From the definition, the tree pair generative probability $\Pr(T^F,T^E|A)$ equals to the root sub-tree pair generative probability $\Pr(T_1^F,T_1^E|A)$. The alignment of the sub-tree pair T_j^F and T_i^E may have the following configurations, based on which the tree pair generative probability $\Pr(T_j^F,T_i^E|A)$ can be calculated:

(1) If N_m^F is aligned with N_i^E, and the children of N_m^F are aligned with children of N_i^E (as is shown in Fig. 3a), then we have

$$\Pr(T_m^F,T_i^E|A) = \Pr(N_m^F,N_i^E)\Pr(N_m^F.CF,N_i^E.CF|A)$$

(2) If N_m^F is deleted, and the children of N_m^F is aligned with N_i^E (as shown in Fig. 3b), then we have

$$\Pr(T_m^F,T_i^E|A) = \Pr(N_m^F|NULL)\Pr(N_m^F.CF,T_i^E|A)$$

(3) If N_i^E is deleted, and N_m^F is aligned with children of N_i^E (as shown in Fig. 3c), then we have

$$\Pr(T_m^F,T_i^E|A) = \Pr(T_m^F,N_i^E.CF|A)\Pr(N_i^E|NULL)$$

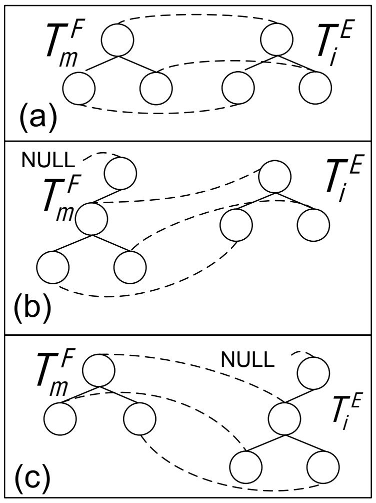

Figure. 3

The above equations involve forest pair generative probabilities. The alignment of the forest $T_{[m,n]}^F$ and $T_{[i,j]}^E$ may have the following configurations, based on which their forest pair generative probability $\Pr(T_{[m,n]}^F,T_{[i,j]}^E|A)$ can be calculated:

(4) If T_m^F is aligned with T_i^E, and $T_{[m+1,n]}^F$ is aligned with $T_{[i+1,j]}^E$ (as is shown in Fig. 4a), then

$$\Pr(T_{[m,n]}^F, T_{[i,j]}^E | A) = \Pr(T_m^F, T_i^E | A)\Pr(T_{[m+1,n]}^F, T_{[i+1,j]}^E | A)$$

(5) If N_m^F is deleted, and the forest rooted at N_m^F's children $N_m^F.CF$ is combined with $T_{[m+1,n]}^F$ for alignment with $T_{[i,j]}^E$, then

$$\Pr(T_{[m,n]}^F, T_{[i,j]}^E | A) = \Pr(N_m^F | NULL)\Pr(N_m^F.CF\ T_{[m+1,n]}^F, T_{[i,j]}^E | A)$$

(6) If N_i^E is deleted, and the forest rooted at N_i^E's children $N_i^E.CF$ is combined with $T_{[i,j]}^E$ for alignment with $T_{[m,n]}^F$, then

$$\Pr(T_{[m,n]}^F, T_{[i,j]}^E | A) = \Pr(N_i^E | NULL)\Pr(T_{[m,n]}^F, N_m^F.CF\ T_{[i+1,j]}^E | A)$$

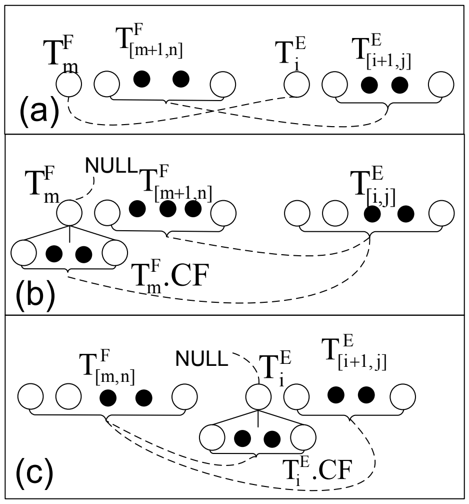

Figure. 4

Finally, the node pair probability is modeled as $\Pr(N_m^F, N_i^E) = \Pr(N_m^F.t, N_i^E.t)\Pr(N_m^F.l, N_i^E.l)$, where $\Pr(N_m^F.t, N_i^E.t)$ is the generative probability of the translationally equivalent text chunks in N_m^F and N_i^E, and $\Pr(N_m^F.l, N_i^E.l)$ is their HTML tag pair probability. The text chunk generative probability $\Pr(N_m^F.t, N_i^E.t)$ can be modeled in a variety of ways. The conventional length-based, lexicon-based or hybrid methods used for sentence alignment can be applied here. In the next sub-section, we focus on how to estimate the tag pair probability $\Pr(N_m^F.l, N_i^E.l)$ from a set of parallel web pages. We expect pairs of the same or similar HTML tags to have high probabilities and the probabilities for pairs of disparate tags to be low.

3.2 Parameter Estimation Using Expectation-Maximization

One way to estimate the tag pair generative probability $\Pr(l, l')$ is to manually align nodes between parallel trees, and use the manually aligned trees as the training data for maximum likelihood estimation. However, this is a time-consuming and error-prone procedure. Instead, the Expectation Maximization (EM) (Dempster, Laird and Rubin 1977) algorithm is used to estimate the parameters $\Pr(l, l')$ on 5615 manually verified parallel web page pairs from 45 different bilingual web sites. The parameter estimation proceeds as follows:

1. Start with initial parameter values.
2. Expectation: estimate $\overline{\text{count}}(l, l')$ which is the expectation of aligning tag l with l'.
3. Maximization: update the parameters based to maximum likelihood estimation
$$\Pr(l, l') = \frac{\overline{count}(l, l')}{\sum_{l'} \overline{count}(l, l')}$$ and
$$\Pr(l | NULL) = \frac{\overline{count}(NULL, l) + \overline{count}(l, NULL)}{\sum_{l'} [\overline{count}(NULL, l') + \overline{count}(l', NULL)]}$$
4. Repeat step 2 and 3 until the parameters stabilize

In step 2, $\overline{\text{count}}(l, l')$ is the expected count of l being aligned with l' in the training corpus. By definition, $\overline{\text{count}}(l, l')$ is calculated as

$$\overline{\text{count}}(l, l') = \sum_A \Pr(A | T^F, T^E)\text{count}(l, l')$$

where $\text{count}(l, l')$ is the number of occurrence of l being aligned with l' in the tree alignment A.

To efficiently compute $\overline{\text{count}}(l, l')$ without enumerating the exponential number of A's in the above equation, we extended the inside-outside algorithm presented in (Lari and Young, 1990). The inside probability $\alpha(N_j^F, N_i^E)$ is defined as the probability of generating sub-tree pair $\{T_j^F, T_i^E\}$ when N_i^E is aligned with N_j^F. It is estimated as:

$$\alpha\left(N_m^F, N_i^E\right) = \Pr\left(N_m^F, N_i^E\right)\alpha\left(N_m^F.CF, N_i^E.CF\right)$$

where $\alpha(N_m^F.CF, N_i^E.CF)$ is the inside probability for the forest pair $(N_m^F.CF, N_i^E.CF)$

$$\alpha\left(N_m^F.CF, N_i^E.CF\right) = \sum_A \Pr\left(N_m^F.CF, N_i^E.CF \middle| A\right).$$

The inside probability can be estimated recursively according to the various alignment configurations presented in Figure 3 and Figure 4. The outside probability $\beta(N_j^F, N_i^E)$ is defined as the probability of generating the part of T^E and T^F excluding the sub-trees T_j^F and T_i^E, when N_i^E is aligned with N_j^F. It is estimated as:

$$\begin{aligned}\beta\left(N_m^F, N_i^E\right) = \sum_{p,q} [\beta\left(a_{m,q}^F, a_{i,p}^E\right) \\ \times \alpha\left(a_{m,q}^F.LCF\left(N_m^F\right), a_{i,p}^E.LCF\left(N_i^E\right)\right) \\ \times \alpha\left(a_{m,q}^F.RCF\left(N_m^F\right), a_{i,p}^E.RCF\left(N_i^E\right)\right) \\ \times \prod_{k<q} \Pr(a_{m,k}^F \mid NULL) \prod_{k<p} \Pr(a_{i,k}^E \mid NULL)]\end{aligned}$$

where $a_{m,q}^F$ is the qth ancestor of N_m^F, and $a_{i,q}^E$ is the pth ancestor of N_i^E. $a_{m,k}^F (k < q)$ is an ancestor of N_m^F and a decedent of $a_{m,q}^F$. Similarly $a_{i,k}^E (k <$ p is an ancestor of *NiE*, and a decedent of *ai,pE*. *a.LCF(N)* is the forest rooted at *a* and to the left of *N*, and *a.RCF(N)*. *a.RCF(N)* is the forest rooted as *a* and to the right of *N*. Once inside and outside probabilities are computed, the expected counts can be calculated as

$$\overline{count}\left(l, l'\right) = \sum_{\{T^F, T^E\}} \sum_{\substack{N_i^E.l=l \\ N_m^F.l=l}} \frac{\alpha\left(N_m^F, N_i^E\right)\beta\left(N_m^F, N_i^E\right)}{\Pr(T^F, T^E)}$$

where $\Pr(T^F, T^E)$ is the generative probability of the tree pair $\{T^F, T^E\}$ over all possible alignment configurations. $\Pr(T^F, T^E)$ can be estimated using dynamic programming techniques that will be presented in the next sub-section. Furthermore, the expected count of tag deletion is estimated as:

$$\overline{\mathrm{count}}(l, NULL) = \sum_i \mathrm{count}(l, l') - \sum_{i \neq NULL} \overline{\mathrm{count}}(l, l')$$

$$\overline{\mathrm{count}}(NULL, l) = \sum_i \mathrm{count}(l', l) - \sum_{i \neq NULL} \overline{\mathrm{count}}(l', l)$$

3.3 Dynamic Programming for Decoding

An intuitive way to find the optimal tree alignment is to enumerate all alignments and pick the one with the highest probability. But it is intractable since the total number of alignments is exponential. Based on the observation that if two trees are optimally aligned, the alignment of their sub-trees must also be optimal, dynamic programming can be applied to find the optimal tree alignment using that of the sub-trees in a bottom-up manner. That is we first compute the optimal alignment probabilities of small trees and use them to compute that of the bigger tree by trying different alignment configurations. This procedure is recursive until the optimal alignment probability of the whole tree is obtained. The following is the pseudo-code of the bottom-up decoding algorithm:

```
for i=$|T^E|$ to 1 (bottom-up) {
  for j=$|T^F|$ to 1 (bottom-up) {
    Select and store optimal alignments of their children forests $T_m^F$.CF and $T_i^E$.CF by testing configurations 4-6;
    Select and store the optimal alignment of the sub-tree pair $T_m^F$ and $T_i^E$ by testing configurations 1-3;
    Store the optimal configuration}}
```

where $|T^F|$ and $|T^E|$ are the number of nodes in T^F and T^E. The decoding algorithm finds the optimal alignment and its probability for every sub-trees and forests. By replacing the selection operation with summing probabilities of all configurations, the sub-tree pair generative probability $\Pr(T^F, T^E)$ can be calculated along the way. The worst-case time complexity of the algorithm is $O(|T^F||T^E|\left(degr(T^F) + degr(T^E)\right)^2)$, where the degree of a tree is defined as the largest degree of its nodes.

4 Sentence Alignment with Tree Alignment Model

Since the tree alignment model aligns parallel web pages at the tree node level instead of the sentence level, we integrate the tree alignment model with the sentence alignment model in a cascaded mode, in which the whole sentence alignment process is divided into two steps. In the first step, the tree alignment decoder finds the optimal alignment of the two trees. Nodes having texts should be aligned with nodes containing their translations. Then in the second step, the conventional sentence aligner is used to align sentences within text chunks in the aligned nodes. In this step, various sentence alignment models can be applied, including the length-based model, the lexicon-based model and the hybrid model. Language or corpus specific information may also be used to further improve sentence alignment accuracy. The tree alignment acts as constraints that confine the scope of the search of sentence aligners.

5 Evaluation

To evaluate the effectiveness of exploiting web page document structure with the tree alignment model for improving sentence alignment accuracy, we compared the performance of three types of sentence alignment methods on parallel web pages.

The first type is to simply discard web page layout information. Web pages are converted to plain texts, and HTML tags are removed prior to performing sentence alignment. The second type is the baseline method of using web page document information. Instead of exploiting full HTML document structure, it follows Chen's approach (Chen and Nie 2000) which uses HTML tags in the same way as cognates used in (Simard et al. 1992). The third type is the combination of tree alignment model and conventional sentence models.

computer and literature. By manual annotation, 9,824 parallel sentence pairs are found. All sentence aligners run through the test parallel web pages, and each extracts a set of sentence pairs that it regards as parallel. The output pairs are matched with the annotated parallel sentences from the test corpus. Only exact matches of the sentence pairs are counted as correct.

Our evaluation metrics are precision (P), recall (R) and F-measure (F) defined as:

$$\mathrm{P} = \frac{\#\text{ of correctly aligned sentence pairs}}{\#\text{ of total output pairs}}$$

$$\mathrm{R} = \frac{\#\text{ of correctly aligned sentence pairs}}{\#\text{ of true parallel pairs}}$$

$$\mathrm{F} = \frac{2 * \mathrm{P} * \mathrm{R}}{\mathrm{P} + \mathrm{R}}$$

Based on the results in table 1, we can see that both Type 2 and Type 3 aligners outperform conventional sentence alignment models. Leveraging HTML document information can enhance sentence alignment quality. Especially, by using the tree alignment model, Type 3 aligners achieve a

	Length			Lexicon			Hybrid		
	P	R	F	P	R	F	P	R	F
Type I	85.6%	72.8%	78.7%	83.1%	75.2%	78.9%	87.3%	76.4%	81.5%
Type II	86.3%	74.8%	80.1%	85.7%	77.0%	81.1%	88.1%	78.6%	83.1%
Type III	93.2%	79.3%	85.7%	92.9%	80.4%	86.2%	94.3%	83.1%	88.3%

Table 1. Performance comparison between different types of sentence alignment methods

Each type of the web page sentence aligner makes use of three conventional sentence alignment models, one is the length based model following (Brown 1991), one is the lexicon based model following (Chen 1993), and the other one is the hybrid model presented in (Zhao 2002). To be fair in performance comparisons, the text generative probability $\Pr(N^F.t, N^E.t)$ in tree node alignment is modeled in accordance with that in the sentence alignment model. All these sentence aligners are implemented to handle sentence bead types of "1-0", "0-1","1-1", "1-2","1-3","2-1" and "3-1".

The test corpus is 150 parallel web page pairs randomly drawn from 20 Chinese-English bilingual web sites on topics related to politics, sports,

significant increase of around 7% on both precision and recall. Compared with the tree alignment model, the improvement by the Type 2 aligners is marginal. A reason for this is that the tree alignment model not only exploits HTML tag similarities as in the Type 2 method, but also takes into account location of texts. In the tree alignment model, texts at similar locations in the tree hierarchical structure are more probable to be translations than those in disparate locations, even though they all have the same tag.

We also evaluate the performance of the tree aligner. Since sentence alignment is performed within the text chunks of aligned nodes, tree alignment accuracy is very important for correct sentence alignment. We measure the alignment accuracy on all nodes as well as that specifically on text nodes on the test corpus. The evaluation result is shown in table 2.

	total	correct	accuracy
all node alignment	18492	17966	97.2%
text node alignment	3646	3577	98.1%

Table 2. Tree Alignment Metrics

Benchmarks in Table 2 show that the tree alignment model yields very reliable results with high accuracy in aligning both text nodes and non-text nodes. After an analysis on text node alignment errors, we find that 79.7% of them have texts of very short length (no more than 4 words), which may not contain sufficient information to be identified as parallel.

6 Conclusions

In this paper, we present a new approach to sentence alignment on parallel web pages. Due to the diversity and noisy nature of web corpora, a stochastic tree alignment model is employed to exploit document structure in parallel web pages as useful information for identifying parallel sentences. The tree alignment model can be combined with various conventional sentence alignment models to extract parallel sentences from parallel web pages. Experimental results show that exploiting structural parallelism inherent in parallel web pages provides superior alignment performance over conventional sentence alignment methods and significant improvement (around 7% in both precision and recall) is achieved by using the stochastic tree alignment model. With improved sentence alignment performance, web parallel data mining systems are able to acquire parallel sentences of higher quality and quantity from the web.

Abstract

Previously topic models such as PLSI (Probabilistic Latent Semantic Indexing) and LDA (Latent Dirichlet Allocation) were developed for modeling the contents of *plain texts*. Recently, topic models for processing *hypertexts* such as web pages were also proposed. The proposed hypertext models are generative models giving rise to both *words* and *hyperlinks*. This paper points out that to better represent the contents of hypertexts it is more essential to assume that the hyperlinks are fixed and to define the topic model as that of generating words only. The paper then proposes a new topic model for hypertext processing, referred to as Hypertext Topic Model (HTM). HTM defines the distribution of words in a document (i.e., the content of the document) as a mixture over latent topics in the document *itself* and latent topics in the documents which *the document cites*. The topics are further characterized as distributions of words, as in the conventional topic models. This paper further proposes a method for learning the HTM model. Experimental results show that HTM outperforms the baselines on topic discovery and document classification in three datasets.

1 Introduction

Topic models are probabilistic and generative models representing contents of documents. Examples of topic models include PLSI (Hofmann, 1999) and LDA (Blei et al., 2003). The key idea in topic modeling is to represent topics as distributions of words and define the distribution of words in document (i.e., the content of document) as a mixture over hidden topics. Topic modeling technologies have been applied to natural language processing, text mining, and information retrieval, and their effectiveness have been verified.

In this paper, we study the problem of topic modeling for *hypertexts*. There is no doubt that this is an important research issue, given the fact that more and more documents are available as hypertexts currently (such as web pages). Traditional work mainly focused on development of topic models for plain texts. It is only recently several topic models for processing hypertexts were proposed, including Link-LDA and Link-PLSA-LDA (Cohn and Hofmann, 2001; Erosheva et al., 2004; Nallapati and Cohen, 2008).

We point out that existing models for hypertexts may not be suitable for *characterizing contents of hypertext documents*. This is because all the models are assumed to generate both words and hyperlinks (outlinks) of documents. The generation of the latter type of data, however, may not be necessary for the tasks related to contents of documents.

In this paper, we propose a new topic model for hypertexts called HTM (Hypertext Topic Model), within the Bayesian learning approach (it is similar to LDA in that sense). In HTM, the hyperlinks of hypertext documents are supposed to be given. Each document is associated with one topic distribution. The word distribution of a document is defined as a mixture of latent topics of the document *itself* and latent topics of documents *which the document cites*. The topics are further defined as distributions

* This work was conducted when the first author visited Microsoft Research Asia as an intern.

of words. That means the content (topic distributions for words) of a hypertext document is not only determined by the topics of itself but also the topics of documents it cites. It is easy to see that HTM contains LDA as a special case. Although the idea of HTM is simple and straightforward, it appears that this is the first work which studies the model.

We further provide methods for learning and inference of HTM. Our experimental results on three web datasets show that HTM outperforms the baseline models of LDA, Link-LDA, and Link-PLSA-LDA, in the tasks of topic discovery and document classification.

The rest of the paper is organized as follows. Section 2 introduces related work. Section 3 describes the proposed HTM model and its learning and inference methods. Experimental results are presented in Section 4. Conclusions are made in the last section.

2 Related Work

There has been much work on topic modeling. Many models have been proposed including PLSI (Hofmann, 1999), LDA (Blei et al., 2003), and their extensions (Griffiths et al., 2005; Blei and Lafferty, 2006; Chemudugunta et al., 2007). Inference and learning methods have been developed, such as variational inference (Jordan et al., 1999; Wainwright and Jordan, 2003), expectation propagation (Minka and Lafferty, 2002), and Gibbs sampling (Griffiths and Steyvers, 2004). Topic models have been utilized in topic discovery (Blei et al., 2003), document retrieval (Xing Wei and Bruce Croft, 2006), document classification (Blei et al., 2003), citation analysis (Dietz et al., 2007), social network analysis (Mei et al., 2008), and so on. Most of the existing models are for processing plain texts. There are also models for processing hypertexts, for example, (Cohn and Hofmann, 2001; Nallapati and Cohen, 2008; Gruber et al., 2008; Dietz et al., 2007), which are most relevant to our work.

Cohn and Hofmann (2001) introduced a topic model for hypertexts within the framework of PLSI. The model, which is a combination of PLSI and PHITS (Cohn and Chang, 2000), gives rise to both the words and hyperlinks (outlinks) of the document in the generative process. The model is useful when the goal is to understand the distribution of links as well as the distribution of words. Erosheva et al (2004) modified the model by replacing PLSI with LDA. We refer to the modified mode as Link-LDA and take it as a baseline in this paper. Note that the above two models do not directly associate the topics of the citing document with the topics of the cited documents.

Nallapati and Cohn (2008) proposed an extension of Link-LDA called Link-PLSA-LDA, which is another baseline in this paper. Assuming that the citing and cited documents share similar topics, they explicitly model the information flow from the citing documents to the cited documents. In Link-PLSA-LDA, the link graph is converted into a bipartite graph in which links are connected from citing documents to cited documents. If a document has both inlinks and outlinks, it will be duplicated on both sides of the bipartite graph. The generative process for the citing documents is similar to that of Link-LDA, while the cited documents have a different generative process.

Dietz et al (2007) proposed a topic model for citation analysis. Their goal is to find topical influence of publications in research communities. They convert the citation graph (created from the publications) into a bipartite graph as in Link-PLSA-LDA. The content of a citing document is assumed to be generated by a mixture over the topic distribution of the citing document and the topic distributions of the cited documents. The differences between the topic distributions of citing and cited documents are measured, and the cited documents which have the strongest influence on the citing document are identified.

Note that in most existing models described above the hyperlinks are assumed to be generated and link prediction is an important task, while in the HTM model in this paper, the hyperlinks are assumed to be given in advance, and the key task is topic identification. In the existing models for hypertexts, the content of a document (the word distribution of the document) are not decided by the other documents. In contrast, in HTM, the content of a document is determined by itself as well as its cited documents. Furthermore, HTM is a generative model which can generate the contents of all the hypertexts in a collection, given the link structure of the collection. Therefore, if the goal is to accurately learn and pre-

Table 1: Notations and explanations.

T	Number of topics
$\mathbf{D}$	Documents in corpus
D	Number of documents
$\alpha_\theta, \alpha_\beta$	Hyperparameters for θ and β
λ	Hyperparameter to control the weight between the citing document and the cited documents
θ	Topic distributions for all documents
β	Word distribution for topic
b, c, z	Hidden variables for generating word
d	document (index)
$\mathbf{w}_d$	Word sequence in document d
N_d	Number of words in document d
L_d	Number of documents cited by document d
I_d	Set of cited documents for document d
i_{dl}	Index of l^{th} cited document of document d
ξ_d	Distribution on cited documents of document d
θ_d	Topic distribution associated with document d
b_{dn}	Decision on way of generating n^{th} word in document d
c_{dn}	Cited document that generates n^{th} word in document d
z_{dn}	Topic of n^{th} word in document d

Algorithm 1 Generative Process of HTM

```

  end if
  Draw a word $w_{dn} \sim P(w_{dn} \mid z_{dn}, \beta)$
end for
```

dict contents of documents, the use of HTM seems more reasonable.

3 Hypertext Topic Model

3.1 Model

In topic modeling, a probability distribution of words is employed for a given document. Specifically, the probability distribution is defined as a mixture over latent topics, while each topic is future characterized by a distribution of words (Hofmann, 1999; Blei et al., 2003). In this paper, we introduce an extension of LDA model for hypertexts. Table 1 gives the major notations and their explanations.

The graphic representation of conventional LDA is given in Figure 1(a). The generative process of LDA has three steps. Specifically, in each document a topic distribution is sampled from a prior distribution defined as Dirichlet distribution. Next, a topic is sampled from the topic distribution of the document, which is a multinominal distribution. Finally, a word is sampled according to the word distribution of the topic, which also forms a multinormal distribution.

The graphic representation of HTM is given in Figure 1(b). The generative process of HTM is described in Algorithm 1. First, a topic distribution is sampled for each document according to Dirichlet distribution. Next, for generating a word in a document, it is decided whether to use the current document or documents which the document cites. (The weight between the citing document and cited documents is controlled by an adjustable hyperparameter λ.) It is also determined which cited document to use (if it is to use cited documents). Then, a topic is sampled from the topic distribution of the selected document. Finally, a word is sampled according to the word distribution of the topic. HTM naturally mimics the process of writing a hypertext document by humans (repeating the processes of writing native texts and anchor texts).

The formal definition of HTM is given below. Hypertext document d has N_d words $\mathbf{w_d} = w_{d1} \cdots w_{dN_d}$ and L_d cited documents $I_d = \{i_{d1}, \ldots, i_{dL_d}\}$. The topic distribution of d is θ_d and topic distributions of the cited documents are $\theta_i, i \in I_d$. Given λ, θ, and β, the conditional probability distribution of $\mathbf{w_d}$ is defined as:

$$p(\mathbf{w_d}|\lambda, \theta, \beta) = \prod_{n=1}^{N_d} \sum_{b_{dn}} p(b_{dn}|\lambda) \sum_{c_{dn}} p(c_{dn}|\xi_d)$$

$$\sum_{z_{dn}} p(z_{dn}|\theta_d)^{b_{dn}} p(z_{dn}|\theta_{i_{dc_{dn}}})^{1-b_{dn}} p(w_{dn}|z_{dn}, \beta).$$

Here ξ_d, b_{dn}, c_{dn}, and z_{dn} are hidden variables. When generating a word w_{dn}, b_{dn} determines whether it is from the citing document or the cited documents. c_{dn} determines which cited document it is when $b_{dn} = 0$. In this paper, for simplicity we assume that the cited documents are equally likely to be selected, i.e., $\xi_{di} = \frac{1}{L_d}$.

Note that θ represents the topic distributions of all the documents. For any d, its word distribution is affected by both θ_d and $\theta_i, i \in I_d$. There is a propagation of topics from the cited documents to the citing document through the use of $\theta_i, i \in I_d$.

For a hypertext document d that does not have cited documents. The conditional probability distribution degenerates to LDA:

$$p(\mathbf{w_d}|\theta_d, \beta) = \prod_{n=1}^{N_d} \sum_{z_{dn}} p(z_{dn}|\theta_d) p(w_{dn}|z_{dn}, \beta).$$

By taking the product of the marginal probabilities of hypertext documents, we obtain the conditional probability of the corpus $\mathbf{D}$ given the hyperparameters $\lambda, \alpha_\theta, \beta$,

$$\begin{aligned}
&p(\mathbf{D}|\lambda, \alpha_\theta, \beta) = \\
&\int \prod_{d=1}^{D} p(\theta_d|\alpha_\theta) \prod_{n=1}^{N_d} \sum_{b_{dn}} p(b_{dn}|\lambda) \sum_{c_{dn}} p(c_{dn}|\xi_d) \\
&\sum_{z_{dn}} p(z_{dn}|\theta_d)^{b_{dn}} p(z_{dn}|\theta_{I_{dc_{dn}}})^{1-b_{dn}} \\
&p(w_{dn}|z_{dn}, \beta) d\theta. \qquad (1)
\end{aligned}$$

Note that the probability function (1) also covers the special cases in which documents do not have cited documents.

In HTM, the content of a document is decided by the topics of the document as well as the topics of the documents which the document cites. As a result contents of documents can be 'propagated' along the hyperlinks. For example, suppose web page A cites page B and page B cites page C, then the content of page A is influenced by that of page B, and the content of page B is further influenced by the content of page C. Therefore, HTM is able to more accurately represent the contents of hypertexts, and thus is more useful for text processing such as topic discovery and document classification.

3.2 Inference and Learning

An exact inference of the posterior probability of HTM may be intractable, we employ the mean field variational inference method (Wainwright and Jordan, 2003; Jordan et al., 1999) to conduct approximation. Let $I[\cdot]$ be an indicator function. We first define the following factorized variational posterior distribution q with respect to the corpus:

$$q = \prod_{d=1}^{D} q(\theta_d|\gamma_d)$$

$$\prod_{n=1}^{N_d} \left(q(x_{dn}|\rho_{dn})(q(c_{dn}|\psi_{dn}) \right)^{I[L_d>0]} q(z_{dn}|\phi_{dn}) \, ,$$

where γ, ψ, ϕ, and ρ denote free variational parameters. Parameter γ is the posterior Dirichlet parameter corresponding to the representations of documents in the topic simplex. Parameters ψ, ϕ, and ρ correspond to the posterior distributions of their associated random variables. We then minimize the KL divergence between q and the true posterior probability of the corpus by taking derivatives of the loss function with respect to variational parameters. The solution is listed as below.

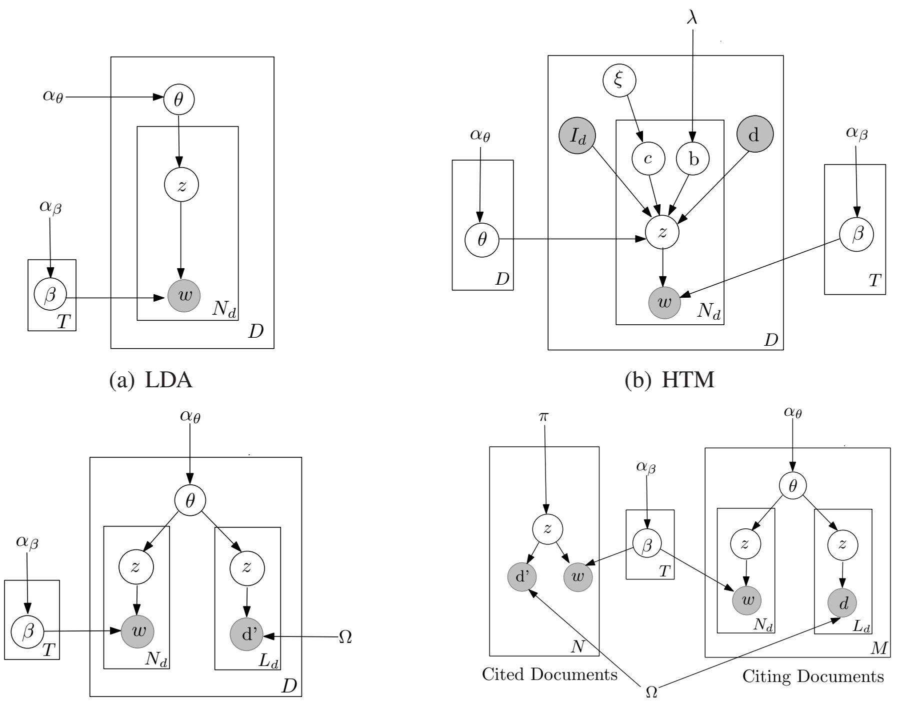
Let β_{iv} be $p(w_{dn}^v = 1|z^i = 1)$ for the word v. If $L_d > 0$, we have

E-step:

$$\begin{aligned}
\gamma_{d_i} &= \alpha_{\theta_i} + \sum_{n=1}^{N_d} \rho_{dn}\phi_{dni} + \sum_{d'=1}^{D} \sum_{l=1}^{L_{d'}} I\left[i_{d'l} = d\right] \\
&\quad \sum_{n=1}^{N_{d'}} (1 - \rho_{d'n})\psi_{d'nl}\phi_{d'ni} \, .
\end{aligned}$$

$$\begin{aligned}
\phi_{dni} &\propto \beta_{iv} \exp\left\{\rho_{dn} E_q\left[\log\left(\theta_{di}\right)|\gamma_d\right]\right. \\
&+ \left.(1 - \rho_{dn}) \sum_{l=1}^{L_d} \psi_{dnl} E_q\left[\log\left(\theta_{I_{dl}i}\right)|\gamma_{I_{dl}}\right]\right\} .
\end{aligned}$$

$$\begin{aligned}
\rho_{dn} &= \Bigg(1 + \Big(\exp\Big\{\sum_{i=1}^{k} \big((\phi_{dni} E_q[\log(\theta_{di})|\gamma_d] \\
&- \sum_{l=1}^{L_d} \psi_{dnl}\phi_{dni} E_q[\log(\theta_{I_{dl}i})|\gamma_{I_{dl}}]\big) \\
&+ \log\lambda - \log\left(1 - \lambda\right)\Big\}\Big)^{-1}\Bigg)^{-1} .
\end{aligned}$$



(a) LDA (b) HTM (c) Link-LDA (d) Link-PLSA-LDA

Figure 1: Graphical model representations

$$\varphi_{dnl} \propto \xi_{dl} \exp\{(1-\rho_{dn}) \sum_{i=1}^{k} \phi_{dni} E_q[\log(\theta_{I_{dl}i})|\gamma_{I_{dl}}]\}.$$

Otherwise,

$$\gamma_{d_i} = \alpha_{\theta_i} + \sum_{n=1}^{N_d} \phi_{dni} + \sum_{d'=1}^{D} \sum_{l=1}^{L_{d'}} I\left[i_{d'l} = d\right] \sum_{n=1}^{N_{d'}} (1-\rho_{d'n}) \psi_{d'nl} \phi_{d'ni} \, .$$

$$\phi_{dni} \propto \beta_{iv} \exp\left\{E_q\left[\log\left(\theta_{di}\right)|\gamma_d\right]\right\}.$$

From the first two equations we can see that the cited documents and the citing document jointly affect the distribution of the words in the citing document.

M-step:

$$\beta_{ij} \propto \sum_{d=1}^{D} \sum_{n=1}^{N_d} \phi_{dni} w_{dn}^{j}.$$

In order to cope with the data sparseness problem due to large vocabulary, we employ the same technique as that in (Blei et al., 2003). To be specific, we treat β as a $K * V$ random matrix, with each row being independently drawn from a Dirichlet distribution $\beta_i \sim Dir(\alpha_\beta)$. Variational inference is modified appropriately.

4 Experimental Results

We compared the performances of HTM and three baseline models: LDA, Link-LDA, and Link-PLSA-LDA in topic discovery and document classification. Note that LDA does not consider the use of link information; we included it here for reference.

4.1 Datasets

We made use of three datasets. The documents in the datasets were processed by using the Lemur Took kit (http://www.lemurproject.org), and the low frequency words in the datasets were removed.

The first dataset WebKB (available at http://www.cs.cmu.edu/˜webkb) contains six subjects (categories). There are 3,921 documents and 7,359 links. The vocabulary size is 5,019.

The second dataset Wikipedia (available at http://www.mpi-inf.mpg.de/˜angelova) contains four subjects (categories): Biology, Physics, Chemistry, and Mathematics. There are 2,970 documents and 45,818 links. The vocabulary size is 3,287.

The third dataset is ODP composed of homepages of researchers and their first level outlinked pages (cited documents). We randomly selected five subjects from the ODP archive. They are Cognitive Science (CogSci), Theory, NeuralNetwork (NN), Robotics, and Statistics. There are 3,679 pages and 2,872 links. The vocabulary size is 3,529.

WebKB and Wikipedia are public datasets widely used in topic model studies. ODP was collected by us in this work.

4.2 Topic Discovery

We created four topic models HTM, LDA, Link-LDA, and Link-PLSA-LDA using all the data in each of the three datasets, and evaluated the topics obtained in the models. We heuristically set the numbers of topics as 10 for ODP, 12 for WebKB, and 8 for Wikipedia (i.e., two times of the number of true subjects). We found that overall HTM can construct more understandable topics than the other models. Figure 2 shows the topics related to the subjects created by the four models from the ODP dataset. HTM model can more accurately extract the three topics: Theory, Statistic, and NN than the other models. Both LDA and Link-LDA had mixed topics, labeled as 'Mixed' in Figure 2. Link-PLSA-LDA missed the topic of Statistics. Interestingly, all the four models split Cognitive Science into two topics (showed as CogSci-1 and CogSci-2), probably because the topic itself is diverse.

4.3 Document Classification

We applied the four models in the three datasets to document classification. Specifically, we used the word distributions of documents created by the models as feature vectors of the documents and used the subjects in the datasets as categories. We further randomly divided each dataset into three parts (training, validation, and test) and conducted 3-fold cross-validation experiments. In each trial, we trained an SVM classifier with the training data, chose parameters with the validation data, and conducted evaluation on classification with the test data. For HTM, we chose the best λ value with the validation set in each trial. Table 2 shows the classification accuracies. We can see that HTM performs better than the other models in all three datasets.

Table 2: Classification accuracies in 3-fold cross-validation.

	LDA	HTM	Link-LDA	Link-PLSA-LDA
ODP	0.640	**0.698**	0.535	0.581
WebKB	0.786	**0.795**	0.775	0.774
Wikipedia	0.845	**0.866**	0.853	0.855

Table 3: Sign-test results between HTM and the three baseline models.

	LDA	Link-LDA	Link-PLSA-LDA
ODP	0.0237	2.15e-05	0.000287
WebKB	0.0235	0.0114	0.00903
Wikipedia	1.79e-05	0.00341	0.00424

We conducted sign-tests on all the results of the datasets. In most cases HTM performs statistically significantly better than LDA, Link-LDA, and Link-PLSA-LDA (p-value < 0.05). The test results are shown in Table 3.

4.4 Discussion

We conducted analysis on the results to see why HTM can work better. Figure 3 shows an example homepage from the ODP dataset, where superscripts denote the indexes of outlinked pages. The homepage contains several topics, including Theory, Neural network, Statistics, and others, while the cited pages contain detailed information about the topics. Table 4 shows the topics identified by the four models for the homepage. We can see that HTM can really more accurately identify topics than the other models.

The major reason for the better performance by HTM seems to be that it can fully leverage the infor-

Table 4: Comparison of topics identified by the four models for the example homepage. Only topics with probabilities > 0.1 and related to the subjects are shown.

mation from the cited documents. We can see that the content of the example homepage is diverse and not very rich. It might be hard for the other baseline models to identify topics accurately. In contrast, HTM can accurately learn topics by the help of the cited documents. Specifically, if the content of a document is diverse, then words in the document are likely to be assigned into wrong topics by the existing approaches. In contrast, in HTM with propagation of topic distributions from cited documents, the words of a document can be more accurately assigned into topics. Table 5 shows the first 15 words and the last 10 words for the homepage given by HTM, in ascending order of b_{dn}, which measures the degree of influence from the cited documents on the words (the smaller the stronger). The table also gives the values of c_{dn}, indicating which cited documents have the strongest influence. Furthermore, the topics having the largest posterior probabilities for the words are also shown. We can see that the words 'experiment', 'sample', 'parameter', 'perform', and 'energy' are accurately classified. Table 6 gives the most salient topics of cited documents. It also shows the probabilities of the topics given by HTM. We can see that there is a large agreement between the most salient topics in the cited documents and the topics which are affected the most in the citing document.

Parameter λ is the only parameter in HTM which needs to be tuned. We found that the performance of HTM is not very sensitive to the values of λ, which reflects the degree of influence from the cited documents to the citing document. HTM can perform well with different λ values. Figure 4 shows the classification accuracies of HTM with respect to different λ values for the three datasets. We can see that HTM works better than the other models in most of the cases (cf., Table 2).

5 Conclusion

In this paper, we have proposed a novel topic model for hypertexts called HTM. Existing models for processing hypertexts were developed based on the assumption that both words and hyperlinks are stochastically generated by the model. The generation of latter type of data is actually unnecessary for representing *contents* of hypertexts. In the HTM model, it is assumed that the hyperlinks of hypertexts are given and only the words of the hypertexts are stochastically generated. Furthermore, the word distribution of a document is determined not only by the topics of the document in question but also from the topics of the documents which the document cites. It can be regarded as 'propagation' of topics reversely along hyperlinks in hypertexts, which can lead to more accurate representations than the existing models. HTM can naturally mimic human's process of creating a document (i.e., by considering using the topics of the document and at the same time the topics of the documents it cites). We also developed methods for learning and inferring an HTM model within the same framework as LDA (Latent Dirichlet Allocation). Experimental results show that the proposed HTM model outperforms the existing models of LDA, Link-LDA, and Link-PLSA-LDA on three datasets for topic discovery and document classification.

As future work, we plan to compare the HTM model with other existing models, to develop learning and inference methods for handling extremely large-scale data sets, and to combine the current method with a keyphrase extraction method for extracting keyphrases from web pages.

Abstract

This paper describes a new automatic method for Japanese predicate argument structure analysis. The method learns relevant features to assign case roles to the argument of the target predicate using the features of the words located closest to the target predicate under various constraints such as dependency types, words, semantic categories, parts of speech, functional words and predicate voices. We constructed decision lists in which these features were sorted by their learned weights. Using our method, we integrated the tasks of semantic role labeling and zero-pronoun identification, and achieved a 17% improvement compared with a baseline method in a sentence level performance analysis.

1 Introduction

Recently, predicate argument structure analysis has attracted the attention of researchers because this information can increase the precision of text processing tasks, such as machine translation, information extraction (Hirschman et al., 1999), question answering (Narayanan and Harabagiu, 2004) (Shen and Lapata, 2007), and summarization (Melli et al., 2005). In English predicate argument structure analysis, large corpora such as FrameNet (Fillmore et al., 2001), PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004) have been created and utilized. Recently, the GDA Corpus (Hashida, 2005), Kyoto Text Corpus Ver.4.0 (Kawahara et al., 2002) and NAIST Text Corpus (Iida et al., 2007) were constructed in Japanese, and these corpora have become the target of an automatic Japanese predicate argument structure analysis system. We conducted Japanese predicate argument structure (PAS) analysis for the NAIST Text Corpus, which is the largest of these three corpora, and, as far as we know, this is the first time PAS analysis has been conducted for whole articles of the corpus.

The NAIST Text Corpus has the following characteristics, i) semantic roles for both predicates and event nouns are annotated in the corpus, ii) three major case roles,[1] namely the ga, wo and ni-cases in Japanese are annotated for the base form of predicates and event nouns, iii) both the case roles in sentences containing the target predicates and those outside the sentences (zero-pronouns) are annotated, and iv) coreference relations are also annotated.

As regards i), recently there has been an increase in the number of papers dealing with nominalized predicates (Pradhan et al., 2004) (Jiang and Ng, 2006) (Xue, 2006) (Liu and Ng, 2007). For example, 'trip' in the sentence "During my trip to Italy, I met him." refers not only to the event "I met him" but also to the event "I traveled to Italy." As in this example, nouns sometimes have argument structures referring to an event. Such nouns are called *event nouns* (Komachi et al., 2007) in the NAIST Text Corpus. At the same time, the problems related to compound nouns are also important. In Japanese, a compound noun sometimes simultaneously contains both an event noun and its arguments. For example, the compound noun, '企業買収 (corporate buyout)' contains an event noun '買収 (buyout)' and its accusative, '企業 (corporate).' However, compound

[1]Kyoto Text Corpus has about 15 case roles.

nouns provide no information about syntactic dependency or about case markers, so it is difficult to specify the predicate-argument structure. Komachi et al. investigated the argument structure of event nouns using the co-occurrence of target nouns and their case roles in the same sentence (Komachi et al., 2007). In these approaches, predicates and event nouns are dealt with separately. Here, we try to unify these different argument structures using decision lists.

As regards ii), for example, in the causative sentence, 'メアリーはトムに夕食を作らせる (Mary makes Tom fix dinner),' the basic form of the causative verb, '作らせる (make fix)' is '作る (fix),' and its nominative is 'トム (Tom)' and the accusative case role (wo-case) is '夕食 (dinner),' although the surface case particle is ni (dative). We must deal with syntactic transformations in passive, causative, and benefactive constructions when analyzing the corpus.

As regards iii) and iv), in Japanese, zero pronouns often occur, especially when the argument has already been mentioned in previous sentences. There have been many studies of zero-pronoun identification (Walker et al., 1994) (Nakaiwa, 1997) (Iida et al., 2006).

In this paper, we present a general procedure for handling both the case role assignment of predicates and event nouns, and zero-pronoun identification. We use the decision list learning of rules to find the closest words with various constraints, because with decision lists the readability of learned lists is high and the learning is fast.

The rest of this paper is organized as follows. We describe the NAIST Text Corpus, which is our target corpus in Section 2. We describe our proposed method in Section 3. The result of experiments using the NAIST Text Corpus and our method are reported in Section 4 and our conclusions are provided in Section 5.

2 NAIST Text Corpus

In the NAIST Text Corpus, three major obligatory Japanese case roles are annotated, namely the ga-case (nominative or subjective case), the wo-case (accusative or direct object) and the ni-case (dative or in-direct object). The NAIST Text Corpus is based on the Kyoto Text Corpus Ver. 3.0, which contains 38,384 sentences in 2,929 texts taken from news articles and editorials in a Japanese newspaper, the 'Mainichi Shinbun'.

We divided these case roles into four types by location in the article as in (Iida et al., 2006), i) the case role depends on the predicate or the predicate depends on the case role in the intra-sentence ('dependency relations'), ii) the case role does not depend on the predicate and the predicate does not depend on the case role in the intra-sentence ('zero-anaphoric (intra-sentential)'), iii) the case role is not in the sentence containing the predicate ('zero-anaphoric (inter-sentential)'), and iv) the case role and the predicate are in the same phrase ('in same phrase'). Here, we do not deal with exophora.

We show the distribution of the above four types in test samples in our split of the NAIST Text Corpus in Tables 1 and 2. In predicates, the 'dependency relations' type in the wo-case and the ni-case occur frequently. In event nouns, the 'zero-anaphoric (intra-sentential)' and 'zero-anaphoric (inter-sentential)' types in the ga-case occur frequently. With respect to the 'in same phrase' type, the wo-case occurs frequently.

3 Predicate Argument Structure Analysis using Features of Closest Words

In this section, we describe our algorithm. In the algorithm, we used various constraints when searching for the words located closest to the target predicate. We described these constraints as features with the direct products of dependency types (ic, oc, ga_c, wo_c, ni_c, sc, nc, fw and bw), generalization levels (words, semantic categories, parts of speech), functional words and voices.

3.1 Dependency Types

In Japanese, the functional words in a phrase (*Bunsetsu* in Japanese) and the interdependency of bunsetsu phrases are important for determining the predicate argument structure. In accordance with the character of the dependency between the case roles and the predicates or event nouns, we divided Japanese word dependency into the following seven types that cover all dependency types in Japanese. Additionally, we use two optional dependency types.

Table 1: Distribution of case roles for predicates (Test Data)

	predicate					
	ga (Nominative)		wo (Accusative)		ni (Dative)	
all	15,996	(100.00%)	8,348	(100.00%)	4,871	(100.00%)
dependency relations	9,591	(59.96%)	7,184	(86.06%)	4,276	(87.78%)
zero-anaphoric (intra-sentential)	3,856	(24.11%)	870	(10.42%)	360	(7.39%)
zero-anaphoric (inter-sentential)	2,496	(15.60%)	225	(2.70%)	132	(2.71%)
in same phrase	53	(0.33%)	69	(0.83%)	103	(2.11%)

Table 2: Distribution of case roles for event nouns (Test Data)

	event noun					
	ga (Nominative)		wo (Accusative)		ni (Dative)	
all	4,099	(100.00%)	2,314	(100.00%)	423	(100.00%)
dependency relations	977	(23.84%)	648	(28.00%)	105	(24.82%)
zero-anaphoric (intra-sentential)	1,672	(40.79%)	348	(15.04%)	135	(31.91%)
zero-anaphoric (inter-sentential)	1,040	(25.37%)	165	(7.13%)	44	(10.40%)
in same phrase	410	(10.00%)	1,153	(49.83%)	139	(32.86%)

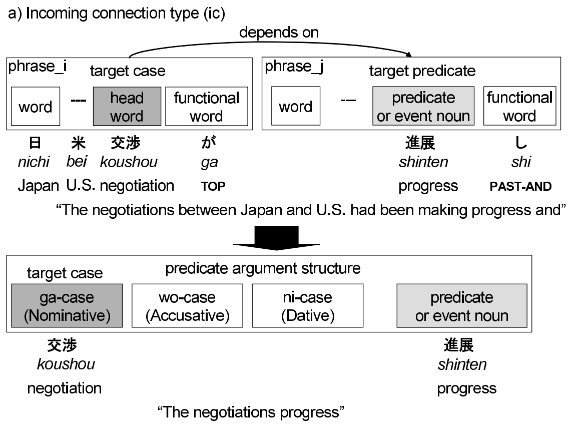

Figure 1: Type ic

3.1.1 Incoming Connection Type (ic)

With this type, the target case role is the headword of a bunsetsu phrase and the case role phrase depends on the target predicate phrase (Figure 1).

3.1.2 Outgoing Connection Type (oc)

With this type, the target case role is the headword of a phrase and a phrase containing a target predicate or event noun depends on the case role phrase (Figure 2).

Figure 2: Type oc

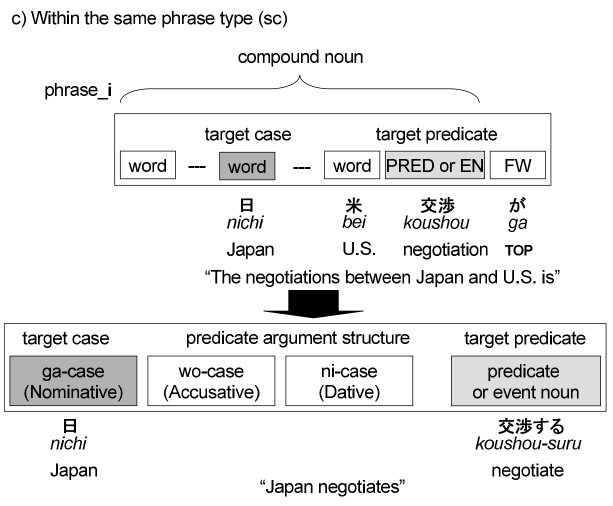

Figure 3: Type sc

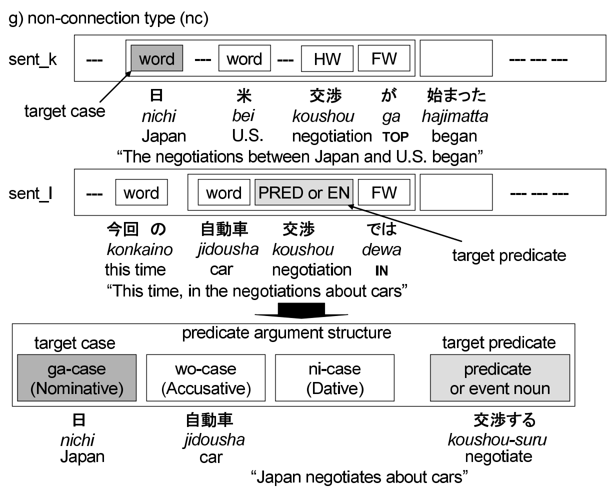

Figure 5: Type nc

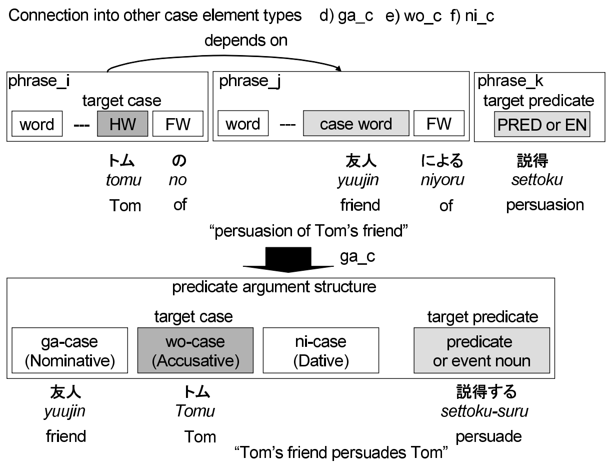

Figure 4: Type ga_c, wo_c, ni_c

3.1.3 'Within the Same Phrase' Type (sc)

With this type, the target case role and the target predicate or event noun are in the same phrase (Figure 3).

3.1.4 'Connection into Other Case role Types (ga_c, wo_c, ni_c)

With these types, a phrase containing the target case role depends on a phrase containing another predetermined case role (Figure 4). We use the terms 'ga_c', 'wo_c' and 'ni_c' when the predetermined case roles are the ga-case, wo-case and ni-case, respectively.

3.1.5 Non-connection Type (nc)

With this type, a phrase containing the target case role and a phrase containing the target predicate or event noun are in the same article, but these phrases do not depend on each other (Figure 5).

3.1.6 Optional Type (fw and bw)

Type fw and bw stand for 'forward' and 'backward' types, respectively. Type fw means the word located closest to the target predicate or event noun without considering functional words or voices. With fw, the word is located between the top of the article containing the target predicate and the target predicate or event noun. Similarly, type bw means the word located closest to the target predicate or noun, which is located between the targeted predicate or event noun, and the tail of the article containing the predicate.

3.2 Generalization Levels

We used three levels of generalization for every case role candidate, that is, word, semantic category, and part of speech. Every word is annotated with a part of speech in the Kyoto Text Corpus, and we used these annotations. With regard to semantic categories, we annotated every word with a semantic category based on a Japanese thesaurus, Nihongo Goi Taikei. The thesaurus consists of a hierarchy of 2,710 semantic classes, defined for over 264,312 nouns, with a maximum depth of twelve (Ikehara et al., 1997). We mainly used the semantic classes of

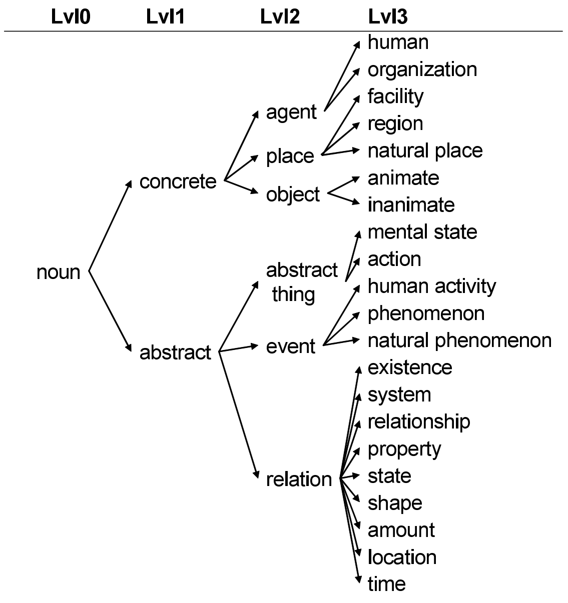

Figure 6: Top 3 levels of the Japanese thesaurus, 'Nihongo Goi Taikei'

the third level, and partly the fourth level, which are similar to semantic roles. We show the top three levels of the Nihongo Goi Taikei common noun thesaurus in Figure 6. We annotated the words with their semantic category by hand.

3.3 Functional Word and Voice

We used a functional word in the phrase containing the target case role and active and passive voices for the predicate as base features.

3.4 Training Algorithm

The training algorithm used for our method is shown in Figure 7. First, the algorithm constructs features that search for the words located closest to the target predicate under various constraints. Next, the algorithm learns by using linear Support Vector Machines (SVMs) (Vapnik, 1995). SVMs learn effective features by the one vs. rest method for every case role. We used TinySVM [2] as an SVM implementation. Moreover, we construct decision lists sorted by weight from linear SVMs. Finally, the algorithm calculates the existing probabilities of case roles for every predicate or event noun. This step produces the criterion that decides whether or not we will determine the case roles when there is no interdependency between the case role candidate and the predicate.

Our split of the NAIST Text Corpus has only 62,264 training samples for 2,874 predicates, and we predict that there will be a shortage of training samples when adopting traditional learning algorithms, such as learning algorithms using entropy. So, we used SVMs with a high generalization capability to learn the decision lists.

3.5 Test Algorithm

The test algorithm of our method is shown in Figure 8. In the test phase, we analyzed test samples using decision lists and the existing probabilities of case roles learned in the training phase. In step 1, we determined case roles using a decision list consisting of features exhibiting case role and predicate interdependency, that is, ic, oc, ga_c, wo_c, and ni_c. This is because there are many cases in Japanese where the syntactic constraint is stronger than the semantic constraint when we determine the case roles. In step 2, we determined case roles using a decision list of sc ('in same phrase') for the case roles that were not determined in step 1. This step was mainly for event nouns. Japanese event nouns frequently form compound nouns that contain case roles. In step 3, we decided whether or not to proceed to the next step by using the existing probabilities of case roles. If the probability was less than a certain threshold (50%), then the algorithm stopped. In step 4, we determined case roles using a decision list of the features that have no interdependency, that is, nc, fw and bw. This step will be executed when the target case role is syntactically necessary and determined by the co-occurrence of the case roles and predicate or event noun without syntactic clues, such as dependency, functional words and voices.

4 Experimental Results

4.1 Experimental Setting

We performed our experiments using the NAIST Text Corpus 1.4β (Iida et al., 2007). We used 49,527 predicates and 12,737 event nouns from articles published from January 1st to January 11th and the editorials from January to August as training ex-

Figure 8: Test algorithm

amples. We used 11,023 predicates and 3,161 event nouns from articles published on January 12th and 13th and the September editorials as development examples. And we used 19,501 predicate and 5,276 event nouns from articles dated January 14th to 17th and editorials dated October to December as test examples. This is a typical way to split the data.

We used the annotations in the Kyoto Text Corpus as the interdependency of bunsetsu phrases. We used both individual and multiple words as case roles. We used the phrase boundaries annotated in the NAIST Text Corpus in the training phase, and used those annotated automatically by our system using POSs and simple rules in the test phase. The accuracy of the automatic annotation is about 90%.

4.2 Baseline Method

To evaluate our algorithm, we conducted experiments using a baseline method. With the method, we used only nouns that depended on predicates or event nouns as case role candidates. If the functional word (post-positional case) in the phrase is 'ga','wo' and 'ni', we determined the ga-case, wo-case, or ni-case for the candidates. Next, as regards event nouns in compound nouns, if there was another word in a compound noun containing an event noun and it co-occurred with the event noun as a case role with a higher probability in the training samples, then the word was selected for the case role.

4.3 Entropy Method

The conventional approach for making decision lists utilizes the entropy of samples selected by the rules (Yarowsky, 1994) (Goodman, 2002). We performed comparative experiments using Yarowsky's entropy algorithm (Yarowsky, 1994).

Table 3: Existing probabilities of case roles for predicates and event nouns

Predicate	Existing Probability		
or Event Noun	ga (NOM)	wo (ACC)	ni (DAT)
使う (use)	44.72%	82.92%	5.33%
交渉 (negotiation)	77.41%	30.70%	0.00%
参加 (participation)	87.09%	0.00%	72.46%
基づく (based on)	81.89%	0.00%	100.00%

4.4 Overall Results

The overall results are shown in Table 7. Here, 'entropy' indicates Yarowsky's algorithm, which uses entropy (Yarowsky, 1994). Throughout the test data, the F-measure (%) of our method exceeded that of the baseline system and the 'entropy' system. With the ga-case (nominative) in particular, the F-measure increased 9 points.

Table 3 shows some examples of the existing probabilities of case roles for predicates or event nouns. When the probabilities are extreme values such as the ni-case (dative) of 交渉 (negotiation), the wo-case (accusative) of 参加 (participation), and the wo-case and ni-base of 基づく (based on), we can decide to fill the targeted case role or not with high precision. However, it is difficult to decide to fill the targeted case role or not when the probability is close to 50 percent as in the ga-case of 使う (use).

We show the learned decision list of the ic type (the case role depends on the predicate or event noun), sc type (in the same phrase) and the other types for event noun 交渉 (negotiation) in Tables 4, 5 and 6, respectively. Here, 'word' in the 'level' column means 'base form of predicate' and 'sem' means 'semantic category of predicate.' In the ic and sc type decision lists, features with semantic categories, such as 'REGION', 'LOCATION' and 'EVENT', occupy a higher order. In contrast, in the list of the other types, the features that occupy the higher order are the features of the word base

in same phrase	58.76 / **78.93**	47.44 / **77.96**	28.91 / **58.13**

form. This means local knowledge of relations between case roles and predicates or event nouns in the word level is more important than semantic level knowledge.

4.5 Results for Predicates in Test Sets

We show the results we obtained for predicates in Table 8. The results reveal that our method is superior to the baseline system. Our algorithm is particularly effective in the ga-case.

4.6 Results for Event Nouns in Test Sets

We show the results we obtained for event nouns in Table 9. This also shows that our method is superior to the baseline system. The precision with sc type is high and our method is effective as regards event nouns.

5 Conclusion

We presented a new method for Japanese automatic predicate argument structure analysis using decision lists based on the features of the words located closest to the target predicate under various constraints. The method learns the relative weights of these different features for case roles and ranks them using decision lists. Using our method, we integrated the knowledge of case role determination and zero-pronoun identification, and generally achieved a high precision in Japanese PAS analysis. In particular, we can extract knowledge at various levels from the corpus for event nouns. In future, we will use richer constraints and research better ways of distinguishing whether or not cases are obligatory.

Acknowledgments

We thank Ryu Iida and Yuji Matsumoto of NAIST for the definitions of the case roles in the NAIST Text Corpus and functional words, and Franklin Chang for valuable comments.

Abstract

Obtaining labeled data is a significant obstacle for many NLP tasks. Recently, online games have been proposed as a new way of obtaining labeled data; games attract users by being fun to play. In this paper, we consider the application of this idea to collecting semantic relations between words, such as hypernym/hyponym relationships. We built three online games, inspired by the real-life games of Scattergories^{TM} and Taboo^{TM}. As of June 2008, players have entered nearly 800,000 data instances, in two categories. The first type of data consists of category/answer pairs ("Types of vehicle","car"), while the second is essentially free association data ("submarine","underwater"). We analyze both types of data in detail and discuss potential uses of the data. We show that we can extract from our data set a significant number of new hypernym/hyponym pairs not already found in WordNet.

1 Introduction

One of the main difficulties in natural language processing is the lack of labeled data. Typically, obtaining labeled data requires hiring human annotators. Recently, building online games has been suggested an alternative to hiring annotators. For example, von Ahn and Dabbish (2004) built the ESP Game[1], an online game in which players tag images with words that describe them. It is well known that there are large numbers of web users who will play online games. If a game is fun, there is a good chance that sufficiently many online users will play.

We have several objectives in this paper. The first is to discuss design decisions in building word games for collecting data, and the effects of these decisions. The second is to describe the word games that we implemented and the kinds of data they are designed to collect. As of June 2008, our games have been online for nearly a year, and have collected nearly 800,000 data instances. The third goal is to analyze the resulting data and demonstrate that the data collected from our games is potentially useful in linguistic applications. As an example application, we show that the data we have collected can be used to augment WordNet (Fellbaum, 1998) with a significant number of new hypernyms.

2 General Design Guidelines

Our primary goal is to produce a large amount of clean, useful data. Each of these three objectives ("large", "clean", and "useful") has important implications for the design of our games.

First, in order to collect large amounts of data, the game must be attractive to users. If the game is not fun, people will not play it. This requirement is perhaps the most significant factor to take into account when designing a game. For one thing, it tends to discourage extremely complicated labeling tasks, since these are more likely to be viewed as work. It would certainly be a challenge (although not necessarily impossible) to design a game that yields labeled parse data, for example.

In this paper, we assume that if people play a game in real life, there is a good chance they will play it online as well. To this end, we built online versions of two popular "real-world" games: Scattergories^{TM} and Taboo^{TM}. Not only are these games fun, but there is also a preexisting demand for online versions of these games, driving search traffic to our site. We will go into more detail about these games in the next section.

An important characteristic of these games is that they involve more than one player. Interacting with another player increases the sense of fun. Another important feature these games share is that they are timed. Timing has several advantages. First, timing helps make the games feel more "game-like", by adding a sense of urgency. Without timing, it risks feeling more like a labeling task than a game.

The next requirement is that the data be clean. First, the players must be capable of producing high-quality annotations. Second, the game should encourage users to enter relevant data. We award points as a motivating factor, but this can lead players to enter irrelevant data, or collude with other players, in order to get a higher score. In particular, collusion is more likely when players can freely communicate. An excellent technique for producing good data, used effectively in the ESP game, is to require the players to match on their inputs. Requiring players to match their partner's hidden answers discourages off-topic answers and makes it quite difficult to collude (requiring outside communication). We use this technique in all of our games.

Finally, the data must be useful. Ideally, it would be directly applicable to an NLP task. This requirement can come into conflict with the other goals. There are certainly many kinds of data that would be useful for NLP tasks (such as labeled parses), but designing a game to collect this data that people will play and that produces clean data is difficult.

In this paper, we focus on a particular kind of linguistic data: semantic relationships between pairs of words and/or phrases. We do this for several reasons. First, this kind of data is relatively simple, leading to fun games which produce relatively clean data. Second, the real-world games we chose to emulate naturally produce this kind of data. Third, there are a number of recent works which focus on extracting these kinds of relationships, e.g. (Snow et al., 2006; Nakov & Hearst, 2008). Our work presents an interesting new way of extracting this type of data. Finally, at least one of these kinds of relationships, the hypernym, or "X is a Y" relation, has proven to be useful for a variety of NLP tasks.

3 Description of Our Games

We now describe our three games in detail.

3.1 Categorilla

Categorilla, inspired by Scattergories™, asks players to supply words or phrases which fit specific categories, such as "Things that fly" or "Types of fish". In addition, each game has a specific letter which all answers must begin with. Thus, if the current game has letter "b", reasonable answers would be "bird" and "barracuda", respectively. In each game, a randomly matched pair of players are given the same 10 categories; they receive points when they match with the other player for a particular category. Players are allowed to type as may answers for a given category as they wish (until a match is made for that category). After a match is made, the players get to see what word they matched on for that category. Each answer is supposed to fit into a specific category, so the data is automatically structured.

Our system contains 8 types of categories, many of which were designed to correspond to linguistic resources used in NLP applications. Table 1 describes the category types.

The purpose of the first three types of categories is to extract hypernym/hyponym pairs like those found in WordNet (e.g., "food" is a hypernym of "pizza"). In fact, the categories were automatically generated from WordNet, as follows. First, we assigned counts C_s to each synset s in WordNet using the SemCor[2] labeled data set of word senses. Let $desc(s)$ be the set of descendants of s in the hypernym hierarchy. Then for each pair of synsets s, d, where $d \in desc(s)$, we computed a conditional distribution $P(d|s) = \frac{C_d}{\sum_{d' \in desc(s)} C_{d'}}$, the probability that we choose node d from among the descendants of s. Finally, we computed the entropy of each node s in WordNet, $\sum_{d \in desc(s)} P(d|s) log P(d|s)$. Synsets with many different descendants occurring in SemCor will have higher entropies. Each node with a sufficiently high entropy was chosen as a category.

We then turned each synset into a category by taking the first word in that synset and plugging it into one of several set phrases. For nouns, we tried two variants ("Types of food" and "Foods"). Depending on the noun, either of these may be more natural (consider "Cities" vs. "Types of city"). "Types of food" tends to produce more adjectival answers than "Foods". We tried only one variation for verbs ("Methods of paying"). This phrasing is not perfect; in particular, it encourages non-verb answers like "credit card".

The second group of categories tries to capture selectional preferences of verbs – for example, "ba-

Name	#	Description	Example	Good Answer
NHyp	269	Members of a class of nouns	“Vehicles”	“car”
NType	269	Members of a class of nouns	“Types of vehicle”	“car”
VHyp	70	Members of a class of verbs	“Methods of cutting”	“trimming”
VS	1380	Subjects of a verb	“Things that eat”	“cats”
VO	909	Direct objects of a verb	“Things that are abandoned”	“family”
VPP	77	Preposition arguments of a verb	“Things that are accused of”	“crime”
Adj	219	Things described by an adjective	“Things that are recycled”	“cans”
O	105	Other; mostly “Things found at/in ...”	“Things found in a school”	“teachers”

Table 1: Summary of category types. # indicates the number of categories of that type.

nana” makes sense as the object of “eat” but not as the subject. Our goal with these categories was to produce data useful for automatically labeling semantic roles (Gildea & Jurafsky, 2002), where selectional preferences play an important role. We tried three different types of categories, corresponding to subjects, objects, and prepositional objects. Examples are “Things that eat”, “Things that are eaten”, and “Things that are eaten with”, to which good answers would be “animals”, “food”, and “forks”. These categories were automatically generated using the labeled parses in Penn Treebank (Marcus et al., 1993) and the labeled semantic roles of PropBank (Kingsbury et al., 2002). To generate the object categories, for example, for each verb we then counted the number of times a core argument (ARG0-ARG5) appeared as the direct object of that verb (according to the gold-standard parses), and used all verbs with count at least 5. This guaranteed that all generated categories were grammatically correct and captured information about core arguments for that verb. Most of the prepositional object categories proved to be quite confusing (e.g., “Things that are acted as”), so we manually removed all but the most clear. Not surprisingly, the use of the Wall Street Journal had a noticeable effect on the types of categories extracted; they have a definite financial bias.

The third group of categories only has one type, which consists of adjective categories such as “Things that are large”. While we did not have any specific task in mind for this category type, having a database of attributes/noun pairs seems potentially useful for various NLP tasks. To generate these categories, we simply took the most common adjectives in the SemCor data set. Again, the resulting set of adjectives reflect the corpus; for example, “Things that are green” was not generated as a category, while “Things that are corporate” was.

The final group of categories were hand-written. This group was added to make sure that a sufficient number of “fun” categories were included, since some of the category types, particularly the verb categories, are somewhat confusing and difficult. Most of the hand-written categories are of the form “Things found at/in X”, where X is a location, such as “Japan” or “the ocean”.

The starting letter requirement also has important consequences for data collection. It was designed to increase the variety of obtained data; without this restriction, players might produce a smaller set of “obvious” answers. As we will see in the results, this restriction did indeed lead to a great diversity of answers, but at a severe cost to data quality.

3.2 Categodzilla

Categodzilla is a slightly modified version of Categorilla, with the starting letter constraint relaxed. The combination of difficult categories and rare letters often leads to bad answers in Categorilla. To increase data quality, in Categodzilla for each category there are three boxes. In the first box you can type any word you want. Answers in the second box must start with a given “easy” letter such as “c”. Answers in the third box must start with a given “hard” letter, such as “k”. The boxes much be matched in order; guesses typed in the first box which match either of the other two boxes are automatically propagated.

3.3 Free Association

Free Association, inspired by Taboo^{TM}, simply asks players to type words related to a given “seed” word. Players are not allowed to type any of several words on a “taboo” list, specific to the current seed word.

As soon as a match is achieved, players move on to a new seed word.

The seed words came from two sources. The first was the most common words in SemCor. The second was the Google unigram data, which lists the most common words on the web. In both cases, we filtered out stop words (including all prepositions).

Unlike Categorilla, we found that nearly all collected Free Association data was of good quality, due to the considerably easier nature of the task. Of course, we do lose the structure present in Categorilla. As the name suggests, the collected data is essentially free word association pairs. We analyze the data in depth to see what kinds of relations we got.

4 Existing Word Games

Two notable word games already exist for collecting linguistic data. The first is the Open Mind Common Sense system[3] (Chklovski, 2003). The second is Verbosity[4] (von Ahn et al., 2006). Both these games are designed to extract common sense facts, and thus have a different focus than our games.

5 Bots

There may not always be enough players available online to match a human player with another human player. Therefore, one important part of designing an online game is building a bot which can function in the place of a player. The bots for all of our games are similar. Each has a simple random model which determines how long to wait between guesses. The bot's guesses are drawn from past guesses made by human players for that category/seed word (plus starting letter in the case of Categorilla). Just as with a human player, as soon as one of the bot's guesses matches one of the player's, a match is made.

If there are no past guesses, the bot instead makes "imaginary" guesses. For example, in Categorilla, we make the (obviously false) assumption that for every category and every starting letter there are exactly 20 possible answers, and that both the player's guesses and the bot's imaginary guesses are drawn from those 20 answers. Then, given the number of guesses made by the player and the number of imaginary guesses made by the bot, the probability of a match can be computed (assuming that all guesses are made independently). Once this probability passes a certain threshold, randomly generated for each category at the start of each game, the bot matches one of the player's guesses, chosen at random. The Free Association bot works similarly.

Guesses per minute	6.6	8.7	9.9

Table 2: Statistics for Categorilla, Categodzilla, and Free Association.

For Free Association, the bot rarely has to resort to generating these imaginary guesses. In Categorilla, due to the starting letter requirement, the bot has to make imaginary guesses much more often. Imaginary guessing can encourage poor behavior on the part of players, since they see that matches can occur for obviously bad answers. They may also realize that they are playing against a bot.

An additional complication for Categorilla and Categodzilla is that the bot has to decide which categories to make guesses for, and in what order. Our current guessing model takes into account past difficulty of the category and the current guessing of the human player to determine where to guess next.

6 Users and Usage

Table 2 shows statistics of each of the games, as of late June 2008. While we have collected nearly 800,000 data instances, nearly all of the games were between a human and the bot. Over the course of a year, our site received between 40 and 100 visits a day; this was not enough to make it likely for human-human games to occur. The fact that we still collected this amount of data suggests that our bot is a satisfactory substitue for a human teammate. We have anecdotally found that most players do not realize they are playing against a bot. While most of the data comes from games between a human and a bot, our data set consists only of input by the human players.

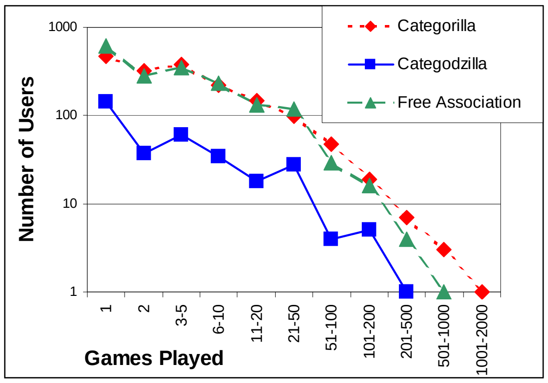

Figure 1: Users are grouped by number of games played. Note that this graph is on a double-log scale.

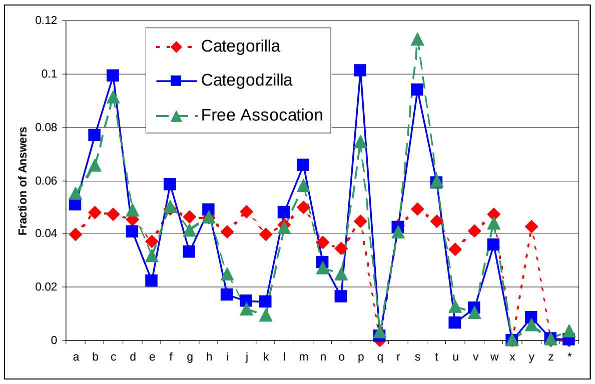

Figure 2: Fraction of answers with given initial letter. * denotes everything nonalphabetical.

Our main tool for attracting traffic to our site was Google. First, we obtained $1 a day in AdWords, which pays for between 7 to 10 clicks on our ad a day. Second, our site is in the top 10 results for many relevant searches, such as “free online scattergories”.

Categorilla was the most popular of the games, with about 25% more games played than Free Association. Taking the longer length of Categorilla games into account (see Table 2), this corresponds to almost 90% more play time. This is despite the fact that Free Association is the first game listed on our home page. We hypothesize that this is because Scattergories^{TM} is a more popular game in real life, and so many people come to our site specifically looking for an online Scattergories^{TM} game. Categodzilla has been played signficantly less; it has been available for less time and is listed third on the site. Even for Categodzilla, the least played game, we have collected on average 24 guesses per category.

Several of our design decisions for the games were based on trying to increase the diversity of answers. Categorilla has the highest answer diversity. For a given category, each answer occurred on average only 1.15 times. In general, this average should increase with the amount of collected data. However, Categodzilla and Free Association have collected significantly fewer answers per category than Categorilla, but still have a higher average, around 1.4. The high answer diversity of Categorilla is a direct result of the initial letter constraint. For all three games, the majority of category/answer pairs occurred only once.

Figure 1 shows the distribution over users of the number of games played. Not surprisingly, it follows the standard Zipfian curve; there are a large number of users who have played only a few games, and a few users who have played a lot of games. The middle of the curve is quite thick; for both Categorilla and Free Association there are more than 100 players who have played between 21 and 50 games.

Figure 2 shows the distribution of initial letters of collected answers for each game. Categorilla is nearly flat over all letters besides ’q’, ’x’, and ’z’ which are never chosen as the inital letter constraint. This means players make a similar number of guesses even for difficult initial letters. In contrast, the distribution of initial letters for Free Association data reflects the relatively frequency of initial letters in English. Even though Categodzilla does have letter constraints in the 2nd and 3rd columns, its statistics over initial letter are very similar to Free Association.

7 Categorilla and Categodzilla Data

In our analyses, we take ALL guesses made at any time, whether or not they actually produced a match. This greatly increases the amount of usable data, but also increases the amount of noise in the data.

The biggest question about the data collected from Categorilla and Categodzilla is the quality of the data. Many categories can be difficult or somewhat confusing, and the initial letter constraint further increases the difficulty.

To evaluate the quality of the data, we asked three volunteer labelers to label 1000 total category/answer pairs. Each labeler labeled every pair with one of three labels, ’y’, ’n’, or ’k’. ’y’ means that the answer fit the category. ’n’ means that it

Annotator	y	k	n
#1	72	13	115
#2	77	27	96
#3	88	42	70
Majority	76	29	95

Data Set	y	k	n
Control	30	14	156
Categorilla	76	29	95
Categodzilla	144	23	33

Table 4: Overall answer accuracy

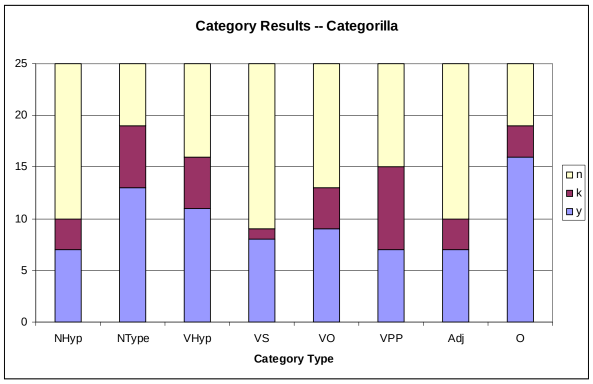

Figure 3: Categorilla accuracy by category type

does not fit. 'k' means that it "kind of" fits. This was mostly left up to the labelers; the only suggestion was that one use of 'k' could be if the category was "Things that eat" and the answer was "sandwich." Here, the answer is clearly related to the category, but doesn't actually fit.

The inter-annotator agreement was reasonable, with a Fleiss' kappa score of .49. The main difference between annotators was how permissive they were; the percentage of answers labeled 'n' ranged from 58% for the first annotator to 35% for the third. The labeled pairs were divided into 5 subgroups of 200 pairs each (described below); Table 3 shows the number of each label for the Categorilla-Random subset. We aggregated the different annotations by taking a majority vote; if all three answers were different, the item was labeled 'k'. Table 3 also shows the statistics of the majority vote on the same subset.

Overall Data Quality. We compared results for three random subsets of answers, Control-Random, Categorilla-Random, and Categodzilla-Random. Categorilla-Random was built by selecting 200 random category/answer pairs from the Categorilla data. Note that category/answer pairs that occurred more than once were more likely to be selected. Categodzilla-Random was built similarly. Control-Random was built by randomly selecting two sets of 200 category/answer pairs each (including data from both Categorilla and Categodzilla), and then combining the categories from the first set with the answers from the second to generate a set of random category/answer pairs.

Table 4 shows results for these three subsets. The chance for a control answer to be labeled 'y' was 15%. Categorilla produces data that is significantly better than control, with 38% of answers labeled 'y'. Categodzilla, which is more relaxed about initial letter restrictions, is significantly better than Categorilla, with 72% of answers labeled 'y'. This relaxation has an enormous impact on the quality of the data. Note however that these statistics are not adjusted for accuracy of individual players; it may be that only more accurate players play Categodzilla.

Effect of Category Type on Data Quality. Within each type of category (see Table 1), certain categories appear much more often than others due to the way categories are selected (at least two "easy" categories are guaranteed every game). To adjust for this, we built a subset of 200 category/answer pairs by selecting 25 different categories randomly from each type of category. We then selected an answer at random from among the answers submitted for that category. In addition, we built a control set using the same 200 categories but instead using answers selected at random from the entire Categorilla data set. Results for Categorilla data are shown in Figure 3; we omit the corresponding graph for control for lack of space. For most categories, the Categorilla data is significantly better than the control. The hand-written category type, O, has the best data quality, which is not surprising because these categories allow the most possible answers, and thus are easiest of think of answers for. These categories also have the highest number of 'y' labels for the control. Next best are the hypernym categories, NType. NType is much higher than the other noun hypernym category NHyp because the "Type of" phrasing is generally more natural and allows for adjectival answers. The VPP category type, which tries to extract prepositional objects, contains

Data Set	Letters	Size	y	k	n
Control	Easy	127	.14	.08	.78
Control	Hard	72	.15	.06	.79
Categorilla	Easy	106	.45	.14	.41
Categorilla	Hard	94	.30	.15	.55

Table 5: Accuracy of easy letters vs. hard letters. Size is the number of answers for that row.

the most number of 'k' annotations; this is because players often put answers that are subjects or objects of the verb, such as "pizza" for "Things that are eaten with". The adjective category type, Adj, has the lowest increase over the control; this is likely due to the nature of the extracted adjectives.

Effect of Initial Letter on Data Quality. In general, we would expect common initial letters to yield better data since there are more possible answers to choose from. We did not have enough labeled data to do letter by letter statistics. Instead, we broke the letters into two groups, based on the empirical difficulty of obtaining matches when given that initial letter. The easy letters were 'abcfhlmnprst', while the hard letters were 'degijkouvwy'. Table 5 shows the results on Categorilla-Random and Control-Random on these two subsets. First, note that the results on Control-Random are the same for hard letters and easy letters. This means that words starting with common letters are not more likely to fit in a category. For both hard letters and easy letters, the accuracy is considerably better on the Categorilla data. However, the increase in the number of 'y' labels for easy letters is twice that for hard letters. The quality of data for hard letters is considerably worse than that for easy letters.

8 Free Association Data

In contrast to Categorilla and even Categodzilla, we found that the Free Association data was quite clean. However, it is also not structured; we simply get pairs of related words. Thus, the essential question for this game is what kind of data we get.

To analyze the types of relationships between words, the authors labeled 500 randomly extracted unique pairs with a rich set of word-word relations, described in Table 6. This set of relations was designed to capture the observed relationships encountered in the Free Association data. Unlike our Categorilla labeled set, pairs that occurred more than once were NOT more likely to be selected than pairs that occurred once (i.e., the category/answer pairs were aggregated prior to sampling). Sampling in this way led to more diversity in the pairs extracted.

To label each pair, the authors found a sequence of relationships which connected the two words. In many cases, this was a single link. For example, "dragon" and "wing" are connected by a single link, "wing" IS PART OF "dragon". In others, multiple links were required. For the seed word "dispute" and answer "arbitrator", we can connect using two links: "dispute" IS OBJECT OF "resolve", "arbitrator" IS SUBJECT OF "resolve". There were two other possible ways to label a pair. First, they might be totally unrelated (i.e., a bad answer). Second, they might be related, but not connectable using our set of basic relations. For example, "echo" is clearly related to "valley", but in a complicated way.

The quality of the data is considerably higher than Categorilla and Categodzilla; under 10% of words are unrelated. Slightly over 20% of the pairs are labeled Misc, i.e., the words are related but in a complicated way. 3% of the pairs can be linked with a chain of two simple relations. The remaining 67% of all pairs were linked with a single simple relation.

The category Desc deserves some discussion. This category included both simple adjective descriptions, such as "creek" and "noisy", and also qualifiers, such as "epidemic" and "typhoid", where one word specifies what kind of thing the other is. The distinction between Desc and Phrase was simply based on to what extent the combination of the two words was a set phrase (such as "east" and "Germany").

Schulte im Walde et al. (2008) address very similar issues to those discussed in this section. They built a free association data set containing about 200,000 German word pairs using a combination of online and offline volunteers (but not a game). They then analyze the resulting associations by comparing the resulting pairs to a large-scale lexical resource, GermaNet (the German counterpart of WordNet). Our data analysis was by hand, making it comparatively small scale but more detailed. It would be interesting to compare the data sets to see whether the use of a game affects the resulting data.

9 Filtering Bad Data

In this section, we consider a simple heuristic for filtering bad data: only retaining answers that were

Name	#	Description	Example
Misc	103	Words related, but in a complicated way	“echo”, “valley”
Desc	76	One of the words describes the other	“cards”, “business”
None	47	Words are not related	“congress”,“store”
Syn	46	The words are synonyms	“downturn”, “dip”
Obj	33	One word is the object of the other	“exhale”,“emission”
Hyp	30	One word is an example of the other	“cabinet”,“furniture”
$\approx$Syn	29	The words are “approximate” synonyms	“maverick”,“outcast”
Cousin	21	The words share a common hypernym (is-a) relation	“meter”,“foot”
Has	18	One word “has” the other	“supermarket”,“carrots”
2-Chain	15	Words are linked by a chain of two simple relations	“arbitrator”,“dispute”
Phrase	13	Words make a phrase; similar to Desc	“East”, “Germany”
Part	11	One is a part of the other	“dragon”,“wings”
At	10	One is found at the other	“harbor”, “lake”
Subj	8	One is the subject of the other	“actor”, “pretend”
Form	7	One is a form of the other	“revere”,“reverence”
Def	7	One defines the other	“blind”,”unable to see”
Opp	7	The two are opposites	“positive”,“negative”
Sound	6	The two words sound similar	“boutique”,“antique”
Sub	5	One is a subword of the other	“outlet”, “out”
Unit	2	One is a unit of the other	“reel”,“film”
Made	2	One is made of the other	“knee”,“bone”

Table 6: Relation types for 500 hand-labeled examples. # indicates the number of pairs with that label.

guessed some minimum number of times. Note that in this section all answers were stemmed in order to combine counts across plurals and verb tenses.

For the Categorilla data, filtering out category/answer pairs that only occurred once from Categorilla-Random left a total of 64 answers (from an original 200), of which 36 were labeled ’y’ and 8 were labeled ’k’. The fraction of ’y’ labels in the reduced set is 56%, up from 38% in the original set. This gain in quality comes at the cost of losing slightly over two-thirds of the data.

For Categodzilla-Random, a similar filter left 88 (out of 200), with 79 labeled ’y’ and 7 labeled ’k’. For the hand-labeled Free Association data, applying this filter yielded a total of 123 pairs (out of an original 500), with only 2 having no relation[5]. In these two games, this filter eliminates nearly all bad data while keeping a reasonable fraction of the data.

Clearly, this filter is less effective for Categorilla than the other two games. One of the main reasons for this is that the letter constraints cause people to try to fit words starting with that letter into all categories that they even vaguely relate to, rather than thinking of words that really fit that category. Examples include {“Art supplies”,“jacket”}, {“Things found in Chicago”,“king”} and {“Things that are African”,“yak”}. Of course, we can further increase the quality of the data by making the filter more restrictive, at the cost of losing more data. For example, removing answers occuring fewer than 5 times from Categorilla-Random leaves only 8 answers (out of 200), 7 labeled ’y’ and 1 labeled ’n’.

There are other ways we could filter the data. For example, suppose we are given an outside database of pairs of words which are known to be semantically related. We could apply the following heuristic: if an answer to a particular category is similar to many other answers for that category, then that answer is likely to be a good one. Preliminary experiments using distributional similarity of words as the similarity metric suggest that this heuristic captures complimentary information to the guess frequency heuristic. We leave as future work a full integration of the two heuristics into a single improved filter.

[5]The higher fraction of lost pairs for Free Association is primarily due to the method of sampling pairs for evaluation, as discussed in Section 8.

Classified Type	#	Example
Real hypernyms	96	“equipment”,“racquet”
Compound hypernyms	32	“arrangement”,“flower”
Adjectives	25	“building”,“old”
Sort-of hypernyms	14	“vegetable”,“salad”
Not hypernyms	33	“profession”,“money”

Table 7: Breakdown of potential hypernym pairs

10 Using the Data

Categorilla and Categodzilla produce structured data which is already in a usable or nearly usable form. For example, the NHyp and NType categories produce lists of hypernyms, which could be used to augment WordNet. We looked at this particular application in some detail.

First, in order to remove noisy data, we used only Categodzilla data and removed answers which occurred only once. We took all category/answer pairs where the category was of type either NHyp or NType, and where the answer was a noun. This resulted in 1604 potential hypernym/hyponym pairs. Of these, 733 (or 46%) were already in WordNet. The remaining 871 were not found in WordNet. We then hand-labeled a random subset of 200 of the 871 to determine how many of them were real hypernym/hyponym pairs. The results are shown in Table 7. Counting compound hyponyms, nearly two-thirds of the pairs are real hypernym/hyponym pairs. These new pairs could directly augment WordNet. For example, for the word “crime”, WordNet has as hyponyms “burglary” and “fraud”. However, it doesn’t have “arson”, “homicide”, or “murder”, which are among the 871 new pairs. WordNet lists “wedding” as being an “event”, but not “birthday”.

The verb subject, object, and prepositional object categories were designed to collect data about the selectional preferences of verbs. These categories turned out to be problematic for several reasons. First, statistics about selectional preferences of verbs are not too difficult to extract from the web (although in some cases they might be somewhat noisy). Thus, the motivation for extracting this data using a game is not as apparent. Second, providing arguments of verbs out of the context of a sentence may be too difficult. For example, for the category “Things that are accumulated”, there a couple of obvious answers, such as “wealth” or “money”, but beyond these it becomes more difficult. In the context of an actual document, quite a lot of things can accumulate, but outside of that context it is difficult to think of them.

One solution to this problem would be to provide context. For example, the category “Things that accumulate in your body” is both easier to think of answers for and probably collects more useful data. However, automatically creating categories with the right level of specificity is not a trivial task; our initial experiments suggested that it is easy to generate too much context, creating an uninteresting category.

The Free Association game produces a lot of very clean data, but does not classify the relationships between the words. While a web of relationships might be useful by itself, classifying the pairs by relation type would clearly be valuable. Snow et al. (2006) and Nakov and Hearst (2008), among others, look at using a large amount of unlabeled data to classify relations between words. One issue with extracting new relations from text, for example meronyms (part-of relationships), is that they tend to occur fairly rarely. Thus, it is very easy to get a large number of spurious pairs. Using our data as a set of candidate pairs for relation extraction could greatly reduce the resulting noise. We believe that application of existing techniques to the data from the Free Association game could lead to a clean, classified set of word-word relations, but leave this as future work.

11 Discussion and Future Work

One way to extend Categorilla and Categodzilla would be to add additional types of categories. For example, a meronym category type (e.g. “Parts of a car”) would work well. Further developing the verb categories (e.g., “Things that accumulate in your body”) is another challenging but interesting direction; these categories would produce phrase-word relationships rather than word-word relationships.

Probably the most interesting direction for future work is trying to increase the complexity of the data collected from a game. There are two significant difficulties: keeping the game fun, and making sure the collected data is not too noisy. One interesting question for future research is whether different game architectures might be better suited to certain kinds of data. For example, a “telephone” style game, where players relay a phrase or sentence through some noisy channel, might be an interesting way to obtain paraphrase data.

Abstract

We examine the problem of content selection in statistical novel sentence generation. Our approach models the processes performed by professional editors when incorporating material from additional sentences to support some initially chosen key summary sentence, a process we refer to as *Sentence Augmentation*. We propose and evaluate a method called "Seed and Grow" for selecting such auxiliary information. Additionally, we argue that this can be performed using schemata, as represented by word-pair co-occurrences, and demonstrate its use in statistical summary sentence generation. Evaluation results are supportive, indicating that a schemata model significantly improves over the baseline.

1 Introduction

In the context of automatic text summarisation, we examine the problem of statistical novel sentence generation, with the aim of moving from the current state-of-the-art of sentence extraction to abstract-like summaries. In particular, we focus on the task of selecting content to include within a generated sentence.

Our approach to novel sentence generation is to model the processes underlying summarisation as performed by professional editors and abstractors. An example of the target output of this kind of generation is presented in Figure 1. In this example, the human authored summary sentence was taken verbatim from the executive summary of a United Nations proposal for the provision of aid addressing a particular humanitarian crisis. Such documents typically exceed a hundred pages.

Human-Authored Summary Sentence:
Repeated [poor seasonal rains]$_1$ [in 2004]$_2$, culminating in [food insecurity]$_3$, indicate [another year]$_4$ of crisis, the scale of which is larger than last year's and is further [exacerbated by diminishing coping assets]$_5$ [in both rural and urban areas]$_6$.

Key Source Sentence:
The consequences of [another year]$_4$ of [poor rains]$_1$ on [food security]$_3$ are severe.

Auxiliary Source Sentence(s):
However in addition to the needs of economic recovery activities for IDPs, [food insecurity]$_3$ [over the majority of 2004]$_2$ [has created great stress]$_5$ on the poorest families in the country, [both within the urban and rural settings]$_6$.

Figure 1: Alignment of a summary sentence to sentences in the full document. Phrases of similar meaning are co-indexed.

To write such summaries, we assume that the human abstractor begins by choosing key sentences from the full document. Then, for each key sentence, a set of auxiliary material is identified. The key sentence is revised incorporating these auxiliary sentences to produce the eventual summary sentence.

To study this phenomenon, a corpus of UN documents was collected and analysed.[1] Each document was divided into two parts comprising its executive summary, and the remainder, referred to here as the *source*. We manually aligned each executive summary sentence with one or more sentences from the source, by choosing a key sentence that provided

[1]This corpus is described in detail in Section 5.1.

evidence for the content of the summary sentence along with additional sentences that provided supporting material.

We refer to the resulting corpus as the UN Consolidated Appeals Process (UN CAP) corpus. It is a collection of sentence alignments, each referred to as an *aligned sentence tuple*, which consists of:

1. A human authored summary sentence from the executive summary;
2. A *key* sentence from the *source*;
3. Zero or more *auxiliary* sentences from the *source*.

The key and any auxiliary sentences are referred to collectively as the *aligned source sentences*.

We argue that some process that combines information from multiple sentences is required if we are to generate summary sentences similar to that portrayed in Figure 1. This is supported by our analysis of the UN CAP corpus. Of the 580 aligned sentence tuples, the majority, 61% of cases, appear to be examples of such a process.

Furthermore, the auxiliary sentences are clearly necessary. We found that only 30% of the open-class words in the summary are found in the key sentence. If one selects all the open-class words from aligned source sentences, recall increases to an upper limit of 45% without yet accounting for stemming. This upper bound is consistent with the upper limit of 50% found by Daumé III and Marcu (2005) which takes into account stemming differences.

This demonstrates that the auxiliary material is a valuable source of content which should be integrated into the summary sentence, allowing an improvement in recall of up to 15% prior to accounting for morphological, synonym and paraphrase differences. Of course, the trick is to improve recall without hurting precision. A naive addition of all words in the aligned source sentences incurs a drop in precision from 30% to 23%. The problem thus is one of selecting the relevant auxiliary content words without introducing unimportant content. We refer to this problem of incorporating material from auxiliary sentences to supplement a key sentence as *Sentence Augmentation*.

In this paper, sentence augmentation is modelled as a noisy channel process and has two facets: content selection and language modelling. This paper focuses on the former, in which the system must rank text segments—in this case, words—for inclusion in the generated sentence. Given a ranked selection of words, a language model would then order them appropriately, as described in work on sentence regeneration (for example, see Soricut and Marcu (2005); Wan et al. (2005)).

Provided with an aligned sentence tuple, the problem lies in effectively selecting words from the auxiliary sentences to bolster those taken from the key sentence. Given that there are on average 2.7 auxiliary sentences per aligned sentence tuple, this additional influx of words poses a considerable challenge.

We begin with the premise that, for documents of a homogeneous type (in this case, the genre is a funding proposal, and the domain is humanitarian aid), it may be possible to identify patterns in the organisation of information in summaries. For example, Figure 2 presents three summary sentences from our corpus that share the same patterned juxtaposition of two concepts *DisplacedPersons* and *HostingCommunities*. Documents may exhibit common patterns since they have a similar goal: namely, to convince donors to give financial support. In the above example, the juxtaposition highlights the fact that those in need are not just those people from the 'epicenter' of the crisis but also those that look after them.

We propose and evaluate a method called "Seed and Grow" for selecting content from auxiliary sentences. That is, we first select the core meaning of the summary, given here by the key sentence, and then we find those pieces of *additional* information that are conventionally juxtaposed with it.

Such patterns are reminiscent of *Schemata*, the organisations of propositional content introduced by McKeown (1985). Schemata typically involve a symbolic representation of each proposition's semantics. However, in our case, a text-to-text generation scenario, we are without such representations and so must find other means to encode these patterns.

To alleviate the situation, we turn to word-pair co-occurrences to approximate schematic patterns. Fig-

Sentence 1:
The increased number of [internally displaced persons]$_1$ and the continued presence of refugees have further strained the scarce natural resources of [host communities]$_2$, stretching their capacity to the limit.

Sentence 2:
100,000 people, a significant portion of the population, remain [displaced]$_1$, burdening the already precarious living conditions of [host families]$_2$ in Dili and the Districts.

Sentence 3:
The current humanitarian situation in Timor-Leste is characterised by: An estimated [100,000 displaced people]$_1$ (10% of the population) living in camps and with [host families]$_2$ in the districts; A total or partial destruction of over 3,000 homes in Dili affecting at least 14,000 IDPs

Figure 2: Examples of the pattern $\langle$*DisplacedPersons*[1], *HostingCommunities*[2]$\rangle$.

ure 2 showed that mentions of the plight of internationally displaced persons are often followed by descriptions of the impact on the host communities that look after them. In this particular example, this is realised lexically in the co-occurrences of the words *displaced* and *host*.

Corpus-based methods inspired by the notion of schemata have been explored in the past by Lapata (2003) and Barzilay and Lee (2004) for ordering sentences extracted in a multi-document summarisation application. However, to our knowledge, using word co-occurrences in this manner to represent schematic knowledge for the purposes of selecting content in a statistically-generated summary sentence has not previously been explored.

This paper seeks to determine whether or not such patterns exist in homogeneous data; and furthermore, whether such patterns can be used to better select words from auxiliary sentences. In particular, we propose the "Seed and Grow" approach for this task. The results show that even simple modelling approaches are able to model this schematic information.

In the remainder of this paper, we contrast our approach to related text-to-text research in Section 2. The Content Selection model is presented in Section 3. Section 4 describes how a binary classification model is used in a statistical text generation system. Section 5 describes our evaluation of the model for a summary generation task. We conclude, in Section 6, that domain-specific schematic patterns can be acquired and applied to content selection for statistical sentence generation.

2 Related Work

2.1 Content Selection in Text-to-Text Systems

Statistical text-to-text summarisation applications have borrowed much from the related field of statistical machine translation. In one of the first works to present summarisation as a noisy channel approach, Witbrock and Mittal (1999) presented a conditional model for learning the suitability of words from a news article for inclusion in headlines, or 'ultra-summaries'. Inspired by this approach, and with the intention of designing a robust statistical generation system, our work is also based on the noisy channel model. Into this, we incorporate our content selection model, which includes Witbrock and Mittal's model supplemented with schema-based information.

Roughly, text-to-text transformations fall into three categories: those in which information is *compressed*, *conserved*, and *augmented*. We use these distinctions to organise this overview of the literature.

In *Sentence Compression* work, a single sentence undergoes pruning to shorten its length. Previous approaches have focused on statistical syntactic transformations (Knight and Marcu, 2002). For content selection, discourse-level considerations were proposed by Daumé III and Marcu (2002), who explored the use of Rhetorical Structure Theory (Mann and Thompson, 1988). More recently, Clarke and Lapata (2007) use Centering Theory (Grosz et al., 1995) and Lexical Chains (Morris and Hirst, 1991) to identify which information to prune. Our work is similar in incorporating discourse-level phenomena for content selection. However, we look at schema-like information as opposed to chains of references and focus on the sentence augmentation task.

The work of Barzilay and McKeown (2005) on *Sentence Fusion* introduced the problem of converting multiple sentences into a single summary sentence. Each sentence set ideally tightly clusters around a single news event. Thus, there is one general proposition to be realised in the summary sentence, identified by finding the common elements in the input sentences. We see this as an example of *conservation*. In our work, this general proposition is equivalent to the core information for the summary sentence *before* the incorporation of supplementary material.

In contrast to both *compression* and *conservation* work, we focus on *augmenting* the information in a key sentence. The closest work is that of Jing and McKeown (1999) and Daumé III and Marcu (2005), in which multiple sentences are processed, with fragments within them being recycled to generate the novel generated text.

In both works, recyclable fragments are identified by automatic means. Jing and McKeown (1999) use models that are based on "copy-and-paste" operations learnt from the behaviour of human abstractors as found in a corpus. Daumé III and Marcu (2005) propose a model that encodes how likely it is that different sized spans of text are skipped to reach words and phrases to recycle.

While similar in task, our models differ substantially in the nature of the phenomenon modelled. In this work, we focus on content-based considerations that model which words can be combined to build up a new sentence.

