operative words such as ‘grant’, ‘deny’, ‘moot’, ‘strike’, etc., which, almost entirely decide the class of the docket entry, irrespective of the existence of other highly correlated features. The information gain metric as well as the SVM are not able to fully capture such features in this problem.

[7]We tried other numbers as well, but top 100 features achieves the best performance.

We leave the problem of accurate feature selection to future work, but in this work, we address the issue by asking for human intervention, as we describe in the next section. One reason for seeking human assistance is that it will give us an estimate of upperbound performance of an automatic feature selection system. In addition, it will also offer us a hint as to whether the poor performance of the SVM is because of poor feature selection. We will aim to answer this question in the next section.

3.2 Human feature selection

Using human assistance for feature selection is a relatively new idea in the text classification domain. (Raghavan et al., 2006) propose a framework in which the system asks the user to label documents and features alternatively. They report that this results in substantial improvement in performance especially when the amount of labeled data is meagre. (Druck et al., 2008) propose a new Generalized Expectation criterion that learns a classification function from labeled features alone (and no labeled documents). They showed that feature labeling can reduce annotation effort from humans compared to document labeling, while achieving almost the same performance.

Following this literature, we asked our annotators to identify a minimal but definitive list of discriminative features from labeled data. The annotators were specifically instructed to identify the features that are most critical in tagging a docket entry one way or the other. In addition, they were also asked to assign a polarity to each feature. In other words, the polarity tells us whether or not the features belong to the positive class. Table 3 lists the complete set of features identified by the annotators.

As an obvious next step, we trained the SVM in the standard way, but using only the features from table 3 as the pruned set of features. Remarkably, the performance improves to 86.77% in F1, as shown in entry 3 of table 5. Again, this illustrates the uniqueness of this dataset, where a small number of hand selected features (< 40) makes a huge difference in performance compared to a state-of-the-art SVM combined with automatic feature selection. We believe this calls for more future work in improving feature selection algorithms.

Label	Features
Positive	grant, deny, amend, reverse, adopt, correct, reconsider, dismiss
Negative	strike, proposed, defer, adjourn, moot, exclude, change, extend, leave, exceed, premature, unseal, hearing, extend, permission, oral argument, schedule, ex parte, protective order, oppose, without prejudice, withdraw, response, suspend, request, case management order, to file, enlarge, reset, supplement placing under seal, show cause reallocate, taken under submission

Table 3: Complete set of hand-selected features: morphological variants not listed

Notice that despite using human assistance, the performance of the SVM is still not at a desirable level. This clearly points to deficiencies in the model other than poor feature selection. To understand the problem, we examined the errors made by the SVM and found that there are essentially two types of errors: *conjunctive* and *disjunctive*. Representative examples for both kinds of errors are displayed in table 4. The first example in the table corresponds to a conjunctive error, where the SVM is unable to model the binary switch like behavior of features. In this example, although 'deny' is rightly assigned a positive weight and 'moot' is rightly assigned a negative weight, when both features co-occur in a docket entry (as in 'deny as moot'), it makes the label negative.[8] However, the combined weight of the linear SVM is positive since the absolute value of the weight assigned to 'deny' is higher than that of 'moot', resulting in a net positive score. The second example falls into the category of disjunctive errors, where the SVM fails to model disjunctive behavior of sentences. In this example, the first sentence contains an OSJ event, but the second and third sentences are negatives for OSJ. As we have discussed earlier, this docket entry belongs to the OSJ category since it contains at least one OSJ event. However, we see that the negative weights assigned by the SVM to the second and third sentences result in an overall negative classification.

As a first attempt, we tried to reduce the conjunctive errors in our system. Towards this objective, we built a decision tree[9] using the same features listed in table 3. Our intuition was that a decision tree makes a categorical decision at each node in the tree, hence it could capture the binary-switch like behavior of features. However, the performance of the decision tree is found to be statistically indistinguishable from the linear SVM as shown in entry 4 of table 5. As an alternative, we used an SVM with a quadratic kernel, since it can also capture such pairwise interactions of features. This resulted in a fractional improvement in performance, but is again statistically indistinguishable from the decision tree. We also tried higher order polynomial kernels and the RBF kernel, but the performance got no better.[10] It is not easy to analyze the behavior of non-linear kernels since they operate in a higher kernel space. Our hypothesis is that polynomial functions capture higher order interactions between features, but they do not capture conjunctive behavior precisely.

As an alternative, we considered the following heuristic: whenever two or more of the hand selected features occur in the same sentence, we merged them to form an n-gram. The intuition behind this heuristic is the following: using the same example as before, if words such as 'deny' and 'moot' occur in the same sentence, we form the bigram 'deny-moot', forcing the SVM to consider the bigram as a separate feature. We hope to capture the conjunctive behavior of some features using this heuristic. The result of this approach, as displayed in entry 6 of table 5, shows small but statistically significant improvement over the quadratic SVM, confirming our theory. We also attempted a quadratic kernel using sentence level n-grams, but it did not show any improvement.

Note that all the models and heuristics we used above only address conjunctive errors, but not disjunctive errors. From the discussion above, we suspect the reader already has a good picture of what

[8]This is very similar to the conjunction of two logical variables where the conjunction of the variables is negative when at least one of them is negative. Hence the name conjunctive error.

[9]We used the publicly available implementation from www.run.montefiore.ulg.ac.be/∼francois/software/jaDTi/

[10]We also tried various parameter settings for these kernels with no success.

an appropriate model for this data might look like. The next section introduces this new model developed using the intuition gained above.

3.3 Propositional Logic using Human Features and Labels

So far, the classifiers we considered received a performance boost by piggybacking on the human selected features. However, they did not take into account the polarity of these features. A logical next step would be to exploit this information as well. An appropriate model would be the generalized expectation criterion model by (Druck et al., 2008) which learns by matching model specific label expectations conditioned on each feature, with the corresponding empirical expectations. However, the base model they use is a logistic regression model, which is a log-linear model, and hence would suffer from the same limitations as the linear SVM. There is also other work on combining SVMs with labeled features using transduction on unlabeled examples, that are soft-labeled using labeled features (Wu and Srihari, 2004), but we believe it will again suffer from the same limitations as the SVM on this domain.

In order to address the conjunctive and disjunctive errors simultaneously, we propose a new, but simple approach using propositional logic. We consider each labeled feature as a propositional variable, where true or false corresponds to whether the label of the feature is positive or negative respectively. Given a docket entry, we first extract its sentences, and for each sentence, we extract its labeled features, if present. Then, we construct a sentence-level formula formed by the conjunction of the variables representing the labeled features. The final classifier is a disjunction of the formulas of all sentences in the docket entry. Formally, the propositional logic based classifier can be expressed as follows:

$$C(D) = \vee_{i=1}^{N(D)} (\wedge_{j=1}^{M_i} L(f_{ij})) \tag{1}$$

where D is the docket entry, $N(D)$ is its number of sentences, M_i is the number of labeled features in the i^{th} sentence, f_{ij} is the j^{th} labeled feature in the i^{th} sentence and $L()$ is a mapping from a feature to its label, and $C(D)$ is the classification function where 'true' implies the docket entry contains an OSJ event.

The propositional logic model is designed to address the within-sentence conjunctive errors and without-sentence disjunctive errors simultaneously. Clearly, the within-sentence conjunctive behavior of the labeled features is captured by applying logical conjunctions to the labeled features within a sentence. Similarly, the disjunctive behavior of sentences is captured by applying disjunctions to the sentence-level clauses. This model requires no training, but for reasons of fairness in comparison, at testing time, we used only those human features (and their labels) that exist in the training set in each cross-validation run. The performance of this new approach, listed in table 5 as entry 7, is slightly better than the best performing SVM in entry 6. The difference in performance in this case is statistically significant, as measured by a paired, 2-tailed t-test at 95% confidence level (p-value = 0.007).

Although the improvement for this model is statistically significant, it does not entirely match our

#	Model	Recall (%)	Precision (%)	F1 (%)
1	Linear SVM with uni/bigrams only	75.19	84.21	79.44
2	Linear SVM with uni/bigrams only FS100	82.47	83.69	83.08*
3	Linear SVM with HF only	84.68	88.97	86.77*
4	Decision Tree with HF only	85.22	89.38	87.25
5	Quadratic SVM with HF only	84.14	90.98	87.43
6	Linear SVM with HF sentNgrams	84.63	93.37	88.78*
7	Propositional Logic with HF and their labels	**85.71**	**93.45**	**89.67***

Table 5: Results for 'Order re: Summary Judgment': FS100 indicates that only top 100 features were selected using Information Gain metric; HF stands for human built features, sentNgrams refers to the case where all the human-built features in a given sentence were merged to form an n-gram feature. A '*' next to F1 value indicates statistically significant result compared to its closest lower value, measured using a paired 2-tailed T-test, at 95% confidence level. The highest numbers in each column are highlighted using boldface.

expectations. Our data analysis showed a variety of errors caused mostly due to the following issues:

- *Imperfect sentence boundary detection:* since the propositional logic model considers sentences as strong conjunctions, it is more sensitive to errors in sentence boundary detection than SVMs. Any errors would cause the model to form conjunctions with features in neighboring sentences and deliver an incorrect labeling.

- *Incomplete feature set:* Some errors are caused because the feature set is not complete. For example, negative example 4 in table 2 is tagged as positive by the new model. This error could have been avoided if the word 'shorten' had been identified as a negative feature.

- *Relevant but bipolar features:* Although our model assumes that the selected features exhibit binary nature, this may not always be true. For example the word *allow* is sometimes used as a synonym for 'grant' which is a positive feature, but other times, as in negative example 8 in table 2, it exhibits negative polarity. Hence it is not always possible to encode all relevant features into the logic based model.

- *Limitations in expressiveness:* Some natural language sentences such as negative example 5 in table 2 are simply beyond the scope of the conjunctive and disjunctive formulations.

4 Discussion and Conclusions

Clearly, there is a significant amount of work to be done to further improve the performance of the propositional logic based classifier. One obvious line of work is towards better feature selection in this domain. One plausible technique would be to use shallow natural language processing techniques to extract the operative verbs acting on the phrase "summary judgment", and use them as the pruned feature set.

Another potential direction would be to extend the SVM-based system to model disjunctive behavior of sentences.[11] One way to accomplish this would be to classify each sentence individually and then to combine the outcomes using a disjunction. But for this to be implemented, we would also need labels at the sentence level during training time. One could procure these labels from annotators, but as an alternative, one could learn the sentence-level labels in an unsupervised fashion using a latent variable at the sentence level, but a supervised model at the docket-entry level. Such models may also be appropriate for traditional document classification where each document could be multi-labeled, and it is something we would like attempt in the future.

In addition, instead of manually constructing the logic based system, one could also automatically learn the rules by using ideas from earlier work on ILP (Muggleton, 1997), FOIL (Quinlan and Cameron-Jones, 1993), etc.

[11]Recall that the heuristics we presented for SVMs only address the conjunctive errors.

To summarize, we believe it is remarkable that a simple logic-based classifier could outperform an SVM that is already boosted by hand picked features and heuristics such as sentence level n-grams. This work clearly exposes some of the limitations of the state-of-the-art models in capturing the intricacies of natural language, and suggests that there is more work to be done in improving the performance of text based classifiers in specialized domains. As such, we hope our work motivates other researchers towards building better classifiers for this and other related problems.

Abstract

String transformation, which maps a source string s into its desirable form t^*, is related to various applications including stemming, lemmatization, and spelling correction. The essential and important step for string transformation is to generate candidates to which the given string s is likely to be transformed. This paper presents a discriminative approach for generating candidate strings. We use substring substitution rules as features and score them using an L_1-regularized logistic regression model. We also propose a procedure to generate negative instances that affect the decision boundary of the model. The advantage of this approach is that candidate strings can be enumerated by an efficient algorithm because the processes of string transformation are tractable in the model. We demonstrate the remarkable performance of the proposed method in normalizing inflected words and spelling variations.

1 Introduction

String transformation maps a source string s into its destination string t^*. In the broad sense, string transformation can include labeling tasks such as part-of-speech tagging and shallow parsing (Brill, 1995). However, this study addresses string transformation in its narrow sense, in which a part of a source string is rewritten with a substring. Typical applications of this task include stemming, lemmatization, spelling correction (Brill and Moore, 2000; Wilbur et al., 2006; Carlson and Fette, 2007), OCR error correction (Kolak and Resnik, 2002), approximate string matching (Navarro, 2001), and duplicate record detection (Bilenko and Mooney, 2003).

Recent studies have formalized the task in the discriminative framework (Ahmad and Kondrak, 2005; Li et al., 2006; Chen et al., 2007),

$$t^* = \underset{t \in \mathrm{gen}(s)}{\mathrm{argmax}}\, P(t|s). \qquad (1)$$

Here, the *candidate generator* $\mathrm{gen}(s)$ enumerates candidates of destination (correct) strings, and the *scorer* $P(t|s)$ denotes the conditional probability of the string t for the given s. The scorer was modeled by a noisy-channel model (Shannon, 1948; Brill and Moore, 2000; Ahmad and Kondrak, 2005) and maximum entropy framework (Berger et al., 1996; Li et al., 2006; Chen et al., 2007).

The candidate generator $\mathrm{gen}(s)$ also affects the accuracy of the string transformation. Previous studies of spelling correction mostly defined $\mathrm{gen}(s)$,

$$\mathrm{gen}(s) = \{t \mid \mathrm{dist}(s,t) < \delta\}. \qquad (2)$$

Here, the function $\mathrm{dist}(s,t)$ denotes the weighted Levenshtein distance (Levenshtein, 1966) between strings s and t. Furthermore, the threshold δ requires the distance between the source string s and a candidate string t to be less than δ.

The choice of $\mathrm{dist}(s,t)$ and δ involves a tradeoff between the precision, recall, and training/tagging speed of the scorer. A less restrictive design of these factors broadens the search space, but it also increases the number of confusing candidates, amount of feature space, and computational cost for the scorer. Moreover, the choice is highly dependent on the target task. It might be sufficient for a spelling correction program to gather candidates from known words, but a stemmer must handle unseen words appropriately. The number of candidates can be huge when we consider transformations from and to unseen strings.

This paper addresses these challenges by exploring the discriminative training of candidate generators. More specifically, we build a binary classifier that, when given a source string s, decides whether a candidate t should be included in the candidate set or not. This approach appears straightforward, but it must resolve two practical issues. First, the task of the classifier is not only to make a binary decision for the two strings s and t, but also to enumerate a set of positive strings for the string s,

$$\mathrm{gen}(s) = \{t \mid \mathrm{predict}(s,t) = 1\}. \tag{3}$$

In other words, an efficient algorithm is necessary to find a set of strings with which the classifier $\mathrm{predict}(s,t)$ yields positive labels for the string s.

Another issue arises when we prepare a training set. A discriminative model requires a training set in which each instance (pair of strings) is annotated with a positive or negative label. Even though some existing resources (e.g., inflection table and query log) are available for positive instances, such resources rarely contain negative instances. Therefore, we must generate negative instances that are effective for discriminative training.

To address the first issue, we design features that express transformations from a source string s to its destination string t. Feature selection and weighting are performed using an L_1-regularized logistic regression model, which can find a sparse solution to the classification model. We also present an algorithm that utilizes the feature weights to enumerate candidates of destination strings efficiently. We deal with the second issue by generating negative instances from unlabeled instances. We describe a procedure to choose negative instances that affect the decision boundary of the classifier.

This paper is organized as follows. Section 2 formalizes the task of the candidate generator as a binary classification modeled by logistic regression. Features for the classifier are designed using the rules of substring substitution. Therefore, we can obtain, efficiently, candidates of destination strings and negative instances for training. Section 3 reports the remarkable performance of the proposed method in various applications including lemmatization, spelling normalization, and noun derivation. We briefly review previous work in Section 4, and conclude this paper in Section 5.

2 Candidate generator

2.1 Candidate classification model

In this section, we first introduce a binary classifier that yields a label $y \in \{0,1\}$ indicating whether a candidate t should be included in the candidate set (1) or not (0), given a source string s. We express the conditional probability $P(y|s,t)$ using a logistic regression model,

$$P(1|s,t) = \frac{1}{1 + \exp\left(-\mathbf{\Lambda}^T \boldsymbol{F}(s,t)\right)}, \tag{4}$$

$$P(0|s,t) = 1 - P(1|s,t). \tag{5}$$

In these equations, $\boldsymbol{F} = \{f_1, ..., f_K\}$ denotes a vector of the Boolean feature functions; K is the number of feature functions; and $\mathbf{\Lambda} = \{\lambda_1, ..., \lambda_K\}$ presents a weight vector of the feature functions.

We obtain the following decision rule to choose the most probable label y^* for a given pair $\langle s, t\rangle$,

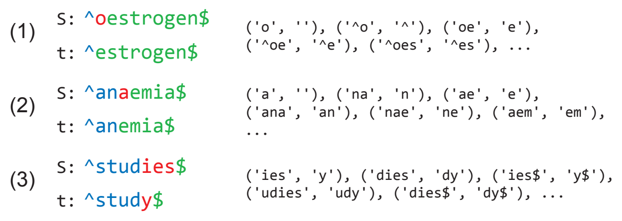
$$y^* = \operatorname*{argmax}_{y \in \{0,1\}} P(y|s,t) = \begin{cases} 1 & \left(\mathbf{\Lambda}^T \boldsymbol{F}(s,t) > 0\right) \\ 0 & (\text{otherwise}) \end{cases}. \tag{6}$$

Finally, given a source string s, the generator function $\mathrm{gen}(s)$ is defined to collect all strings to which the classifier assigns positive labels:

$$\begin{aligned} \mathrm{gen}(s) &= \{t \mid P(1|s,t) > P(0|s,t)\} \\ &= \{t \mid \mathbf{\Lambda}^T \boldsymbol{F}(s,t) > 0\}. \end{aligned} \tag{7}$$

2.2 Substitution rules as features

The binary classifier can include any arbitrary feature. This is exemplified by the Levenshtein distance and distributional similarity (Lee, 1999) between two strings s and t. These features can improve the classification accuracy, but it is unrealistic to compute these features for every possible string, as in equation 7. For that reason, we specifically examine *substitution rules*, with which the process



```
(1)  S: ^oestrogen$    ('o', ''), ('^o', '^'), ('oe', 'e'),
     t: ^estrogen$     ('^oe', '^e'), ('^oes', '^es'), ...
(2)  S: ^anaemia$      ('a', ''), ('na', 'n'), ('ae', 'e'),
     t: ^anemia$       ('ana', 'an'), ('nae', 'ne'), ('aem', 'em'),
                       ...
(3)  S: ^studies$      ('ies', 'y'), ('dies', 'dy'), ('ies$', 'y$'),
     t: ^study$        ('udies', 'udy'), ('dies$', 'dy$'), ...
```

Figure 1: Generating substitution rules.

of transforming a source string s into its destination form t is tractable.

In this study, we assume that every string has a prefix '`^`' and postfix '`$`', which indicate the head and tail of a string. A substitution rule $r = (\alpha, \beta)$ replaces every occurrence of the substring α in a source string into the substring β. Assuming that a string s can be transformed into another string t with a single substitution operation, substitution rules express the different portion between strings s and t.

Equation 8 defines a binary feature function with a substitution rule between two strings s and t,

$$f_k(s,t) = \begin{cases} 1 & \text{(rule } r_k \text{ can convert } s \text{ into } t\text{)} \\ 0 & \text{(otherwise)} \end{cases}. \tag{8}$$

We allow multiple substitution rules for a given pair of strings. For instance, substitution rules ('`a`', ''), ('`na`', '`n`'), ('`ae`', '`e`'), ('`nae`', '`ne`'), etc. form feature functions that yield 1 for strings s = '`^anaemia$`' and t = '`^anemia$`'. Equation 6 produces a decision based on the sum of feature weights, or scores of substitution rules, representing the different portions between s and t.

Substitution rules for the given two strings s and t are obtained as follows. Let l denote the longest common prefix between strings s and t, and r the longest common postfix. We define c_s as the substring in s that is not covered by the longest common prefix l and postfix r, and define c_t for t analogously. In other words, strings s and t are divided into three regions, lc_sr and lc_tr, respectively. For strings s = '`^anaemia$`' and t = '`^anemia$`' in Figure 1 (2), we obtain c_s = '`a`' and c_t = '' because l = '`^an`' and r = '`emia$`'.

Because substrings c_s and c_t express different portions between strings s and t, we obtain the *minimum substitution rule* (c_s, c_t), which can convert the string s into t by replacing substrings c_s in s with c_t; the minimum substitution rule for the same example is ('`a`', ''). However, replacing letters '`a`' in '`^anaemia$`' into empty letters does not produce the correct string '`^anemia$`' but '`^nemi$`'. Furthermore, the rule might be inappropriate for expressing string transformation because it always removes the letter '`a`' from every string.

Therefore, we also obtain *expanded substitution rules*, which insert postfixes of l to the head of minimum substitution rules, and/or append prefixes of r to the rules. For example, we find an expanded substitution rule ('`na`', '`n`'), by inserting a postfix of l = '`^an`' to the head of the minimum substitution rule ('`a`', ''); similarly, we obtain an expanded substitution rule ('`ae`', '`e`'), by appending a prefix of r = '`emia$`' to the tail of the rule ('`a`', '').

Figure 1 displays examples of substitution rules (the right side) for three pairs of strings (the left side). Letters in blue, green, and red respectively represent the longest common prefixes, longest common postfixes, and different portions. In this study, we expand substitution rules such that the number of letters in rules is does not pass a threshold θ[1].

2.3 Parameter estimation

Given a training set that consists of N instances, $\mathcal{D} = \left((s^{(1)}, t^{(1)}, y^{(1)}), ..., (s^{(N)}, t^{(N)}, y^{(N)})\right)$, we optimize the feature weights in the logistic regression model by maximizing the log-likelihood of the conditional probability distribution,

$$\mathcal{L}_{\mathbf{\Lambda}} = \sum_{i=1}^{N} \log P(y^{(i)}|s^{(i)}, t^{(i)}). \tag{9}$$

The partial derivative of the log-likelihood with respect to a feature weight λ_k is given as equation 10,

$$\frac{\partial \mathcal{L}_{\mathbf{\Lambda}}}{\partial \lambda_k} = \sum_{i=1}^{N} \left\{ y^{(i)} - P(1|s^{(i)}, t^{(i)}) \right\} f_k(s^{(i)}, t^{(i)}). \tag{10}$$

The maximum likelihood estimation (MLE) is known to suffer from overfitting the training set. The

[1]The number of letters for a substitution rule $r = (\alpha, \beta)$ is defined as the sum of the quantities of letters in α and β, i.e., $|\alpha| + |\beta|$. We determined the threshold $\theta = 12$ experimentally.

common approach for addressing this issue is to use the maximum a posteriori (MAP) estimation, introducing a regularization term of the feature weights $\mathbf{\Lambda}$, i.e., a penalty on large feature weights. In addition, the generation algorithm of substitution rules might produce inappropriate rules that transform a string incorrectly, or overly specific rules that are used scarcely. Removing unnecessary substitution rules not only speeds up the classifier but also the algorithm for candidate generation, as presented in Section 2.4.

In recent years, L_1 regularization has received increasing attention because it produces a sparse solution of feature weights in which numerous feature weights are zero (Tibshirani, 1996; Ng, 2004). Therefore, we regularize the log-likelihood with the L_1 norm of the weight vector $\mathbf{\Lambda}$ and define the final form the objective function to be minimized as

$$E_{\mathbf{\Lambda}} = -\mathcal{L}_{\mathbf{\Lambda}} + \frac{|\mathbf{\Lambda}|}{\sigma}. \tag{11}$$

Here, σ is a parameter to control the effect of L_1 regularization; the smaller the value we set to σ, the more features the MAP estimation assigns zero weights to: it removes a number of features from the model. Equation 11 is minimized using the Orthant-Wise Limited-memory Quasi-Newton (OW-LQN) method (Andrew and Gao, 2007) because the second term of equation 11 is not differentiable at $\lambda_k = 0$.