2.2 Schemata and Text Generation

There exists related work from Natural Language Generation (NLG) in finding material to build up sentences. As mentioned above, our content selection model is inspired by work on schemata from NLG (McKeown, 1985). Barzilay and Lee (2004) showed that it is possible to obtain schema-like knowledge automatically from a corpus for the purposes of *extracting* sentences and ordering them. However, their work represents patterns at the sentence level, and is thus not directly comparable to our work, given our focus on sentence *generation*.

In our system, what is required is a means to rank words for use in generation. Thus, we focus on commonly occurring word co-occurrences, with the aim of encoding conventions in the texts we are trying to generate. In this respect, this is similar to work by Lapata (2003), who builds a conditional model of words across adjacent sentences, focusing on words in particular semantic roles. Like Barzilay and Lee (2004), this model was used to order extracted sentences in summaries. In contrast, our work focuses on word patterns found within a summary sentence, not between sentences. Additionally, our tasks differ as we examine the statistical sentence generation instead of sentence ordering.

3 Linguistic Intuitions behind Word Selection

The "Seed and Grow" approach proposed in this paper divides the word-level content selection problem into two underlying subproblems. We address these with two separate models, called the *salience* and *schematic* models. The salience model chooses the key content for the summary sentence while the schematic model attempts to identify what else is typically mentioned given those salient pieces of information.

3.1 A Salience Model: Learning "Buzzwords"

There are a variety of methods for determining the salient information in a text, and these underpin most work in automatic text summarisation. As an example of a salience model trained on corpus data, Witbrock and Mittal (1999) introduced a method for scoring summary words for inclusion within news headlines. In their model, headlines were treated as 'ultra-summaries'. Their model learns which words are typically used in headlines and encodes, at least to some degree, which words are attention grabbing.

In the domain of funding proposals, key words that grab attention may amount to domain-specific buzzwords. Intuitively, a reader, perhaps someone in charge of allocating donations, tends to look for certain types of key information matching donation criteria, and so human abstract authors will target their summaries for this purpose.

We thus adapt the Witbrock and Mittal (1999) model to identify such domain specific buzzwords (BWM, for 'buzzword model'). For an aligned sentence tuple, the probability that a word is selected based on the salience of a word with respect to the domain is defined as:

$$\text{prob}_{bwm}(\text{select} = 1|w) = \frac{|\text{summary}_w|}{|\text{source}_w|} \qquad (1)$$

where summary$_w$ is the set of aligned sentence tuples that contain the word *w* in the summary sentence *and* in the source sentences. The denominator, source$_w$, is the set of aligned sentence tuples that have the word *w* in either the key or an auxiliary sentence.

As is implicit in this equation, we could just use this buzzword model to select content not only from the key sentence, but from the auxiliary sentences as well. While it is intended ultimately to find the key content of the summary, it can also serve as an alternative baseline for auxiliary content selection to compare against the "Seed and Grow" model.

3.2 A Schema Model: Approximation via Word co-Occurrences

To restate the problem at hand: the task is one of finding elements of secondary importance that schematically elaborate on the key information. We do this by examining sample summary sentences for conventional juxtapositions of concepts. As mentioned in Section 1, schemata are approximated here with patterns of word-pair co-occurrences. Using a corpus of human-authored summaries in the domain of our application, it is thus possible to learn what those common combinations of words are.

Roughly, the process is as follows. To begin with, a *seed set* of words is chosen. The purpose of the seed set is to represent the core proposition of the summary sentence.

In this work, this core proposition is given by the key sentence and so the non-stopwords belonging to it are used to populate the seed set. In the "Seed and Grow" approach, we check to see which words from auxiliary sentences pair well with words in the seed set.

3.2.1 Collecting Word-level Patterns

Each training case in the corpus contains a single human-authored summary sentence that can be used to learn which pairs of words conventionally occur in a summary. For each summary sentence, stopwords are removed. Then, each pairing of words in the sentence is used to update a pair-wise word co-occurrence frequency table. When looking up and storing a frequency, the order of words is ignored.

3.2.2 Scoring Word-Pair Co-occurrence Strength

For any two words, w_1 from the seed set and w_2 from an auxiliary sentence, the word-pair co-occurrence probability is defined as follows:

$$\begin{aligned} & \text{prob}_{co\text{-}oc}(w_1, w_2) \\ & = \frac{\text{freq}(w_1, w_2)}{\text{freq}(w_1) + \text{freq}(w_2) - \text{freq}(w_1, w_2)} \end{aligned} \quad (2)$$

where $freq(w_1, w_2)$ is a lookup in the word-pair co-occurrence frequency table. This table stores co-occurrence word pairs occurring in the summary sentence.

3.2.3 Combining a Set of Co-occurrence Scores

Each auxiliary word now has a series of scores, one for each comparison with a seed word. To rank each auxiliary word, these need to be combined into a single score for sorting.

When combining the set of co-occurrence scores, one might want to account for the fact that each pairing of a seed word with an auxiliary word might not contribute equally to the overall selection of that auxiliary word. Intuitively, a word in the seed set, derived from the key sentence, may only make a minor contribution to the core meaning of the summary sentence. For example, words that are part of an adjunct phrase in the key sentence might not be good candidates to elaborate upon. Thus, one might want to weight these seed words lower, to reduce their influence on triggering schematically associated words.

To allow for this, a seed weight vector is maintained, storing a weight per seed word. Different weighting schemes are possible. For example, a scheme might indicate the salience of a word. In addition to the buzzword model (BWM) described earlier, one might employ a standard vector space approach (Salton and McGill, 1983) from Information Retrieval, which uses term frequency scores weighted with an inverse document frequency factor, or *tf-idf*. We also implement the case in which all seed words are treated equally using binary weights, where 1 indicates the presence of a seed word, and 0 indicates its absence. In the evaluations described in Section 5, we refer to these three seed weighting schemes as *bwm* and *tf-idf*, and *binary* respectively.

To find the probability of selecting an auxiliary word using the schematic word-pair co-occurrence model (WCM), an averaged probability is found by normalising the sum of the weighted probabilities, where weights are provided by one of the three schemes above:

$$\text{prob}_{wcm}(w_i) = \frac{1}{Z} \times \sum_{k=0}^{|\text{seed}|} \text{weights}_k \times \text{prob}_{co\text{-}oc}(w_i, w_k) \quad (3)$$

where *seed* is the set of seed words and w_k is the k^{th} word in that set. The vector, *weights*, stores the seed weights. The normalisation factor for the weighted average, Z, is the number of auxiliary words.

Finally, since the WCM model only serves to select words from the *auxiliary* sentences, words from the key sentence must be given scores as well. For these words, the scoring is as follows:

$$\text{prob}_{wcm}(w) = \frac{1}{Z}\left(\frac{1}{|\text{seed}|} + \text{prob}_{wcm}(w)\right) \quad (4)$$

where Z is a normalisation across the set of seed words.

4 Combining Buzzwords and Word-Pair Co-Occurrence Models for Generation

As mentioned above, the noisy channel approach is used for producing the augmented sentence. Although the focus of this paper is on Content Selection, an overview of the end-to-end generation process is presented for completeness.

Sentence augmentation is essentially a text-to-text process: A key sentence and auxiliary material are transformed into a single summary sentence. Following Witbrock and Mittal (1999), the task is to search for the string of words that maximises the probability $prob(summary|source)$. Standardly reformulating this probability using Bayes' rule results in the following:

$$prob_{cm}(source|summary) \times prob_{lm}(summary) \quad (5)$$

In this paper, we are concerned with the first factor, $prob_{cm}(source|summary)$, referred to as the channel model (CM), which combines both the buzzword (BWM) and word-pair co-occurrence (WCM) models. An examination of differences between the two approaches revealed only a 20% word overlap on the Jaccard metric.

In order to combine multiple models, we intend to use machine learning approaches to combine the information in each model in a similar manner to Berger et al. (1996). We are currently exploring the use of logistic regression methods to learn a function that would treat, as features, the probabilities defined by the salience and schematic content selection models. Although generation is possible using each content selection model in isolation, evaluations of the combined model are on-going and are not presented in this paper.

5 Evaluation

In this evaluation, the task is to select n words from the aligned source sentences for inclusion in a summary. As a gold-standard for comparison, we simply examine what words were actually chosen in the summary sentence of the aligned sentence tuple. We are specifically interested in open-class words, and so a stopword list of closed-class words is used to filter the sentences in each test case.

We evaluate against the set of open-class words in the human-authored summary sentence using recall and precision metrics. Recall is the size of the intersection of the selected and gold-standard sets, normalised by the length of the gold-standard sentence (in words). This recall metric is similar to the ROUGE-1 metric, the unigram version of the ROUGE metric (Lin and Hovy, 2003) used in the Document Understanding Conferences[2] (DUC). Precision is the size of the intersection normalised by the number of words selected. We also report the F-measure, which is the harmonic mean of the recall and precision scores.

Recall, precision and F-measure are measured at various values of n ranging from 1 to the number of open-class words in the gold-standard summary sentence for a particular test case. For the purposes of evaluation, differences in tokens due to morphology were explored crudely via the use of Porter's stemming algorithm. However, the results from stemming are not that different from exact token matches when examining performance on the entire data set

[2]http://duc.nist.gov

Number of training cases	530
Average words in summary sentence	27.0

Word count: source sentences	21356
Word type count in corpus	3800

Table 1: Statistics for the UN CAP training set

and so, for simplicity, these are omitted in this discussion.

5.1 The Data

The corpus is made up of a number of humanitarian aid proposals called Consolidated Appeals Process (UN CAP) documents, which are archived at the United Nations website.[3] 135 documents from the period 2002 to 2007 were downloaded by the authors. A preprocessing stage extracted text from the PDF files and segmented the documents into executive summary and source sections. These were then automatically segmented further into sentences.

Executive summary sentences were manually aligned by the authors to source key and auxiliary sentences, producing a corpus of 580 aligned sentence tuples referred to here as the UN CAP corpus. Of these, 230 tuples were paraphrase cases (i.e. without aligned auxiliary sentences). The remaining 550 cases were instances of sentence augmentation (with at least one auxiliary sentence).

Of the 580 cases, 50 cases were set aside for testing. The remaining 530 cases were used for training. Statistics for the training portion of the sentence augmentation set are provided in Table 1.

In this paper, aligned sentence tuples are obtained via manual annotation. Automatic construction of these sentence-level alignments is possible and has been explored by Jing and McKeown (1999). We also envisage using tools for scoring sentence similarity (for example, see Hatzivassiloglou et al. (2001)) for automatically constructing them; this is the focus of work by Wan and Paris (2008).

5.2 The Baselines

Three baselines were used in this work: the *random*, *tf-idf* and *position* baselines. A *random* word selector shows what performance might be achieved in the absence of any linguistic knowledge.

We also sorted all words in the aligned source sentences by their weighted *tf-idf* scores. This baseline selects words in order until the desired word limit is reached. This baseline is referred to as the *tf-idf* baseline.

Finally, we selected words based on their sentence order, choosing first those words from the key sentence. When these are exhausted, auxiliary sentences are sorted by their sentence positions in the original document. Words from the first auxiliary sentence are then chosen. This continues until either the desired number of words have been chosen, or no words remain. This baseline is known as the *position* baseline.

5.3 Content Selection Results

We compare the three baselines to the two models presented in Section 3. These are the buzzword salience model (BWM) and the schematic word-pair co-occurrence model (WCM).

We begin by presenting recall, precision and F-measure graphs when selecting from the aligned source sentences, comprising the key and auxiliary sentences. Figure 3 shows the results for the two models against the three baselines. The two models, the positional, and the *tf-idf* baselines perform better than the random baseline, as measured by a two-tailed Wilcoxon Matched Pairs Signed Ranks test ($\alpha = 0.05$).

The WCM consistently out-performs the BWM on all metrics, and the differences are statistically significant. In fact, the BWM also generally performs worse than the position and *tf-idf* baselines. WCM and the position baseline both significantly outperform the *tf-idf* baseline on all metrics for longer sentence lengths.

That the position baseline and WCM should perform similarly is not really surprising since, in effect, the position baseline first chooses words from the key sentence and then selects auxiliary words. The difference essentially lies in how the auxiliary words are chosen.

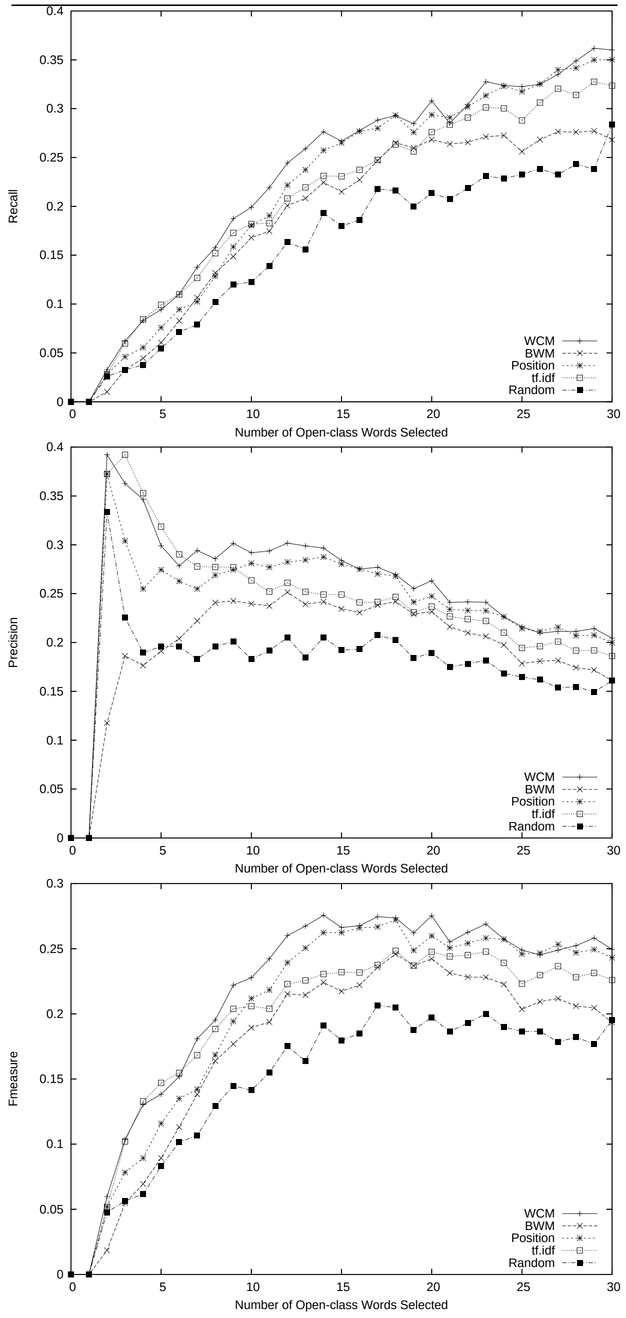

Figure 3: Recall, Precision and F-measure performance for open-class words from the entire input set (key and auxiliary). Models presented are the Buzzword Model (BWM), the Word-Pair Co-occurrence Model (WCM) and position, *tf-idf* and random baselines.

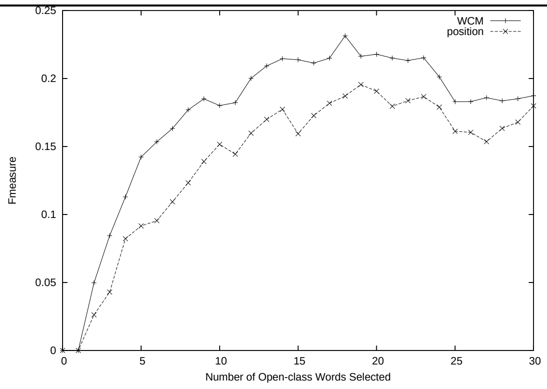

Figure 4: F-measure scores for content selection on just the auxiliary sentences. Models presented are the Word-Pair Co-occurrence model (WCM) and the position baseline.

The results of Figure 3 weakly support the hypothesis that using schematic word-pair co-occurrences helps improve performance over models without discourse-related features. The graphs show that WCM edges above the position baseline when the number of selected open-class words ranges from 10 to 15. Note that the average number of open-class words in a human authored summary sentence is 16. The only significant difference found was in the F-measure and precision scores for 19 selected open-class words. Nevertheless, a general trend can be observed in which WCM performs better than the position baseline.

Ultimately, however, what we want to do is select auxiliary content to supplement the key sentence. To examine the effect of two best performing approaches, WCM and the position baseline, on this task, were both modified so that the key sentence words were explicitly given a zero probability. Thus, the recall, precision and F-measure scores obtained are based solely on the ability of either to select auxiliary words. The F-measure scores are presented Figure 4. WCM consistently outperforms the position baseline for the selection of auxiliary words. Differences are significant for 6 or more selected open-class words.

The results show that even when considering only exact token matches, we can improve on the recall of open-class words, and do so without penalty in precision. Our working hypothesis is that such gains are possible because the corpus has a homogeneous quality and key patterns are sufficiently repeated even when the overall data set is of the order of hundreds of cases. The benefit of using a model encoding some schematic information is further shown by the performance of WCM over the position baseline when selecting words from auxiliary sentences.

This is an interesting finding given that domain independent methods are increasingly used on domain-specific corpora such as financial and biomedical texts, for which we may have access to only a limited amount of data. We anticipate that as we introduce methods to account for paraphrase and synonym differences, performance might rise further still.

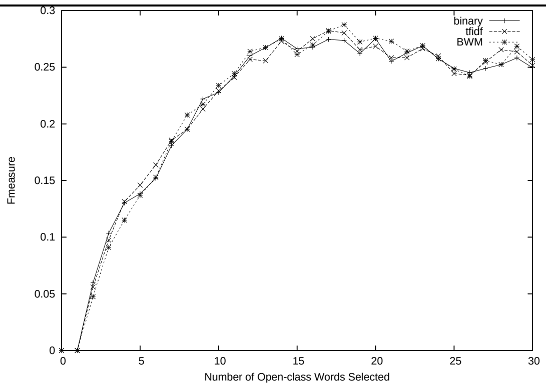

Figure 5: F-measure performance for open-class words from the entire input set (key and auxiliary). Models presented are variants of the Word-Pair Co-occurrence Model (WCM) that differ in the seed weighting schemes.

5.4 Testing Seed Weighting Schemes

We can also weight seed words in the "Seed and Grow" approach in a variety of ways. To test whether weighting schemes have any effect on content selection performance, we examined the use of three schemes. We were particularly interested in those schemes that indicate the contribution of a seed word to the core meaning of a sentence. These are the *binary*, *tf-idf* and *buzzword* weighting schemes described in Section 3. We present the F-measure graph for these three variants of the schematic word-pair co-occurrence model (WCM) in Figure 5.

The graphs show that there is no discernible difference between the seed weighting schemes. No scheme significantly outperforms another. Thus, we conclude that the choice of these particular seed weighting schemes has no effect on performance. In future work, we intend to examine whether weighting schemes encoding syntactic information might fare better, since such information might more accurately represent the contribution of a substring to the main clause of the sentence.

6 Conclusions and Future Work

In this paper, we argued a case for *sentence augmentation*, a component that facilitates abstract-like text summarisation. We showed that such a process can account for summary sentences as authored by professional editors. We proposed the use of schemata, as approximated with a word-pair co-occurrence model, and advocated a new schema-based "Seed and Grow" content selection model used for statistical sentence generation.

We also showed that domain-specific patterns, schematic word-pair co-occurrences in this case, can be acquired from a limited amount of data as indicated by modest performance gains for content selection using schemata information. We postulate that this is particularly true when dealing with homogeneous data.

In future work, we intend to explore other string matches corresponding to variations due to paraphrases and synonymy. We would also like to study the effects of corpus size when learning schematic patterns. Finally, we are currently investigating the use of machine learning methods to combine the best of the Salience and Schemata models in order to provide a single model for use in decoding.

Using Bilingual Knowledge and Ensemble Techniques for Unsupervised Chinese Sentiment Analysis

Abstract

It is a challenging task to identify sentiment polarity of Chinese reviews because the resources for Chinese sentiment analysis are limited. Instead of leveraging only monolingual Chinese knowledge, this study proposes a novel approach to leverage reliable English resources to improve Chinese sentiment analysis. Rather than simply projecting English resources onto Chinese resources, our approach first translates Chinese reviews into English reviews by machine translation services, and then identifies the sentiment polarity of English reviews by directly leveraging English resources. Furthermore, our approach performs sentiment analysis for both Chinese reviews and English reviews, and then uses ensemble methods to combine the individual analysis results. Experimental results on a dataset of 886 Chinese product reviews demonstrate the effectiveness of the proposed approach. The individual analysis of the translated English reviews outperforms the individual analysis of the original Chinese reviews, and the combination of the individual analysis results further improves the performance.

1 Introduction

In recent years, sentiment analysis (including subjective/objective analysis, polarity identification, opinion extraction, etc.) has drawn much attention in the NLP field. In this study, the objective of sentiment analysis is to annotate a given text for polarity orientation (positive/negative). Polarity orientation identification has many useful applications, including opinion summarization (Ku et al., 2006) and sentiment retrieval (Eguchi and Lavrenko, 2006).

To date, most of the research focuses on English and a variety of reliable English resources for sentiment analysis are available, including polarity lexicon, contextual valence shifters, etc. However, the resources for other languages are limited. In particular, few reliable resources are available for Chinese sentiment analysis[1] and it is not a trivial task to manually label reliable Chinese sentiment resources.

Instead of using only the limited Chinese knowledge, this study aims to improve Chinese sentiment analysis by making full use of bilingual knowledge in an unsupervised way, including both Chinese resources and English resources. Generally speaking, there are two unsupervised scenarios for "borrowing" English resources for sentiment analysis in other languages: one is to generate resources in a new language by leveraging on the resources available in English via cross-lingual projections, and then perform sentiment analysis in the English language based on the generated resources, which has been investigated by Mihalcea et al. (2007); the other is to translate the texts in a new language into English texts, and then perform sentiment analysis in the English language, which has not yet been investigated.

In this study, we first translate Chinese reviews into English reviews by using machine translation services, and then identify the sentiment polarity of English reviews by directly leveraging English resources. Furthermore, ensemble methods are employed to combine the individual analysis results in each language (i.e. Chinese and English) in order to obtain improved results. Given machine translation services between the selected target language and English, the proposed approach can be applied to any other languages as well.

Experiments have been performed on a dataset of 886 Chinese product reviews. Two commercial

[1] This study focuses on Simplified Chinese.

machine translation services (i.e. Google Translate and Yahoo Babel Fish) and a baseline dictionary-based system are used for translating Chinese reviews into English reviews. Experimental results show that the analysis of English reviews translated by the commercial translation services outperforms the analysis of original Chinese reviews. Moreover, the analysis performance can be further improved by combining the individual analysis results in different languages. The results also demonstrate that our proposed approach is more effective than the approach that leverages generated Chinese resources.

The rest of this paper is organized as follows: Section 2 introduces related work. The proposed approach is described in detail in Section 3. Section 4 shows the experimental results. Lastly we conclude this paper in Section 5.

2 Related Work

Polarity identification can be performed on word level, sentence level or document level. Related work for word-level polarity identification includes (Hatzivassiloglou and McKeown, 1997; Kim and Hovy. 2004; Takamura et al., 2005; Yao et al. 2006; Kaji and Kitsuregawa, 2007), and related work for sentence-level polarity identification includes (Yu and Hatzivassiloglou, 2003; Kim and Hovy. 2004) Word-level or sentence-level sentiment analysis is not the focus of this paper.

Generally speaking, document-level polarity identification methods can be categorized into unsupervised and supervised.

Unsupervised methods involve deriving a sentiment metric for text without training corpus. Turney (2002) predicates the sentiment orientation of a review by the average semantic orientation of the phrases in the review that contain adjectives or adverbs, which is denoted as the semantic oriented method. Kim and Hovy (2004) build three models to assign a sentiment category to a given sentence by combining the individual sentiments of sentiment-bearing words. Hiroshi et al. (2004) use the technique of deep language analysis for machine translation to extract sentiment units in text documents. Kennedy and Inkpen (2006) determine the sentiment of a customer review by counting positive and negative terms and taking into account contextual valence shifters, such as negations and intensifiers. Devitt and Ahmad (2007) explore a computable metric of positive or negative polarity in financial news text.

Supervised methods consider the sentiment analysis task as a classification task and use labeled corpus to train the classifier. Since the work of Pang et al. (2002), various classification models and linguistic features have been proposed to improve the classification performance (Pang and Lee, 2004; Mullen and Collier, 2004; Wilson et al., 2005a; Read, 2005). Most recently, McDonald et al. (2007) investigate a structured model for jointly classifying the sentiment of text at varying levels of granularity. Blitzer et al. (2007) investigate domain adaptation for sentiment classifiers, focusing on online reviews for different types of products. Andreevskaia and Bergler (2008) present a new system consisting of the ensemble of a corpus-based classifier and a lexicon-based classifier with precision-based vote weighting.

Research work focusing on Chinese sentiment analysis includes (Tsou et al., 2005; Ye et al., 2006; Li and Sun, 2007; Wang et al., 2007). Such work represents heuristic extensions of the unsupervised or supervised methods for English sentiment analysis.

To date, the most closely related work is Mihalcea et al. (2007), which explores cross-lingual projections to generate subjectivity analysis resources in Romanian by leveraging on the tools and resources available in English. They have investigated two approaches: a lexicon-based approach based on Romanian subjectivity lexicon translated from English lexicon, and a corpus-based approach based on Romanian subjectivity-annotated corpora obtained via cross-lingual projections. In this study, we focus on unsupervised sentiment polarity identification and we only investigate the lexicon-based approach in the experiments.

Other related work includes subjective/objective analysis (Hatzivassiloglon and Wiebe, 2000; Riloff and Wiebe, 2003) and opinion mining and summarization (Liu et al., 2005; Popescu and Etzioni. 2005; Choi et al., 2006; Ku et al., 2006; Titov and McDonald, 2008).

3 The Proposed Approach

3.1 Overview

The motivation of our approach is to make full use of bilingual knowledge to improve sentiment analysis in a target language, where the resources for sentiment analysis are limited or unreliable. This study focuses on unsupervised polarity identification of Chinese product reviews by using both the rich English knowledge and the limited Chinese knowledge.

The framework of our approach is illustrated in Figure 1. A Chinese review is translated into the corresponding English review using machine translation services, and then the Chinese review and the English review are analyzed based on Chinese resources and English resources, respectively. The analysis results are then combined to obtain more accurate results under the assumption that the individual sentiment analysis can complement each other. Note that in the framework, different machine translation services can be used to obtain different English reviews, and the analysis of English reviews translated by a specific machine translation service is conducted separately. For simplicity, we consider the English reviews translated by different machine translation services as reviews in different languages, despite the fact that in essence, they are still in English.

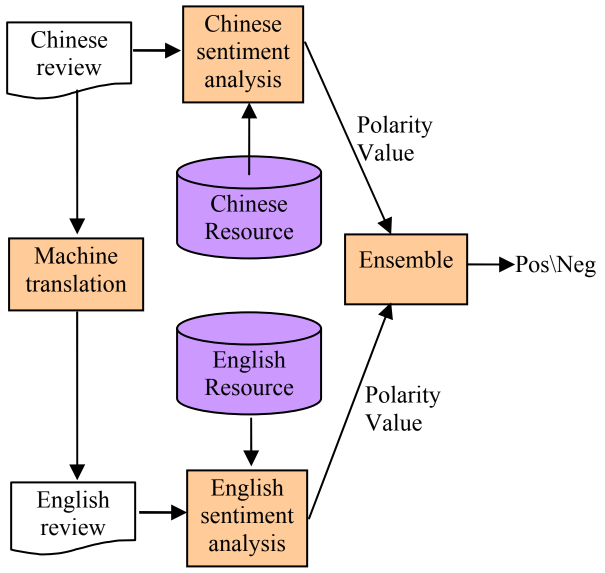

Figure 1. Framework of our approach

Formally, give a review rev^0 in the target language (i.e. Chinese), the corresponding review rev_i in the ith language is obtained by using a translation function: $rev^i = f^i_{Trans}(rev^0)$, where $1 \le i \le p$ and p is the total number of machine translation services. For each review rev^k in the kth language ($0 \le k \le p$), we employ the semantic oriented approach to assign a semantic orientation value $f^k_{SO}(rev^k)$ to the review, and the polarity orientation of the review can be simply predicated based on the value by using a threshold. Given a set of semantic orientation values $F_{SO}=\{f^k_{SO}(rev^k) \mid 0 \le k \le p\}$, the ensemble methods aim to derive a new semantic orientation value $f^{Ensemble}_{SO}(rev^0)$ based on the values in F_{SO}, which can be used to better classify the review as positive or negative.

The steps of review translation, individual semantic orientation value computation and ensemble combination are described in details in the next sections, respectively.

3.2 Review Translation

Translation of a Chinese review into an English review is the first step of the proposed approach. Manual translation is time-consuming and labor-intensive, and it is not feasible to manually translate a large amount of Chinese product reviews in real applications. Fortunately, machine translation techniques have been well developed in the NLP field, though the translation performance is far from satisfactory. A few commercial machine translation services can be publicly accessed. In this study, the following two commercial machine translation services and one baseline system are used to translate Chinese reviews into English reviews.

Google Translate [2] (***GoogleTrans***): Google Translate is one of the state-of-the-art commercial machine translation systems used today. Google Translate applies statistical learning techniques to build a translation model based on both monolingual text in the target language and aligned text consisting of examples of human translations between the languages.

Yahoo Babel Fish [3] (***YahooTrans***): Different from Google Translate, Yaho Babel Fish uses SYSTRAN's rule-based translation engine. SYSTRAN was one of the earliest developers of machine translation software. SYSTRAN applies complex sets of specific rules defined by linguists to analyze and then transfer the grammatical structure of the source language into the target language.

Baseline Translate (*DictTrans*): We simply develop a translation method based only on one-to-one term translation in a large Chinese-to-English

[2] http://translate.google.com/translate_t
[3] http://babelfish.yahoo.com/translate_txt

dictionary. Each term in a Chinese review is translated by the first corresponding term in the Chinese-to-English dictionary, without any other processing steps. In this study, we use the LDC_CE_DIC2.0[4] constructed by LDC as the dictionary for translation, which contains 128366 Chinese terms and their corresponding English terms.

The Chinese-to-English translation performances of the two commercial systems are deemed much better than the weak baseline system. Google Translate has achieved very good results on the Chinese-to-English translation tracks of NIST open machine translation test (MT)[5] and it ranks the first on most tracks. In the Chinese-to-English task of MT2005, the BLEU-4 score of Google Translate is 0.3531, and the BLEU-4 score of SYSTRAN is 0.1471. We can deduce that Google Translate is better than Yahoo Babel Fish, without considering the recent improvements of the two systems.

Here are two running example of Chinese reviews and the translated English reviews (*HumanTrans* refers to human translation):

***Positive Example:** 优点很多,外形也很好。*

HumanTrans: Many advantages and very good shape.

GoogleTrans: Many advantages, the shape is also very good.

YahooTrans: Merit very many, the contour very is also good.

DictTrans: merit very many figure also very good

***Negative example:** 内存太小不支持红外。*

HumanTrans: The memory is too small to support IR.

GoogleTrans: Memory is too small not to support IR.

YahooTrans:The memory too is small does not support infrared.

DictTrans: memory highest small negative not to be in favor of ir.

3.3 Individual Semantic Orientation Value Computation

For any specific language, we employ the semantic orientated approach (Kennedy and Inkpen, 2006) to compute the semantic orientation value of a review. The unsupervised approach is quite straightforward and it makes use of the following sentiment lexicons: **positive Lexicon (*Positive_Dic*)** including terms expressing positive polarity, **Negative Lexicon (*Negative_Dic*)** including terms expressing negative polarity, **Negation Lexicon (*Negation_Dic*)** including terms that are used to reverse the semantic polarity of a particular term, and **Intensifier Lexicon (*Intensifier_Dic*)** including terms that are used to change the degree to which a term is positive or negative. In this study, we conduct our experiments within two languages, and we collect and use the following popular and available Chinese and English sentiment lexicons[6], without any further filtering and labeling:

1) Chinese lexicons

***Positive_Dic^{cn}*:** 3730 Chinese positive terms were collected from the Chinese Vocabulary for Sentiment Analysis (VSA)[7] released by HOWNET.

***Negative_Dic^{cn}*:** 3116 Chinese negative terms were collected from Chinese Vocabulary for Sentiment Analysis (VSA) released by HOWNET.

***Negation_Dic^{cn}*:** 13 negation terms were collected from related papers.

***Intensifier_Dic^{cn}*:** 148 intensifier terms were collected from Chinese Vocabulary for Sentiment Analysis (VSA) released by HOWNET.

2) English lexicons

***Positive_Dic^{en}*:** 2718 English positive terms were collected from the feature file *subjclueslen1-HLTEMNLP05.tff* [8] containing the subjectivity clues used in the work (Wilson et al., 2005a; Wilson et al., 2005b). The clues in this file were collected from a number of sources. Some were culled from manually developed resources, e.g. *general inquirer*[9] (Stone et al., 1966). Others were identified automatically using both annotated and unannotated data. A majority of the clues were collected as part of work reported in Riloff and Wiebe (2003).

***Negative_Dic^{en}*:** 4910 English negative terms were collected from the same file described above.

***Negation_Dic^{en}*:** 88 negation terms were collected from the feature file *valenceshifters.tff* used in the work (Wilson et al., 2005a; Wilson et al., 2005b).

***Intensifier_Dic^{en}*:** 244 intensifier terms were collected from the feature file *intensifiers2.tff* used in the work (Wilson et al., 2005a; Wilson et al., 2005b).

[4] http://projects.ldc.upenn.edu/Chinese/LDC_ch.htm

[5] http://www.nist.gov/speech/tests/mt/

[6] In this study, we focus on using a few popular resources in both Chinese and English for comparative study, instead of trying to collect and use all available resources.

[7] http://www.keenage.com/html/e_index.html

[8] http://www.cs.pitt.edu/mpqa/

[9] http://www.wjh.harvard.edu/~inquirer/homecat.htm

The semantic orientation value $f^k_{SO}(rev^k)$ for rev^k is computed by summing the polarity values of all words in the review, making use of both the word polarity defined in the positive and negative lexicons and the contextual valence shifters defined in the negation and intensifier lexicons. The algorithm is illustrated in Figure 2.

```
Input: a review rev^k in the kth language. Four lexicons in the kth language: Positive_Dic^k, Negative_Dic^k, Negation_Dic^k, Intensifier_Dic^k, which are either Chinese or English lexicons;
Output: Polarity Value $f^k_{SO}(rev^k)$;
Algorithm Compute_SO:
1. Tokenize review $rev_k$ into sentence set S and each sentence $s \in S$ is tokenized into word set $W_s$;
2. For any word w in a sentence $s \in S$, compute its SO value SO(w) as follows:
    1) if $w \in Positive\_Dic^k$, SO(w)=PosValue;
    2) If $w \in Negative\_Dic^k$, SO(w)=NegValue;
    3) Otherwise, SO(w)=0;
    4) Within the window of q words previous to w, if there is a term $w' \in Negation\_Dic^k$, SO(w)= –SO(w);
    5) Within the window of q words previous to w, if there is a term $w' \in Intensifier\_Dic^k$, SO(w) =ρ×SO(w);
3. $f^k_{SO}(rev^k) = \sum_{s \in S} \sum_{w \in W_s} SO(w)$;
```

Figure 2. The algorithm for semantic orientation value computation

In the above algorithm, *PosValue* and *NegValue* are the polarity values for positive words and negative words respectively. We empirically set *PosValue*=1 and *NegValue*= –2 because negative words usually contribute more to the overall semantic orientation of the review than positive words, according to our empirical analysis. ρ>1 aims to intensify the polarity value and we simply set ρ=2. q is the parameter controlling the window size within which the negation terms and intensifier terms have influence on the polarity words and here q is set to 2 words. Note that the above parameters are tuned only for Chinese sentiment analysis, and they are used for sentiment analysis in the English language without further tuning. The tokenization of Chinese reviews involves Chinese word segmentation.

Usually, if the semantic orientation value of a review is less than 0, the review is labeled as negative, otherwise, the review is labeled as positive.

3.4 Ensemble Combination

After obtaining the set of semantic orientation values $F_{SO}=\{f^k_{SO}(rev^k) \mid 0 \le k \le p\}$ by using the semantic oriented approach, where p is the number of English translations for each Chinese review, we exploit the following ensemble methods for deriving a new semantic orientation value $f_{SO}^{Ensemble}(rev^0)$:

1) Average

It is the most intuitive combination method and the new value is the average of the values in F_{SO}:

$$f_{SO}^{Ensemble}(rev^0) = \frac{\sum_{k=0}^{p} f_{SO}^{k}(rev^k)}{p+1}$$

Note that after the new value of a review is obtained, the polarity tag of the review is assigned in the same way as described in Section 3.3.

2) Weighted Average

This combination method improves the average combination method by associating each individual value with a weight, indicating the relative confidence in the value.

$$f_{SO}^{Ensemble}(rev^0) = \sum_{k=0}^{p} \lambda_k f_{SO}^{k}(rev^k)$$

where $\lambda_k \in [0, 1]$ is the weight associated with $f^k_{SO}(rev^k)$. The weights can be set in the following two ways:

Weighting Scheme1: The weight of $f^k_{SO}(rev^k)$ is set to the accuracy of the individual analysis in the *k*th language.

Weighting Scheme2: The weight of $f^k_{SO}(rev^k)$ is set to be the maximal correlation coefficient between the analysis results in the *k*th language and the analysis results in any other language. The underlying idea is that if the analysis results in one language are highly consistent with the analysis results in another language, the results are deemed to be more reliable. Given two lists of semantic values for all reviews, we use the Pearson's correlation coefficient to measure the correlation between them. The weight associated with function $f^k_{SO}(rev^k)$ is then defined as the maximal Pearson's correlation coefficient between the reviews' values in the *k*th language and the reviews' values in any other language.

3) Max

The new value is the maximum value in F_{SO}:

$$f_{SO}^{Ensemble}(rev^0) = \max\left\{f_{SO}^k(rev^k) \mid 0 \le k \le p\right\}$$

4) Min

The new value is the minimum value in F_{SO}:

$$f_{SO}^{Ensemble}(rev^0) = \min\left\{f_{SO}^k(rev^k) \mid 0 \le k \le p\right\}$$

5) Average Max&Min

The new value is the average of the maximum value and the minimum value in F_{SO}:

$$f_{SO}^{Ensemble}(rev^0) = \frac{\max\left\{f_{SO}^k(rev^k) \mid 0 \le k \le p\right\} + \min\left\{f_{SO}^k(rev^k) \mid 0 \le k \le p\right\}}{2}$$

6) Majority Voting

This combination method relies on the final polarity tags, instead of the semantic orientation values. A review can obtain p+1 polarity tags based on the individual analysis results in the p+1 languages. The polarity tag receiving more votes is chosen as the final polarity tag of the review.

4 Empirical Evaluation

4.1 Dataset and Evaluation Metrics

In order to assess the performance of the proposed approach, we collected 1000 product reviews from a popular Chinese IT product web site-IT168[10]. The reviews were posted by users and they focused on such products as mp3 players, mobile phones, digital camera and laptop computers. Users usually selected for each review an icon indicating "postive" or "negative". The reviews were first categorized into positive and negative classes according to the associated icon. The polarity labels for the reviews were then checked by subjects. Finally, the dataset contained 886 product reviews with accurate polarity labels. All the 886 reviews were used as test set.

We used the standard precision, recall and F-measure to measure the performance of positive and negative class, respectively, and used the MacroF measure and accuracy metric to measure the overall performance of the system. The metrics are defined the same as in general text categorization.

4.2 Individual Analysis Results

In this section, we investigate the following individual sentiment analysis results in each specified language:

CN: This method uses only Chinese lexicons to analyze Chinese reviews;

GoogleEN: This method uses only English lexicons to analyze English reviews translated by *GoogleTrans*;

YahooEN: This method uses only English lexicons to analyze English reviews translated by *YahooTrans*;

DictEN: This method uses only English lexicons to analyze English reviews translated by *DictTrans*;

In addition to the above methods for using English resources, the lexicon-based method investigated in Mihalcea et al. (2007) can also use English resources by directly projecting English lexicons into Chinese lexicons. We use a large English-to-Chinese dictionary - LDC_EC_DIC2.0[11] with 110834 entries for projecting English lexicons into Chinese lexicons via one-to-one translation. Based on the generated Chinese lexicons, two other individual methods are investigated in the experiments:

CN2: This method uses only the generated Chinese Resources to analyze Chinese reviews.

CN3: This method combines the original Chinese lexicons and the generated Chinese lexicons and uses the extended lexicons to analyze Chinese reviews.

Table 1 provides the performance values of all the above individual methods. Seen from the table, the performances of **GoogleEN** and **YahooEN** are much better than the baseline **CN** method, and even the **DictEN** performs as well as **CN**. The results demonstrate that the use of English resources for sentiment analysis of translated English reviews is an effective way for Chinese sentiment analysis. We can also see that the English sentiment analysis performance relies positively on the translation performance, and **GoogleEN** performs the best while **DictEN** performs the worst, which is consistent with the fact the *GoogleTrans* is deemed the best of the three machine translation systems, while *DictTrans* is the weakest one.

Furthermore, the **CN** method outperforms the **CN2** and **CN3** methods, and the **CN2** method performs the worst, which shows that the generated Chinese lexicons do not give any contributions to the performance of Chinese sentiment analysis. We explain the results by the fact that the term-based one-to-one translation is inaccurate and the generated Chinese lexicons are not reliable. Overall, the

[10] http://www.it168.com

[11] http://projects.ldc.upenn.edu/Chinese/LDC_ch.htm

approach through cross-lingual lexicon translation does not work well for Chinese sentiment analysis in our experiments.

4.3 Ensemble Results

In this section, we first use the simple average ensemble method to combine different individual analysis results. Table 2 provides the performance values of the average ensemble results based on different individual methods.

Seen from Tables 1 and 2, almost all of the average ensembles outperforms the baseline **CN** method and the corresponding individual methods, which shows that each individual methods have their own evidences for sentiment analysis, and thus fusing the evidences together can improve performance. For the methods of **CN+GoogleEN, CN+YahooEN** and **CN+DictEN**, we can see the ensemble performance is not positively relying on the translation performance: **CN+YahooEN** performs better than **CN+GoogleEN**, and even **CN+DictEN** performs as well as **CN+GoogleEN**. The results show that the individual methods in the ensembles can complement each other, and even the combination of two weak individual methods can achieve good performance. However, the **DictEN** method is not effective when the ensemble methods have already included **GoogleEN** and **YahooEN**. Overall, the performances of the ensemble methods rely on the performances of the most effective constituent individual methods: the methods including both **GoogleEN** and **YahooEN** perform much better than other methods, and **CN+GoogleEN+YahooEN** performs the best out of all the methods.

We further show the results of four typical average ensembles by varying the combination weights. The combination weights are respectively specified as λ·**CN**+(1-λ)·**GoogleEN**, λ·**CN**+(1-λ)·**YahooEN**, λ·**CN**+(1-λ)·**DictEN**, λ_1·**CN**+λ_2·**GoogleEN**+(1-λ_1-λ_2)·**YahooEN**. The results over the MacroF metric are shown in Figures 3 and 4 respectively. We can see from the figures that **GoogleEN** and **YahooEN** are dominant factors in the ensemble methods.

We then investigate to use other ensemble methods introduced in Section 3.4 to combine the **CN**, **GoogleEN** and **YahooEN** methods. Table 3 gives the comparison results. The methods of "**Weighted Average1**" and "**Weighted Average2**" are two weighted average ensembles using the two weighing schemes, respectively. We can see that all the ensemble methods outperform the constituent individual method, while the two weighted average ensembles perform the best. The results further demonstrate the good effectiveness of the ensemble combination of individual analysis results for Chinese sentiment analysis.

Individual Method	Positive			Negative			Total

5 Conclusion and Future Work

This paper proposes a novel approach to use English sentiment resources for Chinese sentiment analysis by employing machine translation and ensemble techniques. Chinese reviews are translated into English reviews and the analysis results of both Chinese reviews and English reviews are combined to improve the overall accuracy. Experimental results demonstrate the encouraging performance of the proposed approach.

In future work, more additional English resources will be used to further improve the results. We will also apply the idea to supervised Chinese sentiment analysis.

A Tale of Two Parsers: investigating and combining graph-based and transition-based dependency parsing using beam-search

Yue Zhang and **Stephen Clark**

{yue.zhang,stephen.clark}@comlab.ox.ac.uk

Abstract

Graph-based and transition-based approaches to dependency parsing adopt very different views of the problem, each view having its own strengths and limitations. We study both approaches under the framework of beam-search. By developing a graph-based and a transition-based dependency parser, we show that a beam-search decoder is a competitive choice for both methods. More importantly, we propose a beam-search-based parser that combines both graph-based and transition-based parsing into a single system for training and decoding, showing that it outperforms both the pure graph-based and the pure transition-based parsers. Testing on the English and Chinese Penn Treebank data, the combined system gave state-of-the-art accuracies of 92.1% and 86.2%, respectively.

1 Introduction

Graph-based (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras et al., 2006) and transition-based (Yamada and Matsumoto, 2003; Nivre et al., 2006) parsing algorithms offer two different approaches to data-driven dependency parsing. Given an input sentence, a graph-based algorithm finds the highest scoring parse tree from all possible outputs, scoring each complete tree, while a transition-based algorithm builds a parse by a sequence of actions, scoring each action individually.

The terms "graph-based" and "transition-based" were used by McDonald and Nivre (2007) to describe the difference between MSTParser (McDonald and Pereira, 2006), which is a graph-based parser with an exhaustive search decoder, and MaltParser (Nivre et al., 2006), which is a transition-based parser with a greedy search decoder. In this paper, we do not differentiate graph-based and transition-based parsers by their search algorithms: a graph-based parser can use an approximate decoder while a transition-based parser is not necessarily deterministic. To make the concepts clear, we classify the two types of parser by the following two criteria:

1. whether or not the outputs are built by explicit transition-actions, such as "Shift" and "Reduce";
2. whether it is dependency graphs or transition-actions that the parsing model assigns scores to.

By this classification, beam-search can be applied to both graph-based and transition-based parsers.

Representative of each method, MSTParser and MaltParser gave comparable accuracies in the CoNLL-X shared task (Buchholz and Marsi, 2006). However, they make different types of errors, which can be seen as a reflection of their theoretical differences (McDonald and Nivre, 2007). MSTParser has the strength of exact inference, but its choice of features is constrained by the requirement of efficient dynamic programming. MaltParser is deterministic, yet its comparatively larger feature range is an advantage. By comparing the two, three interesting research questions arise: (1) how to increase the flexibility in defining features for graph-based parsing; (2) how to add search to transition-based parsing; and (3) how to combine the two parsing approaches so that the strengths of each are utilized.

In this paper, we study these questions under one framework: beam-search. Beam-search has been successful in many NLP tasks (Koehn et al., 2003;

```
Inputs: training examples $(x_i, y_i)$
Initialization: set $\vec{w} = 0$
Algorithm:
 // R training iterations; N examples
 for $t = 1..R$, $i = 1..N$:
     $z_i = \arg\max_{y \in \text{GEN}(x_i)} \Phi(y) \cdot \vec{w}$
     if $z_i \neq y_i$:
         $\vec{w} = \vec{w} + \Phi(y_i) - \Phi(z_i)$
Outputs: $\vec{w}$
```

Figure 1: The perceptron learning algorithm

Collins and Roark, 2004), and can achieve accuracy that is close to exact inference. Moreover, a beam-search decoder does not impose restrictions on the search problem in the way that an exact inference decoder typically does, such as requiring the "optimal subproblem" property for dynamic programming, and therefore enables a comparatively wider range of features for a statistical system.

We develop three parsers. Firstly, using the same features as MSTParser, we develop a graph-based parser to examine the accuracy loss from beam-search compared to exact-search, and the accuracy gain from extra features that are hard to encode for exact inference. Our conclusion is that beam-search is a competitive choice for graph-based parsing. Secondly, using the transition actions from MaltParser, we build a transition-based parser and show that search has a positive effect on its accuracy compared to deterministic parsing. Finally, we show that by using a beam-search decoder, we are able to combine graph-based and transition-based parsing into a single system, with the combined system significantly outperforming each individual system. In experiments with the English and Chinese Penn Treebank data, the combined parser gave 92.1% and 86.2% accuracy, respectively, which are comparable to the best parsing results for these data sets, while the Chinese accuracy outperforms the previous best reported by 1.8%. In line with previous work on dependency parsing using the Penn Treebank, we focus on projective dependency parsing.

2 The graph-based parser

Following MSTParser (McDonald et al., 2005; McDonald and Pereira, 2006), we define the graph-

```
Variables: $agenda$ – the beam for state items
           $item$ – partial parse tree
           $output$ – a set of output items
           $index, prev$ – word indexes
Input: $x$ – POS-tagged input sentence.
Initialization: $agenda$ = [""]
Algorithm:
for $index$ in 1..$x$.length():
    clear $output$
    for $item$ in $agenda$:
        // for all $prev$ words that can be linked with
        // the current word at $index$
        $prev = index - 1$
        while $prev \neq 0$: // while $prev$ is valid
            // add link making $prev$ parent of $index$
            $newitem = item$ // duplicate $item$
            $newitem$.link($prev$, $index$)  // modify
            $output$.append($newitem$)  // record
            // if $prev$ does not have a parent word,
            // add link making $index$ parent of $prev$
            if $item$.parent($prev$) == 0:
                $item$.link($index$, $prev$)  // modify
                $output$.append($item$)  // record
            $prev$ = the index of the first word before
                     $prev$ whose parent does not exist
                     or is on its left; 0 if no match
    clear $agenda$
    put the best items from $output$ to $agenda$
Output: the best item in $agenda$
```

Figure 2: A beam-search decoder for graph-based parsing, developed from the deterministic Covington algorithm for projective parsing (Covington, 2001).

based parsing problem as finding the highest scoring tree y from all possible outputs given an input x:

$$F(x) = \underset{y \in \text{GEN}(x)}{\arg\max}\, \text{Score}(y)$$

where GEN(x) denotes the set of possible parses for the input x. To repeat our earlier comments, in this paper we do not consider the method of finding the $\arg\max$ to be part of the definition of graph-based parsing, only the fact that the dependency graph itself is being scored, and factored into scores attached to the dependency links.

The score of an output parse y is given by a linear model:

$$\text{Score}(y) = \Phi(y) \cdot \vec{w}$$

where $\Phi(y)$ is the global feature vector from y and $\vec{w}$ is the weight vector of the model.

We use the discriminative perceptron learning algorithm (Collins, 2002; McDonald et al., 2005) to train the values of $\vec{w}$. The algorithm is shown in Figure 1. Averaging parameters is a way to reduce overfitting for perceptron training (Collins, 2002), and is applied to all our experiments.

While the MSTParser uses exact-inference (Eisner, 1996), we apply beam-search to decoding. This is done by extending the deterministic Covington algorithm for projective dependency parsing (Covington, 2001). As shown in Figure 2, the decoder works incrementally, building a state item (i.e. partial parse tree) word by word. When each word is processed, links are added between the current word and its predecessors. Beam-search is applied by keeping the B best items in the agenda at each processing stage, while partial candidates are compared by scores from the graph-based model, according to partial graph up to the current word.

Before decoding starts, the agenda contains an empty sentence. At each processing stage, existing partial candidates from the agenda are extended in all possible ways according to the Covington algorithm. The top B newly generated candidates are then put to the agenda. After all input words are processed, the best candidate output from the agenda is taken as the final output.

The projectivity of the output dependency trees is guaranteed by the incremental Covington process. The time complexity of this algorithm is $O(n^2)$, where n is the length of the input sentence.

During training, the "early update" strategy of Collins and Roark (2004) is used: when the correct state item falls out of the beam at any stage, parsing is stopped immediately, and the model is updated using the current best partial item. The intuition is to improve learning by avoiding irrelevant information: when all the items in the current agenda are incorrect, further parsing steps will be irrelevant because the correct partial output no longer exists in the candidate ranking.

Table 1 shows the feature templates from the MSTParser (McDonald and Pereira, 2006), which are defined in terms of the context of a word, its parent and its sibling. To give more templates, features from templates 1 – 5 are also conjoined with the link direction and distance, while features from template 6 are also conjoined with the direction and distance between the child and its sibling. Here "distance" refers to the difference between word indexes. We apply all these feature templates to the graph-based parser. In addition, we define two extra feature templates (Table 2) that capture information about grandchildren and arity (i.e. the number of children to the left or right). These features are not conjoined with information about direction and distance. They are difficult to include in an efficient dynamic programming decoder, but easy to include in a beam-search decoder.

1	Parent word (P)	Pw; Pt; Pwt

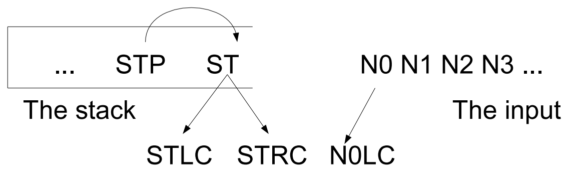

Figure 3: Feature context for the transition-based algorithm

3 The transition-based parser

We develop our transition-based parser using the transition model of the MaltParser (Nivre et al., 2006), which is characterized by the use of a stack and four transition actions: Shift, ArcRight, ArcLeft and Reduce. An input sentence is processed from left to right, with an index maintained for the current word. Initially empty, the stack is used throughout the parsing process to store unfinished words, which are the words before the current word that may still be linked with the current or a future word.

The Shift action pushes the current word to the stack and moves the current index to the next word. The ArcRight action adds a dependency link from the stack top to the current word (i.e. the stack top becomes the parent of the current word), pushes the current word on to the stack, and moves the current index to the next word. The ArcLeft action adds a dependency link from the current word to the stack top, and pops the stack. The Reduce action pops the stack. Among the four transition actions, Shift and ArcRight push a word on to the stack while ArcLeft and Reduce pop the stack; Shift and ArcRight read the next input word while ArcLeft and ArcRight add a link to the output. By repeated application of these actions, the parser reads through the input and builds a parse tree.

The MaltParser works deterministically. At each step, it makes a single decision and chooses one of the four transition actions according to the current context, including the next input words, the stack and the existing links. As illustrated in Figure 3, the contextual information consists of the top of stack (ST), the parent (STP) of ST, the leftmost (STLC) and rightmost child (STRC) of ST, the current word (N0), the next three words from the input (N1, N2, N3) and the leftmost child of N0 (N0LC). Given the context s, the next action T is decided as follows:

$$T(s) = \operatorname*{arg\,max}_{T \in \text{ACTION}} \text{Score}(T, s)$$

where ACTION $=$ $\{$Shift, ArcRight, ArcLeft, Reduce$\}$.

One drawback of deterministic parsing is error propagation, since once an incorrect action is made, the output parse will be incorrect regardless of the subsequent actions. To reduce such error propagation, a parser can keep track of multiple candidate outputs and avoid making decisions too early. Suppose that the parser builds a set of candidates GEN(x) for the input x, the best output $F(x)$ can be decided by considering all actions:

$$F(x) = \operatorname*{arg\,max}_{y \in \text{GEN}(x)} \textstyle\sum_{T' \in \text{act}(y)} \text{Score}(T', s_{T'})$$

Here T' represents one action in the sequence (act(y)) by which y is built, and $s_{T'}$ represents the corresponding context when T' is taken.

Our transition-based algorithm keeps B different sequences of actions in the agenda, and chooses the one having the overall best score as the final parse. Pseudo code for the decoding algorithm is shown in Figure 4. Here each state item contains a partial parse tree as well as a stack configuration, and state items are built incrementally by transition actions. Initially the stack is empty, and the agenda contains an empty sentence. At each processing stage, one transition action is applied to existing state items as a step to build the final parse. Unlike the MaltParser, which makes a decision at each stage, our transition-based parser applies all possible actions to each existing state item in the agenda to generate new items; then from all the newly generated items, it takes the B with the highest overall score and puts them onto the agenda. In this way, some ambiguity is retained for future resolution.

Note that the number of transition actions needed to build different parse trees can vary. For example, the three-word sentence “A B C” can be parsed by the sequence of three actions “Shift ArcRight ArcRight” (B modifies A; C modifies B) or the sequence of four actions “Shift ArcLeft Shift ArcRight” (both A and C modifies B). To ensure that all final state items are built by the same number of transition actions, we require that the final state

```
Variables: $agenda$ – the beam for state items
           $item$ – (partial tree, stack config)
           $output$ – a set of output items
           $index$ – iteration index
Input: $x$ – POS-tagged input sentence.
Initialization: $agenda$ = [(“”, [])]
Algorithm:
for $index$ in 1 .. $2 \times x$.length() $-1$:
    clear $output$
    for $item$ in $agenda$:
        // when all input words have been read, the
        // parse tree has been built; only pop.
        if $item$.length() == $x$.length():
            if $item$.stacksize() $> 1$:
                $item$.Reduce()
                $output$.append($item$)
        // when some input words have not been read
        else:
            if $item$.lastaction() $\neq$ Reduce:
                $newitem = item$
                $newitem$.Shift()
                $output$.append($newitem$)
            if $item$.stacksize() $> 0$:
                $newitem = item$
                $newitem$.ArcRight()
                $output$.append($newitem$)
                if ($item$.parent($item$.stacktop())==0):
                    $newitem = item$
                    $newitem$.ArcLeft()
                    $output$.append($newitem$)
                else:
                    $newitem = item$
                    $newitem$.Reduce()
                    $output$.append($newitem$)
    clear $agenda$
    transfer the best items from $output$ to $agenda$
Output: the best item in $agenda$
```

Figure 4: A beam-search decoding algorithm for transition-based parsing

items must 1) have fully-built parse trees; and 2) have only one root word left on the stack. In this way, popping actions should be made even after a complete parse tree is built, if the stack still contains more than one word.

Now because each word excluding the root must be pushed to the stack once and popped off once during the parsing process, the number of actions needed to parse a sentence is always $2n-1$, where n is the length of the sentence. Therefore, the decoder has linear time complexity, given a fixed beam size. Because the same transition actions as the MaltParser are used to build each item, the projectivity of the output dependency tree is ensured.

We use a linear model to score each transition action, given a context:

$$Score(T, s) = \Phi(T, s) \cdot \vec{w}$$

$\Phi(T, s)$ is the feature vector extracted from the action T and the context s, and $\vec{w}$ is the weight vector. Features are extracted according to the templates shown in Table 3, which are based on the context in Figure 3. Note that our feature definitions are similar to those used by MaltParser, but rather than using a kernel function with simple features (e.g. STw,

```
Inputs: training examples $(x_i, y_i)$
Initialization: set $\vec{w} = 0$
Algorithm:
// R training iterations; N examples
for $t = 1..R$, $i = 1..N$:
    $z_i = \arg\max_{y \in \text{GEN}(x_i)} \sum_{T' \in \text{act}(y_i)} \Phi(T', c') \cdot \vec{w}$
    if $z_i \neq y_i$:
        $\vec{w} = \vec{w} + \sum_{T' \in \text{act}(y_i)} \Phi(T', c_{T'})$
                $- \sum_{T' \in \text{act}(z_i)} \Phi(T', c_{T'})$
Outputs: $\vec{w}$
```

w – word; t – POS-tag.

N0t, but not STwt or STwN0w), we combine features manually.

As with the graph-based parser, we use the discriminative perceptron (Collins, 2002) to train the transition-based model (see Figure 5). It is worth noticing that, in contrast to MaltParser, which trains each action decision individually, our training algorithm globally optimizes all action decisions for a parse. Again, "early update" and averaging parameters are applied to the training process.

4 The combined parser

The graph-based and transition-based approaches adopt very different views of dependency parsing. McDonald and Nivre (2007) showed that the MSTParser and MaltParser produce different errors. This observation suggests a combined approach: by using both graph-based information and transition-based information, parsing accuracy can be improved.

The beam-search framework we have developed facilitates such a combination. Our graph-based and transition-based parsers share many similarities. Both build a parse tree incrementally, keeping an agenda of comparable state items. Both rank state items by their current scores, and use the averaged perceptron with early update for training. The key differences are the scoring models and incremental parsing processes they use, which must be addressed when combining the parsers.

Firstly, we combine the graph-based and the transition-based score models simply by summation. This is possible because both models are global and linear. In particular, the transition-based model can be written as:

$$\begin{aligned}\text{Score}_{\text{T}}(y) &= \textstyle\sum_{T' \in \text{act}(y)} \text{Score}(T', s_{T'}) \\ &= \textstyle\sum_{T' \in \text{act}(y)} \Phi(T', s_{T'}) \cdot \vec{w_{\text{T}}} \\ &= \vec{w_{\text{T}}} \cdot \textstyle\sum_{T' \in \text{act}(y)} \Phi(T', s_{T'})\end{aligned}$$

If we take $\sum_{T' \in \text{act}(y)} \Phi(T', s_{T'})$ as the global feature vector $\Phi_{\text{T}}(y)$, we have:

$$Score_{\text{T}}(y) = \Phi_{\text{T}}(y) \cdot \vec{w_{\text{T}}}$$

which has the same form as the graph-based model:

$$Score_{\text{G}}(y) = \Phi_{\text{G}}(y) \cdot \vec{w_{\text{G}}}$$

	Sections	Sentences	Words
Training	2–21	39,832	950,028
Dev	22	1,700	40,117
Test	23	2,416	56,684

Table 4: The training, development and test data from PTB

We therefore combine the two models to give:

$$\begin{aligned}Score_{\text{C}}(y) &= Score_{\text{G}}(y) + Score_{\text{T}}(y) \\ &= \Phi_{\text{G}}(y) \cdot \vec{w_{\text{G}}} + \Phi_{\text{T}}(y) \cdot \vec{w_{\text{T}}}\end{aligned}$$

Concatenating the feature vectors $\Phi_{\text{G}}(y)$ and $\Phi_{\text{T}}(y)$ to give a global feature vector $\Phi_{\text{C}}(y)$, and the weight vectors $\vec{w_{\text{G}}}$ and $\vec{w_{\text{T}}}$ to give a weight vector $\vec{w_{\text{C}}}$, the combined model can be written as:

$$Score_{\text{C}}(y) = \Phi_{\text{C}}(y) \cdot \vec{w_{\text{C}}}$$

which is a linear model with exactly the same form as both sub-models, and can be trained with the perceptron algorithm in Figure 1. Because the global feature vectors from the sub models are concatenated, the feature set for the combined model is the union of the sub model feature sets.

Second, the transition-based decoder can be used for the combined system. Both the graph-based decoder in Figure 2 and the transition-based decoder in Figure 4 construct a parse tree incrementally. However, the graph-based decoder works on a per-word basis, adding links without using transition actions, and so is not appropriate for the combined model. The transition-based algorithm, on the other hand, uses state items which contain partial parse trees, and so provides all the information needed by the graph-based parser (i.e. dependency graphs), and hence the combined system.

In summary, we build the combined parser by using a global linear model, the union of feature templates and the decoder from the transition-based parser.

5 Experiments

We evaluate the parsers using the English and Chinese Penn Treebank corpora. The English data is prepared by following McDonald et al. (2005). Bracketed sentences from the Penn Treebank (PTB) 3 are split into training, development and test sets

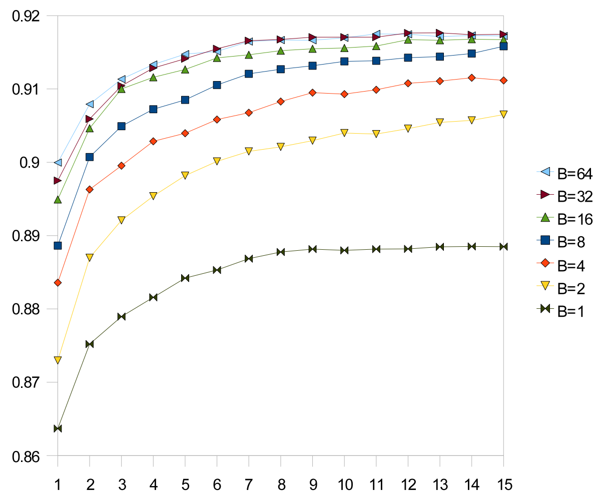

Figure 6: The influence of beam size on the transition-based parser, using the development data
X-axis: number of training iterations
Y-axis: word precision

as shown in Table 4, and then translated into dependency structures using the head-finding rules from Yamada and Matsumoto (2003).

Before parsing, POS tags are assigned to the input sentence using our reimplementation of the POS-tagger from Collins (2002). Like McDonald et al. (2005), we evaluate the parsing accuracy by the precision of lexical heads (the percentage of input words, excluding punctuation, that have been assigned the correct parent) and by the percentage of complete matches, in which all words excluding punctuation have been assigned the correct parent.

5.1 Development experiments

Since the beam size affects all three parsers, we study its influence first; here we show the effect on the transition-based parser. Figure 6 shows different accuracy curves using the development data, each with a different beam size B. The X-axis represents the number of training iterations, and the Y-axis the precision of lexical heads.

The parsing accuracy generally increases as the beam size increases, while the quantity of increase becomes very small when B becomes large enough. The decoding times after the first training iteration are 10.2s, 27.3s, 45.5s, 79.0s, 145.4s, 261.3s and 469.5s, respectively, when $B = 1, 2, 4, 8, 16, 32, 64$.

	Word	Complete
MSTParser 1	90.7	36.7
Graph [M]	91.2	40.8
Transition	91.4	41.8
Graph [MA]	91.4	42.5
MSTParser 2	91.5	42.1
Combined [TM]	92.0	45.0
Combined [TMA]	92.1	45.4

Table 5: Accuracy comparisons using PTB 3

In the rest of the experiments, we set $B = 64$ in order to obtain the highest possible accuracy.

When $B = 1$, the transition-based parser becomes a deterministic parser. By comparing the curves when $B = 1$ and $B = 2$, we can see that, while the use of search reduces the parsing speed, it improves the quality of the output parses. Therefore, beam-search is a reasonable choice for transition-based parsing.

5.2 Accuracy comparisons

The test accuracies are shown in Table 5, where each row represents a parsing model. Rows "MSTParser 1/2" show the first-order (using feature templates 1 – 5 from Table 1) (McDonald et al., 2005) and second-order (using all feature templates from Table 1) (McDonald and Pereira, 2006) MSTParsers, as reported by the corresponding papers. Rows "Graph [M]" and "Graph [MA]" represent our graph-based parser using features from Table 1 and Table 1 + Table 2, respectively; row "Transition" represents our transition-based parser; and rows "Combined [TM]" and "Combined [TMA]" represent our combined parser using features from Table 3 + Table 1 and Table 3 + Table 1 + Table 2, respectively. Columns "Word" and "Complete" show the precision of lexical heads and complete matches, respectively.

As can be seen from the table, beam-search reduced the head word accuracy from $91.5\%/42.1\%$ ("MSTParser 2") to $91.2\%/40.8\%$ ("Graph [M]") with the same features as exact-inference. However, with only two extra feature templates from Table 2, which are not conjoined with direction or distance information, the accuracy is improved to $91.4\%/42.5\%$ ("Graph [MA]"). This improvement can be seen as a benefit of beam-search, which allows the definition of more global features.

	Sections	Sentences	Words
Training	001–815; 1001–1136	16,118	437,859
Dev	886–931; 1148–1151	804	20,453
Test	816–885; 1137–1147	1,915	50,319

Table 6: Training, development and test data from CTB

	Non-root	Root	Comp.
Graph [MA]	83.86	71.38	29.82
Duan 2007	84.36	73.70	32.70
Transition	84.69	76.73	32.79
Combined [TM]	86.13	77.04	35.25
Combined [TMA]	86.21	76.26	34.41

Table 7: Test accuracies with CTB 5 data

The combined parser is tested with various sets of features. Using only graph-based features in Table 1, it gave 88.6% accuracy, which is much lower than 91.2% from the graph-based parser using the same features ("Graph [M]"). This can be explained by the difference between the decoders. In particular, the graph-based model is unable to score the actions "Reduce" and "Shift", since they do not modify the parse tree. Nevertheless, the score serves as a reference for the effect of additional features in the combined parser.

Using both transition-based features and graph-based features from the MSTParser ("Combined [TM]"), the combined parser achieved 92.0% per-word accuracy, which is significantly higher than the pure graph-based and transition-based parsers. Additional graph-based features further improved the accuracy to $92.1\%/45.5\%$, which is the best among all the parsers compared.[1]

5.3 Parsing Chinese

We use the Penn Chinese Treebank (CTB) 5 for experimental data. Following Duan et al. (2007), we split the corpus into training, development and test data as shown in Table 6, and use the head-finding rules in Table 8 in the Appendix to turn the bracketed sentences into dependency structures. Most of the head-finding rules are from Sun and Jurafsky (2004), while we added rules to handle NN and FRAG, and a default rule to use the rightmost node as the head for the constituent that are not listed.

Like Duan et al. (2007), we use gold-standard POS-tags for the input. The parsing accuracy is evaluated by the percentage of non-root words that have been assigned the correct head, the percentage of correctly identified root words, and the percentage of complete matches, all excluding punctuation.

The accuracies are shown in Table 7. Rows "Graph [MA]", "Transition", "Combined [TM]" and "Combined [TMA]" show our models in the same way as for the English experiments from Section 5.2. Row "Duan 2007" represents the transition-based model from Duan et al. (2007), which applies beam-search to the deterministic model from Yamada and Matsumoto (2003), and achieved the previous best accuracy on the data.

Our observations on parsing Chinese are essentially the same as for English. Our combined parser outperforms both the pure graph-based and the pure transition-based parsers. It gave the best accuracy we are aware of for dependency parsing using CTB.

6 Related work

Our graph-based parser is derived from the work of McDonald and Pereira (2006). Instead of performing exact inference by dynamic programming, we incorporated the linear model and feature templates from McDonald and Pereira (2006) into our beam-search framework, while adding new global features. Nakagawa (2007) and Hall (2007) also showed the effectiveness of global features in improving the accuracy of graph-based parsing, using the approximate Gibbs sampling method and a reranking approach, respectively.

Our transition-based parser is derived from the deterministic parser of Nivre et al. (2006). We incorporated the transition process into our beam-search framework, in order to study the influence of search on this algorithm. Existing efforts to add search to deterministic parsing include Sagae

[1]A recent paper, Koo et al. (2008) reported parent-prediction accuracy of 92.0% using a graph-based parser with a different (larger) set of features (Carreras, 2007). By applying separate word cluster information, Koo et al. (2008) improved the accuracy to 93.2%, which is the best known accuracy on the PTB data. We excluded these from Table 5 because our work is not concerned with the use of such additional knowledge.

and Lavie (2006b), which applied best-first search to constituent parsing, and Johansson and Nugues (2006) and Duan et al. (2007), which applied beam-search to dependency parsing. All three methods estimate the probability of each transition action, and score a state item by the product of the probabilities of all its corresponding actions. But different from our transition-based parser, which trains all transitions for a parse globally, these models train the probability of each action separately. Based on the work of Johansson and Nugues (2006), Johansson and Nugues (2007) studied global training with an approximated large-margin algorithm. This model is the most similar to our transition-based model, while the differences include the choice of learning and decoding algorithms, the definition of feature templates and our application of the "early update" strategy.

Our combined parser makes the biggest contribution of this paper. In contrast to the models above, it includes both graph-based and transition-based components. An existing method to combine multiple parsing algorithms is the ensemble approach (Sagae and Lavie, 2006a), which was reported to be useful in improving dependency parsing (Hall et al., 2007). A more recent approach (Nivre and McDonald, 2008) combined MSTParser and MaltParser by using the output of one parser for features in the other. Both Hall et al. (2007) and Nivre and McDonald (2008) can be seen as methods to combine separately defined models. In contrast, our parser combines two components in a single model, in which all parameters are trained consistently.

7 Conclusion and future work

We developed a graph-based and a transition-based projective dependency parser using beam-search, demonstrating that beam-search is a competitive choice for both parsing approaches. We then combined the two parsers into a single system, using discriminative perceptron training and beam-search decoding. The appealing aspect of the combined parser is the incorporation of two largely different views of the parsing problem, thus increasing the information available to a single statistical parser, and thereby significantly increasing the accuracy. When tested using both English and Chinese dependency data, the combined parser was highly competitive compared to the best systems in the literature.

The idea of combining different approaches to the same problem using beam-search and a global model could be applied to other parsing tasks, such as constituent parsing, and possibly other NLP tasks.

Abstract

Syntactic word reordering is essential for translations across different grammar structures between syntactically distant language-pairs. In this paper, we propose to embed local and non-local word reordering decisions in a synchronous context free grammar, and leverages the grammar in a chart-based decoder. Local word-reordering is effectively encoded in Hiero-like rules; whereas non-local word-reordering, which allows for long-range movements of syntactic chunks, is represented in tree-based reordering rules, which contain variables correspond to source-side syntactic constituents. We demonstrate how these rules are learned from parallel corpora. Our proposed shallow Tree-to-String rules show significant improvements in translation quality across different test sets.

1 Introduction

One of the main issues that a translator (human or machine) must address during the translation process is how to match the different word orders between the source language and the target language. Different language-pairs require different levels of word reordering. For example, when we translate between English and Spanish (or other Romance languages), most of the word reordering needed is local because of the shared syntactical features (e.g., Spanish noun modifier constructs are written in English as modifier noun). However, for syntactically distant language-pairs such as Chinese-English, long-range reordering is required where whole phrases are moved across the sentence.

The idea of "*syntactic cohesion*" (Fox, 2002) is characterized by its simplicity, which has attracted researchers for years. Previous works include several approaches of incorporating syntactic information to *preprocess* the source sentences to make them more like the target language in structure. Xia and McCord (2004) (Niessen and Ney, 2004; Collins et al., 2005) described approaches applied to language-pairs such as French-English and German-English. Later, Wang et al. (2007) presented specific rules to pre-order long-range movements of words, and improved the translations for Chinese-to-English. Overall, these works are similar, in that they design a few language-specific and linguistically motivated reordering rules, which are generally simple. The *eleven* rules described in Wang et al. (2007) are appealing, as they have rather simple structure, modeling only NP, VP and LCP via one-level sub-tree structure with two children, in the source parse-tree (a special case of ITG (Wu, 1997)). It effectively enhances the quality of the phrase-based translation of Chinese-to-English. One major weakness is that the reordering decisions were done in the preprocessing step, therefore rendering the decoding process unable to recover the reordering errors from the rules if incorrectly applied to. Also the reordering decisions are made without the benefits of additional models (e.g., the language models) that are typically used during decoding.

Another method to address the re-ordering problem in translation is the Hiero model proposed by Chiang (2005), in which a probabilistic synchronous context free grammar (PSCFG) was applied to guide the decoding. Hiero rules generalize phrase-pairs by introducing a single generic nonterminal (i.e., a variable) [X]. The combination of variables and lexicalized words in a Hiero rule nicely captures local word and phrase reordering (modeling an implicit reordering window of max-phrase length). These rules are then applied in a CYK-style decoder. In Hiero rules, any nested phrase-pair can be generalized as variables [X]. This usually leads to too many redundant translations, which worsens the *spurious ambiguities* (Chiang, 2005) problems for both decoding and optimization (i.e., parameter tuning). We found that*variables* (*nonterminal* [X]) in Hiero rules offer a generalization too coarse to improve the effectiveness of hierarchical models' performance.

We propose to enrich the variables in Hiero rules with additional source syntactic reordering information, in the form of shallow Tree-to-String syntactic structures. The syntactic information is represented by flat one-level sub-tree structures, with Hiero-like nonterminal variables at the leaf nodes. The syntactic rules, proposed in this paper, are composed of (possibly lexicalized) source treelets and target surface strings, with one or more variables that help capture local-reordering similar to the Hiero rules. Variables in a given rule are derived not only from the embedded aligned blocks (phrase-pairs), but also from the aligned source syntactic constituents. The aligned constituents, as in our empirical observations for Chinese-English, tend to move together in translations. The decoder is guided by these rules to reduce spurious derivations; the rules also constrain the exploration of the search space toward better translation quality and sometime improved speed by breaking long sentences into pieces. Overall, what we want is to enable the long-range reordering decisions to be local in a chart-based decoder.

To be more specific, we think the simple shallow syntactic structure is powerful enough for capturing the major structure-reordering patterns, such as NP, VP and LCP structures. We also use simple frequency-based feature functions, similar to the blocks used in phrase-based decoder, to further improve the rules' representation power. Overall, this enables us to avoid either a complex decoding process to generate the source parse tree, or difficult combinatorial optimizations for the feature functions associated with rules.

In Marton and Resnik (2008), hiero variables were disambiguated with additional binary feature functions, with their weights optimized in standard MER training. The combinatorial effects of the added feature functions can make the feature selection and optimization of the weights rather difficult. Since the grammar is essentially the same as the Hiero ones, a standard CYK decoder can be simply applied in their work. Word reordering can also be addressed via distortion models. Work in (Al-Onaizan and Kishore, 2006; Xiong et al., 2006; Zens et al., 2004; Kumar and Byrne, 2005; Tillmann and Zhang, 2005) modeled the limited information available at phrase-boundaries. Syntax-based approaches such as (Yamada and Knight, 2001; Graehl and Knight, 2004; Liu et al., 2006) heavily rely on the parse-tree to constrain the search space by assuming a strong mapping of structures across distant language-pairs. Their algorithms are also subject to parsers' performances to a larger extent, and have high complexity and less scalability in reality. In Liu et al. (2007), multi-level tree-structured rules were designed, which made the decoding process very complex, and auxiliary rules have to be designed and incorporated to shrink multiple source nonterminals into one target nonterminal. From our empirical observations, most of the time, however, the multi-level tree-structure is broken in the translation process, and POS tags are frequently distorted. Indeed, strictly following the source parse tree is usually not necessary, and maybe too expensive for the translation process.

The remainder of this paper is structured as follows: in section § 2, we define the notations in our synchronous context free grammar, in section § 3, the rule extractions are illustrated in details, in section § 4, the decoding process of applying these rules is described. Experiments in § 5 were carried out using GALE Dev07 datasets. Improved translation qualities were obtained by applying the proposed Tree-to-String rules. Conclusions and discussions are given in § 6.

2 Shallow Tree-to-String Rules

Our proposed rules are in the form of probabilistic synchronous context free grammar (PSCFG). We adopt the notations used in (Chiang, 2005). Let N be a set of nonterminals, a rule has the following form:

$$X \rightarrow < \ell; \gamma; \alpha; \sim; \bar{w} >, \qquad (1)$$

where X abstracts nonterminal symbols in N; $\gamma \in [N, V_S]^+$ is a sequence of one or more source [1] words (as in the vocabulary of V_S) and nonterminal symbols in N; $\alpha \in [N, V_T]^+$ is a sequence of one or more target words (in V_T) and nonterminals in N . $\sim$ is the one-to-one alignment of the nonterminals between γ and α; $\bar{w}$ contains non-negative weights associated with each rule; ℓ is a label-symbol specifying the root node of the source span covering γ. In our grammar, ℓ is one of the labels (e.g., NP) defined in the source treebank tagset (in our case UPenn Chinese tagset) indicating that the source span γ is rooted at ℓ. Additionally, a NULL tag Ø in ℓ denotes a flat structure of γ, in which no constituent structure was found to cover the span, and we need to back off to the normal Hiero-style rules. Our nonterminal symbols include the labels and the POS tags in the source parse trees.

In the following, we will illustrate the Tree-to-String rules we are proposing. At the same time, we will describe the extraction algorithm, with which we derive our rules from the word-aligned source-parsed parallel text. Our nonterminal set N is a reduced set of the treebank tagset (Xue et al., 2005). It consists of 17 unique labels.

The rules we extract belong to one of the following categories:

- γ contains only words, and ℓ is NULL; this corresponds to the general blocks used in phrase-based decoder (Och and Ney, 2004);
- γ contains words and variables of [X,0] and [X,1], and ℓ is NULL; this corresponds to the Hiero rules as in Chiang (2005);
- γ contains words and variables in the form of [X,TAG[2]], in which TAG is from the LDC tagset; this defines a well formed subtree, in which at least one child (constituent) is aligned to continuous target ngrams. If γ contains only variables from LDC tag set, this indicates all the constituents (children) in the subtree are aligned. This is a superset of rules generalizing those in Wang et al. (2007). If γ contains variables from POS tags, this essentially produces a superset of the monolingual side POS-based reordering rules explored in Tillmann (2008).

We focus on the third category — a syntactic label ℓ over the span of γ, indicating the covered source words consist of a linguistically well-defined phrase. ℓ together with γ define a tree-like structure: the root node is ℓ, and the aligned children are nonterminals in γ. The structure information is encoded in (ℓ, γ) pair-wise connections, and the variables keep the generalizations over atomic translation-pairs similar to Hiero models. When the rule is applied during decoding time, the labels, the tree-structure and the lexical items need to be all matched.

3 Learning and Applying Rules

A parser is assumed for the source language in the parallel data. In our case, a Chinese parser is applied for training and test data. A word alignment model is used to align the source words with the target words.

3.1 Extractions

Our rule extraction is a three-step process. First, traditional blocks (phrase-pairs) extraction is carried out. Secondly, Tree-to-String rules, are then extracted from the aligned blocks, of which the source side is covered by a complete subtree, with different permutations of the embedded aligned constituents, or partially lexicalized constituents. Otherwise, the Hiero-like rules will be extracted when there is no sub-tree structure identified, in our final step. Frequencies of extracted rules were counted to compute feature functions.

Figure 1-(a) shows that a subtree (with root at VP) is aligned to the English string. Considering the huge quantity of all the permutations of the aligned constituents under the tree, only part of the Tree-to-String rules extracted are shown in Figure 1-(c). The variables incorporate linguistic information in the assigned tag by the parser. When there is no aligned constituent for further generalization, the variables, defined in our grammar, back off to the Hiero-like ones without any label-identity information. One such example is in the rule "在 [X,0] 前 [X,VP] $\rightarrow$ [X,VP] before the [X,0]", in which the Hiero-style

[1]we use end-user terminologies for *source* and *target*.

[2]we index the tags for multiple occurrences in one rule

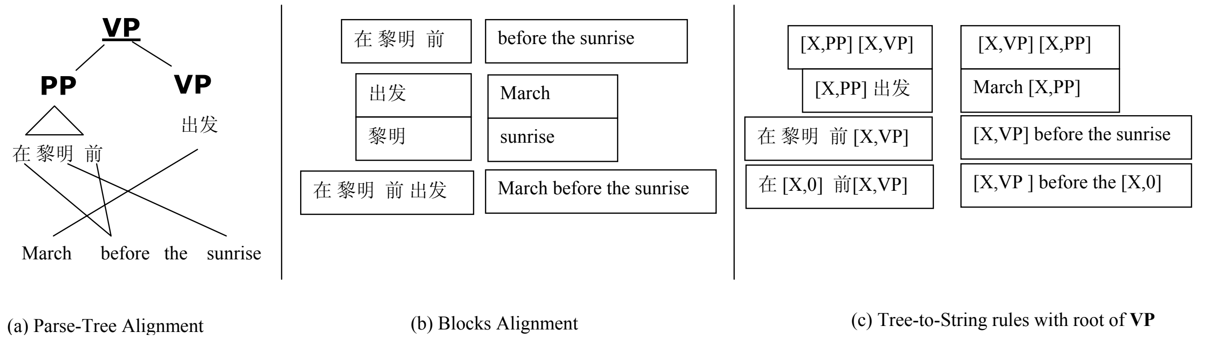

Figure 1: Example rules extracted. (a) the aligned source parse tree with target string; (b) general blocks alignment; (c) Tree-to-String rules, with root of VP. The tree structure is aligned with target strings

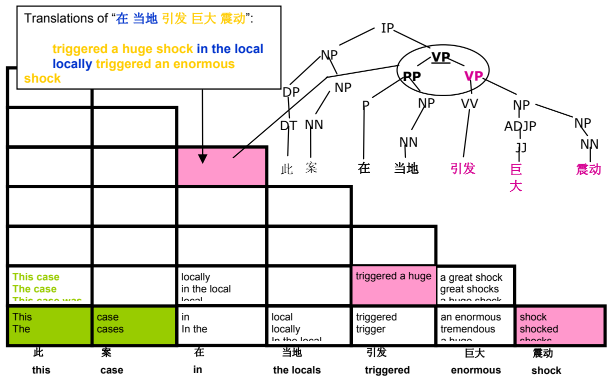

Figure 2: Subtree of "VP(PP,VP)" triggered a reordering pattern of swapping the order of the two children PP and VP in the source parse tree. This will move the translation "in the local" after the translation of "triggered a huge shock", to form the preferred translation in the highlighted cell: "triggered a huge shock in the local".

variable [X,0] and the label-based variable [X,VP] co-exist in our proposed rule.

We illustrate several special cases of our extracted Tree-to-String rules in the following. We index the variables with their positions to indicate the alignment $\sim$, and skip the feature function $\bar{w}$ to simplify the notations.

$$
\begin{aligned}
X \;\; \rightarrow< \;\; & [X, IP]; [X, NP0]\ [X, VP0]; \\
& [X, NP0]\ is\ [X, VP0] > .
\end{aligned} \tag{2}
$$

The rule in Eqn. 2 shows that a source tree rooted at IP, with two children of NP and VP generalized into variables [X,NP] and [X,VP]; they are rewritten into "[X,NP] is [X,VP]", with the spontaneous word *is* inserted. Such rules are not allowed in Hiero-style models, as there is no lexical item between the two variables (Chiang, 2005) in the source side. This rule will generate a spontaneous word "is" from the given subtree structure. Usually, it is very hard to align the spontaneous word correctly, and the rules we proposed indicate that spontaneous words are generated directly from the source sub-tree structure, and they might not necessarily get aligned to some particular source words.

A second example is shown in Eqn. 3, which is similar to the Hiero rules:

$$
\begin{aligned}
X \;\; \rightarrow< \;\; & \emptyset; [X, 0]\ \text{zhiyi}; \\
& one\ of\ the\ [X, 0] > .
\end{aligned} \tag{3}
$$

The rule in Eqn. 3 shows that when there is no linguistically-motivated root covering the span, ([X,NULL] is then assigned), we simply back off to the Hiero rules. In this case, the source span of $[X, 0]$ zhiyi is rewritten into the target "$one\ of\ the\ [X, 0]$", without considering the mapping of the root of the span. In this way, the representation power is kept in the variables in our rules, even if the source subtree is aligned to a discontinuous sequence on the target side. This is important for Chinese-to-English, because the grammar structure is so different that more than 40% of the subtree structures were not kept during the translation in our study on hand-aligned data. Following strictly the source side syntax will derail from these informative translation patterns.

$$X \rightarrow < [X, NP]; [X, NN1][X, NN2][X, NN3]; [X, NN3][X, NN1][X, NN2] > . \tag{4}$$

Eqn. 4. is a POS-based rule — a special case in our proposed rules. This rule shows the reordering patterns for three adjacent NN's. POS based rules can be very informative for some language-pairs such as Arabic-to-English, where the ADJ is usually moved before NN during the translations.

As also shown in Eqn. 4 for POS sequences, in the UPenn treebank-style parse trees, a root usually have more than two variables. Our rule set for subtree, therefore, contain more than two variables: "$X \rightarrow < [X, IP]; [X, ADVP0][X, NP0][X, VP0]; [X, NP0] [X, ADVP0][X, VP0] >$". A CYK-style decoder has to rely on *binarization* to preprocess the grammar as did in (Zhang et al., 2006) to handle multi-nonterminal rules. We adopt the so-called *dotted-rule* or *dotted-production*, similar to the Early-style algorithm (Earley, 1970), to handle the multi-nonterminal rules in our chart-based decoder.

3.2 Feature Functions

As used in most of the SMT decoders for a phrase-pair, a set of standard feature functions are applied in our decoder, including IBM Model-1 like scores in both directions, relative frequencies in both directions. In addition to these features, a counter is associated to each rule to collect how many rules were applied so far to generate a hypothesis. The standard Minimum Error Rate training (Och, 2003) was applied to tune the weights for all feature types.

The number of extracted rules from the GALE data is generally large. We pruned the rules according to their frequencies, and only keep at most the top-50 frequent candidates for each source side.

4 Chart-based Decoder

Given the source sentence, with constituent parse-trees, the decoder is to find the best derivation D^* which yield the English string e^*:

$$e^* = \arg\max_{D^*} \{\phi(D)\phi(e)\phi(f|e)\}, \tag{5}$$

where $\phi(D)$ is the cost for each of the derivations that lead to e from a given source-parsed f; $\phi(e)$ is for cost functions from the standard n-gram language models; $\phi(f|e)$ is the cost for the standard translation models, including general blocks. We separate the costs for normal blocks and the generalized rules explicitly here, because the blocks contain stronger lexical evidences observed directly from data, and we assign them with less cost penalties via a different weight factor visible for optimization, and prefer the lexical match over the derived paths during the decoding.

Our decoder is a chart-based parser with beam-search for each cell in a chart. Because the tree-structure can have more than two children, therefore, the Tree-to-String rules extracted usually contain more than two variables. Slightly different from the decoder in (Chiang, 2005), we implemented the *dotted-rule* in Early-style parser to handle rules containing more than two variables. Our cube-expansion, implemented the cube-pruning in Chiang (2007), and integrated *piece-wise* cost computations for language models via LM states. The intermediate hypotheses were merged (recombined) according to their LM states and other cost model states. We use MER (Och, 2003) to tune the decoder's parameters using a development data set.

Figure 2 shows an example of a tree-based rule fired at the subtree of VP covering the highlighted cell. When a rule is applied at a certain cell in the chart, the covered source ngram should match not only the lexical items in the rules, but also the tree-structures as well. The two children under the subtree root VP are PP ("在当地": in the local) and VP ("引发巨大震动": triggered a huge shock). This rule triggered a swap of these children to generate the correct word order in the translation: "triggered a huge shock in the local".

5 Experiments

Our training data consists of two corpora: the GALE Chinese-English parallel corpus and the LDC hand-aligned corpus[1]. The Chinese side of these two corpora were parsed using a constituency parser (Luo, 2003). The average labeled F-measure of the parser is 81.4%.

Parallel sentences were first word-aligned using a MaxEnt aligner (Ittycheriah and Roukos, 2005). Then, phrase-pairs that overlap with our development and test set were extracted from the word alignments (from both hand alignments and automatically aligned GALE corpora) based on the projection principle (Tillmann, 2003). Besides the regular phrase-pairs, we also extracted the Tree-to-String rules from the two corpora. The detailed statistics are shown in Table 1. Our re-implementation of Hiero system is the baseline. We integrated the eleven reordering rules described in (Wang et al., 2007), in our chart-based decoder. In addition, we report the results of using the Tree-to-String rules extracted from the hand-aligned training data and the automatically aligned training data. We also report the result of our translation quality in terms of both BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) against four human reference translations.

5.1 The Data

Table 1 shows the statistics of our training, development and test data. As our word aligner (Ittycheriah and Roukos, 2005) can introduce errors in extracting Tree-to-String rules, we use a small hand-aligned data set "CE16K", which consists of 16K sentence-pairs, to get relatively clean rules, free from alignment errors. A much larger GALE data set, which consists of 10 million sentence-pairs, is used to investigate the scalability of our proposed approach.

Table 1: Training and Test Data

Train/test	sentences	src words	tgt words
CE16K	16379	380103	477801
GALE	10.5M	274M	310M
MT03	919	24099	-
Dev07	2303	61881	-

[1]LDC2006E93

The NIST 2003 MT Evaluation (MT03) is used as our development data set to tune the decoder's parameters toward better BLEU score. The text part of GALE 2007 Chinese-to-English Development set (GALE DEV07) is used as our test set. MT03 consists of 919 sentences, whereas GALE DEV07 consists of 2303 sentences under two genres: NewsWire and WebLog. Both have four human reference translations.

5.2 Details of Extracted Rules

From the hand-aligned data, the rules we extracted fall into three categories: regular blocks (phrase-pairs), Hiero-like rules, and Tree-to-String rules. The statistics of the extracted rules are shown in Table 2

Table 2: Rules extracted from hand-aligned data

Types	Frequency
Block	846965
Hiero	508999
Tree-to-String	409767
Total	1765731

We focus on Tree-to-String rules. Table 3 shows the detailed statistics of the Tree-to-String rules extracted from the Chinese-to-English hand-aligned training data. The following section provides a detailed analysis of the most frequent subtrees observed in our training data.

5.2.1 Frequent Subtrees: NP, VP, and DNP

The majority of Tree-to-String rules we extracted are rooted at the following labels: NP (46%), VP(22.8%), DNP (2.23%), and QP(2.94%).

Wang et al. (2007) covers only subtrees of NP, VP, and LCP, which are a subset of our proposed Tree-to-String rules here. They apply these rules as a pre-processing step to reorder the input sentences with hard decisions. Our proposed Tree-to-String rules, on the contrary, are applied during the decoding process which allows for considering many possible competing reordering options for the given sentences, and the decoder will choose the best one according to the cost functions.

Table 4 shows the statistics of reordering rules for subtrees rooted at VP. The statistics suggest that

Table 5: Hiero, Tree-Based (eleven rules in Wang et al. (2007)), and Tree-to-String Rules with "DE"

Ruleset	Root	Src	Tgt	Frequency
Hiero	NULL	[X,0] 的 [X,1]	[X,0] 's [X,1]	347
	NULL	[X,0] 的 [X,1]	[X,1] of [X,0]	306
	NULL	[X,0] 的 [X,1]	[X,0] of [X,1]	174
Tree-Based	NP	DNP(NP) NP	NP DNP(NP)	-
	NP	DNP(PP) NP	NP DNP(PP)	-
	NP	DNP(LCP) NP	NP DNP(LCP)	-
Tree-to-String	[X,DNP]	[X,NP] [X,DEG]	[X,NP] [X,DEG]	580
	[X,DNP]	[X,NP] [X,DEG]	[X,DEG] [X,NP]	2163
	[X,DNP]	[X,NP] [X,DEG]	[X,NP] , [X,DEG]	4

Table 3: Distributions of the NP, VP, QP, LCP rules

Root	Frequency	Percentage (%)
NP	189616	46.2
VP	93535	22.8
IP	68341	16.6
PP	18519	4.51
DNP	9141	2.23
QP	12064	2.94
LCP	4127	1.00
CP	2994	0.73
PRN	2810	0.68
DP	1415	0.34
Others	6879	1.67
Total	409767	-

Table 4: Distribution of the reordering rules for subtrees rooted at VP: [X,VP]; [X,PP] [X,VP]; statistics are collected from GALE training data

Root	Target	Frequency
VP	[X,PP] [X,VP]	126310
	[X,VP] [X,PP]	22144
	[X,PP] , [X,VP]	1524
	[X,PP] that [X,VP]	1098
	[X,PP] and [X,VP]	831

it is impossible to come up with a reordering rule that is always applicable. For instance, (Wang et al., 2007) will always swap the children of the subtree VP(PP,VP). However, the statistics shown in Table 4 suggest that might not be best way. In fact, due to parser's performance and word alignment accuracies, the statistics we collected from the GALE dataset, containing 10 million sentence-pairs, show that the children in the subtree VP(PP,VP) is translated monotonically 126310 times, while reordered of only 22144 times. However, the hand-aligned data support the swap for 1245 times, and monotonically for only 168 times. Part of this disagreement is due to the word segmentation errors, incorrect word alignments and unreliable parsing results.

Another observations through our extracted Tree-to-String rules is on the controlled insertion of the target spontaneous[2] (function) words. Instead of hypothesizing spontaneous words based only on the language model or only on observing in phrase-pairs, we make use of the Tree-to-String rules to get suggestion on the insertion of spontaneous words. In this way, we can make sure that the spontaneous words are generated from the structure information, as opposed to those from a pure hypothesis. The advantage of this method is shown in Table 4. For instance, the word "that" and the punctuation "," were generated in the target side of the rule. This proves that our model can provide a more principled way to generate spontaneous words needed for fluent translations.

5.2.2 DEG and DEC

An interesting linguistic phenomenon that we investigated is the Chinese word DE "的". "的" is an informative lexical clue that indicates the need for long range phrasal movements. Table 5 shows a few

[2]Target spontaneous words are function words that do not have specific lexical source informants and are needed to make the target translation fluent.

high-frequent reordering rules that contain the Chinese word "DE".

The three type of rules handle "DE" differently. A major difference is the structure in the source side. Hiero rules do not consider any structure, and apply the rule of "[X,0] 的 [X,1]". Tree-based rules, as described in Wang et al. (2007) do not handle 的 directly; they are often implicitly taken care of when reordering DNPs instead. Our proposed Tree-to-String rules model 的 directly in a subtree containing DEG/DEC, which triggers word reordering within the structure. Our rule set includes all the above three rule-types with the associated frequencies, this enriched the reordering choices to be chosen by the chart-based decoder, guided by the statistics collected from the data and the language model costs.

5.3 Evaluation

We tuned the decoding parameters using the MT03 data set, and applied the updated parameters to the GALE evaluation set. The *eleven* rules of VP, NP, and LCP (tree-based) improved the Hiero baseline[3] from 32.43 to 33.02 on BLEU. The reason, the tree-reordering does not gain much over Hiero baseline, is probably that the reordering patterns covered by tree-reordering rules, are potentially handled in the standard Hiero grammar.

A small but noticeable further improvement over tree-based rules, from 33.02 to 33.26, was obtained on applying Tree-to-String rules extracted from hand-aligned dataset. We think that the Tree-based rules covers major reordering patterns for Chinese-English, and our hand-aligned dataset is also too small to capture representative statistics and more reordering patterns. A close check at the rules we learned from the hand-aligned data shows that the tree-based rules are simply the subset of the rules extracted. The Tree-to-String grammar improved the Hiero baseline from 32.43 to 33.26 on BLEU; considering the effects from the tree-based rules only, the additional information improved the BLEU scores from 33.02 to 33.26. Similar pictures of improvements were observed for the two unseen tests of newswire and weblog in GALE data.

When applying the rules extracted from the much larger GALE training set with about ten million sentence-pairs, we achieved significant improvements from both genres (newswire and web data). The improvements are significant in both BLEU and TER. BLEU improved from 32.44 to 33.51 on newswire, and from 25.88 to 27.91 on web data. Similar improvements were found in TER as shown in the table. The gain came mostly from the richer extracted rule set, which not only presents robust statistics for reordering patterns, but also offers more target spontaneous words generated from the syntactic structures. Since the top-frequent rules extracted are NP, VP, and IP as shown in Table 3, our proposed rules will be able to win the correct word order with reliable statistics, as long as the parser shows acceptable performances on these structures. This is especially important for weblog data, where the parser's overall accuracy potentially might not be very good.

Table 7 shows the translations from different grammars for the same source sentence. Both Tree-based and Tree-to-String methods get the correct reordering, while the latter can suggest insertions of target spontaneous words like "a" to allow the translation to run more fluently.

6 Conclusion and Discussions

In this paper, we proposed our approach to model both local and non-local word-reordering in one probabilistic synchronous CFG. Our current model incorporates source-side syntactic information, to model the observations that the source syntactic constituent tends to move together during translations. The proposed rule set generalizes over the variables in Hiero-rules, and we also showed the special cases of the Tree-based rules and the POS-based rules. Since the proposed rules has at most one-level tree structure, they can be easily applied in a chart-based decoder. We analyzed the statistics of our rules, qualitatively and quantitatively. Next, we compared our work with other research, especially with the work in Wang et al. (2007). Finally, we reported our empirical results on Chinese-English translations. Our Tree-to-String rules showed significant improvements over the Hiero baseline on the GALE DEV07 test set.

Given the low accuracy of the parsers, and the potential errors from Chinese word-segmentations, and

[3]Hiero results are from our own re-implementation.

Tree-to-String	the case triggered a huge uproar in the local .

word-alignments, our rules learned are still noisy. Exploring better cost functions associate each rule might lead to further improvement. Because of the relative high accuracy of English parsers, many works such as Zollmann and Venugopal (2006) and Shen et al. (2008) emphasize on using syntax in target languages, to directly influence the fluency aspect of the translation output. In future, we plan to incorporate features from target-side syntactic information, and connect them with the source information explored in this paper, to model long-distance reordering for better translation quality.

Abstract

We present a graph-based semi-supervised label propagation algorithm for acquiring open-domain labeled classes and their instances from a combination of unstructured and structured text sources. This acquisition method significantly improves coverage compared to a previous set of labeled classes and instances derived from free text, while achieving comparable precision.

1 Introduction

1.1 Motivation

Users of large document collections can readily acquire information about the instances, classes, and relationships described in the documents. Such relations play an important role in both natural language understanding and Web search, as illustrated by their prominence in both Web documents and among the search queries submitted most frequently by Web users (Jansen et al., 2000). These observations motivate our work on algorithms to extract instance-class information from Web documents.