2.4 Candidate generation

The advantage of our feature design is that we can enumerate strings to which the classifier is likely to assign positive labels. We start by observing the necessary condition for t in equation 7,

$$\mathbf{\Lambda}^T \boldsymbol{F}(s,t) > 0 \Rightarrow \exists k : f_k(s,t) = 1 \land \lambda_k > 0. \tag{12}$$

The classifier might assign a positive label to strings s and t when at least one feature function whose weight is positive can transform s to t.

Let R^+ be a set of substitution rules to which MAP estimation has assigned positive feature weights. Because each feature corresponds to a substitution rule, we can obtain $\mathrm{gen}(s)$ for a given string s by application of every substitution rule $r \in R^+$,

$$\mathrm{gen}(s) = \{r(s) \mid r \in R^+ \land \mathbf{\Lambda}^T \boldsymbol{F}(s, r(s)) > 0\}. \tag{13}$$

```
Input: $s = (s_1, ..., s_l)$: an input string $s$ (series of letters)
Input: $D$: a trie dictionary containing positive features
Output: $T$: $\mathrm{gen}(s)$
1  $T = \{\}$;
2  $U = \{\}$;
3  foreach $i \in (1, ..., |s|)$ do
4      $F \leftarrow D$.prefix_search($s, i$);
5      foreach $f \in F$ do
6          if $f \notin U$ then
7              $t \leftarrow f$.apply($s$);
8              if classify($s, t$) $= 1$ then
9                  add $t$ to $T$;
10             end
11             add $f$ to $U$;
12         end
13     end
14 end
15 return $T$;
```

Algorithm 1: A pseudo-code for $\mathrm{gen}(s)$.

Here, $r(s)$ presents the string to which the substitution rule r transforms the source string s. We can compute $\mathrm{gen}(s)$ with a small computational cost if the MAP estimation with L_1 regularization reduces the number of active features.

Algorithm 1 represents a pseudo-code for obtaining $\mathrm{gen}(s)$. To search for positive substitution rules efficiently, the code stores a set of rules in a trie structure. In line 4, the code obtains a set of positive substitution rules F that can rewrite substrings starting at offset #i in the source string s. For each rule $f \in F$, we obtain a candidate string t by application of the substitution rule f to the source string s (line 7). The candidate string t is qualified to be included in $\mathrm{gen}(s)$ when the classifier assigns a positive label to strings s and t (lines 8 and 9). Lines 6 and 11 prevent the algorithm from repeating evaluation of the same substitution rule.

2.5 Generating negative instances

The parameter estimation requires a training set $\mathcal{D}$ in which each instance (pair of strings) is annotated with a positive or negative label. Negative instances (counter examples) are essential for penalizing inappropriate substitution rules, e.g. (‘a’, ‘’). Even though some existing resources (e.g. verb inflection table) are available for positive instances, such resources rarely contain negative instances.

A common approach for handling this situation is to assume that every pair of strings in a resource

```
Input: $\mathcal{D}^+ = [(s_1, t_1), ..., (s_l, t_l)]$: positive instances
Input: $V$: a suffix array of all strings (vocabulary)
Output: $\mathcal{D}^-$: negative instances
Output: $R$: substitution rules (features)
1  $\mathcal{D}^- = []$;
2  $R = \{\}$;
3  foreach $d \in \mathcal{D}^+$ do
4      foreach $r \in$ features($d$) do
5          add $r$ to $R$;
6      end
7  end
8  foreach $r \in R$ do
9      $S \leftarrow V$.search($r.src$);
10     foreach $s \in S$ do
11         $t \leftarrow r$.apply($s$);
12         if $(s, t) \notin \mathcal{D}^+$ then
13             if $t \in V$ then
14                 append $(s, t)$ to $\mathcal{D}^-$;
15             end
16         end
17     end
18 end
19 return $\mathcal{D}^-$, $R$;
```

Algorithm 2: Generating negative instances.

is a negative instance; however, negative instances amount to ca. $V(V-1)/2$, where V represents the total number of strings. Moreover, substitution rules expressing negative instances are innumerable and sparse because the different portions are peculiar to individual negative instances. For instance, the minimum substitution rule for unrelated words *anaemia* and *around* is (‘naemia’, ‘round’), but the rule cannot be too specific to generalize the conditions for other negative instances.

In this study, we generate negative instances so that they can penalize inappropriate rules and settle the decision boundary of the classifier. This strategy is summarized as follows. We consider every pair of strings as candidates for negative instances. We obtain substitution rules for the pair using the same algorithm as that described in Section 2.2 if a string pair is not included in the dictionary (i.e., not in positive instances). The pair is used as a negative instance only when any substitution rule generated from the pair also exists in the substitution rules generated from positive instances.

Algorithm 2 presents the pseudo-code that implements the strategy for generating negative instances efficiently. First, we presume that we have positive instances $\mathcal{D}^+ = [(s_1, t_1), ..., (s_l, t_l)]$ and unlabeled strings V. For example, positive instance $\mathcal{D}^+$ represent orthographic variants, and unlabeled strings V include all possible words (vocabulary). We insert the vocabulary into a suffix array, which is used to locate every occurrence of substrings in V.

The algorithm first generates substitution rules R only from positive instances $\mathcal{D}^+$ (lines 3 to 7). For each substitution rule $r \in R$, we enumerate known strings S that contain the source substring $r.src$ (line 9). We apply the substitution rule to each string $s \in S$ and obtain its destination string t (line 11). If the pair of strings $\langle s, t \rangle$ is not included in D^+ (line 12), and if the destination string t is known (line 13), the substitution rule r might associate incorrect strings s and t, which do not exist in D^+. Therefore, we insert the pair to the negative set D^- (line 14).

Table	Description	# Entries
LRSPL	Spelling variants	90,323

3 Evaluation

3.1 Experiments

We evaluated the candidate generator using three different tasks: normalization of orthographic variants, noun derivation, and lemmatization. The datasets for these tasks were obtained from the *UMLS SPECIALIST Lexicon*[2], a large lexicon that includes both commonly occurring English words and biomedical vocabulary. Table 1 displays the list of tables in the SPECIALIST Lexicon that were used in our experiments. We prepared three datasets, *Orthography*, *Derivation*, and *Inflection*.

The Orthography dataset includes spelling variants (e.g., *color* and *colour*) in the LRSPL table. We

[2]UMLS SPECIALIST Lexicon: http://specialist.nlm.nih.gov/

chose entries as positive instances in which spelling variants are caused by (case-insensitive) alphanumeric changes[3]. The Derivation dataset was built directly from the LRNOM table, which includes noun derivations such as *abandon* $\rightarrow$ *abandonment*. The LRAGR table includes base forms and their inflectional variants of nouns (singular and plural forms), verbs (infinitive, third singular, past, past participle forms, etc), and adjectives/adverbs (positive, comparative, and superlative forms). For the Inflection dataset, we extracted the entries in which inflectional forms differ from their base forms[4], e.g., *study* $\rightarrow$ *studies*.

For each dataset, we applied the algorithm described in Section 2.5 to generate substitution rules and negative instances. Table 2 shows the number of positive instances (# +), negative instances (# -), and substitution rules (# Rules). We evaluated the performance of the proposed method in two different goals of the tasks: classification (Section 3.2) and normalization (Section 3.3).

3.2 Experiment 1: Candidate classification

In this experiment, we measured the performance of the classification task in which pairs of strings were assigned with positive or negative labels. We trained and evaluated the proposed method by performing ten-fold cross validation on each dataset[5]. Eight baseline systems were prepared for comparison: Levenshtein distance (LD), normalized Levenshtein distance (NLD), Dice coefficient on letter bigrams (DICE) (Adamson and Boreham, 1974), Longest Common Substring Ratio (LCSR) (Melamed, 1999), Longest Common Prefix Ratio (PREFIX) (Kondrak, 2005), Porter's stemmer (Porter, 1980), Morpha (Minnen et al., 2001), and CST's lemmatiser (Dalianis and Jongejan, 2006)[6].

The five systems LD, NLD, DICE, LCSR, and PREFIX employ corresponding metrics of string distance or similarity. Each system assigns a positive label to a given pair of strings $\langle$s, t$\rangle$ if the distance/similarity of strings s and t is smaller/larger than the threshold δ (refer to equation 2 for distance metrics). The threshold of each system was chosen so that the system achieves the best F1 score.

The remaining three systems assign a positive label only if the system transforms the strings s and t into the identical string. For example, a pair of two words *studies* and *study* is classified as positive by Porter's stemmer, which yields the identical stem *studi* for these words. We trained CST's lemmatiser for each dataset to obtain flex patterns that are used for normalizing word inflections.

To examine the performance of the L_1-regularized logistic regression as a discriminative model, we also built two classifiers based on the Support Vector Machine (SVM). These SVM classifiers were implemented by the SVM^{perf}[7] on a linear kernel[8]. An SVM classifier employs the same feature set (substitution rules) as the proposed method so that we can directly compare the L_1-regularized logistic regression and the linear-kernel SVM. Another SVM classifier incorporates the five string metrics; this system can be considered as our reproduction of the discriminative string similarity proposed by Bergsma and Kondrak (2007).

Table 3 reports the precision (P), recall (R), and F1 score (F1) based on the number of correct decisions for positive instances. The proposed method outperformed the baseline systems, achieving 0.919, 0.888, and 0.984 of F1 scores, respectively. Porter's stemmer worked on the Inflection set, but not on the Orthography set, which is beyond the scope of the stemming algorithms. CST's lemmatizer suffered from low recall on the Inflection set because it removed suffixes of base forms, e.g., (*cloning*, *clone*) $\rightarrow$ (*clone*, *clo*). Morpha and CST's lemma-

[3]LRSPL table includes trivial spelling variants that can be handled using simple character/string operations. For example, the table contains spelling variants related to case sensitivity (e.g., *deg* and *Deg*) and symbols (e.g., *Feb* and *Feb.*).

[4]LRAGR table also provides agreement information even when word forms do not change. For example, the table contains an entry indicating that the first-singular present form of the verb *study* is *study*, which might be readily apparent to English speakers.

[5]We determined the regularization parameter $\sigma = 5$ experimentally. Refer to Figure 2 for the performance change.

[6]We used CST's lemmatiser version 2.13: `http://www.cst.dk/online/lemmatiser/uk/index.html`

[7]SVM for Multivariate Performance Measures (SVM^{perf}): `http://svmlight.joachims.org/svm_perf.html`

[8]We determined the parameter $C = 500$ experimentally; it controls the tradeoff between training error and margin.

tizer were not designed for orthographic variants and noun derivations.

Levenshtein distance ($\delta = 1$) did not work for the Derivation set because noun derivations often append two or more letters (e.g., *happy* $\rightarrow$ *happiness*). No string similarity/distance metrics yielded satisfactory results. Some metrics obtained the best F1 scores with extreme thresholds only to classify every instance as positive. These results imply the difficulty of the string metrics for the tasks.

The L_1-regularized logistic regression was comparable to the SVM with linear kernel in this experiment. However, the presented model presents the advantage that it can reduce the number of active features (features with non-zero weights assigned); the L_1 regularization can remove 74%, 48%, and 82% of substitution rules in each dataset. The performance improvements by incorporating string metrics as features were very subtle (less than 0.7%). What is worse, the distance/similarity metrics do not specifically derive destination strings to which the classifier is likely to assign positive labels. Therefore, we can no longer use the efficient algorithm as a candidate generator (in Section 2.4) with these features.

Table 4 demonstrates the ability of our approach to obtain effective features; the table shows the top 10 features with high weights assigned for the Orthography data. An interesting aspect of the proposed method is that the process of the orthographic variants is interpretable through the feature weights.

Figure 2 shows plots of the F1 scores (y-axis) for the Inflection data when we change the number of active features (x-axis) by controlling the regularization parameter σ from 0.001 to 100. The larger the value we set for σ, the better the classifier performs, generally, with more active features. In extreme cases, the number of active features drops to 97 with $\sigma = 0.01$; nonetheless, the classifier still achieves 0.961 of the F1 score. The result suggests that a small set of substitution rules can accommodate most cases of inflectional variations.

3.3 Experiment 2: String transformation

The second experiment examined the performance of the string normalization tasks formalized in equation 1. In this task, a system was given a string s and was required to yield either its transformed form t^* ($s \neq t^*$) or the string s itself when the transformation is unnecessary for s. The conditional probability distribution (scorer) in equation 1 was modeled

Table 5: Performance of string transformation

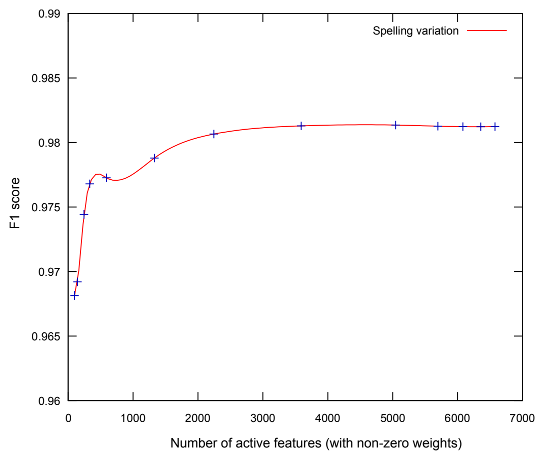

Figure 2: Number of active features and performance.

by the maximum entropy framework. Features for the maximum entropy model consist of: substitution rules between strings s and t, letter bigrams and trigrams in s, and letter bigrams and trigrams in t.

We prepared four datasets, *Orthography*, *Derivation*, *Inflection*, and *XTAG morphology*. Each dataset is a list of string pairs $\langle s, t\rangle$ that indicate the transformation of the string s into t. A source string s is identical to its destination string t when string s should not be changed. These instances correspond to the case where string s has already been lemmatized. For each string pair (s, t) in LRSPL[9], LRNOM, and LRAGR tables, we generated two instances $\langle s, t\rangle$ and $\langle t, t\rangle$. Consequently, a system is expected to leave the string t unchanged. We also used XTAG morphology[10] to perform a cross-domain evaluation of the lemmatizer trained on the Inflection dataset[11]. The entries in XTAG morphology that also appear in the Inflection dataset were 39,130 out of 317,322 (12.3 %). We evaluated the proposed method and CST's lemmatizer by performing ten-fold cross validation.

Table 5 reports the performance based on the number of correct transformations. The proposed method again outperformed the baseline systems with a wide margin. It is noteworthy that the proposed method can accommodate morphological inflections in the XTAG morphology corpus with no manual tuning or adaptation.

Although we introduced no assumptions about target tasks (e.g. a known vocabulary), the average number of positive substitution rules relevant to source strings was as small as 23.9 (in XTAG morphology data). Therefore, the candidate generator performed 23.9 substitution operations for a given string. It applied the decision rules (equation 7) 21.3 times, and generated 1.67 candidate strings per source string. The experimental results described herein demonstrated that the candidate generator was modeled successfully by the discriminative framework.

4 Related work

The task of string transformation has a long history in natural language processing and information retrieval. As described in Section 1, this task is related closely to various applications. Therefore, we specifically examine several prior studies that are relevant to this paper in terms of technical aspects.

Some researchers have reported the effectiveness of the discriminative framework of string similarity. MaCallum et al. (2005) proposed a method to train the costs of edit operations using Conditional Random Fields (CRFs). Bergsma and Kondrak (2007)

[9]We define that s precedes t in dictionary order.

[10]XTAG morphology database 1.5:
`ftp://ftp.cis.upenn.edu/pub/xtag/morph-1.5/morph-1.5.tar.gz`

[11]We found that XTAG morphology contains numerous incorrect comparative and superlative adjectives, e.g., *unpopular* → *unpopularer* → *unpopularest* and *refundable* → *refundabler* → *refundablest*. Therefore, we removed inflection entries for comparative and superlative adjectives from the dataset.

presented an alignment-based discriminative string similarity. They extracted features from substring pairs that are consistent to a character-based alignment of two strings. Aramaki et al. (2008) also used features that express the different segments of the two strings. However, these studies are not suited for a candidate generator because the processes of string transformations are intractable in their discriminative models.

Dalianis and Jongejan (2006) presented a lemmatiser based on suffix rules. Although they proposed a method to obtain suffix rules from a training data, the method did not use counter-examples (negatives) for reducing incorrect string transformations. Tsuruoka et al. (2008) proposed a scoring method for discovering a list of normalization rules for dictionary look-ups. However, their objective was to transform given strings, so that strings (e.g., *studies* and *study*) referring to the same concept in the dictionary are mapped into the same string (e.g., *stud*); in contrast, this study maps strings into their destination strings that were specified by the training data.

5 Conclusion

We have presented a discriminative approach for generating candidates for string transformation. Unlike conventional spelling-correction tasks, this study did not assume a fixed set of destination strings (e.g. correct words), but could even generate unseen candidate strings. We used an L_1-regularized logistic regression model with substring-substitution features so that candidate strings for a given string can be enumerated using the efficient algorithm. The results of experiments described herein showed remarkable improvements and usefulness of the proposed approach in three tasks: normalization of orthographic variants, noun derivation, and lemmatization.

The method presented in this paper allows only one region of change in string transformation. A natural extension of this study is to handle multiple regions of changes for morphologically rich languages (e.g. German) and to handle changes at the phrase/term level (e.g., "estrogen receptor" and "receptor of oestrogen"). Another direction would be to incorporate the methodologies for semi-supervised machine learning to accommodate situations in which positive instances and/or unlabeled strings are insufficient.

Abstract

Most attempts to integrate FrameNet in NLP systems have so far failed because of its limited coverage. In this paper, we investigate the applicability of distributional and WordNet-based models on the task of *lexical unit induction*, i.e. the expansion of FrameNet with new lexical units. Experimental results show that our distributional and WordNet-based models achieve good level of accuracy and coverage, especially when combined.

1 Introduction

Most inference-based NLP tasks require a large amount of semantic knowledge at the predicate-argument level. This type of knowledge allows to identify meaning-preserving transformations, such as active/passive, verb alternations and nominalizations, which are crucial in several linguistic inferences. Recently, the integration of NLP systems with manually-built resources at the predicate argument-level, such as FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005) has received growing interest. For example, Shen and Lapata (2007) show the potential improvement that FrameNet can bring on the performance of a Question Answering (QA) system. Similarly, several other studies (e.g. (Bar-Haim et al., 2005; Garoufi, 2007)) indicate that frame semantics plays a central role in Recognizing Textual Entailment (RTE). Unfortunately, most attempts to integrate FrameNet or similar resources in QA and RTE systems have so far failed, as reviewed respectively in (Shen and Lapata, 2007) and (Burchardt and Frank, 2006). These studies indicate *limited coverage* as the main reason of insuccess. Indeed, the FrameNet database only contains 10,000 lexical units (LUs), far less than the 210,000 entries in WordNet 3.0. Also, frames are based on more complex information than word senses, so that their manual development is much more demanding (Burchardt et al., 2006; Subirats and Petruck, 2003).

Therefore, there is nowadays a pressing need to adopt learning approaches to extend the coverage of the FrameNet lexicon by automatically acquiring new LUs, a task we call **LU induction**, as recently proposed at SemEval-2007 (Baker et al., 2007). Unfortunately, research in this area is still somehow limited and fragmentary. The aim of our study is to pioneer in this field by proposing two unsupervised models for LU induction, one based on distributional techniques and one using WordNet as a support; and a combined model which mixes the two. The goal is to investigate to what extent distributional and WordNet-based models can be used to induce frame semantic knowledge in order to safely extend FrameNet, thus limiting the high costs of manual annotation.

In Section 2 we introduce the LU induction task and present related work. In Sections 3, 4 and 5 we present our distributional, WordNet-based and combined models. Then, in Section 6 we report experimental results and comparative evaluations. Finally, in Section 7 we draw final conclusions and outline future work.

2 Task Definition and Related Work

As defined in (Fillmore, 1985), a frame is a conceptual structure modeling a prototypical situation, evoked in texts through the occurrence of its lexical units. A *lexical unit* (LU) is a predicate that linguistically expresses the situation of the frame. Lexical units of the same frame share semantic arguments. For example the frame KILLING has lexical units such as *assassin, assassinate, blood-bath, fatal, murderer, kill, suicide* that share semantic arguments such as KILLER, INSTRUMENT, CAUSE, VICTIM. Building on this frame-semantic model, the Berkeley FrameNet project (Baker et al., 1998) has been developing a frame-semantic lexicon for the core vocabulary of English since 1997. The current FrameNet release contains 795 frames and about 10,000 LUs. Part of FrameNet is also a corpus of 135,000 annotated example sentences from the British National Corpus (BNC).

LU induction is a fairly new task. Formally, it can be defined as the task of assigning a generic lexical unit not yet present in the FrameNet database (hereafter called *unknown LU*) to the correct frame(s). As the number of frames is very large (about 800) the task is intuitively hard to solve. A further complexity regards multiple assignments. Lexical units are sometimes ambiguous and can then be mapped to more than one frame (for example the word *tea* could map both to FOOD and SOCIAL_EVENT). Also, even unambiguous words can be assigned to more than one frame – e.g. *child* maps to both KINSHIP and PEOPLE_BY_AGE.

LU induction is relevant to many NLP tasks, such as the semi-automatic creation of new FrameNets, and semantic role labelling. LU induction has been integrated at SemEval-2007 as part of the Frame Semantic Structure Extraction shared task (Baker et al., 2007), where systems are requested to assign the correct frame to a given LU, even when the LU is not yet present in FrameNet. Johansson and Nugues (2007) approach the task as a machine learning problem: a Support Vector Machine trained on existing LUs is applied to assign unknown LUs to the correct frame, using features derived from the WordNet hierarchy. Tested on the FrameNet gold standard, the method achieves an accuracy of 0.78, at the cost of a low coverage of 31% (i.e. many LUs are not assigned). Johansson and Nugues (2007) also experiment with a simple model based on standard WordNet similarity measures (Pedersen et al., 2004), achieving lower performance. Burchardt and colleagues (2005) present Detour, a rule-based system using words in a WordNet relation with the unknown LU to find the correct frame. The system achieves an accuracy of 0.39 and a coverage of 87%. Unfortunately this algorithm requires the LU to be previously disambiguated, either by hand or using contextual information.

In a departure from previous work, our first model leverages distributional properties to induce LUs, instead of relying on pre-existing lexical resources as WordNet. This guarantees two main advantages. First, it can predict a frame for any unknown LU, while WordNet based approaches can be applied only to words having a WordNet entry. Second, it allows to induce LUs in languages for which WordNet is not available or has limited coverage. Our second WordNet-based model uses sense information to characterize the frame membership for unknown LU, by adopting a semantic similarity measure which is sensitive to *all* the known LUs of a frame.

3 Distributional model

The basic idea behind the distributional approach is to induce new LUs by modelling existing frames and unknown LUs in a semantic space, where they are represented as distributional co-occurrence vectors computed over a corpus.

Semantic spaces are widely used in NLP for representing the meaning of words or other lexical entities. They have been successfully applied in several tasks, such as information retrieval (Salton et al., 1975) and harvesting thesauri (Lin, 1998). The intuition is that the meaning of a word can be described by the set of textual contexts in which it appears (*Distributional Hypothesis* (Harris, 1964)), and that words with similar vectors are semantically related. In our setting, the goal is to find a semantic space model able to capture the notion of *frame* – i.e. the property of *"being characteristic of a frame"*. In such a model, an unknown LU is induced by first computing the similarity between its vector and the vectors of the existing frames, and then assigning the LU to the frame with the highest similarity.

3.1 Assigning unknown LUs to frames

In our model, a LU l is represented by a vector $\vec{l}$ whose dimensions represent the set of contexts C of the semantic space. The value of each dimension is given by the co-occurrence value of the LU with a contextual feature $c \in C$, computed over a large corpus using an association measure. We experiment with two different association measures: normalized frequency and pointwise mutual information. We approximate these measures by using Maximum Likelihood Estimation, as follows:

$$F(l,c) =_{MLE} \frac{|l,c|}{|*,*|}$$
$$MI(l,c) =_{MLE} \frac{|l,c||*,*|}{|*,c||l,*|} \tag{1}$$

where $|l,c|$ denotes the co-occurrence counts of the pair (l,c) in the corpus, $|*,c| = \sum_{l \in L} |l,c|$, $|l,*| = \sum_{c \in C} |l,c|$ and finally $|*,*| = \sum_{l \in L, c \in C} |l,c|$.

A frame f is modeled by a vector $\vec{f}$, representing the distributional profile of the frame in the semantic space. We here assume that a frame can be fully described by the set of its lexical units F. We implement this intuition by computing $\vec{f}$ as the weighted centroid of the set F, as follows:

$$\vec{f} = \sum_{l \in F} w_{lf} * \vec{l} \tag{2}$$

where w_{lf} is a weighting factor, accounting for the relevance of a given lexical unit with respect to the frame, estimated as:

$$w_{lf} = \frac{|l|}{\sum_{l \in F} |l|} \tag{3}$$

where $|l|$ denotes the counts of l in the corpus. From a more cognitive perspective, the vector $\vec{f}$ represents the prototypical lexical unit of the frame.

Given the set of all frames $\mathcal{N}$ and an unknown lexical unit ul, we assign ul to the frame $fmax_{ul}$ which is distributionally most similar – i.e. we intuitively map an unknown lexical unit to the frame whose prototypical lexical unit $\vec{f}$ has the highest similarity with $\vec{ul}$:

$$fmax_{ul} = argmax_{f \in \mathcal{N}} sim_D(\vec{ul}, \vec{f}) \tag{4}$$

In our model, we used the traditional cosine similarity:

$$sim_{cos}(ul, f) = \frac{\vec{ul} \cdot \vec{f}}{|\vec{ul}| * |\vec{f}|} \tag{5}$$

3.2 Choosing the space

Different types of contexts C define spaces with different semantic properties. We are here looking for a space able to capture the properties which characterise a frame. The most relevant of these properties is that LUs in the same frame tend to be either co-occurring or substitutional words (e.g. *assassin/kill* or *assassinate/kill*) – i.e. they are either in paradigmatic and syntagmatic relation. In an ideal space, a high similarity value sim_D would be then given both to *assassinate/kill* and to *assassin/kill*. We explore three spaces which seem to capture the above property well:

Word-based space: Contexts are words appearing in a n-window of the lexical unit. Such spaces model a generic notion of *semantic relatedness*. Two LUs close in the space are likely to be related by some type of generic semantic relation, either paradigmatic (e.g. synonymy, hyperonymy, antonymy) or syntagmatic (e.g. meronymy, conceptual and phrasal association).[1]

Syntax-based space: Contexts are syntactic relations (e.g. *X-VSubj-man* where X is the LU), as described in (Padó, 2007). These spaces are good at modeling *semantic similarity*. Two LUs close in the space are likely to be in a paradigmatic relation, i.e. to be close in a is-a hierarchy (Budanitsky and Hirst, 2006; Lin, 1998; Padó, 2007). Indeed, as contexts are syntactic relations, targets with the same part of speech are much closer than targets of different types.

Mixed space: In a combination of the two above spaces, contexts are words connected to the LU by a dependency path of at most length n. Unlike word-based spaces, contexts are selected in a more principled way: only syntactically related words are contexts, while other (possibly noisy) material is filtered out. Unlike syntax-based spaces, the context c does not explicitly state the type of syntactic relation with the LU: this usually allows to capture both paradigmatic and syntagmatic relations.

4 WordNet-based model

In a departure from previous work, our WordNet-based model does not rely on standard WordNet similarity measures (Pedersen et al., 2004), as these measures can only be applied to *pairs* of words, while we here need to capture the meaning of whole frames, which typically consist of larger sets of LUs. Our intuition is that senses able to evoke a frame can be detected via WordNet, by jointly considering the WordNet synsets activated by *all* LUs of the frame.

We implement this intuition in a weakly-supervised model, where each frame f is represented as a set of specific sub-graphs of the WordNet

[1]See (Padó, 2007; Sahlgren, 2006) for an in depth analysis.

hyponymy hierarchy. As different parts of speech have different WordNet hierarchies, we build a sub-graph for each of them: S_f^n for nouns, S_f^v for verbs and S_f^a for adjectives.[2] These sub-graphs represent the lexical semantic properties characterizing the frame. An unknown LU ul of a given part of speech is assigned to the frame whose corresponding sub-graph is semantically most similar to one of the senses of ul:

$$fmax_{ul} = argmax_{f \in \mathcal{N}} sim_{WN}(ul, f) \quad (6)$$

where sim_{WN} is a WordNet-based similarity measure. In the following subsections we will describe how we build sub-graphs and model the similarity measure for the different part of speech.

Figure 1 reports an excerpt of the noun sub-graph for the frame PEOPLE_BY_AGE, covering the suitable senses of its nominal LUs $\{adult, baby, boy, kid, youngster, youth\}$. The relevant senses (e.g. sense 1 of *youth* out of the 6 potential ones) are generally selected, as they share the most specific generalizations in WordNet with the other words.

Nouns. To compute similarity for *nouns* we adopt *conceptual density* (*cd*) (Agirre and Rigau, 1996), a semantic similarity model previously applied to word sense disambiguation tasks.

Given a frame f and its set of nominal lexical units F_n, the nominal subgraph S_f^n is built as follows. All senses of all words in F_n are activated in WordNet. All hypernyms H_f^n of these senses are then retrieved. Every synset $\sigma \in H_f^n$ is given a *cd* score, representing the *density* of the WordNet sub-hierarchy rooted at σ in representing the set of nouns F_n. The intuition behind this model is that the larger the number of LUs in F_n that are generalized by σ is, the better it captures the lexical semantics intended by the frame f. Broader generalizations are penalized as they give rise to bigger hierarchies, not well correlated with the full set of targets F_n.

To build the final sub-graph S_f^n, we apply the greedy algorithm proposed by Basili and colleagues (2004). It first computes the set of WordNet synsets that generalize at least two LUs in F_n, and then selects the subset of most dense ones $S_f^n \subset H_f^n$ that cover F_n. If a LU has no common hypernym with other members of F_n, it is not represented in S_f^n, and its similarity is set to 0 . S_f^n disambiguates words in F_n as only the lexical senses with at least one hypernym in S_f^n are considered.

Figure 1 shows the nominal sub-graph automatically derived using conceptual density for the frame PEOPLE_BY_AGE. The word *boy* is successfully disambiguated, as its only hypernym in the sub-graph refers to its third sense (*a male human offspring*) which correctly maps to the given frame. Notice that this model departs from the first sense heuristics largely successful in word sense disambiguation: most frames in fact are characterized by non predominant senses. The only questionable disambiguation is for the word $adult$: the wrong sense (*adult mammal*) is selected. However, even in these cases, the *cd* values are very low (about 10^{-4}), so that they do not impact much on the quality of the resulting inference.

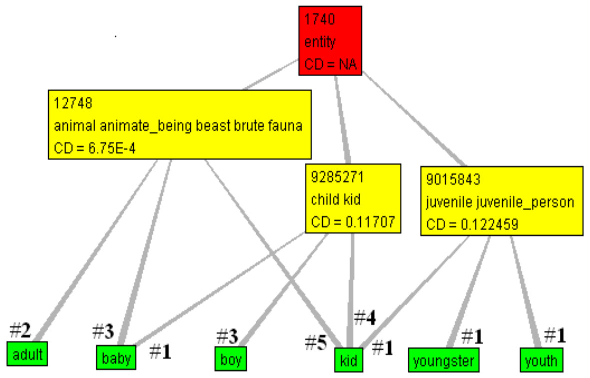

Figure 1: The noun sub-graph for the frame PEOPLE_BY_AGE as evoked by a subset of the words. Sense numbers #n refers to WordNet 2.0.

Using this model, LU induction is performed as follows. Given an unknown lexical unit ul, for each frame $f \in \mathcal{N}$ we first build the sub-graph S_f^n from the set $F_n \cup \{ul\}$. We then compute $sim_{WN}(f, ul)$ as the maximal *cd* of any synset $\sigma \in S_f^n$ that generalizes one of the lexical senses of ul. In the example *baby* would receive a score of 0.117 according to its first sense in WordNet 2.0 ("*baby,babe,infant*"). In a final step, we assign the LU to the most similar frame, according to Eq. 6

Verbs and Adjectives. As the conceptual density algorithm can be used only for nouns, we apply different similarity measures for verbs and adjectives.

[2]Our WordNet model does not cover the limited number of LUs which are not nouns, verbs or adjectives.

For *verbs* we exploit the co-hyponymy relation: the sub-graph S^v_f is given by all hyponyms of all verbs F_v in the frame f. Similarity $sim_{WN}(f, ul)$ is computed as follows:

$$sim_{WN}(ul, f) = \begin{cases} 1 & \textbf{iff } \exists K \subset F \text{ such that} \\ & |K| > \tau \textbf{ AND} \\ & \forall l \in K, l \text{ is a co-hyponym of } ul \\ \epsilon & \text{otherwise} \end{cases} \tag{7}$$

As for *adjectives*, WordNet does not provide a hyponymy hierarchy. We then compute similarity simply on the basis of the synonymy relation, as follows:

$$sim_{WN}(ul, f) = \begin{cases} 1 & \textbf{iff } \exists l \in F \text{ such that} \\ & l \text{ is a synonym of } ul \\ \epsilon & \text{otherwise} \end{cases} \tag{8}$$

5 Combined model

The methods presented so far use two independent information sources to induce LUs: distributional similarity sim_D and WordNet similarity sim_{WN}. We also build a joint model, leveraging both approaches: we expect the combination of different information to raise the overall performance. We here choose to combine the two approaches using a simple back-off model, that uses the WordNet-based model as a default and backs-off to the distributional one when no frame is proposed by the former. The intuition is that WordNet should guarantee the highest precision in the assignment, while distributional similarity should recover cases of low coverage.

6 Experiments

In this section we present a comparative evaluation of our models on the task of inducing LUs, in a leave-one-out setting over a reference gold standard.

6.1 Experimental Setup

Our gold standard is the FrameNet 1.3 database, containing 795 frames and a set L of 7,522 unique LUs (in all there are 10,196 LUs possibly assigned to more than one frame). Given a lexical unit $l \in L$, we simulate the induction task by executing a leave-one-out procedure, similarly to Burchardt and colleagues (2005). First, we remove l from all its original frames. Then, we ask our models to reassign it to the most similar frame(s) f, according to the similarity measure[3]. We repeat this procedure for all lexical units. Though our experiment is not completely realistic (we test over LUs already in FrameNet), it has the advantage of a reliable gold standard produced by expert annotators. A second, more realistic, small-scale experiment is described in Section 6.2.

We compute *accuracy* as the fraction of LUs in L that are correctly re-assigned to the original frame. Accuracy is computed at different levels k: a LU l is correctly assigned if its gold standard frame appears among the best-*k* frames f ranked by the model using the $sim(l, f)$ measure. As LUs can have more than one correct frame, we deem as correct an assignment for which at least one of the correct frames is among the best-*k*.

We also measure *coverage*, intended as the percentage of LUs that have been assigned to at least one frame by the model. Notice that when no sense preference can be found above the threshold ϵ, the WordNet-based model cannot predict any frame, thus decreasing coverage.

We present results for the following models and parametrizations (further parametrizations have revealed comparable performance).

Dist-word : the word-based space described in Section 3. Contextual features correspond to the set of the 4,000 most frequent words in the BNC.[4] The association measure between LUs and contexts is the pointwise mutual information. Valid contexts for LUs are fixed to a 20-window.

Dist-syntax : the syntax-based space described in Section 3. Context features are the 10,000 most frequent syntactic relations in the BNC[5]. As association measure we apply log-likelihood ratio (Dunning, 1993) to normalized frequency. Syntactic relations are extracted using the Minipar parser.

Dist-mixed : the mixed space described in Sec-

[3]In the distributional model, we recompute the centroids for each frame f in which the LU appeared, applying Eq. 2 to the set $F - \{l\}$.

[4]We didn't use the FrameNet corpus directly, as it is too small to obtain reliable statistics.

[5]Specifically, we use the minimum context selection function and the plain path value function described in Pado (2007).

tion 3. As for the *Dist-word* model, contextual features are 4,000 and pointwise mutual information is the association measure. The maximal dependency path length for selecting each context word is 3. Syntactic relations are extracted using Minipar.

WNet-full : the WordNet based model described in Section 4.

WNet-bsense : this model is computed as *WNet-full* but using only the most frequent sense for each LU as defined in WordNet.

Combined : the combined method presented in Section 5. Specifically, it uses *WNet-full* as a default and *Dist-word* as back-off.

Baseline-rnd : a baseline model, randomly assigning LUs to frames.

Baseline-mostfreq : a model predicting as best-*k* frames the most likely ones in FrameNet – i.e. those containing the highest number of LUs.

6.2 Experimental Results

Table 1 reports accuracy and coverage results for the different models, considering only 6792 LUs with frequency higher than 5 in the BNC, and frames with more than 2 lexical units (to allow better generalizations in all models). Results show that all our models largely outperform both baselines, achieving a good level of accuracy and high coverage. In particular, accuracy for the best-10 frames is high enoungh to support tasks such as the semi-automatic creation of new FrameNets. This claim is supported by a further task-driven experiment, in which we asked 3 annotators to assign 60 unknown LUs (from the Detour system log) to frames, with and without the support of the *Dist-word* model's predictions as suggestions[6]. We verified that our model guarantee an annotation speed-up of 25% – i.e. in average an annotator saves 25% of annotation time by using the system's suggestions.

Distributional vs. WordNet-based models. WordNet-based models are significantly better than distributional ones, for several reasons. First, distributional models acquire information only from the contexts in the corpus. As we do not use a FrameNet annotated corpus, there is no guarantee that the usage of a LU in the texts reflects exactly the semantic properties of the LU in FrameNet. In the extreme cases of polysemous LUs, it may happen that the textual contexts refer to senses which are not accounted for in FrameNet. In our study, we explicitly ignore the issue of polisemy, which is a notoriously hard task to solve in semantics spaces (see (Schütze, 1998)), as the occurrences of different word senses need to be clustered separately. We will approach the problem in future work. The WordNet-based model suffers from the problem of polisemy to a much lesser extent, as all senses are explicitly represented and separated in WordNet, including those related to the FrameNet gold standard.

A second issue regards data sparseness. The vectorial representation of LUs with few occurrences in the corpus is likely to be semantically incomplete, as not enough statistical evidence is available. Particularly skewed distributions can be found when some frames are very rarely represented in the corpus. A more in-depth descussion on these two issues is given later in this section.

Regarding the WordNet-based models, *WNet-full* in most cases outperforms *WNet-bsense*. The first sense heuristic does not seem to be as effective as in other tasks, such as Word Sense Disambiguation. Although sense preferences (or predominance) across two general purpose resources, such as WordNet and FrameNet, should be a useful hint, the conceptual density algorithm seems to produce better distributions (i.e. higher accuracy), especially when several solutions are considered. Indeed, for many LUs the first WordNet sense is not the one represented in the FrameNet database.

As for distributional models, results show that the *Dist-word* model performs best. In general, syntactic relations (*Dist-syntax* model) do not help to capture frame semantic properties better than a simple window-based approach. This seems to indicate that LUs in a same frame are related both by paradigmatic and syntagmatic relations, in accordance to the definition given in Section 3.2 – i.e. they are mostly semantically *related*, but not *similar*.

Coverage. Distributional models show a coverage 15% higher than WordNet-based ones. Indeed, as far as corpus evidence is available (i.e. the unknown LU appears in the corpus), distributional methods are always able to predict a frame. WordNet-based mod-

[6]For this purpose, the dataset is evenly split in two parts.

MODEL	B-1	B-2	B-3	B-4	B-5	B-6	B-7	B-8	B-9	B-10	COVERAGE

els cannot make predictions in two specific cases. First, when the LU is not present in WordNet. Second, when the function sim_{WN} does not has sufficient relational information to find a similar frame. This second factor is particularly evident for adjectives, as Eq. 8 assigns a frame only when a synonym of the unknown LU is found. It is then not surprising that 68% of the missed assignment are indeed adjectives.

Results for the *Combined* model suggest that the integration of distributional and WordNet-based methods can offer a viable solution to the coverage problem, as it achieves an accuracy comparable to the pure WordNet approaches, while keeping the coverage high.

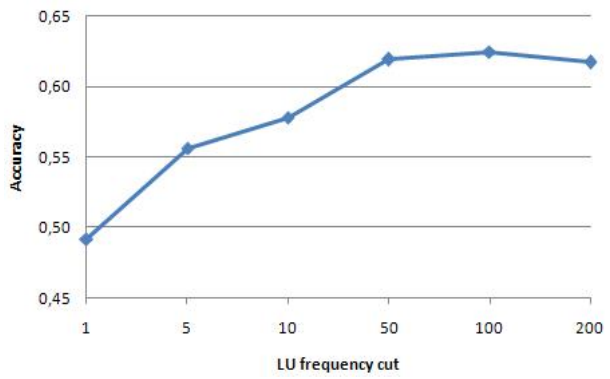

Figure 2: *Dist-word* model accuracy at different LU frequency cuts.

Data Sparseness. A major issue when using distributional approaches is that words with low frequency tend to have a very sparse non-meaningful representation in the vector space. This highly impacts on the accuracy of the models. To measure the impact of data sparseness, we computed the accuracy at different frequency cuts – i.e. we exclude LUs below a given frequency threshold from centroid computation and evaluation. Figure 2 reports the results for best-*10* assignment at different cuts, for the *Dist-word* model. As expected, accuracy improves by excluding infrequent LUs. Only at a frequency cut of 200 performance becomes stable, as statistical evidence is enough for a reliable prediction. Yet, in a real setting the improvement in accuracy implies a lower coverage, as the system would not classify LUs below the threshold. For example, by discarding LUs occurring less than 200 times in the corpus, we obtain a +0.12 improvement in accuracy, but the coverage decreases to 57%. However, uncovered LUs are also the most rare ones and their relevance in an application may be negligible.

Lexical Semantics, Ambiguity and Plausible Assignments. The overall accuracies achieved by our methods are "pessimistic", in the sense that they should be intended as lower-bounds. Indeed, a qualitative analysis of erroneous predictions reveals that in many cases the frame assignments produced by the models are semantically plausible, even if they are considered incorrect in the leave-one-out test. Consider for example the LU *guerrilla*, assigned in FrameNet to the frame PEOPLE BY VOCATION. Our mixed model proposes as two most similar frames MILITARY and TERRORISM, which could still be considered plausible assignment. The same holds for the LU *caravan*, for which the most similar frame is VEHICLE, while in FrameNet the LU is assigned only to the frame BUILDINGS. These cases are due to the low FrameNet coverage, i.e LUs are not fully annotated and they appear only in a subset of their potential frames. The real accuracy of our models is therefore expected to be higher.

To explore the issue, we carried out a qualitative analysis of 5 words (i.e. *abandon.v*, *accuse.v*, *body.n*, *charge.v* and *partner.n*). For each of them, we randomly picked 60 sentences from the BNC corpus, and asked two human annotators to assign to the correct frame the occurrence of the word in the given sentence. For 2 out of 5 words, no frame could be found for most of the sentences, suggesting that the most frequent frames for these words were missing from FrameNet[7]. We can then conclude that 100% accuracy cannot be considered as the upper-bound of our experiment, as word usage in texts is not well reflected in the FrameNet modelling.

Further experiments. We also tested our models on a realistic gold-standard set of 24 unknown LUs extracted from the SemEval-2007 corpus (Baker et al., 2007). These are words not present in FrameNet 1.3 which have been assigned by human annotators to an existing frame[8]. *WNet-full* achieves an accuracy of 0.25 for best-1 and 0.69 for best-10, with a coverage of 67%. A qualitative analysis showed that the lower performance wrt to our main experiment is due to higher ambiguity of the LUs (e.g. we assign *tea* to SOCIAL_EVENT instead of FOOD).

Comparison to other approaches. We compare our models to the system presented by Johansson and Nugues (2007) and Burchardt and colleagues (2005). Johansson and Nugues (2007) evaluate their machine learning system using 7,000 unique LUs to train the Support Vector Machine, and the remaining LUs as test. They measure accuracy at different coverage levels. At 80% coverage accuracy is about 0.42, 10 points below our best WordNet-based system. At 90% coverage, the system shows an accuracy below 0.10 and is significantly outperformed by both our distributional and combined methods. These results confirm that WordNet-based approaches, while being highly accurate wrt distributional ones, present strong weaknesses as far as coverage is concerned. Furthermore, Johansson and Nugues (2007) show that their machine learning approach outperforms a simple approach based on WordNet similarity: thus, our results indirectly prove that our WordNet-based method is more effective than the application of the similarity measure presented in (Pedersen et al., 2004).

We also compare our results to those reported by Burchardt and colleagues (2005) for Detour. Though the experimental setting is slightly different (LU assignment is done at the text-level), they use the same gold standard and leave-one-out technique, reporting a best-1 accuracy of 0.38 and a coverage of 87%. Our WordNet-based models significantly outperform Detour on best-1 accuracy, at the cost of lower coverage. Yet,our *combined* model is significantly better both on accuracy (+5%) and coverage (+8%). Also, in most cases Detour cannot predict more than one frame (best-1), while our accuracies can be improved by relaxing to any best-k level.

7 Conclusions

In this paper we presented an original approach for FrameNet LU induction. Results show that models combining distributional and WordNet information offer the most viable solution to model the notion of frame, as they allow to achieve a reasonable trade-off between accuracy and coverage. We also showed that in contrast to previous work, simple semantic spaces are more helpful than complex syntactic ones. Results are accurate enough to support the creation and the development of new FrameNets.

As future work, we will evaluate new types of spaces (e.g. dimensionality reduction methods) to improve the generalization capabilities of the space models. We will also address the data sparseness issue, by testing smoothing techniques to better model low frequency LUs. Finally, we will implement the presented models in a complex architecture for semi-supervised FrameNets development, both for specializing the existing English FrameNet in specific domains, and for creating new FrameNets in other languages.

Acknowledgements

This work has partly been funded by the German Research Foundation DFG (grant PI 154/9-3). Thanks to Richard Johansson and Aljoscha Burchardt for providing the data of their systems.

[7]Note that the need of new frames to account for semantic phenomena in free texts has been also demonstrated by the SemEval-2007 competition.

[8]The set does not contain 4 LUs which have no frame in FrameNet.

Abstract

We investigate the combination of several sources of information for the purpose of subjectivity recognition and polarity classification in meetings. We focus on features from two modalities, transcribed words and acoustics, and we compare the performance of three different textual representations: words, characters, and phonemes. Our experiments show that character-level features outperform word-level features for these tasks, and that a careful fusion of all features yields the best performance. [1]

1 Introduction

Opinions, sentiments and other types of subjective content are an important part of any meeting. Meeting participants express pros and cons about ideas, they support or oppose decisions, and they make suggestions that may or may not be adopted. When recorded and archived, meetings become a part of the organizational knowledge, but their value is limited by the ability of tools to search and summarize meeting content, including subjective content. While progress has been made on recognizing primarily objective meeting content, for example, information about the topics that are discussed (Hsueh and Moore, 2006) and who is assigned to work on given tasks (Purver et al., 2006), there has been fairly little work specifically directed toward recognizing subjective content.