While work on named-entity recognition traditionally focuses on the acquisition and identification of instances within a small set of coarse-grained classes, the distribution of instances within query logs indicates that Web search users are interested in a wider range of more fine-grained classes. Depending on prior knowledge, personal interests and immediate needs, users submit for example medical queries about the symptoms of *leptospirosis* or the treatment of *monkeypox*, both of which are instances of *zoonotic diseases*, or the risks and benefits of *surgical procedures* such as *PRK* and *angioplasty*. Other users may be more interested in *African countries* such as *Uganda* and *Angola*, or *active volcanoes* like *Etna* and *Kilauea*. Note that *zoonotic diseases*, *surgical procedures*, *African countries* and *active volcanoes* serve as useful class labels that capture the semantics of the associated sets of class instances. Such interest in a wide variety of specific domains highlights the utility of constructing large collections of fine-grained classes.

Comprehensive and accurate class-instance information is useful not only in search but also in a variety of other text processing tasks including co-reference resolution (McCarthy and Lehnert, 1995), named entity recognition (Stevenson and Gaizauskas, 2000) and seed-based information extraction (Riloff and Jones, 1999).

1.2 Contributions

We study the acquisition of open-domain, labeled classes and their instances from both structured and unstructured textual data sources by combining and ranking individual extractions in a principled way with the Adsorption label-propagation algorithm (Baluja et al., 2008), reviewed in Section 3 below.

A collection of labeled classes acquired from text (Van Durme and Paşca, 2008) is extended in two ways:

1. Class label coverage is increased by identifying additional class labels (such as *public agencies* and *governmental agencies*) for existing

[*]Contributions made during internships at Google.

instances such as *Office of War Information*),

2. The overall instance coverage is increased by extracting additional instances (such as *Addison Wesley* and *Zebra Books*) for existing class labels (*book publishers*).

The WebTables database constructed by Cafarella et al. (2008) is used as the source of additional instances. Evaluations on gold-standard labeled classes and instances from existing linguistic resources (Fellbaum, 1998) indicate coverage improvements relative to that of Van Durme and Paşca (2008), while retaining similar precision levels.

2 First Phase Extractors

To show Adsorption's ability to uniformly combine extractions from multiple sources and methods, we apply it to: 1) high-precision open-domain extractions from free Web text (Van Durme and Paşca, 2008), and 2) high-recall extractions from WebTables, a large database of HTML tables mined from the Web (Cafarella et al., 2008). These two methods were chosen to be representative of two broad classes of extraction sources: free text and structured Web documents.

2.1 Extraction from Free Text

Van Durme and Paşca (2008) produce an open-domain set of instance clusters $C \in \mathcal{C}$ that partitions a given set of instances $\mathcal{I}$ using distributional similarity (Lin and Pantel, 2002), and labels using *is-a* patterns (Hearst, 1992). By filtering the class labels using distributional similarity, a large number of high-precision labeled clusters are extracted. The algorithm proceeds iteratively: at each step, all clusters are tested for label *coherence* and all coherent labels are tested for high cluster *specificity*. Label L is coherent if it is shared by at least $J\%$ of the instances in cluster C, and it is specific if the total number of other clusters $C' \in \mathcal{C}, C' \neq C$ containing instances with label L is less than K. When a cluster is found to match these criteria, it is removed from $\mathcal{C}$ and added to an output set. The procedure terminates when no new clusters can be removed from $\mathcal{C}$. Table 1 shows a few randomly chosen classes and representative instances obtained by this procedure.

2.2 Extraction from Structured Text

To expand the instance sets extracted from free text, we use a *table-based extraction* method that mines structured Web data in the form of HTML tables. A significant fraction of the HTML tables in Web pages is assumed to contain coherent lists of instances suitable for extraction. Identifying such tables from scratch is hard, but seed instance lists can be used to identify potentially coherent table columns. In this paper we use the WebTables database of around 154 million tables as our structured data source (Cafarella et al., 2008).

We employ a simple ranking scheme for candidate instances in the WebTables corpus $\mathcal{T}$. Each table $\mathbf{T} \in \mathcal{T}$ consists of one or more columns. Each column $g \in \mathbf{T}$ consists of a set of candidate instances $i \in g$ corresponding to row elements. We define the set of unique *seed matches* in g relative to semantic class $C \in \mathcal{C}$ as

$$M_C(g) \overset{\text{def}}{=} \{i \in I(C) : i \in g\}$$

where $I(C)$ denotes the set of instances in seed class C. For each column g, we define its α-*unique class coverage*, that is, the set of classes that have at least α unique seeds in g,

$$Q(g;\alpha) \overset{\text{def}}{=} \{C \in \mathcal{C} : |M_C(g)| \geq \alpha\}.$$

Using M and Q we define a method for scoring columns relative to each class. Intuitively, such a score should take into account not only the number of matches from class C, but also the total number of classes that contribute to Q and their relative overlap. Towards this end, we introduce the scoring function

$$score(C, g; \alpha) \overset{\text{def}}{=} \underbrace{|M_C(g)|}_{\text{seed matches}} \cdot \overbrace{\frac{|M_C(g)|}{|\bigcup_{C' \in Q(g;\alpha)} I(C')|}}^{\text{class coherence}}$$

which is the simplest scoring function combining the number of seed matches with the coherence of the table column. Coherence is a critical notion in WebTables extraction, as some tables contain instances across many diverse seed classes, contributing to extraction noise. The class coherence introduced here also takes into account class overlap; that

Class	Size	Examples of Instances
Book Publishers	70	crown publishing, kluwer academic, prentice hall, puffin
Federal Agencies	161	catsa, dhs, dod, ex-im bank, fsis, iema, mema, nipc, nmfs, tdh, usdot

Table 1: A sample of the open-domain classes and associated instances from (Van Durme and Paşca, 2008).

is, a column containing many semantically similar classes is penalized less than one containing diverse classes.[1] Finally, an extracted instance i is assigned a score relative to class C equal to the sum of all its column scores,

$$score(i, C; \alpha) \overset{\text{def}}{=} \frac{1}{Z_C} \sum_{g \in \mathbf{T}, \mathbf{T} \in \mathcal{T}} score(C, g; \alpha)$$

where Z_C is a normalizing constant set to the maximum score of any instance in class C. This scoring function assigns high rank to instances that occur frequently in columns with many seed matches and high class specificity.

The ranked list of extracted instances is post-filtered by removing all instances that occur in less than d unique Internet domains.

3 Graph-Based Extraction

To combine the extractions from both free and structured text, we need a representation capable of encoding efficiently all the available information. We chose a graph representation for the following reasons:

- Graphs can represent complicated relationships between classes and instances. For example, an ambiguous instance such as *Michael Jordan* could belong to the class of both *Professors* and *NBA players*. Similarly, an instance may belong to multiple nodes in the hierarchy of classes. For example, *Blue Whales* could belong to both classes *Vertebrates* and *Mammals*, because *Mammals* are a subset of *Vertebrates*.
- Extractions from multiple sources, such as Web queries, Web tables, and text patterns can be represented in a single graph.
- Graphs make explicit the potential paths of information propagation that are implicit in the more common local heuristics used for weakly-supervised information extraction. For example, if we know that the instance *Bill Clinton* belongs to both classes *President* and *Politician* then this should be treated as evidence that the class of *President* and *Politician* are related.

Each instance-class pair (i, C) extracted in the first phase (Section 2) is represented as a weighted edge in a graph $G = (V, E, W)$, where V is the set of nodes, E is the set of edges and $W : E \rightarrow \mathbb{R}^+$ is the weight function which assigns positive weight to each edge. In particular, for each (i, C, w) triple from the set of base extractions, i and C are added to V and (i, C) is added to E, [2] with $W(i, C) = w$. The weight w represents the total score of all extractions with that instance and class. Figure 1 illustrates a portion of a sample graph. This simple graph representation could be refined with additional types of nodes and edges, as we discuss in Section 7.

In what follows, all nodes are treated in the same way, regardless of whether they represent instances or classes. In particular, all nodes can be assigned class labels. For an instance node, that means that the instance is hypothesized to belong to the class; for a class node, that means that the node's class is hypothesized to be semantically similar to the label's class (Section 5).

We now formulate the task of assigning labels to nodes as graph label propagation. We are given a

[1]Note that this scoring function does not take into account class containment: if all seeds are both *wind Instruments* and *instruments*, then the column should assign higher score to the more specific class.

[2]In practice, we use two directed edges, from i to C and from C to i, both with weight w.

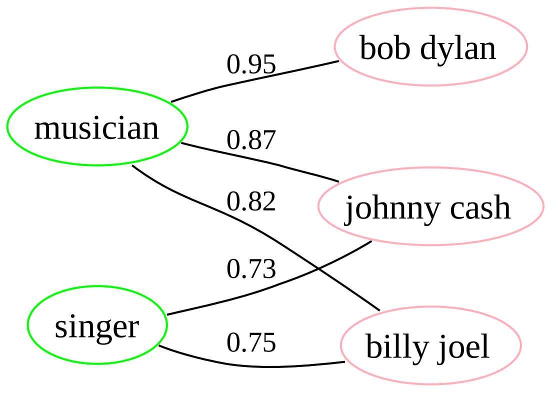

Figure 1: Section of a graph used as input into Adsorption. Though the nodes do not have any type associated with them, for readability, instance nodes are marked in pink while class nodes are shown in green.

set of instances $\mathcal{I}$ and a set of classes $\mathcal{C}$ represented as nodes in the graph, with connecting edges as described above. We annotate a few instance nodes with labels drawn from $\mathcal{C}$. That is, classes are used both as nodes in the graph and as labels for nodes. There is no necessary alignment between a class node and any of the (class) labels, as the final labels will be assigned by the Adsorption algorithm.

The Adsorption label propagation algorithm (Baluja et al., 2008) is now applied to the given graph. Adsorption is a general framework for label propagation, consisting of a few nodes annotated with labels and a rich graph structure containing the universe of all labeled and unlabeled nodes. Adsorption proceeds to label all nodes based on the graph structure, ultimately producing a probability distribution over labels for each node.

More specifically, Adsorption works on a graph $G = (V, E, W)$ and computes for each node v a *label distribution* L_v that represents which labels are more or less appropriate for that node. Several interpretations of Adsorption-type algorithms have appeared in various fields (Azran, 2007; Zhu et al., 2003; Szummer and Jaakkola, 2002; Indyk and Matousek, 2004). For details, the reader is referred to (Baluja et al., 2008). We use two interpretations here:

Adsorption through Random Walks: Let $G_r = (V, E_r, W_r)$ be the edge-reversed version of the original graph $G = (V, E, W)$ where $(a, b) \in E_r$ iff $(b, a) \in E$; and $W_r(a, b) = W(b, a)$. Now, choose a node of interest $q \in V$. To estimate L_q for q, we perform a random walk on G_r starting from q to generate values for a random label variable L. After reaching a node v during the walk, we have three choices:

1. With probability p_v^{cont}, continue the random walk to a neighbor of v.
2. With probability p_v^{abnd}, abandon the random walk. This abandonment probability makes the random walk stay relatively close to its source when the graph has high-degree nodes. When the random walk passes through such a node, it is likely that further transitions will be into regions of the graph unrelated to the source. The abandonment probability mitigates that effect.
3. With probability p_v^{inj}, stop the random walk and emit a label L from I_v.

L_q is set to the expectation of all labels L emitted from random walks initiated from node q.

Adsorption through Averaging: For this interpretation we make some changes to the original graph structure and label set. We extend the label distributions L_v to assign a probability not only to each label in $\mathcal{C}$ but also to the *dummy* label $\perp$, which represents lack of information about the actual label(s). We represent the initial knowledge we have about some node labels in an *augmented* graph $G' = (V', E', W')$ as follows. For each $v \in V$, we define an *initial* distribution $I_v = L^{\perp}$, where $L^{\perp}$ is the *dummy* distribution with $L^{\perp}(\perp) = 1$, representing lack of label information for v. In addition, let $V_s \subseteq V$ be the set of nodes for which we have some actual label knowledge, and let $V' = V \cup \{\bar{v} : v \in V_s\}, E' = E \cup \{(\bar{v}, v) : v \in V_s\}$, and $W'(\bar{v}, v) = 1$ for $v \in V_s$, $W'(u, v) = W(u, v)$ for $u, v \in V$. Finally, let $I_{\bar{v}}$ (seed labels) specify the knowledge about possible labels for $v \in V_s$. Less formally, the $\bar{v}$ nodes in G' serve to *inject* into the graph the prior label distributions for each $v \in V_s$.

The algorithm proceeds as follows: For each node use a fixed-point computation to find label distributions that are weighted averages of the label distributions for all their neighbors. This causes the non-dummy initial distribution of V_s nodes to be propagated across the graph.

Baluja et al. (2008) show that those two views are equivalent. Algorithm 1 combines the two views: instead of a random walk, for each node v, it iteratively computes the weighted average of label distributions from neighboring nodes, and then uses the random walk probabilities to estimate a new label distribution for v.

For the experiments reported in Section 4, we used the following heuristics from Baluja et al. (2008) to set the random walk probabilities:

- Let $c_v = \frac{\log \beta}{\log(\beta + \exp H(v))}$ where $H(v) = -\sum_u p_{uv} \times \log(p_{uv})$ with $p_{uv} = \frac{W(u,v)}{\sum_{u'} W(u',v)}$. $H(v)$ can be interpreted as the entropy of v's neighborhood. Thus, c_v is lower if v has many neighbors. We set $\beta = 2$.

- $j_v = (1 - c_v) \times \sqrt{H(v)}$ if $I_v \neq L^\top$ and 0 otherwise.

- Then let

$$\begin{aligned} z_v &= \max(c_v + j_v, 1) \\ p_v^{cont} &= c_v / z_v \\ p_v^{inj} &= j_v / z_v \\ p_v^{abnd} &= 1 - p_v^{cont} - p_v^{abnd} \end{aligned}$$

  Thus, abandonment occurs only when the continuation and injection probabilities are low enough.

The algorithm is run until convergence which is achieved when the label distribution on each node ceases to change within some tolerance value. Alternatively, the algorithm can be run for a fixed number of iterations which is what we used in practice[3].

Finally, since Adsorption is memoryless, it easily scales to tens of millions of nodes with dense edges and can be easily parallelized, as described by Baluja et al. (2008).

[3]The number of iterations was set to 10 in the experiments reported in this paper.

Algorithm 1 Adsorption Algorithm.
Input: $G' = (V', E', W')$, I_v $(\forall v \in V')$.
Output: Distributions $\{L_v : v \in V\}$.

```

6:     **for all** $v \in V'$ **do**
7:         $L_v = p_v^{cont} \times D_v + p_v^{inj} \times I_v + p_v^{abnd} \times L^\top$
8:     **end for**
9: **until** convergence
```

4 Experiments

4.1 Data

As mentioned in Section 3, one of the benefits of using Adsorption is that we can combine extractions by different methods from diverse sources into a single framework. To demonstrate this capability, we combine extractions from free-text patterns and from Web tables. To the best of our knowledge, this is one of the first attempts in the area of minimally-supervised extraction algorithms where unstructured and structured text are used in a principled way within a single system.

Open-domain (instance, class) pairs were extracted by applying the method described by Van Durme and Paşca (2008) on a corpus of over 100M English web documents. A total of 924K (instance, class) pairs were extracted, containing 263K unique instances in 9081 classes. We refer to this dataset as A8.

Using A8, an additional 74M unique (instance,class) pairs are extracted from a random 10% of the WebTables data, using the method outlined in Section 2.2. For maximum coverage we set $\alpha = 2$ and $d = 2$, resulting in a large, but somewhat noisy collection. We refer to this data set as WT.

4.2 Graph Creation

We applied the graph construction scheme described in Section 3 on the A8 and WT data combined, resulting in a graph with 1.4M nodes and 75M edges. Since extractions in A8 are not scored, weight of all

Seed Class	Seed Instances
Book Publishers	millbrook press, academic press, springer verlag, chronicle books, shambhala publications

Table 2: Classes and seeds used to initialize Adsorption.

edges originating from A8 were set at 1[4]. This graph is used in all subsequent experiments.

5 Evaluation

We evaluated the Adsorption algorithm under two experimental settings. First, we evaluate Adsorption's extraction precision on (instance, class) pairs obtained by Adsorption but not present in A8 (Section 5.1). This measures whether Adsorption can add to the A8 extractions at fairly high precision. Second, we measured Adsorption's ability to assign labels to a fixed set of gold instances drawn from various classes (Section 5.2).

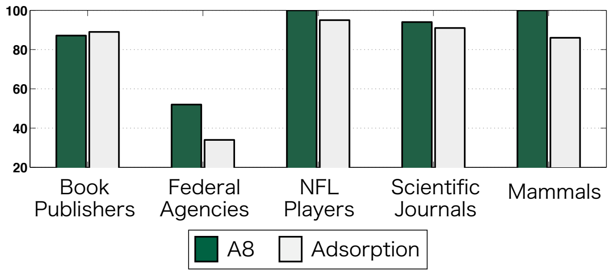

Figure 2: Precision at 100 comparisons for A8 and Adsorption.

5.1 Instance Precision

First we manually evaluated precision across five randomly selected classes from A8: Book Publishers, Federal Agencies, NFL Players, Scientific Journals and Mammals. For each class, 5 seed instances were chosen manually to initialize Adsorption. These classes and seeds are shown in Table 2. Adsorption was run for each class separately and the resulting ranked extractions were manually evaluated.

Since the A8 system does not produce ranked lists of instances, we chose 100 random instances from the A8 results to compare to the top 100 instances produced by Adsorption. Each of the resulting 500 instance-class pairs (i, C) was presented to two human evaluators, who were asked to evaluate whether the relation "i is a C" was correct or incorrect. The user was also presented with Web search link to verify the results against actual documents. Results from these experiments are presented in Figure 2 and Table 4. The results in Figure 2 show that the A8 system has higher precision than the Adsorption system. This is not surprising since the A8 system is tuned for high precision. When considering individual evaluation classes, changes in precision scores between the A8 system and the Adsorption system vary from a small increase from 87% to 89% for the class Book Publishers, to a significant decrease from 52% to 34% for the class Federal Agencies, with a decrease of 10% as an average over the 5 evaluation classes.

Class	Precision at 100 (non-A8 extractions)
Book Publishers	87.36
Federal Agencies	29.89
NFL Players	94.95
Scientific Journals	90.82
Mammal Species	84.27

Table 4: Precision of top 100 Adsorption extractions (for five classes) which were **not** present in A8.

Table 4 shows the precision of the Adsorption system for instances not extracted by the A8 system.

[4]A8 extractions are assumed to be high-precision and hence we assign them the highest possible weight.

Seed Class	Non-Seed Class Labels Discovered by Adsorption
Book Publishers	small presses, journal publishers, educational publishers, academic publishers, commercial publishers
Federal Agencies	public agencies, governmental agencies, modulation schemes, private sources, technical societies
NFL Players	sports figures, football greats, football players, backs, quarterbacks
Scientific Journals	prestigious journals, peer-reviewed journals, refereed journals, scholarly journals, academic journals
Mammal Species	marine mammal species, whale species, larger mammals, common animals, sea mammals

Table 3: Top class labels ranked by their similarity to a given seed class in Adsorption.

Seed Class	Sample of Top Ranked Instances Discovered by Adsorption
Book Publishers	small night shade books, house of anansi press, highwater books, distributed art publishers, copper canyon press
NFL Players	tony gonzales, thabiti davis, taylor stubblefield, ron dixon, rodney hannah
Scientific Journals	journal of physics, nature structural and molecular biology, sciences sociales et santé, kidney and blood pressure research, american journal of physiology–cell physiology

Table 5: Random examples of top ranked extractions (for three classes) found by Adsorption which were not present in A8.

Such an evaluation is important as one of the main motivations of the current work is to increase coverage (recall) of existing high-precision extractors without significantly affecting precision. Results in Table 4 show that Adsorption is indeed able to extraction with high precision (in 4 out of 5 cases) new instance-class pairs which were not extracted by the original high-precision extraction set (in this case A8). Examples of a few such pairs are shown in Table 5. This is promising as almost all state-of-the-art extraction methods are high-precision and low-recall. The proposed method shows a way to overcome that limitation.

As noted in Section 3, Adsorption ignores node type and hence the final ranked extraction may also contain classes along with instances. Thus, in addition to finding new instances for classes, it also finds additional class labels similar to the seed class labels with which Adsorption was run, at no extra cost. Some of the top ranked class labels extracted by Adsorption for the corresponding seed class labels are shown in Table 3. To the best of our knowledge, there are no other systems which perform both tasks simultaneously.

5.2 Class Label Recall

Next we evaluated each extraction method on its relative ability to assign labels to class instances. For each test instance, the five most probably class labels are collected using each method and the Mean Reciprocal Rank (MRR) is computed relative to a gold standard target set. This target set, WN-gold, consists of the 38 classes in Wordnet containing 100 or more instances.

In order to extract meaningful output from Adsorption, it is provided with a number of labeled seed instances (1, 5, 10 or 25) from each of the 38 test classes. Regardless of the actual number of seeds used as input, all 25 seed instances from each class are removed from the output set from all methods, in order to ensure fair comparison.

The results from this evaluation are summarized in Table 6; AD x refers to the adsorption run with x seed instances. Overall, Adsorption exhibits higher MRR than either of the baseline methods, with MRR increasing as the amount of supervision is increased. Due to its high coverage, WT assigns labels to a larger number of the instance in WN-gold than any other method. However, the average rank of the correct class assignment is lower, resulting is

Method	MRR (full)	MRR (found only)	# found
A8	0.16	0.47	2718
WT	0.15	0.21	**5747**
AD 1	0.26	0.45	4687
AD 5	0.29	0.48	4687
AD 10	0.30	0.51	4687
AD 25	**0.32**	**0.55**	4687

Table 6: Mean-Reciprocal Rank scores of instance class labels over 38 Wordnet classes (WN-gold). MRR (full) refers to evaluation across the entire gold instance set. MRR (found only) computes MRR only on recalled instances.

lower MRR scores compared to Adsorption. This result highlights Adsorption's ability to effectively combine high-precision, low-recall (A8) extractions with low-precision, high-recall extractions (WT) in a manner that improves *both* precision and coverage.

6 Related Work

Graph based algorithms for minimally supervised information extraction methods have recently been proposed. For example, Wang and Cohen (2007) use a random walk on a graph built from entities and relations extracted from semi-structured text. Our work differs both conceptually, in terms of its focus on open-domain extraction, as well as methodologically, as we incorporate both unstructured and structured text. The re-ranking algorithm of Bellare et al. (2007) also constructs a graph whose nodes are instances and attributes, as opposed to instances and classes here. Adsorption can be seen as a generalization of the method proposed in that paper.

7 Conclusion

The field of open-domain information extraction has been driven by the growth of Web-accessible data. We have staggering amounts of data from various structured and unstructured sources such as general Web text, online encyclopedias, query logs, web tables, or link anchor texts. Any proposed algorithm to extract information needs to harness several data sources and do it in a robust and scalable manner. Our work in this paper represents a first step towards that goal. In doing so, we achieved the following:

1. Improved coverage relative to a high accuracy instance-class extraction system while maintaining adequate precision.

2. Combined information from two different sources: free text and web tables.

3. Demonstrated a graph-based label propagation algorithm that given as little as five seeds per class achieved good results on a graph with more than a million nodes and 70 million edges.

In this paper, we started off with a simple graph. For future work, we plan to proceed along the following lines:

1. Encode richer relationships between nodes, for example instance-instance associations and other types of nodes.

2. Combine information from more data sources to answer the question of whether more data or diverse sources are more effective in increasing precision and coverage.

3. Apply similar ideas to other information extraction tasks such as relation extraction.

Abstract

Relationship discovery is the task of identifying salient relationships between named entities in text. We propose novel approaches for two sub-tasks of the problem: identifying the entities of interest, and partitioning and describing the relations based on their semantics. In particular, we show that term frequency patterns can be used effectively instead of supervised NER, and that the p-median clustering objective function naturally uncovers relation exemplars appropriate for describing the partitioning. Furthermore, we introduce a novel application of relationship discovery: the unsupervised identification of protein-protein interaction phrases.

1 Introduction

Relationship extraction (RE) is the task of extracting named relationships between entities in text given some information about the relationships of interest. Relationship discovery (RD), on the other hand, is the task of finding which relations exist in a corpus without any prior knowledge. The discovered relationships can then be used to bootstrap RE, which is why RD has also been called unsupervised relation extraction (Rosenfeld and Feldman, 2006). RD generally involves three sub-tasks: entities of interest are either supplied or recognized in the corpus; second, of all phrases in which entities co-occur, those which express a relation are picked out; finally, these relationship phrases are partitioned based on their semantics and described. This work considers only binary relations (those between exactly two entities).

Finding entities of interest has involved either named entity recognition (NER) or general noun phrase (NP) chunking, to create the initial pool of candidate entities. In Section 2, we describe a corpus statistics approach, previously applied for web mining (Davidov and Rappoport, 2006), which we extend for relation discovery. Unlike supervised machine learning methods, this algorithm does not need training, is computationally efficient, and requires as input only the raw corpus and a small set of seed entities (as few as two). The result is a set of entities likely to be related to the seeds.

An assumption commonly held in RD work is that frequently co-occurring entity tuples are likely to stand in some fixed relation (Hasegawa et al., 2004; Shinyama and Sekine, 2006; Rosenfeld and Feldman, 2006; Rosenfeld and Feldman, 2007). Tuples which share similar contexts (the exact definition of context varies) are then grouped together in clusters of relations using variants of hierarchical agglomerate clustering (HAC). However, to our knowledge, no prior work has satisfactorily addressed the problem of describing the resulting clusters. In Section 3, we propose an approach which incorporates this requirement directly into the clustering objective: to find relation clusters which are well-described by a single exemplar.

In Section 4, we apply RD to recognize protein-protein interaction (PPI) sentences, using proteins as seeds for the entity discovery phase. We compare our results against special-purpose methods in terms of precision and recall on standard data sets.

The remainder of this paper is outlined below: Section 2 describes how a small number of input words (the entities of interest) are used as seeds for unsupervised entity discovery. Section 3 describes how discovered entities are used to discover relationships. Section 4 describes evaluation methodology and results. Section 5 describes related work. Section 6 concludes and discusses

*This work was conducted while author was at Virginia Tech.

directions for future work.

2 Entity discovery

For a corpus C, each sentence $s \in C$ with words $s = (w_1, w_2, ..., w_n)$, is mapped to the sequence $s' = f(s)$. The function f maps each word $w \in s$ to a symbol based on its frequency in C as follows:

$$f(w) = \begin{cases} S & \text{if } w \text{ is a seed word} \\ H & \text{otherwise if } w \text{ is a frequent word} \\ X & \text{otherwise} \end{cases}$$

For example, the sentence:

A and B are usually mediated by an overproduced C.

might be mapped to the sequence $(S, H, X, H, H, X, H, H, X, X)$, which we will write as $SHXHHXHHXX$ for brevity. In this case, A is a seed term, while B and C are not. The underlying assumption is that content words can be distinguished from other words based on their frequency in the corpus.

2.1 Pattern induction

In the example sentence, 'A and B are usually mediated by an overproduced C', 'and' is a good indicator that A,B share some aspect of their semantics; in this case, that they are both mediated by an overproduced C, and are therefore also likely to belong to same family or type of entities. The indicators 'and' and 'or' have together been used to discover word categories in lexical acquisition (Dorow et al., 2005). However, there can be many other such indicators, many discourse or corpus specific. To discover them, we use a slightly modified version of the method presented in (Davidov and Rappoport, 2006). In particular, in this work we consider named entities of arbitrary length (i.e., longer than a single token).

The corpus is searched for all instances of the frequency pattern $H_1\mathbf{S_1}H_2\mathbf{S_2}H_3$, for seed words S_1, S_2, and pattern (H_1, H_2, H_3). Of all these pattern instances, we keep those which also appear as $H_1\mathbf{S_2}H_2\mathbf{S_1}H_3$. If seed words appear on either side of the pattern, it is a good indication that the symmetric pattern expresses some sort of a conjunction, often domain specific. This procedure is repeated for variations of $HSHSH$ with the goal of capturing different forms of speech; for example, $HSHSH$ will capture '; A , B and', while $HSHHSH$ will capture '; A but not B ,' and so on. We enforce that frequent words appear before and after (i.e., surround) the two seed words to ensure they are standalone entities, and not part of a longer noun phrase. For example, the phrase 'IFN-gamma mRNA and IL-6 are' maps to $XXHSH$, and therefore 'mRNA' would (correctly) not be added to the entity pool.

New entities are added to the initial set of seed by matching symmetric patterns. If a seed word S is found to occur with an infrequent word X in any discovered symmetric pattern (as $H\mathbf{S}HXH$ or $HXH\mathbf{S}H$), then we add X to the pool of entities. This process can be bootstrapped as needed.

2.2 Chunking

In Section 3.1, sentences in which entities co-occur are clustered based on a measure of pairwise similarity. The features used in this similarity calculation are based on the surrounding or connecting words in the sentence in which entities co-occur. To ensure the context is not polluted with words which actually belong the entity NP (such as 'IFN-gamma *mRNA*') rather than the context, we use frequency patterns to search the corpus for common NP chunks.

In each sentence in which entities occur, we form a candidate chunk by matching the regular expression HX^*SX^*H, which returns all content-words X bracketing the entity S. Of all candidate chunks, we keep those which occur frequently enough to significantly affect the similarity calculations. The remaining chunks are pruned based on the entropy of the words appearing immediately before and after the chunk in the corpus; if a given chunk appears in a variety of contexts, it is more likely to express a meaningful collocation (Shimohata et al., 1997). Therefore, as an efficient filter on the candidate chunks, we discard those which tend to occur in the same contexts (where the context is $H...H$).

3 Identifying relation phrases

Once the pool of entities has been recognized in the corpus, those which frequently co-occur are taken as likely to stand in a relation. Order matters in that $S_1..S_2$ is considered a different entity co-occurrence (and therefore potential relation) than $S_2..S_1$. The effect of the co-occurrence threshold on the resulting relations is investigated in Section 4.

3.1 Clustering relation phrases

Partitioning the candidate relationships serves to identify groups of differently expressed relationships of similar semantics. The resulting clusters should cover the most important relations in a corpus between the entities of interest. The phrases in each cluster are expected to capture most syntactic variation in the expression of a given relationship. Therefore, the largest clusters are well suited as positive examples for training a relationship extractor (Rosenfeld and Feldman, 2006).

We take the context of a co-occurring tuple to be the terms connecting the two entities within the sentence in which they appear, and call the connecting terms a relation phrase (RP). Each RP is treated separately in the similarity calculations and the clustering. Relations are modeled using a vector space model. Each relation is treated as a vector of term frequencies (tf) weighted by tf $\times$ idf. RPs are preprocessed by filtering stopwords[1]. However, we do not stem the remaining words, as suffixes can be highly discriminative in determining the semantics of a relation (e.g., 'production' vs 'produced'). After normalizing vectors to unit length, we compute a similarity matrix by computing the dot product between the vectors for each distinct RP pair. The similarity matrix is then used as input for the clustering.

3.2 p-Median clustering

Prior approaches to relationship discovery have used HAC to identify relation clusters. HAC is attractive in unsupervised applications since the number of clusters is not required *a priori*, but can be determined from the resulting dendogram. On the other hand, a typical HAC implementation runs in $\Theta(N^2 \log(N))$, which can be prohibitive on larger data sets[2].

A further feature of HAC, and many other partitional clustering algorithms such as k-means and spectral cuts, is that the resulting clusters are not necessarily well-described by single instance. Relations, however, typically have a base or root form which would be desirable to uncover to describe the relation clusters. For example, in the following RPs:

induced transient increases in
induced biphasic increases in
induced an increase in
induced an increase in both
induced a further increase in

the phrase 'induced an increase in' is well suited as a base form of the relation and a descriptor for the cluster. The p-median clustering objective is to find p clusters which are well-described by a single exemplar. Formally, given an $N \times N$ similarity matrix, the goal is to select p columns such that the sum of the maximum values within each row of the selected columns are maximized.

Note that an exemplar can also be chosen *a posteriori* using some heuristic; for example, the most frequently occurring instance in a cluster can be taken as the exemplar. However, the p-median clustering objective is robust, and ensures that only those clusters which are well described by a single exemplar appear in the resulting partition of the relations. This means that the optimal number of clusters for the p-median clustering objective in a given data set will usually be quite different (usually higher) than the optimal number of groups according to the HAC, k-means, or normalized cut objectives.

Affinity propagation (AP) is the most efficient approximation for the p-median problem that we are aware of, which also has the property of not requiring the number of clusters as an explicit input (Frey and Dueck, 2007). Runtime is linear in the number of similarities, which in the worst case is N^2 (for N relations), but in practice many relations share no words in common, and therefore do not need to have their similarity considered in the clustering.

AP is an iterative message-passing procedure in which the objects being clustered compete to serve as cluster exemplars by exchanging two types of messages. The responsibility $r(x,m)$, sent from object $x \in \mathcal{X}$ (for set $\mathcal{X}$ of objects to be clustered) to candidate exemplar $m \in \mathcal{X}$, denotes how well-suited m is of being the exemplar for x by considering all other potential exemplars m' of x:

$$s(x,m) - \max_{m' \in \mathcal{X}, m' \neq m} a(x,m') + s(x,m')$$

where $s(x,m)$ is the similarity between x, m. The availability $a(x,m)$ of each object $x \in \mathcal{X}$ is initially set to zero. Availabilities, sent from candidate exemplar m to object x, increase as evidence for m to serve as the exemplar for x increases:

$$\min\left\{0, r(m,m) + \sum_{x' \in \mathcal{X}, x' \notin \{x,m\}} \max\{0, r(x',m)\}\right\}$$

Each object to be clustered is assigned an initial preference of becoming a cluster exemplar. If there are no *a priori* preferences for cluster exemplars, the preferences are set to the median similarity (which can be thought of as the 'knee' of the objective function graph vs. number of clusters), and exemplars emerge from the message passing procedure. However, shorter RP are more likely to contain base

[1]We use the English stopword list from the Snowball project, available at `http://snowball.tartarus.org/`

[2]An optimization to $\Theta(N^2)$ is possible for single-linkage HAC.

forms of relations (because longer phrases likely contain additional words specific to the sentence). Therefore, we include a slight scaling factor in the preferences, which assigns shorter RP higher initial values (up to $1.5\times$ the median similarity).

3.3 Pruning clusters

After clustering relation phrases with AP, we prune the resulting partition by evaluating the number of different relation instances appearing in each cluster, as well as the entities involved. In our experiments, we discard all clusters smaller than a certain threshold, since we ultimately wish to use the clustering to train RE, and small clusters do not provide enough positive examples for training (we investigate the effect of this threshold in Section 4.2). We further assume that for a relationship to be useful, a number of different entities should stand in this relation. In particular, we inspect the set of left and right arguments in the cluster, which (in English) usually correspond to the subject and object of the sentence. If a single entity constitutes more than two thirds ($\frac{2}{3}$) of the left or right arguments of a cluster, then this cluster is discarded from the results. Our assumption is that these clusters describe relations too specific to be useful.

4 Evaluation

RD systems are usually evaluated based on their results for a particular task such as RE (Rosenfeld and Feldman, 2006), or by a manual inspection of their results (Davidov et al., 2007; Rosenfeld and Feldman, 2007; Hasegawa et al., 2004), but we are not aware of any which examines the effects of parameters on performance exhaustively. In this section we test several hypotheses of RD using data sets which are already labeled for sentences which contain entities of a particular type and in a fixed relation of some kind. In particular, we adapt the output of the discovery phase to identify phrases which express PPIs. While this task is traditionally performed using supervised algorithms such as support vector machines (Erkan et al., 2007), we show that RD is capable of achieving similar levels of precision without any manually annotated training data.

4.1 Method

We construct a corpus of 87300 abstracts by querying the PubMed database with the proteins shown in Table 1. The 60 most frequent words are considered definite non-entities; all remaining words are candidate entities. This corpus serves as input for the relationship discovery. As seeds, we use the same 25 proteins used to query the database. Since all seeds are proteins, we expect the entities discovered to be proteins. The pattern induction found roughly 200 symmetric extraction patterns, which yield 4402 unique entities after 1 pass through the corpus. Depending on the frequency of the seeds in the corpus, more passes through the corpus might be needed (bootstrapping with the discovered entities after each pass). We retain all chunks that appear at least 10 times in the corpus, yielding 3282 additional entities after entropy pruning.

Table 1: Proteins queried to create the evaluation corpus.

Seed entities (proteins)				
c-cbl	AmpC	CD18	CD54	CD5
CD59	CK	c-myc	CNP	DM
EBNA	GSH	IL-8	IL-1beta	JNK1
p38	PABP	PCNA	PP1	PP2a
PPAR	PSM	TAT	TNF-alpha	TPO

A PPI denotes a broad class of bio-medical relationships between two proteins. One example of an interaction is where the two proteins bind together to form a structural complex of cellular machinery such as signal transduction machinery. A second example is when one protein binds upstream of the DNA sequence encoding a gene which encodes the second protein. A final example is when proteins serve as enzymes catalyzing successive steps of a biochemical reaction. More categories of interactions are continually being catalogued and hence unsupervised identification of PPIs is important in biomedical text mining.

4.2 Experiment 1: PPI sentence identification

Method: To evaluate the performance of our system, we measure how well the relationships discovered compare with manually selected PPI sentences. To do so, we follow the same procedure and data sets used to evaluate semi-supervised classification of PPI sentences (Erkan et al., 2007). The two data sets are AIMED and CB, which have been marked for protein entities and interaction phrases[3].

For each sentence in which n proteins appear, we build $\binom{n}{2}$ phrases. Each phrase consists of the words between each entity combination, and is labeled as positive if it describes a PPI, or negative otherwise. This results in 4026 phrases for the

[3]Available in preprocessed form at `http://belabog.si.umich.edu/biocreative`

AIMED data set (951 positive, 3075 negative), and 4056 phrases for the CB data set (2202 positive, 1854 negative).

The output of the discovery phase is a clustering of RPs. For purpose of this experiment, we ignore the partition and treat the phrases in aggregate. A phrase in the evaluation data set is classified as positive (describing a PPI) if any substring of the phrase matches an RP in our output. For example, if the phrase is:

A significantly inhibited B

and the string 'inhibited' appears as a relation in our output, then this phrase is marked positive. Otherwise, the phrase is marked negative.

Performance is evaluated using standard metrics of precision (P), recall (R), and F-measure (F_1), defined as:

$$P = \frac{TP}{TP + FP}; \quad R = \frac{TP}{TP + FN}$$

where TP is the number of phrases correctly identified as describing a PPI, FP is the number of phrases incorrectly classified as describing a relation, and FN is the number of interaction phrases (positives) marked negative. F_1 is defined as:

$$F_1 = \frac{2PR}{P + R}$$

We calculate P, R, and F_1 for three parameters affecting which phrases are identified as expressing a relation:

- the minimum co-occurrence threshold that controls which entity tuples are kept as likely to stand in some fixed relation
- the minimum cluster size that controls which groups of relations are discarded
- the minimum RP length that controls the smallest number of words appearing in relations

The threshold on the length of the relations can be thought of as controlling the amount of contextual information expressed. A single term relation will be very general, while longer RPs express a relation very specific to the context in which they are written. The results are reported in Figures 1 through 6. Odd numbered figures use the AIMED corpus; even numbered figures the CB corpus. **Results:** Discarding clusters below a certain size had no significant effect on precision. However, this step is still necessary for bootstrapping RE, since machine learning approaches require a sufficient number of positive examples to train the extractor.

Table 2: Comparison with supervised methods–AIMED corpus

Method	P	R	F_1
RD-F_1	30.08	60.67	40.22
RD-P	**55.17**	5.04	9.25
(Yakushiji et al., 2005)	33.70	33.10	33.40
(Mitsumori et al., 2006)	54.20	42.60	47.70
(Erkan et al., 2007)	**59.59**	60.68	59.96

Table 3: Comparison with supervised methods–CB corpus

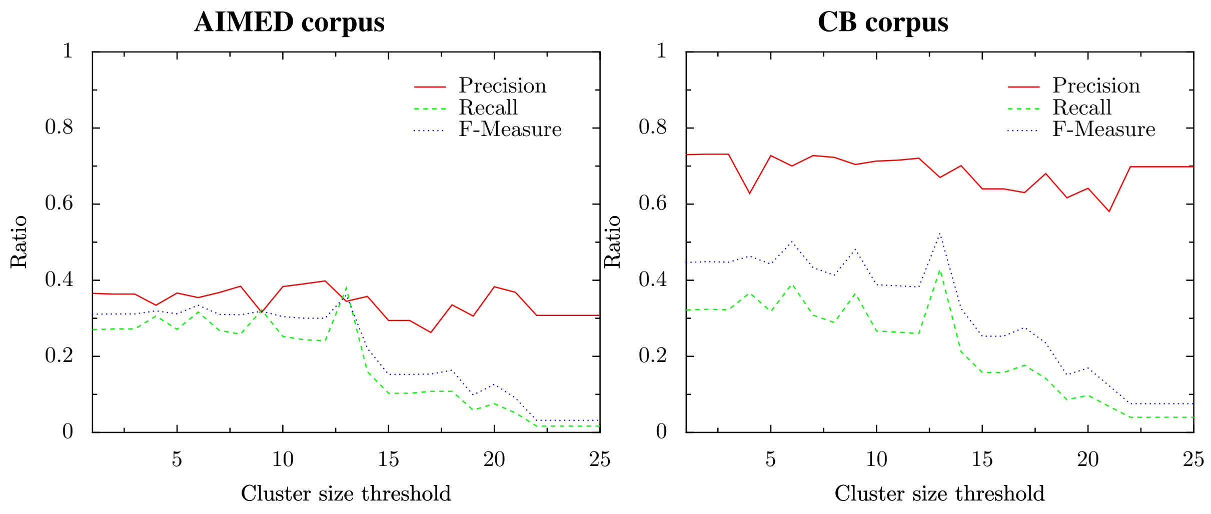
Method	P	R	F_1
RD-F_1	65.03	69.16	67.03
RD-P	**86.27**	2.00	3.91
(Erkan et al., 2007)	**85.62**	84.89	85.22

On the other hand, our results confirm the observation that frequently co-occurring pairs of entities are likely to stand in a fixed relation. On the CB corpus, precision ranges from 0.63 to 0.86 for phrases between entities co-occurring at least 50 times. On the AIMED corpus, precision ranges from 0.29 to 0.55 in the same threshold range.

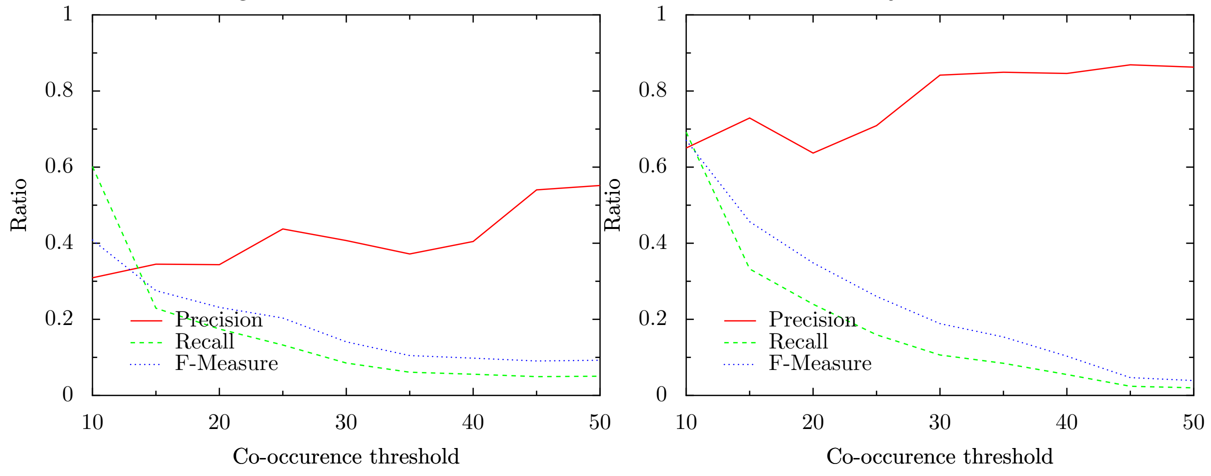
The minimum phrase length had the most impact on performance, which was particularly evident in the CB corpus: this corpus reached perfect precision discarding all RPs of fewer than 3 words. Lower thresholds result in significantly more relations, at the cost of precision.

The generally lower performance on the AIMED corpus suggests that our training data (retrieved from the seed proteins) provided less coverage for those interactions than for the those in the CB corpus.

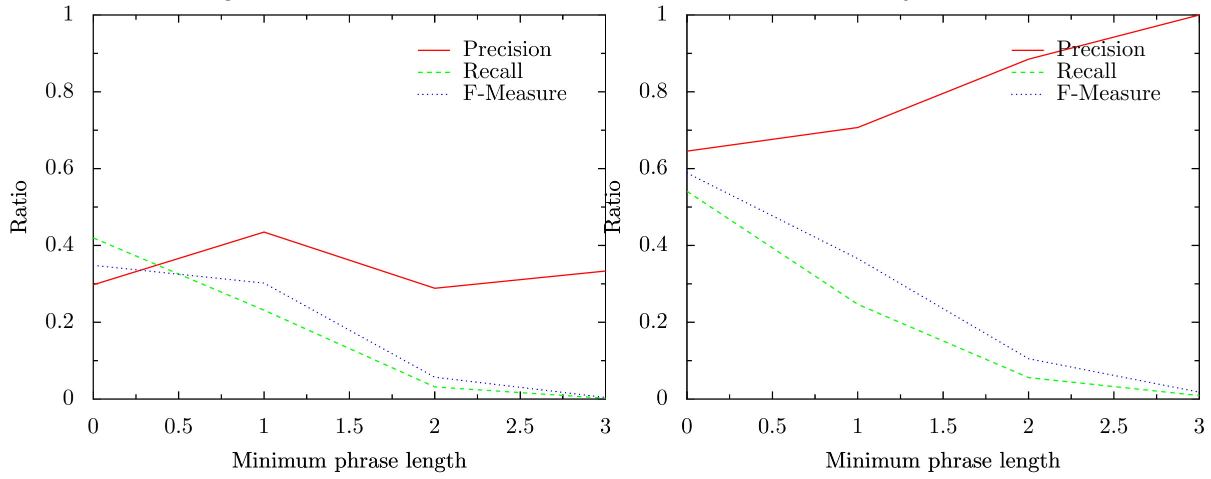
Table 2 and Table 3 compare our results at fixed parameter settings with supervised approaches. RD-F_1 reports parameters which give highest recall and RD-P highest precision. Specifically, both RD-F_1 and RD-P use a minimum RP length of 1, RD-F_1 uses a co-occurrence threshold of 10, and RD-P uses a co-occurrence threshold of 50. As expected, RD alone does not match combined precision and recall of state-of-the-art supervised systems. However, we show better performance than expected. RD-F_1 outperforms the best results of (Yakushiji et al., 2005). RD-P settings outperform or match the precision of top-performing systems on both datasets.



Figures 1 & 2: Performance as minimum cluster size is adjusted



Figures 3 & 4: Performance as co-occurrence threshold is adjusted



Figures 5 & 6: Performance as minimum phrase length is adjusted

4.3 Experiment 2: clustering relations

Method: We evaluate the appropriateness of the p-median clustering as follows. For each cluster, we take the cluster exemplar as defining the base relation. If the base relation does not express something meaningful, then we mark each member of the cluster incorrect. Otherwise, we label each member of the cluster either as semantically similar to the exemplar (correct) or different than the exemplar (incorrect). Thus, clusters with inappropriate exemplars are heavily penalized. These results are reported in Table 4. For purpose of this experiment, we use the same parameters as for RD-P, and evaluate the 20 largest clusters.

Results: In the 20 largest clusters, each cluster exemplar expressed something meaningful. 3 of the cluster exemplars were not representative of their other members. We found that most error was due to stopwords not being considered in our similarity calculations. For example, 'detected by' and 'detected in' express the same relationship in our similarity calculations; however, they are clearly quite different. Another source of error evident in Table 4 are mistakes in the pattern and entropy based chunking. The exemplar 'mrna expression in' includes the token 'mrna', which belongs with the left protein NP in the relation chosen as an exemplar.

5 Related work

RD is a relatively new area of research. Existing methods differ primarily in the amount of supervision required and in how contextual features are defined and used.

(Hasegawa et al., 2004) use NER to identify frequently co-occurring entities as likely relation phrases. As in this work, they use the vector model and cosine similarity to define a measure of similarity between relations, but build relation vectors out of *all* instances of each frequently co-occurring entity pair. Therefore, each mention of the same co-occurring pair is assumed to express the same relationship. These aggregate feature vectors are clustered using complete-linkage HAC, and cluster exemplars are determined by manual inspection for evaluation purposes. (Shinyama and Sekine, 2006) rely further on supervised methods, defining features over a full syntactic parse, and exploit multiple descriptions of the same event in newswire to identify useful relations.

(Rosenfeld and Feldman, 2006) consider the use of RD for unsupervised relation extraction, and use a more complex pattern-learning approach to define feature vectors to cluster candidate relations, reporting gains in accuracy compared with the tf $\times$ idf weighed features used in (Hasegawa et al., 2004) and in this work. They also use HAC, and do not address the description of the relations. Arbitrary noun phrases obtained through shallow parsing are used as entities. (Rosenfeld and Feldman, 2007) use a feature ranking scheme using separability-based scores, and compare the performance of different variants of HAC (finding single-linkage to perform best). The complexity of the feature ranking-scheme described can be greater than the clustering itself; in contrast, while we use simple features, our approach is much more efficient.

(Davidov et al., 2007) introduce the use of term frequency patterns for relationship discovery. However, they search for a specific type of relationship; namely, attributes common to all entities of a particular type (for example, all countries have the attribute *capital*), and use a special purpose set of filters rather than entity co-occurrence and clustering. Our work can be seen as a generalization of theirs to relationships of any kind, and we extend the use of frequency patterns to finding general n-gram entities rather than single word entities.

(Madkour et al., 2007) give an excellent overview of biomedical NER and RE. They propose a statistical system for RE, but rely on NER, POS tagging, and the creation of a dictionary for each domain of application. Also, they do not cluster relationships into semantically related groups.

6 Conclusion

Our work makes a series of important improvements to the state-of-the-art in relationship discovery. First, by incorporating entity discovery into the relationship discovery pipeline, our method does not require distinct training phases to accommodate different entity types, relations, or discourse types. Second, p-median clustering effectively uncovers the base form of relations present in the corpus, addressing an important limitation in usability. In terms of specific hypotheses, we have tested and confirmed that co-occurrence can be a good indicator of the presence of a relationship but the size of a cluster is not necessarily a good indicator of the importance or strength of the discovered relationship. Furthermore, we have shown that longer RPs with more context give higher precision (at the cost of reduced coverage). Finally, the integration of ideas in our approach—unsupervisedness, efficiency, flexibility (in application), and specificity—is novel in itself.

In future work, we seek to expand upon our RD methods in three directions. First, we would like to generalize the scope of our discovery pipeline beyond binary relations and with richer considerations of context, even across sentences. Second, we hope to achieve greater tunability of performance, to account for additional discovery metrics besides precision. Finally, we intend to induce entire concept maps from text using the discovered relations to bootstrap an RE phase, where the underlying problem is not just of inferring multiple types of relations, but to have sufficient co-ordination among the discovered relations to ensure connectedness among the resulting concepts.

While our method requires no supervision in the form of manually annotated entities or relations, the effectiveness of the system relies on the careful tuning of a number of parameters. Nevertheless, the results reported in Section 4.2 suggest that the two parameters that most significantly affect performance exhibit predictable precision/recall behavior. Of the parameters not considered in Section 4.2, we would like to further investigate the benefits of chunking entities on the resulting base relations, experimenting with different measures of collocation.

Mention Detection Crossing the Language Barrier

Abstract

While significant effort has been put into annotating linguistic resources for several languages, there are still many left that have only small amounts of such resources. This paper investigates a method of propagating information (specifically mention detection information) into such low resource languages from richer ones. Experiments run on three language pairs (Arabic-English, Chinese-English, and Spanish-English) show that one can achieve relatively decent performance by propagating information from a language with richer resources such as English into a foreign language alone (no resources or models in the foreign language). Furthermore, while examining the performance using various degrees of linguistic information in a statistical framework, results show that propagated features from English help improve the source-language system performance even when used in conjunction with all feature types built from the source language. The experiments also show that using propagated features in conjunction with lexically-derived features only (as can be obtained directly from a mention annotated corpus) yields similar performance to using feature types derived from many linguistic resources.

1 Introduction

Information extraction is a crucial step toward understanding a text, as it identifies the important conceptual objects and relations between them in a discourse. It includes classification, filtering, and selection based on the language content of the source data, i.e., based on the meaning conveyed by the data. It is a crucial step for several applications, such as summarization, information retrieval, data mining, question answering, language understanding, etc. This paper addresses an important and basic task of information extraction: *mention detection*[1]: the identification and classification of textual references to objects/abstractions *mentions*, which can be either named (e.g. John Smith), nominal (the president) or pronominal (e.g. he, she). For instance, in the sentence

> <u>President</u> <u>*John Smith*</u> said <u>*he*</u> has no comments.

there are three mentions: *President*, *John Smith* and *he*. This is similar to the named entity recognition (NER) task with the additional twist of also identifying nominal and pronominal mentions.

A few languages have received a lot of attention in terms of natural language resources that were created – for instance, in English one has access to labeled part-of-speech data, word sense information, parse tree structure, discourse, semantic role labeles, named entity data, to name just a few (our apologies if we missed your favorite resource). There are a few other languages that also have annotated resources (such as Arabic, Chinese, German, French, Spanish, etc), but also a very large number of languages with few resources. It would be very useful if one could make use of the resources in the former languages to help bootstrapping (or just the projection) of resource in any resource-challenged language.

Information transfer from a language to another can be very useful when the "donor" language has more resources than the receiving one. As resources grow in quantity and quality in the receiving language, it becomes less and less likely that there will be a gain in performance by transfering information, as there are several sources of noise involved in the

[1]We adopt here the ACE (NIST, 2007) nomenclature

process - such as the translation (machine generated or not) and the inherent imperfection of the mention detection in the donor language. To test this hypothesis, we conducted experiments on systems build with a varied amount of resources in the receiving language, starting with the case where there are none[2] (all information is transferred through translation alignment), and ending with the case where we used all the resources we could gather for that language. The experiments will show that the gain in performance decreases with the amount of resources used in the source language, but, still, even when all resources were used, a statistically significant gain was still observed.

Similarly to classical NLP tasks such as text chunking (Ramshaw and Marcus, 1995) and named entity recognition (Tjong Kim Sang, 2002), we formulate mention detection as a sequence classification problem, by assigning a label to each token in the text, indicating whether it starts a specific mention, is inside a specific mention, or is outside any mentions. The classification is performed with a statistical approach, built around the maximum entropy (MaxEnt) principle (Berger et al., 1996), that has the advantage of combining arbitrary types of information in making a classification decision.

2 Previous Work

There are several investigations in literature that explore using parallel corpora to transfer information content from one language (most of the time English) to another. The earliest investigations of the subject have been performed, on word sense disambiguation (Dagan et al., 1991; P.F.Brown et al., 1991; Gale et al., 1992) (perhaps unsurprisingly given its close connection to machine translation) – all propose and (lightly) evaluate methods to use word sense information extracted from the target language to help the sense resolution in the source language and machine translation. (Dagan and Itai, 1994) explicitly suggests performing word sense disambiguation in the target language (English in the article) with the goal of resolving ambiguity in the source language (Hebrew), and show moderate improvement on a small data set[3]. More recently, (Diab and Resnik, 2001) presents a method for performing word sense tagging in both the source and target texts of parallel bilingual corpora with the English WordNet sense inventory, by using translation correspondences.

On more general cross-language information transfer, (Yarowsky et al., 2001) proposed and evaluated a method of propagating POS tagging, named mention, base noun phrase, and morphological information from English into a foreign language, which is very similar to the one presented in this article (experiments were run on French, Chinese, Czech, and Spanish – on human-generated translations). Their results show a significant improvement in performance while building an automatic classifier on the projected annotations over the same automatic classifier trained on a small amount of annotated data in the source language. (Riloff et al., 2002) extends the ideas in (Yarowsky et al., 2001), by showing how it can be used, in conjunction with an automatically trained information extraction system on the source language, to bootstrap the annotation of resources in the target language. They show that they can obtain 48 F-measure on a information extraction task identifying locations, vehicles and victims in plane crashes. (Hwa et al., 2002) proposes a framework that enables the acquisition of syntactic dependency trees for low-resource languages by importing linguistic annotation from rich-resource languages (English). The authors run a large-scale experiment in which Chinese dependency parses were induced from English, and show that a parser trained on the resulting trees outperformed simple baselines. (Cabezas et al., 2001) investigates a similar method of propagating syntactic treebank-like annotations from English to Spanish.

Finally, a large body of research has been done on *cross-language information retrieval*, where the goal is to find information in one language (e.g. Chinese newswire) corresponding to a query in a different language (e.g. English) – although the list of relevant papers is too long to be mentioned here (see, for instance, (Grefenstette, 1998)).

The work presented here differs from the information extraction investigations presented above in two aspects:

- it handles unrestricted text and a full set of

[2]While applying this method in the case where the source language has absolutely no resources might be an interesting test case, we don't see it as being realistic. Resources are build nowadays in a large variety of languages, and not making use of them is rather foolish (a certain big bird and sand comes to mind).

[3]Very small by "modern" standards - 137 examples. Probably because at the time the article was written, there were no large publicly annotated databases, such as Semcor.

mention types (the ACE entity types) during the information transfer

- it investigates whether using a resource-rich language (English) can improve on the performance obtained by using various degrees of existent resources in the source language (Arabic, Chinese, Spanish)
- the information transfer is performed over machine generated translations and alignments.

3 Mention Detection

As mentioned in the introduction, the mention detection problem is formulated as a classification problem, by assigning to each token in the text a label, indicating whether it starts a specific mention, is inside a specific mention, or is outside any mentions.

Good performance in many natural language processing tasks has been shown to depend heavily on integrating many sources of information (Florian et al., 2004).[4] Given this observation, we are interested in algorithms that can easily integrate and make effective use of diverse input types. We select a exponential classifier, the Maximum Entropy (MaxEnt henceforth) classifier that integrates arbitrary types of information and makes a classification decision by aggregating all information available for a given classification. But the reader can replace it with her favorite feature-based classifier throughout the paper.

To help with the presentation, we introduce some notations: let $\mathcal{Y} = \{y_1, \ldots, y_n\}$ be the set of predicted classes, $\mathcal{X}$ be the example space and $\mathcal{F} = \{0,1\}^m$ be a feature space. Each example $x \in \mathcal{X}$ has associated a vector of m binary features $f(x) = (f_1(x), \ldots, f_m(x))$. The goal of the training process is to associate examples $x \in \mathcal{X}$ with either a probability distribution over the labels from $\mathcal{Y}$, $P(\cdot|x)$(if we are interested in *soft* classification) or associate one label $y \in \mathcal{Y}$ (if we are interested in *hard* classification).

The MaxEnt algorithm associates a set of weights $\{\alpha_{ij}\}_{j=1\ldots m}^{i=1\ldots n}$ with the features $(f_j)_i$, and computes the probability distribution as

$$P(y_i|x) = \frac{1}{Z(x)} \prod_{j=1}^{m} \alpha_{ij}^{f_j(x,y_i)}, \qquad (1)$$

$$Z(x) = \sum_i \prod_j \alpha_{ij}^{f_j(x,y_i)}$$

where $Z(x)$ is a normalization factor. The $\{\alpha_{ij}\}_{j=1\ldots m}$ weights are estimated during the training phase to maximize the likelihood of the data (Berger et al., 1996). In this paper, the MaxEnt model is trained using the *sequential conditional generalized iterative scaling* (SCGIS) technique (Goodman, 2002), and it uses a *Gaussian prior* for regularization (Chen and Rosenfeld, 2000).

Now take $x_1^N = (x_1, x_2, \ldots x_N)$, a sequence of contiguous tokens (i.e., a sentence or a document) in the source language. The goal of mention detection system is to find the most likely sequence of labels $y_1^N = (y_1, y_2 \ldots y_N)$ that best matches the input x_1^N. In the mention detection case, each token x_i in x_1^N is tagged with a label y_i as follows:[5]

- if it's not part of any entity, $y_i = O$ (O for "outside any mentions")
- if it is part of an entity, it is composed of a subtag specifying whether it starts a mention (*B*-) or is inside a mention (*I*-), and a sub-type corresponding to mention type (e.g. *B-PERSON*). In ACE, there are seven possible types: person, organization, location, facility, geopolitical entity (GPE), weapon, and vehicle.

To compute the best sequence y_1^N, we use

$$\begin{aligned} y_1^N &= \arg\max_{\hat{y}_1^N} P\left(\hat{y}_1^N | x_1^N\right) \\ &= \arg\max_{\hat{y}} \prod P\left(\hat{y}_j | x_1^N, \hat{y}_1^{j-1}\right) \\ &= \arg\max_{\hat{y}} \prod_j P\left(\hat{y}_j | x_1^N, y_{j-k}^{j-1}\right) \end{aligned}$$

where $P\left(\hat{y}_j | x_1^N, y_{j-k}^{j-1}\right)$ has an exponential form of the type (2). We also used the standard Markov assumption that the probability $P\left(\hat{y}_j | x_1^N, \hat{y}_1^{j-1}\right)$ only depends on the previous k classifications. This model is similar to the MEMM model (McCallum et al., 2000), but it does not separate the probability into generation probabilities and transition probabilities, and, crucially, has access to "future" observed features (i.e. it can examine the entire x_1^N sequence, though in practice it will only examine some small part of it) – which is one way of eliminating label

[4]In fact, the feature set used for classification has a much larger impact on the performance of the resulting system than the classifier method itself.

[5]The mention encoding is the IOB2 encoding presented in (Tjong Kim Sang and Veenstra, 1999) and introduced by (Ramshaw and Marcus, 1994) for base noun phrase chunking.

bias observed by (Lafferty et al., 2001).[6]

The experiments are run on four languages, part of the ACE-2007 evaluation (NIST, 2007): Arabic, Chinese, English and Spanish.[7] Systems across the languages use a large range of features, including lexical (words and morphs in a 3-word window, prefixes and suffixes of length up to 4 characters, WordNet (Miller, 1995) for English), syntactic (POS tags, text chunks), and the output of other information extraction models. These features were described in (Florian et al., 2004), and are not discussed here. In this paper we focus on the examining the benefit of cross-language mention propagation information in improving mention detection systems.

Besides generic types of features, we also have implemented language-specific features:

- In Arabic, blank-delimited words are composed of zero or more prefixes, followed by a stem and zero or more suffixes. Each prefix, stem or suffix is a token; any contiguous sequence of tokens can represent a mention. Similar to the approaches described in (Florian et al., 2004) and (Zitouni et al., 2005), we decided to "condition" the output of the system on the segmented data: the text is segmented first into tokens and classification is then performed on tokens. The segmentation model is similar to the one presented by (Lee et al., 2003) and obtains an accuracy of 98%.

- In Chinese text, unlike in Indo-European languages, words neither are white-space delimited nor do they have capitalization markers. Instead of a word-based model, we build a character-based one, since word segmentation errors can lead to irrecoverable mention detection errors; Jing et al. (2003) also observes that character-based models are better performing than word-based ones. Word segmentation information is still useful and is integrated as an additional feature stream.

- In English and in Spanish mention detection systems are similar to those described in (Florian et al., 2004) where words are the tokens to classify.

[6]In fact their example of label bias can be trivially solved by allowing the classifier to examine features for subsequent words.

[7]The ACE data has the nice property of being consistent in annotations across these languages.

4 Cross-Language Mention Propagation

The approach proposed in this article requires a mention detection system build in a resource-rich language, and a *translation* from the source language to the resource-rich language, together with *word alignment*. This assumption is realistic: while truly parallel data (humanly created) might be in short supply or harder to acquire, adapting statistical machine translation (SMT) systems from one language-pair to another is not as challenging as it used to be (Al-Onaizan and Papineni, 2006). We also find that there is a large number of parallel corpora available these days which cover many language pairs. For example, for the European Union's 23 official languages we find 253 language pairs; each document in one language might have to be translated in all other 22 languages. This is in addition to parallel corpora one could get from books, including religious texts such as the Bible, that are translated to a large number of languages. On the other hand, even though mention detection system is important for many natural language processing applications, we still find lack of mention-annotated corpora in many languages. In the approach we propose below, the annotated corpus used to train the mention detection classifier does not have to be part of a parallel corpus.

To start the process, we first use a SMT system to translate the source unit (document or sentence) x_1^N into the resource-rich language, yielding the sequence $\xi_1^M = (\xi_1, \xi_2, \ldots \xi_M)$. Taking the sequence of tokens ξ_1^M as input, the MaxEnt classifier assigns a mention label to each token, building the label sequence $\psi_1^M = (\psi_1, \psi_2 \ldots \psi_M)$. Using the SMT-produced word alignment between source text x_1^N and translated text ξ_1^M (Koehn, 2004),we propagate the target labels ψ_1^M to the source language building the label sequence $\tilde{y}_1^N = (\tilde{y}_1, \tilde{y}_2 \ldots \tilde{y}_N)$.[8] As an example, if a sequence of tokens in the resource-rich language $\xi_i \xi_{i+1} \xi_{i+2}$ is aligned to $x_j x_{j+1}$ in the source language and if $\xi_i \xi_{i+1} \xi_{i+2}$ is tagged as a location mention, then the sequence $x_j x_{j+1}$ can be labeled as a location mention: B-LOC, I-LOC. Hence, each token x_i in x_1^N is tagged with a corresponding propagated label $\tilde{y}_i$ in $\tilde{y}_1^N$, $\tilde{y}_i = \phi\left(i, A, \psi_1^M\right)$, where A is the alignment between the source and resource-rich languages. In cases when the alignment is 1-to-1 the function becomes the identity, but one can imagine different scenarios which can be used in

[8]Or by using Giza++ if your favorite engine does not give you word alignment.

Figure 1: Word alignment for a Spanish sentence and its English machine-translation. The mention labels shown are the gold-standard ones for Spanish and the automatically detected ones for English. If mentions were to be propagated from English to Spanish, the last mention would be a miss, due to the fact that the English mention detection failed to identify 'minustah' as an organization.

many-to-many alignment cases. The alignement we use in this paper is 1-to-many ($\{1...n\}$) from the source language (eg., Arabic) to the resource-rich language (e.g., English). Once we use SMT word alignment to propagate label sequence ψ_1^M of ξ_1^M to the corresponding text x_1^N in the target language, we end up with a sequence of labels $\tilde{y}_1^N$ where for each token x_i in x_1^N we attach its label $\tilde{y}_i$ in $\tilde{y}_1^N$. Hence, we label te entire span and if the strategy results in two mentions where one contains the other, we eliminate the inner one.

Figure 1 displays the alignment between a Spanish sentence and its English automatic translation. It also shows a good match between the gold-standard tags in Spanish and the automatically extracted tags in English.

There are three ways in which we propose using these propagated labels:

1. Consider $\tilde{y}_1^N$ as the result of propagating the detected mentions in the original text x_1^N, basically selecting $y_1^N = \tilde{y}_1^N$. This situation corresponds to a case where no resources (annotated data) are available/needed on the source side, where the propagated labels are the output of the system.

2. Use the label sequence $\tilde{y}_1^N$ as an additional feature in the MaxEnt framework when predicting $P\left(y_j|x_1^N, y_{j-k}^{j-1}\right)$, together with other features built from resources available on the source language. We will call this model *CDP* (Context Dependent Propagation).

3. Starting with a large corpus (possibly including the training data), translate it into the resource-rich language and run mention detection. Then select the word sequences in the source language associated with the found mentions in the translation and add them to a machine-generated gazetteer $\mathcal{G}$[9]. This gazetteer $\mathcal{G}$ is then used to construct features for classification. We will call this model *CIP* (Context Independent Propagation).

From a runtime point of view, the CIP method has the advantage that there is no need to perform machine translation, and it can incorporate data from a very large amount of text. The CDP method, on the other hand, has the advantage that features are computed in context, and will not fire unless the corresponding mentions were found in the translated version (hence the name). Of course, the CDP method can incorporate features generated in the dictionary $\mathcal{G}$. The experimental section analyzes the impact of each of these techniques on mention detection task performance.

5 Resources

Experiments are conducted on the ACE 2007 data sets[10], in four languages: Arabic, Chinese, English, and Spanish. This data is selected from a variety of sources (broadcast news, broadcast conversations, newswire, web log, newswire, conversational telephony) and is labeled with 7 types: person, organization, location, facility, GPE (geo-political entity), vehicle and weapon. Besides mention level information, also labeled are coreference between the mentions, relations, events, and time resolution.

Since the evaluation tests set are not publicly available, we have split the publicly available *training* corpus into an 85%/15% data split. To facilitate future comparisons with work presented here, and to simulate a realistic scenario, the splits are created based on article dates: the test data is selected as the latest 15% of the data in chronological order, in each of the covered genres. This way, the documents in

[9]This is in fact a way to automatically construct a source-side mention dictionary.

[10]Same data as for ACE 2008.

Language	Training	Test
Arabic	323	56
Chinese	538	95
English	499	100
Spanish	467	52

Table 1: Datasets size (number of documents)

the training and test data sets do not overlap in time, and the content of the test data is more recent than the training data. Table 1 presents the number of documents in the training/test datasets for each of the four languages.

While performance on the ACE data is usually evaluated using a special-purpose measure - the ACE value metric (NIST, 2007), given that we are interested in the mention detection task only, we decided to use the more intuitive and popular (unweighted) F-measure, the harmonic mean of precision and recall.

6 Resource-Rich Languages

From the set of four languages in ACE 2007, we will unsurprisingly select English as the resource-rich language. Table 2 shows the performance of mention detection systems in all 4 languages one can obtain by using all available resources in that language, including lexical (words and morphs in a 3-word window, prefixes and suffixes of length up to 4, WordNet (Miller, 1995) for English), syntactic (POS tags, text chunks), and the output of other information extraction models.

	N	P	R	F
Arabic	3566	83.6	76.8	**80.0**
Chinese	4791	81.1	71.3	**75.8**
English	8170	84.6	80.8	**82.7**
Spanish	2487	79.1	73.5	**76.2**

Table 2: Performance of Arabic, Chinese, English and Spanish mention detection systems. Performance is presented in terms of Precision (P), Recall (R), and F-measure (F). The column (N) displays the number of mentions in the test set.

Results show that the English mention detection system has a better performance when compared to systems dealing with other languages such as Arabic, Chinese and Spanish. These results are not unexpected since the English model has access to a larger training data and uses richer set of information such as WordNet (Miller, 1995) and the output of a larger set of information extraction models.

Language Pair	BLEU Score
Arabic-English	0.55
Chinese-English	0.32
Spanish-English	0.55

Table 3: BLEU performance of the SMT systems on the 3 language pairs

7 Experiments

To show the effectiveness of cross-language mention propagation information in improving mention detection system performance in Arabic, Chinese and Spanish, we use three SMT systems with very competitive performance in terms of BLEU[11] (Papineni et al., 2002).

To give an idea of the SMT performance, Table 3 shows the performance of the translation systems on the three language pairs, computed on standard test sets. The Arabic to English SMT system is similar to the one described in (Huang and Papineni, 2007); it has 0.55 BLEU score on NIST 2003 Arabic-English machine translation evaluation test set. The Chinese to English SMT system has similar architecture to the one described in (Al-Onaizan and Papineni, 2006). This system obtains a score of 0.32 cased BLUE on NIST 2003 Arabic-English machine translation evaluation test set. The Spanish to English SMT system is similar to the one described in (Lee et al., 2006); it has a 0.55 BLEU score on the final text edition of the European Parliament Plenary Speech corpus in TC-STAR 2006 evaluation. As mentioned earlier, these three SMT systems have very competitive performance and are ranked among top 2 systems participating to NIST or TC-STAR evaluations. Also, the English mention detection system used for experiments has an F-measure of 82.7 and that has very competitive results among systems participating in the ACE 2007 evaluation.

Experiments are conducted under several conditions in order to investigate the effectiveness of our approach in improving mention detection system performance on languages with different levels of resource availability (from simple to more complex):

1. the system does not have access to any training data in the source language (no resources

[11]BLEU is an automatic measure for the translation quality which makes good use of multiple reference translations.

needed besides the MT system);

2. the system has access to only lexical information (information that can be directly derived exclusively from mention-labeled text);

3. the system has access to lexical and syntactic (e.g., POS tags, text chunks) information (requires mention-labeled text, and models to predict POS tags, etc);

4. the system that has access to lexical, syntactic, and semantic information (requires even more models and labeled data).

The rest of this section examines in detail these four cases.

To measure whether the improvement in performance of a particular system over another one is statistically significant or not, we use the stratified bootstrap re-sampling significance test (Noreen, 1989). This approach was used in the named entity recognition shared task of CoNNL-2002 (http://www.cnts.ua.ac.be/conll2002/ner/, 2002). In the following tables, we add a dagger sign † to results that are *not* statistically significant when compared to the baseline results.

7.1 No Source Language Training Data

In this first case, as described in Section 4, the mention labels in the source language are obtained directly through the alignment from the mentions in the translated text. This is a very simple scenario, which can be implemented with ease, and, as we will see, yields reasonable performance out-of-the-box.

	N	P	R	F
Arabic	3566	52.7	49.6	**51.1**
Chinese	4791	66.4	52.2	**58.5**
Spanish	2487	63.4	63.6	**63.5**

Table 4: Performance of the cross-language propagation from English mention detection system onto Arabic, Chinese and Spanish texts. Performance is presented in terms of Precision (P), Recall (R), and F-measure (F). The column (N) shows the number of mentions in the test set.

Experimental results presented in Table 4 show the performance of applying this information transfer approach. For each source language (Arabic, Chinese, or Arabic), we show the performance of propagating mentions from the English text. Even though no training data to build a source language mention classifier is available, we still can detect mentions with reasonably high accuracy. We consider the obtained accuracy as reasonably good because, as an example, the performance of a system that attaches to every word its most frequent label (unigram) is around 25% F-measure on Arabic. Results in Table 4 also show that even though the Chinese-to-English SMT system is lower in term of BLEU than the Arbic-to-English SMT system (0.32 vs. 0.55), performance of the cross-language propagation from English mention detection system onto Chinese is better than the performance of the propagation from English mention detection system onto Arabic. One reason for this is that we notice that Chinese-to-English SMT system translates and aligns ACE categories better than Arabic-to-English SMT system.

7.2 Lexical Resources

In this section, we consider the case when we have available training data in the source language to be able to train a statistical classifier. We also consider that the classifier has access to lexical information *only*. Our goal here is to study the effectiveness of *adding* cross-language mention propagation information to improve mention detection performance on languages with limited resources.

Table 5 shows the performance of the 3 languages with and without cross-language mention propagation information from English, with the 3 propagation methods described in Section 4. One can see that propagating mention propagation information results in system performance increase[12]. When systems use the CIP method, no improvement can be observed on Arabic and Chinese, while a small improvement of 0.5F point is obtained on Spanish (74.5 vs. 75.0). In contrast, when systems use the CDP method an improvement is obtained in recall – which is to be expected, given the method – leading to systems with better performance in terms of F-measure: 1.6F points improvement for Arabic, 1.5F points improvement for Chinese and almost 3F points improvement for Spanish. The results for all the CDP transfers and the CIP for Spanish are statistically significant.

7.3 Lexical and Syntactic Resources

We represent in Table 6 mention detection system performance when syntactic resources are available in the source language, in addition to lexical re-

[12]Only systems' performance marked with † is not statistically significantly better.

		Baseline			CIP			CDP		
	N	P	R	F	P	R	F	P	R	F
Arabic:	3566	81.8	71.7	**76.4**	82.2	71.3	**76.4**†	82.6	73.9	**78.0**
Chinese:	4791	79.3	70.2	**74.5**	79.4	70.5	**74.7**†	79.8	72.5	**76.0**
Spanish:	2478	79.1	70.4	**74.5**	79.7	70.8	**75.0**	80.4	74.6	**77.4**

Table 5: Performance of Arabic, Chinese and Spanish mention detection using lexical features ("Baseline" column). Columns "CIP" stands for systems that add cross-language context independent mention propagation information and column "CDP" is for systems that add cross-language context dependent mention propagation information.

		Baseline			CIP			CDP		
	N	P	R	F	P	R	F	P	R	F
Arabic:	3566	82.2	72.6	**77.1**	82.7	72.9	**77.5**	83.2	74.5	**78.6**
Chinese:	4791	80.0	71.3	**75.5**	79.9	71.5	**75.5**†	81.0	72.4	**76.5**
Spanish:	2487	79.1	71.2	**74.9**	79.9	71.9	**75.7**	80.7	74.6	**77.5**

Table 6: Performance of Arabic, Chinese and Spanish mention detection using lexical and syntactic features (POS tags, chunk information, etc).

sources available in the previous Subsection. This experiment is important because it tests the effectiveness of the propagation approach in improving performance on languages with a typical level of resources.

Results show that even in this situation, the use of cross language mention propagation information still lead to considerable improvement: using the CDP transfer method yields improvements from $1.1F$ in Chinese to $2.6F$ in Spanish. Similar to the previous section, the use of CIP information did not improve performance significantly on Arabic (77.5 vs. 77.1) and Chinese (75.5 vs. 75.5) systems, but we notice an improvement in Spanish[13].

7.4 Lexical, Syntactic and Semantic Resources

This final section investigates whether the access to cross-language mention propagation information can still improve the performance of existing competitive mention detection systems trained on languages with large resources. In this case, systems have access to a full array of lexical, syntax, semantic information, including the output from other information extraction models. Table 7 presents the performance of mention detection systems on the three languages, in the familiar 3 propagation methods: again, results show that better performance is obtained when cross language mention information is used. Under CIP, almost no change in terms of performance is obtained for Arabic and Spanish, though a slight improvement can be observed for Chinese (76.9F vs. 75.8F). When CDP is used the performance of mention detection systems is improved by 0.9F for Arabic (80.9 vs. 80.0), 2.3F for Chinese (78.1F vs. 75.8F) and 1.9F for Spanish (78.1 vs. 76.2F). Once again, the results prove that the use of cross language mention propagation information, especially through CDP, is effective in improving the performance even in this case.

By comparing results across tables, one can note that systems having access to only lexical and cross language mention propagation information are as effective as systems having access to large set of information. For Chinese, we obtain a performance of 75.8F when the system has access to lexical, syntactic and output of other information extraction models. On the other hand, the same system has a slightly better performance of 76.0 when it has access to lexical and cross language mention propagation information. The same behavior is observed for Spanish, we obtain a performance of 76.2F when the system has access to lexical, syntactic and output of other information extraction models; compared to 77.4F when lexical and cross language mention information are used. This is not true for Arabic where having access to larger set of information led to better performance when compared to systems having access to lexical information and CDP information (80.0F vs. 78.0). We attribute this difference to the fact that in Arabic we use the output of larger number of information extraction models, and consequently a richer set of information.

[13]The dagger sign † marks the systems that are not statistically significantly better.

		Baseline			CIP			CDP		
	N	P	R	F	P	R	F	P	R	F
Arabic:	3566	83.6	76.8	**80.0**	83.9	77.0	**80.2**†	84.2	77.8	**80.9**
Chinese:	4791	81.1	71.3	**75.8**	81.4	73.0	**76.9**	81.7	74.8	**78.1**
Spanish:	2487	79.1	73.5	**76.2**	79.3	73.4	**76.2**†	80.1	76.2	**78.1**

Table 7: Performance of Arabic, Chinese and Spanish mention detection using lexical, syntactic and output of other information extraction models: full-blown systems.

The other observation that is worth making is that the improvement in performance has a decreasing tendency as more resources are available. The performance gain for CDP in Arabic goes from 1.6 to 1.5 to 0.9, and the one on Spanish goes from 2.9 to 2.6 to 1.9. The one on Chinese follows part of this trend, as it goes from 1.4 to 1.1 to 2.3. While the evidence here is not definitive, one can indeed note the reduced effectiveness of the method as more resources are available, which was indeed what we expected.

Results obtained by all these experiments help answer an important question: when trying to improve mention detection systems in a resource-poor language, should we invest in building resources or should we use propagation from a resource-rich language to (at least) bootstrap the process? The answer seems to be the latter.

8 Conclusion

This paper presents a new approach to mention detection in low, medium or high-resource languages, which benefits from projecting the output from a resource-rich language such as English. We show that even when no training data is available in one source language, we can still build a decently performing baseline mention detection system by only using resources from English. This approach requires a mention detection system on a resource-rich language and an SMT system that translate text from the source to the resource-rich language, both of which can be attained.

In cases when large resources are available in the source language, our cross language mention propagation technique is still able to further improve mention detection system performance. Experiments performed on the four languages of ACE 2007, with English chosen as the *resource-rich* language, show consistent and significant improvements across conditions and levels of linguistic sophistication. The experiments are conducted on clearly specified partitions of the ACE 2007 data set, so future comparisons against the presented work can be correctly and accurately made. We also note that systems that have access to lexical and cross language mention propagation information are as accurate as those that have access to lexical, syntactic and output of other information extraction models in the source language (but no cross-language resources). As future work, we plan to extend this work to use semi-supervised and unsupervised approaches that can make use of cross-language information propagation.

We believe that it is important for the research community to continue to invest in building better resources in “source” languages, as it looks the most promising approach. However, using a propagation approach can definitely help bootstrap the process.

Abstract

Bleu is the *de facto* standard for evaluation and development of statistical machine translation systems. We describe three real-world situations involving comparisons between different versions of the same systems where one can obtain improvements in Bleu scores that are questionable or even absurd. These situations arise because Bleu lacks the property of *decomposability*, a property which is also computationally convenient for various applications. We propose a very conservative modification to Bleu and a cross between Bleu and word error rate that address these issues while improving correlation with human judgments.

1 Introduction

Bleu (Papineni et al., 2002) was one of the first automatic evaluation metrics for machine translation (MT), and despite being challenged by a number of alternative metrics (Melamed et al., 2003; Banerjee and Lavie, 2005; Snover et al., 2006; Chan and Ng, 2008), it remains the standard in the statistical MT literature. Callison-Burch et al. (2006) have subjected Bleu to a searching criticism, with two real-world case studies of significant failures of correlation between Bleu and human adequacy/fluency judgments. Both cases involve comparisons between statistical MT systems and other translation methods (human post-editing and a rule-based MT system), and they recommend that the use of Bleu be restricted to comparisons between related systems or different versions of the same systems. In Bleu's defense, comparisons between different versions of the same system were exactly what Bleu was designed for.

However, we show that even in such situations, difficulties with Bleu can arise. We illustrate three ways that properties of Bleu can be exploited to yield improvements that are questionable or even absurd. All of these scenarios arose in actual practice and involve comparisons between different versions of the same statistical MT systems. They can be traced to the fact that Bleu is not *decomposable* at the sentence level: that is, it lacks the property that improving a sentence in a test set leads to an increase in overall score, and degrading a sentence leads to a decrease in the overall score. This property is not only intuitive, but also computationally convenient for various applications such as translation reranking and discriminative training. We propose a minimal modification to Bleu that reduces its nondecomposability, as well as a cross between Bleu and word error rate (WER) that is decomposable down to the subsentential level (in a sense to be made more precise below). Both metrics correct the observed problems and correlate with human judgments better than Bleu.

2 The Bleu metric

Let $g_k(w)$ be the multiset of all k-grams of a sentence w. We are given a sequence of candidate translations $\mathbf{c}$ to be scored against a set of sequences of reference translations, $\{\mathbf{r}^j\} = \mathbf{r}^1, \ldots, \mathbf{r}^R$:

$$\begin{aligned}
\mathbf{c} &= c_1, c_2, c_3, \ldots, c_N \\
\mathbf{r}^1 &= r^1_1, r^1_2, r^1_3, \ldots, r^1_N \\
&\vdots \\
\mathbf{r}^R &= r^R_1, r^R_2, r^R_3, \ldots, r^R_N
\end{aligned}$$

Then the Bleu score of **c** is defined to be

$$\text{Bleu}(\mathbf{c}, \{\mathbf{r}^j\}) = \prod_{k=1}^{4} pr_k(\mathbf{c}, \{\mathbf{r}^j\})^{\frac{1}{4}} \times bp(\mathbf{c}, \{\mathbf{r}^j\}) \quad (1)$$

where[1]

$$pr_k(\mathbf{c}, \{\mathbf{r}^j\}) = \frac{\sum_i \left| g_k(c_i) \cap \bigcup_j g_k(r_i^j) \right|}{\sum_i |g_k(c_i)|} \quad (2)$$

is the k-gram precision of **c** with respect to $\{\mathbf{r}^j\}$, and $bp(\mathbf{c}, \mathbf{r})$, known as the *brevity penalty*, is defined as follows. Let $\phi(x) = \exp(1 - 1/x)$. In the case of a single reference **r**,

$$bp(\mathbf{c}, \mathbf{r}) = \phi\left(\min\left\{1, \frac{\sum_i |c_i|}{\sum_i |r_i|}\right\}\right) \quad (3)$$

In the multiple-reference case, the length $|r_i|$ is replaced with an *effective reference length*, which can be calculated in several ways.

- In the original definition (Papineni et al., 2002), it is the length of the reference sentence whose length is *closest* to the test sentence.
- In the NIST definition, it is the length of the *shortest* reference sentence.
- A third possibility would be to take the *average* length of the reference sentences.

The purpose of the brevity penalty is to prevent a system from generating very short but precise translations, and the definition of effective reference length impacts how strong the penalty is. The NIST definition is the most tolerant of short translations and becomes more tolerant with more reference sentences. The original definition is less tolerant but has the counterintuitive property that decreasing the length of a test sentence can eliminate the brevity penalty. Using the average reference length seems attractive but has the counterintuitive property that an exact match with one of the references may not get a 100% score. Throughout this paper we use the NIST definition, as it is currently the definition most used in the literature and in evaluations.

The brevity penalty can also be seen as a stand-in for recall. The fraction $\frac{\sum_i |c_i|}{\sum_i |r_i|}$ in the definition of the brevity penalty (3) indeed resembles a weak recall score in which every guessed item counts as a match. However, with recall, the per-sentence score $\frac{|c_i|}{|r_i|}$ would never exceed unity, but with the brevity penalty, it can. This means that if a system generates a long translation for one sentence, it can generate a short translation for another sentence without facing a penalty. This is a serious weakness in the Bleu metric, as we demonstrate below using three scenarios, encountered in actual practice.

3 Exploiting the Bleu metric

3.1 The sign test

We are aware of two methods that have been proposed for significance testing with Bleu: bootstrap resampling (Koehn, 2004b; Zhang et al., 2004) and the sign test (Collins et al., 2005). In bootstrap resampling, we sample with replacement from the test set to synthesize a large number of test sets, and then we compare the performance of two systems on those synthetic test sets to see whether one is better 95% (or 99%) of the time. But Collins et al. (2005) note that it is not clear whether the conditions required by bootstrap resampling are met in the case of Bleu, and recommend the sign test instead. Suppose we want to determine whether a set of outputs **c** from a test system is better or worse than a set of baseline outputs **b**. The sign test requires a function $f(b_i, c_i)$ that indicates whether c_i is a better, worse, or same-quality translation relative to b_i. However, because Bleu is not defined on single sentences, Collins et al. use an approximation: for each i, form a composite set of outputs $\mathbf{b}' = \{b_1, \ldots, b_{i-1}, c_i, b_{i+1}, \ldots, b_N\}$, and compare the Bleu scores of **b** and $\mathbf{b}'$.

The goodness of this approximation depends on to what extent the comparison between **b** and $\mathbf{b}'$ is dependent only on b_i and c_i, and independent of the other sentences. However, Bleu scores are highly context-dependent: for example, if the sentences in **b** are on average ϵ words longer than the reference sentences, then c_i can be as short as $(N-1)\epsilon$ words

[1]We use the following definitions about multisets: if X is a multiset, let $\#_X(a)$ be the number of times a occurs in X. Then:

$$|X| \equiv \sum_a \#_X(a)$$
$$\#_{X\cap Y}(a) \equiv \min\{\#_X(a), \#_Y(a)\}$$
$$\#_{X\cup Y}(a) \equiv \max\{\#_X(a), \#_Y(a)\}$$

shorter than r_i without incurring the brevity penalty. Moreover, since the c_i are substituted in one at a time, we can do this for all of the c_i. Hence, $\mathbf{c}$ could have a disastrously low BLEU score (because of the brevity penalty) yet be found by the sign test to be significantly better than the baseline.

We have encountered this situation in practice: two versions of the same system with BLEU scores of 29.6 (length ratio 1.02) and 29.3 (length ratio 0.97), where the sign test finds the second system to be significantly better than the first (and the first system significantly better than the second). Clearly, in order for a significance test to be sensible, it should not contradict the observed scores, and should certainly not contradict itself. In the rest of this paper, except where indicated, all significance tests are performed using bootstrap resampling.

3.2 Genre-specific training

For several years, much statistical MT research has focused on translating newswire documents. One likely reason is that the DARPA TIDES program used newswire documents for evaluation for several years. But more recent evaluations have included other genres such as weblogs and conversation. The conventional wisdom has been that if one uses a single statistical translation system to translate text from several different genres, it may perform poorly, and it is better to use several systems optimized separately for each genre.

However, if our task is to translate documents from multiple known genres, but they are evaluated together, the BLEU metric allows us to use that fact to our advantage. To understand how, notice that our system has an optimal number of words that it should generate for the entire corpus: too few and it will be penalized by BLEU's brevity penalty, and too many increases the risk of additional non-matching k-grams. But these words can be distributed among the sentences (and genres) in any way we like. Instead of translating sentences from each genre with the best genre-specific systems possible, we can generate longer outputs for the genre we have more confidence in, while generating shorter outputs for the harder genre. This strategy will have mediocre performance on each individual genre (according to both intuition and BLEU), yet will receive a higher BLEU score on the combined test set than the combined systems optimized for each genre.

In fact, knowing which sentence is in which genre is not even always necessary. In one recent task, we translated documents from two different genres, without knowing the genre of any given sentence. The easier genre, newswire, also tended to have shorter reference sentences (relative to the source sentences) than the harder genre, weblogs. For example, in one dataset, the newswire reference sets had between 1.3 and 1.37 English words per Arabic word, but the weblog reference set had 1.52 English words per Arabic word. Thus, a system that is uniformly verbose across both genres will apportion more of its output to newswire than to weblogs, serendipitously leading to a higher score. This phenomenon has subsequently been observed by Och (2008) as well.

We trained three Arabic-English syntax-based statistical MT systems (Galley et al., 2004; Galley et al., 2006) using max-BLEU training (Och, 2003): one on a newswire development set, one on a weblog development set, and one on a combined development set containing documents from both genres. We then translated a new mixed-genre test set in two ways: (1) each document with its appropriate genre-specific system, and (2) all documents with the system trained on the combined (mixed-genre) development set. In Table 3, we report the results of both approaches on the entire test dataset as well as the portion of the test dataset in each genre, for both the genre-specific and mixed-genre trainings.

The genre-specific systems each outperform the mixed system on their own genre as expected, but when the same results are combined, the mixed system's output is a full BLEU point higher than the combination of the genre-specific systems. This is because the mixed system produces outputs that have about 1.35 English words per Arabic word on average: longer than the shortest newswire references, but shorter than the weblog references. The mixed system does worse on each genre but better on the combined test set, whereas, according to intuition, a system that does worse on the two subsets should also do worse on the combined test set.

3.3 Word deletion

A third way to take advantage of the BLEU metric is to permit an MT system to delete arbitrary words in the input sentence. We can do this by introducing new phrases or rules into the system that match words in the input sentence but generate no output; to these rules we attach a feature whose weight is tuned during max-Bleu training. Such rules have been in use for some time but were only recently discussed by Li et al. (2008).

When we add word-deletion rules to our MT system, we find that the Bleu increases significantly (Table 6, line 2). Figure 1 shows some examples of deletion in Chinese-English translation. The first sentence has a proper name, 麦格赛赛/*maigesaisai* 'Magsaysay', which has been mistokenized into four tokens. The baseline system attempts to translate the first two phonetic characters as "wheat Georgia," whereas the other system simply deletes them. On the other hand, the second sentence shows how word deletion can sacrifice adequacy for the sake of fluency, and the third sentence shows that sometimes word deletion removes words that could have been translated well (as seen in the baseline translation).

Does Bleu reward word deletion fairly? We note two reasons why word deletion might be desirable. First, some function words should truly be deleted: for example, the Chinese particle 的/*de* and Chinese measure words often have no counterpart in English (Li et al., 2008). Second, even content word deletion might be helpful if it allows a more fluent translation to be assembled from the remnants. We observe that in the above experiment, word deletion caused the absolute number of k-gram matches, and not just k-gram precision, to increase for all $1 \leq k \leq 4$.

Human evaluation is needed to conclusively determine whether Bleu rewards deletion fairly. But to control for these potentially positive effects of deletion, we tested a *sentence-deletion* system, which is the same as the word-deletion system but constrained to delete *all* of the words in a sentence or none of them. This system (Table 6, line 3) deleted 8–10% of its input and yielded a Bleu score with no significant decrease ($p \geq 0.05$) from the baseline system's. Given that our model treats sentences independently, so that it cannot move information from one sentence to another, we claim that deletion of nearly 10% of the input is a grave translation deficiency, yet Bleu is insensitive to it.

What does this tell us about word deletion? While acknowledging that some word deletions can improve translation quality, we suggest in addition that because word deletion provides a way for the system to translate the test set selectively, a behavior which we have shown that Bleu is insensitive to, part of the score increase due to word deletion is likely an artifact of Bleu.

4 Other metrics

Are other metrics susceptible to the same problems as the Bleu metric? In this section we examine several other popular metrics for these problems, propose two of our own, and discuss some desirable characteristics for any new MT evaluation metric.

4.1 Previous metrics

We ran a suite of other metrics on the above problem cases to see whether they were affected. In none of these cases did we repeat minimum-error-rate training; all these systems were trained using max-Bleu. The metrics we tested were:

- METEOR (Banerjee and Lavie, 2005), version 0.6, using the exact, Porter-stemmer, and WordNet synonmy stages, and the optimized parameters $\alpha = 0.81, \beta = 0.83, \gamma = 0.28$ as reported in (Lavie and Agarwal, 2007).

- GTM (Melamed et al., 2003), version 1.4, with default settings, except $e = 1.2$, following the WMT 2007 shared task (Callison-Burch et al., 2007).

- MaxSim (Chan and Ng, 2008), more specifically MaxSim$_n$, which skips the dependency relations.

On the sign test (Table 2), all metrics found significant differences consistent with the difference in score between the two systems. The problem related to genre-specific training does not seem to affect the other metrics (see Table 4), but they still manifest the unintuitive result that genre-specific training is sometimes worse than mixed-genre training. Finally, all metrics but GTM disfavored both word deletion and sentence deletion (Table 7).

4.2 Strict brevity penalty

A very conservative way of modifying the Bleu metric to combat the effects described above is to im-

Figure 1: Examples of word deletion. Underlined Chinese words were deleted in the word-deletion system; underlined English words correspond to deleted Chinese words.

pose a stricter brevity penalty. In Section 2, we presented the brevity penalty as a stand-in for recall, but noted that unlike recall, the per-sentence score $\frac{|c_i|}{|r_i|}$ can exceed unity. This suggests the simple fix of clipping the per-sentence recall scores in a similar fashion to the clipping of precision scores:

$$bp(\mathbf{c}, \mathbf{r}) = \phi\left(\frac{\sum_i \min\{|c_i|, |r_i|\}}{\sum_i |r_i|}\right) \quad (4)$$

Then if a translation system produces overlong translations for some sentences, it cannot use those translations to license short translations for other sentences. Call this revised metric Bleu-sbp (for Bleu *with strict brevity penalty*).

We can test this revised definition on the problem cases described above. Table 2 shows that Bleu-sbp resolves the inconsistency observed between Bleu and the sign test, using the example test sets from Section 3.1 (no max-Bleu-sbp training was performed). Table 5 shows the new scores of the mixed-genre example from Section 3.2 after max-Bleu-sbp training. These results fall in line with intuition—tuning separately for each genre leads to slightly better scores in all cases. Finally, Table 8 shows the Bleu-sbp scores for the word-deletion example from Section 3.3, using both max-Bleu training and max-Bleu-sbp training. We see that Bleu-sbp reduces the benefit of word deletion to an insignificant level on the test set, and severely punishes sentence deletion. When we retrain using max-Bleu-sbp, the rate of word deletion is reduced and sentence deletion is all but eliminated, and there are no significant differences on the test set.

4.3 4-gram recognition rate

All of the problems we have examined—except for word deletion—are traceable to the fact that Bleu is not a sentence-level metric. Any metric which is defined as a weighted average of sentence-level scores, where the weights are system-independent, will be immune to these problems. Note that any metric involving micro-averaged precision (in which the sentence-level counts of matches and guesses are summed separately before forming their ratio) cannot have this property. Of the metrics surveyed in the WMT 2007 evaluation-evaluation (Callison-Burch et al., 2007), at least the following metrics have this property: WER (Nießen et al., 2000), TER (Snover et al., 2006), and ParaEval-Recall (Zhou et al., 2006).

Moreover, this evaluation concern dovetails with a frequent engineering concern, that sentence-level scores are useful at various points in the MT pipeline: for example, minimum Bayes risk decoding (Kumar and Byrne, 2004), selecting oracle translations for discriminative reranking (Liang et al., 2006; Watanabe et al., 2007), and sentence-by-sentence comparisons of outputs during error analysis. A variation on Bleu is often used for these purposes, in which the k-gram precisions are "smoothed" by adding one to the numerator and denominator (Lin and Och, 2004); this addresses the problem of a zero k-gram match canceling out the entire score, but it does not address the problems illustrated above.

The remaining issue, word deletion, is more difficult to assess. It could be argued that part of the gain due to word deletion is caused by Bleu allowing a system to selectively translate those *parts* of a sentence on which higher precision can be obtained. It would be difficult indeed to argue that an evaluation metric, in order to be fair, must be decomposable into subsentential scores, and we make no such claim. However, there is again a dovetailing engineering concern which is quite legitimate. If one wants to select the minimum-Bayes-risk translation from a *lattice* (or shared forest) instead of an n-best list (Tromble et al., 2008), or to select an oracle translation from a lattice (Tillmann and Zhang, 2006; Dreyer et al., 2007; Leusch et al., 2008), or to perform discriminative training on all the examples contained in a lattice (Taskar et al., 2004), one would need a metric that can be calculated on the edges of the lattice.

Of the metrics surveyed in the WMT 2007 evaluation-evaluation, only one metric, to our knowledge, has this property: word error rate (Nießen et al., 2000). Here, we deal with the related *word recognition rate* (McCowan et al., 2005),

$$\begin{aligned}\mathrm{WRR} &= 1 - \mathrm{WER}\\ &= 1 - \min \frac{I + D + S}{|r|}\\ &= \max \frac{M - I}{|r|}\end{aligned} \tag{5}$$

where I is the number of insertions, D of deletions, S of substitutions, and $M = |r| - D - S$ the number of matches. The dynamic program for WRR can be formulated as a Viterbi search through a finite-state automaton: given a candidate sentence c and a reference sentence r, find the highest-scoring path matching c through the automaton with states $0, \ldots, |r|$, initial state 0, final state $|r|$, and the following transitions (a $\star$ matches any symbol):

For $0 \leq i < |r|$:

$$i \xrightarrow{r_{i+1}:1} i + 1 \qquad \text{match}$$

$$i \xrightarrow{\epsilon:0} i + 1 \qquad \text{deletion}$$

$$i \xrightarrow{\star:0} i + 1 \qquad \text{substitution}$$

For $0 \leq i \leq |r|$:

$$i \xrightarrow{\star:-1} i \qquad \text{insertion}$$

This automaton can be intersected with a typical stack-based phrase-based decoder lattice (Koehn, 2004a) or CKY-style shared forest (Chiang, 2007) in much the same way that a language model can, yielding a polynomial-time algorithm for extracting the best-scoring translation from a lattice or forest (Wagner, 1974). Intuitively, the reason for this is that WRR, like most metrics, implicitly constructs a word alignment between c and r and only counts matches between aligned words; but unlike other metrics, this alignment is constrained to be monotone.

We can combine WRR with the idea of k-gram matching in Bleu to yield a new metric, the *4-gram recognition rate*:

$$\text{4-GRR} = \max \frac{\sum_{k=1}^{4} M_k - \alpha I - \beta D}{\sum_{k=1}^{4} |g_k(r)|} \tag{6}$$

where M_k is the number of k-gram matches, α and β control the penalty for insertions and deletions, and g_k is as defined in Section 2. We presently set $\alpha = 1, \beta = 0$ by analogy with WRR, but explore other settings below. To calculate 4-GRR on a whole test set, we sum the numerators and denominators as in micro-averaged recall.

The 4-GRR can also be formulated as a finite-state automaton, with states $\{(i, m) \mid 0 \leq i \leq |r|, 0 \leq m \leq 3\}$, initial state $(0, 0)$, final states $(|r|, m)$, and the following transitions:

For $0 \leq i < |r|$, $0 \leq m \leq 3$:

$$(i, m) \xrightarrow{r_{i+1}:m+1} (i + 1, \min\{m + 1, 3\}) \qquad \text{match}$$

$$(i, m) \xrightarrow{\epsilon:-\beta} (i + 1, 0) \qquad \text{deletion}$$

$$(i, m) \xrightarrow{\star:0} (i + 1, 0) \qquad \text{substitution}$$

Metric	Adq	Flu	Rank	Con	Avg
Sem. role overlap	77.4	83.9	80.3	74.1	78.9
ParaEval recall	71.2	74.2	76.8	79.8	75.5
METEOR	70.1	71.9	74.5	66.9	70.9
Bleu	68.9	72.1	67.2	60.2	67.1
WER	51.0	54.2	34.5	52.4	48.0
Bleu-sbp	73.9	76.7	73.5	63.4	71.9
4-GRR	72.3	75.5	74.3	64.2	71.6

Table 1: Our new metrics correlate with human judgments better than Bleu (case-sensitive). Adq = Adequacy, Flu = Fluency, Con = Constituent, Avg = Average.

For $0 \leq i \leq |r|$, $0 \leq m \leq 3$:

$$(i, m) \xrightarrow{\star:-\alpha} (i, 0) \qquad \text{insertion}$$

Therefore 4-GRR can also be calculated efficiently on lattices or shared forests.

We did not attempt max-4-GRR training, but we evaluated the word-deletion test sets obtained by max-Bleu and max-Bleu-sbp training using 4-GRR. The results are shown in Table 7. In general, the results are very similar to Bleu-sbp except that 4-GRR sometimes scores word deletion slightly lower than baseline.

5 Correlation with human judgments

The shared task of the 2007 Workshop on Statistical Machine Translation (Callison-Burch et al., 2007) was conducted with several aims, one of which was to measure the correlation of several automatic MT evaluation metrics (including Bleu) against human judgments. The task included two datasets (one drawn from the Europarl corpus and the other from the News Commentary corpus) and across three language pairs (from German, Spanish, and French to English, and back). In our experiments, we focus on the tasks where the target language is English.

For human evaluations of the MT submissions, four different criteria were used:

- Adequacy: how much of the meaning expressed in the reference translation is also expressed in the hypothesis translation.
- Fluency: how well the translation reads in the target language.
- Rank: each translation is ranked from best to worst, relative to the other translations of the same sentence.
- Constituent: constituents are selected from source-side parse-trees, and human judges are asked to rank their translations.

We scored the workshop shared task submissions with Bleu-sbp and 4-GRR, then converted the raw scores to rankings and calculated the Spearman correlations with the human judgments. Table 1 shows the results along with Bleu and the three metrics that achieved higher correlations than Bleu: semantic role overlap (Giménez and Márquez, 2007), ParaEval recall (Zhou et al., 2006), and METEOR (Banerjee and Lavie, 2005). We find that both our proposed metrics correlate with human judgments better than Bleu does.

However, recall the parameters α and β in the definition of 4-GRR that control the penalty for inserted and deleted words. Experimenting with this parameter reveals that $\alpha = -0.9, \beta = 1$ yields a correlation of 78.9%. In other words, a metric that unboundedly rewards spuriously inserted words correlates better with human judgments than a metric that punishes them. We assume this is because there are not enough data points (systems) in the sample and ask that all these figures be taken with a grain of salt. As a general remark, it may be beneficial for human-correlation datasets to include a few straw-man systems that have very short or very long translations.

6 Conclusion

We have described three real-world scenarios involving comparisons between different versions of the same statistical MT systems where Bleu gives counterintuitive results. All these issues center around the issue of decomposability: the sign test fails because substituting translations one sentence at a time can improve the overall score yet substituting them all at once can decrease it; genre-specific training fails because improving the score of two halves of a test set can decrease the overall score; and sentence deletion is not harmful because generating empty translations for selected sentences does not necessarily decrease the overall score.

We proposed a minimal modification to Bleu, called Bleu-sbp, and showed that it ameliorates these problems. We also proposed a metric, 4-GRR, that is decomposable at the sentence level and is therefore guaranteed to solve the sign test, genre-specific tuning, and sentence deletion problems; moreoever, it is decomposable at the subsentential level, which has potential implications for evaluating word deletion and promising applications to translation reranking and discriminative training.

Acknowledgments

Our thanks go to Daniel Marcu for suggesting modifying the Bleu brevity penalty, and to Jonathan May and Kevin Knight for their insightful comments. This research was supported in part by DARPA grant HR0011-06-C-0022 under BBN Technologies subcontract 9500008412.

Abstract

We present Minimum Bayes-Risk (MBR) decoding over translation lattices that compactly encode a huge number of translation hypotheses. We describe conditions on the loss function that will enable efficient implementation of MBR decoders on lattices. We introduce an approximation to the BLEU score (Papineni et al., 2001) that satisfies these conditions. The MBR decoding under this approximate BLEU is realized using Weighted Finite State Automata. Our experiments show that the Lattice MBR decoder yields moderate, consistent gains in translation performance over N-best MBR decoding on Arabic-to-English, Chinese-to-English and English-to-Chinese translation tasks. We conduct a range of experiments to understand why Lattice MBR improves upon N-best MBR and study the impact of various parameters on MBR performance.

1 Introduction

Statistical language processing systems for speech recognition, machine translation or parsing typically employ the Maximum A Posteriori (MAP) decision rule which optimizes the 0-1 loss function. In contrast, these systems are evaluated using metrics based on string-edit distance (Word Error Rate), n-gram overlap (BLEU score (Papineni et al., 2001)), or precision/recall relative to human annotations. Minimum Bayes-Risk (MBR) decoding (Bickel and Doksum, 1977) aims to address this mismatch by selecting the hypothesis that minimizes the expected error in classification. Thus it directly incorporates the loss function into the decision criterion. The approach has been shown to give improvements over the MAP classifier in many areas of natural language processing including automatic speech recognition (Goel and Byrne, 2000), machine translation (Kumar and Byrne, 2004; Zhang and Gildea, 2008), bilingual word alignment (Kumar and Byrne, 2002), and parsing (Goodman, 1996; Titov and Henderson, 2006; Smith and Smith, 2007).

In statistical machine translation, MBR decoding is generally implemented by re-ranking an N-best list of translations produced by a first-pass decoder; this list typically contains between 100 and $10,000$ hypotheses. Kumar and Byrne (2004) show that MBR decoding gives optimal performance when the loss function is matched to the evaluation criterion; in particular, MBR under the sentence-level BLEU loss function (Papineni et al., 2001) gives gains on BLEU. This is despite the fact that the sentence-level BLEU loss function is an approximation to the exact corpus-level BLEU.

A different MBR inspired decoding approach is pursued in Zhang and Gildea (2008) for machine translation using Synchronous Context Free Grammars. A forest generated by an initial decoding pass is rescored using dynamic programming to maximize the expected count of synchronous constituents in the tree that corresponds to the translation. Since each constituent adds a new 4-gram to the existing translation, this approach approximately maximizes the expected BLEU.

In this paper we explore a different strategy to perform MBR decoding over *Translation Lattices* (Ueffing et al., 2002) that compactly encode a huge number of translation alternatives relative to an N-best list. This is a model-independent approach in that the lattices could be produced by any statistical MT system — both phrase-based and syntax-based systems would work in this framework. We will introduce conditions on the loss functions that can be incorporated in Lattice MBR decoding. We describe an approximation to the BLEU score (Papineni et al., 2001) that will satisfy these conditions. Our Lattice MBR decoding is realized using Weighted Finite State Automata.

We expect Lattice MBR decoding to improve upon N-best MBR primarily because lattices contain many more candidate translations than the N-best list. This has been demonstrated in speech recognition (Goel and Byrne, 2000). We conduct a range of translation experiments to analyze lattice MBR and compare it with N-best MBR. An important aspect of our lattice MBR is the linear approximation to the BLEU score. We will show that MBR decoding under this score achieves a performance that is at least as good as the performance obtained under sentence-level BLEU score.

The rest of the paper is organized as follows. We review MBR decoding in Section 2 and give the formulation in terms of a gain function. In Section 3, we describe the conditions on the gain function for efficient decoding over a lattice. The implementation of lattice MBR with Weighted Finite State Automata is presented in Section 4. In Section 5, we introduce the corpus BLEU approximation that makes it possible to perform efficient lattice MBR decoding. An example of lattice MBR with a toy lattice is presented in Section 6. We present lattice MBR experiments in Section 7. A final discussion is presented in Section 8.

2 Minimum Bayes Risk Decoding

Minimum Bayes-Risk (MBR) decoding aims to find the candidate hypothesis that has the least expected loss under the probability model (Bickel and Doksum, 1977). We begin with a review of MBR decoding for Statistical Machine Translation (SMT).

Statistical MT (Brown et al., 1990; Och and Ney, 2004) can be described as a mapping of a word sequence F in the source language to a word sequence E in the target language; this mapping is produced by the MT decoder $\delta(F)$. If the reference translation E is known, the decoder performance can be measured by the loss function $L(E, \delta(F))$. Given such a loss function $L(E, E')$ between an automatic translation E' and the reference E, and an underlying probability model $P(E|F)$, the MBR decoder has the following form (Goel and Byrne, 2000; Kumar and Byrne, 2004):

$$\begin{aligned}\hat{E} &= \operatorname*{argmin}_{E' \in \mathcal{E}} R(E') \\ &= \operatorname*{argmin}_{E' \in \mathcal{E}} \sum_{E \in \mathcal{E}} L(E, E') P(E|F),\end{aligned}$$

where $R(E')$ denotes the Bayes risk of candidate translation E' under the loss function L.

If the loss function between any two hypotheses can be bounded: $L(E, E') \leq L_{max}$, the MBR decoder can be rewritten in terms of a gain function $G(E, E') = L_{max} - L(E, E')$:

$$\hat{E} = \operatorname*{argmax}_{E' \in \mathcal{E}} \sum_{E \in \mathcal{E}} G(E, E') P(E|F). \qquad (1)$$

We are interested in performing MBR decoding under a sentence-level BLEU score (Papineni et al., 2001) which behaves like a gain function: it varies between 0 and 1, and a larger value reflects a higher similarity. We will therefore use Equation 1 as the MBR decoder.

We note that $\mathcal{E}$ represents the space of translations. For N-best MBR, this space $\mathcal{E}$ is the N-best list produced by a baseline decoder. We will investigate the use of a translation lattice for MBR decoding; in this case, $\mathcal{E}$ will represent the set of candidates encoded in the lattice.

In general, MBR decoding can use different spaces for hypothesis selection and risk computation: argmax and the sum in Equation 1 (Goel, 2001). As an example, the hypothesis could be selected from the N-best list while the risk is computed based on the entire lattice. Therefore, the MBR decoder can be more generally written as follows:

$$\hat{E} = \operatorname*{argmax}_{E' \in \mathcal{E}_h} \sum_{E \in \mathcal{E}_e} G(E, E') P(E|F), \qquad (2)$$

where $\mathcal{E}_h$ refers to the *Hypothesis space* from where the translations are chosen, and $\mathcal{E}_e$ refers to the *Evidence space* that is used for computing the Bayes-risk. We will present experiments (Section 7) to show the relative importance of these two spaces.

3 Lattice MBR Decoding

We now present MBR decoding on translation lattices. A translation word lattice is a compact representation for very large N-best lists of translation hypotheses and their likelihoods. Formally, it is an acyclic Weighted Finite State Acceptor (WFSA) (Mohri, 2002) consisting of states and arcs representing transitions between states. Each arc is labeled with a word and a weight. Each path in the lattice, consisting of consecutive transitions beginning at the distinguished initial state and ending at a final state, expresses a candidate translation. Aggregation of the weights along the path[1] produces the weight of the path's candidate $H(E, F)$ according to the model. In our setting, this weight will imply the posterior probability of the translation E given the source sentence F:

$$P(E|F) = \frac{\exp(\alpha H(E, F))}{\sum_{E' \in \mathcal{E}} \exp(\alpha H(E', F))}. \tag{3}$$

The scaling factor $\alpha \in [0, \infty)$ flattens the distribution when $\alpha < 1$, and sharpens it when $\alpha > 1$.

Because a lattice may represent a number of candidates exponential in the size of its state set, it is often impractical to compute the MBR decoder (Equation 1) directly. However, if we can express the gain function G as a sum of *local* gain functions g_i, then we now show that Equation 1 can be refactored and the MBR decoder can be computed efficiently. We loosely call a gain function local if it can be applied to all paths in the lattice via WFSA intersection (Mohri, 2002) without significantly multiplying the number of states.

In this paper, we are primarily concerned with local gain functions that weight n-grams. Let $\mathcal{N} = \{w_1, \dots, w_{|\mathcal{N}|}\}$ be the set of n-grams and let a local gain function $g_w : \mathcal{E} \times \mathcal{E} \to \mathbb{R}$, for $w \in \mathcal{N}$, be as follows:

$$g_w(E, E') = \theta_w \#_w(E') \delta_w(E), \tag{4}$$

where θ_w is a constant, $\#_w(E')$ is the number of times that w occurs in E', and $\delta_w(E)$ is 1 if $w \in E$ and 0 otherwise. That is, g_w is θ_w times the number of occurrences of w in E', or zero if w does not occur in E. We first assume that the overall gain function $G(E, E')$ can then be written as a sum of local gain functions and a constant θ_0 times the length of the hypothesis E'.

$$\begin{aligned} G(E, E') &= \theta_0|E'| + \sum_{w \in \mathcal{N}} g_w(E, E') \qquad (5) \\ &= \theta_0|E'| + \sum_{w \in \mathcal{N}} \theta_w \#_w(E') \delta_w(E) \end{aligned}$$

Given a gain function of this form, we can rewrite the risk (sum in Equation 1) as follows

$$\begin{aligned} &\sum_{E \in \mathcal{E}} G(E, E') P(E|F) \\ = &\sum_{E \in \mathcal{E}} \Big(\theta_0|E'| + \sum_{w \in \mathcal{N}} \theta_w \#_w(E') \delta_w(E)\Big) P(E|F) \\ = &\ \theta_0|E'| + \sum_{w \in \mathcal{N}} \theta_w \#_w(E') \sum_{E \in \mathcal{E}_w} P(E|F), \end{aligned}$$

where $\mathcal{E}_w = \{E \in \mathcal{E} | \delta_w(E) > 0\}$ represents the paths of the lattice containing the n-gram w at least once. The MBR decoder on lattices (Equation 1) can therefore be written as

$$\hat{E} = \operatorname*{argmax}_{E' \in \mathcal{E}} \Big\{\theta_0|E'| + \sum_{w \in \mathcal{N}} \theta_w \#_w(E') p(w|\mathcal{E})\Big\}. \tag{6}$$

Here $p(w|\mathcal{E}) = \sum_{E \in \mathcal{E}_w} P(E|F)$ is the posterior probability of the n-gram w in the lattice. We have thus replaced a summation over a possibly exponential number of items ($E \in \mathcal{E}$) with a summation over the number of n-grams that occur in $\mathcal{E}$, which is at worst polynomial in the number of edges in the lattice that defines $\mathcal{E}$. We compute the posterior probability of each n-gram w as:

$$p(w|\mathcal{E}) = \sum_{E \in \mathcal{E}_w} P(E|F) = \frac{Z(\mathcal{E}_w)}{Z(\mathcal{E})}, \tag{7}$$

where $Z(\mathcal{E}) = \sum_{E' \in \mathcal{E}} \exp(\alpha H(E', F))$ (denominator in Equation 3) and $Z(\mathcal{E}_w) = \sum_{E' \in \mathcal{E}_w} \exp(\alpha H(E', F))$. $Z(\mathcal{E})$ and $Z(\mathcal{E}_w)$ represent the sums[2] of weights of all paths in the lattices $\mathcal{E}_w$ and $\mathcal{E}$ respectively.

4 WFSA MBR Computations

We now show how the Lattice MBR Decision Rule (Equation 6) can be implemented using Weighted Finite State Automata (Mohri, 1997). There are four steps involved in decoding starting from weighted finite-state automata representing the candidate outputs of a translation system. We will describe these

[1] using the log semiring's *extend* operator

[2] in the log semiring, where $\log +(x, y) = \log(e^x + e^y)$ is the *collect* operator (Mohri, 2002)

steps in the setting where the evidence lattice $\mathcal{E}_e$ may be different from the hypothesis lattice $\mathcal{E}_h$ (Equation 2).

1. Extract the set of n-grams that occur in the evidence lattice $\mathcal{E}_e$. For the usual BLEU score, n ranges from one to four.

2. Compute the posterior probability $p(w|\mathcal{E})$ of each of these n-grams.

3. Intersect each n-gram w, with an appropriate weight (from Equation 6), to an initially unweighted copy of the hypothesis lattice $\mathcal{E}_h$.

4. Find the best path in the resulting automaton.

Computing the set of n-grams $\mathcal{N}$ that occur in a finite automaton requires a traversal, in topological order, of all the arcs in the automaton. Because the lattice is acyclic, this is possible. Each state q in the automaton has a corresponding set of n-grams $\mathcal{N}_q$ ending there.

1. For each state q, $\mathcal{N}_q$ is initialized to $\{\epsilon\}$, the set containing the empty n-gram.

2. Each arc in the automaton extends each of its source state's n-grams by its word label, and adds the resulting n-grams to the set of its target state. (ϵ arcs do not extend n-grams, but transfer them unchanged.) n-grams longer than the desired order are discarded.

3. $\mathcal{N}$ is the union over all states q of $\mathcal{N}_q$.

Given an n-gram, w, we construct an automaton matching any path containing the n-gram, and intersect that automaton with the lattice to find the set of paths containing the n-gram ($\mathcal{E}_w$ in Equation 7). Suppose $\mathcal{E}$ represent the weighted lattice, we compute[3]: $\mathcal{E}_w = \mathcal{E} \cap (\overline{w}\ w\ \Sigma^*)$, where $\overline{w} = (\overline{\Sigma^*\ w\ \Sigma^*})$ is the language that contains all strings that do not contain the n-gram w. The posterior probability $p(w|\mathcal{E})$ of n-gram w can be computed as a ratio of the total weights of paths in $\mathcal{E}_w$ to the total weights of paths in the original lattice (Equation 7).

For each n-gram $w \in \mathcal{N}$, we then construct an automaton that accepts an input E with weight equal to the product of the number of times the n-gram occurs in the input ($\#_w(E)$), the n-gram factor θ_w from Equation 6, and the posterior probability $p(w|\mathcal{E})$. The automaton corresponds to the weighted regular expression (Karttunen et al., 1996): $\bar{w}(w/(\theta_w p(w|\mathcal{E}))\ \bar{w})^*$.

We successively intersect each of these automata with an automaton that begins as an unweighted copy of the lattice $\mathcal{E}_h$. This automaton must also incorporate the factor θ_0 of each word. This can be accomplished by intersecting the unweighted lattice with the automaton accepting $(\Sigma/\theta_0)^*$. The resulting MBR automaton computes the total expected gain of each path. A path in this automaton that corresponds to the word sequence E' has cost: $\theta_0|E'| + \sum_{w\in\mathcal{N}} \theta_w \#_w(E) p(w|\mathcal{E})$ (expression within the curly brackets in Equation 6).

Finally, we extract the best path from the resulting automaton[4], giving the lattice MBR candidate translation according to the gain function (Equation 6).

5 Linear Corpus BLEU

Our Lattice MBR formulation relies on the decomposition of the overall gain function as a sum of local gain functions (Equation 5). We here describe a linear approximation to the log(BLEU score) (Papineni et al., 2001) which allows such a decomposition. This will enable us to rewrite the log(BLEU) as a linear function of n-gram matches and the hypothesis length. Our strategy will be to use a first order Taylor-series approximation to what we call the corpus log(BLEU) gain: the change in corpus log(BLEU) contributed by the sentence relative to not including that sentence in the corpus.

Let r be the reference length of the corpus, c_0 the candidate length, and $\{c_n|1 \leq n \leq 4\}$ the number of n-gram matches. Then, the corpus BLEU score $B(r, c_0, c_n)$ can be defined as follows (Papineni et al., 2001):

$$\begin{aligned} \log B &= \min\left(0, 1 - \frac{r}{c_0}\right) + \frac{1}{4}\sum_{n=1}^{4} \log \frac{c_n}{c_0 - \Delta_n}, \\ &\approx \min\left(0, 1 - \frac{r}{c_0}\right) + \frac{1}{4}\sum_{n=1}^{4} \log \frac{c_n}{c_0}, \end{aligned}$$

where we have ignored Δ_n, the difference between the number of words in the candidate and the num-

[3]in the log semiring (Mohri, 2002)

[4]in the $(\max, +)$ semiring (Mohri, 2002)

ber of n-grams. If L is the average sentence length in the corpus, $\Delta_n \approx (n-1)\frac{c_0}{L}$.

The corpus log(BLEU) gain is defined as the change in log(BLEU) when a new sentence's (E') statistics are added to the corpus statistics:

$$G = \log B' - \log B,$$

where the counts in B' are those of B plus those for the current sentence. We will assume that the brevity penalty (first term in the above approximation) does not change when adding the new sentence. In experiments not reported here, we found that taking into account the brevity penalty at the sentence level can cause large fluctuations in lattice MBR performance on different test sets. We therefore treat only c_ns as variables.

The corpus log BLEU gain is approximated by a first-order vector Taylor series expansion about the initial values of c_n.

$$G \approx \sum_{n=0}^{N} (c'_n - c_n) \left. \frac{\partial \log B'}{\partial c'_n} \right|_{c'_n = c_n}, \qquad (8)$$

where the partial derivatives are given by

$$\begin{aligned} \frac{\partial \log B}{\partial c_0} &= \frac{-1}{c_0}, \\ \frac{\partial \log B}{\partial c_n} &= \frac{1}{4c_n}. \end{aligned} \qquad (9)$$

Substituting the derivatives in Equation 8 gives

$$G = \Delta \log B \approx -\frac{\Delta c_0}{c_0} + \frac{1}{4}\sum_{n=1}^{4} \frac{\Delta c_n}{c_n}, \qquad (10)$$

where each $\Delta c_n = c'_n - c_n$ counts the statistic in the sentence of interest, rather than the corpus as a whole. This score is therefore a linear function in counts of words Δc_0 and n-gram matches Δc_n. Our approach ignores the count clipping present in the exact BLEU score where a correct n-gram present once in the reference but several times in the hypothesis will be counted only once as correct. Such an approach is also followed in Dreyer et al. (2007).

Using the above first-order approximation to gain in log corpus BLEU, Equation 9 implies that θ_0, θ_w from Section 3 would have the following values:

$$\begin{aligned} \theta_0 &= \frac{-1}{c_0} \\ \theta_w &= \frac{1}{4c_{|w|}}. \end{aligned} \qquad (11)$$

5.1 N-gram Factors

We now describe how the n-gram factors (Equation 11) are computed. The factors depend on a set of n-gram matches and counts (c_n; $n \in \{0, 1, 2, 3, 4\}$). These factors could be obtained from a decoding run on a development set. However, doing so could make the performance of lattice MBR very sensitive to the actual BLEU scores on a particular run. We would like to avoid such a dependence and instead, obtain a set of parameters which can be estimated from multiple decoding runs without MBR. To achieve this, we make use of the properties of n-gram matches. It is known that the average n-gram precisions decay approximately exponentially with n (Papineni et al., 2001). We now assume that the number of matches of each n-gram is a constant ratio r times the matches of the corresponding $n-1$ gram.

If the unigram precision is p, we can obtain the n-gram factors ($n \in \{1, 2, 3, 4\}$) (Equation 11) as a function of the parameters p and r, and the number of unigram tokens T:

$$\begin{aligned} \theta_0 &= \frac{-1}{T} \\ \theta_n &= \frac{1}{4Tp \times r^{n-1}} \end{aligned} \qquad (12)$$

We set p and r to the average values of unigram precision and precision ratio across multiple development sets. Substituting the above factors in Equation 6, we find that the MBR decision does not depend on T; therefore any value of T can be used.

6 An Example

Figure 1 shows a toy lattice and the final MBR automaton (Section 4) for BLEU with a maximum n-gram order of 2. We note that the MBR hypothesis (*bcde*) has a higher decoder cost relative to the MAP hypothesis (*abde*). However, *bcde* gets a higher expected gain (Equation 6) than *abde* since it shares more n-grams with the Rank-3 hypothesis (*bcda*). This illustrates how a lattice can help select MBR translations that can differ from the MAP translation.

7 Experiments

We now present experiments to evaluate MBR decoding on lattices under the linear corpus BLEU

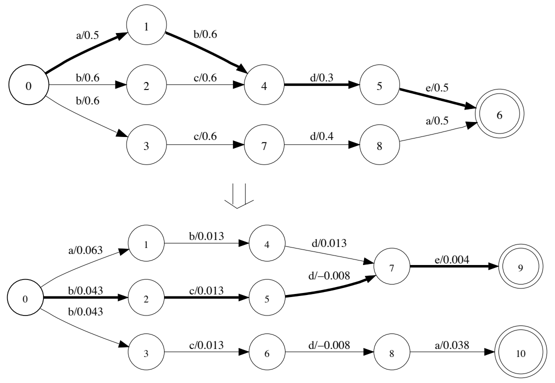

Figure 1: An example translation lattice with decoder costs (top) and its MBR Automaton for BLEU-2 (bottom). The bold path in the top is the MAP hypothesis and the bold path in the bottom is the MBR hypothesis. The precision parameters in Equation 12 are set to: $T = 10, p = 0.85, r = 0.72$.

gain. We start with a description of the data sets and the SMT system.

7.1 Development and Blind Test Sets

We present our experiments on the constrained data track of the NIST 2008 Arabic-to-English (aren), Chinese-to-English (zhen), and English-to-Chinese (enzh) machine translation tasks.[5] In all language pairs, the parallel and monolingual data consists of all the allowed training sets in the constrained track.

For each language pair, we use two development sets: one for Minimum Error Rate Training (Och, 2003; Macherey et al., 2008), and the other for tuning the scale factor for MBR decoding. Our development sets consists of the NIST 2004/2003 evaluation sets for both aren and zhen, and NIST 2006 (NIST portion)/2003 evaluation sets for enzh. We report results on NIST 2008 which is our blind test set. Statistics computed over these data sets are reported in Table 1.

[5]http://www.nist.gov/speech/tests/mt/

7.2 MT System Description

Our phrase-based statistical MT system is similar to the alignment template system described in Och and Ney (2004). The system is trained on parallel corpora allowed in the constrained track. We first perform sentence and sub-sentence chunk alignment on the parallel documents. We then train word alignment models (Och and Ney, 2003) using 6 Model-1 iterations and 6 HMM iterations. An additional 2 iterations of Model-4 are performed for zhen and enzh pairs. Word Alignments in both source-to-target and target-to-source directions are obtained using the Maximum A-Posteriori (MAP) framework (Matusov et al., 2004). An inventory of phrase-pairs up to length 5 is then extracted from the union of source-target and target-source alignments. Several feature functions are then computed over the phrase-pairs. 5-gram word language models are trained on the allowed monolingual corpora. Minimum Error Rate Training under BLEU is used for estimating approximately 20 feature function weights over the dev1 development set.

Translation is performed using a standard dynamic programming beam-search decoder (Och and Ney, 2004) using two decoding passes. The first decoder pass generates either a lattice or an N-best list. MBR decoding is performed in the second pass. The MBR scaling parameter (α in Equation 3) is tuned on the dev2 development set.

7.3 Translation Results

We next report translation results from lattice MBR decoding. All results will be presented on the NIST 2008 evaluation sets. We report results using the NIST implementation of the BLEU score which computes the brevity penalty using the shortest reference translation for each segment (NIST, 2002 2008). The BLEU scores are reported at the word-level for aren and zhen but at the character level for enzh. We measure statistical significance using 95% confidence intervals computed with paired bootstrap resampling (Koehn, 2004). In all tables, systems in a column show statistically significant differences unless marked with an asterisk.

We first compare lattice MBR to N-best MBR decoding and MAP decoding (Table 2). In these experiments, we hold the likelihood scaling factor α a

	BLEU(%)

1000-best	1000-best	44.2^*	28.1^*	42.2

Table 4: Lattice MBR with restrictions on hypothesis and evidence spaces. In each column, entries with an asterisk do not show statistically significant differences.

constant; it is set to 0.2 for aren and enzh, and 0.1 for zhen. The translation lattices are pruned using Forward-Backward pruning (Sixtus and Ortmanns, 1999) so that the average numbers of arcs per word (lattice density) is 30. For N-best MBR, we use N-best lists of size 1000. To match the loss function, Lattice MBR is performed at the word level for aren/zhen and at the character level for enzh. Our lattice MBR is implemented using the Google OpenFst library.[6] In our experiments, p, r (Equation 12) have values of 0.85/0.72, 0.80/0.62, and 0.63/0.48 for aren, zhen, and enzh respectively.

We note that Lattice MBR provides gains of 0.2-1.0 BLEU points over N-best MBR, which in turn gives 0.2-0.6 BLEU points over MAP. These gains are obtained on top of a baseline system that has competitive performance relative to the results reported in the NIST 2008 Evaluation.[7] This demonstrates the effectiveness of lattice MBR decoding as a realization of MBR decoding which yields substantial gains over the N-best implementation.

The gains from lattice MBR over N-best MBR could be due to a combination of factors. These include: 1) better approximation of the corpus BLEU score, 2) larger hypothesis space, and 3) larger evidence space. We now present experiments to tease apart these factors.

Our first experiment restricts both the hypothesis and evidence spaces in lattice MBR to the 1000-best list (Table 3). We compare this to N-best MBR with: a) sentence-level BLEU, and b) sentence-level log BLEU.

The results show that when restricted to the 1000-best list, Lattice MBR performs slightly better than N-best MBR (with sentence BLEU) on aren/enzh while N-best MBR is better on zhen. We hypothesize that on aren/enzh, the linear corpus BLEU gain (Equation 10) is better correlated to the actual corpus BLEU than sentence-level BLEU while the opposite is true on zhen. N-best MBR gives similar results with either sentence BLEU or sentence log BLEU. This confirms that using a log BLEU score does not change the outcome of MBR decoding and further justifies our Taylor-series approximation of the log BLEU score.

We next attempt to understand factors 2 and 3. To do that, we carry out lattice MBR when either the hypothesis or the evidence space in Equation 2 is restricted to 1000-best hypotheses (Table 4). For comparison, we also include results from lattice MBR when both hypothesis and evidence spaces are identical: either the full lattice or the 1000-best list (from Tables 2 and 3).

These results show that lattice MBR results are almost unchanged when the hypothesis space is restricted to a 1000-best list. However, when the evidence space is shrunk to a 1000-best list, there is a significant degradation in performance; these latter results are almost identical to the scenario when both evidence and hypothesis spaces are restricted to the 1000-best list. This experiment throws light on what makes lattice MBR effective over N-best MBR. Relative to the N-best list, the translation lattice provides a better estimate of the expected BLEU score. On the other hand, there are few hypotheses

[6]http://www.openfst.org/

[7] http://www.nist.gov/speech/tests/mt/2008/doc/mt08_official_results_v0.html

outside the 1000-best list which are selected by lattice MBR.

Finally, we show how the performance of lattice MBR changes as a function of the lattice density. The lattice density is the average number of arcs per word and can be varied using Forward-Backward pruning (Sixtus and Ortmanns, 1999). Figure 2 reports the average number of lattice paths and BLEU scores as a function of lattice density. The results show that Lattice MBR performance generally improves when the size of the lattice is increased. However, on zhen, there is a small drop beyond a density of 10. This could be due to low quality (low posterior probability) hypotheses that get included at the larger densities and result in a poorer estimate of the expected BLEU score. On aren and enzh, there are some gains beyond a lattice density of 30. These gains are relatively small and come at the expense of higher memory usage; we therefore work with a lattice density of 30 in all our experiments. We note that Lattice MBR is operating over lattices which are gigantic in comparison to the number of paths in an N-best list. At a lattice density of 30, the lattices in aren contain on an average about 10^{81} hypotheses!

7.4 Lattice MBR Scale Factor

We next examine the role of the scale factor α in lattice MBR decoding. The MBR scale factor determines the flatness of the posterior distribution (Equation 3). It is chosen using a grid search on the dev2 set (Table 1). Figure 3 shows the variation in BLEU scores on eval08 as this parameter is varied. The results show that it is important to tune this factor. The optimal scale factor is identical for all three language pairs. In experiments not reported in this paper, we have found that the optimal scaling factor on a moderately sized development set carries over to unseen test sets.

7.5 Maximum n-gram Order

Lattice MBR Decoding (Equation 6) involves computing a posterior probability for each n-gram in the lattice. We would like to speed up the Lattice MBR computation (Section 4) by restricting the maximum order of the n-grams in the procedure. The results (Table 5) show that on aren, there is no degradation if we limit the maximum order of the n-grams to 3. However, on zhen/enzh, there is improvement by considering 4-grams. We can therefore reduce Lattice MBR computations in aren.

	BLEU(%)		
Max n-gram order	aren	zhen	enzh
1	38.7	26.8	40.0
2	44.1	27.4	42.2
3	44.9	28.0	42.4
4	44.9	28.5	42.6

Table 5: Lattice MBR as a function of max n-gram order.

8 Discussion

We have presented a procedure for performing Minimum Bayes-Risk Decoding on translation lattices. This is a significant development in that the MBR decoder operates over a very large number of translations. In contrast, the current N-best implementation of MBR can be scaled to, at most, a few thousands of hypotheses. If the number of hypotheses is greater than, say 20,000, the N-best MBR becomes computationally expensive. The lattice MBR technique is efficient when performed over enormous number of hypotheses (up to 10^{80}) since it takes advantage of the compact structure of the lattice. Lattice MBR gives consistent improvements in translation performance over N-best MBR decoding, which is used in many state-of-the-art research translation systems. Moreover, we see gains on three different language pairs.

There are two potential reasons why Lattice MBR decoding could outperform N-best MBR: a larger hypothesis space from which translations could be selected or a larger evidence space for computing the expected loss. Our experiments show that the main improvement comes from the larger evidence space: a larger set of translations in the lattice provides a better estimate of the expected BLEU score. In other words, the lattice provides a better posterior distribution over translation hypotheses relative to an N-best list. This is a novel insight into the workings of MBR decoding. We believe this could be possibly employed when designing discriminative training approaches for machine translation. More generally, we have found a component in machine translation where the posterior distribution over hypotheses plays a crucial role.

We have shown the effect of the MBR scaling fac-

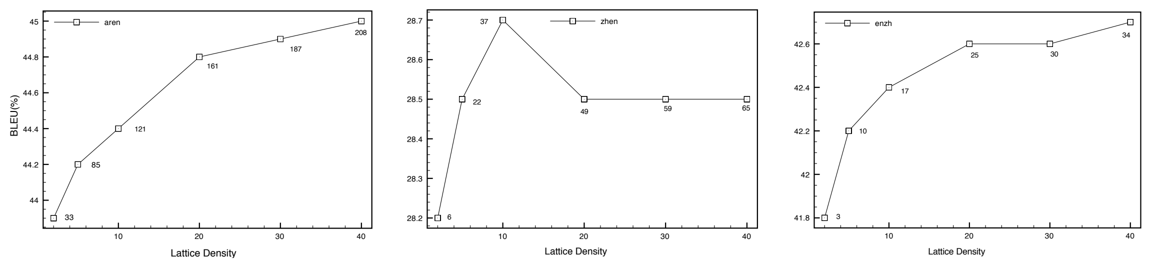

Figure 2: Lattice MBR vs. lattice density: aren/zhen/enzh. Each point also shows the $\log_e$(Avg. # of paths).

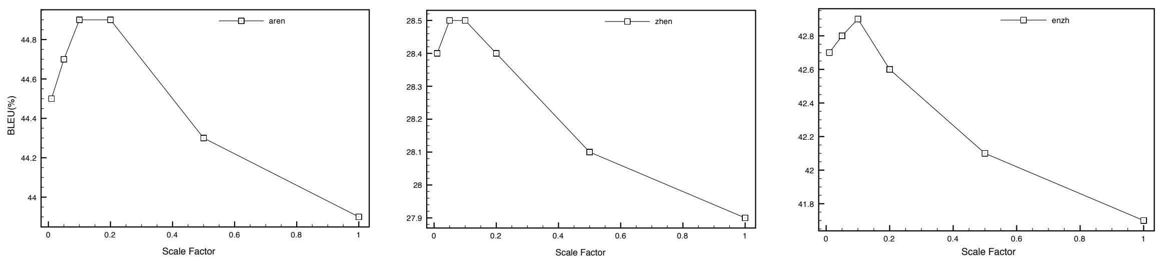

Figure 3: Lattice MBR with various scale factors α: aren/zhen/enzh.

tor on the performance of lattice MBR. The scale factor determines the flatness of the posterior distribution over translation hypotheses. A scale of 0.0 means a uniform distribution while 1.0 implies that there is no scaling. This is an important parameter that needs to be tuned on a development set. There has been prior work in MBR speech recognition and machine translation (Goel and Byrne, 2000; Ehling et al., 2007) which has shown the need for tuning this factor. Our MT system parameters are trained with Minimum Error Rate Training which assigns a very high posterior probability to the MAP translation. As a result, it is necessary to flatten the probability distribution so that MBR decoding can select hypotheses other than the MAP hypothesis.

Our Lattice MBR implementation is made possible due to the linear approximation of the BLEU score. This linearization technique has been applied elsewhere when working with BLEU: Smith and Eisner (2006) approximate the expectation of log BLEU score. In both cases, a linear metric makes it easier to compute the expectation. While we have applied lattice MBR decoding to the approximate BLEU score, we note that our procedure (Section 3) is applicable to other gain functions which can be decomposed as a sum of local gain functions. In particular, our framework might be useful with translation metrics such as TER (Snover et al., 2006) or METEOR (Lavie and Agarwal, 2007).

In contrast to a phrase-based SMT system, a syntax based SMT system (e.g. Zollmann and Venugopal (2006)) can generate a hypergraph that represents a generalized translation lattice with words and hidden tree structures. We believe that our lattice MBR framework can be extended to such hypergraphs with loss functions that take into account both BLEU scores as well as parse tree structures.

Lattice and Forest based search and training procedures are not yet common in statistical machine translation. However, they are promising because the search space of translations is much larger than the typical N-best list (Mi et al., 2008). We hope that our approach will provide some insight into the design of lattice-based search procedures along with the use of non-linear, global loss functions such as BLEU.

Abstract

The conditional phrase translation probabilities constitute the principal components of phrase-based machine translation systems. These probabilities are estimated using a heuristic method that does not seem to optimize any reasonable objective function of the word-aligned, parallel training corpus. Earlier efforts on devising a better understood estimator either do not scale to reasonably sized training data, or lead to deteriorating performance. In this paper we explore a new approach based on three ingredients (1) A generative model with a prior over latent segmentations derived from Inversion Transduction Grammar (ITG), (2) A phrase table containing all phrase pairs without length limit, and (3) Smoothing as learning objective using a novel Maximum-A-Posteriori version of Deleted Estimation working with Expectation-Maximization. Where others conclude that latent segmentations lead to overfitting and deteriorating performance, we show here that these three ingredients give performance equivalent to the heuristic method *on reasonably sized training data*.

1 Motivation

A major component in phrase-based statistical Machine translation (PBSMT) (Zens et al., 2002; Koehn et al., 2003) is the table of conditional probabilities of phrase translation pairs. The pervading method for estimating these probabilities is a simple heuristic based on the relative frequency of the phrase pair *in the multi-set of the phrase pairs extracted from the word-aligned corpus* (Koehn et al., 2003). While this heuristic estimator gives good empirical results, it does not seem to optimize any intuitively reasonable objective function of the (word-aligned) parallel corpus (see e.g., (DeNero et al., 2006)) The mounting number of efforts attacking this problem over the last few years (DeNero et al., 2006; Marcu and Wong, 2002; Birch et al., 2006; Moore and Quirk, 2007; Zhang et al., 2008) exhibits its difficulty. So far, none has lead to an alternative method that performs as well as the heuristic on *reasonably sized data (approx. 1000k sentence pair)*.

Given a parallel corpus, an estimator for phrase-tables in PBSMT involves two interacting decisions (1) which phrase pairs to extract, and (2) how to assign probabilities to the extracted pairs. The heuristic estimator employs word-alignment (Giza++) (Och and Ney, 2003) and a few thumb rules for defining phrase pairs, and then extracts a multi-set of phrase pairs and estimates their conditional probabilities based on the counts in the multi-set. Using this method for extracting a set of phrase pairs, (DeNero et al., 2006; Moore and Quirk, 2007) aim at defining a better estimator for the probabilities. Generally speaking, both efforts report deteriorating translation performance relative to the heuristic.

Instead of employing word-alignment to guide phrase pair extraction, it is theoretically more appealing to aim at phrase alignment as part of the estimation process (Marcu and Wong, 2002; Birch et al., 2006). This way, phrase pair extraction goes hand-in-hand with estimating the probabilities. However, in practice, due to the huge number of possible phrase pairs, this task is rather challenging, both computationally and statistically. It is hard to define both a manageable phrase pair translation model and a well-founded training regime that would scale up to reasonably sized parallel corpora (see e.g., (Birch et al., 2006)). It remains to be seen whether this theoretically interesting approach will lead to improved phrase probability estimates.

In this paper we also start out from a standard phrase extraction procedure based on word-alignment and aim solely at estimating the conditional probabilities for the phrase pairs and their reverse translation probabilities. Unlike preceding work, we extract *all phrase pairs* from the training corpus and estimate their probabilities, i.e., without limit on length. We present a novel formulation of a conditional translation model that works with a *prior over segmentations* and a bag of conditional phrase pairs. We use binary Synchronous Context-Free Grammar (bSCFG), based on Inversion Transduction Grammar (ITG) (Wu, 1997; Chiang, 2005a), to define the set of eligible segmentations for an aligned sentence pair. We also show how the number of spurious derivations per segmentation in this bSCFG can be used for devising a prior probability over the space of segmentations, capturing the bias *in the data* towards monotone translation. The heart of the estimation process is a new *smoothing estimator*, a penalized version of Deleted Estimation, which averages the temporary **probability estimates** of multiple parallel EM processes at each joint iteration.

For evaluation we use a state-of-the-art baseline system (Moses) (Hoang and Koehn, 2008) which works with a log-linear interpolation of feature functions optimized by MERT (Och, 2003). We simply substitute our own estimates for the heuristic phrase translation estimates (both directions and the phrase penalty score) and compare the two within the Moses decoder. While our estimates differ substantially from the heuristic, their performance is on par with the heuristic estimates. This is remarkable given the fact that comparable previous work (DeNero et al., 2006; Moore and Quirk, 2007) did not match the performance of the heuristic estimator using large training sets. We find that smoothing is crucial for achieving good estimates. This is in line with earlier work on consistent estimation for similar models (Zollmann and Sima'an, 2006), and agrees with the most up-to-date work that employs Bayesian priors over the estimates (Zhang et al., 2008).

2 Related work

Marcu and Wong (Marcu and Wong, 2002) realize that the problem of extracting phrase pairs should be intertwined with the method of probability estimation. They formulate a joint phrase-based model in which a source-target sentence pair is generated jointly. However, the huge number of possible *phrase-alignments* prohibits scaling up the estimation by Expectation-Maximization (EM) (Dempster et al., 1977) to large corpora. Birch et al (Birch et al., 2006) provide soft measures for including word-alignments in the estimation process and obtain improved results only on small data sets.

Coming up-to-date, (Blunsom et al., 2008) attempt a related estimation problem to (Marcu and Wong, 2002), using the expanded phrase pair set of (Chiang, 2005a), working with an exponential model and concentrating on marginalizing out the latent segmentation variable. Also most up-to-date, (Zhang et al., 2008) report on a multi-stage model, *without* a latent segmentation variable, but with a strong prior preferring sparse estimates embedded in a Variational Bayes (VB) estimator and concentrating the efforts on pruning both the space of phrase pairs and the space of (ITG) analyses. The latter two efforts report improved performance, albeit again on a limited training set (approx. 140k sentences up to a certain length).

DeNero et al (2006) have explored estimation using EM of phrase pair probabilities under a conditional translation model based on the original source-channel formulation. This model involves a hidden segmentation variable that is set uniformly (or to prefer shorter phrases over longer ones). Furthermore, the model involves a reordering component akin to the one used in IBM model 3. Despite this, the heuristic estimator remains superior because ”EM learns overly determinized segmentations and translation parameters, overfitting the training data and failing to generalize”. More recently, (Moore and Quirk, 2007) devise a estimator working with a model that does not include a hidden segmentation variable but works with a heuristic iterative procedure (rather than MLE or EM). The translation results remain inferior to the heuristic but the authors note an interesting trade-off between decoding speed and the various settings of this estimator.

Our work expands on the general approach taken by (DeNero et al., 2006; Moore and Quirk, 2007) but arrives at insights similar to those of the most recent work (Zhang et al., 2006), albeit in a completely different manner. The present work differs from all preceding work in that it employs the set of *all phrase pairs* during training. It differs from (Zhang et al., 2008) in that it does postulate a latent segmentation variable and puts the prior directly over that variable rather than over the ITG synchronous rule estimates. Our method neither excludes phrase pairs before estimation nor does it prune the space of possible segmentations/analyses during training/estimation. As well as smoothing, we find (in the same vein as (Zhang et al., 2008)) that setting effective priors/smoothing is crucial for EM to arrive at better estimates.

3 The Translation Model

Given a word-aligned parallel corpus of source-target sentences, it is common practice to extract a set of phrase pairs using extraction heuristics (cf. (Koehn et al., 2003; Och and Ney, 2004)). These heuristics define a phrase pair to consist of a source and target ngrams of a word-aligned source-target sentence pair such that if one end of an alignment is in the one ngram, the other end is in the other ngram (and there is at least one such alignment) (Och and Ney, 2004; Koehn et al., 2003). For efficiency and sparseness, the practitioners of PBSMT constrain the length of the source phrase to a certain maximum number of words.

An All Phrase Pairs Model: In this work we train a phrase-translation table that consists of *all phrase-pairs* that can be extracted from the word-aligned training data according to the standard phrase extraction heuristic. After training, we can still limit the set of phrase pairs to those selected by a cut-off on phrase length. The reason for using all phrase pairs during training is that it gives a clear point of reference for an estimator, without implicit, accidental biases that might emerge due to length cut-off[1].

The Generative Model: Given a word-aligned source-target sentence pair $\langle \mathbf{f}, \mathbf{e}, \mathbf{a} \rangle$, the generative story underlying our model goes as follows:

1. Abiding by the word-alignments in $\mathbf{a}$, segment the source-target sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle$ into a sequence of I containers σ_1^I, and a bag of I phrase pairs $\sigma_1^I(\mathbf{f}, \mathbf{e}) = \{\langle f_j, e_j \rangle\}_{j=1}^I$. Each container $\sigma_j = \langle l_f, r_f, l_e, r_e \rangle$ consists of the start l_f and end r_f positions[2] for a phrase in $\mathbf{f}$ and the start l_e and end r_e positions for an aligned phrase in $\mathbf{e}$.

2. For a given segmentation σ_1^I, for every container σ_j ($1 \leq j \leq I$) generate the phrase-pair $\langle f_j, e_j \rangle$, independently from all other phrase-pairs.

This leads to the following probabilistic model:

$$P(\mathbf{f} \mid \mathbf{e}; \mathbf{a}) = \sum_{\sigma_1^I \in \Sigma(\mathbf{a})} P(\sigma_1^I) \prod_{\langle f_j, e_j \rangle \in \sigma_1^I(\mathbf{f}, \mathbf{e})} P(f_j \mid e_j) \quad (1)$$

Where $\Sigma(\mathbf{a})$ is the set of *binarizable* segmentations (defined next) that are eligible according to the word-alignments $\mathbf{a}$ between $\mathbf{f}$ and $\mathbf{e}$. These segmentations into bilingual containers (where segmentations are taken inside the containers) are different from the monolingual segmentations used in earlier comparable conditional models (e.g., (DeNero et al., 2006)) which must generate the alignment on top of the segmentations. Note how the different phrase pairs $\langle f_j, e_j \rangle$ are generated from their bilingual containers in the given segmentation σ_1^I. We will discuss our choice of prior probability over segmentations $P(\sigma_1^I)$ after we discuss the definition of the binarizable segmentations $\Sigma(\mathbf{a})$.

3.1 Binarizable segmentations $\Sigma(\mathbf{a})$

Following (Zhang et al., 2006; Huang et al., 2008), every sequence of *phrase alignments* can be viewed

[1]For example, if the cut-off on phrase pairs is ten words, all sentence pairs smaller than ten words in the training data will be included as phrase pairs as well. These sentences are treated differently from longer sentences, which are not allowed to be phrase pairs.

[2]The NULL alignments (word-to-NULL) in the training data can also be marked with actual positions on both sides in order to allow for this definition of containers.

as a sequence of integers $1, \ldots I$ together with a permuted version of this sequence $\pi(1), \ldots, \pi(I)$, where the two copies of an integer in the two sequences are assumed aligned/paired together. For example, possible permutations of $\{1, 2, 3, 4\}$ are $\{2, 1, 3, 4\}$ and $\{2, 4, 1, 3\}$. Because a segmentation σ_1^I of a sentence pair is also a sequence of aligned phrases, it also constitutes a permuted sequence. A binarizable permutation $\mathbf{x}$ is either of length one, or can be **properly split** into two binarizable sub-sequences $\mathbf{y}$ and $\mathbf{z}$ such that either[3] $\mathbf{z} < y$ or $\mathbf{y} < z$. For example, one way to binarize the permutation $\{2, 1, 3, 4\}$ is to introduce a proper split into $\{2, 1; 3, 4\}$, then recursively another proper split of $\{2, 1\}$ into $\{2; 1\}$ and $\{3, 4\}$ into $\{3; 4\}$. In contrast, the permutation $\{2, 4, 1, 3\}$ is non-binarizable.

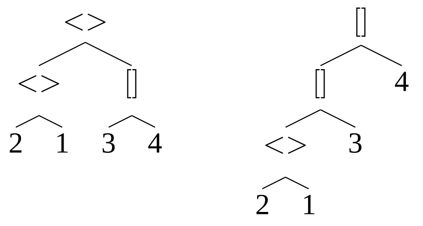

Figure 1: Multiple ways to binarize a permutation

Graphically speaking, the recursive definition of binarizable permutations can be depicted as a binary tree structure where the nodes correspond to recursive proper splits of the permutation, and the leaves are decorated with the naturals. Figure 1 exhibits two possible binarizations of the same permutation where <> and [] denote inverted and monotone proper splits respectively. Note that the number of possible binarizations of a binarizable permutation is a recursive function of the number of possible proper splits and reaches its maximum for fully monotone permutations (all binary trees, which is a factorial function of the length of the permutation).

By definition (cf. (Zhang et al., 2006; Huang et al., 2008)), a binarizable segmentation/permutation can be recognized by a binarized Synchronous Context-Free Grammar (SCFG), i.e., an SCFG in which the right hand sides of all non-lexical rules constitute binarizable permutations. In particular, this holds for the SCFG implementing Inversion Transduction Grammar (Wu, 1997). This SCFG (Chiang, 2005b) has two binary synchronous rules that correspond resp. to the contiguous monotone and inverted alignments:

$$\begin{aligned} XP &\rightarrow XP^{\boxed{1}}\, XP^{\boxed{2}},\ XP^{\boxed{1}}\, XP^{\boxed{2}} \\ XP &\rightarrow XP^{\boxed{1}}\, XP^{\boxed{2}},\ XP^{\boxed{2}}\, XP^{\boxed{1}} \end{aligned} \tag{2}$$

The boxed integers in the superscripts on the non-terminal XP denote synchronized rewritings. In this work, we employ a binary SCFG (bSCFG) working with these two synchronous rules together with a set of lexical rules $\{XP \rightarrow f,\ e \mid \langle f, e\rangle\ is\ a\ phrase\ pair\}$.

In this bSCFG, every derivation corresponds to a binarization of a segmentation of the input. Note that the bSCFG defined in equation 2 generates all possible binarizations for every segmentation of the input. It is possible to constrain this bSCFG such that it generates a single, canonical derivation per segmentation. However, in section 3.2 we show that the number of such derivations is a good measure of phrase pair productivity.

It is well known that there are alignments and segmentations that this bSCFG does not cover (see (Huang et al., 2008)). Recently, strong evidence emerged (e.g., (Huang et al., 2008)) showing that most word-alignments of actual parallel corpora can be covered by a binarized SCFG of the ITG type. Furthermore, because our model employs the set of *all phrase-pairs* that can be extracted from a given training set, it will always find segmentations that cover every sentence pair in the training data[4]. This implies that while our model might discard non-binarizable segmentations for certain complex word alignments, we do manage to train the model on the binarizable segementations of all sentence pairs.

Up to the prior over segmentations (see next), we implement the above model using a weighted version of the binary SCFG as follows:

- The weight for lexical rules is given by $P(XP \rightarrow f, e) := P(f \mid e)$, where $\langle f, e\rangle$ is a phrase-pair. These are the trainable parameters of our model.

[3]For two sequences of numbers, the notation $\mathbf{y} < z$ stands for $\forall y \in \mathbf{y}, \forall z \in \mathbf{z} : y < z$.

[4]In the worst case the whole sentence pair is a phrase pair with a trivial segmentation.

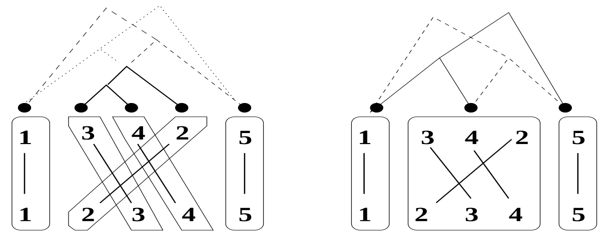

Figure 2: Two segmentations of an alignment/permutation. Both segmentations have the same number of binarizations despite differences in container sizes.

- The weights for the two non-lexical rules in equation 2 are fixed at 1.0. These weights are not trained at all.

Where we use the notation $P(.)$ for the weight of a synchronous rule.

3.2 Prior over segmentations

As it has been found out by (DeNero et al., 2006), it is not easy to come up with a simple, effective prior distribution over segmentations that allows for improved phrase pair estimates. Within a Maximum-Likelihood estimator, preference for segmentations σ_1^I consisting of longer containers could lead to overfitting as we will explain in section 4. Alternatively, it is tempting to have preference for segmentations σ_1^I that consist of shorter containers, because (generally speaking) shorter containers have higher expected coverage of new sentence pairs. However, mere bias for shorter containers will not give better estimates as observed by (DeNero et al., 2006). One case where this bias clearly fails is the case of a contiguous sequence of containers with a complex alignment structure (crossing alignments). For example (see figure 2), for the alignment $\{1, 3, 4, 2, 5\}$ there is a segmentation into five containers $\{1; 3; 4; 2; 5\}$, and another into three $\{1; 3, 4, 2; 5\}$. The first segmentation involves shorter containers that have crossing brackets among them, while the second one consists of three containers including a longer container $\{3, 4, 2\}$. In the first segmentation, due to their crossing alignments, each of the containers $\{3\}$, $\{4\}$ and $\{2\}$ will not combine with the surrounding context ($\{1\}$ and $\{5\}$) on its own, i.e., without the other two containers. Furthermore, there is only a single binarization of $\{3, 4, 2\}$. Hence, while the first segmentation involves shorter containers than the second one, these shorter containers are as *productive* as the large container $\{3, 4, 2\}$, i.e., they combine with surrounding containers in the same number of ways as the large container. In such and similar cases, there are no grounds for the bias towards shorter phrases/containers.

The notion of *container productivity* (the number of ways in which it combines with surrounding containers during training) seems to correlate with the expected number of ways a container can be used during decoding, which should be correlated with expected coverage. During training, containers that are often surrounded by other, monotonically aligned containers are expected to be more productive than alternative containers that are often surrounded by crossing alignments. Hence, the number of binarizations that a segmentation has under the bSCFG is a direct function of the ways in which the containers combine among themselves (monotone vs. inverted/crossing) within segmentations, and provides a more accurate measure of container productivity than container length. Hence, the final model we employ is the following:

$$P(\mathbf{f} \mid \mathbf{e}; \mathbf{a}) = \sum_{\sigma_1^I \in \Sigma(\mathbf{a})} \frac{N(\sigma_1^I)}{Z(\Sigma(\mathbf{a}))} \prod_{\langle f_j, e_j \rangle \in \sigma_1^I(\mathbf{f}, \mathbf{e})} P(f_j \mid e_j) \quad (3)$$

Where $N(\sigma_1^I)$ is the number of binary derivations/trees that σ_1^I has in the binary SCFG (bSCFG), and $Z(\Sigma(\mathbf{a})) = \sum_{\sigma_1^J \in \Sigma(\mathbf{a})} N(\sigma_1^J)$, i.e., this prior is the ratio of number of derivations of σ_1^I to the total number of derivations that $\langle \mathbf{f}, \mathbf{e}, \mathbf{a} \rangle$ has under the bSCFG.

3.3 Contrast with similar models:

In contrast with the model of (DeNero et al., 2006), who define the segmentations over the source sentence $\mathbf{f}$ alone, our model employs bilingual containers thereby segmenting both source and target sides simultaneously. Therefore, unlike (DeNero et al., 2006), our model does not need to generate the word-alignments explicitly, as these are embedded in the segmentations. Similarly, our model does not include *explicit* penalty terms for reordering/inversion but includes a related bias in the prior probabilities over segmentations $P(\sigma_1^I)$.

In a way, the segmentations and bilingual containers we use can be viewed as similar to the concepts used in the Joint Model of Marcu and Wong (Marcu and Wong, 2002). Unlike (Marcu and Wong, 2002), however, our model works with conditional probabilities and starts out from the word-alignments.

The novel aspects of our model are three (1) It defines the set of segmentations using a bSCFG, (2) It includes a novel, refined prior probability over segmentations, and (3) It employs all phrase pairs that can be extracted from a word-aligned training parallel corpus. For these novel elements to produce reasonable estimates, we devise our own estimator.

4 Estimation by Smoothing

In principle, we are dealing here with a translation model that employs all phrase pairs (of unbounded size), extracted from a word-aligned parallel corpus. Under this model, where a phrase pair and its sub-phrase pairs are included in the model, the MLE can be expected to overfit the data[5] unless a suitable prior probability over segmentations is employed. Indeed, the prior over segmentations defined in the preceding section prevents the MLE from completely overfitting the training data. However, we find empirical evidence that this prior is insufficient for avoiding overfitting.

Our model behaves like a *memory-based model* because it memorizes all extractable phrase pairs found in the training data including the training sentence pairs themselves. Such memory-based models are related to nonparametric models such as K-NN and kernel methods (Hastie et al., 2001). For memory-based models, consistent estimation for novel instances proceeds by local density estimation from the surroundings of the instance, which is akin to smoothing for parametric models. Hence, next we describe our own version of a *smoothed* Maximum-Likelihood estimator for phrase translation probabilities.

```
INPUT: Word-aligned parallel training data $T$
OUTPUT: Estimates $\pi$ for all $P(f \mid e)$
{
Split training data $T$ into equal parts $H_1, \ldots, H_{10}$.
For $1 \leq i \leq 10$ do
    Extract from $E_i = \cup_{j \neq i} H_j$ all phrase pairs $\pi_i$
    Initialize $\widehat{\pi}_i^0$ to uniform conditional probs
Let $j = 0$
Repeat
  Let $j = j + 1$        // EM iteration counter
  For $1 \leq i \leq 10$ do
      E-step: calculate expected counts for pairs
          in $\pi_i^j$ on $H_i$ using counts from $\widehat{\pi}_i^{j-1}$.
      M-step: calculate probabilities for pairs in
          $\pi_i^j$ from the expected counts
  For $1 \leq i \leq 10$ do $\widehat{\pi}_i^j := \frac{1}{10} \sum_{i=1}^{10} \pi_i^j$
Until $\pi := \{\widehat{\pi}_1^j, \ldots, \widehat{\pi}_{10}^j\}$ has converged
}
```

Figure 3: Penalized Deleted Estimation

For a latent variable model, it is usually common to employ Expectation-Maximization (EM) (Dempster et al., 1977) as a search method for a (local) maximum-likelihood estimate (MLE) of the training data. Instead of mere EM we opt for a *smoothed* version: we present a new method, that combines Deleted Estimation (Jelinek and Mercer, 1980) with the Jackknife (Duda et al., 2001) as the core estimator.

Figure 3 shows the pseudo-code for our estimator. Like in Deleted Estimation, we split the training data into ten equal portions. This way we create ten different splits of *extraction/heldout sets* of respectively 90%/10% of the training set. For every split $1 \leq i \leq 10$, we extract a set of phrase pairs π_i from the *extraction* set E_i and train it (under our model) on the *heldout set* H_i. Naturally, the phrase pair sets π_i ($1 \leq i \leq 10$) are subsets of (or equal to) the set of phrase pairs $\pi = \cup_i \pi_i$ extracted from the total training data (i.e., π is the set of model parameters). The training of the different π_i's, each on its corresponding heldout set H_i, is done by ten separate EM processes, which are synchronized in their initializa-

[5]One trivial MLE solution would give the longest container, consisting of the longest phrase pairs, a probability of one, at the cost of all shorter alternatives. A similar problem arises in Data-Oriented Parsing, see (Sima'an and Buratto, 2003; Zollmann and Sima'an, 2006). Note that models that employ an upperbound on phrase pair length will still risk overfitting training sentences of lengths that fall within this upperbound.

tion, their iterations as well as stop condition. The EM processes start out from uniform conditional estimates of the phrase pairs in all π_i. After every EM iteration j, when the M-step has finished, the estimates in all π_i^j ($1 \leq i \leq 10$) are set to the average (over $1 \leq i \leq 10$) of the estimates in π_i^j leading to $\widehat{\pi}_i^j$ (following the Jackknife method). The resulting averaged probabilities in $\widehat{\pi}_i^j$ are then used as the current phrase pair estimates, which feed into the next iteration $j+1$ of the different EM processes (each working on a different heldout set H_i with a different set of phrase pairs π_i).

There are two special boundary cases which demand special attention during estimation:

Sparse distributions: For a phrase e that does occur both in H_i and E_i, there could be a phrase pair $\langle f, e\rangle$ that does occur in H_i but does *not* occur in π_i. To prevent EM from giving the extra probability mass to all other pairs $\langle f, e^{'}\rangle$ unjustifiably, we apply smoothing. We add the missing pair $\langle f, e\rangle$ to π_i and set its probability to a fixed number 10^{-5*len}, where len is the length of the phrase pair. In effect, we backoff our model (equation 1) to a word-level model with fixed word translation probability (10^{-5}).

Zero distributions: When a phrase e does not occur in H_i, all its pairs $\langle f, e\rangle$ in π_i will have zero counts. During each EM iteration, when the M-step is applied, the distribution $P(\cdot \mid e)$ is undefined by MLE, since it is irrelevant for the likelihood of H_i. In this case any choice of proper distribution $P(\cdot \mid e)$ will constitute an MLE solution. We choose to set this case to a uniform distribution every time again.

Since our model and estimator are implemented within the bSCFG framework, we use a bilingual CYK parser (Younger, 1967) under the grammar in equation 2. This parser builds for every input $\langle \mathbf{f}, \mathbf{a}, \mathbf{e}\rangle$ all binarizations/derivations for every segmentation in $\Sigma(\mathbf{a})$. For implementing EM, we employ the Inside-Outside algorithm (Lari and Young, 1990; Goodman, 1998). During estimation, because the input, output and word-alignment are known in advance, the time and space requirements remain manageable despite the worst-case complexity $O(n^6)$ in target sentence length n.

Penalized Deleted Estimation: In contrast with our method, Deleted Estimation sums the *expected counts* (rather than probabilities) obtained from the different splits before applying the M-step (normalization). While the rationale behind Deleted Estimation comes from MLE over the original training data, our method has a smoothing objective (inspired by the Jackknife): generally speaking, the averages over different heldout sets (under different subsets of the model) give less sharp estimates than MLE. By averaging the different heldout estimates, this estimator employs a penalty term that depends on the marginal count of e in the heldout set[6]. Interestingly, when the phrase e is very frequent[7], it will approximately occur almost as often in the different heldout sets. In this case, our method reduces to Deleted Estimation, where it effectively sums the counts[8]. Yet, when the target phrase e does occur only very few times, it is likely that its count in some splits will be zero. In our method, at every EM iteration, during the Maximization step, we set such cases back to uniform. By averaging the probabilities from the different splits over many EM iterations, setting these cases to uniform constitutes a kind of prior that prevents the final estimates from falling too far from uniform. In contrast, in Deleted Interpolation the zero counts are simply summed with the other corresponding counts of the same phrase pair, which leads to sharper probability distributions. In all experiments that we conducted, our method (which we call *Penalized Deleted Estimation*) gave more successful estimates than mere Deleted Estimation.

On the theoretical side, the choice for a fixed

[6]Define $count_y(x)$ to be the count of event x in data y. The Deleted Estimation (DE) estimate is $\sum_H count_H(f,e)/count_T(e)$, which can be written as $\sum_H [count_H(f,e)/count_H(e)][count_H(e)/count_T(e)] = \sum_H \pi_H(f|e)[count_H(e)/count_T(e)]$ where $\pi_H(f|e)$ is the estimate from heldout set H. Hence, DE linearly interpolated π_H with factors $count_H(e)/count_T(e)$. Our estimator employs uniform interpolation factors instead, thereby penalizing the DI counts (hence Penalized DI).

[7]Theoretically speaking, when the training data is unboundedly large, our estimator will converge to the same estimates as the Deleted Estimation. When the data is still sparse, our estimator is biased, unlike the MLE which will overfit.

[8]When calculating the conditional probabilities, the denominators used are approximately equal to one another.

prior over segmentations (ITG prior) implies that our model cannot be estimated to converge (in probability) to the relative frequency estimates (RFE) of source-target sentence pairs in the limit of the training data (a sufficiently large parallel corpus). A prior probability over segmentations that would allow our estimator to converge in the limit to the RFE must gradually prefer segmentations consisting of larger containers as the data grows large. We set the design and estimation of such a prior aside for future work.

Decoding and Baseline Model: In this work we employ an existing decoder, Moses (Hoang and Koehn, 2008), which defines a log-linear model interpolating feature functions, with interpolation scores λ_f $\mathbf{e}^* = \arg\max_{\mathbf{e}} \sum_{f \in \Phi} \lambda_f H_f(\mathbf{f}, \mathbf{e})$. The λ_f are optimized by Minimum-Error Training (MERT) (Och, 2003). The set Φ consists of the following feature functions (see (Hoang and Koehn, 2008)): a 5-gram target language model, the standard reordering scores, the word and phrase penalty scores, the conditional lexical estimates obtained from the word-alignment in both directions, and the conditional phrase translation estimates in both directions $P(f \mid e)$ and $P(e \mid f)$. Keeping the other five feature functions fixed, we compare our estimates of $P(f \mid e)$ and $P(e \mid f)$ (and the phrase penalty) to the commonly used heuristic estimates.

Because our model employs a latent segmentation variable, this variable should be marginalized out during decoding to allow selecting the highest probability translation given the input. This turns out crucial for improved results (cf. (Blunsom et al., 2008)). However, such a marginalization can be NP-Complete, in analogy to a similar problem in Data-Oriented Parsing (Sima'an, 2002)[9]. We do not have a decoder yet that can approximate this marginalization efficiently and we employ the standard Moses decoder for this work.

Experimental Setup: The training, development and test data all come from the French-English translation shared task of the ACL 2007 Second Workshop on Statistical Machine Translation [10]. After pruning sentence pairs with word length more than 40 on either side, we are left with 949K sentence pairs for training. The development and test data are composed of 2K sentence pairs each. All data sets are lower-cased.

For both the baseline system and our method, we produce word-level alignments for the parallel training corpus using GIZA++. We use 5 iterations of each IBM Model 1 and HMM alignment models, followed by 3 iterations of each Model 3 and Model 4. From this aligned training corpus, we extract the phrase pairs according to the heuristics in (Koehn et al., 2003). The baseline system extracts all phrase-pairs upto a certain maximum length on both sides and employs the heuristic estimator. The language model used in all systems is a 5-gram language model trained on the English side of the parallel corpus. Minimum-Error Rate Training (MERT) is applied on the development set to obtain optimal log-linear interpolation weights for all systems. Performance is measured by computing the BLEU scores (Papineni et al., 2002) of the system's translations, when compared against a single reference translation per sentence.

Results: We compare different versions of our system against the baseline system using the heuristic estimator. We observe the effects of the ITG prior in the translation model as well as the method of estimation (Deleted Estimation vs. Penalized Deleted Estimation).

Table 1 exhibits the BLEU scores for the sys-

[9]A reduction of simple instances of the first problem to instances of the latter problem should be possible.

[10]http://www.statmt.org/wmt07

tems. Our own system (with ITG prior and Penalized Deleted Estimation and maximum phrase-length ten words) scores (33.14), slightly outperforming the best baseline system (33.03). When using straight Deleted Estimation over EM, this leads to deterioration (32.73). When also the ITG prior is excluded (by having a single derivation per segmentation) this leads to further deterioration (32.67). By using mere EM with an ITG prior, performance goes down to 32.50, exhibiting the crucial role of the estimation by smoothing. Clearly, Penalized Deleted Estimation and the ITG prior are important for the improved phrase translation estimates.

As table 1 shows we also varied the phrase length cutoff (seven, ten or none=all phrase pairs). The length cutoff pertains to both sides of a phrase-pair. For our estimator, we always train all phrase pairs, applying the length cutoff only after training (no re-normalization is applied at that point).

Interestingly, we find out that the heuristic estimator cannot benefit performance by including longer phrase pairs. Our estimator does benefit performance by including phrase pairs of length upto ten words, but then it degrades again when including all phrase pairs. We take the latter finding to signal remaining overfitting that proved resistant to the smoothing applied by our estimator. The heuristic estimator exhibits a similar degradation.

We also tried to vary the treatment of Sparse Distributions (section 4, page 7) during heldout estimation from fixed word-translation probabilities to the lexical model probabilities. This lead to slight deterioration of results (32.94). It is unclear whether this deterioration is meaningful or not. We did not explore mere EM without any smoothing or ITG prior, as we expect it will directly overfit the training data as reported by (DeNero et al., 2006).

We note that for French-English translation it is hard to outperform the heuristic within the PBSMT framework, since it already performs very well. Preliminary, most recent experiments on German-English (also WMT07 data) exhibit that our estimator outperforms the heuristic.

6 Discussion and Future Research

The most similar efforts to ours, mainly (DeNero et al., 2006), conclude that segmentation variables in the generative translation model lead to overfitting while attaining higher likelihood of the training data than the heuristic estimator. Based on this advise (Moore and Quirk, 2007) exclude the latent segmentation variables and opt for a heuristic training procedure. In this work we also start out from a generative model with latent segmentation variables. However, we find out that concentrating the learning effort on smoothing is crucial for good performance. For this, we devise ITG-based priors over segmentations and employ a penalized version of Deleted Estimation working with EM at its core. The fact that our results (at least) match the heuristic estimates on a reasonably sized data set (947k parallel sentence pairs) is rather encouraging.

The work in (Zhang et al., 2008) has a similar flavor to our work, yet the two differ substantially. Both depart from Maximum-Likelihood towards non-overfitting estimators. Where Zhang et al choose for sparse priors (leading to sharp phrase distributions) and put the smoothing burden on the ITG rule parameters and a pruning strategy, we choose for a prior over segmentations determined by the ITG derivation space and smooth the MLE directly with a penalized version of Deleted Estimation. It remains to be seen how the two biases compare to one another on the same task.

There are various strands of future research. Firstly, we plan to explore our estimator on other language pairs in order to obtain more evidence on its behavior. Secondly, as (Blunsom et al., 2008) show, marginalizing out the different segmentations during decoding leads to improved performance. We plan to build our own decoder (based on ITG) where different ideas can be tested including tractable ways for achieving a marginalization effect. Apart from a new decoder, it will be worthwhile adapting the prior probability in our model to allow for consistent estimation. Finally, it would be interesting to study properties of the penalized Deleted Estimation used in this paper.

Unsupervised Models for Coreference Resolution

vince@hlt.utdallas.edu

Abstract

We present a generative model for unsupervised coreference resolution that views coreference as an EM clustering process. For comparison purposes, we revisit Haghighi and Klein's (2007) fully-generative Bayesian model for unsupervised coreference resolution, discuss its potential weaknesses and consequently propose three modifications to their model. Experimental results on the ACE data sets show that our model outperforms their original model by a large margin and compares favorably to the modified model.

1 Introduction

Coreference resolution is the problem of identifying which *mentions* (i.e., noun phrases) refer to which real-world *entities*. The availability of annotated coreference corpora produced as a result of the MUC conferences and the ACE evaluations has prompted the development of a variety of supervised machine learning approaches to coreference resolution in recent years. The focus of learning-based coreference research has also shifted from the acquisition of a *pairwise* model that determines whether two mentions are co-referring (e.g., Soon et al. (2001), Ng and Cardie (2002), Yang et al. (2003)) to the development of rich linguistic features (e.g., Ji et al. (2005), Ponzetto and Strube (2006)) and the exploitation of advanced techniques that involve joint learning (e.g., Daumé III and Marcu (2005)) and joint inference (e.g., Denis and Baldridge (2007)) for coreference resolution and a related extraction task. The rich features, coupled with the increased complexity of coreference models, have made these supervised approaches more dependent on labeled data and less applicable to languages for which little or no annotated data exists. Given the growing importance of multi-lingual processing in the NLP community, however, the development of unsupervised and weakly supervised approaches for the automatic processing of resource-scarce languages has become more important than ever.

In fact, several popular weakly supervised learning algorithms such as self-training, co-training (Blum and Mitchell, 1998), and EM (Dempster et al., 1977) have been applied to coreference resolution (Ng and Cardie, 2003) and the related task of pronoun resolution (Müller et al., 2002; Kehler et al., 2004; Cherry and Bergsma, 2005). Given a small number of coreference-annotated documents and a large number of unlabeled documents, these weakly supervised learners aim to incrementally augment the labeled data by iteratively training a classifier[1] on the labeled data and using it to label mention pairs randomly drawn from the unlabeled documents as COREFERENT or NOT COREFERENT. However, classifying mention pairs using such iterative approaches is undesirable for coreference resolution: since the non-coreferent mention pairs significantly outnumber their coreferent counterparts, the resulting classifiers generally have an increasing tendency to (mis)label a pair as non-coreferent as bootstrapping progresses (see Ng and Cardie (2003)).

Motivated in part by these results, we present a generative, unsupervised model for probabilistically

[1]For co-training, a pair of *view* classifiers are trained; and for EM, a generative model is trained instead.

inducing coreference *partitions* on unlabeled *documents*, rather than classifying mention pairs, via EM clustering (Section 2). In fact, our model combines the best of two worlds: it operates at the document level, while exploiting essential linguistic constraints on coreferent mentions (e.g., gender and number agreement) provided by traditional pairwise classification models.

For comparison purposes, we revisit a fully-generative Bayesian model for unsupervised coreference resolution recently introduced by Haghighi and Klein (2007), discuss its potential weaknesses and consequently propose three modifications to their model (Section 3). Experimental results on the ACE data sets show that our model outperforms their original model by a large margin and compares favorably to the modified model (Section 4).

2 Coreference as EM Clustering

In this section, we will explain how we recast unsupervised coreference resolution as EM clustering. We begin by introducing some of the definitions and notations that we will use in this paper.

2.1 Definitions and Notations

A *mention* can be a pronoun, a name (i.e., a proper noun), or a nominal (i.e., a common noun). An *entity* is a set of coreferent mentions. Given a document D consisting of n mentions, $m_1, \ldots, m_n$, we use $Pairs(D)$ to denote the set of $\binom{n}{2}$ mention pairs, $\{m_{ij} \mid 1 \leq i < j \leq n\}$, where m_{ij} is formed from mentions m_i and m_j. The *pairwise probability* formed from m_i and m_j refers to the probability that the pair m_{ij} is coreferent and is denoted as $P_{coref}(m_{ij})$. A *clustering* of n mentions is an n x n Boolean matrix C, where C_{ij} (the (i,j)-th entry of C) is 1 if and only if mentions m_i and m_j are coreferent. An entry in C is *relevant* if it corresponds to a mention pair in $Pairs(D)$. A *valid clustering* is a clustering in which the relevant entries satisfy the transitivity constraint. In other words, C is valid if and only if $(C_{ij} = 1 \wedge C_{jk} = 1) \Longrightarrow C_{ik} = 1$ $\forall\ 1 \leq i < j < k \leq n$. Hence, a valid clustering corresponds to a *partition* of a given set of mentions, and the goal of coreference resolution is to produce a valid clustering in which each cluster corresponds to a distinct entity.

2.2 The Model

As mentioned previously, our generative model operates at the document level, inducing a valid clustering on a given document D. More specifically, our model consists of two steps. It first chooses a clustering C based on some clustering distribution $P(C)$, and then generates D given C:

$$P(D, C) = P(C)P(D \mid C).$$

To facilitate the incorporation of linguistic constraints defined on a pair of mentions, we represent D by its mention pairs, $Pairs(D)$. Now, assuming that these mention pairs are generated conditionally independently of each other given C_{ij},

$$P(D \mid C) = \prod_{m_{ij} \in Pairs(D)} P(m_{ij} \mid C_{ij}).$$

Next, we represent m_{ij} as a set of seven features that is potentially useful for determining whether m_i and m_j are coreferent (see Table 1).[2] Hence, we can rewrite $P(D \mid C)$ as

$$\prod_{m_{ij} \in Pairs(D)} P(m_{ij}^1, \ldots, m_{ij}^7 \mid C_{ij}),$$

where m_{ij}^k is the value of the kth feature of m_{ij}.

To reduce data sparseness and improve the estimation of the above probabilities, we make conditional independence assumptions about the generation of these feature values. Specifically, as shown in the first column of Table 1, we divide the seven features into three *groups* (namely, strong coreference indicators, linguistic constraints, and mention types), assuming that two feature values are conditionally independent if and only if the corresponding features belong to different groups. With this assumption, we can decompose $P(m_{ij}^1, \ldots m_{ij}^7 \mid C_{ij})$ into a product of three probabilities: $P(m_{ij}^1, m_{ij}^2, m_{ij}^3 \mid C_{ij})$, $P(m_{ij}^4, m_{ij}^5, m_{ij}^6 \mid C_{ij})$, and $P(m_{ij}^7 \mid C_{ij})$. Each of these distributions represents a pair of multinomial distributions, one for the coreferent mention pairs (C_{ij} = 1) and the other for the non-coreferent mention pairs (C_{ij} = 0). Hence, the set of parameters of our model, Θ, consists of $P(m^1, m^2, m^3 \mid c)$, $P(m^4, m^5, m^6 \mid c)$, and $P(m^7 \mid c)$.

[2]See Soon et al. (2001) for details on feature value computations. Note that all feature values are computed automatically.

Feature Type	Feature ID	Feature	Description
Strong Coreference Indicators	1	STR_MATCH	T if neither of the two mentions is a pronoun and after discarding determiners, the string denoting mention m_i is identical to that of mention m_j; else F.
	2	ALIAS	T if one mention is an acronym, an abbreviation, or a name variant of the other; else F. For instance, *Bill Clinton* and *President Clinton* are aliases, so are *MIT* and *Massachusetts Institute of Technology*.
	3	APPOSITIVE	T if the mentions are in an appositive relationship; else F.
Linguistic Constraints	4	GENDER	T if the mentions agree in gender; F if they disagree; NA if gender information for one or both mentions cannot be determined.
	5	NUMBER	T if the mentions agree in number; F if they disagree; NA if number information for one or both mentions cannot be determined.
	6	SEM_CLASS	T if the mentions have the same semantic class; F if they don't; NA if the semantic class information for one or both mentions cannot be determined.
Mention Types	7	NPTYPE	the feature value is the concatenation of the mention type of the two mentions, $t_i t_j$, where $t_i, t_j \in \{$ PRONOUN, NAME, NOMINAL $\}$.

Table 1: Feature set for representing a mention pair. The first six features are relational features that test whether some property P holds for the mention pair under consideration and indicate whether the mention pair is **T**RUE or **F**ALSE w.r.t. P; a value of **N**OT **A**PPLICABLE is used when property P does not apply.

2.3 The Induction Algorithm

To induce a clustering C on a document D, we run EM on our model, treating D as observed data and C as hidden data. Specifically, we use EM to iteratively estimate the model parameters, Θ, from documents that are probabilistically labeled (with clusterings) and apply the resulting model to probabilistically re-label a document (with clusterings). More formally, we employ the following EM algorithm:

E-step: Compute the posterior probabilities of the clusterings, $P(C|D, \Theta)$, based on the current Θ.

M-step: Using $P(C|D, \Theta)$ computed in the E-step, find the Θ' that maximizes the expected complete log likelihood, $\sum_C P(C|D, \Theta) \log P(D, C|\Theta')$.

We begin the induction process at the M-step.[3] To find the Θ that maximizes the expected complete log likelihood, we use maximum likelihood estimation with add-one smoothing. Since $P(C|D, \Theta)$ is not available in the first EM iteration, we instead use an initial distribution over clusterings, $P(C)$. The question, then, is: which $P(C)$ should we use? One possibility is the uniform distribution over all (possibly invalid) clusterings. Another, presumably better, choice is a distribution that assigns non-zero probability mass to only the valid clusterings. Yet another possibility is to set $P(C)$ based on a document labeled with coreference information. In our experiments, we employ this last method, assigning a probability of one to the correct clustering of the labeled document (see Section 4.1 for details).

After (re-)estimating Θ in the M-step, we proceed to the E-step, where the goal is to find the conditional clustering probabilities. Given a document D, the number of coreference clusterings is exponential in the number of mentions in D, even if we limit our attention to those that are valid. To cope with this computational complexity, we approximate the E-step by computing only the conditional probabilities that correspond to the N most probable coreference clusterings given the current Θ. We identify the N most probable clusterings and compute their probabilities as follows. First, using the current Θ, we reverse the generative model and compute $P_{coref}(m_{ij})$ for each mention pair m_{ij} in $Pairs(D)$. Next, using these pairwise probabilities, we apply Luo et al.'s (2004) Bell tree approach to coreference resolution to compute the N-best clusterings and their probabilities (see Section 2.4 for details). Finally, to obtain the required conditional clustering probabilities for the E-step, we normalize the probabilities assigned to the N-best clusterings so that they sum to one.

2.4 Computing the N-Best Partitions

As described above, given the pairwise probabilities, we use Luo et al.'s (2004) algorithm to heuristically compute the N-best clusterings (or, more precisely, N-best partitions[4]) and their probabilities based on

[3]Another possibility, of course, is to begin at the E-step by making an initial guess at Θ.

[4]Note that Luo et al.'s search algorithm only produces valid clusterings, implying that the resulting N-best clusterings are

```
Input: $M = \{m_1, ..., m_n\}$: mentions, $N$: no. of best partitions
Output: $N$-best partitions
 1: // initialize the data structures that store partial partitions
 2: $H_1 := \{PP := \{[m_1]\}\}$, $S(PP) = 1$
 3: $H_2, ..., H_n = \emptyset$
 4: for $i$ = 2 to $n$
 5:    // process each partial partition
 6:    foreach $PP \in H_{i-1}$
 7:       // process each cluster in PP
 8:       foreach $C \in PP$
 9:          Extend $PP$ to $PP'$ by linking $m_i$ to $C$
10:          Compute $S(PP')$
11:          $H_i := H_i \cup \{PP'\}$
12:       Extend $PP$ to $PP^\delta$ by putting $m_i$ into a new cluster
13:       Compute $S(PP^\delta)$
14:       $H_i := H_i \cup \{PP^\delta\}$
15: return $N$ most probable partitions in $H_n$
```

Figure 1: Our implementation of Luo et al.'s algorithm

the Bell tree. Informally, each node in a Bell tree corresponds to an ith-order *partial* partition (i.e., a partition of the first i mentions of the given document), and the ith level of the tree contains *all* possible ith-order partial partitions. Hence, the set of leaf nodes constitutes all possible partitions of all of the mentions. The search for the N most probable partitions starts at the root, and a partitioning of the mentions is incrementally constructed as we move down the tree. Since an exhaustive search is computationally infeasible, Luo et al. employ a beam search procedure to explore only the most probable paths at each step of the search process. Figure 1 shows our implementation of this heuristic search algorithm.

The algorithm takes as input a set of n mentions (and their pairwise probabilities), and returns the N most probable partitionings of the mentions. It uses data structures S and the H_i's to store intermediate results. Specifically, $S(PP)$ stores the score of the partial partition PP. H_i is associated with the ith level of the Bell tree, and is used to store the most probable ith-order partial partitions. Each H_i has a maximum size of $2N$: if more than $2N$ partitions are inserted into a given H_i, then only the $2N$ most probable ones will be stored. This amounts to pruning the search space by employing a beam size of $2N$ (i.e., expanding only the $2N$ most probable partial partitions) at each step of the search.

The algorithm begins by initializing H_1 with the only partial partition of order one, $\{[m_1]\}$, which has a score of one (line 2). Then it processes the mentions sequentially, starting with m_2 (line 4). When processing m_i, it takes each partial partition PP in H_{i-1} and creates a set of ith-order partitions by extending PP with m_i in all possible ways. Specifically, for each cluster C (formed by a subset of the first i–1 mentions) in PP, the algorithm generates a new ith-order partition, PP', by linking m_i to C (line 9), and stores PP' in H_i (line 11). The score of PP', $S(PP')$, is computed by using the pairwise coreference probabilities as follows:

$$S(PP') = S(PP) \cdot \max_{m_k \in C} P_{coref}(m_{ki}).$$

Of course, PP can also be extended by putting m_i into a new cluster (line 12). This yields PP^δ, another partition to be inserted into H_i (line 14), and

$$S(PP^\delta) = \delta \cdot S(PP) \cdot (1 - \max_{k \in \{1,\ldots,i-1\}} P_{coref}(m_{ki})),$$

where δ (the *start penalty*) is a positive constant ($<$ 1) used to penalize partitions that start a new cluster. After processing each of the n mentions using the above steps, the algorithm returns the N most probable partitions in H_n (line 15).

Our implementation of Luo et al.'s search algorithm differs from their original algorithm only in terms of the number of pruning strategies adopted. Specifically, Luo et al. introduce a number of heuristics to prune the search space in order to speed up the search. We employ only the beam search heuristic, with a beam size that is five times larger than theirs. Our larger beam size, together with the fact that we do not use other pruning strategies, implies that we are searching through a larger part of the space than them, thus potentially yielding better partitions.

3 Haghighi and Klein's Coreference Model

To gauge the performance of our model, we compare it with a Bayesian model for unsupervised coreference resolution that was recently proposed by Haghighi and Klein (2007). In this section, we will give an overview of their model, discuss its weaknesses and propose three modifications to the model.

3.1 Notations

For consistency, we follow Haghighi and Klein's (H&K) notations. **Z** is the set of random variables

indeed partitions. This is desirable, as there is no reason for us to put non-zero probability mass on invalid clusterings.

that refer to (indices of) entities. ϕ_z is the set of parameters associated with entity z. ϕ is the entire set of model parameters, which includes all the ϕ_z's. Finally, $\mathbf{X}$ is the set of observed variables (e.g., the head of a mention). Given a document, the goal is to find the most probable assignment of entity indices to its mentions given the observed values. In other words, we want to maximize $P(\mathbf{Z}|\mathbf{X})$. In a Bayesian approach, we compute this probability by integrating out all the parameters. Specifically,

$$P(\mathbf{Z}|\mathbf{X}) = \int P(\mathbf{Z}|\mathbf{X}, \phi)P(\phi|\mathbf{X})d\phi.$$

3.2 The Original H&K Model

The original H&K model is composed of a set of models: the *basic* model and two other models (namely, the *pronoun head* model and the *salience* model) that aim to improve the basic model.[5]

3.2.1 Basic Model

The basic model generates a mention in a two-step process. First, an entity index is chosen according to an *entity distribution*, and then the head of the mention is generated given the entity index based on an entity-specific *head distribution*. Here, we assume that (1) all heads H are observed and (2) a mention is represented solely by its head noun, so nothing other than the head is generated. Furthermore, we assume that the head distribution is drawn from a symmetric Dirichlet with concentration λ_H. Hence,

$$P(H_{i,j} = h|\mathbf{Z}, \mathbf{H}^{-i,j}) \propto n_{h,z} + \lambda_H$$

where $H_{i,j}$ is the head of mention j in document i, and $n_{h,z}$ is the number of times head h is emitted by entity index z in $(\mathbf{Z}, \mathbf{H}^{-i,j})$.[6] On the other hand, since the number of entities in a document is *not* known a priori, we draw the entity distribution from a Dirichlet *process* with concentration α, effectively yielding a model with an infinite number of mixture components. Using the Chinese restaurant process representation (see Teh et al. (2006)),

$$P(Z_{ij} = z|\mathbf{Z}^{-i,j}) \propto \begin{cases} \alpha & , \text{ if } z = z_{new} \\ n_z & , \text{ otherwise} \end{cases}$$

where n_z is the number of mentions in $\mathbf{Z}^{-i,j}$ labeled with entity index z, and z_{new} is a new entity index not already in $\mathbf{Z}^{-i,j}$. To perform inference, we use Gibbs sampling (Geman and Geman, 1984) to generate samples from this conditional distribution:

$$P(Z_{i,j}|\mathbf{Z}^{-i,j}, \mathbf{H}) \propto P(Z_{i,j}|\mathbf{Z}^{-i,j})P(H_{i,j}|\mathbf{Z}, \mathbf{H}^{-i,j})$$

where the two distributions on the right are defined as above. Starting with a random assignment of entity indices to mentions, the Gibbs sampler iteratively re-samples an entity index according to this posterior distribution given the current assignment.

3.2.2 Pronoun Head Model

Head generation in the basic model is too simplistic: it has a strong tendency to assign the same entity index to mentions having the same head. This is particularly inappropriate for pronouns. Hence, we need a different model for generating pronouns.

Before introducing this pronoun head model, we need to augment the set of entity-specific parameters, which currently contains only a distribution over heads (ϕ^h_Z). Specifically, we add distributions ϕ^t_Z, ϕ^g_Z, and ϕ^n_Z over entity *properties*: ϕ^t_Z is a distribution over semantic types (PER, ORG, LOC, MISC), ϕ^g_Z over gender (MALE, FEMALE, EITHER, NEUTER), and ϕ^n_Z over number (SG, PL). We assume that each of these distributions is drawn from a symmetric Dirichlet. A small concentration parameter is used, since each entity should have a dominating value for each of these properties.

Now, to estimate ϕ^t_Z, ϕ^g_Z, and ϕ^n_Z, we need to know the gender, number, and semantic type of each mention. For some mentions (e.g., "he"), these properties are easy to compute; for others (e.g., "it"), they are not. Whenever a mention has unobserved properties, we need to fill in the missing values. We could resort to sampling, but sampling these properties is fairly inefficient. So, following H&K, we keep soft counts for each of these properties and use them rather than perform hard sampling.

When an entity z generates a pronoun h using the pronoun head model,[7] it first generates a gender g, a number n, and a semantic type t independently from the distributions ϕ^g_z, ϕ^n_z, and ϕ^t_z; and then generates h using the distribution $P(H = h|G = g, N =$

[5]H&K also present a cross-document coreference model, but since it focuses primarily on cross-document coreference and improves within-document coreference performance by only 1.5% in F-score, we will not consider this model here.

[6]$\mathbf{H}^{-i,j}$ is used as a shorthand for $\mathbf{H} - \{H_{i,j}\}$.

[7]While pronouns are generated by this pronoun head model, names and nominals continue to be handled by the basic model.

$n, T = t, \theta)$. Note that this last distribution is a global distribution that is independent of the chosen entity index. θ is a parameter drawn from a symmetric Dirichlet (with concentration λ_P) that encodes our prior knowledge of the relationship between a semantic type and a pronoun. For instance, given the type PERSON, there is a higher probability of generating "he" than "it". As a result, we maintain a list of compatible semantic types for each pronoun, and give a pronoun a count of (1 + λ_P) if it is compatible with the drawn semantic type; otherwise, we give it a count of λ_P. In essence, we use this prior to prefer the generation of pronouns that are compatible with the chosen semantic type.

3.2.3 Salience Model

Pronouns typically refer to salient entities, so the basic model could be improved by incorporating salience. We start by assuming that each entity has an activity score that is initially set to zero. Given a set of mentions and an assignment of entity indices to mentions, $\mathbf{Z}$, we process the mentions in a left-to-right manner. When a mention, m, is encountered, we multiply the activity score of each entity by 0.5 and add one to the activity score of the entity to which m belongs. This captures the intuitive notion that frequency and recency both play a role in determining salience. Next, we rank the entities based on their activity scores and discretize the ranks into five "salience" buckets S: TOP (1), HIGH (2–3), MID (4–6), LOW (7+), and NONE. Finally, this salience information is used to modify the entity distribution:[8]

$$P(Z_{ij} = z|\mathbf{Z}^{-i,j}) \propto n_z \cdot P(M_{i,j}|S_{i,j}, \mathbf{Z})$$

where $S_{i,j}$ is the salience value of the jth mention in document i, and $M_{i,j}$ is its mention type, which can take on one of three values: pronoun, name, and nominal. $P(M_{i,j}|S_{i,j}, \mathbf{Z})$, the distribution of mention type given salience, was computed from H&K's development corpus (see Table 2). According to the table, pronouns are preferred for salient entities, whereas names and nominals are preferred for entities that are less active.

[8]Rather than having just one probability term on the right hand side of the sampling equation, H&K actually have a product of probability terms, one for each mention that appears later than mention j in the given document. However, they acknowledge that having the product makes sampling inefficient, and decided to simplify the equation to this form in their evaluation.

Salience Feature	Pronoun	Name	Nominal
TOP	0.75	0.17	0.08
HIGH	0.55	0.28	0.17
MID	0.39	0.40	0.21
LOW	0.20	0.45	0.35
NONE	0.00	0.88	0.12

Table 2: Posterior distribution of mention type given salience (taken from Haghighi and Klein (2007))

3.3 Modifications to the H&K Model

Next, we discuss the potential weaknesses of H&K's model and propose three modifications to it.

Relaxed head generation. The basic model focuses on head matching, and is therefore likely to (incorrectly) posit *the large airport* and *the small airport* as coreferent, for instance. In fact, head matching is a relatively inaccurate indicator of coreference, in comparison to the "strong coreference indicators" shown in the first three rows of Table 1. To improve H&K's model, we replace head matching with these three strong indicators as follows. Given a document, we assign each of its mentions a *head index*, such that two mentions have the same head index if and only if at least one of the three strong indicators returns a value of True. Now, instead of generating a head, the head model generates a head index, thus increasing the likelihood that aliases are assigned the same entity index, for instance. Note that this modification is applied only to the basic model. In particular, pronoun generation continues to be handled by the pronoun head model and will not be affected. We hypothesize that this modification would improve precision, as the strong indicators are presumably more precise than head match.

Agreement constraints. While the pronoun head model naturally prefers that a pronoun be generated by an entity whose gender and number are compatible with those of the pronoun, the entity (index) that is re-sampled for a pronoun according to the sampling equation for $P(Z_{i,j}|\mathbf{Z}^{-i,j}, \mathbf{H})$ may still not be compatible with the pronoun with respect to gender and number. The reason is that an entity index is assigned based not only on the head distribution but also on the entity distribution. Since entities with many mentions are preferable to those with few mentions, it is possible for the model to favor the assignment of a grammatically incompatible entity (index) to a pronoun if the entity is sufficiently large. To eliminate this possibility, we enforce the agreement constraints at the global level. Specifically, we sample an entity index for a given mention with a non-zero probability if and only if the corresponding entity and the head of the mention agree in gender and number. We hypothesize that this modification would improve precision.

Pronoun-only salience. In Section 3.2.3, we motivate the need for salience using pronouns only, since proper names can to a large extent be resolved using string-matching facilities and are not particularly sensitive to salience. Nominals (especially definite descriptions), though more sensitive to salience than names, can also be resolved by simple string-matching heuristics in many cases (Vieira and Poesio, 2000; Strube et al., 2002). Hence, we hypothesize that the use of salience for names and nominals would adversely affect their resolution performance, as incorporating salience could diminish the role of string match in the resolution process, according to the sampling equations. Consequently, we modify H&K's model by limiting the application of salience to the resolution of pronouns only. We hypothesize that this change would improve precision.

4 Evaluation

4.1 Experimental Setup

To evaluate our EM-based model and H&K's model, we use the ACE 2003 coreference corpus, which is composed of three sections: Broadcast News (BNEWS), Newswire (NWIRE), and Newspaper (NPAPER). Each section is in turn composed of a training set and a test set. Due to space limitations, we will present evaluation results only for the test sets of BNEWS and NWIRE, but verified that the same performance trends can be observed on NPAPER as well. Unlike H&K, who report results using only true mentions (extracted from the answer keys), we show results for true mentions as well as system mentions that were extracted by an in-house noun phrase chunker. The relevant statistics of the BNEWS and NWIRE test sets are shown in Table 3.

	BNEWS	NWIRE
Number of documents	51	29
Number of true mentions	2608	2630
Number of system mentions	5424	5197

Table 3: Statistics of the BNEWS and NWIRE test sets

Scoring programs. To score the output of the coreference models, we employ the commonly-used MUC scoring program (Vilain et al., 1995) and the recently-developed CEAF scoring program (Luo, 2005). In the MUC scorer, recall is computed as the percentage of coreference *links* in the reference partition that appear in the system partition; precision is computed in the same fashion as recall, except that the roles of the reference partition and the system partition are reversed. As a *link-based* scoring program, the MUC scorer (1) does not reward successful identification of singleton entities and (2) tends to under-penalize partitions that have too few entities. The *entity-based* CEAF scorer was proposed in response to these two weaknesses. Specifically, it operates by computing the optimal alignment between the set of reference entities and the set of system entities. CEAF precision and recall are both positively correlated with the score of this optimal alignment, which is computed by summing over each aligned entity pair the number of mentions that appear in both entities of that pair. As a consequence, a system that proposes too many entities or too few entities will have low precision and recall.

Parameter initialization. We use a small amount of labeled data for parameter initialization for the two models. Specifically, for evaluations on the BNEWS test data, we use as labeled data one randomly-chosen document from the BNEWS training set, which has 58 true mentions and 102 system mentions. Similarly for NWIRE, where the chosen document has 42 true mentions and 72 system mentions. For our model, we use the labeled document to initialize the parameters. Also, we set N (the number of most probable partitions) to 50 and δ (the start penalty used in the Bell tree) to 0.8, the latter being recommended by Luo et al. (2004).

For H&K's model, we use the labeled data to tune the concentration parameter α. While H&K set α to 0.4 without much explanation, a moment's thought reveals that the choice of α should reflect the fraction of mentions that appear in a singleton cluster. We therefore estimate this value from the labeled document, yielding 0.4 for true mentions (which is consistent with H&K's choice) and 0.7 for system mentions. The remaining parameters, the λ's, are all set to e^{-4}, following H&K. In addition, as is commonly done in Bayesian approaches, we do not sample entities directly from the conditional distribution $P(\mathbf{Z}|\mathbf{X})$; rather, we sample from this distribution raised to the power $\exp \frac{ci}{k-1}$, where c=1.5, i is the current iteration number that starts at 0, and k (the number of sampling iterations) is set to 20. Finally, due to sampling and the fact that the initial assignment of entity indices to mentions is random, all the reported results for H&K's model are averaged over five runs.

4.2 Results and Discussions

The Heuristic baseline. As our first baseline, we employ a simple rule-based system that posits two mentions as coreferent if and only if at least one of the three strong coreference indicators listed in Table 1 returns True. Results of this baseline, reported in terms of recall (R), precision (P), and F-score (F) using the MUC scorer and the CEAF scorer, are shown in row 1 of Tables 4 and 5, respectively. Each row in these tables shows performance using true mentions and system mentions for the BNEWS and NWIRE data sets. As we can see, (1) recall is generally low, since this simple heuristic can only identify a small fraction of the coreference relations; (2) CEAF recall is consistently higher than MUC recall, since CEAF also rewards successful identification of non-coreference relations; and (3) precision for true mentions is higher than that for system mentions, since the number of non-coreferent pairs that satisfy the heuristic is larger for system mentions.

The Degenerate EM baseline. Our second baseline is obtained by running only one iteration of our EM-based coreference model. Specifically, it starts with the M-step by initializing the model parameters using the labeled document, and ends with the E-step by applying the resulting model (in combination with the Bell tree search algorithm) to obtain the most probable coreference partition for each test document. Since there is no parameter re-estimation, this baseline is effectively a purely supervised system trained on one (labeled) document.

Results are shown in row 2 of Tables 4 and 5. As we can see, recall is consistently much higher than precision, suggesting that the model has produced fewer entities than it should. Perhaps more interestingly, in comparison to the Heuristic baseline, Degenerate EM performs consistently worse according to CEAF but generally better according to MUC. This discrepancy stems from the aforementioned properties that MUC under-penalizes partitions with too few entities, whereas CEAF lowers both recall and precision when given such partitions.

Our EM-based coreference model. Our model operates in the same way as the Degenerate EM baseline, except that EM is run until convergence, with the test set being used as unlabeled data for parameter re-estimation. Any performance difference between our model and Degenerate EM can thus be attributed to EM's exploitation of the unlabeled data.