In contrast, there has been a wealth of research over the past several years on automatic subjectivity and sentiment analysis in text, including on-line media. Partly inspired by the rapid growth of social media, such as blogs, as well as on-line news and reviews, researchers are now actively addressing a wide variety of new tasks, ranging from blog mining (e.g., finding opinion leaders in an on-line community), to reputation management (e.g. finding negative opinions about a company on the web), to opinion-oriented summarization and question answering. Yet many challenges remain, including how best to represent and combine linguistic information for subjectivity analysis. With the additional modalities that are present when working with face-to-face spoken communication, these challenges are even more pronounced.

The work in this paper focuses on two tasks: (1) recognizing subjective utterances and (2) discriminating between positive and negative subjective utterances. An utterance may be subjective because the speaker is expressing an opinion, because the speaker is discussing someone else's opinion, or because the speaker is eliciting the opinion of someone else with a question.

We approach the above tasks as supervised machine learning problems, with the specific goal of finding answers to the following research questions:

- Given a variety of information sources, such as text arising from (transcribed) speech, phoneme representations of the words in an utterance, and acoustic features extracted from

[1] This work was supported by the Dutch BSIK-project MultimediaN, and the European IST Programme Project FP6-0033812. This paper only reflects the authors' views and funding agencies are not liable for any use that may be made of the information contained herein.

the audio layer, which of these sources are particularly valuable for subjectivity analysis in multiparty conversation?

- Does the combination of these sources lead to further improvement?
- What are the optimal representations of these information sources in terms of feature design for a machine learning component?

A central tenet of our approach is that subword representations, such as *character* and *phoneme n-grams*, are beneficial for the tasks at hand.

2 Subword Features

Previous work has demonstrated that textual units below the word level, such as character n-grams, are valuable sources of information for various text classification tasks. An example of character n-grams is the set of 3-grams {`#se, sen, ent, nti, tim, ime, men, ent, nt#, t#a, #an, ana, nal, aly, lys, ysi, sis, is#`} for the two-word phrase *sentiment analysis*. The special symbol # represents a word boundary. While it is not directly obvious that there is much information in these truncated substrings, character n-grams have successfully been used for fine-grained classification tasks, such as named-entity recognition (Klein et al., 2003) and subjective sentence recognition (Raaijmakers and Kraaij, 2008), as well as a variety of document-level tasks (Stamatatos, 2006; Zhang and Lee, 2006; Kanaris and Stamatatos, 2007).

The informativeness of these low-level features comes in part from a form of *attenuation* (Eisner, 1996): a slight abstraction of the underlying data that leads to the formation of string equivalence classes. For instance, words in a sentence will invariably share many character n-grams. Since every unique character n-gram in an utterance constitutes a separate feature, this leads to the formation of string classes, which is a form of abstraction. For example, Zhang and Lee (2006) investigate similar subword representations, called key substring group features. By compressing substrings in a corpus in a trie (a prefix tree), and labeling entire sets of distributionally equivalent substrings with one group label, an attenuation effect is obtained that proves very beneficial for a number of text classification tasks.

Aside from attenuation effects, character n-grams, especially those that represent word boundaries, have additional benefits. Treating word boundaries as characters captures micro-phrasal information: short strings that express the transition of one word to another. Stemming occurs naturally within the set of initial character n-grams of a word, where the suffix is left out. Also, some part-of-speech information is captured. For example, the modals *could, would, should* can be represented by the 4-gram, `ould`, and the set of adverbs ending in *-ly* can be represented by the 3-gram `ly#`.

A challenging thought is to extend the use of n-grams to the level of phonemes, which comprise the first symbolic level in the process of sound to grapheme conversion. If n-grams of phonemes compare favorably to word n-grams for the purpose of sentiment classification, then significant speedups can be obtained for online sentiment classification, since tokenization of the raw speech signal can make a halt at the phoneme level.

3 Data

For this work we use 13 meetings from the AMI Meeting Corpus (Carletta et al., 2005). Each meeting has four participants and is approximately 30 minutes long. The participants play specific roles (e.g., Project Manager, Marketing Expert) and together function as a design team. Within the set of 13 meetings, there are a total of 20 participants, with each participant taking part in two or three meetings as part of the same design team. Meetings with the same set of participants represent different stages in the design process (e.g., Conceptual Design, Detailed Design).

The meetings used in the experiments have been annotated for subjective content using the AMIDA annotation scheme (Wilson, 2008). Table 1 lists the types of annotations that are marked in the data. There are three main categories of annotations, *subjective utterances*, *subjective questions*, and *objective polar utterances*. A subjective utterance is a span of words (or possibly sounds) where a *private state* is being expressed either through choice of words or prosody. A private state (Quirk et al., 1985) is an internal mental or emotional state, including opinions, beliefs, sentiments, emotions, evaluations, uncertainties, and speculations, among others. Although typically when a private state is expressed it is the private state of the speaker, as in example (1) below, an utterance may also be subjective because the speaker is talking about the private state of someone else. For example, in (2) the negative opinion attributed to the company is what makes the utterance subjective.

> (1) Finding them is really a pain, you know
> (2) The company's decided that teletext is outdated

Subjective questions are questions in which the speaker is eliciting the private state of someone else. In other words, the speaker is asking about what someone else thinks, feels, wants, likes, etc., and the speaker is expecting a response in which the other person expresses what he or she thinks, feels, wants, or likes. For example, both (3) and (4) below are subjective questions.

> (3) Do you like the large buttons?
> (4) What do you think about the large buttons?

Objective polar utterances are statements or phrases that describe positive or negative factual information about something without conveying a private state. The sentence *The camera broke the first time I used it* gives an example of negative factual information; generally, something breaking the first time it is used is not good.

For the work in this paper, we focus on recognizing subjectivity in general and distinguishing between positive and negative subjective utterances. *Positive subjective* utterances are those in which any of the following types of private states are expressed: agreements, positive sentiments, positive suggestions, arguing for something, beliefs from which positive sentiments can be inferred, and positive responses to subjective questions. *Negative subjective* utterances express private states that are the opposite of those represented by the positive subjective category: disagreements, negative sentiments, negative suggestions, arguing against something, beliefs from which negative sentiments can be inferred, and negative responses to subjective questions. Example (5) below contains two positive subjective utterances and one negative subjective utterance. Each annotation is indicated by a pair of angle brackets.

Table 1: AMIDA Subjectivity Annotation Types

Subjective Utterances

negative objective

> (5) Um ⟨**POS-SUBJ** it's very easy to use⟩. Um ⟨**NEG-SUBJ** but unfortunately it does lack the advanced functions⟩ ⟨**POS-SUBJ** which I I quite like having on the controls⟩.

The *positive and negative subjective* category is for marking cases of positive and negative subjectivity that are so closely interconnected that it is difficult or impossible to separate the two. For example, (6) below is marked as both positive and negative subjective.

> (6) Um ⟨**POS-AND-NEG-SUBJ** they've also suggested that we um we only use the remote control to control the television, not the VCR, DVD or anything else⟩.

In (Wilson, 2008), agreement is measured for each class separately at the level of dialogue act segments. If a dialogue act overlaps with an annotation of a particular type, then the segment is considered to be labelled with that type. Table 2 gives the Kappa (Cohen, 1960) and % agreement for subjective segments, positive and negative subjective segments,[2] and subjective questions.

[2]A positive subjective segment is any dialogue act segment that overlaps with a positive subjective utterance or a positive-and-negative subjective utterance. The negative subjective segments are defi ned similarly.

Table 2: Interannotator agreement for the AMIDA subjectivity annotations

	Kappa	% Agree
Subjective	0.56	79
Pos Subjective	0.58	84
Neg Subjective	0.62	92
Subjective Question	0.56	95

4 Experiments

We conduct two sets of classification experiments. For the first set of experiments (Task 1), we automatically distinguish between subjective and non-subjective utterances. For the second set of experiments (Task 2), we focus on distinguishing between positive and negative subjective utterances. For both tasks, we use the manual dialogue act segments available as part of the AMI Corpus as the unit of classification. For Task 1, a segment is considered subjective if it overlaps with either a subjective utterance or subjective question annotation. For Task 2, the segments being classified are those that overlap with positive or negative subjective utterances. For this task, we exclude segments that are both positive and negative. Although limiting the set of segments to be classified to just those that are positive or negative makes the task somewhat artificial, it also allows us to focus in on the performance of features specifically for this task.[3] We use 6226 subjective and 8707 non-subjective dialog acts for Task 1 (with an average duration of 1.9s, standard deviation of 2.0s), and 3157 positive subjective and 1052 negative subjective dialog acts for Task 2 (average duration of 2.6s, standard deviation of 2.3s).

The experiments are performed using 13-fold cross validation. Each meeting constitutes a separate fold for testing, e.g., all the segments from meeting 1 make up the test set for fold 1. Then, for a given fold, the segments from the remaining 12 meetings are used for training and parameter tuning, with roughly a 85%, 7%, and 8% split between training, tuning, and testing sets for each fold. The assignment to training versus tuning set was random, with the only constraint being that a segment could only be in the tuning set for one fold of the data.

[3]In practice, this excludes about 7% of the positive/negative segments.

The experiments we perform involve two steps. First, we train and optimize a classifier for each type of feature using BoosTexter (Schapire and Singer, 2000) AdaBoost.MH. Then, we investigate the performance of all possible combinations of features using linear combinations of the individual feature classifiers.

4.1 Features

The two modalities that are investigated, prosodic, and textual, are represented by four different sets of features: prosody (PROS), word n-grams (WORDS), character n-grams (CHARS), and phoneme n-grams (PHONES).

Based on previous research on prosody modelling in a meeting context (Wrede and Shriberg, 2003) and on the literature in emotion research (Banse and Scherer, 1996) we extract PROS features that are mainly based on pitch, energy and the distribution of energy in the long-term averaged spectrum (LTAS) (see Table 3). These features are extracted at the word level and aggregated to the dialogue-act level by taking the average over the words per dialogue act. We then normalize the features per speaker per meeting by converting the raw feature values to z-scores ($z = (x - \mu)/\sigma$).

Table 3: Prosodic features used in experiments.

pitch	mean, standard deviation, minimum, maximum, range, mean absolute slope
intensity (energy)	mean, standard deviation, minimum, maximum, range, RMS energy
distribution energy in LTAS	slope, Hammerberg index, centre of gravity, skewness

The textual features, WORDS and CHARS, and the PHONES features are based on a manual transcription of the speech. The PHONES were produced through dictionary lookup on the words in the reference transcription. Both CHARS and PHONES representations include word boundaries as informative tokens. The textual features for a given segment are simply all the WORDS/CHARS/PHONES in that segment. Selection of n-grams is performed by the learning algorithm.

4.2 Single Source Classifiers

We train four single source classifiers using BoosTexter, one for each type of feature. For the WORDS, CHARS, and PHONES, we optimize the classifier by performing a grid search over the parameter space, varying the number of rounds of boosting (100, 500, 1000, 2000, 5000), the length of the n-gram (1, 2, 3, 4, 5), and the type of n-gram. BoosTexter can be run with three different n-gram configurations: n-gram, s-gram, and f-gram. For the default configuration (n-gram), BoosTexter searches for n-grams up to length n. For example, if $n = 3$, BoosTexter will consider 1-grams, 2-grams, and 3-grams. For the s-gram configuration, BoosTexter will in addition consider sparse n-grams (i.e., n-grams containing wildcards), such as *the * idea*. For the f-gram configuration, BoosTexter will only consider n-grams of a maximum fixed length, e.g., if $n = 3$ BoosTexter will only consider 3-grams. For the PROS classifier, only the number of rounds of boosting was varied. The parameters are selected for each fold separately; the parameter set that produces the highest subjective F_1 score on the tuning set for Task 1, and the highest positive subjective F_1 score for Task 2, is used to train the final classifier for that fold.

4.3 Classifier combination

After the single source classifiers have been trained, they have to be combined into an aggregate classifier. To this end, we decided to apply a simple linear interpolation strategy. Linear interpolation of models is the weighted combination of simple models to form complex models, and has its roots in generative language models (Jelinek and Mercer, 1980). (Raaijmakers, 2007) has demonstrated its use for discriminative machine learning.

In the present binary class setting, BoosTexter produces two decision values, one for every class. For every individual single-source classifier (i.e., PROS, WORDS, CHARS and PHONES), separate weights are estimated that are applied to the decision values for the two classes produced by these classifiers. These weights express the relative importance of the single-source classifiers.

The prediction of an aggregate classifier for a class c is then simply the sum of all weights for all participating single-source classifiers applied to the decision values these classifiers produce for this class. The class with the maximum score wins, just as in the simple non-aggregate case.

Formally, then, this linear interpolation strategy finds for n single-source classifiers n interpolation weights $\lambda_1, \dots \lambda_n$ that minimize the empirical loss (measured by a loss function $\mathcal{L}$), with λ_j the weight of classifier j ($\lambda \in [0,1]$), and $C_c^j(x_i)$ the decision value of class c produced by classifier j for datum x_i (a feature vector). The two classes are denoted with $0, 1$. The true class for datum x_i is denoted with $\hat{x}_i$. The loss function is in our case based on subjective F-measure (Task 1) or positive subjective F-measure (Task 2) measured on heldout development training and test data.

The aggregate prediction $\tilde{x_i}$ for datum x_i on the basis of n single-source classifiers then becomes

$$\tilde{x_i} = \arg\max_c \left(\sum_{j=1}^{n} \lambda_j \cdot C_{c=0}^j(x_i), \sum_{j=1}^{n} \lambda_j \cdot C_{c=1}^j(x_i)\right) \tag{1}$$

and the lambdas are defined as

$$\lambda_j^n = \arg \min_{\lambda_j^n \subset [0,1]} \sum_i^k \mathcal{L}(\hat{x}_i, \tilde{x}_i; \lambda_j, \dots, \lambda_n) \tag{2}$$

The search process for these weights can easily be implemented with a simple grid search over admissible ranges.

In the experiments described below, we investigate all possible combinations of the four different sets of features (PROS, WORDS, CHARS, and PHONES) to determine which combination yields the best performance for subjectivity and subjective polarity recognition.

5 Results and Discussion

Results for the two tasks are given in Tables 4 and 5 and in Figures 1 and 2. We use two baselines, listed at the top of each table. The bullets in a given row indicate the features that are being evaluated for a given experiment. In Table 4, subjective F_1, recall, and precision are reported as well as overall accuracy. In Table 4, the F_1, recall, and precision scores are for the positive subjective class. All values in the tables are averages over the 13 folds.

Table 4: Results Task 1: Subjective vs. Non-Subjective.

	PROS	WORDS	CHARS	PHONES	F_1	PREC	REC	ACC

It is quite obvious that the combination of different sources of information is beneficial, and in general, the more information the better the results. The best performing classifier for Task 1 uses all the features, achieving a subjective F_1 of 67.1. For Task 2, the best performing classifier also uses all the features, although it does not perform significantly better than the classifier using only WORDS, CHARS, and PHONES.[4] This classifier achieves a positive-subjective F_1 of 89.9.

We measured the effects of adding more information to the single source classifiers. These results are listed in Table 6. Of the various feature types, prosody seems to be the least informative for both subjectivity and polarity classification. In addition to producing the single-source classifier with the lowest performance for both tasks, Table 6 shows that when prosody is added, of all the features it is least likely to yield significant improvements.

Throughout the experiments, adding an additional type of textual feature always yields higher results. In all cases but two, these improvements are significant. The best performing of the features are the character n-grams. Of the single-source experiments, the character n-grams achieve the best performance, with significant improvements in F_1 over the other single-source classifiers for both Task 1 and Task 2. Also, adding character n-grams to other feature combinations always gives significant improvements in performance.

An obvious question that remains is what the effect is of classifier interpolation on the results. To answer this question, we conducted two additional experiments for both tasks. First, we investigated the performance of an uninterpolated combination of the four single-source classifiers. In essence, this combines the separate feature spaces without explicitly weighting them. Second, we investigated the results of training a single BoosTexter model using all the features, essentially merging all feature spaces

[4]We measured significance with the non-parametric Wilcoxon signed rank test, $p < 0.05$.

Table 6: Addition of features separately (for Task 1 and 2): '+' for a row-column pair (r, c) means that the addition of column feature c to the row features r significantly improved r's F_1; '-' indicates no significant improvement; 'X' means 'not applicable'

into one agglomerate feature space. The results for these experiments are given in Table 7, along with the results from the all-feature interpolated classification for comparison.

The results in Table 7 show that interpolation outperforms both the unweighted and single-model combinations for both tasks. For Task 1, the effect of interpolation compared to a single model is marginal (a .03 point difference in F_1). However, compared to the uninterpolated combination, interpolation gives a clear 3.1 points improvement of F_1. For Task 2, interpolation outperforms both the uninterpolated and single-model classifiers, with 2 and 3 points improvements in F_1, respectively.

6 Related Work

Previous work has demonstrated that textual units below the word level, such as character n-grams, are valuable sources of information. Character-level models have successfully been used for named-entity recognition (Klein et al., 2003), predicting authorship (Keselj et al., 2003; Stamatatos, 2006), text categorization (Zhang and Lee, 2006), web page genre identification (Kanaris and Stamatatos, 2007), and sentence-level subjectivity recognition (Raaijmakers and Kraaij, 2008) In spoken-language data, Hsueh (2008) achieves good results using chains of phonemes to automatically segment meetings according to topic. However, to the best of our knowledge there has been no investigation to date on the

Table 7: Results of interpolated classifiers compared to uninterpolated and single-model classifiers for all features.

Task	Combination	ACC	REC	PREC	F_1
1	interpolated	75.4	61.2	74.5	67.1
	uninterpolated	73.0	58.7	70.6	64.0

combination of character-level, phoneme-level, and word-level models for any natural language classification tasks.

In text, there has been a significant amount of research on subjectivity and sentiment recognition, ranging from work at the phrase level to work on classifying sentences and documents. Sentence-level subjectivity classification (e.g., (Riloff and Wiebe, 2003; Yu and Hatzivassiloglou, 2003)) and sentiment classification (e.g., (Yu and Hatzivassiloglou, 2003; Kim and Hovy, 2004; Hu and Liu, 2004; Popescu and Etzioni, 2005)) is the research in text most closely related to our work. Of the sentence-level research, the most similar is work by Raaijmakers and Kraaij (2008) comparing word-spanning character n-grams to word-internal character n-grams for subjectivity classification in news data. They found that character n-grams spanning words perform the best.

Research on recognizing subjective content in multiparty conversation includes work by Somasundaran et al. (2007) on recognizing sentiments and arguing in meetings, work by Neiberg el al. (2006) on recognizing positive, negative, and neutral emotions in meetings, work on recognizing agreements and disagreements in meetings (Hillard et al., 2003; Galley et al., 2004; Hahn et al., 2006), and work by Wrede and Shriberg (2003) on recognizing meeting hotspots. Somasundaran et al. use lexical and discourse features to recognize sentences and turns where meeting participants express sentiments or arguing. They also use the AMI corpus in their work; however, the use of different annotations and task definitions makes it impossible to directly compare their results and ours. Neiberg et al. use acoustic–prosodic features (Mel-frequency Cepstral Coefficients (MFCCs) and pitch features) and lexical n-grams for recognizing emotions in the ISL Meeting Corpus (Laskowski and Burger, 2006).

Agreements and disagreements are a subset of the private states represented by the positive and negative subjective categories used in this work. To recognise agreements and disagreements automatically, Hillard et al. train 3-way decision tree classifiers (agreement, disagreement, other) using both word-based and prosodic features. Galley et al. model this task as a sequence tagging problem, and investigate whether features capturing speaker interactions are useful for recognizing agreements and disagreements. Hahn et al. investigate the use of contrast classifiers (Peng et al., 2003) for the task, using only lexical features.

Hotspots are places in a meeting in which the participants are highly involved in the discussion. Although high involvement does not necessarily equate subjective content, in practice, we expect more sentiments, opinions, and arguments to be expressed when participants are highly involved in the discussion. In their work on recognizing meeting hotspots, Wrede and Shriberg focus on evaluating the contribution of various prosodic features, ignoring lexical features completely. The results of their study helped to inform our choice of prosodic features for the experiments in this paper.

7 Conclusions

In this paper, we investigated the use of prosodic features, word n-grams, character n-grams, and phoneme n-grams for subjectivity recognition and polarity classification of dialog acts in multiparty conversation. We show that character n-grams outperform prosodic features, word n-grams and phoneme n-grams in subjectiviy recognition and polarity classification. Combining these features significantly improves performance. Comparing the additive value of the four information sources available, prosodic information seem to be least informative while character-level information indeed proves to be a very valuable source. For subjectivity recognition, a combination of prosodic, word-level, character-level, and phoneme-level information yields the best performance. For polarity classification, the best performance is achieved with a combination of words, characters and phonemes.

Adapting a Lexicalized-Grammar Parser to Contrasting Domains

Laura Rimell and **Stephen Clark**

{laura.rimell,stephen.clark}@comlab.ox.ac.uk

Abstract

Most state-of-the-art wide-coverage parsers are trained on newspaper text and suffer a loss of accuracy in other domains, making parser adaptation a pressing issue. In this paper we demonstrate that a CCG parser can be adapted to two new domains, biomedical text and questions for a QA system, by using manually-annotated training data at the POS and lexical category levels only. This approach achieves parser accuracy comparable to that on newspaper data without the need for annotated parse trees in the new domain. We find that retraining at the lexical category level yields a larger performance increase for questions than for biomedical text and analyze the two datasets to investigate why different domains might behave differently for parser adaptation.

1 Introduction

Most state-of-the-art wide-coverage parsers are based on the Penn Treebank (Marcus et al., 1993), making such parsers highly tuned to newspaper text. A pressing question facing the parsing community is how to adapt these parsers to other domains, such as biomedical research papers and web pages. A related question is how to improve the performance of these parsers on constructions that are rare in the Penn Treebank, such as questions. Questions are particularly important since a question parser is a component in most Question Answering (QA) systems (Harabagiu et al., 2001).

In this paper we investigate parser adaptation in the context of lexicalized grammars, by using a parser based on Combinatory Categorial Grammar (CCG) (Steedman, 2000). A key property of CCG is that it is lexicalized, meaning that each word in a sentence is associated with an elementary syntactic structure. In the case of CCG this is a lexical category expressing subcategorization information. We exploit this property of CCG by performing manual annotation in the new domain, but only up to this level of representation, where the annotation can be carried out relatively quickly. Since CCG lexical categories are so expressive, many of the syntactic characteristics of a domain are captured at this level.

The two domains we consider are the biomedical domain and questions for a QA system. We use the term “domain” somewhat loosely here, since questions are best described as a particular set of syntactic constructions, rather than a set of documents about a particular topic. However, we consider question data to be interesting in the context of domain adaptation for the following reasons: 1) there are few examples in the Penn Treebank (PTB) and so PTB parsers typically perform poorly on them; 2) questions form a fairly homogeneous set with respect to the syntactic constructions employed, and it is an interesting question how easy it is to adapt a parser to such data; and 3) QA is becoming an important example of NLP technology, and question parsing is an important task for QA systems.

The CCG parser we use (Clark and Curran, 2007b) makes use of three levels of representation: one, a POS tag level based on the fairly coarse-grained POS tags in the Penn Treebank; two, a lexical category level based on the more fine-grained CCG lexical categories, which are assigned to words by a CCG supertagger; and three, a hierarchical level consisting of CCG derivations. A key idea in this paper, following a pilot study in Clark et al. (2004), is to perform manual annotation only at the first two levels. Since the lexical category level consists of sequences of tags, rather than hierarchical derivations, the annotation can be performed relatively quickly.