Results of our model are shown in row 3 of Tables 4 and 5. In comparison to Degenerate EM, MUC F-score increases by 4-5% for BNEWS and 4-21% for NWIRE; CEAF F-score increases even more dramatically, by 10-17% for BNEWS and 16-27% for NWIRE. Improvements stem primarily from large gains in precision and comparatively smaller loss in recall. Such improvements suggest that our model has effectively exploited the unlabeled data.

In comparison to the Heuristic baseline, we generally see increases in both recall and precision when system mentions are used, and as a result, F-score improves substantially by 7-15%. When true mentions are used, we still see gains in recall, but these gains are accompanied by loss in precision. F-score generally increases (by 2-22%), except for the case with NWIRE where we see a 0.5% drop in CEAF F-score as a result of a larger decrease in precision.

The Original H&K model. We use as our third baseline the Original H&K model (see Section 3.2). Results of this model are shown in row 4 of Tables 4 and 5.[9] Overall, it underperforms our model by 6-16% in MUC F-score and 6-14% in CEAF F-score, due primarily to considerable drop in both recall and precision in almost all cases.

The Modified H&K model. Next, we incorporate our three modifications into the Original H&K baseline one after the other. Results are shown in rows 5-7 of Tables 4 and 5. Several points deserve mentioning. First, the addition of each modification improves the F-score for both true and system mentions

[9]The H&K results shown here are not directly comparable with those reported in Haghighi and Klein (2007), since H&K evaluated their system on the ACE 2004 coreference corpus.

Table 5: Results obtained using the CEAF scoring program for the Broadcast News and Newswire data sets

in both data sets using both scorers. These results provide suggestive evidence that our modifications are highly beneficial. The three modifications, when applied in combination, improve Original H&K substantially by 5-8% in MUC F-score and 7-12% in CEAF F-score, yielding results that compare favorably to those of our model in almost all cases.

Second, the use of agreement constraints yields larger improvements with CEAF than with MUC. This discrepancy can be attributed to the fact that CEAF rewards the correct identification of non-coreference relations, whereas MUC does not. Since agreement constraints are intended primarily for disallowing coreference, they contribute to the successful identification of non-coreference relations and as a result yield gains in CEAF recall and precision.

Third, the results are largely consistent with our hypothesis that these modifications enhance precision. Together, they improve the precision of the Original H&K baseline by 8-16% (MUC) and 11-16% (CEAF), yielding a coreference model that compares favorably with our EM-based approach.

Comparison with a supervised model. Finally, we compare our EM-based model with a fully supervised coreference resolver. Inspired by state-of-the-art resolvers, we create our supervised classification model by training a discriminative learner (the C4.5 decision tree induction system (Quinlan, 1993)) with a diverse set of features (the 34 features described in Ng (2007)) on a large training set (the entire ACE 2003 coreference training corpus), and cluster using the Bell tree search algorithm. The fully supervised results shown in row 8 of Tables 4 and 5 suggest that our EM-based model has room for improvements, especially when system mentions are used.

5 Conclusions

We have presented a generative model for unsupervised coreference resolution that views coreference as an EM clustering process. Experimental results indicate that our model outperforms Haghighi and Klein's (2007) coreference model by a large margin on the ACE data sets and compares favorably to a modified version of their model. Despite these improvements, its performance is still not comparable to that of a fully supervised coreference resolver.

A natural way to extend these unsupervised coreference models is to incorporate additional linguistic knowledge sources, such as those employed by our fully supervised resolver. However, feature engineering is in general more difficult for generative models than for discriminative models, as the former typically require non-overlapping features. We plan to explore this possibility in future work.

Abstract

Machine learning approaches to coreference resolution are typically supervised, and require expensive labeled data. Some unsupervised approaches have been proposed (e.g., Haghighi and Klein (2007)), but they are less accurate. In this paper, we present the first unsupervised approach that is competitive with supervised ones. This is made possible by performing joint inference across mentions, in contrast to the pairwise classification typically used in supervised methods, and by using Markov logic as a representation language, which enables us to easily express relations like apposition and predicate nominals. On MUC and ACE datasets, our model outperforms Haghigi and Klein's one using only a fraction of the training data, and often matches or exceeds the accuracy of state-of-the-art supervised models.

1 Introduction

The goal of coreference resolution is to identify *mentions* (typically noun phrases) that refer to the same *entities*. This is a key subtask in many NLP applications, including information extraction, question answering, machine translation, and others. Supervised learning approaches treat the problem as one of classification: for each pair of mentions, predict whether they corefer or not (e.g., McCallum & Wellner (2005)). While successful, these approaches require labeled training data, consisting of mention pairs and the correct decisions for them. This limits their applicability.

Unsupervised approaches are attractive due to the availability of large quantities of unlabeled text. However, unsupervised coreference resolution is much more difficult. Haghighi and Klein's (2007) model, the most sophisticated to date, still lags supervised ones by a substantial margin. Extending it appears difficult, due to the limitations of its Dirichlet process-based representation.

The lack of label information in unsupervised coreference resolution can potentially be overcome by performing joint inference, which leverages the "easy" decisions to help make related "hard" ones. Relations that have been exploited in supervised coreference resolution include transitivity (McCallum & Wellner, 2005) and anaphoricity (Denis & Baldridge, 2007). However, there is little work to date on joint inference for unsupervised resolution.

We address this problem using Markov logic, a powerful and flexible language that combines probabilistic graphical models and first-order logic (Richardson & Domingos, 2006). Markov logic allows us to easily build models involving relations among mentions, like apposition and predicate nominals. By extending the state-of-the-art algorithms for inference and learning, we developed the first general-purpose unsupervised learning algorithm for Markov logic, and applied it to unsupervised coreference resolution.

We test our approach on standard MUC and ACE datasets. Our basic model, trained on a minimum of data, suffices to outperform Haghighi and Klein's (2007) one. Our full model, using apposition and other relations for joint inference, is often as accurate as the best supervised models, or more.

We begin by reviewing the necessary background on Markov logic. We then describe our Markov logic network for joint unsupervised coreference resolution, and the learning and inference algorithms we used. Finally, we present our experiments and results.

2 Related Work

Most existing supervised learning approaches for coreference resolution are suboptimal since they resolve each mention pair independently, only imposing transitivity in postprocessing (Ng, 2005). Moreover, many of them break up the resolution step into subtasks (e.g., first determine whether a mention is anaphoric, then classify whether it is coreferent with an antecedent), which further forsakes opportunities for joint inference that have been shown to be helpful (Poon & Domingos, 2007). Using graph partitioning, McCallum & Wellner (2005) incorporated transitivity into pairwise classification and achieved the state-of-the-art result on the MUC-6 dataset, but their approach can only leverage one binary relation at a time, not arbitrary relations among mentions. Denis & Baldridge (2007) determined anaphoricity and pairwise classification jointly using integer programming, but they did not incorporate transitivity or other relations.

While potentially more appealing, unsupervised learning is very challenging, and unsupervised coreference resolution systems are still rare to this date. Prior to our work, the best performance in unsupervised coreference resolution was achieved by Haghighi & Klein (2007), using a nonparametric Bayesian model based on hierarchical Dirichlet processes. At the heart of their system is a mixture model with a few linguistically motivated features such as head words, entity properties and salience. Their approach is a major step forward in unsupervised coreference resolution, but extending it is challenging. The main advantage of Dirichlet processes is that they are exchangeable, allowing parameters to be integrated out, but Haghighi and Klein forgo this when they introduce salience. Their model thus requires Gibbs sampling over both assignments and parameters, which can be very expensive. Haghighi and Klein circumvent this by making approximations that potentially hurt accuracy. At the same time, the Dirichlet process prior favors skewed cluster sizes and a number of clusters that grows logarithmically with the number of data points, neither of which seems generally appropriate for coreference resolution.

Further, deterministic or strong non-deterministic dependencies cause Gibbs sampling to break down (Poon & Domingos, 2006), making it difficult to leverage many linguistic regularities. For example, apposition (as in "Bill Gates, the chairman of Microsoft") suggests coreference, and thus the two mentions it relates should always be placed in the same cluster. However, Gibbs sampling can only move one mention at a time from one cluster to another, and this is unlikely to happen, because it would require breaking the apposition rule. Blocked sampling can alleviate this problem by sampling multiple mentions together, but it requires that the block size be predetermined to a small fixed number. When we incorporate apposition and other regularities the blocks can become arbitrarily large, making this infeasible. For example, suppose we also want to leverage predicate nominals (i.e., the subject and the predicating noun of a copular verb are likely coreferent). Then a sentence like "He is Bill Gates, the chairman of Microsoft" requires a block of four mentions: "He", "Bill Gates", "the chairman of Microsoft", and "Bill Gates, the chairman of Microsoft". Similar difficulties occur with other inference methods. Thus, extending Haghighi and Klein's model to include richer linguistic features is a challenging problem.

Our approach is instead based on Markov logic, a powerful representation for joint inference with uncertainty (Richardson & Domingos, 2006). Like Haghighi and Klein's, our model is cluster-based rather than pairwise, and implicitly imposes transitivity. We do not predetermine anaphoricity of a mention, but rather fuse it into the integrated resolution process. As a result, our model is inherently joint among mentions and subtasks. It shares several features with Haghighi & Klein's model, but removes or refines features where we believe it is appropriate to. Most importantly, our model leverages apposition and predicate nominals, which Haghighi & Klein did not use. We show that this can be done very easily in our framework, and yet results in very substantial accuracy gains.

It is worth noticing that Markov logic is also well suited for joint inference in supervised systems (e.g., transitivity, which took McCallum & Wellner (2005) nontrivial effort to incorporate, can be handled in Markov logic with the addition of a single formula (Poon & Domingos, 2008)).

3 Markov Logic

In many NLP applications, there exist rich relations among objects, and recent work in statistical relational learning (Getoor & Taskar, 2007) and structured prediction (Bakir *et al.*, 2007) has shown that leveraging these can greatly improve accuracy. One of the most powerful representations for joint inference is Markov logic, a probabilistic extension of first-order logic (Richardson & Domingos, 2006). A *Markov logic network (MLN)* is a set of weighted first-order clauses. Together with a set of constants, it defines a Markov network with one node per ground atom and one feature per ground clause. The weight of a feature is the weight of the first-order clause that originated it. The probability of a state x in such a network is given by $P(x) = (1/Z)\exp\left(\sum_i w_i f_i(x)\right)$, where Z is a normalization constant, w_i is the weight of the ith clause, $f_i = 1$ if the ith clause is true, and $f_i = 0$ otherwise.

Markov logic makes it possible to compactly specify probability distributions over complex relational domains. Efficient inference can be performed using MC-SAT (Poon & Domingos, 2006). MC-SAT is a "slice sampling" Markov chain Monte Carlo algorithm. Slice sampling introduces auxiliary variables u that decouple the original ones x, and alternately samples u conditioned on x and vice-versa. To sample from the slice (the set of states x consistent with the current u), MC-SAT calls SampleSAT (Wei *et al.*, 2004), which uses a combination of satisfiability testing and simulated annealing. The advantage of using a satisfiability solver (WalkSAT) is that it efficiently finds isolated modes in the distribution, and as a result the Markov chain mixes very rapidly. The slice sampling scheme ensures that detailed balance is (approximately) preserved. MC-SAT is orders of magnitude faster than previous MCMC algorithms like Gibbs sampling, making efficient sampling possible on a scale that was previously out of reach.

Algorithm 1 MC-SAT(*clauses, weights, num_samples*)

```
$x^{(0)} \leftarrow$ Satisfy(hard *clauses*)
**for** $i \leftarrow 1$ to *num_samples* **do**
    $M \leftarrow \emptyset$
    **for all** $c_k \in$ *clauses* satisfied by $x^{(i-1)}$ **do**
        With probability $1 - e^{-w_k}$ add $c_k$ to $M$
    **end for**
    Sample $x^{(i)} \sim \mathcal{U}_{SAT(M)}$
**end for**
```

Algorithm 1 gives pseudo-code for MC-SAT. At iteration $i-1$, the factor ϕ_k for clause c_k is either e^{w_k} if c_k is satisfied in $x^{(i-1)}$, or 1 otherwise. MC-SAT first samples the auxiliary variable u_k uniformly from $(0, \phi_k)$, then samples a new state uniformly from the set of states that satisfy $\phi'_k \geq u_k$ for all k (the slice). Equivalently, for each k, with probability $1 - e^{-w_k}$ the next state must satisfy c_k. In general, we can factorize the probability distribution in any way that facilitates inference, sample the u_k's, and make sure that the next state is drawn uniformly from solutions that satisfy $\phi'_k \geq u_k$ for all factors.

MC-SAT, like most existing relational inference algorithms, grounds all predicates and clauses, thus requiring memory and time exponential in the predicate and clause arities. We developed a general method for producing a "lazy" version of relational inference algorithms (Poon & Domingos, 2008), which carries exactly the same inference steps as the original algorithm, but only maintains a small subset of "active" predicates/clauses, grounding more as needed. We showed that Lazy-MC-SAT, the lazy version of MC-SAT, reduced memory and time by orders of magnitude in several domains. We use Lazy-MC-SAT in this paper.

Supervised learning for Markov logic maximizes the conditional log-likelihood $L(x, y) = \log P(Y = y|X = x)$, where Y represents the non-evidence predicates, X the evidence predicates, and x, y their values in the training data. For simplicity, from now on we omit X, whose values are fixed and always conditioned on. The optimization problem is convex and a global optimum can be found using gradient descent, with the gradient being

$$\begin{aligned}\frac{\partial}{\partial w_i}L(y) &= n_i(y) - \textstyle\sum_{y'} P(Y=y')n_i(y') \\ &= n_i(y) - E_Y[n_i].\end{aligned}$$

where n_i is the number of true groundings of clause i. The expected count can be approximated as

$$E_Y[n_i] \approx \frac{1}{N}\sum_{k=1}^{N} n_i(y_k)$$

where y_k are samples generated by MC-SAT. To combat overfitting, a Gaussian prior is imposed on all weights.

In practice, it is difficult to tune the learning rate for gradient descent, especially when the number of groundings varies widely among clauses. Lowd & Domingos (2007) used a preconditioned scaled conjugate gradient algorithm (PSCG) to address this problem. This estimates the optimal step size in each step as

$$\alpha = \frac{-d^T g}{d^T H d + \lambda d^T d}.$$

where g is the gradient, d the conjugate update direction, and λ a parameter that is automatically tuned to trade off second-order information with gradient descent. H is the Hessian matrix, with the (i,j)th entry being

$$\begin{aligned}\frac{\partial^2}{\partial w_i \partial w_j}L(y) &= E_Y[n_i]\cdot E_Y[n_j] - E_Y[n_i \cdot n_j] \\ &= -Cov_Y[n_i, n_j].\end{aligned}$$

The Hessian can be approximated with the same samples used for the gradient. Its negative inverse diagonal is used as the preconditioner.[1]

The open-source Alchemy package (Kok *et al.*, 2007) provides implementations of existing algorithms for Markov logic. In Section 5, we develop the first general-purpose unsupervised learning algorithm for Markov logic by extending the existing algorithms to handle hidden predicates.[2]

[1]Lowd & Domingos showed that α can be computed more efficiently, without explicitly approximating or storing the Hessian. Readers are referred to their paper for details.

[2]Alchemy includes a discriminative EM algorithm, but it assumes that only a few values are missing, and cannot handle completely hidden predicates. Kok & Domingos (2007) applied Markov logic to relational clustering, but they used hard EM.

4 An MLN for Joint Unsupervised Coreference Resolution

In this section, we present our MLN for joint unsupervised coreference resolution. Our model deviates from Haghighi & Klein's (2007) in several important ways. First, our MLN does not model saliences for proper nouns or nominals, as their influence is marginal compared to other features; for pronoun salience, it uses a more intuitive and simpler definition based on distance, and incorporated it as a prior. Another difference is in identifying heads. For the ACE datasets, Haghighi and Klein used the gold heads; for the MUC-6 dataset, where labels are not available, they crudely picked the rightmost token in a mention. We show that a better way is to determine the heads using head rules in a parser. This improves resolution accuracy and is always applicable. Crucially, our MLN leverages syntactic relations such as apposition and predicate nominals, which are not used by Haghighi and Klein. In our approach, what it takes is just adding two formulas to the MLN.

As common in previous work, we assume that true mention boundaries are given. We do not assume any other labeled information. In particular, we do not assume gold name entity recognition (NER) labels, and unlike Haghighi & Klein (2007), we do not assume gold mention types (for ACE datasets, they also used gold head words). We determined the head of a mention either by taking its rightmost token, or by using the head rules in a parser. We detected pronouns using a list.

4.1 Base MLN

The main query predicate is $\mathtt{InClust(m,c!)}$, which is true iff mention $\mathtt{m}$ is in cluster $\mathtt{c}$. The "$\mathtt{t!}$" notation signifies that for each $\mathtt{m}$, this predicate is true for a unique value of $\mathtt{c}$. The main evidence predicate is $\mathtt{Head(m,t!)}$, where $\mathtt{m}$ is a mention and $\mathtt{t}$ a token, and which is true iff $\mathtt{t}$ is the head of $\mathtt{m}$. A key component in our MLN is a simple head mixture model, where the mixture component priors are represented by the unit clause

$$\mathtt{InClust(+m,+c)}$$

and the head distribution is represented by the *head prediction rule*

$$\mathtt{InClust(m,+c)} \wedge \mathtt{Head(m,+t)}.$$

All free variables are implicitly universally quantified. The "+" notation signifies that the MLN contains an instance of the rule, with a separate weight, for each value combination of the variables with a plus sign.

By convention, at each inference step we name each non-empty cluster after the earliest mention it contains. This helps break the symmetry among mentions, which otherwise produces multiple optima and makes learning unnecessarily harder. To encourage clustering, we impose an exponential prior on the number of non-empty clusters with weight -1.

The above model only clusters mentions with the same head, and does not work well for pronouns. To address this, we introduce the predicate $\texttt{IsPrn}(\texttt{m})$, which is true iff the mention $\texttt{m}$ is a pronoun, and adapt the head prediction rule as follows:

$$\neg\texttt{IsPrn}(\texttt{m}) \wedge \texttt{InClust}(\texttt{m}, +\texttt{c}) \wedge \texttt{Head}(\texttt{m}, +\texttt{t})$$

This is always false when $\texttt{m}$ is a pronoun, and thus applies only to non-pronouns.

Pronouns tend to resolve with mentions that are semantically compatible with them. Thus we introduce predicates that represent entity type, number, and gender: $\texttt{Type}(\texttt{x}, \texttt{e}!)$, $\texttt{Number}(\texttt{x}, \texttt{n}!)$, $\texttt{Gender}(\texttt{x}, \texttt{g}!)$, where $\texttt{x}$ can be either a cluster or mention, $\texttt{e} \in \{\texttt{Person}, \texttt{Organization}, \texttt{Location}, \texttt{Other}\}$, $\texttt{n} \in \{\texttt{Singular}, \texttt{Plural}\}$ and $\texttt{g} \in \{\texttt{Male}, \texttt{Female}, \texttt{Neuter}\}$. Many of these are known for pronouns, and some can be inferred from simple linguistic cues (e.g., "Ms. Galen" is a singular female person, while "XYZ Corp." is an organization).[3] Entity type assignment is represented by the unit clause

$$\texttt{Type}(+\texttt{x}, +\texttt{e})$$

and similarly for number and gender. A mention should agree with its cluster in entity type. This is ensured by the hard rule (which has infinite weight and must be satisfied)

$$\texttt{InClust}(\texttt{m}, \texttt{c}) \Rightarrow (\texttt{Type}(\texttt{m}, \texttt{e}) \Leftrightarrow \texttt{Type}(\texttt{c}, \texttt{e}))$$

[3]We used the following cues: Mr., Ms., Jr., Inc., Corp., corporation, company. The proportions of known properties range from 14% to 26%.

There are similar hard rules for number and gender.

Different pronouns prefer different entity types, as represented by

$$\texttt{IsPrn}(\texttt{m}) \wedge \texttt{InClust}(\texttt{m}, \texttt{c}) \\ \wedge\texttt{Head}(\texttt{m}, +\texttt{t}) \wedge \texttt{Type}(\texttt{c}, +\texttt{e})$$

which only applies to pronouns, and whose weight is positive if pronoun $\texttt{t}$ is likely to assume entity type $\texttt{e}$ and negative otherwise. There are similar rules for number and gender.

Aside from semantic compatibility, pronouns tend to resolve with nearby mentions. To model this, we impose an exponential prior on the distance (number of mentions) between a pronoun and its antecedent, with weight -1.[4] This is similar to Haghighi and Klein's treatment of salience, but simpler.

4.2 Full MLN

Syntactic relations among mentions often suggest coreference. Incorporating such relations into our MLN is straightforward. We illustrate this with two examples: apposition and predicate nominals. We introduce a predicate for apposition, $\texttt{Appo}(\texttt{x}, \texttt{y})$, where $\texttt{x}, \texttt{y}$ are mentions, and which is true iff $\texttt{y}$ is an appositive of $\texttt{x}$. We then add the rule

$$\texttt{Appo}(\texttt{x}, \texttt{y}) \Rightarrow (\texttt{InClust}(\texttt{x}, \texttt{c}) \Leftrightarrow \texttt{InClust}(\texttt{y}, \texttt{c}))$$

which ensures that x, y are in the same cluster if y is an appositive of x. Similarly, we introduce a predicate for predicate nominals, $\texttt{PredNom}(\texttt{x}, \texttt{y})$, and the corresponding rule.[5] The weights of both rules can be learned from data with a positive prior mean. For simplicity, in this paper we treat them as hard constraints.

4.3 Rule-Based MLN

We also consider a rule-based system that clusters non-pronouns by their heads, and attaches a pronoun to the cluster which has no known conflicting

[4]For simplicity, if a pronoun has no antecedent, we define the distance to be ∞. So a pronoun must have an antecedent in our model, unless it is the first mention in the document or it can not resolve with previous mentions without violating hard constraints. It is straightforward to soften this with a finite penalty.

[5]We detected apposition and predicate nominatives using simple heuristics based on parses, e.g., if (NP, comma, NP) are the first three children of an NP, then any two of the three noun phrases are apposition.

type, number, or gender, and contains the closest antecedent for the pronoun. This system can be encoded in an MLN with just four rules. Three of them are the ones for enforcing agreement in type, number, and gender between a cluster and its members, as defined in the base MLN. The fourth rule is

$$\begin{gathered}\neg\texttt{IsPrn(m1)} \wedge \neg\texttt{IsPrn(m2)} \\ \wedge\texttt{Head(m1,h1)} \wedge \texttt{Head(m2,h2)} \\ \wedge\texttt{InClust(m1,c1)} \wedge \texttt{InClust(m2,c2)} \\ \Rightarrow (\texttt{c1} = \texttt{c2} \Leftrightarrow \texttt{h1} = \texttt{h2}).\end{gathered}$$

With a large but not infinite weight (e.g., 100), this rule has the effect of clustering non-pronouns by their heads, except when it violates the hard rules. The MLN can also include the apposition and predicate-nominal rules. As in the base MLN, we impose the same exponential prior on the number of non-empty clusters and that on the distance between a pronoun and its antecedent. This simple MLN is remarkably competitive, as we will see in the experiment section.

5 Learning and Inference

Unsupervised learning in Markov logic maximizes the conditional log-likelihood

$$\begin{aligned} L(x,y) &= \log P(Y=y|X=x) \\ &= \log \textstyle\sum_z P(Y=y, Z=z|X=x) \end{aligned}$$

where Z are unknown predicates. In our coreference resolution MLN, Y includes Head and known groundings of Type, Number and Gender, Z includes InClust and unknown groundings of Type, Number, Gender, and X includes IsPrn, Appo and PredNom. (For simplicity, from now on we drop X from the formula.) With Z, the optimization problem is no longer convex. However, we can still find a local optimum using gradient descent, with the gradient being

$$\frac{\partial}{\partial w_i} L(y) = E_{Z|y}[n_i] - E_{Y,Z}[n_i]$$

where n_i is the number of true groundings of the ith clause. We extended PSCG for unsupervised learning. The gradient is the difference of two expectations, each of which can be approximated using samples generated by MC-SAT. The (i, j)th entry of the Hessian is now

$$\frac{\partial^2}{\partial w_i \partial w_j} L(y) = Cov_{Z|y}[n_i, n_j] - Cov_{Y,Z}[n_i, n_j]$$

and the step size can be computed accordingly. Since our problem is no longer convex, the negative diagonal Hessian may contain zero or negative entries, so we first took the absolute values of the diagonal and added 1, then used the inverse as the preconditioner. We also adjusted λ more conservatively than Lowd & Domingos (2007).

Notice that when the objects form independent subsets (in our cases, mentions in each document), we can process them in parallel and then gather sufficient statistics for learning. We developed an efficient parallelized implementation of our unsupervised learning algorithm using the message-passing interface (MPI). Learning in MUC-6 took only one hour, and in ACE-2004 two and a half.

To reduce burn-in time, we initialized MC-SAT with the state returned by MaxWalkSAT (Kautz *et al.*, 1997), rather than a random solution to the hard clauses. In the existing implementation in Alchemy (Kok *et al.*, 2007), SampleSAT flips only one atom in each step, which is inefficient for predicates with unique-value constraints (e.g., Head(m, c!)). Such predicates can be viewed as multi-valued predicates (e.g., Head(m) with value ranging over all c's) and are prevalent in NLP applications. We adapted SampleSAT to flip two or more atoms in each step so that the unique-value constraints are automatically satisfied. By default, MC-SAT treats each ground clause as a separate factor while determining the slice. This can be very inefficient for highly correlated clauses. For example, given a non-pronoun mention m currently in cluster c and with head t, among the mixture prior rules involving m InClust(m, c) is the only one that is satisfied, and among those head-prediction rules involving m, $\neg$IsPrn(m) $\wedge$ InClust(m, c) $\wedge$ Head(m, t) is the only one that is satisfied; the factors for these rules multiply to $\phi = \exp(w_{\texttt{m,c}} + w_{\texttt{m,c,t}})$, where $w_{\texttt{m,c}}$ is the weight for InClust(m, c), and $w_{\texttt{m,c,t}}$ is the weight for $\neg$IsPrn(m) $\wedge$ InClust(m, c) $\wedge$ Head(m, t), since an unsatisfied rule contributes a factor of $e^0 = 1$. We extended MC-SAT to treat each set of mutually exclusive and exhaustive rules as a single factor. E.g., for the above m, MC-SAT now samples u uniformly from $(0, \phi)$, and requires that in the next state ϕ' be no less than u. Equivalently, the new cluster and head for $\mathtt{m}$ should satisfy $w_{\mathtt{m},\mathtt{c}'} + w_{\mathtt{m},\mathtt{c}',\mathtt{t}'} \geq \log(u)$. We extended SampleSAT so that when it considers flipping any variable involved in such constraints (e.g., `c` or `t` above), it ensures that their new values still satisfy these constraints.

The final clustering is found using the MaxWalkSAT weighted satisfiability solver (Kautz *et al.*, 1997), with the appropriate extensions. We first ran a MaxWalkSAT pass with only finite-weight formulas, then ran another pass with all formulas. We found that this significantly improved the quality of the results that MaxWalkSAT returned.

6 Experiments

6.1 System

We implemented our method as an extension to the Alchemy system (Kok *et al.*, 2007). Since our learning uses sampling, all results are the average of five runs using different random seeds. Our optimization problem is not convex, so initialization is important. The core of our model (head mixture) tends to cluster non-pronouns with the same head. Therefore, we initialized by setting all weights to zero, and running the same learning algorithm on the base MLN, while assuming that in the ground truth, non-pronouns are clustered by their heads. (Effectively, the corresponding `InClust` atoms are assigned to appropriate values and are included in Y rather than Z during learning.) We used 30 iterations of PSCG for learning. (In preliminary experiments, additional iterations had little effect on coreference accuracy.) We generated 100 samples using MC-SAT for each expectation approximation.[6]

6.2 Methodology

We conducted experiments on MUC-6, ACE-2004, and ACE Phrase-2 (ACE-2). We evaluated our systems using two commonly-used scoring programs: MUC (Vilain *et al.*, 1995) and B^3 (Amit & Baldwin, 1998). To gain more insight, we also report pairwise resolution scores and mean absolute error in the number of clusters.

[6]Each sample actually contains a large number of groundings, so 100 samples yield sufficiently accurate statistics for learning.

The MUC-6 dataset consists of 30 documents for testing and 221 for training. To evaluate the contribution of the major components in our model, we conducted five experiments, each differing from the previous one in a single aspect. We emphasize that our approach is unsupervised, and thus the data only contains raw text plus true mention boundaries.

MLN-1 In this experiment, the base MLN was used, and the head was chosen crudely as the rightmost token in a mention. Our system was run on each test document separately, using a minimum of training data (the document itself).

MLN-30 Our system was trained on all 30 test documents together. This tests how much can be gained by pooling information.

MLN-H The heads were determined using the head rules in the Stanford parser (Klein & Manning, 2003), plus simple heuristics to handle suffixes such as "Corp." and "Inc."

MLN-HA The apposition rule was added.

MLN-HAN The predicate-nominal rule was added. This is our full model.

We also compared with two rule-based MLNs: **RULE** chose the head crudely as the rightmost token in a mention, and did not include the apposition rule and predicate-nominal rule; **RULE-HAN** chose the head using the head rules in the Stanford parser, and included the apposition rule and predicate-nominal rule.

Past results on ACE were obtained on different releases of the datasets, e.g., Haghighi and Klein (2007) used the ACE-2004 training corpus, Ng (2005) and Denis and Baldridge (2007) used ACE Phrase-2, and Culotta *et al.* (2007) used the ACE-2004 formal test set. In this paper, we used the ACE-2004 training corpus and ACE Phrase-2 (ACE-2) to enable direct comparisons with Haghighi & Klein (2007), Ng (2005), and Denis and Baldridge (2007). Due to license restrictions, we were not able to obtain the ACE-2004 formal test set and so cannot compare directly to Culotta *et al.* (2007). The English version of the ACE-2004 training corpus contains two sections, BNEWS and NWIRE, with 220 and 128 documents, respectively. ACE-2 contains a

Table 1: Comparison of coreference results in MUC scores on the MUC-6 dataset.

training set and a test set. In our experiments, we only used the test set, which contains three sections, BNEWS, NWIRE, and NPAPER, with 51, 29, and 17 documents, respectively.

6.3 Results

Table 1 compares our system with previous approaches on the MUC-6 dataset, in MUC scores. Our approach greatly outperformed Haghighi & Klein (2007), the state-of-the-art unsupervised system. Our system, trained on individual documents, achieved an F1 score more than 7% higher than theirs trained on 60 documents, and still outperformed it trained on 381 documents. Training on the 30 test documents together resulted in a significant gain. (We also ran experiments using more documents, and the results were similar.) Better head identification (MLN-H) led to a large improvement in accuracy, which is expected since for mentions with a right modifier, the rightmost tokens confuse rather than help coreference (e.g., "the chairman of Microsoft"). Notice that with this improvement our system already outperforms a state-of-the-art supervised system (McCallum & Wellner, 2005). Leveraging apposition resulted in another large improvement, and predicate nominals also helped. Our full model scores about 9% higher than Haghighi & Klein (2007), and about 6% higher than McCallum & Wellner (2005). To our knowledge, this is the best coreference accuracy reported on MUC-6 to date.[7] The B^3 scores of MLN-HAN on the MUC-6 dataset are 77.4 (precision), 67.6 (recall) and 72.2 (F1). (The other systems did not report B^3.) Interestingly, the rule-based MLN (**RULE**) sufficed to outperform Haghighi & Klein (2007), and by using better heads and the apposition and predicate-nominal rules (**RULE-HAN**), it outperformed McCallum & Wellner (2005), the supervised system. The MLNs with learning (**MLN-30** and **MLN-HAN**), on the

# Clusters	BNEWS	NWIRE	NPAPER
Gold	20.4	39.2	55.2
Mean Error	2.5	5.6	6.6

other hand, substantially outperformed the corresponding rule-based ones.

Table 2 compares our system to Haghighi & Klein (2007) on the ACE-2004 training set in MUC scores. Again, our system outperformed theirs by a large margin. The B^3 scores of MLN-HAN on the ACE-2004 dataset are 71.6 (precision), 68.4 (recall) and 70.0 (F1) for BNEWS, and 75.7 (precision), 69.2 (recall) and 72.3 (F1) for NWIRE. (Haghighi & Klein (2007) did not report B^3.) Due to license restrictions, we could not compare directly to Culotta *et al.* (2007), who reported overall B^3-F1 of 79.3 on the formal test set.

Tables 3 and 4 compare our system to two recent supervised systems, Ng (2005) and Denis & Baldridge (2007). Our approach significantly outperformed Ng (2005). It tied with Denis & Baldridge (2007) on NWIRE, and was somewhat less accurate on BNEWS and NPAPER.

Luo *et al.* (2004) pointed out that one can obtain a very high MUC score simply by lumping all mentions together. B^3 suffers less from this problem but is not perfect. Thus we also report pairwise resolution scores (Table 5), the gold number of clusters, and our mean absolute error in the number of clusters (Table 6). Systems that simply merge all mentions will have exceedingly low pairwise precision (far below 50%), and very large errors in the number of clusters. Our system has fairly good pairwise precisions and small mean error in the number of clusters, which verifies that our results are sound.

6.4 Error Analysis

Many of our system's remaining errors involve nominals. Additional features should be considered to distinguish mentions that have the same head but are different entities. For pronouns, many remaining errors can be corrected using linguistic knowledge like binding theory and salience hierarchy. Our heuristics for identifying appositives and predicate nominals also make many errors, which often can be fixed with additional name entity recognition capabilities (e.g., given "Mike Sullivan, VOA News", it helps to know that the former is a person and the latter an organization). The most challenging case involves phrases with different heads that are both proper nouns (e.g., "Mr. Bush" and "the White House"). Handling these cases requires domain knowledge and/or more powerful joint inference.

7 Conclusion

This paper introduces the first unsupervised coreference resolution system that is as accurate as supervised systems. It performs joint inference among mentions, using relations like apposition and predicate nominals. It uses Markov logic as a representation language, which allows it to be easily extended to incorporate additional linguistic and world knowledge. Future directions include incorporating additional knowledge, conducting joint entity detection and coreference resolution, and combining coreference resolution with other NLP tasks.

Abstract

This paper investigates two strategies for improving coreference resolution: (1) training separate models that specialize in particular types of mentions (e.g., pronouns versus proper nouns) and (2) using a ranking loss function rather than a classification function. In addition to being conceptually simple, these modifications of the standard single-model, classification-based approach also deliver significant performance improvements. Specifically, we show that on the ACE corpus both strategies produce f-score gains of more than 3% across the three coreference evaluation metrics (MUC, B^3, and CEAF).

1 Introduction

Coreference resolution is the task of partitioning a set of entity mentions in a text, where each partition corresponds to some entity in an underlying discourse model. While early machine learning approaches for the task relied on local, discriminative classifiers (Soon et al., 2001; Ng and Cardie, 2002b; Morton, 2000; Kehler et al., 2004), more recent approaches use joint and/or global models (McCallum and Wellner, 2004; Ng, 2004; Daumé III and Marcu, 2005; Denis and Baldridge, 2007a). This shift improves performance, but the systems are considerably more complex and often less efficient. Here, we explore two simple modifications of the first type of approach that yield performance gains which are comparable, and sometimes better, to those obtained with these more complex systems. These modifications involve: (i) the use of *rankers* instead of classifiers, and (ii) the use of linguistically motivated, *specialized models* for different types of mentions.

Ranking models provide a theoretically more adequate and empirically better alternative approach to pronoun resolution than standard classification-based approaches (Denis and Baldridge, 2007b). In essence, ranking models directly capture during training the competition among potential antecedent candidates, instead of considering them independently. This gives the ranker additional discriminative power and in turn better antecedent selection accuracy. Here, we show that ranking is also effective for the wider task of coreference resolution.

Coreference resolution involves several different types of anaphoric expressions: third-person pronouns, speech pronouns (i.e., first and second person pronouns), proper names, definite descriptions and other types of nominals (e.g., anaphoric uses of indefinite, quantified, and bare noun phrases). Different anaphoric expressions exhibit different patterns of resolution and are sensitive to different factors (Ariel, 1988; van der Sandt, 1992; Gundel et al., 1993), yet most machine learning approaches have ignored these differences and handle these different phenomena with a single, monolithic model. A few exceptions are worth noting. Morton (2000) and Ng (2005b) propose different classifiers models for different NPs for coreference resolution and pronoun resolution, respectively. Other partially capture the differential preferences between different anaphors via different sample selection strategies during training (Ng and Cardie, 2002b; Uryupina, 2004). More recently, Haghighi and Klein (2007) use the distinction between pronouns, nominals and proper nouns in their unsupervised, generative model for coreference resolution; for their model, this is absolutely critical for achieving better accuracy. Here, we show that using specialized models for different types of referential expressions improves performance for supervised models (both classifiers and rankers).

Both these strategies lead to improvements for all three standard coreference metrics: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and CEAF (Luo, 2005). In particular, our specialized ranker system provides absolute f-score improvements against an otherwise identical standard classifier system by 3.2%, 3.1%, and 3.6% for MUC, B^3, and CEAF, respectively.

2 Ranking

Numerous approaches to anaphora and coreference resolution reduce these tasks to a binary classification task, whereby *pairs* of mentions are classified as coreferential or not (McCarthy and Lehnert, 1995; Soon et al., 2001; Ng and Cardie, 2002b). Usually used in combination with a greedy right-to-left clustering, these approaches make very strong independence assumptions. Not only do they model each coreference decision separately, they actually model *each pair* of mentions as a separate event. Recasting these tasks as ranking tasks partly addresses this problem by directly making the comparison between different candidate antecedents for an anaphor part of the training criterion. Each candidate is assigned a conditional probability with respect to the *entire* candidate set. (Re)rankers have been successfully applied to numerous NLP tasks, such as parse selection (Osborne and Baldridge, 2004; Toutanova et al., 2004), parse reranking (Collins and Duffy, 2002; Charniak and Johnson, 2005), question-answering (Ravichandran et al., 2003).

The twin-candidate classification approach proposed by (Yang et al., 2003) shares some similarities with the ranker in making the comparison between candidate antecedents part of training. An important difference however is that under the twin-candidate approach, candidates are compared in *pairwise* fashion (and the best overall candidate is the one that has won the most round robin contests), while the ranker considers the entire candidate set at once. Another advantage of the ranking approach is that its complexity is only square in the number of mentions, while that of the twin-candidate model is cubic (see Denis and Baldridge (2007b) for a more detailed comparison in the context of pronoun resolution).

Our ranking models for coreference take the following log-linear form:

$$P_{rk}(\alpha_i|\pi) = \frac{\exp \sum_{j=1}^{m} w_j f_j(\pi, \alpha_i)}{\sum_{k} \exp \sum_{j=1}^{m} w_j f_j(\pi, \alpha_k)} \qquad (1)$$

where π stands for the anaphoric expression, α_i for an antecedent candidate, f_j the weighted features of the model. The denominator consists of a normalization factor over the k candidate mentions. Model parameters were estimated with the limited memory variable metric algorithm and Gaussian smoothing (σ^2=1000), using TADM (Malouf, 2002).

For the training of the different ranking models, we use the following procedure. For each model, instances are created by pairing each anaphor of the proper type (e.g., definite description) with a set of candidates which contains: (i) a true antecedent, and (ii) a set of non-antecedents. The selection of the true antecedent varies depending on the model we are training: for pronominal forms, the antecedent is selected as the *closest* preceding mention in the chain; for non-pronominal forms, we used the closest preceding *non-pronominal* mention in the chain as the antecedent. For the creation of the non-antecedent set, we collect all the non-antecedents that appear in a window of two sentences around the antecedent.[1] At test time, we consider *all* preceding mentions as potential antecedents.

Not all referential expressions in a given document are anaphors: some expressions introduce a discourse entity, rather than accessing an existing one. Thus, coreference resolvers must have a way of identifying such "discourse-new" expressions. This is easily handled in the standard classification approach: a mention will not be resolved if none of its candidates is classified positively (i.e., as coreferential). The problem is more troublesome for rankers, which always pick an antecedent from the candidate

[1]We suspect that different varying windows might be more appropriate for different types of expressions, but leaves this for further investigations.

set. A natural solution is to use a model that specifically predicts the discourse status (discourse-new vs. discourse-old) of each expression: only expressions that are classified as "discourse-old" by this model are considered by rankers.

Ng and Cardie (Ng and Cardie, 2002a) introduced the use of an "anaphoricity" classifier to act as a filter for coreference resolution in order to correct errors where antecedents are mistakenly identified for non-anaphoric mentions or antecedents are not determined for mentions which are indeed anaphoric. Their approach produced significant improvements in precision, but with consequent larger losses in recall. Ng (2004) improves recall by optimizing the anaphoricity threshold. By using joint inference for anaphoricity and coreference, Denis and Baldridge (2007a) avoid cascade-induced errors without the need to separately optimize the threshold.

We use a similar discourse status classifier to Ng and Cardie's as a filter on mentions for our rankers. We rely on three main types of information sources: (i) the form of mention (e.g., type of linguistic expression, number of tokens), (ii) positional features in the text, (iii) comparisons of the given mention to the mentions that precede it in the text. Evaluated on the ACE datasets, training the model on the `train` texts, and applying the classifier to the `devtest` texts, the model achieves an overall accuracy score of 80.8%, compared to a baseline of 59.7% when predicting the majority class ("discourse-old").

3 Specialized models

Our second strategy is to use different, specialized models for different referential expressions, similarly to Elwell and Baldridge's (2008) use of connective specific models for identifying the arguments of discourse connectives. For this, one must determine along which dimension to split such expressions. For example, Ng (2005b) learns models for each set of anaphors that are lexically identical (e.g., *I*, *he*, *they*, etc.). This option is possible for closed sets like pronouns, but not for other types of anaphors like proper names and definite descriptions. Another option is to rely on the particular *linguistic form* of the different expressions, as signaled by the head word category and the determiner (if any). More concretely, we use separate models for the following types: (i) third person pronouns, (ii) speech pronouns, (iii) proper names, (iv) definite descriptions, and (v) others (i.e., all expressions that don't fall into the previous categories).

The correlation between the form of a referential expression and its anaphoric behavior is actually central to various linguistic accounts (Prince, 1981; Ariel, 1988; Gundel et al., 1993). Basically, the idea is that linguistic form is an indicator of the status of the corresponding referent in the discourse model. That is, the use by the speaker of a particular linguistic form corresponds to a particular level of activation (or familiarity or salience or accessibility) in (what she thinks is) the addressee's discourse model. For many authors, the relation takes the form of a continuum and is often represented in the form of a referential hierarchy, such as:

> **Accessibility Hierarchy** (Ariel, 1988)
> Zero pronouns >> Pronouns >> Demonstrative pronouns >> Demonstrative NPs >> Short PNs >> Definite descriptions >> Full PNs >> Full PNs + appositive

The higher up, the more accessible (or salient) the entity is. At the extremes are pronouns (these forms typically require a previous mention in the local context) and proper names (these forms are often used without previous mentions of the entity). This type of hierarchy is validated by corpus studies of the distribution of different types of expressions. For instance, pronouns find their antecedents very locally (in a window of 1-2 sentences), while proper names predominantly find theirs at longer distances (Ariel, 1988).[2] Using discourse structure, Asher et al. (2006) show that while anaphoric pronouns systematically obey the right-frontier constraint (i.e., their antecedents have to appear on the right edge of the discourse graph), this is less so for definites, and even less so for proper names.

From a machine learning perspective, these findings suggest that features encoding some aspect of salience (e.g., distance, syntactic context) are likely to receive different sets of parameters depending on the form of the anaphor. This therefore suggests that better parameters are likely to be learned in the

[2]Haghighi and Klein's (2007) generative coreference model mirrors this in the posterior distribution which it assigns to mention types given their salience (see their Table 1).

Type/Count	train	test
3^{rd} pron.	$4,389$	$1,093$
speech pron.	$2,178$	610
proper names	$7,868$	$1,532$
def. NPs	$3,124$	796
others	$1,763$	568
Total	$19,322$	$4,599$

Table 1: Distribution of the different anaphors in ACE

context of different models.[3] While the above studies focus primarily on salience, there are of course other dimensions according to which anaphors differ in their resolution preferences. Thus, the resolution of lexical expressions like definite descriptions and proper names is likely to benefit from the inclusion of features that compare the strings of the anaphor and the candidate antecedent (e.g., string matching) and features that identify particular syntactic configurations like appositive structures. This type of information is however much less likely to help in the resolution of pronominal forms. The problem is that, within a single model, such features are likely to receive strong parameters (due to the fact that they are good predictors for lexical anaphors) in a way that might eventually hurt pronominal resolutions.

Note that our split of referential types only partially cover the referential hierarchies of Ariel (1988) or Gundel et al. (1993). Thus, there is no separate model for demonstrative noun phrases and pronouns: these are very rare in the corpus we used (i.e., the ACE corpus).[4] These expressions were therefore handled through the "others" model. There is however a model for first and second person pronouns (i.e., speech pronouns): this is justified by the fact that these pronouns behave differently from their third person counterparts. These forms indeed often behave like deictics (i.e., they refer to discourse participants) or they appear within a quote.

The total number of anaphors (i.e., of mentions that are not chain heads) in the data is $19,322$ and $4,599$ for training and testing, respectively. The distribution of each anaphoric type is presented in Table 1. Roughly, third person pronouns account for 22-24% of all anaphors in the entire corpus, speech pronouns for 11-13%, proper names for 33-40%, and definite descriptions for 16-17%. The distribution is slightly different from one dataset to another, probably reflecting genre differences. For instance, BNEWS shows a larger proportion of pronouns in general (pronominal forms account for 40-44% of all the anaphoric forms).

Linguistic Form	
pn	α is a proper name {1,0}
def_np	α is a definite description {1,0}
indef_np	α is an indefinite description {1,0}
pro	α is a pronoun {1,0}
Context	
left_pos	POS of the token preceding α
right_pos	POS of the token following α
surr_pos	pair of POS for the tokens surrounding α
Distance	
s_dist	Binned values for sentence distance between π and α
np_dist	Binned values for mention distance between π and α
Morphosyntactic Agreement	
gender	pairs of attributes {masc, fem, neut, unk} for π and α
number	pairs of attributes {sg, pl} for π and α
person	pairs of attributes {1, 2, 3, 4, 5, 6} for π and α
Semantic compatibility	
wn_sense	pairs of Wordnet senses for π and α
String similarity	
str_match	π and α have identical strings {1,0}
left_substr	one mention is a left substring of the other {1,0}
right_substr	one mention is a right substring of the other {1,0}
hd_match	π and α have the same head word {1,0}
Apposition	
apposition	π and α are in an appositive structure {1,0}
Acronym	
acronym	π is an acronym of α or vice versa {1,0}

Table 2: Features used by coreference models.

We use five broad types of features for all mention types, plus three others used by specific types, summarized in Table 3. Our feature extraction relies on limited linguistic processing: we only made use of a sentence detector, a tokenizer, a POS tagger (as provided by the OpenNLP Toolkit[5]) and the WordNet[6] database. Since we did not use parser, lexical heads for the NP mentions were computed using simple heuristics relying solely on POS sequences. Table 2 describes in detail the entire feature set, and Table 3 shows which features were used for which models.

Linguistic form: the referential form of the antecedent candidate: a proper name, a definite de-

[3]Another possible approach would consist in introducing different salience-based features encoding the form of the anaphor.

[4]There are only 114 demonstrative NPs and 12 demonstrative pronouns in the entire ACE training.

Table 3: Features for each type of referential expression.

scription, an indefinite NP, or a pronoun.

Context: the context of the antecedent candidate: these features can be seen as approximations of the grammatical roles, as indicators of the salience of the potential candidate (Grosz et al., 1995). For instance, this includes the part of speech tags surrounding the candidate, as well as a feature that indicates whether the potential antecedent is the first mention in a sentence (approximating subjecthood), and a feature indicating whether the candidate is embedded inside another mention.

Distance: the distance between the anaphor and the candidate, measured by the number of sentences and mentions between them.

Morphosyntactic agreement: indicators of the gender, number, and person of the two mentions. These are determined for non-pronominal NPs with heuristics based on POS tags (e.g., NN vs. NNS for number) and actual mention strings (e.g., whether the mention contains a male/female first name or honorific for gender). These features consist of pairs of attributes, ensuring that not only strict agreement (e.g., *singular-singular*) but also mere compatibility (e.g., *masculine-unknown*) is captured.

Semantic compatibility: features designed to assess whether the two mentions are semantically compatible. For these features, we use the WordNet database: in particular, we collected the synonym set (or synset) as well as the synset of their direct hypernyms associated with each mention. In the case of common nouns, we used the synset associated with the first sense associated with the mention's head word. In the case of proper names, we used the synset associated with the name if available, and the string itself otherwise. For pronouns (which are not part of Wordnet), we simply used the pronominal form.

All these features were used in all five models. While one may question the use of distance for non-pronominal anaphors,[7] their inclusion can be justified in that they might predict some "obviation" effects. Definite descriptions and proper names are sensitive to distance too, although not in the same way as pronouns are: they show a preference for antecedents that appear outside a window of one or two sentences (Ariel, 1988).

Several features are used only for particular mention types:

String similarity: similarity of the anaphor and the candidate strings. Examples are perfect string match, substring matches, and head match (i.e., the two mentions share the same head word).

Appositive: whether the anaphor is an appositive of the antecedent candidate. Since we do not have access to syntactic structure, we use heuristics (e.g., the presence of a comma between the two mentions) to extract this feature.

Acronym: whether the anaphor string is an acronym of the candidate string (or vice versa): e.g., NSF and National Science Foundation.

4 Coreference systems

We evaluate several systems to explore the effect of ranking versus classification and specialized versus monolithic models. The different systems follow a generic architecture. Let $\mathcal{M}$ be the set of mentions present in a document. For all models, each mention $m \in \mathcal{M}$ is associated at test time with a set of antecedent candidates $\mathcal{C}_m$, which includes all the mentions that linearly precede m. The best candidate is determined by the model in use. The final output of each system consists in a list of mention pairs (i.e., the coreference links) which in turn defines (through reflexive, transitive closure) a partition over the set $\mathcal{M}$. Our models are summarized in Table 4.

The use of the discourse status filter is straightforward. For each mention $m \in \mathcal{M}$, the discourse status

[7]In fact, Morton (2000) does not use distance in this case.

Model Name	Model Type	Specialized?	Disc. Status
CLASS	class	No	No
CLASS+DS	class	No	Yes
CLASS+SP	class	Yes	No
CLASS+DS+SP	class	Yes	Yes
RANK+DS+SP	rank	Yes	Yes

Table 4: Model names and their properties.

System	Accuracy
3^{rd} pron.	82.2
speech pron.	66.9
proper names	83.5
def. NPs	66.5
others	63.6

Table 5: Accuracy of the different ranker models.

model is first applied to determine whether m introduces a new discourse entity (i.e., it is classified as "new") or refers back to an existing entity (i.e., it is classified as "old"). If m is classified as "new", the process terminates and goes to the next mention. If m is classified as "old", m along with its set of antecedent candidates $\mathcal{C}_m$ is sent to the model.

For classifiers, we replicate the procedures of Ng and Cardie (2002b). During training, instances are formed by pairing each anaphor with each of its preceding candidates, until the antecedent is reached: the closest preceding antecedent in the case of a pronominal anaphor, or the closest non-pronominal antecedent for other anaphor types. For classifiers, the use of a discourse status filter at test time is optional. When a filter is not used, then a mention is left unresolved if none of the pairs created for a given mention is classified positively. If several pairs for a given mention are classified positively, then the pair with the highest score is selected (i.e., "Best-First" link selection). If a filter is used, then the candidate with the highest score is selected, even if the probability of coreference is less than one-half.[8]

The use of specialized models is simple, for both classifiers and rankers. Specialized models are created for: (i) third person pronouns, (ii) speech pronouns, (iii) proper names, (iv) definite descriptions, (v) other types of phrases. The mention type is determined and the best candidate is chosen by the appropriate model Following Elwell and Baldridge (2008), these models could be interpolated with a monolithic model, or even word specific models, but we have not explored that option here.

The feature sets for the classifiers in the baseline systems includes all the features that were used for the described in Section 3. For the classifiers that do not use specialized models (**CLASS** and **CLASS+DS**), we have also added extra features describing the linguistic form of the potential anaphor (whether it is a pronoun, a proper name, and so on). This is in accordance with standard feature sets in the pairwise approach. It gives these models a chance to learn weights more appropriately for the different types within a single, monolithic model.

5 Experiments

We use the ACE corpus (Phase 2). The corpus has three parts, each corresponding to a different genre: newspaper texts (NPAPER), newswire texts (NWIRE), and broadcast news (BNEWS). Each set is split into a `train` part and a `devtest` part. In our experiments, we consider only *true* ACE mentions.

5.1 Antecedent selection results

We first evaluate the specialized ranker models individually on the task of anaphora resolution: their ability to select a correct antecedent for each anaphor. Following common practice in this task, we report results in terms of *accuracy*, which is simply the ratio of correctly resolved anaphors. The candidate set during testing was formed by taking *all* the mentions that appear before the anaphor. Also, we assume that correctly resolving an anaphor amounts to selecting any of the previous mentions in the entity as the antecedent. The accuracy scores for the different models are presented in Table 5.

[8]This is very similar to the approach of Ng and Cardie (2002a). An important difference is that their system does not necessarily yield an antecedent for each of the anaphors proposed by the discourse status model. In their system, if the coreference classifier finds that none of the candidates for a "new" mention are coreferential, it leaves it unresolved. In this case, the coreference model acts as an additional filter. Not surprisingly, these authors report gains in precision but comparatively larger losses in recall. Our development experiments revealed that forcing a decision on items identified as new provided performed better across all metrics.

The best accuracy results on the entire ACE corpus are found first for the proper name resolver with a score of 83.5%, then for the third person pronoun resolver with 82.2%, then for the definite description and speech pronoun resolvers with 66.9% and 66.5% respectively. The worst scores are obtained for the "others" category. The high scores for the third person pronoun and the proper name rankers most likely follow from the fact that the resolution of these expressions relies on simple, reliable predictors, such as distance and morphosyntactic agreement for pronouns, and string similarity features for proper names. The resolution of definite descriptions and other types of lexical NPs (which are handled through the "others" model) are much more challenging: they rely on lexical semantic and world knowledge, which is only partially encoded via our WordNet-based features. Finally, note that the resolution of speech pronouns is also much harder than that of the other pronominal forms: these expressions are much less (if at all) constrained by recency and agreement. Furthermore, these expressions show a lot of cataphoric uses, which are not considered by our models. The low scores for the "others" category is likely due to the fact that it encompasses very different referential expressions.

5.2 Coreference Results

For evaluating the coreference performance, we rely on three primary metrics: (i) the **link** based MUC metric (Vilain et al., 1995), the **mention** based B^3 metric (Bagga and Baldwin, 1998), and the **entity** based CEAF metric (Luo, 2005). Common to these metrics is: (i) they operate by comparing the set of chains $\mathcal{S}$ produced by the system against the true chains $\mathcal{T}$, and (ii) they report performance in terms of *recall* and *precision*. There are however important differences in how each metric computes these scores, each producing a different bias.

MUC scores are based on the number of *links* (pairs of mentions) common to $\mathcal{S}$ and $\mathcal{T}$. Recall is the number of common links divided by the total number of links in $\mathcal{T}$; precision is the number of common links divided by the total number of links in $\mathcal{S}$. This focus gives MUC two main biases. First, it favors systems that create large chains (and thus fewer entities). For instance, a system that produces a single chain achieves 100% recall without severe degradation in precision. Second, it ignores single mention entities, which are involved in no links.[9]

The B^3 metric was designed to address the MUC metric's shortcomings. It is *mention-based*: it computes both recall and precision scores for each mention i. Let S be the system chain containing m, T be the true chain containing m. The set of correct elements in S is thus $|S \cap T|$. The recall score for a mention i is $\frac{|S \cap T|}{|T|}$, while the precision score for i is $\frac{|S \cap T|}{|S|}$. Overall recall/precision is obtained by averaging over the individual mention scores. The fact that this metric is mention-based by definition solves the problem of single mention entities. Also solved is the bias favoring larger chains, since this will be penalized in the precision score of *each* mention.

The Constrained Entity Aligned F-Measure (CEAF) (Luo, 2005). aligns each system chain S with *at most one* true chain T. It finds the best one-to-one mapping between the set of chains $\mathcal{S}$ and $\mathcal{T}$, which is equivalent to finding the optimal alignment in a bipartite graph. The best mapping maximizes the similarity over pairs of chains (S_i, T_i), where the similarity between two chains is the number of common mentions to the two chains. With CEAF, recall is computed as the total similarity divided by the number of mentions in all the $\mathcal{T}$ (i.e., the self-similarity), while precision is the total similarity divided by the number of mentions in $\mathcal{S}$.

Table 6 gives scores for all three metrics for the different models on the entire ACE corpus. Two main patterns emerge: significant improvements are obtained by using specialized models (**CLASS** vs **CLASS+SP** and **CLASS+DS** vs **CLASS+DS+SP**) and by using a ranker (**CLASS+DS+SP** vs **RANK+DS+SP**). Overall, the **RANK+DS+SP** system significantly outperforms the other systems on the three different metrics.[10]

The f-scores for **RANK+DS+SP** are 71.6% with the MUC metric, 72.7% with the B^3, and 67.0% with the CEAF metric. These scores place the **RANK+DS+SP** among the best coreference resolution systems, since most existing systems are typically under the bar of the 70% in f-score with the

[9]It is worth noting that the MUC corpus does not annotate single mention entities.

[10]Statistical significance was determined with t-tests for both recall and precision scores, with $p < 0.05$.

System	MUC			B^3			CEAF
	R	P	F	R	P	F	F
CLASS	60.8	72.6	66.2	62.4	77.7	69.2	62.3
CLASS+DS	64.9	72.3	68.4	65.6	74.1	69.6	63.4
CLASS+SP	64.8	74.5	69.3	65.3	79.1	71.5	65.0
CLASS+DS+SP	66.8	74.4	70.4	66.4	77.0	71.3	65.3
RANK+DS+SP	67.9	75.7	71.6	66.8	79.8	72.7	67.0

Table 6: Recall (R), Precision (P), and f-score (F) results on the entire ACE corpus using the MUC, B^3, and CEAF metrics. Note that R=P=F for CEAF when using true mentions, as we do here.

MUC and B^3 metrics (Ng, 2005a). An interesting point of comparison is provided by Ng (2007), who also relies on true mentions and reports MUC f-scores only slightly superior to ours (73.8%) while relying on perfect semantic class information. His best results otherwise are 64.6%. The fact that our improvements are consistent across the different evaluation metrics is remarkable, especially given that these three metrics are quite different in the way they compute their scores. The gains in f-score range from 1.2 to 5.4% on the MUC metric (i.e., error reductions of 4 to 15.9%), from 1.4 to 3.5% on the B^3 metric (i.e., error reductions of 4.8 to 11.4%), and from 1.7 to 4.7% on the CEAF metric (i.e., error reductions of 6.9 to 17%). The larger improvements come from recall, with improvements ranging from 1.9 to 7.1% with MUC, from 2.4 to 5.6% with B^3.[11] This suggests that **RANK+DS+SP** predicts many more valid coreference links than the other systems. Smaller but still significant gains are made in precision: **RANK+DS+SP** is also able to reduce the proportion of invalid links.

The overall improvements found with **RANK+DS+SP** suggest that it is able to capitalize on the better antecedent selection capabilities offered by the ranking approach. This is supported by the error analysis on the development data. Errors made by a coreference system can be conceptualized as falling into three main classes: (i) "missed anaphors" (i.e., an anaphoric mention that fails to be linked to a previous mention), (ii) "spurious anaphors" (i.e., an non-anaphoric mention that is linked to a previous mention), and (iii) "invalid resolutions" (i.e., a true anaphor that is linked to a incorrect antecedent). The two first types of error pertain to the determination of the discourse status of the mention, while the third regards the selection of an antecedent (i.e., anaphora resolution). Considering the systems' invalid resolutions, we found that the **RANK+DS+SP** had a much lower error rate: only 17.9% of all true anaphors were incorrectly resolved by this system, against 23.1% for **CLASS**, 24.9% for **CLASS+DS**, 20.4% for **CLASS+SP**, and 22.1% for **CLASS+DS+SP**.

Denis (2007) provides multi-metric scores for the **JOINT-ILP** model of Denis and Baldridge (2007a), which uses integer linear programming for joint inference over coreference resolution and discourse status: f-scores of 73.3%, 68.0%, and 58.9% for MUC, B^3, and CEAF, respectively. Despite the fact that this MUC score beats **RANK+DS+SP**'s, it is actually *worse* than even the basic model **CLASS** for B^3 and CEAF. This difference fact that MUC gives more recall credit for large chains without a consequent precision reduction, and shows the importance of using B^3 and CEAF scores in addition to MUC.

Denis (2007) also extends the **JOINT-ILP** system by adding named entity resolution and constraints on transitivity with respect to coreference links. The best model reported there (**JOINT-DS-NE-AE-ILP**) obtains f-scores of 70.1%, 72.7%, and 66.2% for MUC, B^3, and CEAF, respectively. Interestingly, **RANK+DS+SP** actually performs better across all metrics despite being a simpler model with fewer sources of information.

5.3 Oracle results

Using specialized rankers with a discourse status classifier yields coreference performance superior to that given by various classification-based baseline systems. Crucially, these improvements have been

[11]Recall that recall and precision scores are identical with CEAF, due to the fact that we are using true mention boundaries.

System	MUC			B^3			CEAF
	R	P	F	R	P	F	F
RANK+DS+SP	67.9	75.7	71.6	66.8	79.8	72.7	67.0
RANK+DS-ORACLE+SP	79.1	79.1	79.1	75.4	76.0	75.7	76.9
LINK-ORACLE	78.8	100.0	88.1	74.3	100.0	85.2	79.7

Table 7: Recall (R), Precision (P), and f-score (F) results for **RANK+DS-ORACLE+SP** and **LINK-ORACLE** on the entire ACE corpus.

possible using a discourse status model that has an accuracy of just 80.8%. Clearly, the performance of the discourse status module has a direct impact on the performance of the entire coreference system. On the one hand, misclassified anaphors are simply not resolved by the rankers: this limits the recall of the coreference system. On the other hand, misclassified non-anaphors are linked to a previous mention: this limits precision.

In order to further assess the impact of the errors made by the discourse status classifier, we build two different oracle systems. The first oracle system, **RANK+DS-ORACLE+SP**, uses the specialized rankers in combination with a perfect discourse status classifier. That is, this system knows for each mention whether it is anaphoric or not: the only errors made by such a system are invalid resolutions. **RANK+DS-ORACLE+SP** thus provides an upperbound for the **RANK+DS+SP** model. The results for this oracle are given in Table 7: they show substantial improvements over **RANK+DS+SP**, which suggests that the **RANK+DS+SP** has also the potential to be further improved if used in combination with a more accurate discourse status classifier.

The second oracle system, **LINK-ORACLE**, uses the discourse status classifier with a perfect coreference resolver. That is, this system has perfect knowledge regarding the antecedents of anaphors: the errors made by such a system are only errors in the discourse status of mentions. The results for **LINK-ORACLE** are also reported in Table 7. These figures show that however accurate our models are at picking a correct antecedent for a true anaphor, the best they can achieve in terms of f-scores is 88.1% with MUC, 85.2% with B^3, and 79.7% with CEAF.

6 Conclusion

We present and evaluate two straight-forward tactics for improving coreference resolution: (i) ranking models, and (ii) separate, specialized models for different types of referring expressions. The specialized rankers are used in combination with a discourse status classifier which determines the mentions that are sent to the rankers. This simple pipeline architecture produces significant improvements over various implementations of the standard, classifier-based coreference system. In turn, these strategies could be integrated with the joint inference models we have explored elsewhere (Denis and Baldridge, 2007a; Denis, 2007) and which have obtained performance improvements that are orthogonal to those obtained here.

This paper's improvements are consistent across the three main coreference evaluation metrics: MUC, B^3, and CEAF.[12] We attribute improvements to: (i) the better antecedent selection capabilities offered by the ranking approach, and (ii) the division of labor between specialized models, allowing each one to better model the corresponding distribution.

Learning with Probabilistic Features for Improved Pipeline Models

Razvan C. Bunescu

bunescu@ohio.edu

Abstract

We present a novel learning framework for pipeline models aimed at improving the communication between consecutive stages in a pipeline. Our method exploits the confidence scores associated with outputs at any given stage in a pipeline in order to compute probabilistic features used at other stages downstream. We describe a simple method of integrating probabilistic features into the linear scoring functions used by state of the art machine learning algorithms. Experimental evaluation on dependency parsing and named entity recognition demonstrate the superiority of our approach over the baseline pipeline models, especially when upstream stages in the pipeline exhibit low accuracy.

1 Introduction

Machine learning algorithms are used extensively in natural language processing. Applications range from fundamental language tasks such as part of speech (POS) tagging or syntactic parsing, to higher level applications such as information extraction (IE), semantic role labeling (SRL), or question answering (QA). Learning a model for a particular language processing problem often requires the output from other natural language tasks. Syntactic parsing and dependency parsing usually start with a textual input that is tokenized, split in sentences and POS tagged. In information extraction, named entity recognition (NER), coreference resolution, and relation extraction (RE) have been shown to benefit from features that use POS tags and syntactic dependencies. Similarly, most SRL approaches assume a parse tree representation of the input sentences. The common practice in modeling such dependencies is to use a pipeline organization, in which the output of one task is fed as input to the next task in the sequence. One advantage of this model is that it is very simple to implement; it also allows for a modular approach to natural language processing. The key disadvantage is that errors propagate between stages in the pipeline, significantly affecting the quality of the final results. One solution is to solve the tasks jointly, using the principled framework of probabilistic graphical models. Sutton et al. (2004) use factorial Conditional Random Fields (CRFs) (Lafferty et al., 2001) to jointly predict POS tags and segment noun phrases, improving on the cascaded models that perform the two tasks in sequence. Wellner et al. (2004) describe a CRF model that integrates the tasks of citation segmentation and citation matching. Their empirical results show the superiority of the integrated model over the pipeline approach. While more accurate than their pipeline analogues, probabilistic graphical models that jointly solve multiple natural language tasks are generally more demanding in terms of finding the right representations, the associated inference algorithms and their computational complexity. Recent negative results on the integration of syntactic parsing with SRL (Sutton and McCallum, 2005) provide additional evidence for the difficulty of this general approach. When dependencies between the tasks can be formulated in terms of constraints between their outputs, a simpler approach is to solve the tasks separately and integrate the constraints in a linear programming formulation, as proposed by Roth and

Yih (2004) for the simultaneous learning of named entities and relations between them. More recently, Finkel et al. (2006) model the linguistic pipelines as Bayesian networks on which they perform Monte Carlo inference in order to find the most likely output for the final stage in the pipeline.

In this paper, we present a new learning method for pipeline models that mitigates the problem of error propagation between the tasks. Our method exploits the probabilities output by any given stage in the pipeline as weights for the features used at other stages downstream. We show a simple method of integrating probabilistic features into linear scoring functions, which makes our approach applicable to state of the art machine learning algorithms such as CRFs and Support Vector Machines (Vapnik, 1998; Schölkopf and Smola, 2002). Experimental results on dependency parsing and named entity recognition show useful improvements over the baseline pipeline models, especially when the basic pipeline components exhibit low accuracy.

2 Learning with Probabilistic Features

We consider that the task is to learn a mapping from inputs $x \in \mathcal{X}$ to outputs $y \in \mathcal{Y}(x)$. Each input x is also associated with a different set of outputs $z \in \mathcal{Z}(x)$ for which we are given a probabilistic confidence measure $p(z|x)$. In a pipeline model, z would correspond to the annotations performed on the input x by all stages in the pipeline other than the stage that produces y. For example, in the case of dependency parsing, x is a sequence of words, y is a set of word-word dependencies, z is a sequence of POS tags, and $p(z|x)$ is a measure of the confidence that the POS tagger has in the output z. Let ϕ be a representation function that maps an example (x, y, z) to a feature vector $\phi(x, y, z) \in \mathbb{R}^d$, and $w \in \mathbb{R}^d$ a parameter vector. Equations (1) and (2) below show the traditional method for computing the optimal output $\hat{y}$ in a pipeline model, assuming a linear scoring function defined by w and ϕ.

$$\hat{y}(x) = \operatorname*{argmax}_{y \in \mathcal{Y}(x)} w \cdot \phi(x, y, \hat{z}(x)) \quad (1)$$

$$\hat{z}(x) = \operatorname*{argmax}_{z \in \mathcal{Z}(x)} p(z|x) \quad (2)$$

The weight vector w is learned by optimizing a predefined objective function on a training dataset.

In the model above, only the best annotation $\hat{z}$ produced by upstream stages is used for determining the optimal output $\hat{y}$. However, $\hat{z}$ may be an incorrect annotation, while the correct annotation may be ignored because it was assigned a lower confidence value. We propose exploiting all possible annotations and their probabilities as illustrated in the new model below:

$$\hat{y}(x) = \operatorname*{argmax}_{y \in \mathcal{Y}(x)} w \cdot \psi(x, y) \quad (3)$$

$$\psi(x, y) = \sum_{z \in \mathcal{Z}(x)} p(z|x) \cdot \phi(x, y, z) \quad (4)$$

In most cases, directly computing $\psi(x, y)$ is unfeasible, due to a large number of annotations in $\mathcal{Z}(x)$. In our dependency parsing example, $\mathcal{Z}(x)$ contains all possible POS taggings of sentence x; consequently its cardinality is exponential in the length of the sentence. A more efficient way of computing $\psi(x, y)$ can be designed based on the observation that most components ϕ_i of the original feature vector ϕ utilize only a limited amount of evidence from the example (x, y, z). We define $(\tilde{x}, \tilde{y}, \tilde{z}) \in \mathcal{F}_i(x, y, z)$ to capture the actual evidence from (x, y, z) that is used by one instance of feature function ϕ_i. We call $(\tilde{x}, \tilde{y}, \tilde{z})$ a *feature instance* of ϕ_i in the example (x, y, z). Correspondingly, $\mathcal{F}_i(x, y, z)$ is the set of all feature instances of ϕ_i in example (x, y, z). Usually, $\phi_i(x, y, z)$ is set to be equal with the number of instances of ϕ_i in example (x, y, z), i.e. $\phi_i(x, y, z) = |\mathcal{F}_i(x, y, z)|$. Table 1 illustrates three feature instances $(\tilde{x}, \tilde{y}, \tilde{z})$ generated by three typical dependency parsing features in the example from Figure 1. Because the same feature may be instantiated multiple times in the same example, the components of each feature instance are annotated with their positions relative to the example. Given these definitions, the feature vector $\psi(x, y)$ from (4) can be

rewritten in a component-wise manner as follows:

$$\begin{aligned}
\psi(x,y) &= [\psi_1(x,y)\ \ldots\ \psi_d(x,y)] \qquad (5)\\
\psi_i(x,y) &= \sum_{z\in\mathcal{Z}(x)} p(z|x)\cdot\phi_i(x,y,z)\\
&= \sum_{z\in\mathcal{Z}(x)} p(z|x)\cdot|\mathcal{F}_i(x,y,z)|\\
&= \sum_{z\in\mathcal{Z}(x)} p(z|x) \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,z)} 1\\
&= \sum_{z\in\mathcal{Z}(x)} \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,z)} p(z|x)\\
&= \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,\mathcal{Z}(x))} \sum_{z\in\mathcal{Z}(x),z\supseteq\tilde{z}} p(z|x)
\end{aligned}$$

where $\mathcal{F}_i(x,y,\mathcal{Z}(x))$ stands for:

$$\mathcal{F}_i(x,y,\mathcal{Z}(x)) = \bigcup_{z\in\mathcal{Z}(x)} \mathcal{F}_i(x,y,z)$$

We introduce $p(\tilde{z}|x)$ to denote the expectation:

$$p(\tilde{z}|x) = \sum_{z\in\mathcal{Z}(x),z\supseteq\tilde{z}} p(z|x)$$

Then $\psi_i(x,y)$ can be written compactly as:

$$\psi_i(x,y) = \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,\mathcal{Z}(x))} p(\tilde{z}|x) \qquad (6)$$

The total number of terms in (6) is equal with the number of instantiations of feature ϕ_i in the example (x,y) across all possible annotations $z\in\mathcal{Z}(x)$, i.e. $|\mathcal{F}_i(x,y,\mathcal{Z}(x))|$. Usually this is significantly smaller than the exponential number of terms in (4). The actual number of terms depends on the particular feature used to generate them, as illustrated in the last row of Table 1 for the three features used in dependency parsing. The overall time complexity for calculating $\psi(x,y)$ also depends on the time complexity needed to compute the expectations $p(\tilde{z}|x)$. When z is a sequence, $p(\tilde{z}|x)$ can be computed efficiently using a constrained version of the forward-backward algorithm (to be described in Section 3). When z is a tree, $p(\tilde{z}|x)$ will be computed using a constrained version of the CYK algorithm (to be described in Section 4).

The time complexity can be further reduced if instead of $\psi(x,y)$ we use its subcomponent $\hat{\psi}(x,y)$ that is calculated based only on instances that appear in the optimal annotation $\hat{z}$:

$$\begin{aligned}
\hat{\psi}(x,y) &= [\hat{\psi}_1(x,y)\ \ldots\ \hat{\psi}_d(x,y)] \qquad (7)\\
\hat{\psi}_i(x,y) &= \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,\hat{z})} p(\tilde{z}|x) \qquad (8)
\end{aligned}$$

The three models are summarized in Table 2 below. In the next two sections we illustrate their application to two common tasks in language processing: dependency parsing and named entity recognition.

M_1	$\hat{y}(x) = \operatorname{argmax}_{y\in\mathcal{Y}(x)} w\cdot\phi(x,y)$ $\phi(x,y) = \phi(x,y,\hat{z}(x))$ $\hat{z}(x) = \operatorname{argmax}_{z\in\mathcal{Z}(x)} p(z\|x)$
M_2	$\hat{y}(x) = \operatorname{argmax}_{y\in\mathcal{Y}(x)} w\cdot\psi(x,y)$ $\psi(x,y) = [\psi_1(x,y)\ \ldots\ \psi_d(x,y)]$ $\psi_i(x,y) = \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,\mathcal{Z}(x))} p(\tilde{z}\|x)$
M_3	$\hat{y}(x) = \operatorname{argmax}_{y\in\mathcal{Y}(x)} w\cdot\hat{\psi}(x,y)$ $\hat{\psi}(x,y) = [\hat{\psi}_1(x,y)\ \ldots\ \hat{\psi}_d(x,y)]$ $\hat{\psi}_i(x,y) = \sum_{(\tilde{x},\tilde{y},\tilde{z})\in\mathcal{F}_i(x,y,\hat{z})} p(\tilde{z}\|x)$

Table 2: Three Pipeline Models.

3 Dependency Parsing Pipeline

In a traditional dependency parsing pipeline (model M_1 in Table 2), an input sentence x is first augmented with a POS tagging $\hat{z}(x)$, and then processed by a dependency parser in order to obtain a dependency structure $\hat{y}(x)$. To evaluate the new pipeline models we use MSTPARSER[1], a linearly scored dependency parser developed by McDonald et al. (2005). Following the edge based factorization method of Eisner (1996), the score of a dependency tree in the first order version is defined as the sum of the scores of all edges in the tree. Equivalently, the feature vector of a dependency tree is defined as the sum of the feature vectors of all edges in the tree:

$$M_1\text{: } \phi(x,y) = \sum_{u \to v \in y} \phi(x, u \to v, \hat{z}(x))$$

$$M_2\text{: } \psi(x,y) = \sum_{u \to v \in y} \psi(x, u \to v)$$

$$M_3\text{: } \hat{\psi}(x,y) = \sum_{u \to v \in y} \hat{\psi}(x, u \to v)$$

For each edge $u \to v \in y$, MSTPARSER generates features based on a set of feature templates that take into account the words and POS tags at positions u, v, and their left and right neighbors $u \pm 1$, $v \pm 1$. For example, a particular feature template $\mathcal{T}$ used inside MSTPARSER generates the following POS bigram features:

$$\phi_i(x, u \to v, z) = \begin{cases} 1, & \text{if } \langle z_u, z_v \rangle = \langle t_1, t_2 \rangle \\ 0, & \text{otherwise} \end{cases}$$

where $t_1, t_2 \in \mathcal{P}$ are the two POS tags associated with feature index i. By replacing y with $u \to v$ in the feature expressions from Table 2, we obtain the following formulations:

$$M_1\text{:} \phi_i(x, u \to v) = \begin{cases} 1, & \text{if } \langle \hat{z}_u, \hat{z}_v \rangle = \langle t_1, t_2 \rangle \\ 0, & \text{otherwise} \end{cases}$$

$$M_2\text{:} \psi_i(x, u \to v) = p(\tilde{z} = \langle t_1, t_2 \rangle | x)$$

$$M_3\text{:} \hat{\psi}_i(x, u \to v) = \begin{cases} p(\tilde{z} = \langle t_1, t_2 \rangle | x), & \text{if } \langle \hat{z}_u, \hat{z}_v \rangle = \langle t_1, t_2 \rangle \\ 0, & \text{otherwise} \end{cases}$$

where, following the notation from Section 2, $\tilde{z} = \langle z_u, z_v \rangle$ is the actual evidence from z that is used by feature i, and $\hat{z}$ is the top scoring annotation produced by the POS tagger. The implementation in MSTPARSER corresponds to the traditional pipeline model M_1. Given a method for computing feature probabilities $p(\tilde{z} = \langle t_1, t_2 \rangle | x)$, it is straightforward to modify MSTPARSER to implement models M_2 and M_3 – we simply replace the feature vectors ϕ with ψ and $\hat{\psi}$ respectively. As mentioned in Section 2, the time complexity of computing the feature vectors ψ in model M_2 depends on the complexity of the actual evidence $\tilde{z}$ used by the features. For example, the feature template $\mathcal{T}$ used above is based on the POS tags at both ends of a dependency edge, consequently it would generate $|\mathcal{P}|^2$ features in model M_2 for any given edge $u \to v$. There are however feature templates used in MSTPARSER that are based on the POS tags of up to 4 tokens in the input sentence, which means that for each edge they would generate $|\mathcal{P}|^4 \approx 4.5M$ features. Whether using all these probabilistic features is computationally feasible or not also depends on the time complexity of computing the confidence measure $p(\tilde{z}|x)$ associated with each feature.

3.1 Probabilistic POS features

The new pipeline models M_2 and M_3 require an annotation model that, at a minimum, facilitates the computation of probabilistic confidence values for each output. We chose to use linear chain CRFs (Lafferty et al., 2001) since CRFs can be easily modified to compute expectations of the type $p(\tilde{z}|x)$, as needed by M_2 and M_3.

The CRF tagger was implemented in MALLET (McCallum, 2002) using the original feature templates from (Ratnaparkhi, 1996). The model was trained on sections 2–21 from the English Penn Treebank (Marcus et al., 1993). When tested on section 23, the CRF tagger obtains 96.25% accuracy, which is competitive with more finely tuned systems such as Ratnaparkhi's MaxEnt tagger.

We have also implemented in MALLET a constrained version of the forward-backward procedure that allows computing feature probabilities $p(\tilde{z}|x)$. If $\tilde{z} = \langle t_{i_1} t_{i_2} ... t_{i_k} \rangle$ specifies the tags at k positions in the sentence, then the procedure recomputes the α parameters for all positions between i_1 and i_k by constraining the state transitions to pass through the specified tags at the k positions. A similar approach was used by Culotta et al. in (2004) in order to associate confidence values with sequences of contiguous tokens identified by a CRF model as fields in an information extraction task. The constrained proce-

[1]URL: http://sourceforge.net/projects/mstparser

dure requires $(i_k - i_1)|\mathcal{P}|^2 = O(N|\mathcal{P}|^2)$ multiplications in an order 1 Markov model, where N is the length of the sentence. Because MSTPARSER uses an edge based factorization of the scoring function, the constrained forward procedure will need to be run for each feature template, for each pair of tokens in the input sentence x. If the evidence $\tilde{z}$ required by the feature template $\mathcal{T}$ constrains the tags at k positions, then the total time complexity for computing the probabilistic features $p(\tilde{z}|x)$ generated by $\mathcal{T}$ is:

$$O(N^3|\mathcal{P}|^{k+2}) = O(N|\mathcal{P}|^2) \cdot O(N^2) \cdot O(|\mathcal{P}|^k) \quad (9)$$

As mentioned earlier, some feature templates used in the dependency parser constrain the POS tags at 4 positions, leading to a $O(N^3|\mathcal{P}|^6)$ time complexity for a length N sentence. Experimental runs on the same machine that was used for CRF training show that such a time complexity is not yet feasible, especially because of the large size of $\mathcal{P}$ (46 POS tags). In order to speed up the computation of probabilistic features, we made the following two approximations:

1. Instead of using the constrained forward-backward procedure, we enforce an independence assumption between tags at different positions and rewrite $p(\tilde{z} = \langle t_{i_1} t_{i_2} ... t_{i_k} \rangle | x)$ as:

   $$p(t_{i_1} t_{i_2} ... t_{i_k} | x) \approx \prod_{j=1}^{k} p(t_{i_j}|x)$$

   The marginal probabilities $p(t_{i_j}|x)$ are easily computed using the original forward and backward parameters as:

   $$p(t_{i_j}|x) = \frac{\alpha_{i_j}(t_{i_j}|x)\beta_{i_j}(t_{i_j}|x)}{Z(x)}$$

   This approximation eliminates the factor $O(N|\mathcal{P}|^2)$ from the time complexity in (9).

2. If any of the marginal probabilities $p(t_{i_j}|x)$ is less than a predefined threshold $(\tau|\mathcal{P}|)^{-1}$, we set $p(\tilde{z}|x)$ to 0. When $\tau \geq 1$, the method is guaranteed to consider at least the most probable state when computing the probabilistic features. Looking back at Equation (4), this is equivalent with summing feature vectors only over the most probable annotations $z \in \mathcal{Z}(x)$.

   The approximation effectively replaces the factor $O(|\mathcal{P}|^k)$ in (9) with a quasi-constant factor.

The two approximations lead to an overall time complexity of $O(N^2)$ for computing the probabilistic features associated with any feature template $\mathcal{T}$, plus $O(N|\mathcal{P}|^2)$ for the unconstrained forward-backward procedure. We will use M_2' to refer to the model M_2 that incorporates the two approximations. The independence assumption from the first approximation can be relaxed without increasing the asymptotic time complexity by considering as independent only chunks of contiguous POS tags that are at least a certain number of tokens apart. Consequently, the probability of the tag sequence will be approximated with the product of the probabilities of the tag chunks, where the exact probability of each chunk is computed in constant time with the constrained forward-backward procedure. We will use M_2'' to refer to the resulting model.

3.2 Experimental Results

MSTPARSER was trained on sections 2–21 from the WSJ Penn Treebank, using the gold standard POS tagging. The parser was then evaluated on section 23, using the POS tagging output by the CRF tagger. For model M_1 we need only the best output from the POS tagger. For models M_2' and M_2'' we compute the probability associated with each feature using the corresponding approximations, as described in the previous section. In model M_2'' we consider as independent only chunks of POS tags that are 4 tokens or more apart. If the distance between the chunks is less than 4 tokens, the probability for the entire tag sequence in the feature is computed exactly using the constrained forward-backward procedure. Table 3 shows the accuracy obtained by models M_1, $M_2'(\tau)$ and $M_2''(\tau)$ for various values of the threshold parameter τ. The accuracy is computed over unlabeled dependencies i.e. the percentage of words for which the parser has correctly identified the parent in the dependency tree. The pipeline

Figure 2: Named Entity Recognition Example.

model M_2' that uses probabilistic features outperforms the traditional pipeline model M_1. As expected, M_2'' performs slightly better than M_2', due to a more exact computation of feature probabilities. Overall, only by using the probabilities associated with the POS features, we achieve an absolute error reduction of 0.19%, in a context where the POS stage in the pipeline already has a very high accuracy of 96.25%. We expect probabilistic features to yield a more substantial improvement in cases where the pipeline model contains less accurate upstream stages. Such a case is that of NER based on a combination of POS and dependency parsing features.

4 Named Entity Recognition Pipeline

In Named Entity Recognition (NER), the task is to identify textual mentions of predefined types of entities. Traditionally, NER is modeled as a sequence classification problem: each token in the input sentence is tagged as being either inside (I) or outside (O) of an entity mention. Most sequence tagging approaches use the words and the POS tags in a limited neighborhood of the current sentence position in order to compute the corresponding features. We augment these *flat features* with a set of *tree features* that are computed based on the words and POS tags found in the proximity of the current token in the dependency tree of the sentence. We argue that such dependency tree features are better at capturing predicate-argument relationships, especially when they span long stretches of text. Figure 2 shows a sentence x together with its POS tagging z_1, dependency links z_2, and an output tagging y. Assuming the task is to recognize mentions of people, the word *sailors* needs to be tagged as inside. If we extracted only flat features using a symmetric window of size 3, the relationship between *sailors* and *thought* would be missed. This relationship is useful, since an agent of the predicate *thought* is likely to be a person entity. On the other hand, the nodes *sailors* and *thought* are adjacent in the dependency tree of the sentence. Therefore, their relationship can be easily captured as a dependency tree feature using the same window size.

For every token position, we generate flat features by considering all unigrams, bigrams and trigrams that start with the current token and extend either to the left or to the right. Similarly, we generate tree features by considering all unigrams, bigrams and trigrams that start with the current token and extend in any direction in the undirected version of the dependency tree. The tree features are also augmented with the actual direction of the dependency arcs between the tokens. If we use only words to create n-gram features, the token *sailors* will be associated with the following features:

- **Flat:** *sailors*, *the sailors*, ⟨*S*⟩ *the sailors*, *sailors mistakenly*, *sailors mistakenly thought*.
- **Tree:** *sailors*, *sailors* $\leftarrow$ *the*, *sailors* $\rightarrow$ *thought*, *sailors* $\rightarrow$ *thought* $\leftarrow$ *must*, *sailors* $\rightarrow$ *thought* $\leftarrow$ *mistakenly*.

We also allow n-grams to use word classes such as POS tags and any of the following five categories: ⟨1C⟩ for tokens consisting of one capital letter, ⟨AC⟩ for tokens containing only capital letters, ⟨FC⟩ for tokens that start with a capital letter, followed by small letters, ⟨CD⟩ for tokens containing at least one digit, and ⟨CRT⟩ for the current token.

The set of features can then be defined as a Cartesian product over word classes, as illustrated in Figure 3 for the original tree feature *sailors* $\rightarrow$ *thought* $\leftarrow$ *mistakenly*. In this case, instead of one completely lexicalized feature, the model will consider 12 different features such as *sailors* $\rightarrow$ *VBD* $\leftarrow$ *RB*, *NNS* $\rightarrow$ *thought* $\leftarrow$ *RB*, or *NNS* $\rightarrow$ *VBD* $\leftarrow$ *RB*.

$$\begin{bmatrix} \langle \text{CRT} \rangle \\ \text{NNS} \\ \text{sailors} \end{bmatrix} \times [\rightarrow] \times \begin{bmatrix} \text{VBD} \\ \text{thought} \end{bmatrix} \times [\leftarrow] \times \begin{bmatrix} \text{RB} \\ \text{mistakenly} \end{bmatrix}$$

Figure 3: Dependency tree features.

The pipeline model M_2 uses features that appear in all possible annotations $z = \langle z_1, z_2 \rangle$, where z_1 and z_2 are the POS tagging and the dependency parse respectively. If the corresponding evidence is $\tilde{z} = \langle \tilde{z}_1, \tilde{z}_2 \rangle$, then:

$$p(\tilde{z}|x) = p(\tilde{z}_2|\tilde{z}_1, x)p(\tilde{z}_1|x)$$

For example, $\textit{NNS}_2 \rightarrow \textit{thought}_4 \leftarrow \textit{RB}_3$ is a feature instance for the token *sailors* in the annotations from Figure 2. This can be construed as having been generated by a feature template $\mathcal{T}$ that outputs the POS tag t_i at the current position, the word x_j that is the parent of x_i in the dependency tree, and the POS tag t_k of another dependent of x_j (i.e. $t_i \rightarrow x_j \leftarrow t_k$). The probability $p(\tilde{z}|x)$ for this type of features can then be written as:

$$p(\tilde{z}|x) = p(i \rightarrow j \leftarrow k | t_i, t_k, x) \cdot p(t_i, t_k|x)$$

The two probability factors can be computed exactly as follows:

1. The M_2 model for dependency parsing from Section 3 is used to compute the probabilistic features $\psi(x, u \rightarrow v | t_i, t_k)$ by constraining the POS annotations to pass through tags t_i and t_k at positions i and k. The total time complexity for this step is $O(N^3|\mathcal{P}|^{k+2})$.

2. Having access to $\psi(x, u \rightarrow v | t_i, t_k)$, the factor $p(i \rightarrow j \leftarrow k | t_i, t_k, x)$ can be computed in $O(N^3)$ time using a constrained version of Eisner's algorithm, as will be explained in Section 4.1.

3. As described in Section 3.1, computing the expectation $p(t_i, t_k|x)$ takes $O(N|\mathcal{P}^2|)$ time using the constrained forward-backward algorithm.

The current token position i can have a total of N values, while j and k can be any positions other than i. Also, t_i and t_k can be any POS tag from $\mathcal{P}$. Consequently, the feature template $\mathcal{T}$ induces $O(N^3|\mathcal{P}|^2)$ feature instances. Overall, the time complexity for computing the feature instances generated by $\mathcal{T}$ is $O(N^6|\mathcal{P}|^{k+4})$, as results from:

$$O(N^3|\mathcal{P}|^2) \cdot (O(N^3|\mathcal{P}|^{k+2}) + O(N^3) + O(N|\mathcal{P}|^2))$$

While still polynomial, this time complexity is feasible only for small values of N. In general, the time complexity for computing probabilistic features in the full model M_2 increases with both the number of stages in the pipeline and the complexity of the features.

Motivated by efficiency, we decided to use the pipeline model M_3 in which probabilities are computed only over features that appear in the top scoring annotation $\hat{z} = \langle \hat{z}_1, \hat{z}_2 \rangle$, where $\hat{z}_1$ and $\hat{z}_2$ represent the best POS tagging, and the best dependency parse respectively. In order to further speed up the computation of probabilistic features, we made the following approximations:

1. We consider the POS tagging and the dependency parse independent and rewrite $p(\tilde{z}|x)$ as:

$$p(\tilde{z}|x) = p(\tilde{z}_1, \tilde{z}_2|x) \approx p(\tilde{z}_1|x)p(\tilde{z}_2|x)$$

2. We enforce an independence assumption between POS tags. Thus, if $\tilde{z}_1 = \langle t_{i_1} t_{i_2} ... t_{i_k} \rangle$ specifies the tags at k positions in the sentence, then $p(\tilde{z}_1|x)$ is rewritten as:

$$p(t_{i_1} t_{i_2} ... t_{i_k}|x) \approx \prod_{j=1}^{k} p(t_{i_j}|x)$$

3. We also enforce a similar independence assumption between dependency links. Thus, if $\tilde{z}_2 = \langle u_1 \rightarrow v_1 ... u_k \rightarrow v_k \rangle$ specifies k dependency links, then $p(\tilde{z}_2|x)$ is rewritten as:

$$p(u_1 \rightarrow v_1 ... u_k \rightarrow v_k|x) \approx \prod_{l=1}^{k} p(u_l \rightarrow v_l|x)$$

For example, the probability $p(\tilde{z}|x)$ of the feature instance $\textit{NNS}_2 \rightarrow \textit{thought}_4 \leftarrow \textit{RB}_3$ is approximated as:

$$\begin{aligned} p(\tilde{z}|x) &\approx p(\tilde{z}_1|x) \cdot p(\tilde{z}_2|x) \\ p(\tilde{z}_1|x) &\approx p(t_2 = \textit{NNS}|x) \cdot p(t_3 = \textit{RB}|x) \\ p(\tilde{z}_2|x) &\approx p(2 \rightarrow 4|x) \cdot p(3 \rightarrow 4|x) \end{aligned}$$

We will use M'_3 to refer to the resulting model.

4.1 Probabilistic Dependency Features

The probabilistic POS features $p(t_i|x)$ are computed using the forward-backward procedure in CRFs, as described in Section 3.1. To completely specify the pipeline model for NER, we also need an efficient method for computing the probabilistic dependency features $p(u \rightarrow v|x)$, where $u \rightarrow v$ is a dependency edge between positions u and v in the sentence x. MSTPARSER is a large-margin method that computes an unbounded score $s(x, y)$ for any given sentence x and dependency structure $y \in \mathcal{Y}(x)$ using the following edge-based factorization:

$$s(x,y) = \sum_{u\rightarrow v \in y} s(x, u\rightarrow v) = w \sum_{u\rightarrow v \in y} \phi(x, u\rightarrow v)$$

The following three steps describe a general method for associating probabilities with output substructures. The method can be applied whenever a structured output is associated a score value that is unbounded in $\mathbb{R}$, assuming that the score of the entire output structure can be computed efficiently based on a factorization into smaller substructures.

S1. Map the unbounded score $s(x, y)$ from $\mathbb{R}$ into $[0, 1]$ using the *softmax* function (Bishop, 1995):

$$n(x,y) = \frac{e^{s(x,y)}}{\sum_{y \in \mathcal{Y}(x)} e^{s(x,y)}}$$

The normalized score $n(x, y)$ preserves the ranking given by the original score $s(x, y)$. The normalization constant at the denominator can be computed in $O(N^3)$ time by replacing the *max* operator with the *sum* operator inside Eisner's chart parsing algorithm.

S2. Compute a normalized score for the substructure by summing up the normalized scores of all the complete structures that contain it. In our model, dependency edges are substructures, while dependency trees are complete structures. The normalized score will then be computed as:

$$n(x, u\rightarrow v) = \sum_{y \in \mathcal{Y}(x), u\rightarrow v \in y} n(x,y)$$

The sum can be computed in $O(N^3)$ time using a constrained version of the algorithm that computes the normalization constant in step S1. This constrained version of Eisner's algorithm works in a similar manner with the constrained forward backward algorithm by restricting the dependency structures to contain a predefined edge or set of edges.

S3. Use the isotonic regression method of Zadrozny and Elkan (2002) to map the normalized scores $n(x, u\rightarrow v)$ into probabilities $p(u\rightarrow v|x)$. A potential problem with the softmax function is that, depending on the distribution of scores, the exponential transform could dramatically overinflate the higher scores. Isotonic regression, by redistributing the normalized scores inside $[0, 1]$, can alleviate this problem.

4.2 Experimental Results

We test the pipeline model M_3' versus the traditional model M_1 on the task of detecting mentions of person entities in the ACE dataset[2]. We use the standard training – testing split of the ACE 2002 dataset in which the training dataset is also augmented with the documents from the ACE 2003 dataset. The combined dataset contains 674 documents for training and 97 for testing. We implemented the CRF model in MALLET using three different sets of features: **Tree**, **Flat**, and **Full** corresponding to the union of all flat and tree features. The POS tagger and the dependency parser were trained on sections 2-21 of the Penn Treebank, followed by an isotonic regression step on section 23 for the dependency parser. We compute precision recall (PR) graphs by varying a threshold on the token level confidence output by the CRF tagger, and summarize the tagger performance using the area under the curve. Table 4 shows the results obtained by the two models under the three feature settings. The model based on probabilistic features consistently outperforms the traditional model, especially when only tree features are used. Dependency parsing is significantly less accurate than POS tagging. Consequently, the improvement for the tree based model is more substantial than for the flat

model, confirming our expectation that probabilistic features are more useful when upstream stages in the pipeline are less accurate. Figure 4 shows the PR curves obtained for the tree-based models, on which we see a significant 5% improvement in precision over a wide range of recall values.

5 Related Work

In terms of the target task – improving the performance of linguistic pipelines – our research is most related to the work of Finkel et al. (2006). In their approach, output samples are drawn at each stage in the pipeline conditioned on the samples drawn at previous stages, and the final output is determined by a majority vote over the samples from the final stage. The method needs very few samples for tasks such as textual entailment, where the final outcome is binary, in agreement with a theoretical result on the rate of convergence of the voting Gibbs classifier due to Ng and Jordan (2001). While their sampling method is inherently approximate, our full pipeline model M_2 is exact in the sense that feature expectations are computed exactly in polynomial time whenever the inference step at each stage can be done in polynomial time, irrespective of the cardinality of the final output space. Also, the pipeline models M_2 and M_3 and their more efficient alternatives propagate uncertainty during both training and testing through the vector of probabilistic features, whereas the sampling method takes advantage of the probabilistic nature of the outputs only during testing. Overall, the two approaches can be seen as complementary. In order to be applicable with minimal engineering effort, the sampling method needs NLP researchers to write packages that can generate samples from the posterior. Similarly, the new pipeline models could be easily applied in a diverse range of applications, assuming researchers develop packages that can efficiently compute marginals over output substructures.

6 Conclusions and Future Work

We have presented a new, general method for improving the communication between consecutive stages in pipeline models. The method relies on the computation of probabilities for count features, which translates in adding a polynomial factor to the overall time complexity of the pipeline whenever the inference step at each stage is done in polynomial time, which is the case for the vast majority of inference algorithms used in practical NLP applications. We have also shown that additional independence assumptions can make the approach more practical by significantly reducing the time complexity. Existing learning based models can implement the new method by replacing the original feature vector with a more dense vector of probabilistic features[3]. It is essential that every stage in the pipeline produces probabilistic features, and to this end we have described an effective method for associating probabilities with output substructures.

We have shown for NER that simply using the probabilities associated with features that appear only in the top annotation can lead to useful improvements in performance, with minimal engineering effort. In future work we plan to empirically evaluate NER with an approximate version of the full model M_2 which, while more demanding in terms of time complexity, could lead to even more significant gains in accuracy. We also intend to comprehensively evaluate the proposed scheme for computing probabilities by experimenting with alternative normalization functions.

Cross-Task Knowledge-Constrained Self Training

Abstract

We present an algorithmic framework for learning multiple related tasks. Our framework exploits a form of prior knowledge that relates the output spaces of these tasks. We present PAC learning results that analyze the conditions under which such learning is possible. We present results on learning a shallow parser and named-entity recognition system that exploits our framework, showing consistent improvements over baseline methods.

1 Introduction

When two NLP systems are run on the same data, we expect certain constraints to hold between their outputs. This is a form of prior knowledge. We propose a self-training framework that uses such information to significantly boost the performance of one of the systems. The key idea is to perform self-training *only* on outputs that obey the constraints.

Our motivating example in this paper is the task pair: named entity recognition (NER) and shallow parsing (aka syntactic chunking). Consider a hidden sentence with known POS and syntactic structure below. Further consider four potential NER sequences for this sentence.

POS:	NNP	NNP	VBD	TO	NNP	NN
Chunk:	[- NP	-]	[- VP -]	[-PP-]	[- NP -]	[-NP-]
NER1:	[- Per		-]	[- O -]	[-Org-]	[- 0 -]
NER2:	[- Per	-]	[- O -]	[- O -]	[- O -]	[- O -]
NER3:	[- Per	-]	[- O -]	[- O -]	[- Org	-]
NER4:	[- Per	-]	[- O -]	[- O -]	[-Org-]	[- O -]

Without ever seeing the actual sentence, can we guess which NER sequence is correct? NER1 seems wrong because we feel like named entities should not be part of verb phrases. NER2 seems wrong because there is an NNP[1] (proper noun) that is not part of a named entity (word 5). NER3 is amiss because we feel it is unlikely that a *single* name should span more than one NP (last two words). NER4 has none of these problems and seems quite reasonable. In fact, for the hidden sentence, NER4 is correct[2].

The remainder of this paper deals with the problem of formulating such prior knowledge into a workable system. There are similarities between our proposed model and both self-training and co-training; background is given in Section 2. We present a formal model for our approach and perform a simple, yet informative, analysis (Section 3). This analysis allows us to define what good and bad constraints are. Throughout, we use a running example of NER using hidden Markov models to show the efficacy of the method and the relationship between the theory and the implementation. Finally, we present full-blown results on seven different NER data sets (one from CoNLL, six from ACE), comparing our method to several competitive baselines (Section 4). We see that for many of these data sets, less than one hundred labeled NER sentences are required to get state-of-the-art performance, using a discriminative sequence labeling algorithm (Daumé III and Marcu, 2005).

2 Background

Self-training works by learning a model on a small amount of labeled data. This model is then evalu-

[1]When we refer to NNP, we also include NNPS.

[2]The sentence is: “George Bush spoke to Congress today”

ated on a large amount of unlabeled data. Its predictions are assumed to be correct, and it is retrained on the unlabeled data according to its own predictions. Although there is little theoretical support for self-training, it is relatively popular in the natural language processing community. Its success stories range from parsing (McClosky et al., 2006) to machine translation (Ueffing, 2006). In some cases, self-training takes into account *model confidence*.