For the biomedical and question domains we manually annotated approximately 1,000 and 2,000 sentences, respectively, with CCG lexical categories. We also created a gold standard set of grammatical relations (GR) in the Stanford format (de Marneffe et al., 2006), using 500 of the questions. For the biomedical domain we used the BioInfer corpus (Pyysalo et al., 2007a), an existing gold-standard GR resource also in the Stanford format. We evaluated the parser on both lexical category assignment and recovery of GRs.

The results show that the domain adaptation approach used here is successful in two very different domains, achieving parsing accuracy comparable to state-of-the-art accuracy for newspaper text. The results also show, however, that the two domains have different profiles with regard to the levels of representation used by the parser. We find that simply retraining the POS tagger used by the parser leads to a large improvement in performance for the biomedical domain, and that retraining the CCG supertagger on the annotated biomedical data improves the performance further. For the question data, retraining just the POS tagger also improves parser performance, but retraining the supertagger has a much greater effect. We perform some analysis of the two datasets in order to explain the different behaviours with regard to porting the CCG parser.

2 The CCG Parser

The CCG parser is described in detail in Clark and Curran (2007b) and so we provide only a brief description. The stages in the CCG parsing pipeline are as follows. First, a maximum entropy POS tagger assigns a single POS tag to each word in a sentence. POS tags are fairly coarse-grained grammatical labels indicating part-of-speech; the Penn Treebank set, used here, contains approximately 50 labels.

Second, a maximum entropy supertagger assigns CCG lexical categories to the words in the sentence. Lexical categories can be thought of as fine-grained POS tags expressing subcategorization information, i.e. information about the argument frame of the word. There are 425 categories in the set used by the CCG parser. Supertagging was originally developed for Lexicalized Tree Adjoining Grammar (Bangalore and Joshi, 1999), but has been particularly successful for wide-coverage CCG parsing (Clark and Curran, 2007b). Rather than assign a single category to each word, the supertagger operates as a multi-tagger, sometimes assigning more than one category if the context is not sufficiently discriminating to suggest a single tag (Curran et al., 2006). Since the taggers have linear time complexity, the first two stages can be performed extremely quickly.

Finally, the parsing stage combines the lexical categories, using a small set of combinatory rules that are part of the grammar of CCG, and builds a packed chart representation containing all the derivations which can be built from the lexical categories. The Viterbi algorithm efficiently finds the highest scoring derivation from the packed chart, using a log-linear model to score the derivations. The grammar and training data for the newspaper version of the CCG parser are obtained from CCGbank (Hockenmaier and Steedman, 2007), a CCG version of the Penn Treebank.

The aspect of the pipeline which is most relevant to this paper is the supertagging phase. Figure 1 gives an example sentence from each target domain, with the CCG lexical category assigned to each word shown below the word, and the POS tag to the right. Note that the categories contain a significant amount of grammatical information, in particular subcategorization information. The verb *acts* in the biomedical sentence, for example, looks for a prepositional phrase (PP, *as a linkage protein*) to its right and a noun phrase (NP, *Talin*) to its left, with the resulting category a declarative sentence (S[dcl]).

Bangalore and Joshi (1999) refer to supertagging as *almost parsing*, because once the correct lexical categories have been assigned, the parser is left with much less work to do. The CCG supertagger is not able to assign a single category to each word with extremely high accuracy — hence the need for it to operate as a multi-tagger — but even in multi-tagger mode it dramatically reduces the ambiguity passed through to the parser (Clark and Curran, 2007b).

$$\begin{array}{cccccccc} \text{Talin}|\text{NN} & \text{perhaps}|\text{RB} & \text{acts}|\text{VBZ} & \text{as}|\text{IN} & \text{a}|\text{DT} & \text{linkage}|\text{NN} & \text{protein}|\text{NN} & .|. \\ \overline{NP} & \overline{(S\backslash NP)/(S\backslash NP)} & \overline{(S[dcl]\backslash NP)/PP} & \overline{PP/NP} & \overline{NP[nb]/N} & \overline{N/N} & \overline{N} & \overline{.} \end{array}$$

$$\begin{array}{ccccccc} \text{What}|\text{WDT} & \text{king}|\text{NN} & \text{signed}|\text{VBD} & \text{the}|\text{DT} & \text{Magna}|\text{NNP} & \text{Carta}|\text{NNP} & ?|. \\ \overline{(S[wq]/(S[dcl]\backslash NP))/N} & \overline{N} & \overline{(S[dcl]\backslash NP)/NP} & \overline{NP[nb]/N} & \overline{N/N} & \overline{N} & \overline{.} \end{array}$$

Figure 1: Example sentences with lexical category assignment.

The parser has been evaluated on DepBank (King et al., 2003), using the GR scheme of Briscoe et al. (2006), and it scores 82.4% labelled precision and 81.2% labelled recall overall (Clark and Curran, 2007a). Section 4.4 describes how the CCG dependencies can be mapped into the Stanford GR scheme (de Marneffe et al., 2006) and gives the results of evaluating the parser on biomedical and question GR resources.

The CCG parser is particularly well suited to the biomedical and question domains. First, use of CCG allows recovery of long-distance dependencies. In the sentence *What does target heart rate mean?*, the word *What* is an underlying object of the verb *mean*. The parser recovers this information despite the distance between the two words. This capability is crucial for question parsing, and also useful in the biomedical field for extraction of relationships between biological entities. Additionally, the speed of the parser (tens of sentences per second) is useful for the large volumes of biomedical data that require processing for biomedical text mining.

3 Approach

Our approach to domain adaptation is to target the coarser-grained, less syntactically complex, levels of representation used by the parser, and to train new models with manually annotated data at these levels. The motivation for this approach is twofold. First, accuracy at each stage of the pipeline depends on accuracy at the earlier stages. If the POS tagger assigns incorrect tags, it is unlikely that the supertagger will be able to recover and produce the correct lexical categories, since it relies heavily on POS tags as features. Without the correct categories, the parser in turn will be unable to find a correct parse.

In the sentence *What year did the Vietnam War end?*, the newspaper-trained POS tagger incorrectly assigns the POS tag NN (common noun) to the verb *end*, since verb-final sentences are atypical for the PTB. As a result, the supertagger is virtually certain (greater than 99% probability) that the correct CCG lexical category for *end* is N (noun). The parser then assigns *the Vietnam War end* the structure of a noun phrase, and chooses an unusual subcategorization frame for *did* in which it takes three arguments: *What*, *year*, and *the Vietnam War end*.

In the sentence *How many siblings does she have?*, on the other hand, the supertagger assigns an incorrect category to the word *How* despite it having the correct POS tag (WRB for wh-adverb). The correct category is $((S[wq]/(S[q]/NP))/N)/(NP/N)$, which takes *many* (category NP/N) and *siblings* (category N) as arguments. Instead it is tagged as $S[wq]/S[q]$, the category for a sentential adverb (i.e. the manner reading of *how*), which prevents a correct parse. Our intention was that creating new training data at the lower levels of representation would improve the accuracy of the POS tagger and supertagger in the target domains, thereby improving the accuracy of later stages in the pipeline as well.

The second motivation for our approach is to reduce annotation overhead. Full syntactic derivations are costly to produce by hand. POS tags, however, are relatively easy to annotate; even an out-of-domain tagger will provide a good starting point, and manual correction is quick, especially in a domain without much unfamiliar vocabulary. CCG lexical categories require more expertise, but our experience shows that an out-of-domain supertagger can again provide a starting point for correction, and since the annotation is flat rather than hierarchical, we hypothesize that it is not as difficult or time-consuming as annotation of full derivations.

Our adaptation approach has been partially explored in previous work which targets one or another of the different levels of representation.

Lease and Charniak (2005) obtained an improvement in the accuracy of the Charniak (2000) parser, as well as POS tagging accuracy, when applied to the biomedical domain, by training a new POS tagger model with a combination of newspaper and biomedical data. The parser improvement was due solely to the new POS tagger, without retraining the parser model. Since the Charniak parser does not use a lexicalized grammar with an intermediate level of representation, any further improvements would have to come from the parser model itself.

Clark et al. (2004) obtained an improvement in CCG supertagging accuracy for *What*-questions by training a new supertagger model with a combination of newspaper and question data annotated with CCG lexical categories. Because a question resource annotated with GRs was not available, they did not perform a parser evaluation, and the effects of the POS tagging level were not compared to the lexical category level. In this paper, we extend the pilot experiments performed by Clark et al. (2004) in four ways. First, we use a larger corpus of TREC questions covering additional question types, thus extending the experiments to the question domain more broadly, as well as to the biomedical domain. Second, we create a gold standard GR resource enabling a full parser evaluation on question data. Third, we show that the POS level is important for adaptation, reinforcing the work of Lease and Charniak (2005). A key finding of the present paper is that the combination of retraining at the POS tag and lexical category levels provides additional improvements beyond those gained by retraining at a single level. Finally, we provide analysis comparing the adaptation methodology for question and biomedical data.

Hara et al. (2007) followed a similar approach to Clark et al. (2004), using the parser of Ninomiya et al. (2006), a version of the Enju parser (Miyao and Tsujii, 2005). Enju is based on HPSG, a lexicalized grammar formalism. They obtained an improvement in parsing accuracy in the biomedical domain by training a new probabilistic model of lexical entry assignments on a combination of newspaper and biomedical data without changing the original newspaper-trained parsing model. Hara et al. (2007) did not consider the role of POS tagging. The lexical category data in Hara et al. (2007) was derived from a gold standard treebank, while the annotation of lexical categories in this paper was performed without reference to gold standard syntactic derivations.

Judge et al. (2006) produced a corpus of 4,000 questions annotated with syntactic trees, and obtained an improvement in parsing accuracy for Bikel's reimplementation of the Collins parser (Collins, 1997) by training a new parser model with a combination of newspaper and question data. Our approach differs in retraining only at the levels of representation below parse trees.

4 Experiments and Results

4.1 Resources

We have used a combination of existing resources and new, manually annotated data. The baseline POS tagger, supertagger, and parser are trained on WSJ Sections 02-21 of CCGbank. The baseline performance at each level of representation is on WSJ Section 00 of CCGbank, which contains 1913 sentences and approximately 45,000 words.

For the biomedical domain, we trained the POS tagger on gold-standard POS tags from GENIA (Kim et al., 2003), a corpus of 2,000 MEDLINE abstracts containing a total of approximately 18,500 sentences and 440,000 words. We also annotated the first 1,000 sentences of GENIA with CCG lexical categories. This set of 1,000 sentences, containing approximately 27,000 words, was used for POS tagger evaluation and for development and evaluation of a new supertagger model. For parser evaluation, we used BioInfer (Pyysalo et al., 2007a), a corpus of MEDLINE abstracts (on a different topic from those in GENIA) containing 1,100 sentences, and with syntactic dependencies encoded as grammatical relations in the Stanford GR format. We used the same evaluation set of 500 sentences as in Pyysalo et al. (2007b), and the remaining 600 for development of the mapping to Stanford format. Two parsers have already been evaluated on BioInfer, which makes it a useful resource for comparative evaluation.

For the question domain, we extended the dataset described in Clark et al. (2004). That dataset contained 1,171 questions beginning with the word *What*, from the TREC 9-12 competitions (2000-2003), manually POS tagged and annotated with

CCG lexical categories. We annotated all the additional TREC question types and improved the existing annotation, for a total of 1,828 sentences. We additionally annotated a random subset of 500 of these with GRs in the Stanford format. This subset served as our evaluation set at all levels of representation. It contains approximately 4,000 words, fewer than the other domains because of the significantly shorter sentence lengths of typical questions. The remaining 1,328 sentences were used as training data. A set of about a dozen sentences from the evaluation and training sets were used to develop the mapping to Stanford format for lexical categories not occurring in the biomedical data.

4.2 POS tagger

We began by training new models at the POS tag level of representation. All datasets use the PTB tagset. As a baseline, we used the original WSJ 02-21 model on the biomedical and question datasets. For comparison we also evaluated on Section 00 using the WSJ-trained model.

For the question data, the new POS tagger was trained on CCGbank Sections 02-21 plus ten copies of the 1,328 training sentences. The WSJ data provides additional robustness and wide grammatical coverage, and the weighting factor of ten was chosen in preliminary experiments to prevent the newspaper data from "overwhelming" the question data. For the biomedical data, the new POS tagger was trained on the full GENIA corpus, minus the first 1,000 sentences. GENIA is large enough that combination with the newspaper data was not needed.

Table 1 gives the results. For both of the new domains the performance of the WSJ model decreased compared to Section 00, but the retrained model performed at least as well as the WSJ model did on 00.[1] Improving the POS tagger performance has a positive effect on the performance of the supertagger and parser, which will be discussed in Sections 4.3-4.4.

[1]Since GENIA does not use the proper noun tag, NNP, for names of genes and other biomedical entities, all figures in this paper collapse the NNP-NN distinction where relevant for biomedical data. The question data uses NNP and the distinction is not collapsed.

Qus	71.6	74.0	92.1
Bio	89.0	91.2	93.0

Table 2: Supertagging accuracy (%) and the effect of retraining the POS model and the supertagger model.

4.3 Supertagger

We next trained new models at the CCG lexical category level. The training data consisted of manually annotated biomedical and question sentences; specifically, lexical categories were automatically assigned by the original parsing pipeline and then manually corrected. Whenever possible we used categories from the parser's original set of 425, although occasionally it was necessary to use a new category for a syntactic construction not occurring in CCGbank Sections 02-21. (The parser can be configured to recognize additional categories.) Question data in particular requires the use of categories that are rare or unseen in CCGbank.

For the questions, the new supertagger model, like the POS tagger, was trained on WSJ 02-21 plus ten copies of the 1,328 training sentences. For the biomedical data, a ten-fold cross-validation was performed, training each supertagger model on WSJ 02-21 plus ten copies of 90% of the 1,000 annotated sentences. Table 2 gives the supertagger accuracy with and without the retrained POS and supertagger models. The figure for the retrained biomedical supertagger is the average of the ten-fold split.

The results show an improvement in accuracy of lexical category assignment solely from retraining the POS tagger, and an additional improvement from retraining the supertagger. Supertagger accuracy for the two domains with a retrained supertagger was comparable, and in both cases was at least as high

What car company invented the Edsel?
(nsubj invented company)
(det Edsel the)
(dobj invented Edsel)
(det company What)
(nn company car)

Figure 2: Example of grammatical relations in the Stanford grammatical relation format.

as for the original pipeline on Section 00. The question data started from a much lower baseline figure, however.

4.4 Parser

We evaluated the parser on the 500 questions annotated with Stanford GRs and on the 500 evaluation sentences from the BioInfer corpus. We used the original newspaper pipeline, a pipeline with a retrained POS tagger, and a pipeline with both a retrained POS tagger and supertagger.

In order to perform these evaluations we develooped a mapping from the parser's native CCG syntactic dependencies to GRs in the Stanford format. The mapping was based on the same principles as the mapping that produces GR output in the style of Briscoe et al. (2006). These principles are discussed in detail in Clark and Curran (2007a); in summary, the argument slots in the CCG dependencies are mapped to argument slots in Stanford GRs, a fairly complex, many-to-many mapping. An additional post-processing script applies some manually developed rules to bring the output closer to the Stanford format. Figure 2 gives an example of Stanford GRs, where the label of the relation is followed by two arguments, head and dependent.

Table 3 gives the results of the parser evaluation on GRs. Since the parser model was not retrained, the improvements in accuracy are due solely to the new POS and supertaggers. The results are given as an F-score over labelled GRs.[2]

The F-scores given in Table 3 are only for sentences for which a parse was found. However, there were also improvements in coverage with the retrained models. For the question data, parser coverage was 94% for the original pipeline and the pipeline with just the retrained POS tagger, and 99.6% with the retrained POS and supertaggers. For the biomedical data, coverage was 97.2% for the original pipeline, 99.0% for the pipeline with the retrained POS tagger, and 99.8% for the pipeline with the retrained POS and supertaggers.

[2]Only GRs at the lowest level of the Stanford hierarchy were considered in the evaluation; more generic relations such as *dependent* were not considered.

	Orig POS and super	New POS	New POS and super
Qus	64.4	69.4	86.6
BioInfer	76.0	80.4	81.5

Table 3: Parser F-score on grammatical relations and the effect of retraining the POS and supertagger models.

The final accuracy for both domains is in the same range as that of the original parser on newspaper data (81.8%) (Clark and Curran, 2007b), although the results are not directly comparable, since the newspaper resource uses a different GR scheme. For the BioInfer corpus, the final accuracy is also in line with results reported in the literature for other parsers (Pyysalo et al., 2007b). (No comparable GR results are available for questions.) A score in this range is thought to be near the upper bound when evaluating a CCG parser on GRs, since some loss is inherent in the mapping to GRs (Clark and Curran, 2007a).

5 Analysis

Although domain adaptation was successful for both of our target domains, the impact of the different levels of representation on parsing accuracy was not uniform. Table 3 shows that retraining the POS tagger accounted for a greater proportion of the improvement on biomedical data, while retraining the supertagger accounted for a much greater proportion on questions. In this section we discuss some of the differences between the domains which may have contributed to their behaviour in this regard, with the intention of highlighting attributes that may be relevant for domain adaptation in general.

Informally, we believe that the main difference between newspaper and biomedical text is vocabulary, and that their syntactic structures are essentially similar (with some isolated exceptions, such as more frequent use of parentheses and comma-separated

	Tag	Errors	Freq confused

	VB	46	NN, VBP
	NNP	33	JJ, NN
	NN	32	JJ, NNP
Bio	NN	801	JJ, CD
	JJ	268	NN, VBN
	VBN	113	JJ, VBD
	FW	95	NN, IN

Table 4: Tags with the most frequent errors by the newspaper-trained POS tagger and the tags they were most frequently confused with.

lists in biomedical text). Once the POS tagger had been retrained for biomedical text, accounting for unfamiliar vocabulary, the original supertagger already performed well. The main difference between newspaper and question data, on the other hand, is syntactic. Retraining the POS tagger for questions therefore had less effect; even with the correct POS tags the supertagger was unable to assign the correct lexical categories. Since lexical categories encode syntactic information, the domain with the more divergent syntax is likely to benefit most from new training data at the lexical category level.

5.1 POS tagger

Table 1 showed that the accuracy of the newspaper-trained POS tagger was in the same range for both biomedical and question data. However, the distribution of errors was different. Table 4 shows the tags with the most frequent errors, accounting for about 75% of all POS tag errors in each domain, and the tags that they were most frequently confused with.

For the question data, the most frequent error was tagging a wh-determiner (WDT) as a wh-pronoun (WP). A determiner combines with a noun to form a noun phrase, as in the sentence <u>*What*</u> *Liverpool club spawned the Beatles?*. A pronoun, on the other hand, is a noun phrase in its own right, as in <u>*What*</u> *are the colors of the German flag?*. This tagger error arises from the fact that the word *What* occurs only once in WSJ 02-21 with a WDT tag. The second most common error was on bare verbs (VB), because the newspaper model gives a low probability of bare verbs occurring in sentence-final position, or not directly following an auxiliary.

	Unknown word rate	Unknown word-POS rate
Sec. 00	3.8	4.4
Qus	7.5	8.3
Bio	23.6	25.3

Table 5: Unknown word rate and word-POS tag pair rate (%) compared to WSJ 02-21 (by token).

For the biomedical data, the most frequent errors by far were confusions of noun (NN) and adjective (JJ). This is most likely due to the prevalence of long noun phrases in the biomedical data, such as *major histocompatibility complex class II molecules*. Although the words preceding the head noun are recognized as nominal modifiers, the classification into noun and adjective is difficult, especially when the word is previously unseen. There were also problems distinguishing verbal past participles (VBN) from adjectives (JJ) and identifying foreign words (FW), for example the phrase *in vitro*.

The fact that the newspaper-trained POS tagger performed comparably in the two target domains (Table 1) is surprising, since their lexical profiles are quite different. Lease and Charniak (2005) discussed unknown word rate as a predictor of POS tagger accuracy. However, the unknown word rate compared with WSJ 02-21 is much higher for the biomedical data than for the question data, as seen in Table 5. (The unknown word rate for the question data is still higher than that for WSJ 00, which may be due to the high proportion of proper nouns in the question data.)

Some POS tagging errors can be attributed, not to an unknown word, but to the use of a known word with an unfamiliar tag (as in the WDT example above). However, it is not the case that the question data contains many known words with unknown tags, since the rate of unknown word-tag pairs is also much higher for biomedical than for question data, as seen in the rightmost column of Table 5.

We do know that the newspaper-trained POS tagger performs better on unknown words for biomedical (84.7%) than for question data (80.4%). We hypothesize that the syntactic context of the biomedical data, being more similar to newspaper data, provides more information for the POS tagger in

biomedical than in question data. Syntactic differences are discussed in the next section.

5.2 Supertagger

To quantify the syntactic distance between domains, we propose using the unknown POS n-gram rate compared to WSJ Sections 02-21. In the absence of parse trees, POS n-grams can serve as a rough proxy for the syntactic characteristics of a domain, reflecting local word order configurations. POS n-grams have been used in document modeling for text categorization (Baayen et al., 1996; Argamon-Engelson et al., 1998), but we believe our proposed use of the unknown POS n-gram rate is novel.

The leftmost column of Table 6 gives the unknown POS trigram and 5-gram rates compared to WSJ Sections 02-21. The rates for the biomedical data are quite similar to those for Section 00. The question data, however, shows higher rates of unknown POS n-grams.

For both biomedical and question data, adding in-domain data to the training set makes its syntactic profile more like that of the evaluation set. The rightmost column of Table 6 shows the unknown POS n-gram rates compared to the datasets used for training the new supertagger models, consisting of WSJ 02-21 plus annotated question or biomedical data. (For the biomedical data, the figures are averages of the same ten-fold split used for evaluation). It can be seen that adding in-domain data reduces the rate of unknown POS n-grams to about the same level observed for newspaper text.

The unknown POS n-gram rate requires POS tagged data for a new domain and thus cannot be used with unlabelled data. However, since POS tagging is relatively inexpensive, it might be possible to use this rate as one measure of syntactic distance between a training corpus and a target domain, prior to undertaking parser domain adaptation. The measure does not capture all aspects of syntactic distance, however. As pointed out by an anonymous reviewer, if the syntactic tree structures are similar across domains but lexical distributions are different – e.g. a large number of words with unfamiliar categories in the new domain – this measure will not be sensitive to the difference.

Another useful measure for comparing domain adaptation in the biomedical and question domains is frequent POS n-grams. Table 7 shows how many of the 20 most frequent POS n-grams in each dataset overlap with the 20 most frequent POS n-grams in WSJ 02-21. It can be seen that the overlap is the highest for Section 00, but much lower for the question data than for the biomedical data, again demonstrating that the question data makes frequent use of syntactic constructions which are rare in the PTB.

Table 8 shows the four most frequent POS trigrams in WSJ Sections 02-21,[3] and the four most frequent POS trigrams in the biomedical and question data that are not among the 20 most frequent

[3]Collapsing the NNP-NN distinction yields a slightly different set.

for WSJ 02-21. The frequent question trigrams include two sentence-initial question words as well as the pattern — WP VBZ, occurring in sentences beginning with e.g. *What is* or *Who is*. Though not among the top four, the pattern VB . —, representing a sentence-final bare verb, is also frequent. The most frequent biomedical POS trigrams are not dramatically different from the newspaper trigrams, but do appear to reflect the prevalence of NPs and PPs in the data.

One final measure of syntactic distance is the frequency with which CCG lexical categories that are rare or unseen in CCGbank are used in a domain. It is typical to use a few such categories, even for in-domain data, for unusual syntactic constructions, but each one is usually used only a handful of times. The question data is unique in the frequency with which previously rare or unseen categories are required. For example, the unseen category $(S[wq]/S[q])/N$, representing the word *What* in a question such as *What day did Nintendo 64 come out?* is used 11 times in the evaluation set; the rare category $(S[wq]/(S[dcl]\backslash NP))/N$, used in subject questions like *Which river runs through Dublin?*, is used 61 times; and the rare category $(S[q]/(S[pss]\backslash NP))/NP$, representing passive verbs in sentences like *What is Jane Goodall known for?*, is used 59 times.

6 Conclusion

We have targeted lower levels of representation in order to adapt a lexicalized-grammar parser to two new domains, biomedical text and questions. Although each of the lower levels has been targeted independently in previous work, this is the first study that examines both levels together to determine how they affect parsing accuracy. We achieved an accuracy on grammatical relations in the same range as that of the original parser for newspaper text, without requiring costly annotation of full parse trees.

Both biomedical and question data are domains in which there is an immediate need for accurate parsing. The question dataset is in some ways an extreme example for domain adaptation, since the sentences are syntactically uniform; on the other hand, it is of interest as a set of constructions where the parser initially performed poorly, and is a realistic parsing challenge in the context of QA systems.

Interestingly, although an increase in accuracy at each stage of the pipeline did yield an increase at the following stage, these increases were not uniform across the two domains. The new POS tagger model was responsible for most of the improvement in parsing for the biomedical domain, while the new supertagger model was necessary to see a large improvement in the question domain. We attribute this to the fact that question syntax is significantly different from newspaper syntax. We expect these considerations to apply to any lexicalized-grammar parser.

Of course, it would be useful to have a way of predicting which level of annotation would be most effective for adapting to a new domain before the annotation begins. The utility of measures such as unknown word rate (which can be performed with unlabelled data) and unknown POS n-gram rate (which can be performed with only POS tags) is not yet sufficiently clear to rely on them as predictive measures, but it seems a fruitful avenue for future work to investigate the importance of such measures for parser domain adaptation.

Acknowledgments

We would like to thank Marie-Catherine de Marneffe for advice on the use of the Stanford GR format, Sampo Pyysalo for sharing information about the BioInfer corpus, and Mark Steedman for advice on encoding question data in CCG. We would also like to thank three anonymous reviewers for their suggestions. This work was supported by EPSRC grant EP/E035698/1: Accurate and Efficient Parsing of Biomedical Text.

Abstract

Although Machine Translation (MT) is a very active research field which is receiving an increasing amount of attention from the research community, the results that current MT systems are capable of producing are still quite far away from perfection. Because of this, and in order to build systems that yield correct translations, human knowledge must be integrated into the translation process, which will be carried out in our case in an Interactive-Predictive (IP) framework. In this paper, we show that considering Mouse Actions as a significant information source for the underlying system improves the productivity of the human translator involved. In addition, we also show that the initial translations that the MT system provides can be quickly improved by an expert by only performing additional Mouse Actions. In this work, we will be using word graphs as an efficient interface between a phrase-based MT system and the IP engine.

1 Introduction

Information technology advances in modern society have led to the need of more efficient methods of translation. It is important to remark that current MT systems are not able to produce ready-to-use texts (Kay, 1997; Hutchins, 1999; Arnold, 2003). Indeed, MT systems are usually limited to specific semantic domains and the translations provided require human post-editing in order to achieve a correct high-quality translation.

A way of taking advantage of MT systems is to combine them with the knowledge of a human translator, constituting the so-called Computer-Assisted Translation (CAT) paradigm. CAT offers different approaches in order to benefit from the synergy between humans and MT systems.

An important contribution to interactive CAT technology was carried out around the TransType (TT) project (Langlais et al., 2002; Foster et al., 2002; Foster, 2002; Och et al., 2003). This project entailed an interesting focus shift in which interaction directly aimed at the production of the target text, rather than at the disambiguation of the source text, as in former interactive systems. The idea proposed was to embed data driven MT techniques within the interactive translation environment.

Following these TT ideas, (Barrachina and others, 2008) propose the usage of fully-fledged statistical MT (SMT) systems to produce full target sentence hypotheses, or portions thereof, which can be partially or completely accepted and amended by a human translator. Each partial correct text segment is then used by the SMT system as additional information to achieve further, hopefully improved suggestions. In this paper, we also focus on the interactive and predictive, statistical MT (IMT) approach to CAT. The IMT paradigm fits well within the *Interactive Pattern Recognition* framework introduced in (Vidal and others, 2007).

FINAL	$(\mathbf{p} \equiv \mathbf{y})$	To power on the printer:

Figure 1: IMT session to translate a Spanish sentence into English. Non-validated hypotheses are displayed in italics, whereas accepted prefixes are printed in normal font.

Figure 1 illustrates a typical IMT session. Initially, the user is given an input sentence $\mathbf{x}$ to be translated. The reference $\mathbf{y}$ provided is the translation that the user would like to achieve at the end of the IMT session. At iteration 0, the user does not supply any correct text prefix to the system, for this reason $\mathbf{p}$ is shown as empty. Therefore, the IMT system has to provide an initial complete translation $\mathbf{s}_h$, as it were a conventional SMT system. At the next iteration, the user validates a prefix $\mathbf{p}$ as correct by positioning the cursor in a certain position of $\mathbf{s}_h$. In this case, after the words "*To print a*". Implicitly, he is also marking the rest of the sentence, the suffix $\mathbf{s}_l$, as potentially incorrect. Next, he introduces a new word k, which is assumed to be different from the first word s_{l_1} in the suffix $\mathbf{s}_l$ which was not validated, $k \neq s_{l_1}$. This being done, the system suggests a new suffix hypothesis $\hat{\mathbf{s}}_h$, subject to $\hat{s}_{h_1} = k$. Again, the user validates a new prefix, introduces a new word and so forth. The process continues until the whole sentence is correct that is validated introducing the special word "#".

As the reader could devise from the IMT session described above, IMT aims at reducing the effort and increasing the productivity of translators, while preserving high-quality translation. For instance, in Figure 1, only three interactions were necessary in order to achieve the reference translation.

In this paper, we will show how Mouse Actions performed by the human expert can be taken advantage of in order to further reduce this effort.

2 Statistical interactive-predictive MT

In this section we will briefly describe the statistical framework of IMT. IMT can be seen as an evolution of the SMT framework, which has proved to be an efficient framework for building state-of-the-art MT systems with little human effort, whenever adequate corpora are available (Hutchings and Somers, 1992). The fundamental equation of the statistical approach to MT is

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\text{argmax}}\, Pr(\mathbf{y} \mid \mathbf{x}) \tag{1}$$

$$= \underset{\mathbf{y}}{\text{argmax}}\, Pr(\mathbf{x} \mid \mathbf{y})\, Pr(\mathbf{y}) \tag{2}$$

where $Pr(\mathbf{x} \mid \mathbf{y})$ is the *translation model* modelling the correlation between source and target sentence and $Pr(\mathbf{y})$ is the *language model* representing the well-formedness of the candidate translation $\mathbf{y}$.

In practise, the direct modelling of the posterior probability $Pr(\mathbf{y}|\mathbf{x})$ has been widely adopted. To this purpose, different authors (Papineni et al., 1998; Och and Ney, 2002) propose the use of the so-called log-linear models, where the decision rule is given by the expression

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\text{argmax}} \sum_{m=1}^{M} \lambda_m h_m(\mathbf{x}, \mathbf{y}) \tag{3}$$

where $h_m(\mathbf{x}, \mathbf{y})$ is a score function representing an important feature for the translation of $\mathbf{x}$ into $\mathbf{y}$, M is the number of models (or features) and λ_m are the weights of the log-linear combination.

One of the most popular instantiations of log-linear models is that including phrase-based (PB) models (Zens et al., 2002; Koehn et al., 2003). Phrase-based models allow to capture contextual information to learn translations for whole phrases instead of single words. The basic idea of phrase-based translation is to segment the source sentence into phrases, then to translate each source phrase into a target phrase, and finally to reorder the translated target phrases in order to compose the target sentence. Phrase-based models were employed throughout this work.

In log-linear models, the maximisation problem stated in Eq. 3 is solved by means of the beam search algorithm[1] which was initially introduced in (Lowerre, 1976) for its application in the field of speech recognition. The beam search algorithm attempts to generate partial solutions, called *hypotheses*, until a complete sentence is found; these hypotheses are stored in a stack and ordered by their *score*. Such a score is given by the log-linear combination of feature functions.

However, Eq. 1 needs to be modified according to the IMT scenario in order to take into account part of the target sentence that is already translated, that is $\mathbf{p}$ and k

$$\hat{\mathbf{s}}_h = \underset{\mathbf{s}_h}{\operatorname{argmax}}\, Pr(\mathbf{s}_h|\mathbf{x},\mathbf{p},k) \tag{4}$$

where the maximisation problem is defined over the suffix $\mathbf{s}_h$. This allows us to rewrite Eq. 4, by decomposing the right side appropriately and eliminating constant terms, achieving the equivalent criterion

$$\hat{\mathbf{s}}_h = \underset{\mathbf{s}_h}{\operatorname{argmax}}\, Pr(\mathbf{p},k,\mathbf{s}_h|\mathbf{x}). \tag{5}$$

An example of the intuition behind these variables can be seen in Figure 1.

Note that, since $(\mathbf{p}\,k\,\mathbf{s}_h) = \mathbf{y}$, Eq. 5 is very similar to Eq. 1. The main difference is that the argmax search is now performed over the set of suffixes $\mathbf{s}_h$ that complete $(\mathbf{p}\,k)$ instead of complete sentences ($\mathbf{y}$ in Eq. 1). This implies that we can use the same models if the search procedures are adequately modified (Barrachina and others, 2008).

[1]Also known as stack decoding algorithm.

3 Phrase-based IMT

The phrase-based approach presented above can be easily adapted for its use in an IMT scenario. The most important modification is to rely on a word graph that represents possible translations of the given source sentence. The use of word graphs in IMT has been studied in (Barrachina and others, 2008) in combination with two different translation techniques, namely, the Alignment Templates technique (Och et al., 1999; Och and Ney, 2004), and the Stochastic Finite State Transducers technique (Casacuberta and Vidal, 2007).

3.1 Generation of word graphs

A word graph is a weighted directed acyclic graph, in which each node represents a partial translation hypothesis and each edge is labelled with a word of the target sentence and is weighted according to the scores given by an SMT model (see (Ueffing et al., 2002) for more details). In (Och et al., 2003), the use of a word graph is proposed as interface between an alignment-template SMT model and the IMT engine. Analogously, in this work we will be using a word graph built during the search procedure performed on a PB SMT model.

During the search process performed by the above mentioned beam search algorithm, it is possible to create a *segment graph*. In such a graph, each node represents a state of the SMT model, and each edge a weighted transition between states labelled with a sequence of target words. Whenever a hypothesis is extended, we add a new edge connecting the state of that hypothesis with the state of the extended hypothesis. The new edge is labelled with the sequence of target words that has been incorporated to the extended hypothesis and is weighted appropriately by means of the score given by the SMT model.

Once the segment graph is generated, it can be easily converted into a word graph by the introduction of artificial states for the words that compose the target phrases associated to the edges.

3.2 IMT using word graphs

During the process of IMT for a given source sentence, the system makes use of the word graph generated for that sentence in order to complete the prefixes accepted by the human translator. Specifically,

FINAL	$(\mathbf{p} \equiv \mathbf{y})$	To power on the printer:

Figure 2: Example of non-explicit positioning MA which solves an error of a missing word. In this case, the system produces the correct suffix $\mathbf{s}_h$ immediately after the user validates a prefix $\mathbf{p}$, implicitly indicating that we wants the suffix to be changed, without need of any further action. In **ITER-1**, character | indicates the position where a MA was performed, $\mathbf{s}_l$ is the suffix which was rejected by that MA, and $\hat{\mathbf{s}}_h$ is the new suffix that the system suggests after observing that $\mathbf{s}_l$ is to be considered incorrect. Character # is a special character introduced by the user to indicate that the hypothesis is to be accepted.

the system finds the best path in the word graph associated with a given prefix so that it is able to complete the target sentence, being capable of providing several completion suggestions for each prefix.

A common problem in IMT arises when the user sets a prefix which cannot be found in the word graph, since in such a situation the system is unable to find a path through the word graph and provide an appropriate suffix. The common procedure to face this problem is to perform a tolerant search in the word graph. This tolerant search uses the well known concept of Levenshtein distance in order to obtain the most similar string for the given prefix (see (Och et al., 2003) for more details).

4 Enriching user–machine interaction

Although the IMT paradigm has proved to offer interesting benefits to potential users, one aspect that has not been reconsidered as of yet is the user–machine interface. Hence, in traditional IMT the system only received feedback whenever the user typed in a new word. In this work, we show how to enrich user–machine interaction by introducing Mouse Actions (MA) as an additional information source for the system. By doing so, we will consider two types of MAs, i.e. *non-explicit* (or *positioning*) MAs and *interaction-explicit* MAs.

4.1 Non-explicit positioning MAs

Before typing in a new word in order to correct a hypothesis, the user needs to position the cursor in the place where he wants to type such a word. In this work, we will assume that this is done by performing a MA, although the same idea presented can also be applied when this is done by some other means. It is important to point out that, by doing so, the user is already providing some very useful information to the system: he is validating a prefix up to the position where he positioned the cursor, and, in addition, he is signalling that whatever word is located after the cursor is to be considered incorrect. Hence, the system can already capture this fact and provide a new translation hypothesis, in which the prefix remains unchanged and the suffix is replaced by a new one in which the first word is different to the first word of the previous suffix. We are aware that this does not mean that the new suffix will be correct, but given that we know that the first word in the previous suffix was incorrect, the worst thing which can happen is that the the first word of the new suffix is incorrect as well. However, if the new suffix happens to be correct, the user will happily find that he does not need to correct that word any more.

An example of such behaviour can be seen in Figure 2. In this example, the SMT system first provides a translation which the user does not like. Hence, he positions the cursor before word "*postscript*", with the purpose of typing in "*lists*". By doing so, he is validating the prefix "*To print a*", and signalling that he wants "*postscript*" to be replaced. Before typing in anything, the system realises that he is going to change the word located after the cursor, and replaces the suffix by another one, which is the one the user had in mind in the first place. Finally, the user only has to accept the final translation.

We are naming this kind of MA *non-explicit* because it does not require any additional action from the user: he has already performed a MA in order to position the cursor at the place he wants, and we are taking advantage of this fact to suggest a new suffix hypothesis.

Since the user needs to position the cursor before typing in a new word, it is important to point out that any improvement achieved by introducing non-explicit MAs does not require any further effort from the user, and hence is considered to have no cost.

Hence, we are now considering two different situations: the first one, the traditional IMT framework, in which the system needs to find a suffix according to Eq. 5, and a new one, in which the system needs to find a suffix in which the first word does not need to be a given k, but needs to be *different* to a given s_{l1}. This constraint can be expressed by the following equation:

$$\hat{\mathbf{s}}_h = \underset{\mathbf{s}_h : s_{h_1} \neq s_{l_1}}{\operatorname{argmax}} \; Pr(\mathbf{p}, \mathbf{s}_h | \mathbf{x}, \mathbf{s}_l) \tag{6}$$

where $\mathbf{s}_l$ is the suffix generated in the previous iteration, already discarded by the user, and s_{l_1} is the first word in $\mathbf{s}_l$. k is omitted in this formula because the user did not type any word at all.

4.2 Interaction-explicit MAs

If the system is efficient and provides suggestions which are good enough, one could easily picture a situation in which the expert would ask the system to replace a given suffix, without typing in any word. We will be modelling this as another kind of MA, *interaction-explicit* MA, since the user needs to indicate *explicitly* that he wants a given suffix to be replaced, in contrast to the non-explicit positioning MA. However, if the underlying MT engine providing the suffixes is powerful enough, the user would quickly realise that performing a MA is less costly that introducing a whole new word, and would take advantage of this fact by systematically clicking before introducing any new word. In this case, as well, we assume that the user clicks before an incorrect word, hence demanding a new suffix whose first word is different, but by doing so he is adopting a more participative and interactive attitude, which was not demanded in the case of non-explicit positioning MAs. An example of such an explicit MA correcting an error can be seen in Figure 3

In this case, however, there is a cost associated to this kind of MAs, since the user does need to perform additional actions, which may or may not be beneficial. It is very possible that, even after asking for several new hypothesis, the user will even though need to introduce the word he had in mind, hence wasting the additional MAs he had performed.

If we allow the user to perform n MAs before introducing a word, this problem can be formalised in an analogous way as in the case of non-explicit MAs as follows:

$$\hat{\mathbf{s}}_h = \underset{\mathbf{s}_h : s_{h_1} \neq s^i_{l_1} \forall i \in \{1..n\}}{\operatorname{argmax}} \; Pr(\mathbf{p}, \mathbf{s}_h | \mathbf{x}, \mathbf{s}^1_l, \mathbf{s}^2_l, \ldots, \mathbf{s}^n_l) \tag{7}$$

where s^i_{l1} is the first word of the i-th suffix discarded and $\mathbf{s}^1_l, \mathbf{s}^2_l, \ldots, \mathbf{s}^n_l$ is the set of all n suffixes discarded.

Note that this kind of MA could also be implemented with some other kind of interface, e.g. by typing some special key such as `F1` or `Tab`. However, the experimental results would not differ, and in our user interface we found it more intuitive to implement it as a MA.

5 Experimental setup

5.1 System evaluation

Automatic evaluation of results is a difficult problem in MT. In fact, it has evolved to a research field with own identity. This is due to the fact that, given an input sentence, a large amount of correct *and* different output sentences may exist. Hence, there is no sentence which can be considered ground truth, as is the case in speech or text recognition. By extension, this problem is also applicable to IMT.

In this paper, we will be reporting our results as measured by *Word Stroke Ratio* (WSR) (Barrachina

Figure 3: Example of explicit interactive MA which corrects an erroneous suffix. In this case, a non-explicit MA is performed in **ITER-1** with no success. Hence, the user introduces word "*type*" in **ITER-2**, which leaves the cursor position located immediately after word "*type*". In this situation the user would not need to perform a MA to re-position the cursor and continue typing in order to further correct the remaining errors. However, since he has learnt the potential benefit of MAs, he performs an interaction-explicit MA in order to ask for a new suffix hypothesis, which happens to correct the error.

and others, 2008), which is computed as the quotient between the number of word-strokes a user would need to perform in order to achieve the translation he has in mind and the total number of words in the sentence. In this context, a word-stroke is interpreted as a single action, in which the user types a complete word, and is assumed to have constant cost. Moreover, each word-stroke also takes into account the cost incurred by the user when reading the new suffix provided by the system.

In the present work, we decided to use WSR instead of *Key Stroke Ratio* (KSR), which is used in other works on IMT such as (Och et al., 2003). The reason for this is that KSR is clearly an optimistic measure, since in such a scenario the user is often overwhelmed by receiving a great amount of translation options, as much as one per key stroke, and it is not taken into account the time the user would need to read all those hypotheses.

In addition, and because we are also introducing MAs as a new action, we will also present results in terms of *Mouse Action Ratio* (MAR), which is the quotient between the amount of explicit MAs performed and the number of words of the final translation. Hence, the purpose is to elicit the number of times the user needed to request a new translation (i.e. performed a MA), on a per word basis.

Lastly, we will also present results in terms of uMAR (useful MAR), which indicates the amount of MAs which were *useful*, i.e. the MAs that actually produced a change in the first word of the suffix and such word was accepted. Formally, uMAR is defined as follows:

$$uMAR = \frac{MAC - n \cdot WSC}{MAC} \tag{8}$$

where MAC stands for "Mouse Action Count", WSC for "Word Stroke Count" and n is the maximum amount of MAs allowed before the user types in a word. Note that $MAC - n \cdot WSC$ is the amount of MAs that were useful since WSC is the amount of word-strokes the user performed even though he had already performed n MAs.

Since we will only use single-reference WSR and MAR, the results presented here are clearly pessimistic. In fact, it is relatively common to have the underlying SMT system provide a perfectly correct

Table 1: Characteristics of Europarl for each of the sub-corpora. OoV stands for "Out of Vocabulary" words, Dev. for Development, K for thousands of elements and M for millions of elements.

translation, which is "corrected" by the IMT procedure into another equivalent translation, increasing WSR and MAR significantly by doing so.

5.2 Corpora

Our experiments were carried out on the Europarl (Koehn, 2005) corpus, which is a corpus widely used in SMT and that has been used in several MT evaluation campaigns. Moreover, we performed our experiments on the partition established for the Workshop on Statistical Machine Translation of the NAACL 2006 (Koehn and Monz, 2006). The Europarl corpus (Koehn, 2005) is built from the proceedings of the European Parliament. Here, we will focus on the German–English, Spanish–English and French–English tasks, since these were the language pairs selected for the cited workshop. The corpus is divided into three separate sets: one for training, one for development, and one for test. The characteristics of the corpus can be seen in Table 1.

5.3 Experimental results

As a first step, we built a SMT system for each of the language pairs cited in the previous subsection. This was done by means of the Moses toolkit (Koehn and others, 2007), which is a complete system for building Phrase-Based SMT models. This toolkit involves the estimation from the training set of four different translation models, which are in turn combined in a log-linear fashion by adjusting a weight for each of them by means of the MERT (Och, 2003) procedure, optimising the BLEU (Papineni et al., 2002) score obtained on the development partition.

Table 2: WSR improvement when considering non-explicit MAs. "rel." indicates the relative improvement. All results are given in %.

pair	baseline	non-explicit	rel.
Es–En	63.0±0.9	59.2±0.9	6.0±1.4
En–Es	63.8±0.9	60.5±1.0	5.2±1.6
De–En	71.6±0.8	69.0±0.9	3.6±1.3
En–De	75.9±0.8	73.5±0.9	3.2±1.2
Fr–En	62.9±0.9	59.2±1.0	5.9±1.6
En–Fr	63.4±0.9	60.0±0.9	5.4±1.4

This being done, word graphs were generated for the IMT system. For this purpose, we used a multi-stack phrase-based decoder which will be distributed in the near future together with the Thot toolkit (Ortiz-Martínez et al., 2005). We discarded the use of the Moses decoder because preliminary experiments performed with it revealed that the decoder by (Ortiz-Martínez et al., 2005) performs clearly better when used to generate word graphs for use in IMT. In addition, we performed an experimental comparison in regular SMT with the Europarl corpus, and found that the performance difference was negligible. The decoder was set to only consider monotonic translation, since in real IMT scenarios considering non-monotonic translation leads to excessive waiting time for the user.

Finally, the word graphs obtained were used within the IMT procedure to produce the reference translation contained in the test set, measuring WSR and MAR. The results of such a setup can be seen in Table 2. As a baseline system, we report the traditional IMT framework, in which no MA is taken into account. Then, we introduced non-explicit MAs, obtaining an average improvement in WSR of about 3.2% (4.9% relative). The table also shows the confidence intervals at a confidence level of 95%. These intervals were computed following the bootstrap technique described in (Koehn, 2004). Since the confidence intervals do not overlap, it can be stated that the improvements obtained are statistically significant.