Co-training (Yarowsky, 1995; Blum and Mitchell, 1998) is related to self-training, in that an algorithm is trained on its own predictions. Where it differs is that co-training learns two *separate* models (which are typically assumed to be independent; for instance by training with disjoint feature sets). These models are both applied to a large repository of unlabeled data. Examples on which these two models *agree* are extracted and treated as labeled for a new round of training. In practice, one often also uses a notion of model confidence and only extracts agreed-upon examples for which both models are confident. The original, and simplest analysis of co-training is due to Blum and Mitchell (1998). It does not take into account confidence (to do so requires a *significantly* more detailed analysis (Dasgupta et al., 2001)), but is useful for understanding the process.

3 Model

We define a formal PAC-style (Valiant, 1994) model that we call the "hints model"[3]. We have an instance space $\mathcal{X}$ and *two* output spaces $\mathcal{Y}_1$ and $\mathcal{Y}_2$. We assume two concept classes $\mathcal{C}_1$ and $\mathcal{C}_2$ for each output space respectively. Let $\mathcal{D}$ be a distribution over $\mathcal{X}$, and $f_1 \in \mathcal{C}_1$ (resp., $f_2 \in \mathcal{C}_2$) be target functions. The goal, of course, is to use a finite sample of examples drawn from $\mathcal{D}$ (and labeled—perhaps with noise—by f_1 and f_2) to "learn" $h_1 \in \mathcal{C}_1$ and $h_2 \in \mathcal{C}_2$, which are good approximations to f_1 and f_2.

So far we have not made use of any notion of constraints. Our expectation is that if we constrain h_1 and h_2 to *agree* (vis-a-vis the example in the Introduction), then we should need fewer labeled examples to learn either. (The agreement should "shrink" the size of the corresponding hypothesis spaces.) To formalize this, let $\chi : \mathcal{Y}_1 \times \mathcal{Y}_2 \to \{0, 1\}$ be a *constraint function.* We say that two outputs $y_1 \in \mathcal{Y}_1$ and $y_2 \in \mathcal{Y}_2$ are *compatible* if $\chi(y_1, y_2) = 1$. We need to assume that χ is correct:

Definition 1. *We say that χ is* correct *with respect to $\mathcal{D}, f_1, f_2$ if whenever x has non-zero probability under $\mathcal{D}$, then $\chi(f_1(x), f_2(x)) = 1$.*

RUNNING EXAMPLE

In our example, $\mathcal{Y}_1$ is the space of all POS/chunk sequences and $\mathcal{Y}_2$ is the space of all NER sequences. We assume that $\mathcal{C}_1$ and $\mathcal{C}_2$ are both represented by HMMs over the appropriate state spaces. The functions we are trying to learn are f_1, the "true" POS/chunk labeler and f_2, the "true" NER labeler. (Note that we assume $f_1 \in \mathcal{C}_1$, which is obviously not true for language.)

Our constraint function χ will require the following for agreement: (1) any NNP must be part of a named entity; (2) any named entity must be a subsequence of a noun phrase. This is precisely the set of constraints discussed in the introduction.

The question is: given this additional source of knowledge (i.e., χ), has the learning problem become easier? That is, can we learn f_2 (and/or f_1) using significantly fewer labeled examples than if we did not have χ? Moreover, we have assumed that χ is *correct*, but is this enough? Intuitively, no: a function χ that returns 1 regardless of its inputs is clearly not useful. Given this, what other constraints must be placed on χ. We address these questions in Sections 3.3. However, first we define our algorithm.

3.1 One-sided Learning with Hints

We begin by considering a simplified version of the "learning with hints" problem. Suppose that all we care about is learning f_2. We have a small amount of data labeled by f_2 (call this D) and a *large* amount of data labeled by f_1 (call this D^{unlab}–"unlab" because as far as f_2 is concerned, it is unlabeled).

RUNNING EXAMPLE

In our example, this means that we have a small amount of labeled NER data and a large amount of labeled POS/chunk data. We use 3500 sentences from CoNLL (Tjong Kim Sang and De Meulder, 2003) as the NER data and section 20-23 of the WSJ (Marcus et al., 1993; Ramshaw and Marcus, 1995) as the POS/chunk data (8936 sentences). We are *only* interested in learning to do NER. Details of the exact HMM setup are in Section 4.2.

[3]The name comes from thinking of our knowledge-based constraints as "hints" to a learner as to what it should do.

We call the following algorithm "One-Sided Learning with Hints," since it aims only to learn f_2:

```
1: Learn $h_2$ directly on $D$
2: For each example $(x, y_1) \in D^{\text{unlab}}$
3:     Compute $y_2 = h_2(x)$
4:     If $\chi(y_1, y_2)$, add $(x, y_2)$ to $D$
5: Relearn $h_2$ on the (augmented) $D$
6: Go to (2) if desired
```

RUNNING EXAMPLE

In step 1, we train an NER HMM on CoNLL. On test data, this model achieves an F-score of 50.8. In step 2, we run this HMM on all the WSJ data, and extract 3145 compatible examples. In step 3, we retrain the HMM; the F-score rises to 58.9.

3.2 Two-sided Learning with Hints

In the two-sided version, we assume that we have a small amount of data labeled by f_1 (call this D_1), a small amount of data labeled by f_2 (call this D_2) and a *large* amount of unlabeled data (call this D^{unlab}). The algorithm we propose for learning hypotheses for both tasks is below:

```
1: Learn $h_1$ on $D_1$ and $h_2$ on $D_2$.
2: For each example $x \in D^{\text{unlab}}$:
3:     Compute $y_1 = h_1(x)$ and $y_2 = h_2(x)$
4:     If $\chi(y_1, y_2)$ add $(x, y_1)$ to $D_1$, $(x, y_2)$ to $D_2$
5: Relearn $h_1$ on $D_1$ and $h_2$ on $D_2$.
6: Go to (2) if desired
```

RUNNING EXAMPLE

We use 3500 examples from NER and 1000 from WSJ. We use the remaining 18447 examples as unlabeled data. The baseline HMMs achieve F-scores of 50.8 and 76.3, respectively. In step 2, we add 7512 examples to each data set. After step 3, the new models achieve F-scores of 54.6 and 79.2, respectively. The gain for NER is lower than before as it is trained against "noisy" syntactic labels.

3.3 Analysis

Our goal is to prove that one-sided learning with hints "works." That is, if C_2 is learnable from large amounts of labeled data, then it is also learnable from small amounts of labeled data and large amounts of f_1-labeled data. This is formalized in Theorem 1 (all proofs are in Appendix A). However, before stating the theorem, we must define an "initial weakly-useful predictor" (terminology from Blum and Mitchell(1998)), and the notion of noisy PAC-learning in the structured domain.

Definition 2. *We say that h is a* weakly-useful predictor *of f if for all y:* $\Pr_{\mathcal{D}}[h(x) = y] \geq \epsilon$ *and* $\Pr_{\mathcal{D}}[f(x) = y \mid h(x) = y' \neq y] \geq \Pr_{\mathcal{D}}[f(x) = y] + \epsilon$.

This definition simply ensures that (1) h is non-trivial: it assigns some non-zero probability to every possible output; and (2) h is somewhat indicative of f. In practice, we use the hypothesis learned on the small amount of training data during step (1) of the algorithm as the weakly useful predictor.

Definition 3. *We say that $\mathcal{C}$ is* PAC-learnable with noise (in the structured setting) *if there exists an algorithm with the following properties. For any $c \in \mathcal{C}$, any distribution $\mathcal{D}$ over $\mathcal{X}$, any $0 \leq \eta \leq 1/|\mathcal{Y}|$, any $0 < \epsilon < 1$, any $0 < \delta < 1$ and any $\eta \leq \eta_0 < 1/|\mathcal{Y}|$, if the algorithm is given access to examples drawn $EX^{\eta}_{SN}(c, \mathcal{D})$ and inputs ϵ, δ and η_0, then with probability at least $1 - \delta$, the algorithm returns a hypothesis $h \in \mathcal{C}$ with error at most ϵ. Here, $EX^{\eta}_{SN}(c, \mathcal{D})$ is a structured noise oracle, which draws examples from $\mathcal{D}$, labels them by c and randomly replaces with another label with prob. η.*

Note here the rather weak notion of noise: entire structures are randomly changed, rather than individual labels. Furthermore, the error is 0/1 loss over the entire structure. Collins (2001) establishes learnability results for the class of hyperplane models under 0/1 loss. While not stated directly in terms of PAC learnability, it is clear that his results apply. Taskar et al. (2005) establish *tighter* bounds for the case of Hamming loss. This suggests that the requirement of 0/1 loss is weaker.

As suggested before, it is not sufficient for χ to simply be *correct* (the constant 1 function is correct, but not useful). We need it to be discriminating, made precise in the following definition.

Definition 4. *We say the* discrimination *of χ for h^0 is* $\Pr_{\mathcal{D}}[\chi(f_1(x), h^0(x))]^{-1}$.

In other words, a constraint function is discriminating when it is unlikely that our weakly-useful predictor h^0 chooses an output that satisfies the constraint. This means that if we *do* find examples (in our unlabeled corpus) that satisfy the constraints, they are likely to be "useful" to learning.

RUNNING EXAMPLE

In the NER HMM, let h^0 be the HMM obtained by training on the small labeled NER data set and f_1 is the true syntactic labels. We approximate $\Pr_{\mathcal{D}}$ by an empirical estimate over the unlabeled distribution. This gives a discrimination is 41.6 for the constraint function defined previously. However, if we compare against "weaker" constraint functions, we see the appropriate trend. The value for the constraint based only on POS tags is 39.1 (worse) and for the NP constraint alone is 27.0 (much worse).

Theorem 1. *Suppose C_2 is PAC-learnable with noise in the structured setting, h_2^0 is a weakly useful predictor of f_2, and χ is correct with respect to $\mathcal{D}, f_1, f_2, h_2^0$, and has discrimination $\geq 2(|\mathcal{Y}| - 1)$. Then C_2 is also PAC-learnable with one-sided hints.*

The way to interpret this theorem is that it tells us that if the initial h_2 we learn in step 1 of the one-sided algorithm is "good enough" (in the sense that it is weakly-useful), then we can use it as specified by the remainder of the one-sided algorithm to obtain an arbitrarily good h_2 (via iterating).

The dependence on $|\mathcal{Y}|$ is the discrimination bound for χ is unpleasant for structured problems. If we wish to find M unlabeled examples that satisfy the hints, we'll need a total of at least $2M(|\mathcal{Y}| - 1)$ total. This dependence can be improved as follows. Suppose that our structure is represented by a graph over vertices V, each of which can take a label from a set Y. Then, $|\mathcal{Y}| = \left|Y^V\right|$, and our result requires that χ be discriminating on an order exponential in V. Under the assumption that χ decomposes over the graph structure (true for our example) and that C_2 is PAC-learnable with per-vertex noise, then the discrimination requirement drops to $2\,|V|\,(|Y| - 1)$.

RUNNING EXAMPLE

In NER, $|Y| = 9$ and $|V| \approx 26$. This means that the values from the previous example look not quite so bad. In the 0/1 loss case, they are compared to 10^{25}; in the Hamming case, they are compared to only 416. The ability of the one-sided algorithm follows the same trends as the discrimination values. Recall the baseline performance is 50.8. With both constraints (and a discrimination value of 41.6), we obtain a score of 58.9. With just the POS constraint (discrimination of 39.1), we obtain a score of 58.1. With just the NP constraint (discrimination of 27.0, we obtain a score of 54.5.

The final question is how one-sided learning relates to two-sided learning. The following definition and easy corollary shows that they are related in the obvious manner, but depends on a notion of uncorrelation between h_1^0 and h_2^0.

Definition 5. *We say that h_1 and h_2 are* uncorrelated *if* $\Pr_{\mathcal{D}}\left[h_1(x) = y_1 \mid h_2(x) = y_2, x\right] = \Pr_{\mathcal{D}}\left[h_1(x) = y_1 \mid x\right]$.

Corollary 1. *Suppose C_1 and C_2 are both PAC-learnable in the structured setting, h_1^0 and h_2^0 are weakly useful predictors of f_1 and f_2, and χ is correct with respect to $\mathcal{D}, f_1, f_2, h_1^0$ and h_2^0, and has discrimination $\geq 4(|\mathcal{Y}| - 1)^2$ (for 0/1 loss) or $\geq 4\,|V|^2\,(|Y| - 1)^2$ (for Hamming loss), and that h_1^0 and h_2^0 are uncorrelated. Then C_1 and C_2 are also PAC-learnable with two-sided hints.*

Unfortunately, Corollary 1 depends *quadratically* on the discrimination term, unlike Theorem 1.

4 Experiments

In this section, we describe our experimental results. We have already discussed some of them in the context of the running example. In Section 4.1, we briefly describe the data sets we use. A full description of the HMM implementation and its results are in Section 4.2. Finally, in Section 4.3, we present results based on a competitive, discriminatively-learned sequence labeling algorithm. All results for NER and chunking are in terms of F-score; all results for POS tagging are accuracy.

4.1 Data Sets

Our results are based on syntactic data drawn from the Penn Treebank (Marcus et al., 1993), specifically the portion used by CoNLL 2000 shared task (Tjong Kim Sang and Buchholz, 2000). Our NER data is from two sources. The first source is the CoNLL 2003 shared task date (Tjong Kim Sang and De Meulder, 2003) and the second source is the 2004 NIST Automatic Content Extraction (Weischedel, 2004). The ACE data constitute six separate data sets from six domains: weblogs (wl), newswire (nw), broadcast conversations (bc), United Nations (un), direct telephone speech (dts) and broadcast news (bn). Of these, bc, dts and bn are all speech data sets. All the examples from the previous sections have been limited to the CoNLL data.

4.2 HMM Results

The experiments discussed in the preceding sections are based on a generative hidden Markov model for both the NER and syntactic chunking/POS tagging tasks. The HMMs constructed use first-order transitions and emissions. The emission vocabulary is pruned so that any word that appears ≤ 1 time in the training data is replaced by a unique `*unknown*` token. The transition and emission probabilities are smoothed with Dirichlet smoothing, $\alpha = 0.001$ (this was not-aggressively tuned by hand on one setting). The HMMs are implemented as finite state models in the Carmel toolkit (Graehl and Knight, 2002).

The various compatibility functions are also implemented as finite state models. We implement them as a transducer *from* POS/chunk labels *to* NER labels (though through the reverse operation, they can obviously be run in the opposite direction). The construction is with a single state with transitions:

- (NNP,?) maps to B-* and I-*
- (?,B-NP) maps to B-* and O
- (?,I-NP) maps to B-*, I-* and O
- Single exception: (NNP,x), where x is *not* an NP tag maps to anything (this is simply to avoid empty composition problems). This occurs in 100 of the $212k$ words in the Treebank data and more rarely in the automatically tagged data.

4.3 One-sided Discriminative Learning

In this section, we describe the results of one-sided discriminative labeling with hints. We use the true syntactic labels from the Penn Treebank to derive the constraints (this is roughly 9000 sentences). We use the LaSO sequence labeling software (Daumé III and Marcu, 2005), with its built-in feature set.

Our goal is to analyze two things: (1) what is the effect of the amount of labeled NER data? (2) what is the effect of the amount of labeled syntactic data from which the hints are constructed?

To answer the first question, we keep the amount of syntactic data fixed (at 8936 sentences) and vary the amount of NER data in $N \in \{100, 200, 400, 800, 1600\}$. We compare models with and without the default gazetteer information from the LaSO software. We have the following models for comparison:

- A default "Baseline" in which we simply train the NER model without using syntax.

	Hints vs **Base**	Self-T vs **Base**	Hints vs **Self-T**
Win	29	20	24
Tie	6	12	11
Lose	0	3	0

Table 1: Comparison between hints, self-training and the (best) baseline for varying amount of labeled data.

- In "POS-feature", we do the same thing, but we first label the NER data using a tagger/chunker trained on the 8936 syntactic sentences. These labels are used as features for the baseline.
- A "Self-training" setting where we use the 8936 syntactic sentences as "unlabeled," label them with our model, and then train on the results. (This is equivalent to a hints model where $\chi(\cdot,\cdot) = 1$ is the constant 1 function.) We use model confidence as in Blum and Mitchell (1998).[4]

The results are shown in Figure 1. The trends we see are the following:

- More data always helps.
- Self-training usually helps over the baseline (though not always: for instance in wl and parts of cts and bn).
- Adding the gazetteers help.
- Adding the syntactic features helps.
- Learning with hints, especially for $\leq$ 1000 training data points, helps significantly, even over self-training.

We further compare the algorithms by looking at how many training setting has each as the winner. In particular, we compare both hints and self-training to the two baselines, and then compare hints to self-training. If results are not significant at the 95% level (according to McNemar's test), we call it a tie. The results are in Table 1.

In our second set of experiments, we consider the role of the syntactic data. For this experiment, we hold the number of NER labeled sentences constant (at $N = 200$) and vary the amount of syntactic data in $M \in \{500, 1000, 2000, 4000, 8936\}$. The results of these experiments are in Figure 2. The trends are:

- The POS feature is relatively insensitive to the amount of syntactic data—this is most likely because it's weight is discriminatively adjusted

[4]Results without confidence were significantly worse.

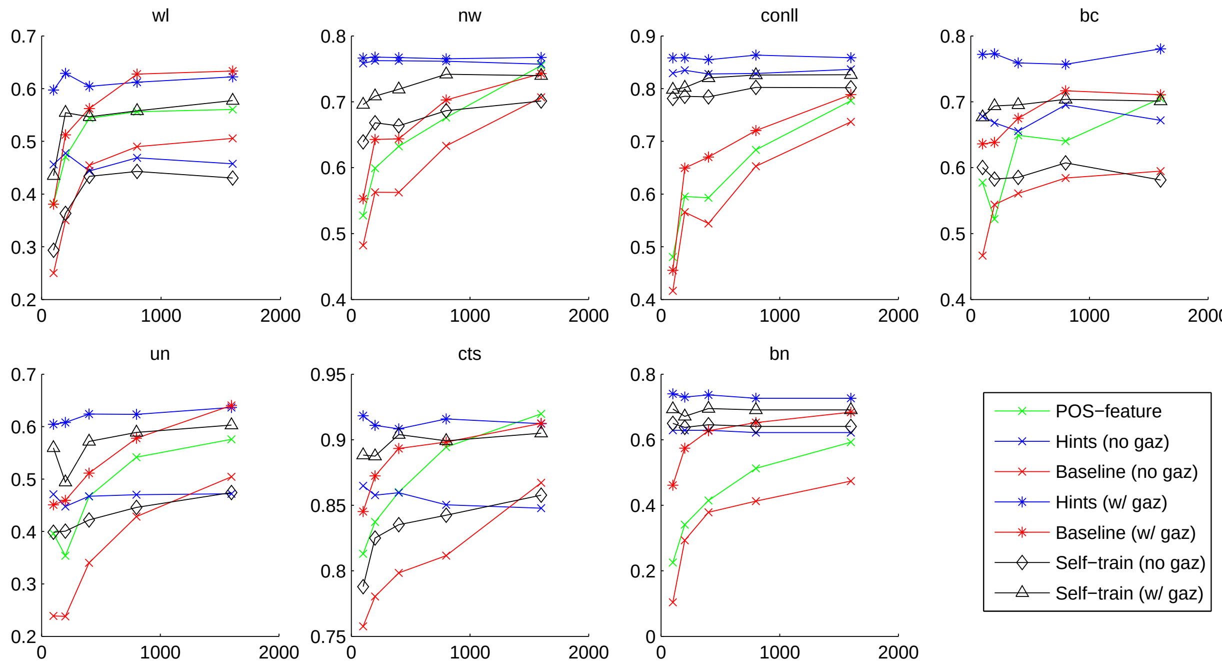

Figure 1: Results of varying the amount of NER labeled data, for a fixed amount ($M = 8936$) of syntactic data.

	Hints vs **Base**	**Self-T** vs **Base**	**Hints** vs **Self-T**
Win	34	28	15
Tie	1	7	20
Lose	0	0	0

Table 2: Comparison between hints, self-training and the (best) baseline for varying amount of unlabeled data.

by LaSO so that if the syntactic information is bad, it is relatively ignored.

- Self-training performance often *degrades* as the amount of syntactic data increases.
- The performance of learning with hints increases steadily with more syntactic data.

As before, we compare performance between the different models, declaring a "tie" if the difference is not statistically significant at the 95% level. The results are in Table 2.

In experiments not reported here to save space, we experimented with several additional settings. In one, we weight the unlabeled data in various ways: (1) to make it equal-weight to the labeled data; (2) at 10% weight; (3) according to the score produced by the first round of labeling. None of these had a significant impact on scores; in a few cases performance went up by $\ll 1$, in a few cases, performance went down about the same amount.

4.4 Two-sided Discriminative Learning

In this section, we explore the use of two-sided discriminative learning to boost the performance of our syntactic chunking, part of speech tagging, and named-entity recognition software. We continue to use LaSO (Daumé III and Marcu, 2005) as the sequence labeling technique.

The results we present are based on attempting to improve the performance of a state-of-the-art system train on *all* of the training data. (This is in contrast to the results in Section 4.3, in which the effect of using limited amounts of data was explored.) For the POS tagging and syntactic chunking, we being with all 8936 sentences of training data from CoNLL. For the named entity recognition, we limit our presentation to results from the CoNLL 2003 NER shared task. For this data, we have roughly $14k$ sentences of training data, all of which are used. In both cases, we reserve 10% as development data. The development data is use to do early stopping in LaSO.

As unlabeled data, we use $1m$ sentences extracted from the North American National Corpus of En-

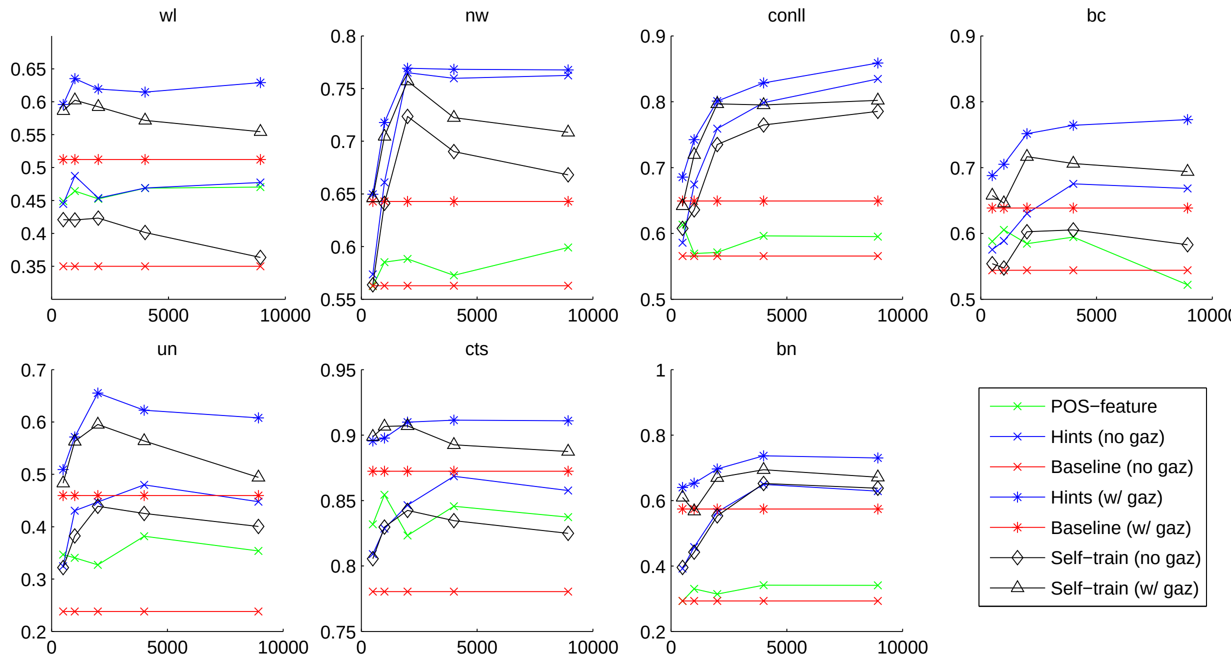

Figure 2: Results of varying amount of syntactic data for a fixed amount of NER data ($N = 200$ sentences).

glish (previously used for self-training of parsers (McClosky et al., 2006)). These $1m$ sentences were selected by dev-set relativization against the union of the two development data sets.

Following similar ideas to those presented by Blum and Mitchell (1998), we employ two slight modifications to the algorithm presented in Section 3.2. First, in step (2b) instead of adding *all* allowable instances to the labeled data set, we only add the top R (for some hyper-parameter R), where "top" is determined by average model confidence for the two tasks. Second, Instead of using the *full* unlabeled set to label at each iteration, we begin with a random subset of $10R$ unlabeled examples and another add random $10R$ every iteration.

We use the same baseline systems as in one-sided learning: a Baseline that learns the two tasks independently; a variant of the Baseline on which the output of the POS/chunker is used as a feature for the NER; a variant based on self-training; the hints-based method. In all cases, we *do* use gazetteers. We run the hints-based model for 10 iterations. For self-training, we use $10R$ unlabeled examples (so that it had access to the same amount of unlabeled data as the hints-based learning after all 10 iterations). We used three values of R: 50, 100, 500. We select the

	Chunking	**NER**
Baseline	94.2	87.5
w/POS	N/A	88.0
Self-train		
$R = 50$	94.2	88.0
$R = 100$	94.3	88.6
$R = 500$	94.1	88.4
Hints		
$R = 50$	94.2	88.5
$R = 100$	94.3	89.1
$R = 500$	94.3	89.0

Table 3: Results on two-sided learning with hints.

best-performing model (by the dev data) over these ten iterations. The results are in Table 3.

As we can see, performance for syntactic chunking is relatively stagnant: there are no significant improvements for any of the methods over the baseline. This is not surprising: the form of the constraint function we use tells us a *lot* about the NER task, but relatively little about the syntactic chunking task. In particular, it tells us nothing about phrases other than NPs. On the other hand, for NER, we see that both self-training and learning with hints improve over the baseline. The improvements are not enormous, but *are* significant (at the 95% level, as measured by McNemar's test). Unfortunately, the improvements for learning with hints over the self-training model are only significant at the 90% level.

5 Discussion

We have presented a method for simultaneously learning two tasks using prior knowledge about the relationship between their outputs. This is related to *joint inference* (Daumé III et al., 2006). However, we do not require that that a single data set be labeled for multiple tasks. In all our examples, we use separate data sets for shallow parsing as for named-entity recognition. Although all our experiments used the LaSO framework for sequence labeling, there is *noting* in our method that assumes any particular learner; alternatives include: conditional random fields (Lafferty et al., 2001), independent predictors (Punyakanok and Roth, 2001), max-margin Markov networks (Taskar et al., 2005), etc.

Our approach, both algorithmically and theoretically, is most related to ideas in co-training (Blum and Mitchell, 1998). The key difference is that in co-training, one assumes that the two "views" are on the *inputs*; here, we can think of the two output spaces as being the difference "views" and the compatibility function χ being a method for reconciling these two views. Like the pioneering work of Blum and Mitchell, the algorithm we employ in practice makes use of incrementally augmenting the unlabeled data and using model confidence. Also like that work, we do not currently have a theoretical framework for this (more complex) model.[5] It would also be interesting to explore *soft* hints, where the range of χ is $[0, 1]$ rather than $\{0, 1\}$.

Recently, Ganchev et al. (2008) proposed a co-regularization framework for learning across multiple related tasks with different output spaces. Their approach hinges on a constrained EM framework and addresses a quite similar problem to that addressed by this paper. Chang et al. (2008) also propose a "semisupervised" learning approach quite similar to our own model. The show very promising results in the context of semantic role labeling. Given the apparent (very!) recent interest in this problem, it would be ideal to directly compare the different approaches.

In addition to an analysis of the theoretical properties of the algorithm presented, the most compelling avenue for future work is to apply this framework to other task pairs. With a little thought, one can imagine formulating compatibility functions between tasks like discourse parsing and summarization (Marcu, 2000), parsing and word alignment, or summarization and information extraction.

Acknowledgments

Many thanks to three anonymous reviewers of this papers whose suggestions greatly improved the work and the presentation. This work was partially funded by NSF grant IIS 0712764.

A Proofs

The proof of Theorem 1 closes follows that of Blum and Mitchell (1998).

Proof (Theorem 1, sketch). Use the following notation: $c_k = \Pr_{\mathcal{D}}[h(x) = k]$, $p_l = \Pr_{\mathcal{D}}[f(x) = l]$, $q_{l|k} = \Pr_{\mathcal{D}}[f(x) = l \mid h(x) = k]$. Denote by $\mathcal{A}$ the set of outputs that satisfy the constraints. We are interested in the probability that $h(x)$ is erroneous, given that $h(x)$ satisfies the constraints:

$$
\begin{aligned}
&p\left(h(x) \in \mathcal{A}\backslash\{l\} \mid f(x) = l\right) \\
&= \sum_{k \in \mathcal{A}\backslash\{l\}} p\left(h(x) = k \mid f(x) = l\right) = \sum_{k \in \mathcal{A}\backslash\{l\}} c_k q_{l|k}/p_l \\
&\le \sum_{k \in \mathcal{A}} c_k (|\mathcal{Y}| - 1 + \epsilon \sum_{l \ne k} 1/p_l) \le 2 \sum_{k \in \mathcal{A}} c_k (|\mathcal{Y}| - 1)
\end{aligned}
$$

Here, the second step is Bayes' rule plus definitions, the third step is by the weak initial hypothesis assumption, and the last step is by algebra. Thus, in order to get a probability of error at most η, we need $\sum_{k \in \mathcal{A}} c_k = \Pr[h(x) \in \mathcal{A}] \le \eta/(2(|\mathcal{Y}| - 1))$. □

The proof of Corollary 1 is straightforward.

Proof (Corollary 1, sketch). Write out the probability of error as a double sum over true labels y_1, y_2 and predicted labels $\hat{y}_1, \hat{y}_2$ subject to $\chi(\hat{y}_1, \hat{y}_2)$. Use the uncorrelation assumption and Bayes' to split this into the product two terms as in the proof of Theorem 1. Bound as before. □

[5]Dasgupta et al. (2001) proved, three years later, that a formal model roughly equivalent to the actual Blum and Mitchell algorithm *does* have solid theoretical foundations.

Online Methods for Multi-Domain Learning and Adaptation

Mark Dredze and **Koby Crammer**
Department of Computer and Information Science

{mdredze,crammer}@cis.upenn.edu

Abstract

NLP tasks are often domain specific, yet systems can learn behaviors across multiple domains. We develop a new multi-domain online learning framework based on parameter combination from multiple classifiers. Our algorithms draw from multi-task learning and domain adaptation to adapt multiple source domain classifiers to a new target domain, learn across multiple similar domains, and learn across a large number of disparate domains. We evaluate our algorithms on two popular NLP domain adaptation tasks: sentiment classification and spam filtering.

1 Introduction

Statistical classifiers routinely process millions of websites, emails, blogs and other text every day. Variability across different data sources means that training a single classifier obscures differences and separate classifiers ignore similarities. Similarly, adding new domains to existing systems requires adapting existing classifiers.

We present new online algorithms for three *multi-domain learning* scenarios: adapting existing classifiers to new domains, learning across multiple similar domains and scaling systems to many disparate domains. Multi-domain learning combines characteristics of both multi-task learning and domain adaptation and drawing from both areas, we develop a multi-classifier parameter combination technique for confidence-weighted (CW) linear classifiers (Dredze et al., 2008). We focus on online algorithms that scale to large amounts of data.

Next, we describe multi-domain learning and review the CW algorithm. We then consider our three settings using multi-classifier parameter combination. We conclude with related work.

2 Multi-Domain Learning

In online multi-domain learning, each instance $\boldsymbol{x}$ is drawn from a domain d specific distribution $\boldsymbol{x} \sim \mathcal{D}_d$ over a vectors space $\mathbb{R}^N$ and labeled with a domain specific function f_d with label $y \in \{-1, +1\}$ (for binary classification.) On round i the classifier receives instance $\boldsymbol{x}_i$ and domain identifier d_i and predicts label $\hat{y}_i \in \{-1, +1\}$. It then receives the true label $y_i \in \{-1, +1\}$ and updates its prediction rule.

As an example, consider a multi-user spam filter, which must give high quality predictions for new users (without new user data), learn on multiple users simultaneously and scale to thousands of accounts. While a single classifier trained on all users would generalize across users and extend to new users, it would fail to learn user-specific preferences. Alternatively, separate classifiers would capture user-specific behaviors but would not generalize across users. The approach we take to solving multi-domain problems is to combine domain-specific classifiers. In the adaptation setting, we combine source domain classifiers for a new target domain. For learning across domains, we combine domain-specific classifiers and a shared classifier learned across all domains. For learning across disparate domains we learn which domain-specific and shared classifiers to combine.

Multi-domain learning combines properties of both multi-task learning and domain adaptation. As in multi-task learning, we consider domains that are labeled with different classification functions. For example, one user may enjoy some emails that another user considers spam: differing in their classification function. The goal of multi-task learning is to generalize across tasks/domains (Dekel et al., 2006; Evgeniou and Pontil, 2004). Furthermore, as in domain adaptation, some examples are draw from different distributions. For example, one user may receive emails about engineering while another about art, differing in their distribution over features. Domain adaptation deals with these feature distribution changes (Blitzer et al., 2007; Jiang and Zhai, 2007). Our work combines these two areas by learning both across distributions and behaviors or functions.

3 Confidence-Weighted Linear Classifiers

Confidence-weighted (CW) linear classification (Dredze et al., 2008), a new online algorithm, maintains a probabilistic measure of parameter confidence, which may be useful in combining parameters from different domain distributions. We summarize CW learning to familiarize the reader.

Parameter confidence is formalized by a Gaussian distribution over weight vectors with mean $\boldsymbol{\mu} \in \mathbb{R}^N$ and diagonal covariance $\Sigma \in \mathbb{R}^{N \times N}$. The values μ_j and $\Sigma_{j,j}$ represent knowledge of and confidence in the parameter for feature j. The smaller $\Sigma_{j,j}$, the more confidence we have in the mean parameter value μ_j. In this work we consider diagonal covariance matrices to scale to NLP data.

A model predicts the highest probability label,

$$\arg \max_{y \in \{\pm 1\}} \Pr_{\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)} \left[y_i (\boldsymbol{w} \cdot \boldsymbol{x}_i) \geq 0 \right] \ .$$

The Gaussian distribution over parameter vectors $\boldsymbol{w}$ induces a univariate Gaussian distribution over the score $S_i = \boldsymbol{w} \cdot \boldsymbol{x}_i$ parameterized by $\boldsymbol{\mu}$, Σ and the instance $\boldsymbol{x}_i$: $S_i \sim \mathcal{N}\left(\mu_i, \sigma_i^2\right)$, with mean $\mu_i = \boldsymbol{\mu} \cdot \boldsymbol{x}_i$ and variance $\sigma_i^2 = \boldsymbol{x}_i^\top \Sigma \boldsymbol{x}_i$.

The CW algorithm is inspired by the Passive Aggressive (PA) update (Crammer et al., 2006) — which ensures a positive margin while minimizing parameter change. CW replaces the Euclidean distance used in the PA update with the Kullback-Leibler (KL) divergence over Gaussian distributions. It also replaces the minimal margin constraint with a minimal probability constraint: with some given probability $\eta \in (0.5, 1]$ a drawn classifier will assign the correct label. This strategy yields the following objective solved on each round of learning:

$$\begin{aligned} &\min \mathbb{D}_{\mathrm{KL}} \left(\mathcal{N}\left(\boldsymbol{\mu}, \Sigma\right) \parallel \mathcal{N}\left(\boldsymbol{\mu}_i, \Sigma_i\right) \right) \\ &\text{s.t. } \Pr\left[y_i \left(\boldsymbol{w} \cdot \boldsymbol{x}_i \right) \geq 0 \right] \geq \eta \ , \end{aligned}$$

where $(\boldsymbol{\mu}_i, \Sigma_i)$ are the parameters on round i and $\boldsymbol{w} \sim \mathcal{N}\left(\boldsymbol{\mu}, \Sigma\right)$. The constraint ensures that the resulting parameters $\left(\boldsymbol{\mu}_{i+1}, \Sigma_{i+1}\right)$ will correctly classify $\boldsymbol{x}_i$ with probability at least η. For convenience we write $\phi = \Phi^{-1}(\eta)$, where Φ is the cumulative function of the normal distribution. The optimization problem above is not convex, but a closed form approximation of its solution has the following additive form: $\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_i + \alpha_i y_i \Sigma_i \boldsymbol{x}_i$ and $\Sigma_{i+1}^{-1} = \Sigma_i^{-1} + 2\alpha_i \phi \boldsymbol{x}_i \boldsymbol{x}_i^\top$ for,

$$\alpha_i = \frac{-(1+2\phi\mu_i) + \sqrt{(1+2\phi\mu_i)^2 - 8\phi\left(\mu_i - \phi\sigma_i^2\right)}}{4\phi\sigma_i^2} \ .$$

Each update changes the feature weights $\boldsymbol{\mu}$, and increases confidence (variance Σ always decreases). We employ CW classifiers since they provide confidence estimates, which are useful for classifier combination. Additionally, since we require per-parameter confidence estimates, other confidence based classifiers are not suitable for this setting.

4 Multi-Classifier Parameter Combination

The basis of our approach to multi-domain learning is to combine the parameters of CW classifiers from separate domains while respecting parameter confidence. A combination method takes M CW classifiers each parameterized by its own mean and variance parameters $\{(\boldsymbol{\mu}^m, \Sigma^m)\}_{m=1}^M$ and produces a single combined classifier $(\boldsymbol{\mu}^c, \Sigma^c)$. A simple technique would be to average the parameters of classifiers into a new classifier. However, this ignores the difference in feature distributions. Consider for example that the weight associated with some word in a source classifier has a value of 0. This could either mean that the word is very rare or that it is neutral for prediction (like the work "the"). The information captured by the variance parameter allow us to distinguish between the two cases: an high-variance indicates a lack of confidence in the value of the weight vectors because of small number of examples (first case), and vise-versa, small-variance indicates that the value of the weight is based on plenty of evidence. We favor combinations sensitive to this distinction.

Since CW classifiers are Gaussian distributions, we formalize classifier parameter combination as finding a new distribution that minimizes the weighted-divergence to a set of given distributions:

$$(\boldsymbol{\mu}^c, \Sigma^c) = \arg\min \sum_m^M \mathbb{D}((\boldsymbol{\mu}^c, \Sigma^c) || (\boldsymbol{\mu}^m, \Sigma^m) \, ; \, \mathbf{b}^m) \, ,$$

where (since Σ is diagonal),

$$\mathbb{D}((\boldsymbol{\mu}^c, \Sigma^c) || (\boldsymbol{\mu}, \Sigma) \, ; \, \mathbf{b}) = \sum_f^N b_f D((\boldsymbol{\mu}^c_f, \Sigma^c_{f,f}) || (\boldsymbol{\mu}_f, \Sigma_{f,f})) \, .$$

The (classifier specific) importance-weights $\mathbf{b}^m \in \mathbb{R}^N_+$ are used to weigh certain parameters of some domains differently in the combination. When $\mathbb{D}$ is the Euclidean distance (L2), we have,

$$D((\boldsymbol{\mu}^c_f, \Sigma^c_{f,f}) || (\boldsymbol{\mu}_f, \Sigma_{f,f})) = (\boldsymbol{\mu}^c_f - \boldsymbol{\mu}_f)^2 + (\Sigma^c_{f,f} - \Sigma_{f,f})^2 \, .$$

and we obtain:

$$\boldsymbol{\mu}^c_f = \frac{1}{\sum_m^M b^m_f} \sum_m^M b^m_f \boldsymbol{\mu}^m_f ,$$

$$\Sigma^c_{f,f} = \frac{1}{\sum_{m \in M} b^m_f} \sum_m^M b^m_f \Sigma^m_{f,f} \, . \qquad (1)$$

Note that this is a (weighted) average of parameters. The other case we consider is when $\mathbb{D}$ is a weighted KL divergence we obtain a weighting of $\boldsymbol{\mu}$ by Σ^{-1}:

$$\boldsymbol{\mu}^c_f = \left(\sum_m^M (\Sigma^m_{f,f})^{-1} b^m_f \right)^{-1} \sum_m^M (\Sigma^m_{f,f})^{-1} \boldsymbol{\mu}^m_f b^m_f$$

$$(\Sigma^c)^{-1} = \left(M \sum_m^M b^m_f \right)^{-1} \sum_m^M (\Sigma^m_f)^{-1} {b_f}^m \, . \qquad (2)$$

While each parameter is weighed by its variance in the KL, we can also explicitly encode this behavior as $b^m_f = a - \Sigma^m_{f,f} \geq 0$, where a is the initialization value for $\Sigma^m_{f,f}$. We call this weighting "variance" as opposed to a uniform weighting of parameters ($b^m_f = 1$). We therefore have two combination methods (L2 and KL) and two weighting methods (uniform and variance).

5 Datasets

For evaluation we selected two domain adaptation datasets: spam (Jiang and Zhai, 2007) and sentiment (Blitzer et al., 2007). The spam data contains two tasks, one with three users (task A) and one with 15 (task B). The goal is to classify an email (bag-of-words) as either spam or ham (not-spam) and each user may have slightly different preferences and features. We used 700 and 100 training messages for each user for task A and B respectively and 300 test emails for each user.

The sentiment data contains product reviews from Amazon for four product types: books, dvds, electronics and kitchen appliances and we extended this with three additional domains: apparel, music and videos. We follow Blitzer *et. al.* for feature extraction. We created different datasets by modifying the decision boundary using the ordinal rating of each instance (1-5 stars) and excluding boundary instances. We use four versions of this data:

- **All** - 7 domains, one per product type
- **Books** - 3 domains of books with the binary decision boundary set to 2, 3 and 4 stars
- **DVDs** - Same as *Books* but with DVD reviews
- **Books+DVDs** - Combined *Books* and *DVDs*

The *All* dataset captures the typical domain adaptation scenario, where each domain has the same decision function but different features. *Books* and *DVDs* have the opposite problem: the same features but different classification boundaries. *Books+DVDs* combines both issues. Experiments use 1500 training and 100 test instances per domain.

6 Multi-Domain Adaptation

We begin by examining the typical domain adaptation scenario, but from an online perspective since learning systems often must adapt to new users or domains quickly and with no training data. For example, a spam filter with separate classifiers trained on each user must also classify mail for a new user. Since other user's training data may have been deleted or be private, the existing classifiers must be combined for the new user.

Table 1: Test error for multi-source adaptation on sentiment and spam data. Combining classifiers improves over selecting a single classifier a priori (*Avg Src*).

We combine the existing user-specific classifiers into a single new classifier for a new user. Since nothing is known about the new user (their decision function), each source classifier may be useful. However, feature similarity – possibly measured using unlabeled data – could be used to weigh source domains. Specifically, we combine the parameters of each classifier according to their confidence using the combination methods described above.

We evaluated the four combination strategies – L2 vs. KL, uniform vs. variance – on spam and sentiment data. For each evaluation, a single domain was held out for testing while separate classifiers were trained on each source domain, i.e. no target training. Source classifiers are then combined and the combined classifier is evaluated on the test data (400 instances) of the target domain. Each classifier was trained for 5 iterations over the training data (to ensure convergence) and each experiment was repeated using 10-fold cross validation. The CW parameter ϕ was tuned on a single randomized run for each experiment. We include several baselines: training on target data to obtain an upper bound on performance (*Target*), training on all source domains together, a useful strategy if all source data is maintained (*All Src*), selecting (with omniscience) the best performing source classifier on target data (*Best Src*), and the expected real world performance of randomly selecting a source classifier (*Avg Src*).

While at least one source classifier achieved high performance on the target domain (*Best Src*), the correct source classifier cannot be selected without target data and selecting a random source classifier yields high error. In contrast, a combined classifier almost always improved over the best source domain classifier (table 1). That some of our results improve over the best training scenario is likely caused by increased training data from using multiple domains. Increases over all available training data are very interesting and may be due to a regularization effect of training separate models.

The L2 methods performed best and KL improved 7 out of 10 combinations. Classifier parameter combination can clearly yield good classifiers without prior knowledge of the target domain.

7 Learning Across Domains

In addition to adapting to new domains, multi-domain systems should learn common behaviors across domains. Naively, we can assume that the domains are either sufficiently similar to warrant one classifier or different enough for separate classifiers. The reality is often more complex. Instead, we maintain shared and domain-specific parameters and combine them for learning and prediction.

Multi-task learning aims to learn common behaviors across related problems, a similar goal to multi-domain learning. The primary difference is the nature of the domains/tasks: in our setting each domain is the same task but differs in the types of features in addition to the decision function. A multi-task approach can be adapted to our setting by using our classifier combination techniques.

Table 3: Test data error: learning across domains (MDR) improves over the baselines and Daumé (2007).

We seek to learn domain specific parameters guided by shared parameters. Dekel et al. (2006) followed this approach for an online multi-task algorithm, although they did not have shared parameters and assumed that a training round comprised an example from each task. Evgeniou and Pontil (2004) achieved a similar goal by using shared parameters for multi-task regularization. Specifically, they assumed that the weight vector for problem d could be represented as $w^c = w^d + w^s$, where w^d are task specific parameters and w^s are shared across all tasks. In this framework, all tasks are close to some underlying mean w^s and each one deviates from this mean by w^d. Their SVM style multi-task objective minimizes the loss of w^c and the norm of w^d and w^s, with a tradeoff parameter allowing for domain deviance from the mean. The simple domain adaptation algorithm of feature splitting used by Daumé (2007) is a special case of this model where the norms are equally weighted. An analogous CW objective is:

$$\begin{aligned}\min \frac{1}{\lambda_1}\mathbb{D}_{\text{KL}}\left(\mathcal{N}\left(\boldsymbol{\mu}^d, \Sigma^d\right) \| \mathcal{N}\left(\boldsymbol{\mu}_i^d, \Sigma_i^d\right)\right) \\ + \frac{1}{\lambda_2}\mathbb{D}_{\text{KL}}\left(\mathcal{N}\left(\boldsymbol{\mu}^s, \Sigma^s\right) \| \mathcal{N}\left(\boldsymbol{\mu}_i^s, \Sigma_i^s\right)\right) \\ \text{s.t. } \Pr_{\boldsymbol{w}\sim\mathcal{N}(\boldsymbol{\mu}^c, \Sigma^c)}\left[y_i\left(\boldsymbol{w}\cdot\boldsymbol{x}_i\right) \geq 0\right] \geq \eta\,. \end{aligned} \quad (3)$$

$\left(\boldsymbol{\mu}^d, \Sigma^d\right)$ are the parameters for domain d, $(\boldsymbol{\mu}^s, \Sigma^s)$ for the shared classifier and $(\boldsymbol{\mu}^c, \Sigma^c)$ for the combination of the domain and shared classifiers. The parameters are combined via (2) with only two elements summed - one for the shared parameters s and the other for the domain parameters d . This captures the intuition of Evgeniou and Pontil: updates enforce the learning condition on the combined parameters and minimize parameter change. For convenience, we rewrite $\lambda_2 = 2 - 2\lambda_1$, where $\lambda_1 \in [0, 1]$. If classifiers are combined using the sum of the individual weight vectors and $\lambda_1 = 0.5$, this is identical to feature splitting (Daumé) for CW classifiers.

The domain specific and shared classifiers can be updated using the closed form solution to (3) as:

$$\begin{aligned}
\boldsymbol{\mu}^s &= \boldsymbol{\mu}_i^s + \lambda_2 \alpha y_i \Sigma^c \boldsymbol{x}_i \\
(\Sigma^s)^{-1} &= (\Sigma_i^s)^{-1} + 2\lambda_2 \alpha \phi \boldsymbol{x}_i \boldsymbol{x}_i^T \\
\boldsymbol{\mu}^d &= \boldsymbol{\mu}_i^d + \lambda_1 \alpha y_i \Sigma_i^c \boldsymbol{x}_i \\
(\Sigma^d)^{-1} &= (\Sigma_i^d)^{-1} + 2\lambda_1 \alpha \phi \boldsymbol{x}_i \boldsymbol{x}_i^T
\end{aligned} \tag{4}$$

We call this objective Multi-Domain Regularization (MDR). As before, the combined parameters are produced by one of the combination methods. On each round, the algorithm receives instance $\boldsymbol{x}_i$ and domain d_i for which it creates a combined classifier $(\boldsymbol{\mu}^c, \Sigma^c)$ using the shared $(\boldsymbol{\mu}^s, \Sigma^s)$ and domain specific parameters $\left(\boldsymbol{\mu}^d, \Sigma^d\right)$. A prediction is issued using the standard linear classifier prediction rule $\text{sign}(\boldsymbol{\mu}^c \cdot \boldsymbol{x})$ and updates follow (4). The effect is that features similar across domains quickly converge in the shared classifier, sharing information across domains. The combined classifier reflects shared and domain specific parameter confidences: weights with low variance (i.e. greater confidence) will contribute more.

We evaluate MDR on a single pass over a stream of instances from multiple domains, simulating a real world setting. Parameters λ_1 and ϕ are iteratively optimized on a single randomized run for each dataset. All experiments use 10-fold CV. In addition to evaluating the four combination methods with MDR, we evaluate the performance of a single classifier trained on all domains (*Single*), a separate classifier trained on each domain (*Separate*), *Feature Splitting* (Daumé) and feature splitting with optimized λ_1 (*MDR*). Table 3 shows results on test data and table 2 shows online training error.

In this setting, L2 combinations prove best on 5 of 6 datasets, with the variance weighted combination doing the best. MDR (optimizing λ_1) slightly improves over feature splitting, and the combination methods improve in every case. Our best result is statistically significant compared to *Feature Splitting* using McNemar's test ($p = .001$) for *Task B*, *Books*, *DVD*, *Books+DVD*. While a single or separate classifiers have a different effect on each dataset, MDR gives the best performance overall.

8 Learning in Many Domains

So far we have considered settings with a small number of similar domains. While this is typical of multi-task problems, real world settings present many domains which do not all share the same behaviors. Online algorithms scale to numerous examples and we desire the same behavior for numerous domains. Consider a spam filter used by a large email provider, which filters billions of emails for millions of users. Suppose that spammers control many accounts and maliciously label spam as legitimate. Alternatively, subsets of users may share preferences. Since behaviors are not consistent across domains, shared parameters cannot be learned. We seek algorithms robust to this behavior.

Since subsets of users share behaviors, these can be learned using our MDR framework. For example, discovering spammer and legitimate mail accounts would enable intra-group learning. The challenge is the online discovery of these subsets while learning model parameters. We augment the MDR framework to additionally learn this mapping.

We begin by generalizing MDR to include k shared classifiers instead of a single set of shared parameters. Each set of shared parameters represents a different subset of domains. If the corresponding shared parameters are known for a domain, we could use the same objective (3) and update (4) as before. If there are many fewer shared parameters than domains ($k \ll D$), we can benefit from multi-domain learning. Next, we augment the learning algorithm to learn a mapping between the domains and shared classifiers. Intuitively, a domain should be mapped to shared parameters that correctly classify that domain. A common technique for learning such experts in the Weighted Majority algorithm (Littlestone and Warmuth, 1994), which weighs a mixture of experts (classifiers). However, since we require a hard assignment — pick a single shared parameter set s — rather than a mixture, the algorithm reduces to picking the classifier s with the fewest mistakes in predicting domain d. This requires tracking the number of mistakes made by each shared classifier on each domain once a label is revealed. For learning, the shared classifier with the fewest mistakes for a domain is selected for an MDR update. Classifier ties are broken randomly. While we experi-

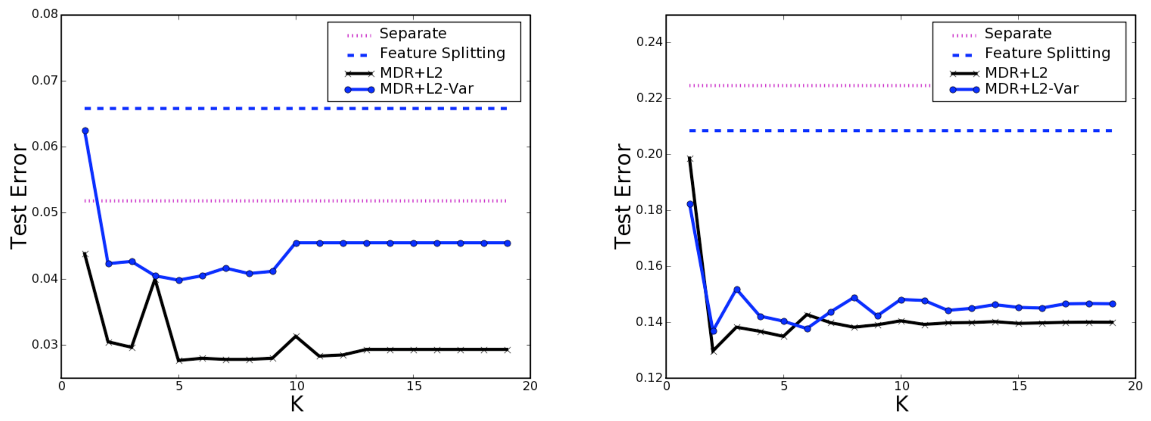

Figure 1: Learning across many domains - spam (left) and sentiment (right) - with MDR using k shared classifiers.

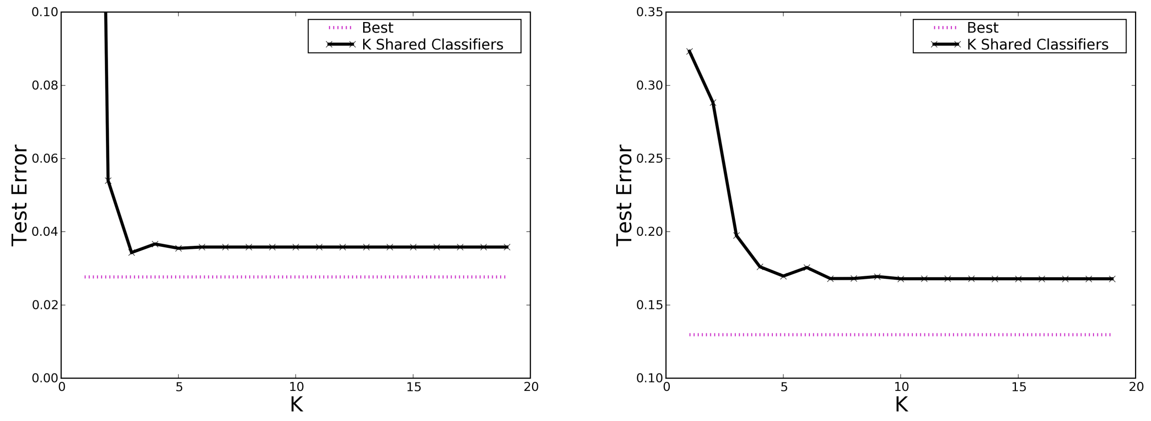

Figure 2: Learning across many domains - spam (left) and sentiment (right) - with no domain specific parameters.

mented with more complex techniques, this simple method worked well in practice. When a new domain is added to the system, it takes fewer examples to learn which shared classifier to use instead of learning a new model from scratch.

While this approach adds another free parameter (k) that can be set using development data, we observe that k can instead be fixed to a large constant. Since only a single shared classifier is updated each round, the algorithm will favor selecting a previously used classifier as opposed to a new one, using as many classifiers as needed but not scaling up to k. This may not be optimal, but it is a simple.

To evaluate a larger number of domains, we created many varying domains using spam and sentiment data. For spam, 6 email users were created by splitting the 3 task A users into 2 users, and flipping the label of one of these users (a malicious user), yielding 400 train and 100 test emails per user. For sentiment, the book domain was split into 3 groups with binary boundaries at a rating of 2, 3 or 4. Each of these groups was split into 8 groups of which half had their labels flipped, creating 24 domains. The same procedure was repeated for DVD reviews but for a decision boundary of 3, 6 groups were created, and for a boundary of 2 and 4, 3 groups were created with 1 and 2 domains flipped respectively, resulting in 12 DVD domains and 36 total domains with various decision boundaries, features, and inverted decision functions. Each domain used 300 train and 100 test instances. 10-fold cross validation with one training iteration was used to train models on these two datasets. Parameters were optimized as before. Experiments were repeated for various settings of k. Since L2 performed well before, we evaluated MDR+L2 and MDR+L2-Var.

The results are shown in figure 1. For both spam and sentiment adding additional shared parameters beyond the single shared classifier significantly reduces error, with further reductions as k increases. This yields a 45% error reduction for spam and a 38% reduction for sentiment over the best baseline. While each task has an optimal k (about 5 for spam, 2 for sentiment), larger values still achieve low error, indicating the flexibility of using large k values.

While adding parameters clearly helps for many domains, it may be impractical to keep domain-specific classifiers for thousands or millions of domains. In this case, we could eliminate the domain-specific classifiers and rely on the k shared classifiers only, learning the domain to classifier mapping. We compare this approach using the best result from MDR above, again varying k. Figure 2 shows that losing domain-specific parameters hurts performance, but is still an improvement over baseline methods. Additionally, we can expect better performance as the number of similar domains increases. This may be an attractive alternative to keeping a very large number of parameters.

9 Related Work

Multi-domain learning intersects two areas of research: domain adaptation and multi-task learning. In domain adaptation, a classifier trained for a source domain is transfered to a target domain using either unlabeled or a small amount of labeled target data. Blitzer et al. (2007) used structural correspondence learning to train a classifier on source data with new features induced from target unlabeled data. In a complimentary approach, Jiang and Zhai (2007) weighed training instances based on their similarity to unlabeled target domain data. Several approaches utilize source data for training on a limited number of target labels, including feature splitting (Daumé, 2007) and adding the source classifier's prediction as a feature (Chelba and Acero, 2004). Others have considered transfer learning, in which an existing domain is used to improve learning in a new domain, such as constructing priors (Raina et al., 2006; Marx et al., 2008) and learning parameter functions for text classification from related data (Do and Ng, 2006). These methods largely require batch learning, unlabeled target data, or available source data at adaptation. In contrast, our algorithms operate purely online and can be applied when no target data is available.

Multi-task algorithms, also known as inductive transfer, learn a set of related problems simultaneously (Caruana, 1997). The most relevant approach is that of Regularized Multi-Task Learning (Evgeniou and Pontil, 2004), which we use to motivate our online algorithm. Dekel et al. (2006) gave a similar online approach but did not use shared parameters and assumed multiple instances for each round. We generalize this work to both include an arbitrary classifier combination and many shared classifiers. Some multi-task work has also considered the grouping of tasks similar to our learning of domain subgroups (Thrun and O'Sullivan, 1998; Bakker and Heskes, 2003).

There are many techniques for combining the output of multiple classifiers for ensemble learning or mixture of experts. Kittler et al. (Mar 1998) provide a theoretical framework for combining classifiers. Some empirical work has considered adding versus multiplying classifier output (Tax et al., 2000), using local accuracy estimates for combination (Woods et al., 1997), and applications to NLP tasks (Florian et al., 2003). However, these papers consider combining classifier output for prediction. In contrast, we consider parameter combination for both prediction and learning.

10 Conclusion

We have explored several multi-domain learning settings using CW classifiers and a combination method. Our approach creates a better classifier for a new target domain than selecting a random source classifier a prior, reduces learning error on multiple domains compared to baseline approaches, can handle many disparate domains by using many shared classifiers, and scales to a very large number of domains with a small performance reduction. These scenarios are realistic for NLP systems in the wild. This work also raises some questions about learning on large numbers of disparate domains: can a hierarchical online clustering yield a better representation than just selecting between k shared parameters? Additionally, how can prior knowledge about domain similarity be included into the combination methods? We plan to explore these questions in future work.

Jointly Combining Implicit Constraints Improves Temporal Ordering

Nathanael Chambers and Dan Jurafsky
Department of Computer Science
Stanford University
Stanford, CA 94305
{natec,jurafsky}@stanford.edu

Abstract

Previous work on ordering events in text has typically focused on local pairwise decisions, ignoring globally inconsistent labels. However, temporal ordering is the type of domain in which global constraints should be relatively easy to represent and reason over. This paper presents a framework that informs local decisions with two types of implicit global constraints: transitivity (*A before B* and *B before C* implies *A before C*) and time expression normalization (e.g. *last month* is before *yesterday*). We show how these constraints can be used to create a more densely-connected network of events, and how global consistency can be enforced by incorporating these constraints into an integer linear programming framework. We present results on two event ordering tasks, showing a 3.6% absolute increase in the accuracy of *before/after* classification over a pairwise model.

1 Introduction

Being able to temporally order events is a necessary component for complete document understanding. Interest in machine learning approaches for this task has recently been encouraged through the creation of the Timebank Corpus (Pustejovsky et al., 2003). However, most work on event-event ordering has focused on improving classifiers for pairwise decisions, ignoring obvious contradictions in the global space of events when misclassifications occur. A global framework to repair these event ordering mistakes has not yet been explored.

This paper addresses three main factors involved in a global framework: the global optimization algorithm, the constraints that are relevant to the task, and the level of connectedness across pairwise decisions. We employ Integer Linear Programming to address the first factor, drawing from related work in paragraph ordering (Bramsen et al., 2006). After finding minimal gain with the initial model, we explore reasons for and solutions to the remaining two factors through temporal reasoning and transitivity rule expansion.

We analyze the connectivity of the Timebank Corpus and show how textual events can be indirectly connected through a time normalization algorithm that automatically creates new relations between time expressions. We show how this increased connectivity is essential for a global model to improve performance.

We present three progressive evaluations of our global model on the Timebank Corpus, showing a 3.6% gain in accuracy over its original set of relations, and an 81% increase in training data size from previous work. In addition, we present the first results on Timebank that include an *unknown* relation, establishing a benchmark for performance on the full task of document ordering.

2 Previous Work

Recent work on classifying temporal relations within the Timebank Corpus built 6-way relation classifiers over 6 of the corpus' 13 relations (Mani et al., 2006; Mani et al., 2007; Chambers et al., 2007). A wide range of features are used, ranging from surface indicators to semantic classes. Classifiers make local pairwise decisions and do not consider global implications between the relations.

The TempEval-07 (Verhagen et al., 2007) contest recently used two relations, *before* and *after*, in a semi-complete textual classification task with a new third relation to distinguish relations that can be labeled with high confidence from those that are uncertain, called *vague*. The task was a simplified classification task from Timebank in that only one verb, the main verb, of each sentence was used. Thus, the task can be viewed as ordering the main events in pairwise sentences rather than the entire document.

This paper uses the core relations of TempEval (*before*,*after*,*vague*) and applies them to a full document ordering task that includes every labeled event in Timebank. In addition, we extend the previous work by including a temporal reasoning component and embedding it within a global constraint model.

3 The Timebank Corpus

The Timebank Corpus (Pustejovsky et al., 2003) is a corpus of 186 newswire articles that are tagged for events, time expressions, and relations between the events and times. The individual events are further tagged for temporal information such as tense, modality and grammatical aspect. Time expressions use the TimeML (Ingria and Pustejovsky, 2002) markup language. There are 6 main relations and their inverses in Timebank: *before*, *ibefore*, *includes*, *begins*, *ends* and *simultaneous*.

This paper describes work that classifies the relations between events, making use of relations between events and times, and between the times themselves to help inform the decisions.

4 The Global Model

Our initial model has two components: (1) a pairwise classifier between events, and (2) a global constraint satisfaction layer that maximizes the confidence scores from the classifier. The first is based on previous work (Mani et al., 2006; Chambers et al., 2007) and the second is a novel contribution to event-event classification.

4.1 Pairwise Classification

Classifying the relation between two events is the basis of our model. A soft classification with confidence scores is important for the global maximization step that is described in the next section. As in Chambers et al. (2007), we build support vector machine (SVM) classifiers and use the probabilities from pairwise SVM decisions as our confidence scores. These scores are then used to choose an optimal global ordering.

Following our previous work, we use the set of features summarized in figure 1. They vary from POS tags and lexical features surrounding the event, to syntactic dominance, to whether or not the events share the same tense, grammatical aspect, or aspectual class. These features are the highest performing set on the basic 6-way classification of Timebank.

Feature	Description
Word*	The text of the event
Lemma*	The lemmatized head word
Synset*	The WordNet synset of head word
POS*	4 POS tags, 3 before, and 1 event
POS bigram*	The POS bigram of the event and its preceding tag
Prep*	Preposition lexeme, if in a prepositional phrase
Tense*	The event's tense
Aspect*	The event's grammatical aspect
Modal*	The modality of the event
Polarity*	Positive or negative
Class*	The aspecual class of the event
Tense Pair	The two concatenated tenses
Aspect Pair	The two concatenated aspects
Class Pair	The two concatenated classes
POS Pair	The two concatenated POS tags
Tense Match	true if the events have the same tense
Aspect Match	true if the events have the same aspect
Class Match	true if the events have the same class
Dominates	true if the first event syntactically dominates the second
Text Order	true if the first event occurs first in the document
Entity Match	true if they share an entity as an argument
Same Sent	true if both events are in the same sentence

Figure 1: The features to learn temporal relations between two events. Asterisks (*) indicate features that are duplicated, one for each of the two events.

We use Timebank's hand tagged attributes in the feature values for the purposes of this comparative

study of global constraints, described next.

4.2 Global Constraints

Pairwise classifiers can make contradictory classifications due to their inability to consider other decisions. For instance, the following three decisions are in conflict:

```
A before B
B before C
A after C
```

Transitivity is not taken into account. In fact, there are several ways to resolve the conflict in this example. Given confidence scores (or probabilities) for each possible relation between the three pairs, we can compute an optimal label assignment. Different scores can lead to different conflict resolutions. Figure 2 shows two resolutions given different sets of scores. The first chooses *before* for all three relations, while the second chooses *after*.

Bramsen et al. (2006) presented a variety of approaches to using transitivity constraints to help inform pairwise decisions. They found that Integer Linear Programming (ILP) performed the best on a paragraph ordering task, consistent with its property of being able to find the optimal solution for a set of constraints. Other approaches are variations on a *greedy* strategy of adding pairs of events one at a time, ordered by their confidence. These can lead to suboptimal configurations, although they are guaranteed to find a solution. Mani et al. (2007) subsequently proposed one of these greedy strategies as well, but published results are not available. We also implemented a greedy best-first strategy, but found ILP outperformed it.

Our Integer Linear Programming framework uses the following objective function:

$$max \sum_i \sum_j p_{ij} x_{ij} \tag{1}$$

with added constraints:

$$\forall i \forall j \;\; x_{ij} \in \{0, 1\} \tag{2}$$

$$\forall i \;\; x_{i1} + x_{i2} + ... + x_{im} = 1 \tag{3}$$

where x_{ij} represents the ith pair of events classified as the jth relation of m relations. Thus, each pair of events generates m variables. Given n pairs of events, there are $n * m$ variables. p_{ij} is the probability of classifying pair i with relation j. Equation 2 (the first constraint) simply says that each variable must be 0 or 1. Equation 3 contains m variables for a single pair of events i representing its m possible relations. It states that one relation must be set to 1 and the rest to 0. In other words, a pair of events cannot have two relations at the same time. Finally, a transitivity constraint is added for all connected pairs i, j, k, for each transitivity condition that infers relation c given a and b:

$$x_{ia} + x_{jb} - x_{kc} <= 1 \tag{4}$$

We generated the set of constraints for each document and used lpsolve[1] to solve the ILP constraint problem.

The transitivity constraints are only effective if the available pairwise decisions constitute a connected graph. If pairs of events are disconnected, then transitivity makes little to no contribution because these constraints are only applicable to connected chains of events.

4.3 Transitive Closure

In order to connect the event graph, we draw on work from (Mani et al., 2006) and apply *transitive closure* to our documents. Transitive closure was first proposed not to address the problem of connected event graphs, but rather to expand the size of training data for relations such as *before*. Timebank is a relatively small corpus with few examples

[1]http://sourceforge.net/projects/lpsolve

Total Event-Event Relations After Closure

	before	*after*
Timebank	592	656
+ closure	3919	3405

Figure 3: The number of event-event relations after transitive closure.

Comparative Results

Training Set	Accuracy
Timebank Pairwise	66.8%
Global Model	66.8%

Figure 4: Using the base Timebank annotated tags for testing, accuracy on before/after tags in the two models.

of each relation. One way of expand the training set is through transitive rules. A few rules are given here:

$A\ simultaneous\ B \wedge A\ before\ C \rightarrow B\ before\ C$
$A\ includes\ B \wedge A\ ibefore\ C \rightarrow B\ before\ C$
$A\ before\ B \wedge A\ ends\ C \rightarrow B\ after\ C$

While the original motivation was to expand the training size of tagged relations, this approach also creates new connections in the graph, replacing previously unlabeled event pairs with their true relations. We adopted this approach and closed the original set of 12 relations to help connect the global constraint model.

4.4 Initial Experiment

The first evaluation of our global temporal model is on the Timebank Corpus over the labeled relations *before* and *after*. We merged *ibefore* and *iafter* into these two relations as well, ignoring all others. We use this task as a reduced evaluation to study the specific contribution of global constraints. We also chose this strict ordering task because it is well defined from a human understanding perspective. Snow et al. (2008) shows that average internet users can make *before/after* decisions with very high confidence, although the distinction with an *unknown* relation is not as clear. An evaluation including *unknown* (or *vague* as in TempEval) is presented later.

We expanded the corpus (prior to selecting the before/after relations) using transitive closure over all 12 relations as described above. Figure 3 shows the increase in data size. The number of *before* and *after* relations increase by a factor of six.

We trained and tested the system with 10-fold cross validation and micro-averaged accuracies. The folds were randomly generated to separate the 186 files into 10 folds (18 or 19 files per fold). The same 10-way split is used for all the evaluations. We used libsvm[2] to implement our SVM classifiers.

Figure 4 shows the results from our ILP model with transitivity constraints. The first row is the baseline pairwise classification trained and tested on the original Timebank relations. The second row gives performance with ILP. The model shows no improvement. The global ILP constraints did affect local decisions, changing 175 of them (out of 7324), but the changes cancelled out and had no affect on overall accuracy.

4.5 Loosely Connected Graph

Why didn't a global model help? The problem lies in the graph structure of Timebank's annotated relations. The Timebank annotators were not required to annotate relations between any particular pair of events. Instead, they were instructed to annotate what seemed appropriate due to the almost insurmountable task of annotating all pairs of events. A modest-sized document of 30 events, for example, would contain $\binom{30}{2} = 435$ possible pairs. Annotators thus marked relations where they deemed fit, most likely between obvious and critical relations to the understanding of the article. The vast majority of possible relations are untagged, thus leaving a large set of unlabeled (and disconnected) *unknown* relations.

Figure 5 graphically shows all relations that are annotated between events and time expressions in one of the shorter Timebank documents. Nodes represent events and times (event nodes start with the letter 'e', times with 't'), and edges represent temporal relations. Solid lines indicate hand annotations, and dotted lines indicate new rules from transitive closure (only one, from event *e4* to time *t14*). As can be seen, the graph is largely disconnected and a global model contributes little information since transitivity constraints cannot apply.

[2]http://www.csie.ntu.edu.tw/˜cjlin/libsvm

Timebank Annotation of wsj_0551

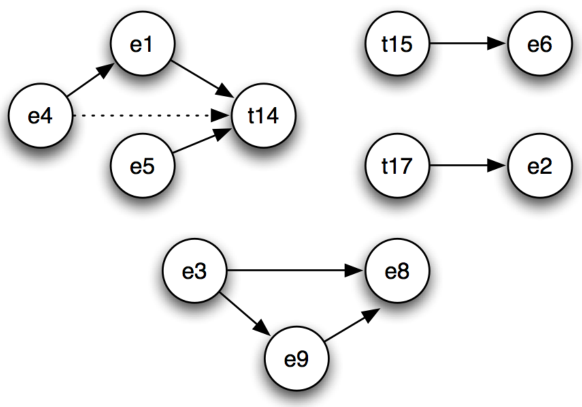

Figure 5: Annotated relations in document wsj_0551.

The large amount of unlabeled relations in the corpus presents several problems. First, building a classifier for these *unknown* relations is easily overwhelmed by the huge training set. Second, many of the untagged pairs have non-*unknown* ordering relations between them, but were missed by the annotators. This point is critical because one cannot filter this noise when training an *unknown* classifier. The noise problem will appear later and will be discussed in our final experiment. Finally, the space of annotated events is very loosely connected and global constraints cannot assist local decisions if the graph is not connected. The results of this first experiment illustrate this latter problem.

Bethard et al. (2007) strengthen the claim that many of Timebank's untagged relations should not be left unlabeled. They performed an independent annotation of 129 of Timebank's 186 documents, tagging all events in verb-clause relationships. They found over 600 valid *before/after* relations that are untagged in Timebank, on average three per document. One must assume that if these nearby verb-clause event pairs were missed by the annotators, the much larger number of pairs that cross sentence boundaries were also missed.

The next model thus attempts to fill in some of the gaps and further connect the event graph by using two types of knowledge. The first is by integrating Bethard's data, and the second is to perform temporal reasoning over the document's time expressions (e.g. *yesterday* or *january 1999*).

5 A Global Model With Time

Our initial model contained two components: (1) a pairwise classifier between events, and (2) a global constraint satisfaction layer. However, due to the sparseness in the event graph, we now introduce a third component addressing connectivity: (3) a temporal reasoning component to inter-connect the global graph and assist in training data expansion.

One important aspect of transitive closure includes the event-time and time-time relations during closure, not just the event-event links. Starting with 5,947 different types of relations, transitive rules increase the dataset to approximately 12,000. However, this increase wasn't enough to be effective in global reasoning. To illustrate the sparsity that still remains, if each document was a fully connected graph of events, Timebank would contain close to 160,000 relations[3], more than a 13-fold increase.

More data is needed to enrich the Timebank event graph. Two types of information can help: (1) more event-event relations, and (2) a separate type of information to indirectly connect the events: event-X-event. We incorporate the new annotations from Bethard et al. (2007) to address (1) and introduce a new temporal reasoning procedure to address (2). The following section describes this novel approach to adding time expression information to further connect the graph.

5.1 Time-Time Information

As described above, we use event-time relations to produce the transitive closure, as well as annotated time-time relations. It is unclear if Mani et al. (2006) used these latter relations in their work.

However, we also add new time-time links that are deduced from the logical time intervals that they describe. Time expressions can be resolved to time intervals with some accuracy through simple rules. New time-time relations can then be added to our space of events through time stamp comparisons. Take this newswire example:

The Financial Times 100-share index shed 47.3 points to close at 2082.1, down 4.5% from the ***previous Friday****, and 6.8% from* ***Oct. 13****, when Wall Street's plunge helped spark the* ***current*** *weakness in London.*

[3]Sum over the # of events n_d in each document d, $\binom{n_d}{2}$

The first two expressions (‘*previous Friday*’ and ‘*Oct. 13*’) are in a clear *before* relationship that Timebank annotators captured. The ‘current’ expression, is correctly tagged with the *PRESENT_REF* attribute to refer to the document’s timestamp. Both ‘*previous Friday*’ and ‘*Oct. 13*’ should thus be tagged as being *before* this expression. However, the annotators did not tag either of these two *before* relations, and so our timestamp resolution procedure fills in these gaps. This is a common example of two expressions that were not tagged by the annotators, yet are in a clear temporal relationship.

We use Timebank’s gold standard TimeML annotations to extract the dates and times from the time expressions. In addition, those marked as *PRESENT_REF* are resolved to the document timestamp. Time intervals that are strictly before or after each other are thus labeled and added to our space of events. We create new *before* relations based on the following procedure:

```
if event1.year < event2.year
  return true
if event1.year == event2.year
  if event1.month < event2.month
    return true
  if event1.month == event2.month
    if event1.day < event2.day
      return true
  end
end
return false
```

All other time-time orderings not including the *before* relation are ignored (i.e. *includes* is not created, although could be with minor changes).

This new time-time knowledge is used in two separate stages of our model. The first is just prior to transitive closure, enabling a larger expansion of our tagged relations set and reduce the noise in the *unknown* set. The second is in the constraint satisfaction stage where we add our automatically computed time-time relations (with the gold event-time relations) to the global graph to help correct local event-event mistakes.

Total Event-Event Relations After Closure

	before	*after*
Timebank	3919	3405
+ time-time	5604	5118
+ time/bethard	7111	6170

Figure 6: The number of event-event *before* and *after* relations after transitive closure on each dataset.

Comparative Results with Closure

Training Set	Accuracy
Timebank Pairwise	66.8%
Global Model	66.8%
Global + time/bethard	70.4%

Figure 7: Using the base Timebank annotated tags for testing, the increase in accuracy on before/after tags.

5.2 Temporal Reasoning Experiment

Our second evaluation continues the use of the two-way classification task with *before* and *after* to explore the contribution of closure, time normalization, and global constraints.

We augmented the corpus with the labeled relations from Bethard et al. (2007) and added the automatically created time-time relations as described in section 5.1. We then expanded the corpus using transitive closure. Figure 6 shows the progressive data size increase as we incrementally add each to the closure algorithm.

The time-time generation component automatically added 2459 new *before* and *after* time-time relations into the 186 Timebank documents. This is in comparison to only 157 relations that the human annotators tagged, less than 1 per document on average. The second row of figure 6 shows the drastic effect that these time-time relations have on the number of available event-event relations for training and testing. Adding both Bethard’s data and the time-time data increases our training set by 81% over closure without it.

We again performed 10-fold cross validation with micro-averaged accuracies, but each fold tested only on the transitively closed Timebank data (the first row of figure 6). The training set used all available data (the third row of figure 6) including the Bethard data as well as our new time-time links.

Figure 7 shows the results from the new model. The first row is the baseline pairwise classification trained and tested on the original relations only. Our model improves by 3.6% absolute. This improvement is statistically significant ($p < 0.000001$, McNemar's test, 2-tailed).

5.3 Discussion

To further illustrate why our model now improves local decisions, we continue our previous graph example. The actual text for the graph in figure 5 is shown here:

docstamp: 10/30/89 ***(t14)***
*Trustcorp Inc. will become****(e1)*** *Society Bank & Trust when its merger****(e3)*** *is completed****(e4)*** *with Society Corp. of Cleveland, the bank said****(e5)****. Society Corp., which is also a bank, agreed****(e6)*** *in June****(t15)*** *to buy****(e8)*** *Trustcorp for 12.4 million shares of stock with a market value of about $450 million. The transaction****(e9)*** *is expected****(e10)*** *to close****(e2)*** *around year end****(t17)****.*

The automatic time normalizer computes and adds three *new* time-time relations, two connecting t15 and t17 with the document timestamp, and one connecting t15 and t17 together. These are not otherwise tagged in the corpus.

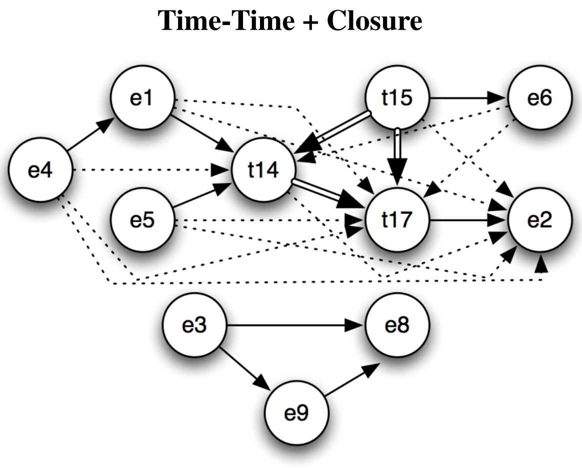

Figure 8: Before and after time-time links with closure.

Figure 8 shows the augmented document. The double-line arrows indicate the three new time-time relations and the dotted edges are the new relations added by our transitive closure procedure. Most critical to this paper, three of the new edges are event-event relations that help to expand our training data. If this document was used in testing (rather than training), these new edges would help inform our transitive rules during classification.

Even with this added information, disconnected segments of the graph are still apparent. However, the 3.6% performance gain encourages us to move to the final full task.

6 Final Experiment with Unknowns

Our final evaluation expands the set of relations to include unlabeled relations and tests on the entire dataset available to us. The following is now a classification task between the three relations: *before*, *after*, and *unknown*.

We duplicated the previous evaluation by adding the labeled relations from Bethard et al. (2007) and our automatically created time-time relations. We then expanded this dataset using transitive closure. Unlike the previous evaluation, we also use this entire dataset for testing, not just for training. Thus, all event-event relations in Bethard as well as Timebank are used to expand the dataset with transitive closure and are used in training and testing. We wanted to fully evaluate document performance on every possible event-event relation that logically follows from the data.

As before, we converted *IBefore* and *IAfter* into *before* and *after* respectively, while all other relations are reduced to *unknown*. This relation set coincides with TempEval-07's core three relations (although they use *vague* instead of *unknown*).

Rather than include all unlabeled pairs in our *unknown* set, we only include the unlabeled pairs that span at most one sentence boundary. In other words, events in adjacent sentences are included in the *unknown* set if they were not tagged by the Timebank annotators. The intuition is that annotators are more likely to label nearby events, and so events in adjacent sentences are more likely to be actual *unknown* relations if they are unlabeled. It is more likely that distant events in the text were overlooked by convenience, not because they truly constituted an *unknown* relationship.

The set of possible sentence-adjacent *unknown* relations is very large (approximately 50000 *unknown* compared to 7000 *before*), and so we randomly select a percentage of these relations for each evalu-

Classification Accuracy

% unk	base	global	global+time
0	72.0%	72.2%	74.0%
1	69.4%	69.5%	71.3%
3	65.5%	65.6%	67.1%
5	63.7%	63.8%	65.3%
7	61.2%	61.6%	62.8%
9	59.3%	59.5%	60.6%
11	58.1%	58.4%	59.4%
13	57.1%	57.1%	58.1%

Figure 9: Overall accuracy when training with different percentages of *unknown* relations included. 13% of *unknowns* is about equal to the number of *befores*.

Base Pairwise Classification

	precision	recall	f1-score
before	61.4	55.4	58.2
after	57.6	53.1	55.3
unk	53.0	62.8	57.5

Global+Time Classification

	precision	recall	f1-score
before	63.7 (+2.3)	57.1 (+2.2)	60.2 (+2.0)
after	60.3 (+2.7)	54.3 (+2.9)	57.1 (+1.8)
unk	52.0 (-1.0)	62.9 (+0.1)	56.9 (-0.6)

Figure 10: Precision and Recall for the base pairwise decisions and the global constraints with integrated time information.

ation. We used the same SVM approach with the features described in section 4.1.

6.1 Results

Results are presented in figure 9. The rows in the table are different training/testing runs on varying sizes of *unknown* training data. There are three columns with accuracy results of increasing complexity. The first, **base**, are results from pairwise classification decisions over Timebank and Bethard with no global model. The second, **global**, are results from the Integer Linear Programming global constraints, using the pairwise confidence scores from the **base** evaluation. Finally, the **global+time** column shows the ILP results when all event-time, time-time, and automatically induced time-time relations are included in the global graph.

The ILP approach does not alone improve performance on the event-event tagging task, but adding the time expression relations greatly increases the global constraint results. This is consistent with the results from out first two experiments. The evaluation with 1% of the *unknown* tags shows an almost 2% improvement in accuracy. The gain becomes smaller as the *unknown* set increases in size (1.0% gain with 13% *unknown*). *Unknown* relations will tend to be chosen as more weight is given to *unknowns*. When there is a constraint conflict in the global model, *unknown* tends to be chosen because it has no transitive implications. All improvements from base to global+time are statistically significant ($p < 0.000001$, McNemar's test, 2-tailed).

The first row of figure 9 corresponds to the results in our second experiment in figure 7, but shows higher accuracy. The reason is due to our different test sets. This final experiment includes Bethard's event-event relations in testing. The improved performance suggests that the clausal event-event relations are easier to classify, agreeing with the higher accuracies originally found by Bethard et al. (2007).

Figure 10 shows the precision, recall, and f-score for the evaluation with 13% *unknowns*. This set was chosen for comparison because it has a similar number of *unknown* labels as *before* labels. We see an increase in precision in both the *before* and *after* decisions by up to 2.7%, an increase in recall up to 2.9%, and an fscore by as much as 2.0%. The *unknown* relation shows mixed results, possibly due to its noisy behavior as discussed throughout this paper.

6.2 Discussion

Our results on the two-way (before/after) task show that adding additional implicit temporal constraints and then performing global reasoning results in significant improvements in temporal ordering of events (3.6% absolute over simple pairwise decisions).

Both *before* and *after* also showed increases in precision and recall in the three-way evaluation. However, *unknown* did not parallel this improvement, nor are the increases as dramatic as in the two-way evaluation. We believe this is consistent with the noise that exists in the Timebank corpus for unlabeled relations. Evidence from Bethard's independent annotations directly point to missing relations, but the dramatic increase in the size of our closure data (81%) from adding a small amount of time-time relations suggests that the problem is widespread. This noise in the *unknown* relation may be dampening the gains that the two way task illustrates.

This work is also related to the task of event-time classification. While not directly addressed in this paper, the global methods described within clearly apply to pairwise models of event-time ordering as well.

Further progress in improving global constraints will require new methods to more accurately identify *unknown* events, as well as new approaches to create implicit constraints over the ordering. We expect such an improved ordering classifier to be used to improve the performance of tasks such as summarization and question answering about the temporal nature of events.

Automatic inference of the temporal location of situations in Chinese text

Abstract

Chinese is a language that does not have morphological tense markers that provide explicit grammaticalization of the temporal location of situations (events or states). However, in many NLP applications such as Machine Translation, Information Extraction and Question Answering, it is desirable to make the temporal location of the situations explicit. We describe a machine learning framework where different sources of information can be combined to predict the temporal location of situations in Chinese text. Our experiments show that this approach significantly outperforms the most frequent tense baseline. More importantly, the high training accuracy shows promise that this challenging problem is solvable to a level where it can be used in practical NLP applications with more training data, better modeling techniques and more informative and generalizable features.

1 Introduction

In a language like English, tense is an explicit (and maybe imperfect) grammaticalization of the temporal location of situations, and such temporal location is either directly or indirectly defined in relation to the moment of speech. Chinese does not have grammaticalized tense in the sense that Chinese verbs are not morphologically marked for tense. This is not to say, however, that Chinese speakers do not attempt to convey the temporal location of situations when they speak or write, or that they cannot interpret the temporal location when they read Chinese text, or even that they have a different way of representing the temporal location of situations. In fact, there is evidence that the temporal location is represented in Chinese in exactly the same way as it is represented in English and most world languages: in relation to the moment of speech. One piece of evidence to support this claim is that Chinese temporal expressions like 今天 ("today"), 明天 ("tomorrow") and 昨天 ("yesterday") all assume a temporal deixis that is the moment of speech in relation to which all temporal locations are defined. Such temporal expressions, where they are present, give us a clear indication of the temporal location of the situations they are associated with. However, not all Chinese sentences have such temporal expressions associated with them. In fact, they occur only infrequently in Chinese text. It is thus theoretically interesting to ask, in the absence of grammatical tense and explicit temporal expressions, how do readers of a particular piece of text interpret the temporal location of situations?

There are a few linguistic devices in Chinese that provide obvious clues to the temporal location of situations, and one such linguistic device is aspect markers. Although Chinese does not have grammatical tense, it does have grammaticalized aspect in the form of aspect markers. These aspect markers often give some indication of the temporal location of an event. For example, Chinese has the perfective aspect marker 了 and 过, and they are often associated with the past. Progressive aspect marker 着, on the other hand, is often associated with the present. In addition to aspect, certain adverbs also provide clues to the temporal location of the situations they are associated with. For example, 已 or 已经 (”already”), often indicates that the situation they are associated with has already occurred and is thus in the past. 在, another adverbial modifier, often indicates that the situation it modifies is in the present. However, such linguistic associations are imperfect, and they can only be viewed as tendencies rather than rules that one can use to deterministically infer the temporal location of a situation. For example, while 已 indeed indicates that the situation described in (1) is in the past, when it modifies a stative verb as it does in (1b), the situation is still in the present.

(1) a. 他 [已] 做完 该 项目 。
he already finish this project .

”He already finished the project.”

b. 中国 [已] 拥有 产生 世界级
China already has produce world-class
软件 的 基础 。
software DE foundation .

”China already has the foundation to produce world-class software.”

More importantly, only a small proportion of verb instances in any given text have such explicit temporal indicators and therefore they cannot be the whole story in the temporal interpretation of Chinese text. It is thus theoretically interesting to go beyond the obvious and investigate what additional information is relevant in determining the temporal location of a situation in Chinese.

Being able to infer the temporal location of a situation has many practical applications as well. For example, this information would be highly valuable to Machine Translation. To translate a language like Chinese into a language like English in which tense is grammatically marked with inflectional morphemes, an MT system will have to infer the necessary temporal information to determine the correct tense for verbs. Statistical MT systems, the currently dominant research paradigm, typically do not address this issue directly. As a result, when evaluated for tense, current MT systems often perform miserably. For example, when a simple sentence like “他/he 明天/tomorrow 返回/return 上海/Shanghai” is given to Google’s state-of-the-art Machine Translation system[1], it produces the output “He returned to Shanghai tomorrow”, instead of the correct “he will return to Shanghai tomorrow”. The past tense on the verb “returned” contradicts the temporal expression “tomorrow”. Determining the temporal location is also important for an Information Extraction task that extracts events so that the extracted events are put in a temporal context. Similarly, for Question Answering tasks, it is also important to know whether a situation has already happened or it is going to happen, for example.

In this paper, we are interested in investigating the kind of information that is relevant in inferring the temporal location of situations in Chinese text. We approach this problem by manually annotating each verb in a Chinese document with a “tense” tag that indicates the temporal location of the verb[2]. We then formulate the tense determination problem as a classification task where standard machine learning techniques can be applied. Figuring out what linguistic information contributes to the determination of the temporal location of a situation becomes a feature engineering problem of selecting features that help with the automatic classification. In Section 2, we present a linguistic annotation framework that annotates the temporal location of situations in Chinese text. In Section 3 we describe our setup for an automatic tense classification experiment and present our experimental results. In Section 4 we focus in on the features we have used in our experiment and attempt to provide a quantitative as well as intuitive explanation of the contribution of the individual features and speculate on what additional features could be useful. In Section 5 we discuss related work and Section 6 concludes the paper and discusses future work.

2 Annotation framework

It is impossible to define the temporal location without a reference point, a temporal deixis. As we have shown in Section 1, there is convincing evidence from the temporal adverbials like 昨天(“yesterday”), 今天(“today”) and 明天

[1]http://www.google.com/language_tools

[2]For simplicity, we use the term “tense” exchangeably with the temporal location of an event or situation, even though tense usually means grammatical tense while temporal location is a more abstract semantic notion.

(“tomorrow”) that Chinese, like most if not all languages of the world, use the moment of speech as this reference point. In written text, which is the primary source of data that we are dealing with, the temporal deixis is the document creation time. All situations are temporally related to this document creation time except in direct quotations, where the temporal location is relative to the moment of speech of the speaker who is quoted.

In addition to the moment of speech or document creation time in the case of written text, Reference Time and Situation Time are generally accepted as important to determining the temporal location since Reichenbach (1947) first proposed them. Situation Time is the time that a situation actually occurs while Reference time is the temporal perspective from which the speaker invites his audience to consider the situation. Reference Time does not necessarily overlap with Situation Time, as in the case of present perfective tense, where the situation happened in the past but the reader is invited to look at it from the present moment and focus on the state of completion of the situation. Reference Time is in our judgment too subtle to be annotated consistently and thus in our annotation scheme we only consider the relation between Situation Time and the document creation time when defining the temporal location of situations. Another key decision we made when formulating our annotation scheme is to define an abstract “tense” that do not necessarily model the actual tense system in any particular language that has grammatical tense. In a given language, the grammatical tense reflected in the morphological system may not have a one-to-one mapping between the grammatical tense and the temporal location of a situation. For example, in an English sentence like “He will call me after he gets here”, while his “getting here” happens at a time in the future, it is assigned the present tense because it is in a clause introduced by “after”. It makes more sense to ask the annotator, who is necessarily a native speaker of Chinese, to make a judgment of the temporal location of the situation defined in terms of the relation between the Situation Time and the moment of speech rather than by such language-specific idiosyncracies of another language.

Temporal locations that can be defined in terms of the relation between Situation Time and the moment of speech are considered to be *absolute tense*. In some cases, the temporal location of a situation cannot be directly defined in relation to the moment of speech. For example in (2), the temporal location of 有意 (“intend”) cannot be determined independently of that of 透露(“reveal”). The temporal location of 有意 is simultaneous with 透露. If the temporal location of 透露 is in the past, then the temporal location of 有意 is also in the past. If the temporal location of 透露 is in the future, then the temporal location of 有意 is also in the future. In this specific case, the situation denoted by the matrix verb 透露 is in the past. Therefore the situation denoted by 有意 is also located in the past.

(2) 他 还 透露 俄罗斯 有意 在 今后 十年
he also reveal Russia intend in next ten years
内 , 向 伊朗 提供 武器 .
within , to Iran provide weapons .

“He also revealed that Russia intended to provide weapons to Iran within the next ten years.”

Therefore in our Chinese “tense” annotation task, we annotate both *absolute* and *relative* tenses. We define three absolute tenses based on whether the situation time is anterior to (in the past), simultaneous with (in the present), or posterior to (in the future) document creation time. In addition to the absolute tenses, we also define one relative tense, future-in-past, which happens when a future situation is embedded in a past context. We do not assign a tense tag to modal verbs or verb particles. The set of tense tags are described in more detail below:

2.1 Present tense

A situation is assigned the present tense if it is true at an interval of time that includes the present moment. The present tense is compatible with states and activities. When non-stative situations are temporally located in the present, they either have an imperfective aspect or have a habitual or frequentive reading which makes them look like states, e.g.,

(3) 他 常常 参加 户外 活动 。
he often attend outdoors activities .

“He often attends outdoors activities.”

2.2 Past tense

Situations that happen before the moment of speech (or the document creation time) are temporally located in the past as in (4):

(4) 中方 人员 及 侨胞
Chinese personnel and Chinese nationals
安全 撤离 乍得 。
safely withdraw from Chad .

"Chinese personnel and Chinese nationals safely withdrew from Chad."

2.3 Future tense

Situations that happen posterior to the moment of speech are temporally located in the future. Future situations are not simply the opposite of past situations. While past situations have already happened by definition, future situations by nature are characterized by uncertainty. That is, future situations may or may not happen. Therefore, future situations are often linked to possibilities, not just to situations that will definitely happen. A example of future tense is given in (5):

(5) 大会 明年 在新加坡 举行 。
conference next year in Singapore hold .

"The conference will be held in Singapore next year."

2.4 Future-in-past

The temporal interpretation of one situation is often bound by the temporal location of another situation. One common scenario in which this kind of dependency occurs is when the target situation, the situation we are interested in at the moment, is embedded in a reference situation as its complement. Just as the absolute "tense" represents a temporal relation between the situation time and the moment of speech or document creation time, the relative "tense" represents a relation between the temporal location of a situation and its reference situation. Although theoretically the target situation can be anterior to, simultaneous with, or posterior to the reference situation, we only have a special tense label when the target situation is posterior to the reference situation and the reference situation is located in the past. In this case the label for the target situation is future-in-past as illusrated in (6):

(6) 公司 员工 透露 《星际2》测试
company personnel reveal " Star 2 " trial
版 即将面世 。
version soon face the world .

"The company personnel revealed that 'Star 2' trial version would soon face the world."

2.5 No tense label

Modals and verb particles do not receive a tense label:

(7) 科索沃 独立 可能 引发 骚乱,
Kosovo independence may cause riot .
联合国人员 已 准备 撤离 。
UN personnel already prepare withdraw .

"Kosovo independence may cause riot. UN personnel have already prepared to leave."

The "situations" that we are interested in are expressed as clauses centered around a verb, and for the sake of convenience we mark the "tense" on the verb itself instead of the entire clause. However, when inferring the temporal location of a situation, we have to take into consideration the entire clause, because the arguments and modifiers of a verb are just as important as the verb itself when determining the temporal location of the situation. The annotation is performed on data selected from the Chinese Treebank (Xue et al., 2005), and more detailed descriptions and justifications for the annotation scheme is described in (Xue et al., 2008). Data selection is important for tense annotation because, unlike POS-tagging and syntactic annotation, which applies equally well to different genres of text, temporal annotation in more relevant in some genres than others. The data selection task is made easier by the fact that the Chinese Treebank is already annotated with POS tags and Penn Treebank-style syntactic structures. Therefore we were able to just select articles based on how many constituents in the article are annotated with the temporal function tag -TMP. We have annotated 42 articles in total, and all verbs in an article are assigned one of the five tags described above: present, past, future, future-in-past, and none.

3 Experimental results

The tense determination task is then a simple five-way classification task. Theoretically any standard machine learning algorithm can be applied to the task. For our purposes we used the Maximum Entropy algorithm implemented as part of the Mallet machine learning package (McCallum, 2002) for its competitive training time and performance tradeoff. There might be algorithms that could achieve higher classification accuracy, but our goal in this paper is not to pursue the absolute high performance. Rather, our purpose is to investigate what information when used as features is relevant to determining the temporal location of a situation in Chinese, so that these features can be used to design high performance practical systems in the future.

The annotation of 42 articles yielded 5709 verb instances, each of which is annotated with one of the five tense tags. For our automatic classification experiments, we randomly divided the data into a training set and a test set based on a 3-to-1 ratio, so that the training data has 4,250 instances while the test set has 1459 instances. As expected, the past tense is the most frequent tense in both the training and test data, although they vary quite a bit in the proportions of verbs that are labeled with the past tense. In the training data, 2145, or 50.5% of the verb instances are labeled with the past tense while in the test data, 911 or 62.4% of the verb instances are labeled with the past tense. The 62.4% can thus be used as a baseline when evaluating the automatic classification accuracy. This is a very high baseline given that the much smaller proportion of verbs that are assigned the past tense in the training data.

Instead of raw text, the input to the classification algorithm is parsed sentences from the Chinese Treebank that has the syntactic structure information as well as the part-of-speech tags. As we will show in the next section, information extracted from the parse tree as well as the part-of-speech tags prove to be very important in determining the temporal location of a situation. The reason for using "correct" parse trees in the Chinese Treebank is to factor out noises that are inevitable in the output of an automatic parser and evaluate the contribution of syntactic information in the "ideal" scenario. In a realistic setting, one of course has to use an automatic parser.

The results are presented in Table 1. The overall accuracy is 67.1%, exceeding the baseline of choosing the most frequent tense in the test, which is 62.4%. It is worth noting that the training accuracy is fairly high, 93%, and there is a steep drop-off from the training accuracy to the test accuracy although this is hardly unexpected given the relatively small training set. The high training accuracy nevertheless attests the relevance of the features we have chosen for the classification, which we will look at in greater detail in the next section.

tense	precision	recall	f-score
present	0.51	0.62	0.56
past	0.75	0.81	0.78
future	0.33	0.45	0.38
future-in-past	0.76	0.18	0.30
none	0.86	0.83	0.84
overall	0.93 (train), 0.671 (test)		

Table 1: Experimental results

4 What information is useful?

Our classification algorithm scans the verbs in a sentence one at a time, from left to right. Features are extracted from the context of the verb in the parse tree as well as from previous verbs the tense of which have already been examined. We view features for the classification algorithm as information that contributes to the determination of the temporal location of situations in the absence of morphological markers of tense. The features we used for the classification task can all be extracted from a parse tree and the POS information of a word. They are described below:

- Verb Itself: The character string of the verbs, e.g., 拥有("own"), 是("be"), etc.

- Verb POS: The part-of-speech tag of the verb, as defined in the Chinese Treebank. There are three POS tags for verbs, *VE* for existential verbs such as 有("have, exist"), *VC* for copula verbs like 是("be"), *VA* for stative verbs like 高("tall"), and *VV* for all other verbs.

- Position of verb in compound: If the target verb is part of a verb compound, the position of the compound is used as a feature in combination with the compound type. The possible values for the position are *first* and *last*, and the compound type is one of the six defined in the Chinese Treebank: *VSB*, *VCD*, *VRD*, *VCP*, *VNV*, and *VPT*. An example feature might be "last+VRD".

- Governing verb and its tense: Chinese is an SVO language, and the governing verb, if there is one, is on the left and is higher up in the tree. Since we are scanning verbs in a sentence from left to right, the tense for the governing verb is available at the time we look at the target verb. So we are using the character string of the governing verb as well as its tense as features. In cases where there are multiple levels of embedding and multiple governing verbs, we select the closest governing verb.

- Left ADV: Adverbial modifiers of the target verb are generally on the left side of the verb, therefore we are only extracting adverbs on the left. We first locate the adverbial phrases and then find the head of the adverbial phrase and use character string of the head as feature.

- Left NT: NT is a POS in the Chinese Treebank for nominal expressions that are used as temporal modifiers of a verb. The procedure for extracting the NT modifers is similar to the procedure for finding adverbial modifiers, the only difference being that we are looking for NPs headed by nouns POS-tagged NT.

- Left PP: Like adverbial modifiers, PP modifiers are also generally left modifiers of a verb. If there is a PP modifier, the character string of the head preposition combined with the character string of the head noun of its NP complement is used as a feature, e.g., "在+期间" ("at+period").