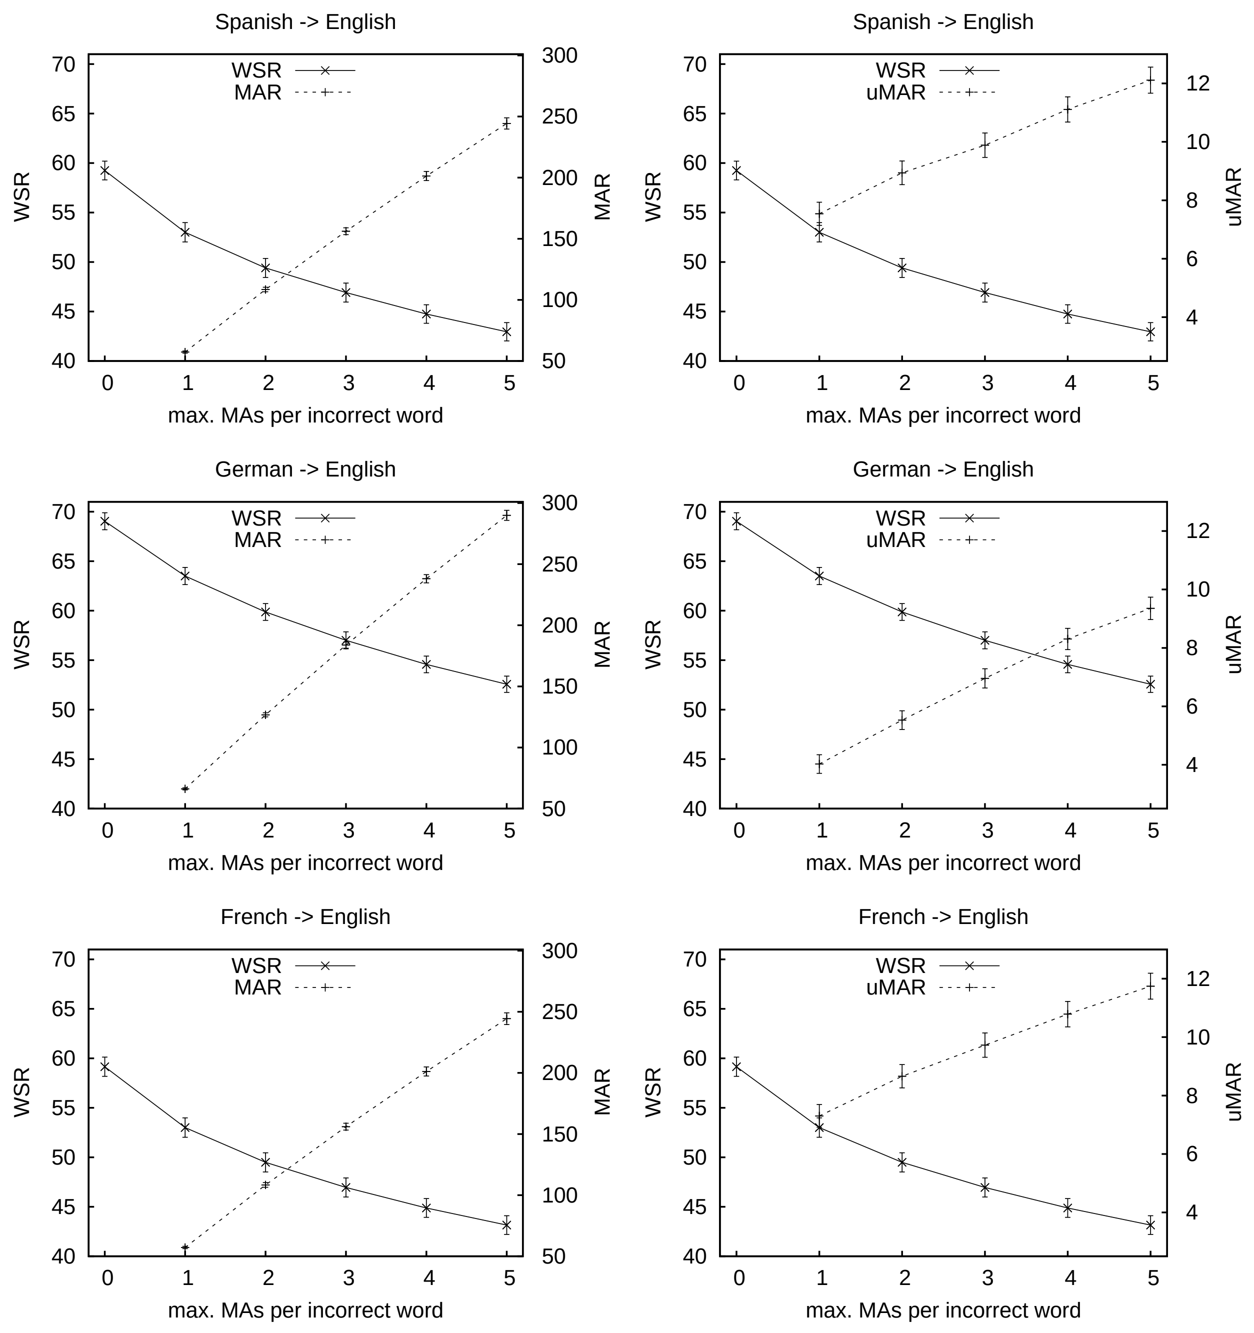

Figure 4: WSR improvement when considering one to five maximum MAs. All figures are given in %. The left column lists WSR improvement versus MAR degradation, and the right column lists WSR improvement versus uMAR. Confidence intervals at 95% confidence level following (Koehn, 2004).

Once the non-explicit MAs were considered and introduced into the system, we analysed the effect of performing up to a maximum of 5 explicit MAs. Here, we modelled the user in such a way that, in case a given word is considered incorrect, he will always ask for another translation hypothesis until he has asked for as many different suffixes as MAs considered. The results of this setup can be seen in Figure 4. This yielded a further average improvement in WSR of about 16% (25% relative improvement) when considering a maximum of 5 explicit MAs. However, relative improvement in WSR and uMAR increase drop significantly when increasing the maximum allowed amount of explicit MAs from 1 to 5. For this reason, it is difficult to imagine that a user would perform more than two or three MAs before actually typing in a new word. Nevertheless, just by asking twice for a new suffix before typing in the word he has in mind, the user might be saving about 15% of word-strokes.

Although the results in Figure 4 are only for the translation direction "foreign"→English, the experiments in the opposite direction (i.e. English→"foreign") were also performed. However, the results were very similar to the ones displayed here. Because of this, and for clarity purposes, we decided to omit them and only display the direction "foreign"→English.

6 Conclusions and future work

In this paper, we have considered new input sources for IMT. By considering Mouse Actions, we have shown that a significant benefit can be obtained, in terms of word-stroke reduction, both when considering only non-explicit MAs and when considering MAs as a way of offering the user several suffix hypotheses. In addition, we have applied these ideas on a state-of-the-art SMT baseline, such as phrase-based models. To achieve this, we have first obtained a word graph for each sentence which is to be translated. Experiments were carried out on a reference corpus in SMT.

Note that there are other systems (Esteban and others, 2004) that, for a given prefix, provide n-best lists of suffixes. However, the functionality of our system is slightly (but fundamentally) different, since the suggestions are demanded to be different in their first word, which implies that the n-best list is scanned deeper, going directly to those hypotheses that may be of interest to the user. In addition, this can be done "on demand", which implies that the system's response is faster and that the user is not confronted with a large list of hypotheses, which often results overwhelming.

As future work, we are planning on performing a human evaluation that assesses the appropriateness of the improvements described.

Abstract

In this paper, we first introduce a new architecture for parsing, bidirectional incremental parsing. We propose a novel algorithm for incremental construction, which can be applied to many structure learning problems in NLP. We apply this algorithm to LTAG dependency parsing, and achieve significant improvement on accuracy over the previous best result on the same data set.

1 Introduction

The phrase "Bidirectional Incremental" may appear self-contradictory at first sight, since incremental parsing usually means left-to-right parsing in the context of conventional parsing. In this paper, we will extend the meaning of incremental parsing.

The idea of bidirectional parsing is related to the bidirectional sequential classification method described in (Shen et al., 2007). In that paper, a tagger assigns labels to words of highest confidence first, and then these labels in turn serve as the context of later labelling operations. The bidirectional tagger obtained the best results in literature on POS tagging on the standard PTB dataset.

We extend this method from labelling to structure learning, The search space of structure learning is much larger, so that it is appropriate to exploit confidence scores in search.

In this paper, we are interested in LTAG dependency parsing because TAG parsing is a well known problem of high computational complexity in regular parsing. In order to get a focus for the learning algorithm, we work on a variant of LTAG based parsing in which we learn the word dependency relations encoded in LTAG derivations instead of the full-fledged trees.

1.1 Parsing

Two types of parsing strategies are popular in natural language parsing, which are chart parsing and incremental parsing.

Suppose the input sentence is $w_1 w_2 ... w_n$. Let cell $[i, j]$ represent $w_i w_{i+1} ... w_j$, a substring of the sentence. As far as CFG parsing is concerned, a chart parser computes the possible structures over all possible cells $[i, j]$, where $1 \leq i \leq j \leq n$. The order of computing on these $n(n+1)/2$ cells is based on some partial order $\preceq$, such that $[p_1, p_2] \preceq [q_1, q_2]$ if $q_1 \leq p_1 \leq p_2 \leq q_2$. In order to employ dynamic programming, one can only use a fragment of a hypothesis to represent the whole hypothesis, which is assumed to satisfy conditional independence assumption. It is well known that richer context representation gives rise to better parsing performance (Johnson, 1998). However, the need for tractability does not allow much internal information to be used to represent a hypothesis. The designs of hypotheses in (Collins, 1999; Charniak, 2000) show a delicate balance between expressiveness and tractability, which play an important role in natural language parsing.

Some recent work on incremental parsing (Collins and Roark, 2004; Shen and Joshi, 2005) showed another way to handle this problem. In these incremental parsers, tree structures are used to represent the left context. In this way, one can access the whole tree to collect rich context information at the expense of being limited to beam search, which only maintains k-best results at each step. Compared to chart parsing, incremental parsing searches for the analyses for only $2n-1$ cells, $[1,1],[2,2],[1,2],..,[i,i],[1,i],..,[1,n]$, incrementally, while complex structures are used for the analyses for each cell, which satisfy conditional independence under a much weaker assumption.

In this paper, we call this particular approach **left-to-right** incremental parsing, since one can also search from right to left incrementally in a similar way. A major problem of the left-to-right approach is that one can only utilize the structural information on the left side but not the right side.

1.2 Parsing as Bidirectional Construction

A natural way to handle this problem is to employ bidirectional search, which means we can dynamically search the space in two directions. So we expand the idea of incremental parsing by introducing greedy search. Specifically, we look for the hypotheses over the cell $[1,n]$ by building analyses over $2n-1$ cells $[a_{i,1},a_{i,2}], i=1,..,2n-1$ step by step, where $[a_{2n-1,1},a_{2n-1,2}]=[1,n]$. Furthermore, for any $[a_{i,1},a_{i,2}]$

- $a_{i,1}=a_{i,2}$, or
- $\exists j,k,$ such that $[a_{i,1},a_{i,2}]=[a_{j,1},a_{k,2}]$, where $j<i$, $k<i$ and $a_{j,2}+1=a_{k,1}$.

It is easy to show that the set $\{[a_{i,1},a_{i,2}] \mid 1 \leq i \leq 2n-1\}$ forms a *tree* relation, which means that each cell except the last one will be used to build another cell just once. In this framework, we can begin with several starting points in a sentence and search in any direction. So left-to-right parsing is only a special case of **incremental** parsing defined in this way. We still use complex structures to represent the partial analyses, so as to employ both top-down and bottom-up information as in (Collins and Roark, 2004; Shen and Joshi, 2005). Furthermore, we can utilize the rich context on both sides of the partial results.

Similar to bidirectional labelling in (Shen et al., 2007), there are two learning tasking in this model. First, we need to learn which cell we should choose. At each step, we can select only one path. Secondly, we need to learn which operation we should take for a given cell. We maintain k-best candidates for each cell instead of only one, which differentiates this model from normal greedy search. So our model is more robust. Furthermore, we need to find an effective way to iterate between these two tasks.

Instead of giving an algorithm specially designed for parsing, we generalize the problem for graphs. A sentence can be viewed as a graph in which words are viewed as vertices and neighboring words are connected with an arc. In Sections 2 and 3, we will propose decoding and training algorithms respectively for graph-based incremental construction, which can be applied to many structure learning problems in NLP.

We will apply this algorithm to dependency parsing of Lexicalized Tree Adjoining Grammar (Joshi and Schabes, 1997). Specifically, we will train and evaluate an LTAG dependency parser over the LTAG treebank described in Shen et al. (2008). We report the experimental results on PTB section 23 of the LTAG treebank. The accuracy on LTAG dependency is 90.5%, which is 1.2 points over 89.3%, the previous best result (Shen and Joshi, 2005) on the same data set.

It should be noted that PTB-based bracketed labelling is not an appropriate evaluation metric here, since the experiments are on an LTAG treebank. The derived trees in the LTAG treebank are different from the CFG trees in PTB. Hence, we do not use metrics such as labeled precision and labeled recall for evaluation.

2 Graph-based Incremental Construction

2.1 Idea and Data Structures

Now we define the problem formally. We will use dependency parsing as an example to illustrate the idea.

We are given a connected graph $G(V,E)$ whose hidden structure is U, where $V=\{v_i\}$, $E \subseteq V \times V$ is a symmetric relation, and $U=\{u_k\}$ is composed of a set of elements that vary with applications. As far as dependency parsing is concerned, the input graph is simply a chain of vertices, where $E(v_{i-1},v_i)$, and its hidden structure is $\{u_k=(v_{s_k},v_{e_k},b_k)\}$, where vertex v_{e_k} depends on vertex v_{s_k} with label b_k.

A graph-based incremental construction algorithm looks for the hidden structure in a bottom-up style.

Let x_i and x_j be two sets of connected vertexes in V, where $x_i \cap x_j = \phi$ and they are directly connected via an edge in E. Let y^{xi} be a hypothesized hidden structure of x_i, and y^{xj} a hypothesized hidden structure of x_j.

Suppose we choose to combine y^{xi} and y^{xj} with an operation r to build a hypothesized hidden structure for $x_k = x_i \cup x_j$. We say the process of construction is **incremental** if the output of the operation, $y^{xk} = r(x_i, x_j, y^{xi}, y^{xj}) \supseteq y^{xi} \cup y^{xj}$ for all the possible x_i, x_j, y^{xi}, y^{xj} and operation r. As far as dependency parsing is concerned, incrementality means that we cannot remove any links coming from the substructures.

Once y^{xk} is built, we can no longer use y^{xi} or y^{xj} as a building block. It is easy to see that left to right incremental construction is a special case of our approach. So the question is how we decide the order of construction as well as the type of operation r. For example, in the very first step of dependency parsing, we need to decide which two words are to be combined as well as the dependency label to be used.

This problem is solved statistically, based on the features defined on the substructures involved in the operation and their context. Suppose we are given the weights of these features, we will show in the next section how these parameters guide us to build a set of hypothesized hidden structures with beam search. In Section 3, we will present a Perceptron like algorithm (Collins, 2002; Daumé III and Marcu, 2005) to obtain the parameters.

Now we introduce the data structure to be used in our algorithms.

A **fragment** is a *connected* sub-graph of $G(V, E)$. Each fragment x is associated with a set of hypothesized hidden structures, or **fragment hypotheses** for short: $Y^x = \{y_1^x, ..., y_k^x\}$. Each y^x is a possible fragment hypothesis of x.

It is easy to see that an operation to combine two fragments may depend on the fragments in the context, i.e. fragments directly connected to one of the operands. So we introduce the **dependency** relation over fragments. Suppose there is a dependency relation $D \subseteq F \times F$, where $F \subseteq 2^V$ is the set of all fragments in graph G. $D(x_i, x_j)$ means that any operation on a fragment hypothesis of x_i depends on the features in the fragment hypothesis of x_j, and vice versa.

We are especially interested in the following two dependency relations.

- *level-0 dependency*: $D_0(x_i, x_j) \iff i = j$.
- *level-1 dependency*: $D_1(x_i, x_j) \iff x_i$ and x_j are directly connected in G.

Level-0 dependency means that the features of a hypothesis for a vertex x_i do not depend on the hypotheses for other vertices. Level-1 dependency means that the features depend on the hypotheses of nearby vertices only.

The learning algorithm for level-0 dependency is similar to the guided learning algorithm for labelling as described in (Shen et al., 2007). Level-1 dependency requires more data structures to maintain the hypotheses with dependency relations among them. However, we do not get into the details of level-1 formalism in this papers for two reasons. One is the limit of page space and depth of a conference paper. On the other hand, our experiments show that the parsing performance with level-1 dependency is close to what level-0 dependency could provides. Interested readers could refer to (Shen, 2006) for detailed description of the learning algorithms for level-1 dependency.

2.2 Algorithms

Algorithm 1 shows the procedure of building hypotheses incrementally on a given graph $G(V, E)$. Parameter k is used to set the beam width of search. Weight vector $\mathbf{w}$ is used to compute score of an operation.

We have two sets, H and Q, to maintain hypotheses. Hypotheses in H are selected in beam search, and hypotheses in Q are candidate hypotheses for the next step of search in various directions.

We first initiate the hypotheses for each vertex, and put them into set H. For example, in dependency parsing, the initial value is a set of possible POS tags for each single word. Then we use a queue Q to collect all the possible hypotheses over the initial hypotheses H.

Whenever Q is not empty, we search for the hypothesis with the highest score according to a given weight vector $\mathbf{w}$. Suppose we find (x, y). We select

Algorithm 1 Incremental Construction

```
Require: graph $G(V, E)$;
Require: beam width $k$;
Require: weight vector $\mathbf{w}$;
1: $H \leftarrow init_H()$;
2: $Q \leftarrow init_Q(H)$;
3: repeat
4:     $(x', y') \leftarrow arg\max_{(x,y)\in Q} score(y)$;
5:     $H \leftarrow update_H(H, x')$;
6:     $Q \leftarrow update_Q(Q, H, x')$;
7: until $(Q = \phi)$
```

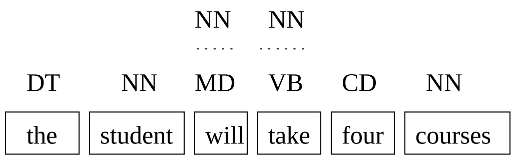

Figure 1: After initialization

top k-best hypotheses for segment x from Q and use them to update H. Then we remove from Q all the hypotheses for segments that have overlap with segment x. In the end, we build new candidate hypotheses with the updated selected hypothesis set H, and add them to Q.

2.3 An Example

We use an example of dependency parsing to illustrate the incremental construction algorithm first.

Suppose the input sentence is *the student will take four courses*. We are also given the candidate POS tags for each word. So the graph is just a linear structure in this case. We use level-0 dependency and set beam width to two.

We use boxes to represent fragments. The dependency links are from the parent to the child.

Figure 1 shows the result after initialization. Figure 2 shows the result after the first step, combining the fragments of *four* and *courses*. Figure 3 shows the result after the second step, combining *the* and *student*, and figure 4 shows the result after the third step, combining *take* and *four courses*. Due to limited space, we skip the rest operations.

2.4 Description

Now we will explain the functions in Algorithm 1 one by one.

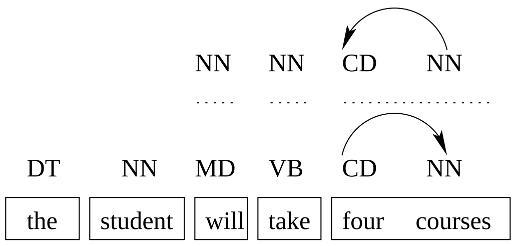

Figure 2: Step 1

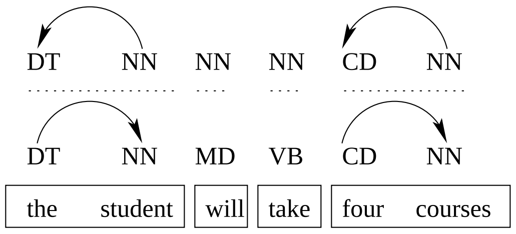

Figure 3: Step 2

- $init_H()$ initiates hypotheses for each vertex. Here we set the initial fragment hypotheses, $Y^{xi} = \{y_1^{xi}, ..., y_k^{xi}\}$, where $x_i = \{v_i\}$ contains only one vertex.

- $init_Q(H)$ initiates the queue of candidate operations over the current hypotheses H. Supposed there exist segments x_i and x_j which are directly connected in G. We apply all possible operations to all fragment hypotheses for x_j and x_j, and add the result hypotheses in Q. For example, we generate (x, y) with some operation r, where segment x is $x_i \cup x_j$.

  All the candidate operations are organized with respect to the segments. For each segment, we maintain top k candidates according to their scores.

- $update_H(H, x)$ is used to update hypotheses in H. First, we remove from H all the hypotheses whose corresponding segment is a sub-set of x. Then, we add into H the top k hypotheses for segment x.

- $update_Q(Q, H, x)$ is also designed to complete two tasks. First, we remove from Q all the hypotheses whose corresponding segment has overlap with segment x. Then, we add new candidate hypotheses depending on x in a way

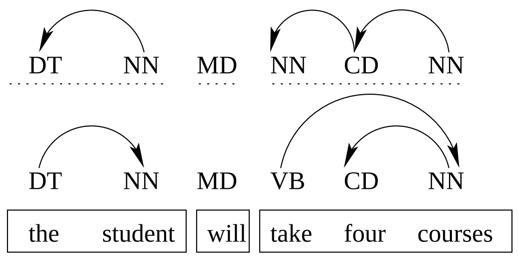

Figure 4: Step 3

Algorithm 2 Parameter Optimization

```
1:  $\mathbf{w} \leftarrow \mathbf{0}$;
2:  for (round $r = 0$; $r < R$; $r$++) do
3:      load graph $G_r(V, E)$, gold standard $H_r$;
4:      initiate $H$ and $Q$;
5:      repeat
6:          $(x', y') \leftarrow arg\max_{(x,y)\in Q} score(y)$;
7:          if ($y'$ is compatible with $H_r$) then
8:              update $H$ and $Q$;
9:          else
10:             $\tilde{y} \leftarrow positive(Q, x')$;
11:             $promote(\mathbf{w}, \tilde{y})$;
12:             $demote(\mathbf{w}, y')$;
13:             update $Q$ with $\mathbf{w}$;
14:         end if
15:     until ($Q = \phi$)
16: end for
```

similar to the $init_Q(H)$ function. For each segment, we maintain the top k candidates for each segment.

3 Parameter Optimization

In the previous section, we described an algorithm for graph-based incremental construction for a given weight vector **w**. In Algorithm 2, we present a Perceptron like algorithm to obtain the weight vector for the training data.

For each given training sample (G_r, H_r), where H_r is the gold standard hidden structure of graph G_r, we first initiate cut T, hypotheses H^T and candidate queue Q by calling $init_H$ and $init_Q$ as in Algorithm 1.

Then we use the gold standard H_r to guide the search. We select candidate (x', y') which has the highest operation score in Q. If y' is compatible with H_r, we update H and Q by calling $update_H$ and $update_Q$ as in Algorithm 1. If y' is incompatible with H_r, we treat y' as a negative sample, and search for a positive sample $\tilde{y}$ in Q with $positive(Q, x')$.

If there exists a hypothesis $\tilde{y}^{x'}$ for fragment x' which is compatible with H_r, then $positive(Q, x')$ returns $\tilde{y}^{x'}$. Otherwise $positive(Q, x')$ returns the candidate hypothesis which is compatible with H_r and has the highest operation score in Q.

Then we update the weight vector $\mathbf{w}$ with $\tilde{y}$ and y'. At the end, we update the candidate Q by using the new weights $\mathbf{w}$.

In order to improve the performance, we use *Perceptron with margin* in the training (Krauth and Mézard, 1987). The margin is proportional to the loss of the hypothesis. Furthermore, we use averaged weights (Collins, 2002; Freund and Schapire, 1999) in Algorithm 1.

4 LTAG Dependency Parsing

We apply the new algorithm to LTAG dependency parsing on an LTAG Treebank (Shen et al., 2008) extracted from Penn Treebank (Marcus et al., 1994) and Proposition Bank (Palmer et al., 2005). Penn Treebank was previously used to train and evaluate various dependency parsers (Yamada and Matsumoto, 2003; McDonald et al., 2005). In these works, Magerman's rules are used to pick the head at each level according to the syntactic labels in a local context.

The dependency relation encoded in the LTAG Treebank reveals deeper information for the following two reasons. First, the LTAG architecture itself reveals deeper dependency. Furthermore, the PTB was reconciled with the Propbank in the LTAG Treebank extraction (Shen et al., 2008).

We are especially interested in the two types of structures in the LTAG Treebank, predicate adjunction and predicate coordination. They are used to encode dependency relations which are unavailable in other approaches. On the other hand, these structures turn out to be a big problem for the general representation of dependency relations, including adjunction and coordination. We will show that the algorithm proposed here provides a nice solution for this problem.

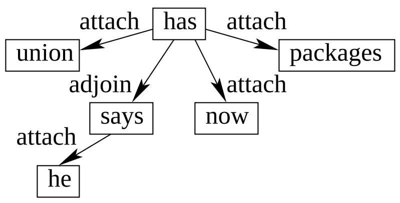

Figure 5: Predicate Adjunction

4.1 Representation of the LTAG Treebank

In the LTAG Treebank (Shen et al., 2008), each word is associated with a spinal template, which represents the projection from the lexical item to the root. Templates are linked together to form a *derivation* tree. The topology of the derivation tree shows a type of dependency relation, which we call **LTAG dependency** here.

There are three types of operations in the LTAG Treebank, which are attachment, adjunction, and coordination. Attachment is used to represent both substitution and sister adjunction in the traditional LTAG. So it is similar to the dependency relation in other approaches.

The LTAG dependency can be a non-projective relation thanks to the operation of adjunction. In the LTAG Treebank, raising verbs and passive ECM verbs are represented as auxiliary trees to be adjoined. In addition, adjunction is used to handle many cases of discontinuous arguments in Propbank. For example, in the following sentence, ARG1 of *says* in Propbank is discontinuous, which is *First Union now has packages for seven customer groups*.

- *First Union, he says, now has packages for seven customer groups.*

In the LTAG Treebank, the subtree for *he says* adjoins onto the node of *has*, which is the root of the derivation tree, as shown in Figure 5.

Another special aspect of the LTAG Treebank is the representation of predicate coordination. Figure 6 is the representation of the following sentence.

- *I couldn't resist rearing up on my soggy loafers and saluting.*

The coordination between *rearing* and *saluting* is represented explicitly with a coord-structure, and

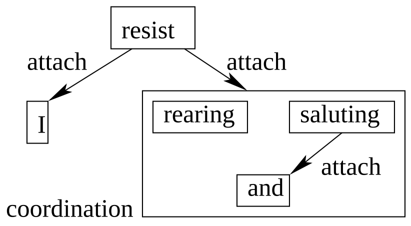

Figure 6: Predicate Coordination

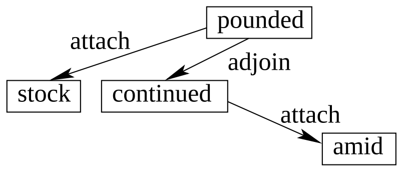

Figure 7: Non-projective Adjunction

this coord-structure attaches to *resist*. It is shown in (Shen et al., 2008) that coord-structures could encode the ambiguity of argument sharing, which can be non-projective also.

4.2 Incremental Construction

We build LTAG derivation trees incrementally. A hypothesis of a fragment is represented with a partial derivation tree. When the fragment hypotheses of two nearby fragments combine, the partial derivation trees are combined into one.

It is trivial to combine two partial derivation trees with attachment. We simply attach the root of one tree to some node on the other tree which is *visible* to this root node. Adjunction is similar to attachment, except that an adjoined subtree may be *visible* from the other side of the derivation tree. For example, in sentence

- *The stock of UAL Corp. continued to be pounded amid signs that British Airways ...*

continued adjoins onto *pounded*, and *amid* attaches to *continued* from the other side of the derivation tree (*pounded* is between *continued* and *amid*), as shown in Figure 7.

The predicate coordination is decomposed into a set of operations to meet the need for incremental processing. Suppose a coordinated structure attaches to the parent node on the left side. We build this structure incrementally by attaching the first

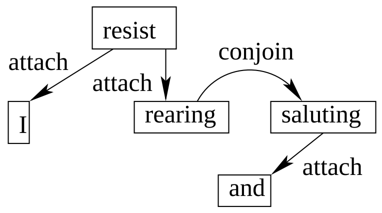

Figure 8: Conjunction

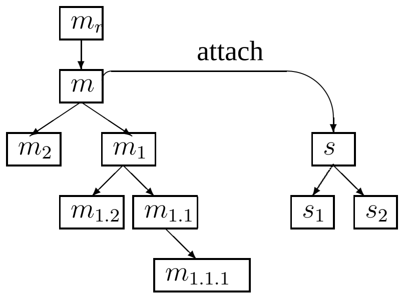

Figure 9: Representation of nodes

conjunct to the parent and conjoining other conjuncts to first one. In this way, we do not need to force the coordination to be built before the attachment. Either can be executed first. A sample is shown in Figure 8.

4.3 Features

In this section, we will describe the features used in LTAG dependency parsing. An operation is represented by a 4-tuple

- $op = (type, dir, pos_{left}, pos_{right})$,

where $type \in \{attach, adjoin, conjoin\}$ and dir is used to represent the direction of the operation. pos_{left} and pos_{right} are the POS tags of the two operands.

Features are defined on POS tags and lexical items of the nodes in the context. In order to represent the features, we use m for the main-node of the operation, s for the sub-node, m_r for the parent of the main-node, $m_1..m_i$ for the children of m, and $s_1..s_j$ for the children of s, as shown in Figure 9. The index always starts from the side where the operation takes place. We use the Gorn addresses to represent the nodes in the subtrees rooted on m and s.

Furthermore, we use l_k and r_k to represent the nodes in the left and right context of the flat sentence. We use h_l and h_r to represent the head of the hypothesis trees on the left and right context respectively. Let x be a node. We use $x.p$ to represent the POS tag of node x, and $x.w$ to represent the lexical item of node x.

Table 1 show the features used in LTAG dependency parsing. There are seven classes of features. The first three classes of features are those defined on only one operand, on both operands, and on the siblings respectively. If gold standard POS tags are used as input, we define features on the POS tags in the context. If level-1 dependency is used, we define features on the root node of the hypothesis partial derivation trees in the neighborhood.

Half check and full check features are designed for grammatical check. For example, in Figure 9, node s attaches onto node m from left. Then nothing can attach onto s from the right side. The children of the right side of s are fixed, so we use the half check features to check the completeness of the children of the right half for s. Furthermore, we notice that all the rightmost descendants of s and the leftmost descendants of m at each level become unavailable for any further operation. So their children are fixed after this operation. All these nodes are in the form of $m_{1.1...1}$ or $s_{1.1...1}$. We use full check features to check the children from both sides for these nodes.

In the discussion above, we ignored adjunction and conjunction. We need to slightly refine the conditions of checking. Due to the limit of space, we skip these cases.

5 Experiments

We use the same data set as in (Shen and Joshi, 2005). We use Sec. 2-21 of the LTAG Treebank for training, Sec. 22 for feature selection, and Sec. 23 for test. Table 2 shows the comparison of different models. Beam size is set to five in our experiments. With level-0 dependency, our system achieves an accuracy of 90.3% at the speed of 4.25 sentences a second on a Xeon 3G Hz processor with JDK 1.5. With level-1 dependency, the parser achieves 90.5% at 3.59 sentences a second. Level-1 dependency does not provide much improvement due to the fact that level-0 features provide most of the useful information for this specific application.

It is interesting to compare our system with other dependency parsers. The accuracy on LTAG depen-

category	description	templates
one operand	Features defined on only one operand. For each template tp, $[type, dir, tp]$ is used as a feature.	$(m.p)$, $(m.w)$, $(m.p, m.w)$, $(s.p)$, $(s.w)$, $(s.p, s.w)$
two operands	Features defined on both operands. For each template tp, $[op, tp]$ is used as a feature. In addition, $[op]$ is also used as a feature.	$(m.w)$, $(s.w)$, $(m.w, s.w)$
siblings	Features defined on the children of the main nodes. For each template tp, $[op, tp]$, $[op, m.w, tp]$, $[op, m_r.p, tp]$ and $[op, m_r.p, m.w, tp]$ are used as features.	$(m_1.p)$, $(m_1.p, m_2.p)$, .., $(m_1.p, m_2.p, .., m_i.p)$
POS context	In the case that gold standard POS tags are used as input, features are defined on the POS tags of the context. For each template tp, $[op, tp]$ is used as a feature.	$(l_2.p)$, $(l_1.p)$, $(r_1.p)$, $(r_2.p)$, $(l_2.p, l_1.p)$, $(l_1.p, r_1.p)$, $(r_1.p, r_2.p)$
tree context	In the case that level-1 dependency is employed, features are defined on the trees in the context. For each template tp, $[op, tp]$ is used as a feature.	$(h_l.p)$, $(h_r.p)$
half check	Suppose $s_1, ..., s_k$ are all the children of s which are between s and m in the flat sentence. For each template tp, $[tp]$ is used as a feature.	$(s.p, s_1.p, s_2.p, .., s_k.p)$, $(m.p, s.p, s_1.p, s_2.p, .., s_k.p)$ and $(s.w, s.p, s_1.p, s_2.p, .., s_k.p)$, $(s.w, m.p, s.p, s_1.p, s_2.p, .., s_k.p)$ if $s.w$ is a verb
full check	Let x_1, x_2, .., x_k be the children of x, and x_r the parent of x. For any $x = m_{1.1...1}$ or $s_{1.1...1}$, template tp, $[tp(x)]$ is used as a feature.	$(x.p, x_1.p, x_2.p, .., x_k.p)$, $(x_r.p, x.p, x_1.p, x_2.p, .., x_k.p)$ and $(x.w, x.p, x_1.p, x_2.p, .., x_k.p)$, $(x.w, x_r.p, x.p, x_1.p, x_2.p, .., x_k.p)$ if $x.w$ is a verb

Table 1: Features defined on the context of operation

model	accuracy%
Shen and Joshi, 2005	89.3
level-0 dependency	90.3
level-1 dependency	90.5

Table 2: Experiments on Sec. 23 of the LTAG Treebank

dency is comparable to the numbers of the previous best systems on dependency extracted from PTB with Magerman's rules, for example, 90.3% in (Yamada and Matsumoto, 2003) and 90.9% in (McDonald et al., 2005). However, their experiments are on the PTB, while ours is on the LTAG corpus.

It should be noted that it is more difficult to learn LTAG dependencies. Theoretically, the LTAG dependencies reveal deeper relations. Adjunction can lead to non-projective dependencies, and the dependencies defined on predicate adjunction are linguistically more motivated, as shown in the examples in Figure 5 and 7. The explicit representation of predicate coordination also provides deeper relations. For example, in Figure 6, the LTAG dependency contains $resist \rightarrow rearing$ and $resist \rightarrow saluting$, while the Magerman's dependency only contains $resist \rightarrow rearing$. The explicit representation of predicate coordination will help to solve for the dependencies for shared arguments.

6 Discussion

In our approach, each fragment in the graph is associated with a hidden structure, which means that we cannot reduce it to a labelling task. Therefore, the problem of interest to us is different from previous work on graphical models, such as CRF (Lafferty et al., 2001) and MMMN (Taskar et al., 2003).

McAllester et al. (2004) introduced Case-Factor Diagram (CFD) to transform a graph based construction problem to a labeling problem. However, adjunction, prediction coordination, and long distance dependencies in LTAG dependency parsing make it difficult to implement. Our approach provides a novel alternative to CFD.

Our learning algorithm stems from Perceptron training in (Collins, 2002). Variants of this method have been successfully used in many NLP tasks, like shallow processing (Daumé III and Marcu, 2005), parsing (Collins and Roark, 2004; Shen and Joshi, 2005) and word alignment (Moore, 2005). Theoretical justification for those algorithms can be applied to our training algorithm in a similar way.

In our algorithm, dependency is defined on complicated hidden structures instead of on a graph. Thus long distance dependency in a graph becomes local in hidden structures, which is desirable from linguistic considerations.

The search strategy of our bidirectional dependency parser is similar to that of the bidirectional CFG parser in (Satta and Stock, 1994; Ageno and Rodrguez, 2001; Kay, 1989). A unique contribution of this paper is that selection of path and decisions about action are trained simultaneously with discriminative learning. In this way, we can employ context information more effectively.

7 Conclusion

In this paper, we introduced bidirectional incremental parsing, a new architecture of parsing. We proposed a novel algorithm for graph-based incremental construction, and applied this algorithm to LTAG dependency parsing, revealing deep relations, which are unavailable in other approaches and difficult to learn. We evaluated the parser on an LTAG Treebank. Experimental results showed significant improvement over the previous best system. Incremental construction can be applied to other structure learning problems of high computational complexity, for example, such as machine translation and semantic parsing.

Abstract

Parallel web pages are important source of training data for statistical machine translation. In this paper, we present a new approach to sentence alignment on parallel web pages. Parallel web pages tend to have parallel structures，and the structural correspondence can be indicative information for identifying parallel sentences. In our approach, the web page is represented as a tree, and a stochastic tree alignment model is used to exploit the structural correspondence for sentence alignment. Experiments show that this method significantly enhances alignment accuracy and robustness for parallel web pages which are much more diverse and noisy than standard parallel corpora such as “Hansard”. With improved sentence alignment performance, web mining systems are able to acquire parallel sentences of higher quality from the web.

1 Introduction

Sentence-aligned parallel bilingual corpora have been essential resources for statistical machine translation (Brown et al. 1993), and many other multi-lingual natural language processing applications. The task of aligning parallel sentences has received considerable attention since the renaissance of data driven machine translation in late 1980s.

During the past decades, a number of methods have been proposed to address the sentence alignment problem. Although excellent performance was reported on clean corpora, they are less robust with presence of noise. A recent study by (Singh and Husain 2005) completed a systematic evaluation on different sentence aligners under various conditions. Their experiments showed that the performance of sentence aligners are sensitive to properties of the text, such as format complexity (presence of elements other than text), structural distance (a scale from literal to free translation), the amount of noise (text deletions or preprocessing errors) and typological distance between languages. Their performance varies on different type of texts and they all demonstrate marked performance degradation over noisy data. The results suggest that there is currently no universal solution to sentence alignment under all conditions, and different methods should be applied to different types of texts.

In this paper, we specifically address sentence alignment on parallel web pages. It has come to attention with the increasing trend of acquiring large-scale parallel data from the web. Currently, large-scale parallel data are not readily available for most language pairs and domains. But due to a sharply increasing number of bilingual web sites, web mining shows great promise as a solution to this knowledge bottleneck problem. Many systems (Ma 1999; Chen 2000; Yang 2002; Resnik 2003; Chen 2004) have been developed to discover parallel web pages, and sentence aligners are used to extract parallel sentences from the mined web corpora. Sentence alignment performance on parallel web pages, therefore, becomes an increasingly important issue for large-scale high-quality parallel data acquisition.

Compared with clean parallel corpora such as "Hansard" (Brown et al. 1993), which consists of

French-English translations of political debates in the Canadian parliament, texts from the web are far more diverse and noisy. They are from many different domains and of various genres. Their translation may be non-literal or written in disparate language pairs. Noise is abundant with frequent insertions, deletions or non-translations. And there are many very short sentences of 1-3 words. Due to the characteristics of web corpora, direct application of conventional alignment methods without exploiting additional web document information acts as useful information to constrain the scope of search for parallel sentences.

The paper is organized as follows: In section 2, we briefly survey previous approaches to sentence alignment. In section 3, we present the stochastic tree alignment model, including parameter estimation and decoding. Then in section 4, we describe how to use the tree alignment model in sentence alignment. Benchmarks are shown in section 5, and the paper is concluded in section 6.

Figure 1. Example of parallel web pages

yields unsatisfactory alignment results.

Our approach to this problem is to make use of the structural parallelism between parallel web pages. Structural parallelism is the phenomenon, that when representing the same content in two different languages, authors have a very strong tendency to use the same document structure. As is shown in Figure 1, sentences located in similar position on both pages are more likely to be translations. Hence, correspondence in the web page structure is an informative indication of parallel sentences. In our approach, the web page is represented as a tree, and a stochastic tree alignment model is used to find the most probable alignment of the tree pair based on their structure and the texts in tree nodes. The tree alignment then

2 Sentence Alignment Models

Sentence alignment methods can be categorized into three major categories: the length-based, lexicon-based and hybrid method which combines the length-based model and lexicon-based model as complement to each other.

The length model was based on the intuition that the length of a translated sentence is likely to be similar to that of the source sentence. (Brown et. at. 1991) used word count as the sentence length, whereas (Gale and Church 1993) used character count. Dynamic programming is used to search the optimal sentence alignment. Both algorithms have achieved remarkably good results for language pairs like English-French and English-German with an error rate of 4% on average. But they are not robust with respect to non-literal translations, deletions and disparate language pairs.

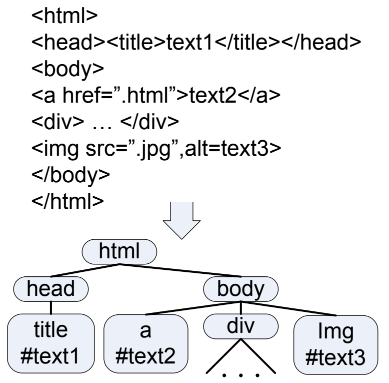
Unlike the length-based model, which totally ignores word identity, lexicon-based methods use lexical information to align parallel sentences. Kay's (Kay and Roscheisen 1993) approach is based on the idea that words that are translations of each other will have similar distribution in source and target texts. By adopting the IBM model 1, (Chen 1993) used word translation probabilities, which he showed gives better accuracy than the sentence length based method. Melamed (Melamed 1996) rather used word correspondence from a different perspective as geometric correspondence for sentence alignment.

The hybrid method combines the length model with the lexical method. (Simard and Plamondon 1996) used a two-pass approach, where the first pass performs length-based alignment at the character level as in (Gale and Church 1993) and the second pass uses IBM Model 1, following (Chen 1993). Moore's (Moore 2002) approach is similar to Simard's. The difference is that Moore used the data obtained in the first pass to train the IBM model in the second pass, so that his approach does not require a priori knowledge about the language pair. Instead of using a two-pass approach, (Zhao and Vogel 2002) combines the length model and the IBM model 1 in a unified framework under a maximum likelihood criterion. To make it more robust on noisy text, they developed a background model to handle text deletions.

To further improve sentence alignment accuracy and robustness, methods that make use of additional language or corpus specific information were developed. In Brown and Church's length-based aligner, they assume prior alignment on some corpus specific anchor points to constrain and keep the Viterbi search on track. (Wu 1994) implemented a length-based model for Chinese-English with language specific lexical clues to improve accuracy. (Simard et al. 1992) used cognates, which only exists in closely related language pairs. (Chuang and Yeh 2005) exploited the statistically ordered matching of punctuation marks in two languages to achieve high accuracy sentence alignment. In their web parallel data mining system, (Chen and Nie 2000) used HTML tags in the same way as cognates in (Simard et al. 1992) for aligning Chinese-English parallel sentences. Tree based alignment models have been successfully applied in machine translation (Wu 1997, Yamada & Knight 2001, Gildea 2003).

3 The Stochastic Tree Alignment Model

The structure of the HTML document is recursive, with HTML markup tags embedded within other markup tags. While converting an HTML document into the tree representation, such hierarchical order is maintained. Each node of the tree is labeled with their corresponding HTML tag (*e.g. body, title, img etc.*) and in labeling tree nodes, only markup tags are used and attribute value pairs are dropped. Among all markup tags in the HTML file, those of our most interest are tags containing content text, which is what we want to align. These tags are those surrounding a text chunk or have the attribute of "ALT". Comments, scripts and style specifications are not regarded as content text and hence are eliminated. Figure 2 illustrates the tree representation of an example HTML document.



```
<html>
<head><title>text1</title></head>
<body>
<a href=".html">text2</a>
<div> … </div>
<img src=".jpg",alt=text3>
</body>
</html>
```

Figure. 2 An example HTML document and its tree representation

3.1 Tree Alignment Model

Given two trees, the tree alignment is the non-directional alignments of their nodes. A node in one tree can be aligned with at most one node in the other tree. It is valid for a node to be aligned with nothing (*NULL*) and such case is regarded as node deletion in tree alignment. To comply with the tree hierarchical structure, we constrain that the alignments keep the tree hierarchy invariant *i.e.* if node *A* is aligned with node *B*, then the children of *A* are either deleted or aligned with the children of *B*. Besides, to simplify the model training and decoding, the tree alignment model also keeps the sequential order invariant, *i.e.* if node A is aligned with node B, then the left sibling nodes of A cannot be aligned with the right sibling nodes of B.

The stochastic tree alignment model assigns probabilities to tree alignments, based on the particular configuration of the alignment and model parameters. Then, the decoder is able to find the most probable (optimal) alignment of two trees. To facilitate the presentation of the tree alignment model, the following symbols are introduced: given a HTML document D, T^D denotes the corresponding tree; N_i^D denotes the ith node of T^D, and T_i^D denotes the sub-tree rooted at N_i^D. Especially, T_1^D is the root of the tree T^D. $T_{[i,j]}^D$ denotes the forest consisting of the sub-trees rooted at sibling nodes from T_i^D to T_j^D. $N_i^D.t$ denotes the text in the node N_i^D, and $N_i^D.t$ denotes the label (*i.e.* HTML tag) of the node N_i^D; $N_i^D.C_i$ denotes the jth child of the node N_i^D; $N_i^D.C_{[m,n]}$ denotes the consecutive sequence of N_i^D's children nodes from $N_i^D.C_m$ to $N_i^D.C_n$; the sub-tree rooted at $N_i^D.C_i$ is represented as $N_i^D.CT_i$ and the forest of the sub-trees rooted at N_i^D's children is represented as $N_i^D.CF$. To accommodate node deletion, $NULL$ is introduced to denote the empty node. Finally, the tree alignment is referred as A.

Given two HTML documents F (in French) and E (in English) represented as trees T^F and T^E, the tree alignment task is defined as finding the alignment A that maximizes the conditional probability $\Pr(A|T^F,T^E)$. Based on the Bayes' Rule, $\Pr(A|T^F,T^E) \propto \Pr(T^F,T^E|A)\Pr(A)$, where $\Pr(T^F,T^E|A)$ is the probability of synchronously generating T^F and T^E given the alignment A, and $\Pr(A)$ is the prior knowledge of the tree alignment. To simplify computation, we assume a uniform prior probability $\Pr(A)$. Hence, the tree alignment task is to find the A that maximizes the synchronous probability $\Pr(T^F,T^E|A)$.

Based on the hierarchical structure of the tree, in order to facilitate the presentation and computation of the tree alignment probabilistic model, the following alignment probabilities are defined in a hierarchically recursive manner:

$\Pr(T_m^F,T_i^E|A)$: The probability of synchronously generating sub-tree pair $\{T_m^F,T_i^E\}$ given the alignment A;

$\Pr(N_m^F,N_i^E|A)$: The probability of synchronously generating node pair $\{N_m^F,N_i^E\}$;

$\Pr(T_{[m,n]}^F,T_{[i,j]}^E|A)$: The probability of synchronously generating forest pairs $\{T_{[m,n]}^F,T_{[i,j]}^E\}$ given the alignment A.