- Left LC: Left localizer phrases. Localizers phrases are also called post-positions by some and they function similarly as left PP modifiers. If the target verb has a left localizer phrase modifier and the character string of its head is used as a feature, e.g., 以来("since").

- Left NN: This feature is intended to capture the head of the subject NP. The character string of the head of the NP is used as a feature.

- Aspect marker. Aspect markers are grammaticalizations of aspect and they immediately follow the verb. If the target verb is associated with an aspect marker, the character string of that aspect marker is used as a feature, e.g., "了".

- DER: DER is the POS tag for 得, a character which introduces a resultative construction when following a verb. When it occurs together with the target verb, it is used as a feature.

- Quantifier in object: When there is a quantifier in the NP object for the target verb, its character string is used as a feature.

- Quotation marks: Finally the quotation marks are used as a feature when they are used to quote the clause that contains the target verb.

We performed an ablation evaluation of the features to see how effective each feature type is. Basically, we took out each feature type, retrained the classifier and reran the classifier on the test data. The accuracy without each of the feature types are presented in Table 2. The features are ranked from the most effective to the least effective. Features that lead to the most drop-off when they are taken out of the classification algorithm are considered to be the most effective. As shown in Table 2, the most effective features are the governing verb and its tense, while the least effective features are the quantifiers in the object. Most of the features are lexicalized in that the character strings of words are used as features. When lexicalized features are used, features that appear in the training data do not necessarily appear in the test data and vice versa. This provides a partial explanation of the large discrepancy between the training and test accuracy. In order to reduce this discrepancy, one would have to use a larger training set, or make the features more generalized. Some of these features can in fact be generalized or normalized. For example, a temporal modifier such as the date "1987" can be reduced to something like "before the document creation time", and this is something that we will experiment with in our future work. The training set used here is sufficient to show the efficacy of the features, but to improve the tense classification to a satisfactory level of accuracy, more training data need to be annotated.

Feature	accuracy (w/o)
Governing verb/tense	0.620
verb itself	0.635
Verb POS	0.656
Position verb in compound	0.656
left ADV	0.657
left NT	0.657
Quotation mark	0.657
left PP	0.663
left LC	0.664
Right DER	0.665
Aspect marker	0.665
left NN	0.665
Quantifier in object	0.669
overall	0.671 (test)

Table 2: Feature Performance

Features like adverbial, prepositional, localizer phrase modifiers and temporal noun modifiers provide explicit temporal information that is relevant in determining the temporal location. The role of the governing verb in determining the temporal location of a situation is also easy to understand. As we have shown in Section 2, when the target verb occurs in an embedded clause, its temporal location is necessarily affected by the temporal location of the governing verb of this embedded clause because the temporal location of the former is often defined in relation to that of the latter. Not surprisingly, the governing verb proves to be the most effective feature. Quotation marks in written text change the temporal deixis from the document creation time to the moment of speech of the quoted speaker, and the temporal location in quoted speech does not follow the same patterns as target verbs in embedded clauses. Aspect markers are tied closely to tense, even though the contributions they made are small due to their rare occurrences in text.

The relevance of other features are less obvious. The target verb itself and its POS made the most contribution other than the governing verb. It is important to understand why they are effective or useful at all. In a theoretic work on the temporal interpretation of verbs in languages like Chinese which lacks tense morphology, Smith and Erbaugh (2005) pointed out that there is a default interpretation for bounded and unbounded situations. Specifically, bounded situations are temporally located in the past by default while unbounded situations are located in the future. The default interpretation, by definition, can be overwritten when there is explicit evidence to the contrary. Recast in statistical terms, this means that bounded events have a tendency to be located in the past while unbounded events have a tendency to be located in the present, and this tendency can be quantified in a machine-learning framework. Boundedness has many surface manifestations that can be directly observed, and one of them is whether the verb is stative or dynamic. The target verb itself and its POS tag represents this information. Resultatives in the form of resultative verb compound and the DER construction, quantifiers in the object are other surface reflections of the abstract notion of boundedness. The fact that these features have contributed to the determination of the temporal location of situations to certain extent lends support to Smith's theoretical claim.

5 Related work

Inferring the temporal location is a difficult problem that is not yet very well understood. It has not been studied extensively in the context of Natural Language Processing. Olson et al (2000; 2001) realized the importance of using the aspectual information (both grammatical and lexical aspect) to infer tense in the context of a Chinese-English Machine Translation system. They encoded the aspectual information such as telicity as part of the Lexical Conceptual Structure and use it to heuristically infer tense when generating the English output. This rule-based approach is not very suited for modeling the temporal location information in Chinese. As they themselves noted, aspectual information can only be used as a tendency rather than a deterministic rule. We believe this problem can be better modeled in a machine learning framework where different sources of information, each one being imperfect, can be combined based on their effectiveness to provide a more reasonable overall prediction.

Ye (2007) did approach this problem with machine learning techniques. She used Chinese-English parallel data to manually map the tense information from English to Chinese and trained a Conditional Random Field classifier to make predictions about tense. She used only a limited number of surface cues such as temporal adverbials and aspect markers as features and did not attempt to model the lexical aspect information such as boundedness, which we believe would have helped her system performance. Her data appeared to have a much larger percentage of verb instances that have the past tense and thus her results are mostly incomparable with that of ours.

6 Conclusion and future work

We have defined the automatic inference of the temporal location of situations in Chinese text as a machine learning problem and demonstrated that a lot more information in the form of features contributes to the solution of this challenging problem than previously realized. The accuracy on the held-out test is a significant improvement over the baseline, the proportion of verbs assigned the most frequent tense (the past tense). Although there is a large drop-off from the training accuracy to the test accuracy due to the lexical nature of the features, the high training accuracy does show promise that this challenging problem is solvable with a larger training set, better modeling techniques and more refined features. In the future we will attempt to solve this problem along these lines and work toward a system that can be used in practical applications.

Acknowledgments

We would like to thank Hua Zhong and Kaiyun Chen for their efforts to annotate the data used in our experiments. Without their help this work would of course be impossible.

Abstract

In this paper we present a machine learning system that finds the scope of negation in biomedical texts. The system consists of two memory-based engines, one that decides if the tokens in a sentence are negation signals, and another that finds the full scope of these negation signals. Our approach to negation detection differs in two main aspects from existing research on negation. First, we focus on finding the scope of negation signals, instead of determining whether a term is negated or not. Second, we apply supervised machine learning techniques, whereas most existing systems apply rule-based algorithms. As far as we know, this way of approaching the negation scope finding task is novel.

1 Introduction

In this paper we present a machine learning system that finds the scope of negation in biomedical texts. The system consists of two classifiers, one that decides if the tokens in a sentence are negation signals (i.e., words indicating negation), and another that finds the full scope of these negation signals. Finding the scope of a negation signal means determining at sentence level which words in the sentence are affected by the negation. Our approach differs in two main aspects from existing research. First, we focus on finding the scope of negation signals, instead of determining whether a term is negated or not. Second, we apply supervised machine learning techniques, whereas most existing systems apply rule-based algorithms.

Predicting the scope of negation is important in information extraction from text for obvious reasons; instead of simply flagging the sentences containing negation as not suited for extraction (which is currently the best that can be done), correct semantic relations can be extracted when the scope of negation is known, providing a better recall.

Not being able to recognize negation can also hinder automated indexing systems (Mutalik et al., 2001; Rokach et al., 2008). As Mutalik et al. (2001) put it, “to increase the utility of concept indexing of medical documents, it is necessary to record whether the concept has been negated or not”. They highlight the need to detect negations in examples like “no evidence of fracture”, so that an information retrieval system does not return irrelevant reports.

Szarvas et al. (2008) report that 13.45% of the sentences in the abstracts section of the BioScope corpus and 13.76% of the sentences in the full papers section contain negations. A system that does not deal with negation would treat these cases as false positives.

The goals of this research are to model the scope finding task as a classification task similar to the semantic role labeling task, and to test the performance of a memory–based system that finds the scope of negation signals. Memory-based language processing (Daelemans and van den Bosch, 2005) is based on the idea that NLP problems can be solved by reuse of solved examples of the problem in memory, applying similarity-based reasoning on these examples in order to solve new problems. As language processing tasks typically involve many subregularities and (pockets of) exceptions, it has been argued that lazy learning is at an advantage in solving these highly disjunctive learning problems compared to eager learning, as the latter eliminates not only noise but also potentially useful exceptions (Daelemans et al., 1999). Memory-based algorithms have been successfully applied in language processing to a wide range of linguistic tasks, from phonology to semantic analysis, such as semantic role labeling (Morante et al., 2008).

The paper is organised as follows. In Section 2, we summarise related work. In Section 3, we describe the corpus with which the system has been trained. In Section 4, we introduce the task to be performed by the system, which is described in Section 5. The results are presented and discussed in Section 6. Finally, Section 7 puts forward some conclusions.

2 Related work

Negation has been a neglected area in open-domain natural language processing. Most research has been performed in the biomedical domain and has focused on detecting if a medical term is negated or not, whereas in this paper we focus on detecting the full scope of negation signals.

Chapman et al. (2001) developed NegEx, a regular expression based algorithm for determining whether a finding or disease mentioned within narrative medical reports is present or absent. The reported results are 94.51 precision and 77.84 recall.

Mutalik et al. (2001) developed Negfinder, a rule-based system that recognises negated patterns in medical documents. It consists of two tools: a lexical scanner called *lexer* that uses regular expressions to generate a finite state machine, and a parser. The reported results are 95.70 recall and 91.80 precision.

Sanchez-Graillet and Poesio (2007) present an analysis of negated interactions in biological texts and a heuristics-based system that extracts such information. They treat all types of negation: (i) Affixal negation, which is expressed by an affix. (ii) Noun phrase or emphatic negation, expressed syntactically by using a negative determiner (e.g. *no*, *nothing*). (iii) Inherent negation, expressed by words with an inherently negative meaning (e.g. *absent*). (iv) Negation with explicit negative particles (e.g. *no*, *not*). The texts are 50 journal articles. The preliminary results reported range from 54.32 F-score to 76.68, depending on the method applied.

Elkin et al. (2005) describe a rule-based system that assigns to concepts a level of certainty as part of the generation of a dyadic parse tree in two phases: First a preprocessor breaks each sentence into text and operators. Then, a rule based system is used to decide if a concept has been positively, negatively, or uncertainly asserted. The system achieves 97.20 recall and 98.80 precision.

The systems mentioned above are essentially based on lexical information. Huang and Lowe (2007) propose a classification scheme of negations based on syntactic categories and patterns in order to locate negated concepts, regardless of their distance from the negation signal. Their hybrid system that combines regular expression matching with grammatical parsing achieves 92.60 recall and 99.80 precision.

Additionally, Boytcheva et al. (2005) incorporate the treatment of negation in a system, MEHR, that extracts from electronic health records all the information required to generate automatically patient chronicles. According to the authors "the negation treatment module inserts markers in the text for negated phrases and determines scope of negation by using negation rules". However, in the paper there is no description of the rules that are used and it is not explained how the results presented for negation recognition (57% of negations correctly recognised) are evaluated.

The above-mentioned research applies rule-based algorithms to negation finding. Machine learning techniques have been used in some cases. Averbuch et al. (2004) developed an algorithm that uses information gain to learn negative context patterns.

Golding and Chapman (2003) experiment with machine learning techniques to distinguish whether a medical observation is negated by the word *not*. Their corpus contains 207 selected sentences from hospital reports, in which a negation appears. They use Naive Bayes and Decision Trees and achieve a maximum of 90 F-score. According to the authors, their main finding is that "when negation of a UMLS term is triggered with the negation phrase *not*, if the term is preceded by *the* then do not negate".

Goryachev et al. (2006) compare the performance of four different methods of negation detection, two regular expression-based methods and two classification-based methods trained on 1745 discharge reports. They show that the regular expression-based methods have better agreement with humans and better accuracy than the classification methods. Like in most of the mentioned work, the task consists in determining if a medical term is negated.

Rokach et al. (2008) present a new pattern-based algorithm for identifying context in free-text medical narratives.The originality of the algorithm lies in that it automatically learns patterns similar to the manually written patterns for negation detection.

Apart from work on determining whether a term is negated or not, we are not aware of research that has focused on learning the full scope of negation signals inside or outside biomedical natural language processing. The research presented in this paper provides a new approach to the treatment of negation scope in natural language processing.

3 Corpus

The corpus used is a part of the BioScope corpus (Szarvas et al., 2008)[1], a freely available resource that consists of medical and biological texts. Every sentence is annotated with information about negation and speculation that indicates the boundaries of the scope and the keywords, as shown in (1).

(1) PMA treatment, and <xcope id="X1.4.1"><cue type="negation" ref="X1.4.1">not<cue> retinoic acid treatment of the U937 cells</xcope> acts in inducing NF-KB expression in the nuclei.

A first characteristic of the annotation of scope in the BioScope corpus is that all sentences that assert the non-existence or uncertainty of something are annotated, in contrast to other corpora where only sentences of interest in the domain are annotated. A second characteristic is that the annotation is extended to the biggest syntactic unit possible so that scopes have the maximal length. In (2) below, negation signal *no* scopes over *primary impairment of glucocorticoid metabolism* instead of scoping only over *primary*.

(2) There is [no] primary impairment of glucocorticoid metabolism in the asthmatics.

[1]Web page: `www.inf.u-szeged.hu/rgai/bioscope`.

The part used in our experiments are the biological paper abstracts from the GENIA corpus (Collier et al., 1999). This part consists of 11,872 sentences in 1,273 abstracts. We automatically discarded five sentences due to annotation errors. The total number of words used is 313,222, 1,739 of which are negation signals that belong to the different types described in (Sanchez-Graillet and Poesio, 2007).

We processed the texts with the GENIA tagger (Tsuruoka and Tsujii, 2005; Tsuruoka et al., 2005), a bidirectional inference based tagger that analyzes English sentences and outputs the base forms, part-of-speech tags, chunk tags, and named entity tags in a tab-separated format[2]. Additionally, we converted the annotation about scope of negation into a token-per-token representation.

Table 1 shows an example sentence of the corpus that results from converting and processing the BioScope representation. Following the standard format of the CoNLL Shared Task 2006 (Buchholz and Marsi, 2006), sentences are separated by a blank line and fields are separated by a single tab character. A sentence consists of tokens, each one starting on a new line. A token consists of the following 10 fields:

1. ABSTRACT ID: number of the GENIA abstract.
2. SENTENCE ID: sentence counter starting at 1 for each new abstract.
3. TOKEN ID: token counter, starting at 1 for each new sentence.
4. FORM: word form or punctuation symbol.
5. LEMMA: lemma of word form.
6. POS TAG: Penn Treebank part-of-speech tags described in (Santorini, 1990).
7. CHUNK TAG: IOB (Inside, Outside, Begin) tags produced by the GENIA tagger that indicate if a token is inside a certain chunk, outside, or at the beginning.
8. NE TAG: IOB named entity tags produced by the GENIA tagger that indicate if a token is in-

[2]The accuracy of the tagger might be inflated due to the fact that it was trained on the GENIA corpus.

Table 1: Example sentence of the BioScope corpus converted into columns format.

side a certain named entity, outside, or at the beginning.

9. NEG SIGNAL: tokens that are negation signals are marked as NEG. Negation signals in the BioScope corpus are not always single words, like the signal *could not*. After the tagging process the signal *cannot* becomes also multiword because the tagger splits it in two words. In these cases we assign the NEG mark to *not*.

10. NEG SCOPE: IO tags that indicate if a token is inside the negation scope (I-NEG), or outside (O-NEG). These tags have been obtained by converting the xml files of BioScope. Each token can have one or more NEG SCOPE tags, depending on the number of negation signals in the sentence.

4 Task description

We approach the scope finding task as a classification task that consists of classifying the tokens of a sentence as being a negation signal or not, and as being inside or outside the scope of the negation signal(s). This happens as many times as there are negation signals in the sentence. Our conception of the task is inspired by Ramshaw and Marcus' representation of text chunking as a tagging problem (Ramshaw and Marcus, 1995) .

The information that can be used to train the system appears in columns 1 to 8 of Table 1. The information to be predicted by the system is contained in columns 9 and 10.

As far as we know, approaching the negation scope finding task as a token per token classification task is novel, whereas at the same time it conforms to the well established standards of the recent CoNLL Shared Tasks[3] on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007) and semantic role labeling (Surdeanu et al., 2008). By setting up the task in this way we show that the negation scope finding task can be modelled in a way similar to semantic role labeling, and by conforming to existing standards we show that learning the scope of negation can be integrated in a joint learning task with dependency parsing and semantic role labeling.

[3]Web page of CoNLL: `http://www.ifarm.nl/signll/conll/`.

5 System description

In order to solve the task, we apply supervised machine learning techniques. We build a memory-based scope finder, that tackles the task in two phases. In the first phase a classifier predicts if a token is a negation signal, and in the second phase another classifier predicts if a token is inside the scope of each of the negation signals. Additionally, the output of the second classifier is postprocessed with an algorithm that converts non-consecutive blocks of scope into consecutive, as explained in Section 5.3.

As for the first and second phases, we use a memory–based classifier as implemented in TiMBL (version 6.1.2) (Daelemans et al., 2007), a supervised inductive algorithm for learning classification tasks based on the k-nearest neighbor classification rule (Cover and Hart, 1967). Similarity is defined by computing (weighted) overlap of the feature values of a test instance and training instances. The metric combines a per-feature value distance metric (Cost and Salzberg, 1993) with gain ratio (Quinlan, 1993) based global feature weights that account for relative differences in discriminative power of the features.

5.1 Negation signal finding

In this phase, a classifier predicts whether a token is a negation signal or not. The memory-based classifier was parameterised by using overlap as the similarity metric, gain ratio for feature weighting, and using 7 k-nearest neighbors. All neighbors have equal weight when voting for a class. The instances represent all tokens in the corpus and they have the following features:

- Of the token: Form, lemma, part of speech, and chunk IOB tag.
- Of the token context: Form, POS, and IOB tag of the three previous and three next tokens.

5.2 Scope finding

In the first step of this phase, a classifier predicts whether a token is in the scope of each of the negation signals of a sentence. A pair of a negation signal and a token from the sentence represents an instance. This means that all tokens in a sentence are paired with all negation signals that occur in the sentence. For example, token *NF-kappa* in Table 1 will be represented in two instances as shown in (3). An instance represents the pair [NF–KAPPA, absent] and another one represents the pair [NF–KAPPA, not].

(3) NF-kappa absent [features] I-NEG
NF-kappa not [features] O-NEG

Negation signals are those that have been classified as such in the previous phase. Only sentences that have negation signals are selected for this phase.

The memory–based algorithm was parameterised in this case by using overlap as the similarity metric, gain ratio for feature weighting, using 7 k-nearest neighbors, and weighting the class vote of neighbors as a function of their inverse linear distance.

The features of the scope finding classifier are:

- Of the negation signal: Form, POS, chunk IOB tag, type of chunk (NP, VP, ...), and form, POS, chunk IOB tag, type of chunk, and named entity of the 3 previous and 3 next tokens.
- Of the paired token: form, POS, chunk IOB tag, type of chunk, named entity, and form, POS, chunk IOB tag, type of chunk, and named entity type of the 3 previous and 3 next tokens.
- Of the tokens between the negation signal and the token in focus: Chain of POS types, distance in number of tokens, and chain of chunk IOB tags.
- Others: A binary feature indicating whether the token and the negation signal are in the same chunk, and location of the token relative to the negation signal (pre, post, same).

5.3 Post-processing

Negation signals in the BioScope corpus always have one consecutive block of scope tokens, including the signal token itself. However, the scope finding classifier can make predictions that result in non-consecutive blocks of scope tokens: we observed that 54% of scope blocks predicted by the system given gold standard negation signals are non–consecutive. This is why in the second step of the scope finding phase, we apply a post-processing algorithm in order to increase the number of fully correct scopes. A scope is fully correct if all tokens in a sentence have been assigned their correct class label for a given negation signal. Post-processing ensures that the resulting scope is one consecutive block of tokens.

In the BioScope corpus negation signals are inside of their scope. The post-processing algorithm that we apply first checks if the negation signal is in its scope. If the signal is out, the algorithm overwrites the predicted scope in order to include the signal in its scope.

Given the position of the signal in the sentence, the algorithm locates the starting and ending tokens of the consecutive block of predicted scope tokens that surrounds the signal. Other blocks of predicted scope tokens may have been predicted outside of this block, but they are separated from the current block, which contains the signal, by tokens that have been predicted not to be in the scope of the negation, as in Figure 1.

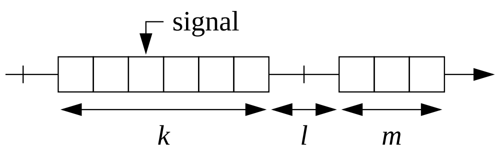

Figure 1: Non-consecutive blocks of scope tokens. For a signal, two blocks of $k = 6$ and $m = 3$ tokens are predicted to be the scope of the signal token, but they are separated by $l = 2$ tokens that are predicted to be out of scope.

The post-processing algorithm decides whether the detached blocks should be connected as one consecutive block of scope tokens, or whether the detached block of scope tokens should be discarded from the scope. Dependent on this decision, either the classification of the separated blocks, or the separating non-scope tokens are considered noisy, and their classification is updated to produce one consecutive block of scope tokens for each signal. This check is performed iteratively for all detached blocks of scope tokens.

As in Figure 1, consider a sentence where the negation signal is in one block K of predicted scope of length k tokens and another block M of m consecutive tokens that is predicted as scope but is separated from the latter scope block by l out-of-scope tokens.

If non-consecutive blocks are near each other, i.e., if l is sufficiently small in comparison with k and m, then the intermediate tokens that have been predicted out of scope could be considered as noise and converted into scope tokens. In contrast, if there are too many intermediate tokens that separate the two blocks of scope tokens, then the additional block of scope is probably wrongly classified.

Following this logic, if $l < \alpha(k + m)$, with a specifically chosen α, the intermediate out-of-scope tokens are re-classified as scope tokens, and the separated blocks are connected to form one bigger block containing the negation signal. Otherwise, the loose block of scope is re-classified to be out of scope. When the main scope is extended, and more blocks are found that are separated from the main scope block, the algorithm reiterates this procedure until one consecutive block of scope tokens has been found.

Our implementation first looks for separated blocks from right to left, and then from left to right. Dependent on whether blocks need to be added before or after the main scope block, we have observed in preliminary tests that $\alpha = 0.2$ for extending the main scope block from right to left, and $\alpha = 0.3$ for extending the block from left to right into the sentence provide the best results. Algorithm 1 details the above procedure in pseudo code.

Algorithm 1 Post-processing

```
$K \leftarrow$ scope block that contains signal
while $M \leftarrow$ nearest separated scope block do
    $L \leftarrow$ non-scope block between $K$ and $M$
    if $|L| < \alpha(|K| + |M|)$ then
        include $L$ in scope
    else
        exclude $M$ from scope
    end if
    $K \leftarrow$ scope block that contains signal
end while
```

6 Results

The results have been obtained by performing 10-fold cross validation experiments. The evaluation is made using the precision and recall measures (Van Rijsbergen, 1979), and their harmonic mean, F-Measure. We calculate micro F1.

In the negation finding task, a negation token is correctly classified if it has been assigned a NEG class. In the scope finding task, a token is correctly classified if all the IO tag(s) that it has been assigned are correct. This means that when there is more than one negation signal in the sentence, the token has to be correctly assigned an IO tag for as many negation signals as there are. For example, token NF-kappa from Table 1 reproduced in (4) will not be correct if it is assigned classes I-NEG I-NEG or O-NEG I-NEG.

(4) 10415075 07 1 NF-kappa NF-kappa NN B-NP B-protein _ I-NEG O-NEG

Additionally, we evaluated the percentage of fully correct scopes (PCS).

6.1 Negation signal finding

We calculate two baselines for negation signal finding. Baseline 1 (B1) is calculated by assigning the NEG class to all the tokens that had *no* or *not* as lemma, which account for 72.80% of the negation signals. The F1 of the baseline is 80.66. Baseline 2 (B2) is calculated by assigning the NEG class to all the tokens that had *no*, *not*, *lack*, *neither*, *unable*, *without*, *fail*, *absence*, or *nor* as lemma. These lemmas account for 85.85 % of the negation signals.

Baseline	Total	Prec.	Recall	F1
B1	1739	90.42	72.80	80.66
B2	1739	89.77	93.38	91.54

Table 2: Baselines of the negation finding system.

Table 3 shows the overall results of the negation signal finding system and the results per negation signal. With F1 94.40, it outperforms Baseline 2 by 2.86 points. Precision and recall are very similar. Scores show a clear unbalance between different negation signals. Those with the lowest frequencies get lower scores than those with the highest frequencies. Probably, this could be avoided by training the system with a bigger corpus.

However, a bigger corpus would not help solve all the errors because some of them are caused by inconsistency in the annotation. For example, *absence* is annotated as a negation signal in 57 cases, whereas in 22 cases it is not annotated as such, although in all cases it is used as a negation signal. Example 5 (a) shows one of the 22 cases of *absence* that has not been annotated, and Example 5 (b) shows one of the 57 cases of *absence* annotated as a negation signal. Also *fail* is not annotated as a negation signal in 13 cases where it should.

Neg signals	Total	Prec.	Recall	F1
lack (v)	55	100.00	100.00	100.00
neither (con)	34	100.00	100.00	100.00
lack (n)	33	100.00	100.00	100.00
unable	30	100.00	100.00	100.00
neither (det)	8	100.00	100.00	100.00
no (adv)	5	100.00	100.00	100.00
without	83	100.00	98.79	99.39
nor	44	100.00	100.00	98.89
rather	19	95.00	100.00	97.43
not	1057	96.15	96.97	96.56
no (det)	204	95.63	96.56	96.09
none	7	85.71	85.71	85.71
fail	57	79.36	87.71	83.33
miss	2	66.66	100.00	80.00
absence	57	67.64	80.70	73.60
failure	8	45.54	62.50	52.63
could	6	66.66	33.33	44.44
absent	13	42.85	23.07	30.00
with	6	0.00	0.00	0.00
either	2	0.00	0.00	0.00
instead	2	0.00	0.00	0.00
never	2	0.00	0.00	0.00
impossible	1	0.00	0.00	0.00
lacking	1	0.00	0.00	0.00
loss	1	0.00	0.00	0.00
negative	1	0.00	0.00	0.00
or	1	0.00	0.00	0.00
Overall	1739	94.21	94.59	94.40

Table 3: F scores of the negation finding classifier.

(5) (a) Retroviral induction of TIMP-1 not only resulted in cell survival but also in continued DNA synthesis for up to 5 d in the **absence** of serum, while controls underwent apoptosis.

(b) A significant proportion of transcripts appear to terminate prematurely in the <xcope id= X654.8.1 ><cue type= negation ref= X654.8.1 > **absence** </cue> of transactivators </xcope>.

Other negation signals are arbitrarily annotated. *Failure* is annotated as a negation signal in 8 cases where it is followed by a preposition, like in Example 6 (a), and it is not annotated as such in 26 cases, like Example 6 (b), where it is modified by an adjective.

(6) (a) ... the <xcope id= X970.8.2> <cue type= negation ref= X970.8.2>**failure**</cue> of eTh1 cells to produce IL-4 in response to an antigen </xcope> is due, at least partially, to a <xcope id= X970.8.1> < cue type= negation ref= X970.8.1> **failure**</cue> to induce high-level transcription of the IL-4 gene by NFAT </xcope></xcope>.

(b) Positive-pressure mechanical ventilation supports gas exchange in patients with respiratory **failure** but is also responsible for significant lung injury.

The errors in detecting *with* as a negation signal are caused by the fact that it is embedded in the expression *with the exception of*, which occurs 6 times in contrast with the 5265 occurrences of *with*. *Could* appears as a negation signal because the tagger does not assign to it the lemma *can*, but *could*, causing the wrong assignment of the tag NEG to *not*, instead of *could* when the negation cue in BioScope is *could not*.

6.2 Scope finding

We provide the results of the classifier and the results of applying the postprocessing algorithm to the output of the classifier.

Table 4 shows results for two versions of the scope finding classifier, one based on gold standard negation signals (GS NEG), and another (PR NEG) based on negation signals predicted by the classifier described in the previous section.

	Prec.	**Recall**	**F1**	**PCS**
GS NEG	86.03	85.53	85.78	39.39
PR NEG	79.83	77.42	78.60	36.31

Table 4: Results of the scope finding classifier with gold-standard (GS NEG) and with predicted negation signals (PR NEG).

The F1 of PR NEG is 7.18 points lower than the F1 of GS NEG, which is an expected effect due to the performance of classifier that finds negation signals. Precision and recall of GS NEG are very balanced, whereas PR NEG has a lower recall than precision. These measures are the result of a token per token evaluation, which does not guarantee that the complete sequence of scope is correct. This is reflected in the low percentage of fully correct scopes of both versions of the classifier.

In Table 5, we present the results of the system after applying the postprocessing algorithm. The most remarkable result is the 29.60 and 21.58 error reduction in the percentage of fully correct scopes of GS NEG and PR NEG respectively, which shows that the algorithm is efficient. Also interesting is the increase in F1 of GS NEG and PR NEG.

	Prec.	**Recall**	**F1**	**PCS**
GS NEG	88.63	88.17	88.40	57.33
PR NEG	80.70	81.29	80.99	50.05

Table 5: Results of the system with gold-standard (GS NEG) and with predicted negation signals (PR NEG) after applying the postprocessing algorithm.

Table 6 shows detailed results of the system based on predicted negation signals after applying the postprocessing algorithm. Classes O-NEG and I-NEG are among the most frequent and get high scores. Classes composed only of O-NEG tags are easier to predict.

Scope tags	**Total**	**Prec.**	**Recall**	**F1**
O-NEG	29590	86.78	84.75	85.75
O-NEG O-NEG O-NEG	46	100.00	63.04	77.33
I-NEG	12990	73.41	80.72	76.89
O-NEG O-NEG	2848	84.11	68.43	75.46
I-NEG I-NEG O-NEG	69	62.92	81.15	70.88
I-NEG I-NEG	684	57.30	65.93	61.31
I-NEG O-NEG O-NEG	20	50.00	75.00	60.00
O-NEG I-NEG	791	72.13	50.06	59.10
I-NEG O-NEG	992	45.32	67.94	54.37
O-NEG I-NEG I-NEG	39	100.00	20.51	34.04
I-NEG I-NEG I-NEG	22	26.66	36.36	30.76
O-NEG O-NEG I-NEG	14	0.00	0.00	0.00
Overall	48105	80.70	81.29	80.99

Table 6: F scores of the system per scope class after applying the postprocessing algorithm.

Table 7 shows information about the percentage of correct scopes per negation signal after applying the algorithm to PR-NEG. A clear example of an incorrect prediction is the occurrence of *box* in the list. The signal with the highest percentage of PCS is *without*, followed by *no* (determiner), *rather* and *not*, which are above 50%. It would be interesting to investigate how the syntactic properties of the negation signals are related to the percentage of correct scopes, and how does the algorithm perform depending on the type of signal.

Neg signals	Total	Correct	PCS
without	82	56	68.29
no (det)	206	133	64.56
rather	20	11	55.00
not	1066	556	52.15
neither (det)	8	4	50.00
none	7	3	42.85
neither (conj)	34	16	47.05
no (adv)	5	2	40.00
fail	63	23	36.50
missing	3	1	33.33
absence	68	22	32.35
lack (v.)	54	17	31.48

lack (n.)	33	9	27.27
nor	43	11	25.58
unable	30	8	26.66
failure	11	0	0.00
could	3	0	0.00
negative	1	0	0.00
never	1	0	0.00
box	1	0	0.00
Overall	1746	874	50.05

Table 7: Information about Percentage of Correct Scopes (PCS) per negation signal in PR-NEG.

7 Conclusions

Given the fact that a significant portion of biomedical text is negated, recognising negated instances is important in NLP applications. In this paper we have presented a machine learning system that finds the scope of negation in biomedical texts. The system consists of two memory-based classifiers, one that decides if the tokens in a sentence are negation signals, and another that finds the full scope of the negation signals.

The first classifier achieves 94.40 F1, and the second 80.99. However, the evaluation in terms of correct scopes shows the weakness of the system. This is why a postprocessing algorithm is applied. The algorithm achieves an error reduction of 21.58, with 50.05 % of fully correct scopes in the system based on predicted negation signals.

These results suggest that unsupervised machine learning algorithms are suited for tackling the task, as it was expected from results obtained in other natural language processing tasks. However, results also suggest that there is room for improvement. A first improvement would consist in predicting the scope chunk per chunk instead of token per token, because most negation scope boundaries coincide with boundaries of chunks.

We have highlighted the fact that our approach to negation detection focuses on finding the scope of negation signals, instead of determining whether a term is negated or not, and on applying supervised machine learning techniques. As far as we know, this approach is novel. Unfortunately, there are no previous comparable approaches to measure the quality of our results.

Additionally, we have shown that negation finding can be modelled as a classification task in a way similar to other linguistic tasks like semantic role labeling. In our model, tokens of a sentence are classified as being a negation signal or not, and as being inside or outside the scope of the negation signal(s). This representation would allow to integrate the task with other semantic tasks and exploring the interaction between different types of knowledge in a joint learning setting.

Further research is possible in several directions. In the first place, other machine learning algorithms could be integrated in the system in order to optimise performance. Secondly, the system should be tested in different types of biomedical texts, like full papers or medical reports to check its robustness. Finally, the postprocessing algorithm could be improved by using more sophisticated sequence classification techniques (Dietterich, 2002) .

Abstract

Minimum Error Rate Training (MERT) is an effective means to estimate the feature function weights of a linear model such that an automated evaluation criterion for measuring system performance can directly be optimized in training. To accomplish this, the training procedure determines for each feature function its exact error surface on a given set of candidate translations. The feature function weights are then adjusted by traversing the error surface combined over all sentences and picking those values for which the resulting error count reaches a minimum. Typically, candidates in MERT are represented as N-best lists which contain the N most probable translation hypotheses produced by a decoder. In this paper, we present a novel algorithm that allows for efficiently constructing and representing the exact error surface of *all* translations that are encoded in a phrase lattice. Compared to N-best MERT, the number of candidate translations thus taken into account increases by several orders of magnitudes. The proposed method is used to train the feature function weights of a phrase-based statistical machine translation system. Experiments conducted on the NIST 2008 translation tasks show significant runtime improvements and moderate BLEU score gains over N-best MERT.

1 Introduction

Many statistical methods in natural language processing aim at minimizing the probability of sentence errors. In practice, however, system quality is often measured based on error metrics that assign non-uniform costs to classification errors and thus go far beyond counting the number of wrong decisions. Examples are the mean average precision for ranked retrieval, the F-measure for parsing, and the BLEU score for *statistical machine translation* (SMT). A class of training criteria that provides a tighter connection between the decision rule and the final error metric is known as *Minimum Error Rate Training* (MERT) and has been suggested for SMT in (Och, 2003).

MERT aims at estimating the model parameters such that the decision under the zero-one loss function maximizes some end-to-end performance measure on a development corpus. In combination with log-linear models, the training procedure allows for a direct optimization of the unsmoothed error count. The criterion can be derived from Bayes' decision rule as follows: Let $\mathbf{f} = f_1, ..., f_J$ denote a source sentence ('French') which is to be translated into a target sentence ('English') $\mathbf{e} = e_1, ..., e_I$. Under the zero-one loss function, the translation which maximizes the *a posteriori* probability is chosen:

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}} \big\{ \Pr(\mathbf{e}|\mathbf{f}) \big\} \tag{1}$$

Since the true posterior distribution is unknown, $\Pr(\mathbf{e}|\mathbf{f})$ is modeled via a log-linear translation model which combines some feature functions $h_m(\mathbf{e}, \mathbf{f})$ with feature function weights λ_m, $m = 1, ..., M$:

$$\begin{aligned} \Pr(\mathbf{e}|\mathbf{f}) &= p_{\lambda_1^M}(\mathbf{e}|\mathbf{f}) \\ &= \frac{\exp\big[\sum_{m=1}^M \lambda_m h_m(\mathbf{e}, \mathbf{f})\big]}{\sum_{\mathbf{e}'} \exp\big[\sum_{m=1}^M \lambda_m h_m(\mathbf{e}', \mathbf{f})\big]} \end{aligned} \tag{2}$$

The feature function weights are the parameters of the model, and the objective of the MERT criterion is to find a parameter set λ_1^M that minimizes the error count on a representative set of training sentences. More precisely, let $\mathbf{f}_1^S$ denote the source sentences of a training corpus with given reference translations

$\mathbf{r}_1^S$, and let $\mathbf{C}_s = \{\mathbf{e}_{s,1}, ..., \mathbf{e}_{s,K}\}$ denote a set of K candidate translations. Assuming that the corpus-based error count for some translations $\mathbf{e}_1^S$ is additively decomposable into the error counts of the individual sentences, i.e., $E(\mathbf{r}_1^S, \mathbf{e}_1^S) = \sum_{s=1}^S E(\mathbf{r}_s, \mathbf{e}_s)$, the MERT criterion is given as:

$$\hat{\lambda}_1^M = \arg\min_{\lambda_1^M} \left\{ \sum_{s=1}^S E\big(\mathbf{r}_s, \hat{\mathbf{e}}(\mathbf{f}_s; \lambda_1^M)\big) \right\} \quad (3)$$

$$= \arg\min_{\lambda_1^M} \left\{ \sum_{s=1}^S \sum_{k=1}^K E(\mathbf{r}_s, \mathbf{e}_{s,k}) \delta\big(\hat{\mathbf{e}}(\mathbf{f}_s; \lambda_1^M), \mathbf{e}_{s,k}\big) \right\}$$

with

$$\hat{\mathbf{e}}(\mathbf{f}_s; \lambda_1^M) = \arg\max_{\mathbf{e}} \left\{ \sum_{m=1}^M \lambda_m h_m(\mathbf{e}, \mathbf{f}_s) \right\} \quad (4)$$

In (Och, 2003), it was shown that linear models can effectively be trained under the MERT criterion using a special line optimization algorithm. This line optimization determines for each feature function h_m and sentence $\mathbf{f}_s$ the exact error surface on a set of candidate translations $\mathbf{C}_s$. The feature function weights are then adjusted by traversing the error surface combined over all sentences in the training corpus and moving the weights to a point where the resulting error reaches a minimum.

Candidate translations in MERT are typically represented as N-best lists which contain the N most probable translation hypotheses. A downside of this approach is, however, that N-best lists can only capture a very small fraction of the search space. As a consequence, the line optimization algorithm needs to repeatedly translate the development corpus and enlarge the candidate repositories with newly found hypotheses in order to avoid overfitting on $\mathbf{C}_s$ and preventing the optimization procedure from stopping in a poor local optimum.

In this paper, we present a novel algorithm that allows for efficiently constructing and representing the unsmoothed error surface for *all* translations that are encoded in a phrase lattice. The number of candidate translations thus taken into account increases by several orders of magnitudes compared to N-best MERT. Lattice MERT is shown to yield significantly faster convergence rates while it explores a much larger space of candidate translations which is exponential in the lattice size. Despite this vast search space, we show that the suggested algorithm is always efficient in both running time and memory.

The remainder of this paper is organized as follows. Section 2 briefly reviews N-best MERT and introduces some basic concepts that are used in order to develop the line optimization algorithm for phrase lattices in Section 3. Section 4 presents an upper bound on the complexity of the unsmoothed error surface for the translation hypotheses represented in a phrase lattice. This upper bound is used to prove the space and runtime efficiency of the suggested algorithm. Section 5 lists some best practices for MERT. Section 6 discusses related work. Section 7 reports on experiments conducted on the NIST 2008 translation tasks. The paper concludes with a summary in Section 8.

2 Minimum Error Rate Training on N-best Lists

The goal of MERT is to find a weights set that minimizes the unsmoothed error count on a representative training corpus (cf. Eq. (3)). This can be accomplished through a sequence of line minimizations along some vector directions $\{d_1^M\}$. Starting from an initial point λ_1^M, computing the most probable sentence hypothesis out of a set of K candidate translations $\mathbf{C}_s = \{\mathbf{e}_1, ..., \mathbf{e}_K\}$ along the line $\lambda_1^M + \gamma \cdot d_1^M$ results in the following optimization problem (Och, 2003):

$$\hat{\mathbf{e}}(\mathbf{f}_s; \gamma) = \arg\max_{\mathbf{e} \in \mathbf{C}_s} \left\{ (\lambda_1^M + \gamma \cdot d_1^M)^\top \cdot h_1^M(\mathbf{e}, \mathbf{f}_s) \right\}$$

$$= \arg\max_{\mathbf{e} \in \mathbf{C}_s} \Bigg\{ \underbrace{\sum_m \lambda_m h_m(\mathbf{e}, \mathbf{f}_s)}_{=a(\mathbf{e},\mathbf{f}_s)} + \gamma \cdot \underbrace{\sum_m d_m h_m(\mathbf{e}, \mathbf{f}_s)}_{=b(\mathbf{e},\mathbf{f}_s)} \Bigg\}$$

$$= \arg\max_{\mathbf{e} \in \mathbf{C}_s} \big\{ \underbrace{a(\mathbf{e}, \mathbf{f}_s) + \gamma \cdot b(\mathbf{e}, \mathbf{f}_s)}_{(*)} \big\} \quad (5)$$

Hence, the total score $(*)$ for any candidate translation corresponds to a line in the plane with γ as the independent variable. For any particular choice of γ, the decoder seeks that translation which yields the largest score and therefore corresponds to the topmost line segment.

Overall, the candidate repository $\mathbf{C}_s$ defines K lines where each line may be divided into at most K line segments due to possible intersections with the other $K - 1$ lines. The sequence of the topmost line segments constitute the *upper envelope* which is the pointwise maximum over all lines induced by $\mathbf{C}_s$. The upper envelope is a convex hull and can be inscribed with a convex polygon whose edges are the segments of a piecewise linear function in γ (Papineni, 1999; Och, 2003):

$$\mathsf{Env}(\mathbf{f}) = \max_{\mathbf{e} \in \mathbf{C}} \big\{ a(\mathbf{e}, \mathbf{f}) + \gamma \cdot b(\mathbf{e}, \mathbf{f}) : \gamma \in \mathbb{R} \big\} \quad (6)$$

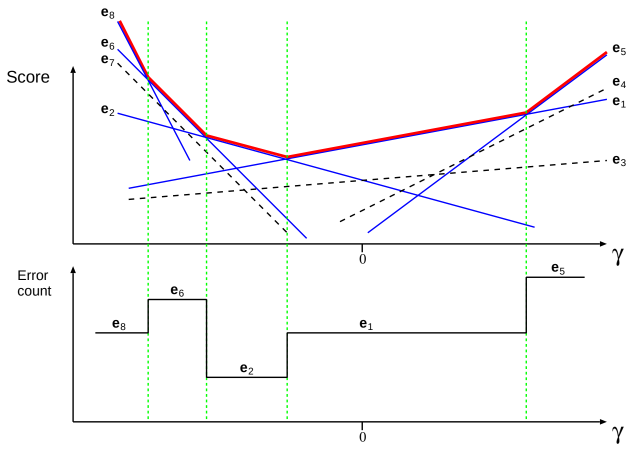

Figure 1: *The upper envelope (bold, red curve) for a set of lines is the convex hull which consists of the topmost line segments. Each line corresponds to a candidate translation and is thus related to a certain error count. Envelopes can efficiently be computed with Algorithm 1.*

The importance of the upper envelope is that it provides a compact encoding of all possible outcomes that a rescoring of $\mathbf{C}_s$ may yield if the parameter set λ_1^M is moved along the chosen direction. Once the upper envelope has been determined, we can project its constituent line segments onto the error counts of the corresponding candidate translations (cf. Figure 1). This projection is independent of *how* the envelope is generated and can therefore be applied to any set of line segments[1].

An effective means to compute the upper envelope is a *sweep line* algorithm which is often used in computational geometry to determine the intersection points of a sequence of lines or line segments (Bentley and Ottmann, 1979). The idea is to shift ("sweep") a vertical ray from $-\infty$ to $+\infty$ over the plane while keeping track of those points where two or more lines intersect. Since the upper envelope is fully specified by the topmost line segments, it suffices to store the following components for each line object ℓ: the x-intercept $\ell.x$ with the left-adjacent line, the slope $\ell.m$, and the y-intercept $\ell.y$; a fourth component, $\ell.t$, is used to store the candidate translation. Algorithm 1 shows the pseudo code for a sweep line algorithm which reduces an input array `a[0..K-1]` consisting of the K line objects of the candidate repository $\mathbf{C}_s$ to its upper envelope. By construction, the upper envelope consists of at most K line segments. The endpoints of each line

Algorithm 1 SweepLine

input: array `a[0..K-1]` containing lines
output: upper envelope of `a`

```
sort(a:$m$);
j = 0; K = size(a);
for (i = 0; i < K; ++i) {
  $\ell$ = a[i];
  $\ell.x$ = -$\infty$;
  if (0 < j) {
    if (a[j-1].m == $\ell.m$) {
      if ($\ell.y$ <= a[j-1].y) continue;
      --j;
    }
    while (0 < j) {
      $\ell.x$ = ($\ell.y$ - a[j-1].y)/
            (a[j-1].m - $\ell.m$);
      if (a[j-1].x < $\ell.x$) break;
      --j;
    }
    if (0 == j) $\ell.x$ = -$\infty$;
    a[j++] = $\ell$;
  } else a[j++] = $\ell$;
}
a.resize(j);
return a;
```

segment define the interval boundaries at which the decision made by the decoder will change. Hence, as γ increases from $-\infty$ to $+\infty$, we will see that the most probable translation hypothesis will change whenever γ passes an intersection point.

Let $\gamma_1^{\mathbf{f}_s} < \gamma_2^{\mathbf{f}_s} < \ldots < \gamma_{N_s}^{\mathbf{f}_s}$ denote the sequence of interval boundaries and let $\Delta E_1^{\mathbf{f}_s}, \Delta E_2^{\mathbf{f}_s}, \ldots, \Delta E_{N_s}^{\mathbf{f}_s}$ denote the corresponding sequence of changes in the error count where $\Delta E_n^{\mathbf{f}_s}$ is the amount by which the error count will change if γ is moved from a point in $[\gamma_{n-1}^{\mathbf{f}_s}, \gamma_n^{\mathbf{f}_s})$ to a point in $[\gamma_n^{\mathbf{f}_s}, \gamma_{n+1}^{\mathbf{f}_s})$. Both sequences together provide an exhaustive representation of the unsmoothed error surface for the sentence $\mathbf{f}_s$ along the line $\lambda_1^M + \gamma \cdot d_1^M$. The error surface for the whole training corpus is obtained by merging the interval boundaries (and their corresponding error counts) over all sentences in the training corpus. The optimal γ can then be found by traversing the merged error surface and choosing a point from the interval where the total error reaches its minimum.

After the parameter update, $\hat{\lambda}_1^M = \lambda_1^M + \gamma_{\text{opt}} \cdot d_1^M$, the decoder may find new translation hypotheses which are merged into the candidate repositories if they are ranked among the top N candidates. The relation $K = N$ holds therefore only in the first iteration. From the second iteration on, K is usually larger than N. The sequence of line optimizations and decodings is repeated until (1) the candidate repositories remain unchanged and (2) $\gamma_{\text{opt}} = 0$.

[1] For lattice MERT, it will therefore suffice to find an efficient way to compute the upper envelope over all translations that are encoded in a phrase graph.

3 Minimum Error Rate Training on Lattices

In this section, the algorithm for computing the upper envelope on N-best lists is extended to phrase lattices. For a description on how to generate lattices, see (Ueffing et al., 2002).

Formally, a phrase lattice for a source sentence $\mathbf{f}$ is defined as a connected, directed acyclic graph $\mathcal{G}_\mathbf{f} = (\mathcal{V}_\mathbf{f}, \mathcal{E}_\mathbf{f})$ with vertice set $\mathcal{V}_\mathbf{f}$, unique source and sink nodes $s, t \in \mathcal{V}_\mathbf{f}$, and a set of arcs $\mathcal{E}_\mathbf{f} \subset \mathcal{V}_\mathbf{f} \times \mathcal{V}_\mathbf{f}$. Each arc is labeled with a phrase $\varphi_{ij} = e_{i_1}, ..., e_{i_j}$ and the (local) feature function values $h_1^M(\varphi_{ij}, \mathbf{f})$. A path $\pi = (v_0, \varepsilon_0, v_1, \varepsilon_1, ..., \varepsilon_{n-1}, v_n)$ in $\mathcal{G}_\mathbf{f}$ (with $\varepsilon_i \in \mathcal{E}_\mathbf{f}$ and $v_i, v_{i+1} \in \mathcal{V}_\mathbf{f}$ as the tail and head of ε_i, $0 \leqslant i < n$) defines a partial translation $\mathbf{e}_\pi$ of $\mathbf{f}$ which is the concatenation of all phrases along this path. The corresponding feature function values are obtained by summing over the arc-specific feature function values:

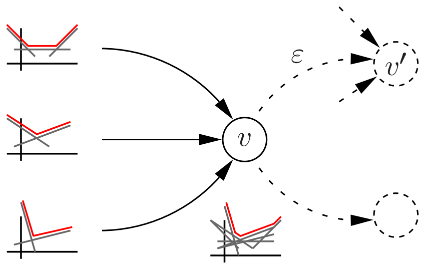
$$\pi : \underset{v_0}{\bullet} \xrightarrow[h_1^M(\varphi_{0,1}, \mathbf{f})]{\varphi_{0,1}} \underset{v_1}{\bullet} \xrightarrow[h_1^M(\varphi_{1,2}, \mathbf{f})]{\varphi_{1,2}} \cdots \xrightarrow[h_1^M(\varphi_{n-1,n}, \mathbf{f})]{\varphi_{n-1,n}} \underset{v_n}{\bullet}$$

$$\mathbf{e}_\pi = \bigcirc_{\substack{i,j:\\ v_i \rightarrow v_j \in \pi}} \varphi_{ij} = \varphi_{0,1} \circ ... \circ \varphi_{n-1,n}$$

$$h_1^M(\mathbf{e}_\pi, \mathbf{f}) = \sum_{\substack{i,j:\\ v_i \rightarrow v_j \in \pi}} h_1^M(\varphi_{ij}, \mathbf{f})$$

In the following, we use the notation $\mathsf{in}(v)$ and $\mathsf{out}(v)$ to refer to the set of incoming and outgoing arcs for a node $v \in \mathcal{V}_\mathbf{f}$. Similarly, $\mathsf{head}(\varepsilon)$ and $\mathsf{tail}(\varepsilon)$ denote the head and tail of $\varepsilon \in \mathcal{E}_\mathbf{f}$.

To develop the algorithm for computing the upper envelope of *all* translation hypotheses that are encoded in a phrase lattice, we first consider a node $v \in \mathcal{V}_\mathbf{f}$ with some incoming and outgoing arcs:



Each path that starts at the source node s and ends in v defines a partial translation hypothesis which can be represented as a line (cf. Eq. (5)). We now assume that the upper envelope for these partial translation hypotheses is known. The lines that constitute this envelope shall be denoted by $f_1, ..., f_N$. Next we consider continuations of these partial translation candidates by following one of the outgoing arcs $\varepsilon \in \mathsf{out}(v)$. Each such arc defines another line denoted by $g(\varepsilon)$. If we add the slope and y-intercept of $g(\varepsilon)$ to each line in the set $\{f_1, ..., f_N\}$, then the upper envelope will be constituted by segments of $f_1 + g(\varepsilon), ..., f_N + g(\varepsilon)$. This operation neither changes the number of line segments nor their relative order in the envelope, and therefore it preserves the structure of the convex hull. As a consequence, we can propagate the resulting envelope over an outgoing arc ε to a successor node $v' = \mathsf{head}(\varepsilon)$. Other incoming arcs for v' may be associated with different upper envelopes, and all that remains is to merge these envelopes into a single combined envelope. This is, however, easy to accomplish since the combined envelope is simply the convex hull of the union over the line sets which constitute the individual envelopes. Thus, by merging the arrays that store the line segments for the incoming arcs and applying Algorithm 1 to the resulting array we obtain the combined upper envelope for *all* partial translation candidates that are associated with paths starting at the source node s and ending in v'. The correctness of this procedure is based on the following two observations:

(1) A single translation hypothesis cannot constitute multiple line segments of the same envelope. This is because translations associated with different line segments are path-disjoint.

(2) Once a partial translation has been discarded from an envelope because its associated line $\tilde{f}$ is completely covered by the topmost line segments of the convex hull, there is no path continuation that could bring back $\tilde{f}$ into the upper envelope

Algorithm 2 Lattice Envelope

input: a phrase lattice $\mathcal{G}_\mathbf{f} = (\mathcal{V}_\mathbf{f}, \mathcal{E}_\mathbf{f})$
output: upper envelope of $\mathcal{G}_\mathbf{f}$

```
a = $\emptyset$;
L = $\emptyset$;
TopSort($\mathcal{G}_\mathbf{f}$);
for $v$ = $s$ to $t$ do {
  a = SweepLine( $\bigcup_{\varepsilon \in \mathsf{in}(v)}$ L[$\varepsilon$]);
  foreach ($\varepsilon \in \mathsf{in}(v)$)
    L.delete($\varepsilon$);
  foreach ($\varepsilon \in \mathsf{out}(v)$) {
    L[$\varepsilon$] = a;
    for (i = 0; i < a.size(); ++i) {
      L[$\varepsilon$][i].m = a[i].m + $\sum_m d_m h_m(\varepsilon, \mathbf{f})$;
      L[$\varepsilon$][i].y = a[i].y + $\sum_m \lambda_m h_m(\varepsilon, \mathbf{f})$;
      L[$\varepsilon$][i].p = a[i].p $\circ \varphi_{v,\mathsf{head}(\varepsilon)}$;
    }
  }
}
return a;
```

again. Proof: Suppose that such a continuation exists, then this continuation can be represented as a line g, and since $\tilde{f}$ has been discarded from the envelope, the path associated with g must also be a valid continuation for the line segments $f_1, ..., f_N$ that constitute the envelope. Thus it follows that $\max(f_1 + g, ..., f_N + g) = \max(f_1, ..., f_N) + g < \tilde{f} + g$ for some $\gamma \in \mathbb{R}$. This, however, is in contradiction with the premise that $\tilde{f} < \max(f_1, ..., f_N)$ for all $\gamma \in \mathbb{R}$.

To keep track of the phrase expansions when propagating an envelope over an outgoing arc $\varepsilon \in \mathsf{tail}(v)$, the phrase label $\varphi_{v,\mathsf{head}(\varepsilon)}$ has to be appended from the right to all partial translation hypotheses in the envelope. The complete algorithm then works as follows: First, all nodes in the phrase lattice are sorted in topological order. Starting with the source node, we combine for each node v the upper envelopes that are associated with v's incoming arcs by merging their respective line arrays and reducing the merged array into a combined upper envelope using Algorithm 1. The combined envelope is then propagated over the outgoing arcs by associating each $\varepsilon \in \mathsf{out}(v)$ with a copy of the combined envelope. This copy is modified by adding the parameters (slope and y-intercept) of the line $g(\varepsilon)$ to the envelope's constituent line segments. The envelopes of the incoming arcs are no longer needed and can be deleted in order to release memory. The envelope computed at the sink node is by construction the convex hull over all translation hypotheses represented in the lattice, and it compactly encodes those candidates which maximize the decision rule Eq. (1) for any point along the line $\lambda_1^M + \gamma \cdot d_1^M$. Algorithm 2 shows the pseudo code. Note that the component $\ell.x$ does not change and therefore requires no update.

It remains to verify that the suggested algorithm is efficient in both running time and memory. For this purpose, we first analyze the complexity of Algorithm 1 and derive from it the running time of Algorithm 2.

After sorting, each line object in Algorithm 1 is visited at most three times. The first time is when it is picked by the outer loop. The second time is when it either gets discarded or when it terminates the inner loop. Whenever a line object is visited for the third time, it is irrevocably removed from the envelope. The runtime complexity is therefore dominated by the initial sorting and amounts to $\mathcal{O}(K \log K)$

Topological sort on a phrase lattice $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ can be performed in time $\Theta(|\mathcal{V}| + |\mathcal{E}|)$. As will be shown in Section 4, the size of the upper envelope for $\mathcal{G}$ can never exceed the size of the arc set $\mathcal{E}$. The same holds for any subgraph $\mathcal{G}_{[s,v]}$ of $\mathcal{G}$ which is induced by the paths that connect the source node s with $v \in \mathcal{V}$. Since the envelopes propagated from the source to the sink node can only increase linearly in the number of previously processed arcs, the total running time amounts to a worst case complexity of $\mathcal{O}(|\mathcal{V}| \cdot |\mathcal{E}| \log |\mathcal{E}|)$.

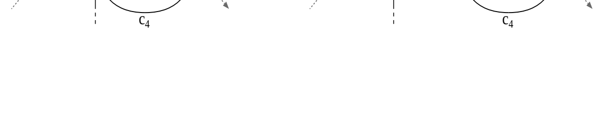
4 Upper Bound for Size of Envelopes

The memory efficiency of the suggested algorithm results from the following theorem which provides a novel upper bound for the number of cost minimizing paths in a directed acyclic graph with arc-specific affine cost functions. The bound is not only meaningful for proving the space efficiency of lattice MERT, but it also provides deeper insight into the structure and complexity of the unsmoothed error surface induced by log-linear models. Since we are examining a special class of shortest paths problems, we will invert the sign of each local feature function value in order to turn the feature scores into corresponding costs. Hence, the objective of finding the best translation hypotheses in a phrase lattice becomes the problem of finding all cost-minimizing paths in a graph with affine cost functions.

Theorem: *Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be a connected directed acyclic graph with vertex set $\mathcal{V}$, unique source and sink nodes $s, t \in \mathcal{V}$, and an arc set $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ in which each arc $\varepsilon \in \mathcal{E}$ is associated with an affine cost function $c_\varepsilon(\gamma) = a_\varepsilon \cdot \gamma + b_\varepsilon$, $a_\varepsilon, b_\varepsilon \in \mathbb{R}$. Counting ties only once, the cardinality of the union over the sets of all cost-minimizing paths for all $\gamma \in \mathbb{R}$ is then upper-bounded by $|\mathcal{E}|$:*

$$\left| \bigcup_{\gamma \in \mathbb{R}} \{\pi \ : \ \pi = \pi(\mathcal{G}; \gamma) \text{ is a cost-minimizing path in } \mathcal{G} \text{ given } \gamma\} \right| \leqslant |\mathcal{E}| \quad (7)$$

Proof: The proposition holds for the empty graph as well as for the case that $\mathcal{V} = \{s, t\}$ with all arcs $\varepsilon \in \mathcal{E}$ joining the source and sink node. Let $\mathcal{G}$ therefore be a larger graph. Then we perform an s-t cut and split $\mathcal{G}$ into two subgraphs $\mathcal{G}_1$ (left subgraph) and $\mathcal{G}_2$ (right subgraph). Arcs spanning the section boundary are duplicated (with the costs of the copied arcs in $\mathcal{G}_2$ being set to zero) and connected with a newly added head or tail node:



The zero-cost arcs in $\mathcal{G}_2$ that emerged from the duplication process are contracted, which can be done without loss of generality because zero-cost arcs do not affect the total costs of paths in the lattice. The contraction essentially amounts to a removal of arcs and is required in order to ensure that the sum of edges in both subgraphs does not exceed the number of edges in $\mathcal{G}$. All nodes in $\mathcal{G}_1$ with out-degree zero are then combined into a single sink node t_1. Similarly, nodes in $\mathcal{G}_2$ whose in-degree is zero are combined into a single source node s_2. Let N_1 and N_2 denote the number of arcs in $\mathcal{G}_1$ and $\mathcal{G}_2$, respectively. By construction, $N_1 + N_2 = |\mathcal{E}|$. Both subgraphs are smaller than $\mathcal{G}$ and thus, due to the induction hypothesis, their lower envelopes consist of at most N_1 and N_2 line segments, respectively. We further notice that either envelope is a convex hull whose constituent line segments inscribe a convex polygon, in the following denoted by $\mathcal{P}_1$ and $\mathcal{P}_2$. Now, we combine both subgraphs into a single graph $\mathcal{G}'$ by merging the sink node t_1 in $\mathcal{G}_1$ with the source node s_2 in $\mathcal{G}_2$. The merged node is an *articulation point* whose removal would disconnect both subgraphs, and hence, all paths in $\mathcal{G}'$ that start at the source node s and stop in the sink node t lead through this articulation point. The graph $\mathcal{G}'$ has at least as many cost minimizing paths as $\mathcal{G}$, although these paths as well as their associated costs might be different from those in $\mathcal{G}$. The additivity of the cost function and the articulation point allow us to split the costs for any path from s to t into two portions: the first portion can be attributed to $\mathcal{G}_1$ and must be a line inside $\mathcal{P}_1$; the remainder can be attributed to $\mathcal{G}_2$ and must therefore be a line inside $\mathcal{P}_2$. Hence, the total costs for any path in $\mathcal{G}'$ can be bounded by the convex hull of the superposition of $\mathcal{P}_1$ and $\mathcal{P}_2$. This convex hull is again a convex polygon which consists of at most $N_1 + N_2$ edges, and therefore, the number of cost minimizing paths in $\mathcal{G}'$ (and thus also in $\mathcal{G}$) is upper bounded by $N_1 + N_2$. $\square$

Corollary: *The upper envelope for a phrase lattice $\mathcal{G}_{\mathbf{f}} = (\mathcal{V}_{\mathbf{f}}, \mathcal{E}_{\mathbf{f}})$ consists of at most $|\mathcal{E}_{\mathbf{f}}|$ line segments.* This bound can even be refined and one obtains (proof omitted) $|\mathcal{E}| - |\mathcal{V}| + 2$. Both bounds are tight.

This result may seem somewhat surprising as it states that, independent of the choice of the direction along which the line optimization is performed, the structure of the error surface is far less complex than one might expect based on the huge number of alternative translation candidates that are represented in the lattice and thus contribute to the error surface. In fact, this result is a consequence of using a log-linear model which constrains how costs (or scores, respectively) can evolve due to hypothesis expansion. If instead quadratic cost functions were used, the size of the envelopes could not be limited in the same way. The above theorem does not, however, provide any additional guidance that would help to choose more promising directions in the line optimization algorithm to find better local optima. To alleviate this problem, the following section lists some best practices that we found to be useful in the context of MERT.

5 Practical Aspects

This section addresses some techniques that we found to be beneficial in order to improve the performance of MERT.

(1) **Random Starting Points:** To prevent the line optimization algorithm from stopping in a poor local optimum, MERT explores additional starting points that are randomly chosen by sampling the parameter space.

(2) **Constrained Optimization:** This technique allows for limiting the range of some or all feature function weights by defining *weights restrictions*. The weight restriction for a feature function h_m is specified as an interval $\mathcal{R}_m = [l_m, r_m]$, $l_m, r_m \in \mathbb{R} \cup \{-\infty, +\infty\}$ which defines the admissible region from which the feature function weight λ_m can be chosen. If the line optimization is performed under the presence of weights restrictions, γ needs to be chosen such that the following constraint holds:

$$l_1^M \leqslant \lambda_1^M + \gamma \cdot d_1^M \leqslant r_1^M \tag{8}$$

(3) **Weight Priors:** Weight priors give a small (positive or negative) boost ω on the objective function if the new weight is chosen such that it matches a certain target value λ_m^*:

$$\gamma_{\text{opt}} = \arg\min_{\gamma} \Big\{ \sum_s E\big(\mathbf{r}_s, \hat{e}(\mathbf{f}_s; \gamma)\big) + \sum_m \delta(\lambda_m + \gamma \cdot d_m, \lambda_m^*) \cdot \omega \Big\} \tag{9}$$

A *zero-weights prior* ($\lambda_m^* = 0$) provides a means of doing feature selection since the weight of a feature function which is not discriminative will be set to zero. An *initial-weights prior* ($\lambda_m^* = \lambda_m$) can be used to confine changes in the parameter update with the consequence that the new parameter may be closer to the initial weights set. Initial weights priors are useful in cases where the starting weights already yield a decent baseline.

(4) **Interval Merging:** The interval $[\gamma_i^{\mathbf{f}_s}, \gamma_{i+1}^{\mathbf{f}_s})$ of a translation hypothesis can be merged with the interval $[\gamma_{i-1}^{\mathbf{f}_s}, \gamma_i^{\mathbf{f}_s})$ of its left-adjacent translation hypothesis if the corresponding change in the error count $\Delta E_i^{\mathbf{f}_s} = 0$. The resulting interval $[\gamma_{i-1}^{\mathbf{f}_s}, \gamma_{i+1}^{\mathbf{f}_s})$ has a larger range, and the choice of γ_{opt} may be more reliable.

(5) **Random Directions:** If the directions chosen in the line optimization algorithm are the coordinate axes of the M-dimensional parameter space, each iteration will result in the update of a single feature function only. While this update scheme provides a ranking of the feature functions according to their discriminative power (each iteration picks the feature function for which changing the corresponding weight yields the highest gain), it does not take possible correlations between the feature functions into account. As a consequence, the optimization procedure may stop in a poor local optimum. On the other hand, it is difficult to compute a direction that decorrelates two or more correlated feature functions. This problem can be alleviated by exploring a large number of random directions which update many feature weights simultaneously. The random directions are chosen as the lines which connect some randomly distributed points on the surface of an M-dimensional hypersphere with the hypersphere's center. The center of the hypersphere is defined as the initial parameter set.

6 Related Work

As suggested in (Och, 2003), an alternative method for the optimization of the unsmoothed error count is Powell's algorithm combined with a grid-based line optimization (Press et al., 2007, p. 509). In (Zens et al., 2007), the MERT criterion is optimized on N-best lists using the Downhill Simplex algorithm (Press et al., 2007, p. 503). The optimization procedure allows for optimizing other objective function as, e.g., the expected BLEU score. A weakness of the Downhill Simplex algorithm is, however, its decreasing robustness for optimization problems in more than 10 dimensions. A different approach to minimize the expected BLEU score is suggested in (Smith and Eisner, 2006) who use deterministic annealing to gradually turn the objective function from a convex entropy surface into the more complex risk surface. A large variety of different search strategies for MERT are investigated in (Cer et al., 2008), which provides many fruitful insights into the optimization process. In (Duh and Kirchhoff, 2008), MERT is used to boost the BLEU score on N-best re-ranking tasks. The incorporation of a large number of sparse feature functions is described in (Watanabe et al., 2007). The paper investigates a perceptron-like online large-margin training for statistical machine translation. The described approach is reported to yield significant improvements on top of a baseline system which employs a small number of feature functions whose weights are optimized under the MERT criterion. A study which is complementary to the upper bound on the size of envelopes derived in Section 4 is provided in (Elizalde and Woods, 2006) which shows that the number of inference functions of any graphical model as, for instance, Bayesian networks and Markov random fields is polynomial in the size of the model if the number of parameters is fixed.

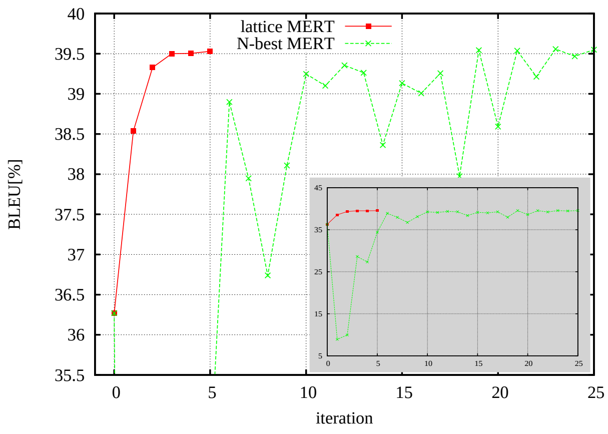

Figure 2: *BLEU scores for N-best MERT and lattice MERT after each decoding step on the zhen-dev1 corpus. The grey shaded subfigure shows the complete graph including the bottom part for N-best MERT.*

Translation results were evaluated using the mixed-case BLEU score metric in the implementation as suggested by (Papineni et al., 2001).

Translation results were produced with a state-of-the-art phrase-based SMT system which uses EM-trained word alignment models (IBM1, HMM) and a 5-gram language model built from the Web-1T collection[2]. Translation hypotheses produced on the blind test data were reranked using the *Minimum-Bayes Risk* (MBR) decision rule (Kumar and Byrne, 2004; Tromble et al., 2008). Each system uses a log-linear combination of 20 to 30 feature functions.

In a first experiment, we investigated the convergence speed of lattice MERT and N-best MERT.

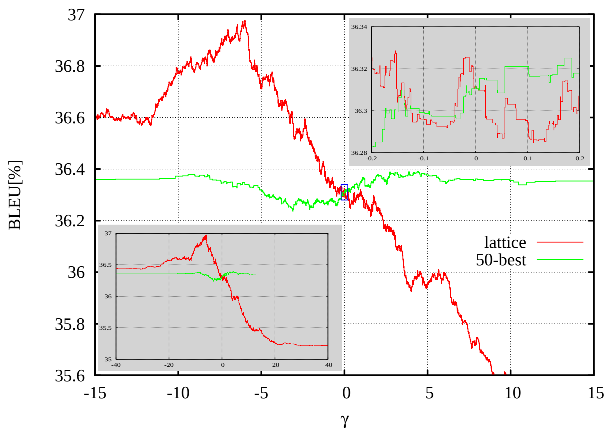

Figure 3: *Error surface of the phrase penalty feature after the first iteration on the zhen-dev1 corpus.*

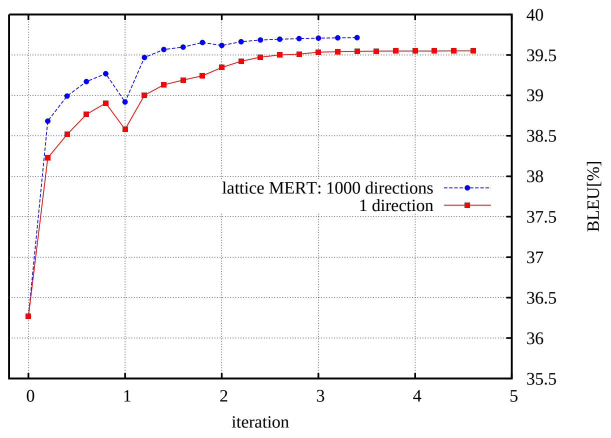

Figure 4: *BLEU scores on the zhen-dev1 corpus for lattice MERT with additional directions.*

Figure 2 shows the evolution of the BLEU score in the course of the iteration index on the zhen-dev1 corpus for either method. In each iteration, the training procedure translates the development corpus using the most recent weights set and merges the top ranked candidate translations (either represented as phrase lattices or N-best lists) into the candidate repositories before the line optimization is performed. For N-best MERT, we used $N = 50$ which yielded the best results. In contrast to lattice MERT, N-best MERT optimizes *all* dimensions in each iteration and, in addition, it also explores a large number of random starting points before it re-decodes and expands the hypothesis set. As is typical for N-best MERT, the first iteration causes a dramatic performance loss caused by overadapting the candidate repositories, which amounts to more than 27.3 BLEU points. Although this performance loss is recouped after the 5th iteration, the initial decline makes the line optimization under N-best MERT more fragile since the optimum found at the end of the training procedure is affected by the initial performance drop rather than by the choice of the initial start weights. Lattice MERT on the other hand results in a significantly faster convergence speed and reaches its optimum already in the 5th iteration. For lattice MERT, we used a graph density of 40 arcs per phrase which corresponds to an N-best size of more than two octillion $(2 \cdot 10^{27})$ entries. This huge number of alternative candidate translations makes updating the weights under lattice MERT more reliable and robust and, compared to N-best MERT, it becomes less likely that the same feature weight needs to be picked again and adjusted in subsequent iterations. Figure 4 shows the evolution of the BLEU score on the zhen-dev1 corpus using

Table 3: *BLEU score results on the NIST-08 tests set obtained after 5 iterations using lattice MERT with different numbers of random directions in addition to the optimization along the coordinate axes.*

task	# random directions	dev1+dev2 0-1	dev1+dev2 MBR	blind 0-1	blind MBR
aren	–	57.4	57.4	43.7	43.9
	1000	57.6	57.7	43.9	44.5
zhen	–	39.6	39.7	27.6	28.2
	500	39.5	39.9	27.9	28.3

lattice MERT with 5 weights updates per iteration. The performance drop in iteration 1 is also attributed to overfitting the candidate repository. The decline of less than 0.5% in terms of BLEU is, however, almost negligible compared to the performance drop of more than 27% in case of N-best MERT. The vast number of alternative translation hypotheses represented in a lattice also increases the number of phase transitions in the error surface, and thus prevents MERT from selecting a low performing feature weights set at early stages in the optimization procedure. This is illustrated in Figure 3, where lattice MERT and N-best MERT find different optima for the weight of the phrase penalty feature function after the first iteration. Table 2 shows the BLEU score results on the NIST 2008 blind test using the combined dev1+dev2 corpus as training data. While only the aren task shows improvements on the development data, lattice MERT provides consistent gains over N-best MERT on all three blind test sets. The reduced performance for N-best MERT is a consequence of the performance drop in the first iteration which causes the final weights to be far off from the initial parameter set. This can impair the ability of N-best MERT to generalize to unseen data if the initial weights are already capable of producing a decent baseline. Lattice MERT on the other hand can produce weights sets which are closer to the initial weights and thus more likely to retain the ability to generalize to unseen data. It could therefore be worthwhile to investigate whether a more elaborated version of an initial-weights prior allows for alleviating this effect in case of N-best MERT. Table 3 shows the effect of optimizing the feature function weights along some randomly chosen directions in addition to the coordinate axes. The different local optima found on the development set by using random directions result in additional gains on the blind test sets and range from 0.1% to 0.6% absolute in terms of BLEU.

8 Summary

We presented a novel algorithm that allows for efficiently constructing and representing the unsmoothed error surface over all sentence hypotheses that are represented in a phrase lattice. The proposed algorithm was used to train the feature function weights of a log-linear model for a statistical machine translation system under the *Minimum Error Rate Training* (MERT) criterion. Lattice MERT was shown analytically and experimentally to be superior over N-best MERT, resulting in significantly faster convergence speed and a reduced number of decoding steps. While the approach was used to optimize the model parameters of a single machine translation system, there are many other applications in which this framework can be useful, too. One possible usecase is the computation of consensus translations from the outputs of multiple machine translation systems where this framework allows us to estimate the system prior weights directly on confusion networks (Rosti et al., 2007; Macherey and Och, 2007). It is also straightforward to extend the suggested method to hypergraphs and forests as they are used, e.g., in hierarchical and syntax-augmented systems (Chiang, 2005; Zollmann and Venugopal, 2006). Our future work will therefore focus on how much system combination and syntax-augmented machine translation can benefit from lattice MERT and to what extent feature function weights can robustly be estimated using the suggested method.

Syntactic Models for Structural Word Insertion and Deletion

Abstract

An important problem in translation neglected by most recent statistical machine translation systems is insertion and deletion of words, such as function words, motivated by linguistic structure rather than adjacent lexical context. Phrasal and hierarchical systems can only insert or delete words in the context of a larger phrase or rule. While this may suffice when translating in-domain, it performs poorly when trying to translate broad domains such as web text. Various syntactic approaches have been proposed that begin to address this problem by learning lexicalized and unlexicalized rules. Among these, the treelet approach uses unlexicalized order templates to model ordering separately from lexical choice. We introduce an extension to the latter that allows for structural word insertion and deletion, without requiring a lexical anchor, and show that it produces gains of more than 1.0% BLEU over both phrasal and baseline treelet systems on broad domain text.

1 Introduction

Among the phenomena that are modeled poorly by modern SMT systems is the insertion and deletion of words, such as function words, that are motivated by the divergent linguistic structure between source and target language. To take the simplest of examples, the English noun compound "*file name*" would typically be translated into Spanish as "*nombre de archivo*", which requires the insertion of the preposition "*de*". Conversely, when translating from Spanish to English, the "*de*" must be deleted. At first glance, the problem may seem trivial, yet the presence and position of these function words can have crucial impact on the adequacy and fluency of translation.

In particular, function words are often used to denote key semantic information. They may be used to denote case information, in languages such as Japanese. Failing to insert the proper case marker may render a sentence unreadable or significantly change its meaning. Learning these operations can be tricky for MT models best suited to contiguous word sequences. From a fluency standpoint, proper insertion of determiners and prepositions can often make the difference between laughably awkward output and natural sounding translations; consider the output "*it's a cake piece*" as opposed to "*it's a piece of cake*".

Furthermore, since missing or spurious function words can confuse the target language model, handling these words properly can have an impact beyond the words themselves.

This paper focuses on methods of inserting and deleting words based on syntactic cues, to be used in the context of a syntax-informed translation system. While the models we build are relatively simple and the underlying templates are easy to extract, they add significant generalization ability to the base translation system, and result in significant gains.

2 Background

As a motivating example, let us return to the English/Spanish pair "*file name*" and "*nombre de archivo*". In principle, we would want a machine translation system to be capable of learning the following general transformation:

$$\text{“ NOUN}_1\text{ NOUN}_2\text{”} \rightarrow \text{“ NOUN}_2\text{ } \textit{de} \text{ NOUN}_1\text{”} \qquad (1)$$

Yet even this simple example is beyond the capabilities of many common approaches.

The heavily lexicalized approaches of phrasal systems (Koehn et al., 2003), are inherently incapable of this generalization. As a proxy, they acquire phrase pairs such as "*nombre de archivo*" → "*file name*", "*nombre de*" → "*name*" and "*de archivo*" → "*file*". Note that the inserted word is attached to adjacent context word(s). When the test set vocabulary has significant overlap with the training vocabulary, the correct translation can often be assembled based on the head or the modifying noun. However, as we show in this paper, this is woefully inadequate when translating truly out-of-domain input.

In principle, phrase-based translation systems may employ insertion phrase pairs such as

"[NULL]" → "*de*" (2)

but the ungrounded nature of this transformation makes its use during decoding difficult. Since there are no constraints on where such a rule may apply and the rule does not consume any input words, the decoder must attempt these rules at every point in the search.

The reverse operation

"*de*" → "[NULL]" (3)

is more feasible to implement, though again, there is great ambiguity – a source word may be deleted at any point during the search, with identical target results. Few systems allow this operation in practice. Estimating the likelihood of this operation and correctly identifying the contexts in which it should occur remain challenging problems.

Hierarchical systems, such as (Chiang, 2005) in principle have the capacity to learn insertions and deletions grounded by minimal lexical cues. However, the extracted rules use a single non-terminal. Hence, to avoid explosive ambiguity, they are constrained to contain at least one aligned pair of words. This restriction successfully limits computational complexity at a cost of generalization power.

Syntax-based approaches provide fertile context for grounding insertions and deletions. Often we may draw a strong correspondence between function words in one language and syntactic constructions in another. For instance, the syntactic approach of Marcu et al. (2006) can learn unlexicalized rules that insert function words in isolation, such as:

NP(NN:x0 NN:x1) → x1 *de* x0 (4)

However, as discussed in (Wang, Knight & Marcu, 2007), joint modeling of structure and lexical choice can exacerbate data sparsity, a problem that they attempt to address by tree binarization. Nevertheless, as we show below, unlexicalized structural transformation rules such as (1) and (4) that allow for insertion of isolated function words, are essential for good quality translation of truly out-of-domain test data.

In the treelet translation approach (Menezes & Quirk, 2007), lexical choice and syntactic re-ordering are modeled separately using lexicalized treelets and unlexicalized order templates. We discuss this approach in more detail in Section 4. In Section 5, we describe how we extend this approach to allow for structural insertion and deletion, without the need for content word anchors.

3 Related Work

There is surprisingly little prior work in this area. We previously (Menezes & Quirk, 2005) explored the use of deletion operations such as (3) above, but these were not grounded in any syntactic context, and the estimation was somewhat heuristic[1].

The tuple translation model of Crego et al. (2005), a joint model over source and target translations, also provides a means of deleting words. In training, sentence pairs such as "*nombre de archivo*" / "*file name*" are first word aligned, then minimal bilingual tuples are identified, such as "*nombre* / *name*", "*de* / NULL" and "*archivo* / *file*". The tuples may involve deletion of words by allowing an empty target side, but do not allow insertion tuples with an empty source side. These inserted words are bound to an adjacent neighbor. An n-gram model is trained over the tuple sequences. As a result, deletion probabilities have the desirable property of being conditioned on adjacent context, yet this context is heavily lexicalized, therefore unlikely to generalize well.

More recently, Li et. al. (2008) describe three models for handling "single word deletion" (they discuss, but do not address, word insertion). The first model uses a fixed probability of deletion

[1] We assigned channel probabilities based on the sum of the Model1 probability of the source word being aligned to NULL or one of a list of "garbage collector" words. This exploits the property of Model1 that certain high-frequency words tend to act as "garbage collectors" for words that should remain unaligned.

P(NULL), independent of the source word, estimated by counting null alignments in the training corpus. The second model estimates a deletion probability per-word, P(NULL|w), also directly from the aligned corpus, and the third model trains an SVM to predict the probability of deletion given source language context (neighboring and dependency tree-adjacent words and parts-of-speech). All three models give large gains of 1.5% BLEU or more on Chinese-English translation. It is interesting to note that the more sophisticated models provide a relatively small improvement over the simplest model in-domain, and no benefit out-of-domain.

4 Dependency treelet translation

As a baseline, we use the treelet translation approach (which we previously described in Menezes & Quirk, 2007), a linguistically syntax-based system leveraging a source parser. It first unifies lexicalized treelets and unlexicalized templates to construct a sentence-specific set of synchronous rewrite rules. It then finds the highest scoring derivation according to a linear combination of models. We briefly review this system before describing our current extension.

4.1 The treelet translation model

Sentence-specific rewrite rules are constructed by unifying information from three sources: a dependency parse of the input sentence, a set of treelet translation pairs, and a set of unlexicalized order templates. Dependency parses are represented as trees: each node has a lexical label and a part of speech, as well as ordered lists of pre- and post-modifiers.

A *treelet* represents a connected subgraph of a dependency tree; *treelet translation pairs* consist of source and target treelets and a node alignment. This alignment is represented by indices: each node is annotated with an integer alignment index. A source node and a target node are aligned *iff* they have the same alignment index. For instance:

$$((\mathit{old}_1/\mathrm{JJ})\ \mathit{man}_2/\mathrm{NN}) \rightarrow (\mathit{hombre}_2\ (\mathit{viejo}_1)) \quad (5)$$
$$(\mathit{man}_1/\mathrm{NN}) \rightarrow (\mathit{hombre}_1) \quad (6)$$

Order templates are unlexicalized transduction rules that describe the reorderings, insertions and deletions associated with a single group of nodes that are aligned together. For instance:

$$((\mathrm{x0}{:}\star/\mathrm{DT})\ (\mathrm{x1}{:}\star/\mathrm{JJ})\ \star_1/\mathrm{NN}) \rightarrow ((\mathrm{x0})\ \star_1\ (\mathrm{x1})) \quad (7)$$
$$((\mathrm{x0}{:}\star/\mathrm{DT})\ (\mathrm{x1}{:}\star/\mathrm{JJ})\ \star_1/\mathrm{NN}) \rightarrow ((\mathrm{x0})\ (\mathrm{x1})\ \star_1) \quad (8)$$
$$((\mathrm{x0}{:}\star/\mathrm{DT})\ \star_1/\mathrm{NN}) \rightarrow ((\mathrm{x0})\ \star_1) \quad (9)$$
$$((\mathrm{x0}{:}\star/\mathrm{RB})\ \star_1/\mathrm{JJ}) \rightarrow ((\mathrm{x0})\ \star_1) \quad (10)$$

Each node is either a placeholder or a variable. Placeholders, such as $\star_1$/NN on the source side or $\star_1$ on the target side, have alignment indices and constraints on their parts-of-speech on the source side, but are unconstrained lexically (represented by the $\star$). These unify at translation time with lexicalized treelet nodes with matching parts-of-speech and alignment.

Variables, such as x0:$\star$/DT on the source side and x0:$\star$ on the target side, also have parts-of-speech constraints on the source side. Variables are used to indicate where rewrite rules are recursively applied to translate subtrees. Thus each variable label such as x0, must occur exactly once on each side.

In effect, a template specifies how all the children of a given source node are reordered during translation. If translation were a word-replacement task, then templates would be just simple, single-level tree transducers. However, in the presence of one-to-many and many-to-one translations and unaligned words, templates may span multiple levels in the tree.

As an example, order template (7) indicates that an NN with two pre-modifying subtrees headed by DT and JJ may be translated by using a single word translation of the NN, placing the translation of the DT subtree as a pre-modifier, and placing the translation of the JJ subtree as a post-modifier. As discussed below, this template can unify with the treelet (6) to produce the following rewrite rule:

$$((\mathrm{x0{:}DT})\ (\mathrm{x1{:}JJ})\ \mathit{man}/\mathrm{NN}) \rightarrow ((\mathrm{x0})\ \mathit{hombre}\ (\mathrm{x1})) \quad (11)$$

Matching: A treelet translation pair matches an input parse *iff* there is a unique correspondence between the source side of the treelet pair and a connected subgraph of the input parse.

An order template matches an input parse *iff* there is a unique correspondence between the source side of the template and the input parse, with the additional restriction that all children of input nodes that correspond to placeholder template nodes must be included in the correspondence. For instance, order template (7) matches the parse

((*the*/DT) (*young*/JJ) *colt*/NN) (12)

but not the parse

((*the*/DT) (*old*/JJ) (*grey*/JJ) *mare*/NN) (13)

Finally, an order template matches a treelet translation pair at a given node *iff*, on both source and target sides, there is a correspondence between the treelet translation nodes and template nodes that is consistent with their tree structure and alignments. Furthermore, all placeholder nodes in the template must correspond to some treelet node.

Constructing a sentence-specific rewrite rule is then a process of unifying each treelet with a matching combination of order templates with respect to an input parse. Each treelet node must be unified with one and only one order template placeholder node. Unifying under these constraints produces a rewrite rule that has a one-to-one correspondence between variables in source and target. For instance, given the input parse:

((*the*/DT) ((very/RB) *old*/JJ) *man*/NN) (14)

we can create a rewrite rule from the treelet translation pair (5) by unifying it with the order template (7), which matches at the node *man* and its descendents, and template (10), which matches at the node *old*, to produce the following sentence-specific rewrite rule:

((*the*/DT) ((x1: ⋆/RB) *old*/JJ) *man*/NN) →
((*el*) *hombre* ((x1) *viejo*)) (15)

Note that by using different combinations of order templates, a single treelet can produce multiple rewrite rules. Also, note how treelet translation pairs capture contextual lexical translations but are underspecified with respect to ordering, while order templates separately capture arbitrary reordering phenomena yet are underspecified lexically. Keeping lexical and ordering information orthogonal until runtime allows for the production of novel transduction rules never actually seen in the training corpus, leading to improved generalization power.

Decoding: Given a set of sentence-specific rewrite rules, a standard beam search algorithm is used to find the highest scoring derivation. Derivations are scored according to a linear combination of models.

4.2 Training

The process of extracting treelet translation pairs and order templates begins with parallel sentences. First, the sentence pairs are word segmented on both sides, and the source language sentences are parsed. Next, the sentence pairs are word aligned and the alignments are used to project a target language dependency tree.

Treelet extraction: From each sentence pair S, T with the alignment relation $\sim$, a treelet translation pair consisting of the source treelet $\mathbf{s} \subseteq S$ and the target treelet $\mathbf{t} \subseteq T$ is extracted *iff*:

(1) There exist $s \in \mathbf{s}$ and $t \in \mathbf{t}$ such that $s \sim t$.
(2) For all $s \in S$, and $t \in T$ such that $s \sim t$, $s \in \mathbf{s}$ *iff* $t \in \mathbf{t}$.

Order template extraction is attempted starting from each node S_{root} in the source whose parent is not also aligned to the same target word(s). We identify T_{root}, the highest target node aligned to S_{root}. We initialize the sets S_0 as $\{S_{root}\}$ and T_0 as $\{T_{root}\}$. We expand S_0 to include all nodes adjacent to some element of S_0 that are (a) unaligned, or (b) aligned to some node in T_0. The converse is applied to T_0. This expansion is repeated until we reach a fixed point. Together, S_0 and T_0 make up the placeholder nodes in the extracted order template. We then create one variable in the order template for each direct child of nodes in S_0 and T_0 that is not already included in the order template. *Iff* there is a one-to-one word alignment correspondence between source and target variables, then a template is extracted. This restriction leads to clean templates, at the cost of excluding all templates involving extraposition.

5 Insertion/deletion order templates

In this paper, we extend our previous work to allow for insertion and deletion of words, by allowing unaligned lexical items as part of the otherwise unlexicalized order templates. Grounding insertions and deletions in templates rather than treelets has two major benefits. First, insertion and deletion can be performed even in the absence of specific lexical context, leading to greater generalization power. Secondly, this increased power is tempered by linguistically informative unlexicalized context. Rather than proposing insertions and deletions in any arbitrary setting, we are guided by specific syntactic phenomena. For instance, when translating English noun compounds into Spanish, we often must include a preposition; this generalization is naturally captured using just parts-of-speech.

The inclusion of lexical items in order templates affects the translation system in only a few places: dependency tree projection, order template extraction, and rewrite rule construction at runtime.

Dependency tree projection: During this step of the baseline treelet system, unaligned words are by default attached low, to the lowest aligned neighbor. Although this worked well in conjunction with the discriminative order model, it prevents unaligned nodes from conditioning on relevant context in order templates. Therefore, we change the default attachment of unaligned nodes to be to the highest aligned neighbor; informal experiments showed that this did not noticeably impact translation quality in the baseline system. For example, consider the source parse and aligned target sentence:

$$((\textit{calibrated}_1/\text{JJ})\ (\textit{camera}_2/\text{NN})\ \textit{file}_3/\text{NN}) \\ \textit{archivo}_3\ \textit{de}_4\ \textit{cámara}_2\ \textit{calibrado}_1 \quad (16)$$

Using the baseline projection algorithm would produce this target dependency tree:

$$(\textit{archivo}_3\ ((\textit{de}_4)\ \textit{cámara}_2)\ (\textit{calibrado}_1)) \quad (17)$$

Instead, we attach unaligned words high:

$$(\textit{archivo}_3\ (\textit{de}_4)\ (\textit{cámara}_2)\ (\textit{calibrado}_1)) \quad (18)$$

Order template extraction: In addition to the purely unlexicalized templates extracted from each training sentence, we also allow templates that include lexical items for each unaligned token. For each point in the original extraction procedure, where S_0 or T_0 contain unaligned nodes, we now extract two templates: The original unlexicalized template, and a new template in which only the unaligned node(s) contain the specific lexical item(s). From the example sentence pair (16), using the projected parse (18) we would extract the following two templates:

$$((\text{x0}{:}\star/\text{JJ})\ (\text{x1}{:}\star/\text{NN})\ \star_1/\text{NN}) \rightarrow \\ (\star_1\ (\star_2)\ (\text{x1})\ (\text{x0})) \quad (19)$$

$$((\text{x0}{:}\star/\text{JJ})\ (\text{x1}{:}\star/\text{NN})\ \star_1/\text{NN}) \rightarrow \\ (\star_1\ (\textit{de}_2)\ (\text{x1})\ (\text{x0})) \quad (20)$$

Template matching and unification: We extend the template matching against the input parse to require that any lexicalized source template nodes match the input exactly. When matching templates to treelet translation pairs, any unaligned treelet nodes must be consistent with the corresponding template node (i.e. the template node must be unlexicalized, or the lexical items must match). On the other hand, lexicalized template nodes do not need to match any treelet nodes -- insertions or deletions may now come from the template alone.

Consider the following example input parse:

$$((\textit{digital}/\text{JJ})\ (\textit{camera}/\text{NN}) \\ (\textit{file}/\text{NN})\ \textit{extension}/\text{NN}) \quad (21)$$

The following treelet translation pair provides a contextual translation for some of the children, including the insertion of one necessary preposition:

$$((\textit{file}_1/\text{NN})\ \textit{extension}_2/\text{NN}) \rightarrow \\ (\textit{extension}_2\ (\textit{de}_3)\ (\textit{archivo}_1)) \quad (22)$$

The following order template can provide relative ordering information between nodes as well as insert the remaining prepositions:

$$((\text{x0}{:}\star/\text{JJ})\ (\text{x1}{:}\star/\text{NN})\ (\text{x2}{:}\star/\text{NN})\ \star_1/\text{NN}) \rightarrow \\ (\star_1\ (\textit{de}_2)\ (\text{x2})\ (\textit{de}_3)\ (\text{x0})\ (\text{x1})) \quad (23)$$

The unification of this template and treelet is somewhat complex: the first inserted *de* is agreed upon by both template and treelet, whereas the second is inserted by the template alone. This results in the following novel rewrite rule:

$$((\text{x0}{:}\star/\text{JJ})\ (\text{x1}{:}\ \star/\text{NN})\ (\textit{file})\ \textit{extension}) \rightarrow \\ (\textit{extension}\ (\textit{de})\ (\textit{archivo})\ (\textit{de})\ (\text{x0})\ (\text{x1})) \quad (24)$$

These relatively minimal changes produce a powerful contextualized model of insertion and deletion.

Parameter estimation: The underlying treelet system includes a template probability estimated by relative frequency. We estimate our lexicalized templates in the same way. However early experiments showed that this feature alone was not enough to allow even common insertions, since the probability of even the most common insertion templates is much lower than that of unlexicalized templates. To improve the modeling capability, we included two additional feature functions: a count of structurally inserted words, and a count of structurally deleted words.

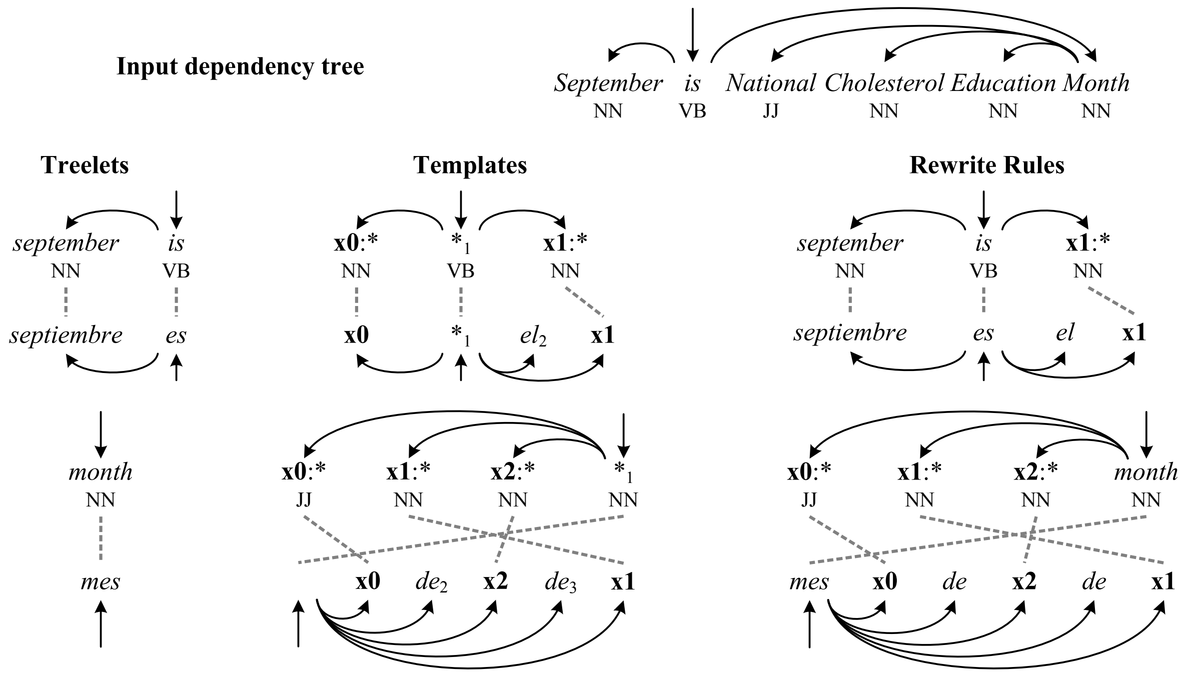

Figure 6.1: Example sentence, matching treelets, structural insertion templates and unified rewrite rules

6 Example

Consider the following English test sentence and corresponding Spanish human translation:

September is National Cholesterol Education Month

Septiembre es el Mes Nacional para la Educación sobre el Colesterol

The baseline treelet system without structural insertions translates this sentence as:

Septiembre es Nacional Colesterol Educación Mes

Not only is the translation missing the appropriate articles and prepositions, but also in their absence, it fails to reorder the content words correctly. Without the missing prepositions, the language model does not show a strong preference among various orderings of "*nacional*" "*colesterol*" "*educación*" and "*mes*".

Using structural insertion templates, the highest scoring translation of the sentence is now:

Septiembre es el Mes Nacional de Educación de colesterol

Although the choice of prepositions is not the same as the reference, the fluency is much improved and the translation is quite understandable. Figure 6.1, lists the structural insertion templates that are used to produce this translation, and shows how they are unified with treelet translation pairs to produce sentence-specific rewrite rules, which are in turn composed during decoding to produce this translation.

7 Experiments

We evaluated the translation quality of the system using the BLEU metric (Papineni et al., 2002). We compared three systems: (a) a standard phrasal system using a decoder based on Pharaoh, (Koehn et al., 2003), (b) A baseline treelet system using unlexicalized order templates and (c) The present work, which adds structural insertion and deletion templates.

7.1 Data

We report results for two language pairs, English-Spanish and English- Japanese. For English-Spanish we use two training sets: (a) the Europarl corpus provided by the NAACL 2006 Statistical Machine Translation workshop (b) a "general-domain" data set that includes a broad spectrum of data such as governmental data, general web data and technical corpora.

For English-Japanese we use only the “general-domain” data set.

	Sentence pairs	Tokens	Phr size	MERT data
Europarl E-S	730K	15M	7	Europarl
General E-S	3.7M	41M	4	Web
General E-J	2.6M	16M	4	Web

Table 7.1 Training data

For English-Spanish we report results using the four test sets listed in Table 7.2. For English-Japanese we use only the web test set. The first two tests are from the 2006 SMT workshop and the newswire test is from the 2008 workshop. The web test sets were selected from a random sampling of English web sites, with target language translations provided by professional translation vendors. All test sets have one reference translation.

Table 7.2 Test data

7.2 Models

The baseline treelet translation system uses all the models described in Menezes & Quirk (2007), namely:

- Treelet log probabilities, maximum likelihood estimates with absolute discounting.
- Forward and backward lexical weighting, using Model-1 translation log probabilities.
- Trigram language model using modified Kneser-Ney smoothing.
- Word and phrase count feature functions.
- Order template log probabilities, maximum likelihood estimates, absolute discounting.
- Count of artificial *source order templates.*[2]
- Discriminative tree-based order model.

The present work does not use the discriminative tree-based order model[3] but adds:

- Count of structural insertions: This counts only words inserted via templates, not lexical insertions via treelets.
- Count of structural deletions: This counts only words deleted via templates, not lexical deletions via treelets.

The comparison phrasal system was constructed using the same alignments and the heuristic combination described in (Koehn et al., 2003). This system used a standard set of models:

- Direct and inverse log probabilities, both relative frequency and lexical weighting.
- Word count, phrase count.
- Trigram language model log probability.
- Length based distortion model.
- Lexicalized reordering model.

7.3 Training

We parsed the source (English) side of the corpus using NLPWIN, a broad-coverage rule-based parser able to produce syntactic analyses at varying levels of depth (Heidorn, 2000). For the purposes of these experiments, we used a dependency tree output with part-of-speech tags and unstemmed, case-normalized surface words. For word alignment we used a training regimen of five iterations of Model 1, followed by five iterations of a word-dependent HMM model (He, 2007) in both directions. The forward and backward alignments were combined using a dependency tree-based heuristic combination. The word alignments and English dependency tree were used to project a target tree. From the aligned tree pairs we extracted treelet and order template tables.

For the Europarl systems, we use a phrase/treelet size of 7 and train model weights using 2000 sentences of Europarl data. For the “general-domain” systems, we use a phrase/treelet size of 4, and train model weights using 2000 sentences of web data.

For any given corpus, all systems used the same treelet or phrase size (see Table 7.1) and the same trigram language model. Model weights were trained separately for each system, data set and experimental condition, using minimum error rate training to maximize BLEU (Och, 2003).

[2] When no template is compatible with a treelet, the decoder creates an artificial template that preserves source order. This count feature allows MERT to deprecate the use of such templates. This is analogous to the glue rules of Chiang (2005).

[3] In our experiments, we find that the impact of this model is small in the presence of order templates; also, it degrades the overall speed of the decoder.

	% BLEU

+Insertion only	16.16
+Deletion and Insertion	**17.01**

Table 8.1: English-Japanese system comparisons

8 Results and Discussion

Tables 8.1 and 8.4 compare baseline phrasal and treelet systems with systems that use various types of insertion and deletion templates.

English-Japanese: As one might expect, the use of structural insertion and deletion has the greatest impact when translating between languages such as English and Japanese that show significant structural divergence. In this language pair, both insertions and deletions have an impact, for a total gain of 1.1% BLEU over the baseline treelet system, and 3.6% over the phrasal system. To aid our understanding of the system, we tabulated the most commonly inserted and deleted words when translating from English into Japanese in Tables 8.2 and 8.3 respectively. Satisfyingly, most of the insertions and deletions correspond to well-known structural differences between the languages. For instance, in English the thematic role of a noun phrase, such as subject or object, is typically indicated by word order, whereas Japanese uses case markers to express this information. Hence, case markers such as "を" and "は" need to be inserted. Also, when noun compounds are translated, an intervening postposition such as "の" is usually needed. Among the most common deletions are "*the*" and "*a*". This is because Japanese does not have a notion of definiteness. Similarly, pronouns are often dropped in Japanese.

English-Spanish: We note, in Table 8.4 that even between such closely related languages, structural insertions give us noticeable improvements over the baseline treelet system. On the smaller Europarl training corpus the improvements range from 0.5% to 1.1% BLEU. On the larger training corpus we find that for the more in-domain governmental[4] and news test sets, the effect is smaller or even slightly negative, but on the very broad web test set we still see an improvement of about 0.7% BLEU.

[4] The "general domain" training corpus is a superset of the Europarl training set, therefore, the Europarl tests sets are "in-domain" in both cases.

Table 8.3: E-J: Most commonly deleted words

As one might expect, as the training data size increases, the generalization power of structural insertion and deletions becomes less important when translating *in-domain* text, as more insertions and deletions can be handled lexically. Nevertheless, the web test results indicate that if one hopes to handle truly general input the need for structural generalizations remains.

Unlike in English-Japanese, when translating from English to Spanish, structural deletions are less helpful. Used in isolation or in combination with insertion templates they have a slightly negative and/or insignificant impact in all cases. We hypothesize that when translating *from* English *into* Spanish, more words need to be inserted than deleted. Conversely, when translating in the reverse direction, deletion templates may play a bigger role. We were unable to test the reverse direction because our syntax-based systems depend on a source language parser. In future work we hope to address this.

Table 8.4: English-Spanish system comparisons, %BLEU

In table 8.5 and 8.6, we list the words most commonly inserted and deleted when translating the web test using the general English-Spanish system. As in English-Japanese, we find that the insertions are what one would expect on linguistic grounds. However, deletions are used much less frequently than insertions and also much less frequently than they are in English-Japanese. Only 53 words are structurally deleted in the 5000 sentence test set, as opposed to 4728 structural insertions. Furthermore, the most common deletion is of quotation marks, which is incorrect in most cases, even though such deletion is evidenced in the training corpus[5].

On the other hand, the next most common deletions "*I*" and "*it*" are linguistically well grounded, since Spanish often drops pronouns.

9 Conclusions and Future Work

We have presented an extension of the treelet translation method to include order templates with structural insertion and deletion, which improves translation quality under a variety of scenarios, particularly between structurally divergent languages. Even between closely related languages, these operations significantly improve the generalizability of the system, providing benefit when handling out-of-domain test data.

Our experiments shed light on a little-studied area of MT, but one that is nonetheless crucial for high quality broad domain translation. Our results affirm the importance of structural insertions, in particular, when translating from English into other languages, and the importance of both insertions and deletions when translating between divergent languages. In future, we hope to study translations from other languages into English to study the role of deletions in such cases.

[5] In many parallel corpora, quotes are not consistently preserved between source and target languages.

Abstract

The performance of machine translation systems varies greatly depending on the source and target languages involved. Determining the contribution of different characteristics of language pairs on system performance is key to knowing what aspects of machine translation to improve and which are irrelevant. This paper investigates the effect of different explanatory variables on the performance of a phrase-based system for 110 European language pairs. We show that three factors are strong predictors of performance in isolation: the amount of reordering, the morphological complexity of the target language and the historical relatedness of the two languages. Together, these factors contribute 75% to the variability of the performance of the system.

1 Introduction

Statistical machine translation (SMT) has improved over the last decade of intensive research, but for some language pairs, translation quality is still low. Certain systematic differences between languages can be used to predict this. Many researchers have speculated on the reasons why machine translation is hard. However, there has never been, to our knowledge, an analysis of what the actual contribution of different aspects of language pairs is to translation performance. This understanding of where the difficulties lie will allow researchers to know where to most gainfully direct their efforts to improving the current models of machine translation.

Many of the challenges of SMT were first outlined by Brown et al. (1993). The original IBM Models were broken down into separate translation and distortion models, recognizing the importance of word order differences in modeling translation. Brown et al. also highlighted the importance of modeling morphology, both for reducing sparse counts and improving parameter estimation and for the correct production of translated forms. We see these two factors, reordering and morphology, as fundamental to the quality of machine translation output, and we would like to quantify their impact on system performance.

It is not sufficient, however, to analyze the morphological complexity of the source and target languages. It is also very important to know how similar the morphology is between the two languages, as two languages which are morphologically complex in very similar ways, could be relatively easy to translate. Therefore, we also include a measure of the family relatedness of languages in our analysis.

The impact of these factors on translation is measured by using linear regression models. We perform the analysis with data from 110 different language pairs drawn from the Europarl project (Koehn, 2005). This contains parallel data for the 11 official language pairs of the European Union, providing a rich variety of different language characteristics for our experiments. Many research papers report results on only one or two languages pairs. By analyzing so many language pairs, we are able to provide a much wider perspective on the challenges facing machine translation. This analysis is important as it provides very strong motivation for further research.

The findings of this paper are as follows: (1) each of the main effects, reordering, target language complexity and language relatedness, is a highly significant predictor of translation performance, (2) individually these effects account for just over a third of the variation of the BLEU score, (3) taken together, they account for 75% of the variation of the BLEU score, (4) when removing Finnish results as outliers, reordering explains the most variation, and finally (4) the morphological complexity of the source language is uncorrelated with performance, which suggests that any difficulties that arise with sparse counts are insignificant under the experimental conditions outlined in this paper.

2 Europarl

In order to analyze the influence of different language pair characteristics on translation performance, we need access to a large variety of comparable parallel corpora. A good data source for this is the Europarl Corpus (Koehn, 2005). It is a collection of the proceedings of the European Parliament, dating back to 1996. Version 3 of the corpus consists of up to 44 million words for each of the 11 official languages of the European Union: Danish (da), German (de), Greek (el), English (en), Spanish (es), Finnish (fi), French (fr), Italian (it), Dutch (nl), Portuguese (pt), and Swedish (sv).

In trying to determine the effect of properties of the languages involved in translation performance, it is very important that other variables be kept constant. Using Europarl, the size of the training data for the different language pairs is very similar, and there are no domain differences as all sentences are roughly trained on translations of the same data.

3 Morphological Complexity

The morphological complexity of the language pairs involved in translation is widely recognized as one of the factors influencing translation performance. However, most statistical translation systems treat different inflected forms of the same lemma as completely independent of one another. This can result in sparse statistics and poorly estimated models. Furthermore, different variations of the lemma may result in crucial differences in meaning that affect the quality of the translation.

Work on improving MT systems' treatment of morphology has focussed on either reducing word forms to lemmas to reduce sparsity (Goldwater and McClosky, 2005; Talbot and Osborne, 2006) or including morphological information in decoding (Dyer, 2007).

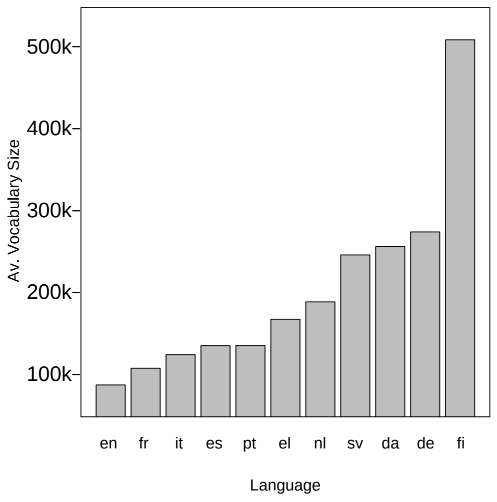

Figure 1. Average vocabulary size for each language.

Although there is a significant amount of research into improving the treatment of morphology, in this paper we aim to discover the effect that different levels of morphology have on translation. We measure the amount of morphological complexity that exists in both languages and then relate this to translation performance.

Some languages seem to be intuitively more complex than others, for instance Finnish appears more complex than English. There is, however, no obvious way of measuring this complexity. One method of measuring complexity is by choosing a number of hand-picked, intuitive properties called *complexity indicators* (Bickel and Nichols, 2005) and then to count their occurrences. Examples of morphological complexity indicators could be the number of inflectional categories or morpheme types in a typical sentence. This method suffers from the major drawback of finding a principled way of choosing which of the many possible linguistic properties should be included in the list of indicators.

A simple alternative employed by Koehn (2005) is to use vocabulary size as a measure of morphological complexity. Vocabulary size is strongly influenced by the number of word forms affected by number, case, tense etc. and it is also affected by the number of agglutinations in the language. The complexity of the morphology of languages can therefore be approached by looking at vocabulary size.

Figure 1 shows the vocabulary size for all relevant languages. Each language pair has a slightly different parallel corpus, and so the size of the vocabularies for each language needs to be averaged. You can see that the size of the Finnish vocabulary is about six times larger (510,632 words) than the English vocabulary size (88,880 words). The reason for the large vocabulary size is that Finnish is characterized by a rich inflectional morphology, and it is typologically classified as an agglutinative-fusional language. As a result, words are often polymorphemic, and become remarkably long.

4 Language Relatedness

The morphological complexity of each language in isolation could be misleading. Large differences in morphology between two languages could be more relevant to translation performance than a complex morphology that is very similar in both languages. Languages which are closely related could share morphological forms which might be captured reasonably well in translation models. We include a measure of language relatedness in our analyses to take this into account.

Comparative linguistics is a field of linguistics which aims to determine the historical relatedness of languages. Lexicostatistics, developed by Morris Swadesh in the 1950s (Swadesh, 1955), is an approach to comparative linguistics that is appropriate for our purposes because it results in a quantitative measure of relatedness by comparing lists of lexical cognates.

The lexicostatistic percentages are extracted as follows. First, a list of universal culture-free meanings are generated. Words are then collected for these meanings for each language under consideration. Lists for particular purposes have been generated. For example, we use the data from Dyen et al. (1992) who developed a list of 200 meanings for 84 Indo-European languages. Cognacy decisions are then made by a trained linguist. For each pair of lists the cognacy of a form can be positive, negative or indeterminate. Finally, the lexicostatistic percentage is calculated. This percentage is related to the proportion of meanings for a particular language pair that are cognates, i.e. relative to the total without indeterminacy. Factors such as borrowing, tradition and taboo can skew the results.

Language	“animal”	“black”
French	animal	noir
Italian	animale	nero
Spanish	animal	negro
English	animal	black
German	tier	schwarz
Swedish	djur	svart
Danish	dyr	sort
Dutch	dier	zwart

Table 1. An example from the (Dyen et al., 1992) cognate list.

A portion of the Dyen et al. (1992) data set is shown in Table 1 as an example. From this data a trained linguist would calculate the relatedness of French, Italian and Spanish as 100% because their words for “animal” and “black” are cognates. The Romance languages share one cognate with English, “animal” but not “black”, which means that the lexicostatistic percentage here would be 50%, and no cognates with the rest of the languages, 0%.

We use the Dyen lexicostatistic percentages as our measure of language relatedness or similarity for all bidirectional language pairs except for Finnish, for which there is not data. Finnish is a Finno-Ugric language and is not part of the Indo-European language family and is therefore not included in the Dyen results. We were not able to recreate the conditions of this study to generate the data for Finnish - expert linguists with knowledge of all the languages would be required. Excluding Finnish would have been a shame as it is an interesting language to look at, however we took care to confirm which effects found in this paper still held when excluding Finnish. Not being part of the Indo-European languages means that its historical similarity with our other languages is very low. For example, English would be more closely related to Hindu than to Finnish. We therefore assume that Finnish has zero similarity with the other languages in the set.

Figure 2 shows the symmetric matrix of language relatedness, where the width of the square is proportional to the value of relatedness. Finnish is the language which is least related to the other languages and has a relatedness score of 0%. Spanish-Portuguese is the most related language pair with a

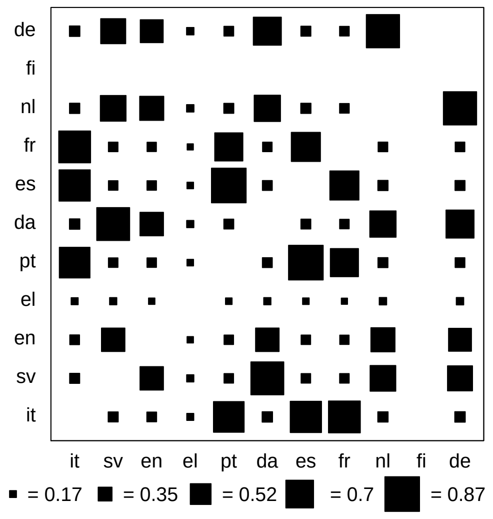

Figure 2. Language relatedness - the width of the squares indicates the lexicostatical relatedness.

score of 0.87%.

A measure of family relatedness should improve our understanding of the relationship between morphological complexity and translation performance.

5 Reordering

Reordering refers to differences in word order that occur in a parallel corpus and the amount of reordering affects the performance of a machine translation system. In order to determine how much it affects performance, we first need to measure it.

5.1 Extracting Reorderings

Reordering is largely driven by syntactic differences between languages and can involve complex rearrangements between nodes in synchronous trees. Modeling reordering exactly would require a synchronous tree-substitution grammar. This representation would be sparse and heterogeneous, limiting its usefulness as a basis for analysis. We make an important simplifying assumption in order for the detection and extraction of reordering data to be tractable and useful. We assume that reordering is a binary process occurring between two blocks that are adjacent in the source. This is similar to the ITG constraint (Wu, 1997), however our reorderings are not dependent on a synchronous grammar or a derivation which covers the sentences. There are also similarities with the Human-Targeted Translation Edit Rate metric (HTER) (Snover et al., 2006) which attempts to find the minimum number of human edits to correct a hypothesis, and admits moving blocks of words, however our algorithm is automatic and does not consider inserts or deletes.

Before describing the extraction of reorderings we need to define some concepts. We define a *block* A as consisting of a source span, $A_{\bar{s}}$, which contains the positions from A_{smin} to A_{smax} and is aligned to a set of target words. The minimum and maximum positions (A_{tmin} and A_{tmax}) of the aligned target words mark the block's target span, $A_{\bar{t}}$.

A reordering r consists of the two blocks r_A and r_B, which are adjacent in the source and where the relative order of the blocks in the source is reversed in the target. More formally:

$$r_{A_{\bar{s}}} < r_{B_{\bar{s}}}, \quad r_{A_{\bar{t}}} > r_{B_{\bar{t}}}, \quad r_{A_{smax}} = r_{B_{smin}} - 1$$

A consistent block means that between A_{tmin} and A_{tmax} there are no target word positions aligned to source words outside of the block's source span $A_{\bar{s}}$. A reordering is consistent if the block projected from $r_{A_{smin}}$ to $r_{B_{smax}}$ is consistent.

The following algorithm detects reorderings and determines the dimensions of the blocks involved. We step through all the source words, and if a word is reordered in the target with respect to the previous source word, then a reordering is said to have occurred. These two words are initially defined as the blocks A and B. Then the algorithm attempts to grow block A from this point towards the source starting position, while the target span of A is greater than that of block B, and the new block A is consistent. Finally it attempts to grow block B towards the source end position, while the target span of B is less than that of A and the new reordering is inconsistent.

See Figure 3 for an example of a sentence pair with two reorderings. Initially a reordering is detected between the Chinese words aligned to "from" and "late". The block A is grown from "late" to include the whole phrase pair "late last night". Then the block B is grown from "from" to include "Beijing" and stops because the reordering is then consistent. The next reordering is detected between "arrived in" and "Beijing". We can see that block A attempts to grow as large a block as possible and block

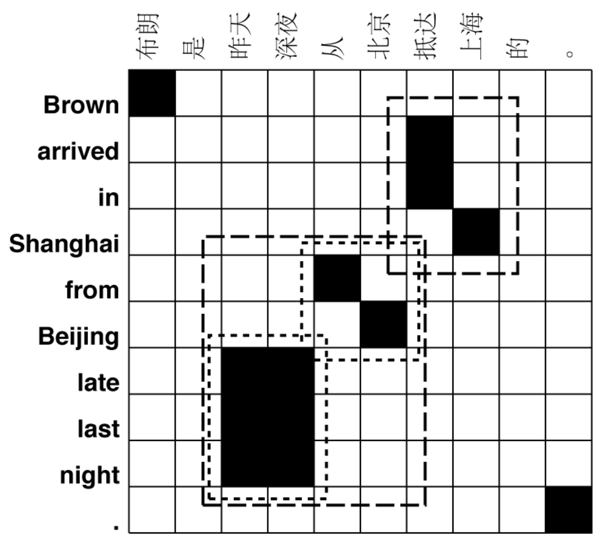

Figure 3. A sentence pair from the test corpus, with its alignment. Two reorderings are shown with two different dash styles.

B attempts to grow the smallest block possible. The reorderings thus extracted would be comparable to those of a right-branching ITG with inversions. This allows for syntactically plausible embedded reorderings. This algorithm has the worst case complexity of $O(\frac{n^2}{2})$ when the words in the target occur in the reverse order to the words in the source.

5.2 Measuring Reordering

Our reordering extraction technique allows us to analyze reorderings in corpora according to the distribution of reordering widths. In order to facilitate the comparison of different corpora, we combine statistics about individual reorderings into a sentence level metric which is then averaged over a corpus.

$$RQuantity = \frac{\sum_{r \in R} |r_{A_{\bar{s}}}| + |r_{B_{\bar{s}}}|}{I}$$

where R is the set of reorderings for a sentence, I is the source sentence length, A and B are the two blocks involved in the reordering, and $|r_{A_{\bar{s}}}|$ is the size or span of block A on the source side. RQuantity is thus the sum of the spans of all the reordering blocks on the source side, normalized by the length of the source sentence.

	RQuantity
Europarl, auto align	0.620
WMT06 test, auto align	0.647
WMT06 test, manual align	0.668

Table 2. The reordering quantity for the different reordering corpora for DE-EN.

5.3 Automatic Alignments

Reorderings extracted from manually aligned data can be reliably assumed to be correct. The only exception to this is that embedded reorderings are always right branching and these might contradict syntactic structure. In this paper, however, we use alignments that are automatically extracted from the training corpus using GIZA++. Automatic alignments could give very different reordering results. In order to justify using reordering data extracted from automatic alignments, we must show that they are similar enough to gold standard alignments to be useful as a measure of reordering.

5.3.1 Experimental Design

We select the German-English language pair because it has a reasonably high level of reordering. A manually aligned German-English corpus was provided by Chris Callison-Burch and consists of the first 220 sentences of test data from the 2006 ACL Workshop on Machine Translation (WMT06) test set. This test set is from a held out portion of the Europarl corpus.

The automatic alignments were extracted by appending the manually aligned sentences on to the respective Europarl v3 corpora and aligning them using GIZA++ (Och and Ney, 2003) and the grow-final-diag algorithm (Koehn et al., 2003).

5.3.2 Results

In order to use automatic alignments to extract reordering statistics, we need to show that reorderings from automatic alignments are comparable to those from manual alignments.

We first look at global reordering statistics and then we look in more detail at the reordering distribution of the corpora. Table 2 shows the amount of reordering in the WMT06 test corpora, with both manual and automatic alignments, and in the automatically aligned Europarl DE-EN parallel corpus.

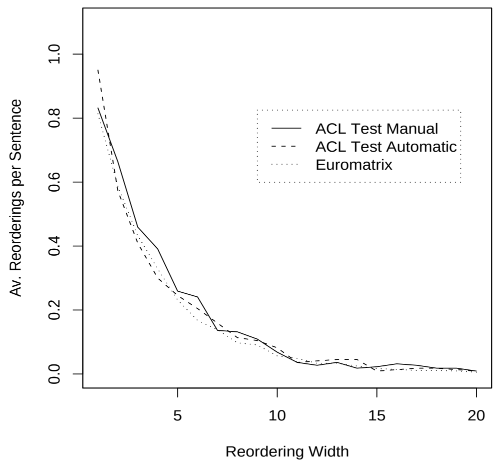

Figure 4. Average number of reorderings per sentence mapped against the total width of the reorderings for DE-EN.

We can see that all three corpora show a similar amount of reordering.

Figure 4 shows that the distribution of reorderings between the three corpora is also very similar. These results provide evidence to support our use of automatic reorderings in lieu of manually annotated alignments. Firstly, they show that our WMT06 test corpus is very similar to the Europarl data, which means that any conclusions that we reach using the WMT06 test corpus will be valid for the Europarl data. Secondly, they show that the reordering behavior of this corpus is very similar when looking at automatic vs. manual alignments.

Although differences between the reorderings detected in the manually and automatically aligned German-English corpora are minor, there we accept that there could be a language pair whose real reordering amount is very different to the expected amount given by the automatic alignments. A particular language pair could have alignments that are very unsuited to the stochastic assumptions of the IBM or HMM alignment models. However, manually aligning 110 language pairs is impractical.

5.4 Amount of reordering for the matrix

Extracting the amount of reordering for each of the 110 language pairs in the matrix required a sampling approach. We randomly extracted a subset of 2000 sentences from each of the parallel training corpora. From this subset we then extracted the average RQuantity.

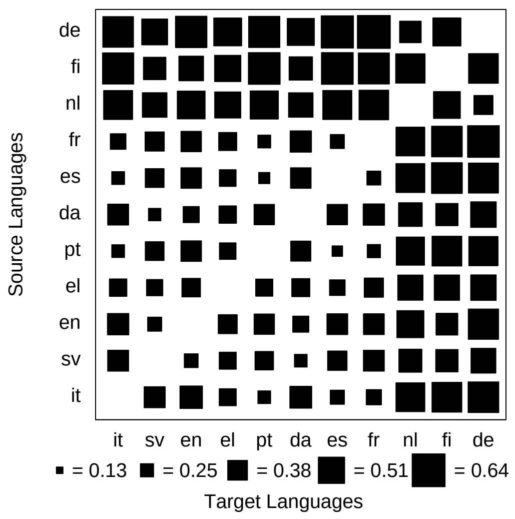

Figure 5. Reordering amount - the width of the squares indicates the amount of reordering or RQuantity.

In Figure 5 the amount of reordering for each of the language pairs is proportional to the width of the relevant square. Note that the matrix is not quite symmetrical - reordering results differ depending on which language is chosen to measure the reordering span. The lowest reordering scores are generally for languages in the same language group (like Portuguese-Spanish, 0.20, and Danish-Swedish, 0.24) and the highest for languages from different groups (like German-French, 0.64, and Finnish-Spanish, 0.61).

5.5 Language similarity and reordering

In this paper we use linear regression models to determine the correlation and significance of various explanatory variables with the dependent variable, the BLEU score. Ideally the explanatory variables involved should be independent of each other, however the amount of reordering in a parallel corpus could easily be influenced by family relatedness. We investigate the correlation between these variables.

Figure 6 shows the plot of the reordering amount against language similarity. The regression is highly significant and has an R^2 of 0.2347. This means that reordering is correlated with language similarity and that 23% of reordering can be explained by language similarity.

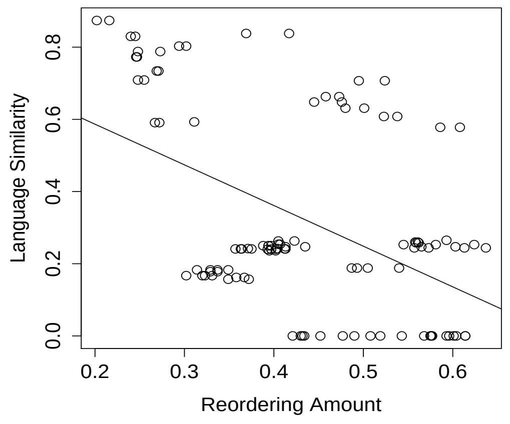

Figure 6. Reordering compared to language similarity with regression.

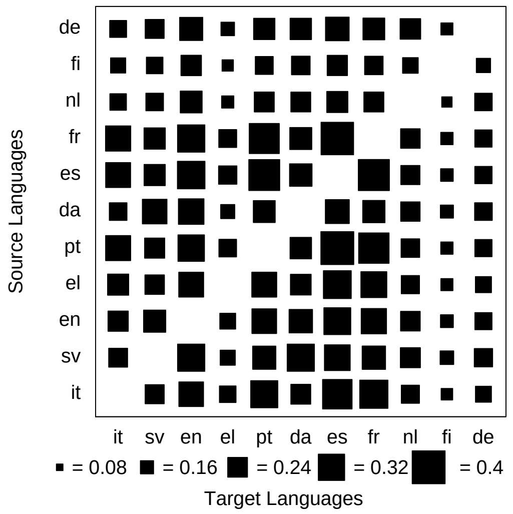

Figure 7. System performance - the width of the squares indicates the system performance in terms of the BLEU score.

6 Experimental Design

We used the phrase-based model Moses (Koehn et al., 2007) for the experiments with all the standard settings, including a lexicalized reordering model, and a 5-gram language model. Tests were run on the ACL WSMT 2008 test set (Callison-Burch et al., 2008).

6.1 Evaluation of Translation Performance

We use the BLEU score (Papineni et al., 2002) to evaluate our systems. While the role of BLEU in machine translation evaluation is a much discussed topic, it is generally assumed to be a adequate metric for comparing systems of the same type.

Figure 7 shows the BLEU score results for the matrix. Comparing this figure to Figure 5 there seems to be a clear negative correlation between reordering amount and translation performance.

6.2 Regression Analysis

We perform multiple linear regression analyses using measures of morphological complexity, language relatedness and reordering amount as our independent variables. The dependent variable is the translation performance metric, the BLEU score.

We then use a t-test to determine whether the coefficients for the independent variables are reliably different from zero. We also test how well the model explains the data using an R^2 test. The two-tailed significance levels of coefficients and R^2 are also given where * means $p < 0.05$, ** means $p < 0.01$, and *** means $p < 0.001$.

Explanatory Variable	Coefficient	
Target Vocab. Size	-3.885	***
Language Similarity	3.274	***
Reordering Amount	-1.883	***
Target Vocab. Size^2	1.017	***
Language Similarity^2	-1.858	**
Interaction: Reord/Sim	-1.4536	***

Table 3. The impact of the various explanatory features on the BLEU score via their coefficients in the minimal adequate model.

7 Results

7.1 Combined Model

The first question we are interested in answering is which factors contribute most and how they interact. We fit a multiple regression model to the data. The source vocabulary size has no significant effect on the outcome. All explanatory variable vectors were normalized to be more comparable.

In Table 3 we can see the relative contribution of the different features to the model. Source vocabulary size did not contribute significantly to the explanatory power of this multiple regression model and was therefore not included. The fraction of the variance explained by the model, or its goodness of fit, the R^2, is 0.750 which means that 75% of the variation in BLEU can be explained by these three factors. The interaction of reordering amount and language relatedness is the product of the values of these two features, and in itself it is an important explanatory feature.

To make sure that our regression is valid, we need to consider the special case of Finnish. Data points where Finnish is the target language are outliers. Finnish has the lowest language similarity with all other languages, and the largest vocabulary size. It also has very high amounts of reordering, and the lowest BLEU scores when it is the target language. The multiple regression of Table 3 where Finnish as the source and target language is excluded, shows that all the effects are still very significant, with the model's R^2 dropping only slightly to 0.68.

The coefficients of the variables in the multiple regression model have only limited usefulness as a measure of the impact of the explanatory variables in the model. One important factor to consider is that if the explanatory variables are highly correlated, then the values of the coefficients are unstable. The model could attribute more importance to one or the other variable without changing the overall fit of the model. This is the problem of multicollinearity. Our explanatory variables are all correlated, but a large amount of this correlation can be explained by looking at language pairs with Finnish as the target language. Excluding these data points, only language relatedness and reordering amount are still correlated, see Section 5.5 for more details.

7.2 Contribution in isolation

In order to establish the relative contribution of variables, we isolate their impact on the BLEU score by modeling them in separate linear regression models.

Figure 8 shows a simple regression model over the plot of BLEU scores against target vocabulary size. This figure shows groups of data points with the same target language in almost vertical lines. Each language pair has a separate parallel training corpus, but the target vocabulary size for one language will be very similar in all of them. The variance in BLEU amongst the group with the same target language is then largely explained by the other factors, similarity and reordering.

Figure 9 shows a simple regression model over the plot of BLEU scores against source vocabulary size.

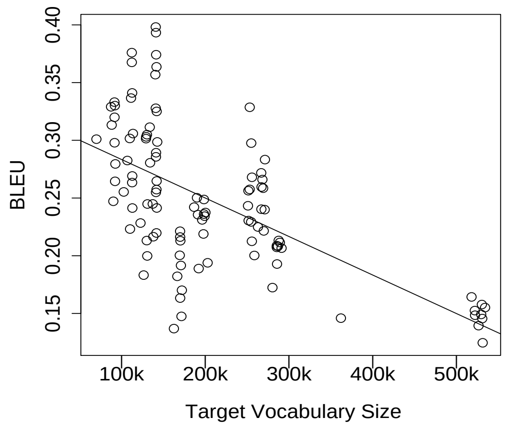

Figure 8. BLEU score of experiments compared to target vocabulary size showing regression

This regression model shows that in isolation source vocabulary size is significant ($p < 0.05$), but that this is due to the distorting effect of Finnish. Excluding results that include Finnish, there is no longer any significant correlation with BLEU. The source morphology might be significant for models trained on smaller data sets, where model parameters are more sensitive to sparse counts.

Figure 10 shows the simple regression model over the plot of BLEU scores against the amount of reordering. This graph shows that with more reordering, the performance of the translation model reduces. Data points with low levels of reordering and high BLEU scores tend to be language pairs where both languages are Romance languages. High BLEU scores with high levels of reordering tend to have German as the source language and a Romance language as the target.

Figure 11 shows the simple regression model over the plot of BLEU scores against the amount of language relatedness. The left hand line of points are the results involving Finnish. The vertical group of points just to the right, are results where Greek is involved. The next set of points are the results where the translation is between Germanic and Romance languages. The final cloud to the right are results where languages are in the same family, either within the Romance or the Germanic languages.

Table 4 shows the amount of the variance of BLEU explained by the different models. As these

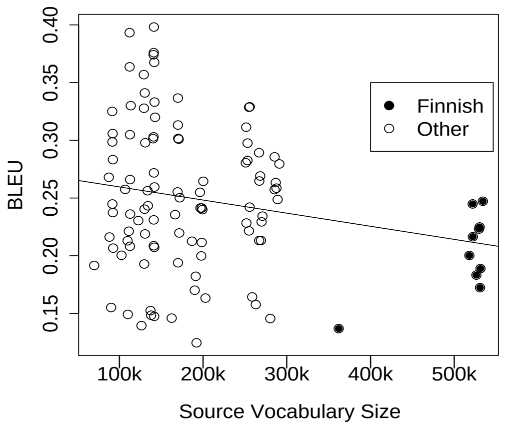

Figure 9. BLEU score of experiments compared to source vocabulary size highlighting the Finnish source vocabulary data points. The regression includes Finnish in the model.

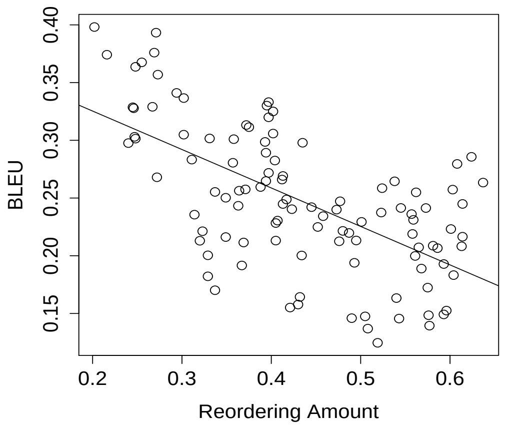

Figure 10. BLEU score of experiments compared to amount of reordering.

Explanatory Variable	R^2	
Target Vocab. Size	**0.388**	***
Reordering Amount	0.384	***
Language Similarity	0.366	***
Source Vocab. Size	0.045	*
Excluding Finnish		
Target Vocab. Size	0.219	***
Reordering Amount	**0.332**	***
Language Similarity	0.188	***
Source Vocab. Size	0.007	

Table 4. Goodness of fit of different simple linear regression models which use just one explanatory variable. The significance level represents the level of probability that the regression is appropriate. The second set of results excludes Finnish in the source and target language.

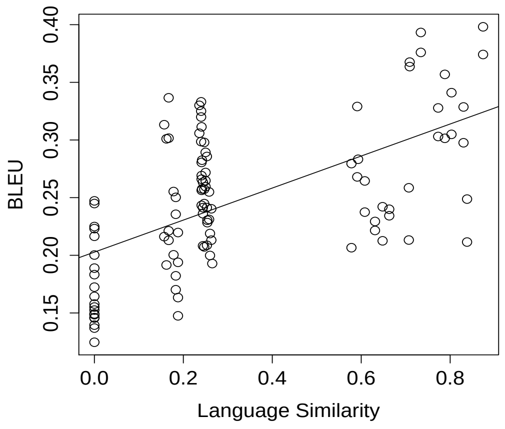

Figure 11. BLEU score of experiments compared to language relatedness.

are simple regression models, with just one explanatory variable, multicolinearity is avoided. This table shows that each of the main effects explains about a third of the variance of BLEU, which means that they can be considered to be of equal importance. When Finnish examples are removed, only reordering retains its power, and target vocabulary and language similarity reduce in importance and source vocabulary size no longer correlates with performance.

8 Conclusion

We have broken down the relative impact of the characteristics of different language pairs on translation performance. The analysis done is able to account for a large percentage (75%) of the variability of the performance of the system, which shows that we have captured the core challenges for the phrase-based model. We have shown that their impact is about the same, with reordering and target vocabulary size each contributing about 0.38%.

These conclusions are only strictly relevant to the model for which this analysis has been performed, the phrase-based model. However, we suspect that the conclusions would be similar for most statistical machine translation models because of their dependence on automatic alignments. This will be the topic of future work.

An Exploration of Document Impact on Graph-Based Multi-Document Summarization

Xiaojun Wan

wanxiaojun@icst.pku.edu.cn

Abstract

The graph-based ranking algorithm has been recently exploited for multi-document summarization by making only use of the sentence-to-sentence relationships in the documents, under the assumption that all the sentences are indistinguishable. However, given a document set to be summarized, different documents are usually not equally important, and moreover, different sentences in a specific document are usually differently important. This paper aims to explore document impact on summarization performance. We propose a document-based graph model to incorporate the document-level information and the sentence-to-document relationship into the graph-based ranking process. Various methods are employed to evaluate the two factors. Experimental results on the DUC2001 and DUC2002 datasets demonstrate that the good effectiveness of the proposed model. Moreover, the results show the robustness of the proposed model.

1 Introduction

Multi-document summarization aims to produce a summary describing the main topic in a document set, without any prior knowledge. Multi-document summary can be used to facilitate users to quickly understand a document cluster. For example, a number of news services (e.g. NewsInEssence[1]) have been developed to group news articles into news topics, and then produce a short summary for each news topic. Users can easily understand the topic they have interest in by taking a look at the short summary, without looking into each individual article within the topic cluster.

[1]http://lada.si.umich.edu:8080/clair/nie1/nie.cgi

Automated multi-document summarization has drawn much attention in recent years. In the communities of natural language processing and information retrieval, a series of workshops and conferences on automatic text summarization (e.g. NTCIR, DUC), special topic sessions in ACL, COLING, and SIGIR have advanced the summarization techniques and produced a couple of experimental online systems.

A particular challenge for multi-document summarization is that a document set might contain diverse information, which is either related or unrelated to the main topic, and hence we need effective summarization methods to analyze the information stored in different documents and extract the globally important information to reflect the main topic. In recent years, both unsupervised and supervised methods have been proposed to analyze the information contained in a document set and extract highly salient sentences into the summary, based on syntactic or statistical features.

Most recently, the graph-based models have been successfully applied for multi-document summarization by making use of the "voting" or "recommendations" between sentences in the documents (Erkan and Radev, 2004; Mihalcea and Tarau, 2005; Wan and Yang, 2006). The model first constructs a directed or undirected graph to reflect the relationships between the sentences and then applies the graph-based ranking algorithm to compute the rank scores for the sentences. The sentences with large rank scores are chosen into the summary. However, the model makes uniform use of the sentences in different documents, i.e. all the sentences are ranked without considering the document-level information and the sentence-to-document relationship. Actually, given a document set, different documents are not equally important. For example, the documents close to the main topics of the document set are usually more important than the documents far away from the main topics of the document set. This document-level information is deemed to have great impact on the sentence ranking process. Moreover, the sentences in the same document cannot be treated uniformly, because some sentences in the document are more important than other sentences because of their different positions in the document or different distances to the document's centroid. In brief, neither the document-level information nor the sentence-to-document relationship has been taken into account in the previous graph-based model.

In order to overcome the limitations of the previous graph-based model, this study proposes the document-based graph model to explore document impact on the graph-based summarization, by incorporating both the document-level information and the sentence-to-document relationship in the graph-based ranking process. We develop various methods to evaluate the document-level information and the sentence-to-document relationship. Experiments on the DUC2001 and DUC2002 datasets have been performed and the results demonstrate the good effectiveness of the proposed model, i.e., the incorporation of document impact can much improve the performance of the graph-based summarization. Moreover, the proposed model is robust with respect to most incorporation schemes.

The rest of this paper is organized as follows. We first introduce the related work in Section 2. The basic graph-based summarization model and the proposed document-based graph model are described in detail in Sections 3 and 4, respectively. We show the experiments and results in Section 5 and finally we conclude this paper in Section 6.

2 Related Work

Generally speaking, summarization methods can be abstractive summarization or extractive summarization. Extractive summarization is a simple but robust method for text summarization and it involves assigning saliency scores to some units (e.g. sentences, paragraphs) of the documents and extracting those with highest scores, while abstraction summarization usually needs information fusion (Barzilay et al., 1999), sentence compression (Knight and Marcu, 2002) and reformulation (McKeown et al., 1999). In this study, we focus on extractive summarization.

The centroid-based method (Radev et al., 2004) is one of the most popular extractive summarization methods. MEAD[2] is an implementation of the centroid-based method that scores sentences based on sentence-level and inter-sentence features, including cluster centroids, position, TFIDF, etc. NeATS (Lin and Hovy, 2002) is a project on multi-document summarization at ISI based on the single-document summarizer-SUMMARIST. Sentence position, term frequency, topic signature and term clustering are used to select important content. MMR (Goldstein et al., 1999) is used to remove redundancy and stigma word filters and time stamps are used to improve cohesion and coherence. To further explore user interface issues, iNeATS (Leuski et al., 2003) is developed based on NeATS. XDoX (Hardy et al., 1998) is a cross document summarizer designed specifically to summarize large document sets. It identifies the most salient themes within the set by passage clustering and then composes an extraction summary, which reflects these main themes. Much other work also explores to find topic themes in the documents for summarization, e.g. Harabagiu and Lacatusu (2005) investigate five different topic representations and introduce a novel representation of topics based on topic themes. In addition, Marcu (2001) selects important sentences based on the discourse structure of the text. TNO's system (Kraaij et al., 2001) scores sentences by combining a unigram language model approach with a Bayesian classifier based on surface features. Nenkova and Louis (2008) investigate how summary length and the characteristics of the input influence the summary quality in multi-document summarization.

Graph-based models have been proposed to rank sentences or passages based on the PageRank algorithm (Page et al., 1998) or its variants. Websumm (Mani and Bloedorn, 2000) uses a graph-connectivity model and operates under the assumption that nodes which are connected to many other nodes are likely to carry salient information. LexPageRank (Erkan and Radev, 2004) is an approach for computing sentence importance based on the concept of eigenvector centrality. It constructs a sentence connectivity matrix and compute sentence importance based on an algorithm similar to PageRank. Mihalcea and Tarau (2005) also propose a similar algorithm based on PageRank to compute sentence importance for document summarization. Wan and Yang (2006) improve the ranking algo-

[2] http://www.summarization.com/mead/

rithm by differentiating intra-document links and inter-document links between sentences. All these methods make use of the relationships between sentences and select sentences according to the "votes" or "recommendations" from their neighboring sentences, which is similar to PageRank.

Other related work includes topic-focused multi-document summarization (Daumé. and Marcu, 2006; Gupta et al., 2007; Wan et al., 2007), which aims to produce summary biased to a given topic or query. It is noteworthy that our proposed approach is inspired by (Liu and Ma, 2005), which proposes the Conditional Markov Random Walk Model based on two-layer web graph in the tasks of web page retrieval.

3 The Basic Graph-Based Model (GM)

The basic graph-based model is essentially a way of deciding the importance of a vertex within a graph based on global information recursively drawn from the entire graph. The basic idea is that of "voting" or "recommendation" between the vertices. A link between two vertices is considered as a vote cast from one vertex to the other vertex. The score associated with a vertex is determined by the votes that are cast for it, and the score of the vertices casting these votes.

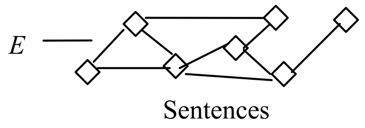

Figure 1. One-layer link graph

Formally, given a document set D, let G=(V, E) be an undirected graph to reflect the relationships between sentences in the document set, as shown in Figure 1. V is the set of vertices and each vertex v_i in V is a sentence in the document set. E is the set of edges. Each edge e_{ij} in E is associated with an affinity weight $f(v_i, v_j)$ between sentences v_i and v_j ($i{\neq}j$). The weight is computed using the standard cosine measure between the two sentences.

$$f(v_i, v_j) = sim_{\cos ine}(v_i, v_j) = \frac{\vec{v}_i \cdot \vec{v}_j}{|\vec{v}_i| \times |\vec{v}_j|} \tag{1}$$

where $\vec{v}_i$ and $\vec{v}_j$ are the corresponding term vectors of v_i and v_j. Here, we have $f(v_i, v_j)$=f(v_j, v_i). Two vertices are connected if their affinity weight is larger than 0 and we let $f(v_i, v_i)$=0 to avoid self transition.

We use an affinity matrix M to describe G with each entry corresponding to the weight of an edge in the graph. $M = (M_{i,j})_{|V|\times|V|}$ is defined as follows:

$$M_{i,j} = \begin{cases} f(v_i, v_j), & \text{if } v_i \text{ and } v_j \text{ is connected} \\ & \text{and } \; i \neq j; \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

Then M is normalized to $\widetilde{M}$ as follows to make the sum of each row equal to 1:

$$\widetilde{M}_{i,j} = \begin{cases} M_{i,j} \Big/ \sum_{j=1}^{|V|} M_{i,j}, & \text{if } \sum_{j=1}^{|V|} M_{i,j} \neq 0 \\ 0 & , \text{ otherwise} \end{cases} \tag{3}$$

Based on matrix $\widetilde{M}$, the saliency score *SenScore*(v_i) for sentence v_i can be deduced from those of all other sentences linked with it and it can be formulated in a recursive form as in the PageRank algorithm:

$$SenScore(v_i) = \mu \cdot \sum_{all\, j \neq i} SenScore(v_j) \cdot \widetilde{M}_{j,i} + \frac{(1-\mu)}{|V|} \tag{4}$$

And the matrix form is:

$$\vec{\lambda} = \mu \widetilde{M}^T \vec{\lambda} + \frac{(1-\mu)}{|V|} \vec{e} \tag{5}$$

where $\vec{\lambda} = [SenScore(v_i)]_{|V|\times 1}$ is the vector of sentence saliency scores. $\vec{e}$ is a vector with all elements equaling to 1. μ is the damping factor usually set to 0.85, as in the PageRank algorithm.

The above process can be considered as a Markov chain by taking the sentences as the states and the corresponding transition matrix is given by $A = \mu \widetilde{M}^T + \frac{(1-\mu)}{|V|} \vec{e}\vec{e}^T$. The stationary probability distribution of each state is obtained by the principal eigenvector of the transition matrix.

For implementation, the initial scores of all sentences are set to 1 and the iteration algorithm in Equation (4) is adopted to compute the new scores of the sentences. Usually the convergence of the iteration algorithm is achieved when the difference between the scores computed at two successive iterations for any sentences falls below a given threshold (0.0001 in this study).

We can see that the basic graph-based model is built on the single-layer sentence graph and the transition probability between two sentences in the Markov chain depends only on the sentences themselves, not taking into account the document-level information and the sentence-to-document relationship.

4 The Document-Based Graph Model (DGM)

4.1 Overview

As we mentioned in previous section, there may be many factors that can have impact on the importance analysis of the sentences. This study aims to examine the document impact by incorporating the document importance and the sentence-to-document correlation into the sentence ranking process. Our assumption is that the sentences, which belong to an important document and are highly correlated with the document, will be more likely to be chosen into the summary.

In order to incorporate the document-level information and the sentence-to-document relationship, the document-based graph model is proposed based on the two-layer link graph including both sentences and documents. The novel representation is shown in Figure 2. As can be seen, the lower layer is just the traditional link graph between sentences that has been well studied in previous work. And the upper layer represents the documents. The dashed lines between these two layers indicate the conditional influence between the sentences and the documents.

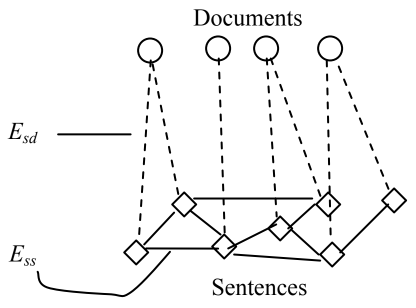

Figure 2. Two-layer link graph

Formally, the new representation for the two-layer graph is denoted as $G^*=<V_s, V_d, E_{ss}, E_{sd}>$, where $V_s=V=\{v_i\}$ is the set of sentences and $V_d=D=\{d_j\}$ is the set of documents; $E_{ss}=E=\{e_{ij}|v_i, v_j\in V_s\}$ includes all possible links between sentences and $E_{sd}=\{e_{ij}|v_i\in V_s, d_j\in V_d$ and $d_j=doc(v_i)\}$ includes the correlation link between any sentence and its belonging document. Here, we use $doc(v_i)$ to denote the document containing sentence v_i. For further discussions, we let $\pi(doc(v_i)) \in[0,1]$ denote the importance of document $doc(v_i)$ in the document set, and let $\omega(v_i, doc(v_i)) \in[0,1]$ denote the strength of the correlation between sentence v_i and its document $doc(v_i)$.

The two factors are incorporated into the affinity weight between sentences and the new sentence-to-sentence affinity weight is denoted as $f(v_i, v_j|doc(v_i), doc(v_j))$, which is conditioned on the two documents containing the two sentences. The new conditional affinity weight is computed by linearly combining the affinity weight conditioned on the first document (i.e. $f(v_i,v_j|doc(v_i))$) and the affinity weight conditioned on the second document (i.e. $f(v_i,v_j|doc(v_j))$).

Formally, the conditional affinity weight is computed as follows to incorporate the two factors:

$$\begin{aligned}
& f(v_i,v_j \mid doc(v_i),doc(v_j)) \\
&= \lambda\cdot f(v_i,v_j \mid doc(v_i)) + (1-\lambda)\cdot f(v_i,v_j \mid doc(v_j)) \\
&= \lambda\cdot f(v_i,v_j)\cdot\pi(doc(v_i))\cdot\omega(v_i,doc(v_i)) \\
&\quad + (1-\lambda)\cdot f(v_i,v_j)\cdot\pi(doc(v_j))\cdot\omega(v_j,doc(v_j)) \\
&= f(v_i,v_j)\cdot(\lambda\cdot\pi(doc(v_i))\cdot\omega(v_i,doc(v_i)) \\
&\quad + (1-\lambda)\cdot\pi(doc(v_j))\cdot\omega(v_j,doc(v_j))) \\
&= sim_{\cos ine}(v_i,v_j)\cdot(\lambda\cdot\pi(doc(v_i))\cdot\omega(v_i,doc(v_i)) \\
&\quad + (1-\lambda)\cdot\pi(doc(v_j))\cdot\omega(v_j,doc(v_j)))
\end{aligned} \tag{6}$$

where $\lambda\in[0,1]$ is the combination weight controlling the relative contributions from the first document and the second document. Note that usually $f(v_i, v_j|doc(v_i), doc(v_j))$ is not equal to $f(v_j, v_i|doc(v_j), doc(v_i))$, but the two scores are equal when λ is set to 0.5. Various methods can be used to evaluate the document importance and the sentence-document correlation, which will be described in next sections.

The new affinity matrix M^* is then constructed based on the above conditional sentence-to-sentence affinity weight.

$$M^*_{i,j} = \begin{cases} f(v_i,v_j \mid doc(v_i),doc(v_j)), & \text{if if } v_i \text{ and } v_j \text{ is connected} \\ & \text{and } i\neq j \\ 0, & \text{otherwise} \end{cases} \tag{7}$$

Likewise, M^* is normalized to $\tilde{M}^*$ and the iterative computation as in Equation (4) is then based on $\tilde{M}^*$. The transition matrix in the Markov chain is then denoted by $A^* = \mu\tilde{M}^{*T} + \frac{(1-\mu)}{|V|}\vec{e}\vec{e}^{\,T}$ and the sentence scores is obtained by the principle eigenvector of the new transition matrix A^*.

4.2 Evaluating Document Importance (π)

The function $\pi(doc(v_i))$ aims to evaluate the importance of document $doc(v_i)$ in the document set D. The following three methods are developed to evaluate the document importance.

***π_1*:** It uses the cosine similarity value between the document and the whole document set as the importance score of the document[3]:

$$\pi_1(doc(v_i)) = sim_{\cos ine}(doc(v_i), D) \quad (8)$$

***π_2*:** It uses the average similarity value between the document and any other document in the document set as the importance score of the document:

$$\pi_2(doc(v_i)) = \frac{\sum_{d' \in D \text{ and } d' \neq doc(v_i)} sim_{\cos ine}(doc(v_i), d')}{|D| - 1} \quad (9)$$

***π_3*:** It constructs a weighted graph between documents and uses the PageRank algorithm to compute the rank scores of the documents as the importance scores of the documents. The link weight between two documents is computed using the cosine measure. The equation for iterative computation is the same with Equation (4).

4.3 Evaluating Sentence-Document Correlation (*ω*)

The function *ω*(v_i, *doc*(v_i)) aims to evaluate the correlation between sentence v_i and its document *doc*(v_i). The following four methods are developed to compute the strength of the correlation. The first three methods are based on sentence position in the document, under the assumption that the first sentences in a document are usually more important than other sentences. The last method is based on the content similarity between the sentence and the document.

***ω_1*:** The correlation strength between sentence v_i and its document *doc*(v_i) is based on the position of the sentence as follows:

$$\omega_1(v_i, doc(v_i)) = \begin{cases} 1 \text{ if } pos(v_i) \leq 3 \\ 0.5 \text{ Otherwise} \end{cases} \quad (10)$$

where *pos*(v_i) returns the position number of sentence v_i in its document. For example, if v_i is the first sentence in its document, *pos*(v_i) is 1.

***ω_2*:** The correlation strength between sentence v_i and its document *doc*(v_i) is based on the position of the sentence as follows:

$$\omega_2(v_i, doc(v_i)) = 1 - \frac{pos(v_i) - 1}{sen\_count(doc(v_i))} \quad (11)$$

where *sen_count*(*doc*(v_i)) returns the total number of sentences in document *doc*(v_i).

***ω_3*:** The correlation strength between sentence v_i and its document *doc*(v_i) is based on the position of the sentence as follows:

$$\omega_3(v_i, doc(v_i)) = 0.5 + \frac{1}{pos(v_i) + 1} \quad (12)$$

***ω_4*:** The correlation strength between sentence v_i and its document *doc*(v_i) is based on the cosine similarity between the sentence and the document:

$$\omega_4(v_i, doc(v_i)) = sim_{\cos ine}(v_i, doc(v_i)) \quad (13)$$

5 Empirical Evaluation

5.1 Dataset and Evaluation Metric

Generic multi-document summarization has been one of the fundamental tasks in DUC 2001[4] and DUC 2002[5] (i.e. task 2 in DUC 2001 and task 2 in DUC 2002), and we used the two tasks for evaluation. DUC2001 provided 30 document sets and DUC 2002 provided 59 document sets (D088 is excluded from the original 60 document sets by NIST) and generic abstracts of each document set with lengths of approximately 100 words or less were required to be created. The documents were news articles collected from TREC-9. The sentences in each article have been separated and the sentence information has been stored into files. The summary of the two datasets are shown in Table 1.

	DUC 2001	**DUC 2002**
Task	Task 2	Task 2
Number of documents	309	567
Number of clusters	30	59
Data source	TREC-9	TREC-9
Summary length	100 words	100 words

Table 1. Summary of datasets

We used the ROUGE (Lin and Hovy, 2003) toolkit (i.e. ROUGEeval-1.4.2 in this study) for evaluation, which has been widely adopted by DUC for automatic summarization evaluation. It measured summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary and the reference summary. ROUGE-N was an n-gram recall measure computed as follows:

$$ROUGE-N = \frac{\sum_{S \in \{\text{Ref Sum}\}} \sum_{n\text{-}gram \in S} Count_{match}(n-gram)}{\sum_{S \in \{\text{Ref Sum}\}} \sum_{n\text{-}gram \in S} Count(n-gram)} \quad (14)$$

[3] A document set is treated as a single text by concatenating all the document texts in the set.

[4] http://www-nlpir.nist.gov/projects/duc/guidelines/2001.html
[5] http://www-nlpir.nist.gov/projects/duc/guidelines/2002.html

where n stood for the length of the n-gram, and $Count_{match}(n\text{-}gram)$ was the maximum number of n-grams co-occurring in a candidate summary and a set of reference summaries. *Count*(*n-gram*) was the number of n-grams in the reference summaries.

ROUGE toolkit reported separate scores for 1, 2, 3 and 4-gram, and also for longest common subsequence co-occurrences. Among these different scores, unigram-based ROUGE score (ROUGE-1) has been shown to agree with human judgment most (Lin and Hovy. 2003). We showed three of the ROUGE metrics in the experimental results: ROUGE-1 (unigram-based), ROUGE-2 (bigram-based), and ROUGE-W (based on weighted longest common subsequence, weight=1.2). In order to truncate summaries longer than length limit, we used the "-l" option in ROUGE toolkit. We also used the "-m" option for word stemming.

5.2 Evaluation Results

In the experiments, the combination weight λ for the proposed summarization model is typically set to 0.5 without tuning, i.e. the two documents for two sentences have equal influence on the summarization process. Note that after the saliency scores of sentences have been obtained, a greedy algorithm (Wan and Yang, 2006) is applied to remove redundancy and finally choose both informative and novel sentences into the summary. The algorithm is actually a variant version of the MMR algorithm (Goldstein et al., 1999).

The proposed document-based graph model (denoted as DGM) with different settings is compared with the basic graph-based Model (denoted as GM), the top three performing systems and two baseline systems on DUC2001 and DUC2002, respectively. The top three systems are the systems with highest ROUGE scores, chosen from the performing systems on each task respectively. The lead baseline and coverage baseline are two baselines employed in the generic multi-document summarization tasks of DUC2001 and DUC2002. The lead baseline takes the first sentences one by one in the last document in the collection, where documents are assumed to be ordered chronologically. And the coverage baseline takes the first sentence one by one from the first document to the last document. Tables 2 and 3 show the comparison results on DUC2001 and DUC2002, respectively. In Table 1, SystemN, SystemP and System T are the top three performing systems for DUC2001. In Table 2, System19, System26, System28 are the top three performing systems for DUC2002. The document-based graph model is configured with different settings (i.e. π_1-π_3, ω_1-ω_4). For example, DGM($\pi_1+\omega_1$) refers to the DGM model with π_1 to evaluate the document importance and ω_1 to evaluate the correlation between a sentence and its document.

System	ROUGE-1	ROUGE-2	ROUGE-W

Lead	0.28684	0.05283	0.09525

Table 3. Comparison results on DUC2002
(* indicates that the improvement over the baseline GM model is statistically significant at 95% confidence level)

Seen from the tables, the proposed document-based graph model with different settings can outperform the basic graph-based model and other baselines over almost all three metrics on both

DUC2001 and DUC2002 datasets. The results demonstrate the good effectiveness of the proposed model, i.e. the incorporation of document impact does benefit the graph-based summarization model. It is interesting that the three methods for computing document importance and the four methods for computing the sentence-document correlation are almost as effective as each other on the DUC2002 dataset. However, π_1 does not perform as well as π_2 and π_3, and ω_1 and ω_4 does not perform as well as ω_2 and ω_3 on the DUC2001 dataset.

In order to investigate the relative contributions from the two documents for two sentences to the summarization performance, we varies the combination weight λ from 0 to 1 and Figures 3-6 show the ROUGE-1 and ROUGE-W curves on DUC2001 and DUC2002 respectively. The similar ROUGE-2 curves are omitted here.

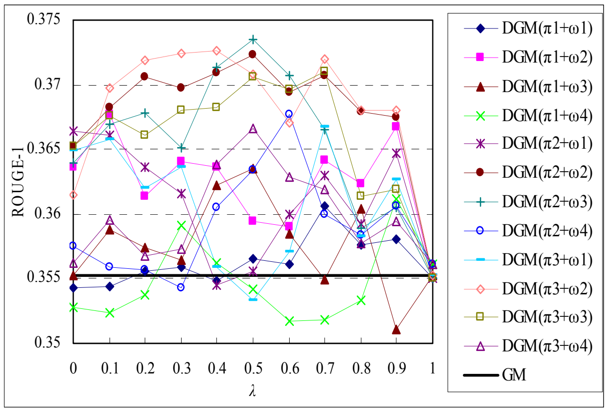

Figure 3. ROUGE-1 vs. λ on DUC2001

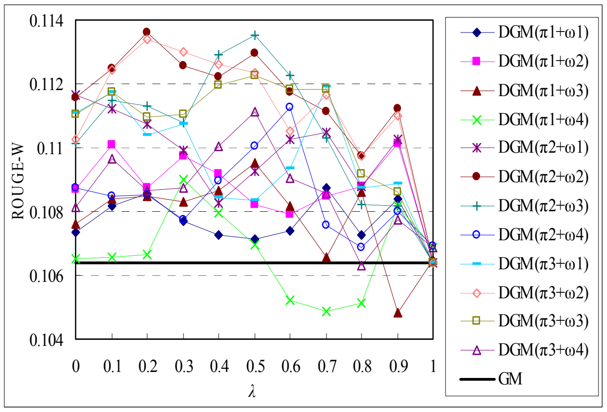

Figure 4. ROUGE-W vs. λ on DUC2001

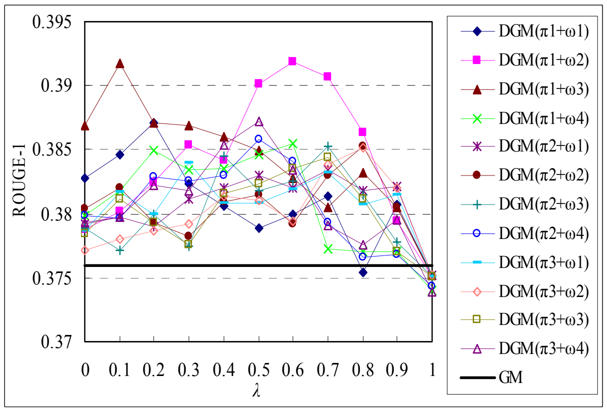

Figure 5. ROUGE-1 vs. λ on DUC2002

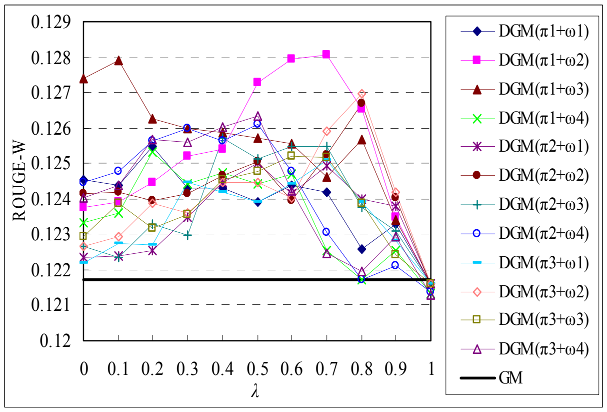

Figure 6. ROUGE-W vs. λ on DUC2002

We can see from the figures that the proposed document-based graph model with different settings can almost always outperform the basic graph-based model, with respect to different values of λ. The results show the robustness of the proposed model. We can also see that for most settings of the propose model, very large values or very small values of λ can deteriorate the summarization performance, i.e. both the first document and the second document in the computation of the conditional affinity weight between sentences have great impact on the summarization performance.

6 Conclusion and Future Work

This paper examines the document impact on the graph-based model for multi-document summarization. The document-level information and the sentence-to-document relationship are incorporated into the graph-based ranking algorithm. The experimental results on DUC2001 and DUC2002 demonstrate the good effectiveness of the proposed model.

In this study, we directly make use of the coarse-grained document-level information. Actually, a document can be segmented into a few subtopic passages by using the TextTiling algorithm (Hearst, 1997), and we believe the subtopic passage is more fine-grained than the original document. In future work, we will exploit this kind of subtopic-level information to further improve the summarization performance.

Topic-Driven Multi-Document Summarization with Encyclopedic Knowledge and Spreading Activation

Vivi Nastase
EML Research gGmbH
Heidelberg, Germany
nastase@eml-research.de

Abstract

Information of interest to users is often distributed over a set of documents. Users can specify their request for information as a query/topic – a set of one or more sentences or questions. Producing a good summary of the relevant information relies on understanding the query and linking it with the associated set of documents. To "understand" the query we expand it using encyclopedic knowledge in Wikipedia. The expanded query is linked with its associated documents through spreading activation in a graph that represents words and their grammatical connections in these documents. The topic expanded words and activated nodes in the graph are used to produce an extractive summary. The method proposed is tested on the DUC summarization data. The system implemented ranks high compared to the participating systems in the DUC competitions, confirming our hypothesis that encyclopedic knowledge is a useful addition to a summarization system.

1 Introduction

Topic-driven summarization reflects a user-based summarization task: from a set of documents derive a summary that contains information on a specific topic of interest to a user. Producing a good summary relies on "understanding" the user's information request, and the documents to be summarized. It is commonly agreed that the verbal part of a text provides pointers to a much larger body of knowledge we assume the listener has. An American citizen, for example, when told *There will be fireworks on July 4^{th}*, understands that there will be a celebration involving fireworks on the occasion of the U.S. Independence Day. Understanding an utterance implies lexical, common-sense and encyclopedic knowledge. Lexical knowledge is usually incorporated in systems through machine readable dictionaries, wordnets or thesauri. Common-sense and encyclopedic knowledge were harder to capture, but recently Wikipedia has opened the possibility of accessing such knowledge on a large scale, and in numerous languages.

To "understand" a user's information request – one or more sentences or questions (the *topic* of the summary) – summarization systems try to expand it. This will provide later stages of processing with more keywords/keyphrases for retrieving from the documents relevant fragments. In this paper we experiment with Wikipedia for topic expansion. The body of research involving Wikipedia as a source of knowledge is growing fast, as the NLP community finds more and more applications of this useful resource: it is used to acquire knowledge (Suchanek et al., 2007; Auer et al., 2007); to induce taxonomies and compute semantic relatedness (Ponzetto & Strube, 2007b; 2007a); as a source of features for text classification (Gabrilovich & Markovitch, 2006) and for answering questions (Ahn et al., 2004; Katz et al., 2005). The work presented here uses hyperlinks in Wikipedia articles to expand keywords and keyphrases extracted from the query. Ambiguous words are disambiguated using the context provided by the query.

"Understanding" the documents to be summarized implies identifying the entities mentioned, how they are connected, and how they are related to the entities in the topic. For this, we start again from the topic, and spread an activation signal in a large graph that covers all documents for this topic – nodes are words/named entities in the texts, links are grammatical relations. This way we cross from the topic to the documents, and combine information which is important in the topic with information which is important and relevant in the documents. We take the most highly activated nodes as additional topic expansions, and produce an extractive summary by choosing from the sentences that connect the topic expansion words in the large document graph.

The experiments confirm that Wikipedia is a source of useful knowledge for summarization, and that further expanding the topic within the associated set of documents improves the summarization results even more. We compare the performance of the summarization system to that of participating systems in the DUC competitions. The system we describe ranks 2^{nd}, 9^{th} and 5^{th} in terms of ROUGE-SU4 on the DUC 2005, DUC 2006 and DUC 2007 data respectively.

2 Related Work

While the recent exponential increase in the amount of information with which we must cope makes summarization a very desirable tool in the present, summarization is not a novel task. Rath et al. (1961) and Edmundson (1969) have explored extractive summary formation, and have raised important evaluation issues for extractive summaries when compared to several human produced gold standards. Nowadays, summarization methods try to incorporate tools, methodologies and resources developed over the past decades. The NIST organized competitions under the Document Understanding Conferences – DUC (since 2008, Text Analysis Conference (TAC))[1] events provide a forum for the comparison of a variety of approaches, ranging from knowledge poor – Gotti et al. (2007) rely exclusively on a parser, without any additional sources of information – to knowledge rich and complex – GISTexter (Hickl et al., 2007) combines question answering, textual entailment, topic signature modules and a variety of knowledge sources for summarization.

[1]`http://duc.nist.gov/`, `http://www.nist.gov/tac`.

The most frequently used knowledge source in NLP in general, and also for summarization, is WordNet (Fellbaum, 1998). Barzilay & Elhadad (1999) use WordNet to model a text's content relative to a topic based on lexical chains. The sentences intersected by the most and strongest chains are chosen for the extractive summary. Alternative sources for query expansion and document processing have also been explored. Amini & Usunier (2007) use the documents to be summarized themselves to cluster terms, and thus expanding the query "internally". More advanced methods for query expansion use "topic signatures" – words and grammatically related pairs of words that model the query and even the expected answer from sets of documents marked as relevant or not (Lin & Hovy, 2000; Harabagiu, 2004).

Graph-based methods for text summarization work usually at the level of sentences (Erkan & Radev, 2004; Mihalcea & Tarau, 2004). Edge weights between sentences represent a similarity measure, and a PageRank algorithm is used to determine the sentences that are the most salient from a collection of documents and closest to a given topic. At the word level, Leskovec et al. (2004) build a document graph using subject-verb-object triples, semantic normalization and coreference resolution. They use several methods (node degree, PageRank, Hubs, etc.) to compute statistics for the nodes in the network, and use these as attribute values in a machine learning algorithm, where the attribute that is learned is whether the node should appear in the final summary or not. Annotations for training come from human produced summaries. Mohamed & Rajasekaran (2006) incrementally build a graph for a document collection by combining graph-representations of sentences. Links between entities in a sentence can be *isa* (within an NP) or *related_to* (between different phrases in a sentence). Nodes and relations are weighted according to their connectivity, and sentence selection for the final summary is based on the most highly connected nodes. Ye & Chua (2006) build an extractive summary based on a concept lattice, which captures in a hierarchical structure co-occurrences of concepts among sentences. Nodes higher in this structure correspond to frequently co-occurring terms, and are

assumed to be more representative with respect to the document topic.

Mani & Bloedorn (1999) build a "chronological" graph, in which sentence order is respected and each occurrence of a concept is a separate node. Edges between nodes cover several types of relations: adjacency (ADJ); identity – instance of the same word (SAME); other semantic links, in particular synonymy and hypernymy; PHRASE links connect components of a phrase; NAME indicate named entities; COREF link coreferential name instances. Among other things, they identify regions of the text salient to a user's query, based on spreading activation starting from query words in this document graph. Spreading activation was introduced in the 60s and 70s to model psychological processes of memory activation in humans (Quillian, 1967; Collins & Loftus, 1975).

In this approach we use Wikipedia as a source of knowledge for related concepts – the texts of hyperlinks in an article describing a concept are taken as its related concepts. The query is further expanded by using spreading activation to move away from the topic in a large graph that covers all documents for a given topic. From the nodes thus reached we select using a PageRank algorithm the ones that are most important in the documents. We study the impact of a decay parameter which controls how far to move from the topic, and the number of highest ranked nodes to be added to the expanded topic. The summary is built based on word associations in the documents' graph.

3 Topic Expansion with Encyclopedic Knowledge or WordNet

In DUC topic-driven multi-document summarization, the topic has a title, an ID that links it to a set of documents, and one or more sentences and/or questions, as illustrated in Figure 1.

Topic processing is done in several steps:

1. Preprocessing: Produce the dependency pair representation of the topics using the Stanford Parser[2]. Pairs that have closed-class words are filtered out, and the remaining words are lemmatized[3]. We extract named entities (NEs), as the parser works at the word level. In the dependency pairs we replace an NE's fragments with the complete NE.

2a. Query expansion with Wikipedia: Extract all open-class words and NEs from the topic, and expand them using Wikipedia articles whose titles are these words or phrases.

For each Wikipedia article we extract as related concepts the texts of the hyperlinks in the first paragraph (see Figure 2[4]). The reason for not including links from the entire article body is that apart from the first paragraph, which is more focused, often times hyperlinks are included whenever the underlying concept appears in Wikipedia, without it being

Mining

Mining is the extraction of valuable minerals or other geological materials from the earth, usually (but not always) from an ore body, vein or (coal) seam. Materials recovered by mining include bauxite, coal, copper, gold, silver, diamonds, iron, precious metals, lead, limestone, magnesite, nickel, phosphate, oil shale, rock salt, tin, uranium and molybdenum . Any material that cannot be grown from agricultural processes, or created artificially in a laboratory or factory , is usually mined. Mining in a wider sense comprises extraction of any non-renewable resource (e.g. petroleum, natural gas ,or even water).

```
'''Mining''' is the extraction of [[value

Mining in a wider sense comprises extraction of any
[[non-renewable resource]] (e.g., [[petroleum]],
[[natural gas]], or even [[fossil water|water]]).
```

Extracted related concepts for *mining*:

value (economics), valuable, mineral, geology, geological, ore, vein (geology), vein, coal, bauxite, copper, gold, silver, diamond, iron, precious metal, lead, limestone, magnesite, nickel, phosphate, oil shale, Sodium chloride, rock salt, agriculture, agricultural, Chemical synthesis, artificially, laboratory, factory, non-renewable resource, petroleum, natural gas, fossil water, water.

Figure 2: First paragraph for article *Mining* in the English Wikipedia, and the extracted related concepts.

Word	Wikipedia expansion	WordNet expansion
mining	lead, agricultural, mineral, gold, ore, petroleum, nickel, iron, coal, tin, value, copper, water, bauxite, silver, diamond	production
flight	lift, air	pass, trip, lam, overflight, ballooning, nonstop flight, aviation, soaring, air, flying, solo, break, escape
status	registered	way, situation, mode, position, place, par, need, light, danger, health, state, standing, face, rank, demand, command, control
Southern Poverty Law Center	racism, American, United States, research, civil rights, litigation	–

Table 1: Expanded concepts from DUC 2007 topics, after filtering based on the documents to be summarized.

particularly relevant to the current article.

To expand a word (or NE) W from the query, we search for an article having W as the title, or part of the title.

1. If one exact match is found (e.g. Southern Poverty Law Center), extract the related concepts for this article.

2. If several exact or partial matches are found, use the larger context of the query to narrow down to the intended meaning. For example, *Turkey* – referring to the country – appears in several topics in the DUC 2007 data. There are multiple entries for "Turkey" in Wikipedia – for the country, the bird, cities with this name in the U.S. among others. We use a Lesk-like measure, and compute the overlap between the topic query and the set of hyperlinks in the first paragraph (Lesk, 1986). We choose the expansion for the entry with the highest overlap. If the query context does not help in disambiguation, we use the expansions for all partial matches that tie for the highest overlap.

3. If an article with the required name does not exist, the word will not be expanded.

2b. Query expansion with WordNet: Extract all nouns and NEs from the topic, and expand them with hypernyms, hyponyms and antonyms in WordNet 2.0:

1. If an word (or NE) W from the query corresponds to an unambiguous entry in WordNet, expand that entry.

2. If W has multiple senses, choose the sense(s) which have the highest overlap with the query. To compute overlap, for a sense we take its expansions (one step hypernyms, hyponyms and antonyms) and the words from the definition.

3. If W has no senses in WordNet, the word will not be expanded.

3. Expansion filtering: Filter the list of related concepts: keep only terms that appear in the document collection for the current topic.

Table 1 includes the expansions obtained from Wikipedia and from WordNet respectively for a number of words in topics from the DUC 2007 collection. *mining* is a specific activity, involving a limited set of materials. While such connections cannot be retrieved through hypernym, meronym or other semantic relations in WordNet, they are part of encyclopedic knowledge, and can be found in Wikipedia. *flight* is a more general concept – there are specific types of flight, which appear as hyponyms in WordNet, while in Wikipedia it is more generally described as the motion of an object through air, which does not provide us with interesting related concepts. *status* is a very general concept, and rather vague, for which neither WordNet nor Wikipedia can provide very useful information. Finally, Wikipedia is rich in named entities, which are not in the scope of a semantic lexicon. WordNet does contain named entities, but not on the scale on which Wikipedia does.

For the 45 topics from DUC 2007, the expansion with Wikipedia generated 1054 additional words, while with WordNet 2510. This difference comes from the fact that with Wikipedia it is mostly the NEs that are expanded, whereas with WordNet the common nouns, which are more numerous in the topics. The overlap between the two sets of expansions is 48 words (0.046 relative to Wikipedia expansions, 0.019 relative to WordNet).

4 Topic Expansion with Spreading Activation and PageRank

Concepts related to the ones in the topic provide a good handle on the documents to summarize – they indicate parts of the document that should be included in the summary. It is however obvious that the summary should contain more than that, and this information comes from the documents to be summarized. Amini & Usunier (2007) have shown that expanding the query within the set of documents leads to good results. Following this idea, to find more relevant concepts we look for words/NEs which are related to the topic, and at the same time important in the collection of documents for the given topic. The methods described in this section are applied on a large graph that covers the entire document collection for one topic. The documents are processed in a similar way to the query – parsed with the Stanford Parser, output in dependency relation format, lemmatized using XTag's morphological data file. The graph consists of nodes corresponding to lemmatized words and NEs in the documents, and edges correspoding to grammatical dependency relations.

4.1 Spreading Activation

To find words/NEs related to the topic we spread an activation signal starting from the topic words and their expansions (in a manner similar to (Mani & Bloedorn, 1999), and using an algorithm inspired by (Anderson, 1983)), which are given a node weight of 1. As we traverse the graph starting from these nodes, the signal is propagated by assigning a weight to each edge and each node traversed based on the signal strength. The signal strength diminishes with the distance from the node of origin depending on a signal decay parameter, according to the formula:

$$\begin{aligned} w_n(N_0) &= 1; \\ s_t &= (1 - decay) * \frac{w_n(N_t)}{Out(N_t)}; \\ w_n(N_{t+1}) &= s_t; \\ w_e(N_t, N_{t+1})_{t+1} &= w_e(N_t, N_{t+1})_t + s_t; \end{aligned}$$

where N_t is the current node; N_{t+1} is the node we are moving towards; $w_n(N_t)$ is the weight of node N_t; s_t is the signal strength at step t; $Out(N_t)$

Table 2: Top ranked nodes after expanding the topic with spreading activation and PageRank

is the number of outgoing edges from node N_t; $w_e(N_t, N_{t+1})_t$ is the weight of the edge between N_t and N_{t+1} at time t (i.e., before actually traversing the edge and spreading the activation from N_t); $w_e(N_t, N_{t+1})_{t+1}$ is the weight of the edge after spreading activation. The weight of the edges is cumulative, to gather strength from all signals that pass through the edge. Activation is spread sequentially from each node in the (expanded) topic.

The $decay$ parameter is used to control how far the influence of the starting nodes should reach – the lower the decay, the farther the signal can reach.

4.2 PageRank

The previous step has assigned weights to edges in the graph, such that higher weights are closer to topic and/or topic expanded words. After this initialization of the graph, we run a PageRank algorithm (Brin & Page, 1998) to determine more important nodes. By running this algorithm after initializing the graph edge weights, from the nodes that are closer to topic and topic expanded words we boost those that are more important in the documents.

The starting point of the PageRank algorithm is the graph with weighted edges obtained in the previous step. The node weights are initialized with 1 (the starting value does not matter). Analysis of the documents graph for several topics has revealed that there is a large highly interconnected structure, and many disconnected small (2-3 nodes) fragments. Page Rank will run on this dense core structure. The PageRank algorithm is guaranteed to converge if the graph is aperiodic and irreducible (Grimmett & Stirzaker, 1989). Aperiodicity implies that the greatest common divisor of the graph's cycles is 1 – this condition is met. Irreducibility of the graph means that it has no leaves, and there are no two nodes with the same set of neighbours. The remedy in such cases is to connect each leaf to all other nodes in the graph, and conflate nodes with the same set of neighbours.

Once the graph topology meets the PageRank convergence conditions, we run the algorithm. The original formula for computing the rank of a node at each iteration step is:

$$PR(n_i) = \frac{1-d}{N} + d \sum_{n_j \in Adj_{n_i}} \frac{PR(n_j)}{Out(n_j)}$$

where n_i is a node, d is the damping factor (usually $d = 0.85$ and this is the value we use as well), N is the number of nodes in the graph, $PR(n_i)$ is the rank of node n_i, Adj_{n_i} is the set of nodes adjacent to n_i, and $Out(n_j)$ is the number of outgoing edges from n_j (our graph is non-directed, so this number is the total number of edges with one end in n_j). We adjust this formula to reflect the weights of the edges, and the version used is the following:

$$PR(n_i) = \frac{1-d}{N} + d \sum_{n_j \in Adj_{n_i}} PR(n_j) w_{out}(n_j);$$

Table 3: Comparison of topic expansion methods with 95% confidence intervals.

$$w_{out}(n_j) = \sum_{n_k \in Adj_{n_j}} w_e(n_k, n_j)$$

In Table 2 we show examples of top ranked nodes for several topics, extracted with this algorithm. The words in italics are keywords/phrases from the topic query, and the top ranked nodes are listed in decreasing order of their rank.

5 Summarization

The summarization method implemented is based on the idea that the entities or events mentioned in the query are somehow connected to each other, and the documents to be summarized contain information that allows us to make these connections. We use again the graph for all the documents in the collection related to one topic, built using the dependency relation representation of the texts. The nodes in this graph are words/NEs, and the links are grammatical relations.

We extract from this graph the subgraph that covers connections between all open class words/NEs in the topic or expanded topic query. Each edge in the extracted subgraph corresponds to a grammatical relation in a sentence of a document. We collect all sentences thus represented in the subgraph, and rerank them based on the number of edges they cover, and the occurrence of topic or expanded topic terms. We use the following formula to compute a sentence score:

$$\begin{aligned} Score(S) &= topicWords * w_{word} \\ &+ expandedWords * w_{expandedWord} \\ &+ topRankedWords * w_{topRankedWord} \\ &+ edgesCovered * w_{subgraphEdge} \\ &+ depRelation * w_{depRelation} \end{aligned}$$

w_{word}, $w_{expandedWord}$, $w_{topRankedWord}$, $w_{subgraphEdge}$ and $w_{depRelation}$ are weight parameters that give different importance to exact words from the topic, expanded words, top ranked words and edges covered in the extracted subgraph. During all experiments these parameters are fixed.[5]

To form the summary we traverse the ranked list of sentences starting with the highest ranked one, and add sentences to a summary, or delete from the existing summary, based on a simple lexical overlap measure. We stop when the desired summary length is reached – for DUC 2005–2007, 250 words (last sentence may be truncated to fill the summary up to the allowed word limit).

6 Evaluation

Experiments are run on DUC 2007 main summarization task data, for the last experiment we used the DUC 2005 and DUC 2006 data as well. Performance is evaluated in terms of ROUGE-2, ROUGE-SU4 and BE recall, following the methodology and using the same parameters as in the DUC summarization events.

We analyze several types of topic expansion: no expansion, WordNet, Wikipedia, and within document collection expansion using spreading activation and Page Rank. The spreading activation method has several parameters whose values must be determined.

We first compare the summaries produced with no topic expansion, WordNet (WN) and Wikipedia (Wiki) respectively. Table 3 shows the results in terms of ROUGE and BE recall on the DUC 2007 (main) data. Word sense disambiguation (WSD) for expansion with WordNet did not work very well, as evidenced by the lower results for disambiguated expansion (WN with WSD) compared to the non-

[5]The values used were set following a small number of experiments on DUC 2007 data, as the purpose was not to tune the system for best performance, but rather to study the impact of more interesting parameters, in particular expansion type, decay and node ranking. The values used are the following: $w_{word} = 5$, $w_{expandedWord} = 2.5$, $w_{topRankedWord} = 0.5$, $w_{subgraphEdge} = 2$, $w_{depRelation} = 0$.

disambiguated one. A better disambiguation algorithm may reverse the situation. Expanding a topic only with Wikipedia hyperlinks gives the best results. At the document level, the results are not as clear cut. Figure 3 shows a comparison in terms of ROUGE-SU4 recall scores at the document level of the Wikipedia and WN (no WSD) expansion methods, sorted in increasing order of the Wikipedia-based expansion scores. The points are connected to allow the reader to follow the results for each method.

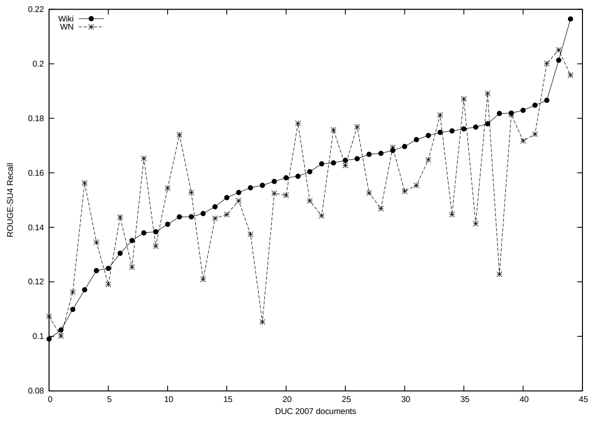

Figure 3: Comparison of Wikipedia and WN ROUGE-SU4 per-document recall results.

Because the overlap between Wikipedia and WordNet expanded queries was very low, we expected the two types of expansion to be complementary, and the combination to give better results than either expansion by itself. An analysis of results for each document with the three expansion methods – Wikipedia, WordNet, and their combination – showed that the simple combination of the expanded words cannot take advantage of the situations when one of the two methods performs better. In future work we will explore how to detect, based on the words in the query, which type of expansion is best, and how to combine them using a weighting scheme.

We choose the best configuration from above (Wikipedia expansion), and further expand the query through spreading activation and PageRank. This new type of expansion has two main parameters which influence the summarization outcome: number of top ranked nodes to add to the topic expansion, and the decay of the spreading activation algorithm.

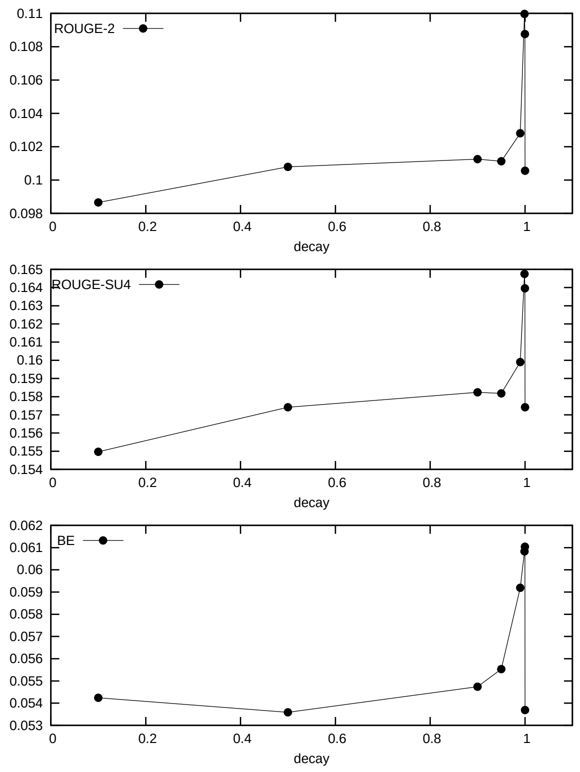

Figure 4: Impact of signal decay in spreading activation on summarization performance.

The decay parameter determines how far the influence of the starting nodes (words from query or Wikipedia-expanded query) should be felt. The results in Figure 4 – for decay values 0.1, 0.5, 0.95, 0.99, 0.999, 0.9999, 1 – indicate that faster decay (reflected through a higher decay value) keeps the summary more focused around the given topic, and leads to better results.[6] For a high enough decay – and eventually a decay of 1 – the weights of the edges become extremely small, and due to real number representation in memory, practically 0. In this situation PageRank has no effect, and all nodes have the same rank.

We fix the decay parameter to 0.9999, and we study the impact of the number of top nodes chosen after ranking with PageRank. Figure 5 shows the results when the number of top ranked nodes chosen varies. Adding highly ranked nodes benefits the performance of the system only up to a certain limit.

[6]During this set of experiments all other parameters are fixed, the number of top ranked nodes added to the topic expansion is 30.

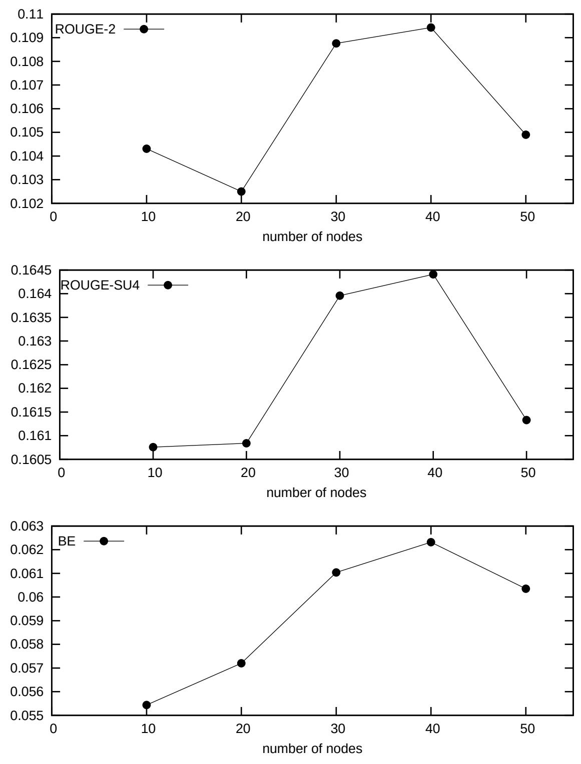

Figure 5: Impact of the number of top ranked nodes added to the expanded topic on summarization performance.

From the values we tested, the best results were obtained when adding 40 nodes to the expanded topic.

The best system configuration from the ones explored[7] is run on the DUC 2005, 2006 and 2007 (main) data. The performance and rank (in parentheses) compared to participating systems is presented in Table 4.

DUC	ROUGE-2	ROUGE-SU4	BE
2005 (32)	0.07074 (3)	0.13002 (2)	–
2006 (35)	0.08091 (11)	0.14022 (9)	0.04223 (11)
2007 (32)	0.11048 (6)	0.16479 (5)	0.06250 (5)

Table 4: System performance (and rank) on the DUC 2005, 2006 and 2007 (main) data. The number in parenthesis after the DUC year indicates the number of competing systems.

[7]Wikipedia expansion + 40 top nodes after spreading activation and PageRank, decay = 0.9999, $w_{expandedWord} = 3.5$, $w_{depRelation} = 1$, the other parameters have the same values as before.

7 Conclusions

The experiments conducted within the summarization framework of the Document Understanding Conference have confirmed that encyclopedic knowledge extracted from Wikipedia can benefit the summarization task. Wikipedia articles are a source of relevant related concepts, that are useful for expanding a summarization query. Furthermore, including information from the documents to be summarized by choosing relevant concepts – based on closeness to topic keywords and relative importance – improves even more the quality of the summaries, judged through ROUGE-2, ROUGE-SU4 and BE recall scores, as it is commonly done in the DUC competitions. The topic expansion methods explored lead to high summarization performance – ranked 2^{nd}, 9^{th} and 5^{th} on DUC 2005, 2006 and 2007 respectively according to ROUGE-SU4 scores – compared to (more than 30) DUC participating systems.

The graph representation of the documents is central to the summarization method we described. Because of this, we plan to improve this representation by collapsing together coreferential nodes and clustering together related concepts, and verify whether such changes impact the summarization results, as we expect they would.

Being able to move away from the topic within the set of documents and discover new relevant nodes is an important issue, especially from the point of view of a new summarization style – updates. In update summaries the starting point is a topic, which a summarization system must track in consecutive sets of documents. We can adjust the spreading activation parameters to how far a new set of documents is from the topic. Future work includes testing the spreading activation and page ranking method in the context of the update summarization task and exploring methods of extracting related concepts from the full text of Wikipedia articles.

Summarizing Spoken and Written Conversations

Gabriel Murray and **Giuseppe Carenini**
Department of Computer Science
University of British Columbia
Vancouver, BC V6T 1Z4 Canada

Abstract

In this paper we describe research on summarizing conversations in the meetings and emails domains. We introduce a conversation summarization system that works in multiple domains utilizing general conversational features, and compare our results with domain-dependent systems for meeting and email data. We find that by treating meetings and emails as conversations with general conversational features in common, we can achieve competitive results with state-of-the-art systems that rely on more domain-specific features.

1 Introduction

Our lives are increasingly comprised of multimodal conversations with others. We email for business and personal purposes, attend meetings in person and remotely, chat online, and participate in blog or forum discussions. It is clear that automatic summarization can be of benefit in dealing with this overwhelming amount of interactional information. Automatic meeting abstracts would allow us to prepare for an upcoming meeting or review the decisions of a previous group. Email summaries would aid corporate memory and provide efficient indices into large mail folders.

When summarizing in each of these domains, there will be potentially useful domain-specific features – e.g. prosodic features for meeting speech, subject headers for emails – but there are also underlying similarites between these domains. They are all multiparty conversations, and we hypothesize that effective summarization techniques can be designed that would lead to robust summarization performance on a wide array of such conversation types. Such a general conversation summarization system would make it possible to summarize a wide variety of conversational data without needing to develop unique summarizers in each domain and across modalities. While progress has been made in summarizing conversations in individual domains, as described below, little or no work has been done on summarizing unrestricted, multimodal conversations.

In this research we take an extractive approach to summarization, presenting a novel set of conversational features for locating the most salient sentences in meeting speech and emails. We demonstrate that using these conversational features in a machine-learning sentence classification framework yields performance that is competitive or superior to more restricted domain-specific systems, while having the advantage of being portable across conversational modalities. The robust performance of the conversation-based system is attested via several summarization evaluation techniques, and we give an in-depth analysis of the effectiveness of the individual features and feature subclasses used.

2 Related Work on Meetings and Emails

In this section we give a brief overview of previous research on meeting summarization and email summarization, respectively.

2.1 Meeting Summarization

Among early work on meeting summarization, Waibel et al. (1998) implemented a modified version of the Maximal Marginal Relevance algorithm (Carbonell and Goldstein, 1998) applied to speech transcripts, presenting the user with the *n* best sentences in a meeting browser interface. Zechner (2002) investigated summarizing several genres of speech, including spontaneous meeting speech. Though relevance detection in his work relied largely on *tf.idf* scores, Zechner also explored cross-speaker information linking and question/answer detection.

More recently, researchers have investigated the utility of employing speech-specific features for summarization, including prosodic information. Murray et al. (2005a; 2005b) compared purely textual summarization approaches with feature-based approaches incorporating prosodic features, with human judges favoring the feature-based approaches. In subsequent work (2006; 2007), they began to look at additional speech-specific characteristics such as speaker status, discourse markers and high-level meta comments in meetings, i.e. comments that refer to the meeting itself. Galley (2006) used skip-chain Conditional Random Fields to model pragmatic dependencies between paired meeting utterances (e.g. QUESTION-ANSWER relations), and used a combination of lexical, prosodic, structural and discourse features to rank utterances by importance. Galley found that while the most useful single feature class was *lexical* features, a combination of acoustic, durational and structural features exhibited comparable performance according to Pyramid evaluation.

2.2 Email Summarization

Work on email summarization can be divided into summarization of individual email messages and summarization of entire email threads. Muresan et al. (2001) took the approach of summarizing individual email messages, first using linguistic techniques to extract noun phrases and then employing machine learning methods to label the extracted noun phrases as salient or not. Corston-Oliver et al. (2004) focused on identifying speech acts within a given email, with a particular interest in task-related sentences.

Rambow et al. (2004) addressed the challenge of summarizing entire threads by treating it as a binary sentence classification task. They considered three types of features: basic features that simply treat the email as text (e.g. *tf.idf*, which scores words highly if they are frequent in the document but rare across all documents), features that consider the thread to be a sequence of turns (e.g. the position of the turn in the thread), and email-specific features such as number of recipients and subject line similarity.

Carenini et al. (2007) took an approach to thread summarization using the Enron corpus (described below) wherein the thread is represented as a fragment quotation graph. A single node in the graph represents an *email fragment*, a portion of the email that behaves as a unit in a fine-grain representation of the conversation structure. A fragment sometimes consists of an entire email and sometimes a portion of an email. For example, if a given email has the structure

A
$>$ B
C

where B is a quoted section in the middle of the email, then there are three email fragments in total: two new fragments A and C separated by one quoted fragment B. Sentences in a fragment are weighted according to the Clue Word Score (CWS) measure, a lexical cohesion metric based on the recurrence of words in parent and child nodes. In subsequent work, Carenini et al. (2008) determined that subjectivity detection (i.e., whether the sentence contains sentiments or opinions from the author) gave additional improvement for email thread summaries.

Also on the Enron corpus, Zajic et al. (2008) compared Collective Message Summarization (CMS) to Individual Message Summarization (IMS) and found the former to be a more effective technique for summarizing email data. CMS essentially treats thread summarization as a multi-document summarization problem, while IMS summarizes individual emails in the thread and then concatenates them to form a thread summary.

In our work described below we also address the task of thread summarization as opposed to summarization of individual email messages, following Carenini et al. and the CMS approach of Zajic et al.

3 Experimental Setup

In this section we describe the classifier employed for our machine learning experiments, the corpora used, the relevant summarization annotations for each corpus, and the evaluation methods employed.

3.1 Statistical Classifier

Our approach to extractive summarization views sentence extraction as a classification problem. For all machine learning experiments, we utilize logistic regression classifiers. This choice was partly motivated by our earlier summarization research, where logistic regression classifiers were compared alongside support vector machines (SVMs) (Cortes and Vapnik, 1995). The two classifier types yielded very similar results, with logistic regression classifiers being much faster to train and thus expediting further development.

The *liblinear* toolkit [1] implements simple feature subset selection based on the F statistic (Chen and Lin, 2006) .

3.2 Corpora Description

For these experiments we utilize two corpora, the Enron corpus for email summarization and the AMI corpus for meeting summarization.

3.2.1 The Enron Email Corpus

The Enron email corpus[2] is a collection of emails released as part of the investigation into the Enron corporation (Klimt and Yang, 2004). It has become a popular corpus for NLP research (e.g. (Bekkerman et al., 2004; Yeh and Harnly, 2006; Chapanond et al., 2005; Diesner et al., 2005)) due to being realistic, naturally-occurring data from a corporate environment, and moreover because privacy concerns mean that there is very low availability for other publicly available email data.

39 threads have been annotated for extractive summarization, with five annotators assigned to each thread. The annotators were asked to select 30% of the sentences in a thread, subsequently labeling each selected sentence as either ’essential’ or ’optional.’ Essential sentences are weighted three times as highly as optional sentences. A sentence score, or GSValue, can therefore range between 0 and 15, with the maximum GSValue achieved when all five annotators consider the sentence essential, and a score of 0 achieved when no annotator selects the given sentence. For the purpose of training a binary classifier, we rank the sentences in each email thread according to their GSValues, then extract sentences until our summary reaches 30% of the total thread word count. We label these sentences as positive instances and the remainder as the negative class. Approximately 19% of sentences are labeled as positive, extractive examples.

Because the amount of labeled data available for the Enron email corpus is fairly small, for our classification experiments we employ a leave-one-out proceedure for the 39 email threads. The labeled data as a whole total just under 1400 sentences.

3.2.2 The AMI Meetings Corpus

For our meeting summarization experiments, we use the *scenario* portion of the AMI corpus (Carletta et al., 2005). The corpus consists of about 100 hours of recorded and annotated meetings. In the scenario meetings, groups of four participants take part in a series of four meetings and play roles within a fictitious company. While the scenario given to them is artificial, the speech and the actions are completely spontaneous and natural. There are 96 meetings in the training set, 24 in the development set, and 20 meetings for the test set.

For this corpus, annotators wrote abstract summaries of each meeting and extracted transcript dialogue act segments (DAs) that best conveyed or supported the information in the abstracts. A many-to-many mapping between transcript DAs and sentences from the human abstract was obtained for each annotator, with three annotators assigned to each meeting. It is possible for a DA to be extracted by an annotator but not linked to the abstract, but for training our binary classifiers, we simply consider a dialogue act to be a positive example if it is linked to a given human summary, and a negative example otherwise. This is done to maximize the likelihood that a data point labeled as “extractive” is truly an informative example for training purposes. Approximately 13% of the total DAs are ultimately labeled

[1]http://www.csie.ntu.edu.tw/˜cjlin/liblinear/

[2]http://www.cs.cmu.edu/˜enron/

as positive, extractive examples.

The AMI corpus contains automatic speech recognition (ASR) output in addition to manual meeting transcripts, and we report results on both transcript types. The ASR output was provided by the AMI-ASR team (Hain et al., 2007), and the word error rate for the AMI corpus is 38.9%.

3.3 Summarization Evaluation

For evaluating our extractive summaries, we implement existing evaluation schemes from previous research, with somewhat similar methods for meetings versus emails. These are described and compared below. We also evaluate our extractive classifiers more generally by plotting the receiver operator characteristic (ROC) curve and calculating the area under the curve (AUROC). This allows us to gauge the true-positive/false-positive ratio as the posterior threshold is varied.

We use the differing evaluation metrics for emails versus meetings for two primary reasons. First, the differing summarization annotations in the AMI and Enron corpora naturally lend themselves to slightly divergent metrics, one based on extract-abstract links and the other based on the essential/option/uninformative distinction. Second, and more importantly, using these two metrics allow us to compare our results with state-of-the-art results in the two fields of speech summarization and email summarization. In future work we plan to use a single evaluation metric.

3.3.1 Evaluating Meeting Summaries

To evaluate meeting summaries we use the weighted f-measure metric (Murray et al., 2006). This evaluation scheme relies on the multiple human annotated summary links described in Section 3.2.2. Both weighted precision and recall share the same numerator

$$num = \sum_{i=1}^{M} \sum_{j=1}^{N} L(s_i, a_j) \qquad (1)$$

where $L(s_i, a_j)$ is the number of links for a DA s_i in the machine extractive summary according to annotator a_i, M is the number of DAs in the machine summary, and N is the number of annotators. Weighted precision is defined as:

$$precision = \frac{num}{N \cdot M} \qquad (2)$$

and weighted recall is given by

$$recall = \frac{num}{\sum_{i=1}^{O} \sum_{j=1}^{N} L(s_i, a_j)} \qquad (3)$$

where O is the total number of DAs in the meeting, N is the number of annotators, and the denominator represents the total number of links made between DAs and abstract sentences by all annotators. The weighted f-measure is calculated as the harmonic mean of weighted precision and recall. The intuition behind weighted f-score is that DAs that are linked multiple times by multiple annotators are the most informative.

3.3.2 Evaluating Email Summaries

For evaluating email thread summaries, we follow Carenini et al. (2008) by implementing their *pyramid precision* scheme, inspired by Nenkova's pyramid scheme (2004). In Section 3.2.1 we introduced the idea of a GSValue for each sentence in an email thread, based on multiple human annotations. We can evaluate a summary of a given length by comparing its total GSValues to the maximum possible total for that summary length. For instance, if in a thread the three top scoring sentences had GSValues of 15, 12 and 12, and the sentences selected by a given automatic summarization method had GSValues of 15, 10 and 8, the pyramid precision would be 0.85.

Pyramid precision and weighted f-score are similar evaluation schemes in that they are both sentence based (as opposed to, for example, n-gram based) and that they score sentences based on multiple human annotations. Pyramid precision is very similar to equation 3 normalized by the maximum score for the summary length. For now we use these two slightly different schemes in order to maintain consistency with prior art in each domain.

4 A Conversation Summarization System

In our conversation summarization approach, we treat emails and meetings as conversations comprised of turns between multiple participants. We follow Carenini et al. (2007) in working at the finer granularity of email fragments, so that for an email thread, a turn consists of a single email fragment in the exchange. For meetings, a turn is a sequence of dialogue acts by one speaker, with the turn boundaries delimited by dialogue acts from other meeting participants. The features we derive for summarization are based on this view of the conversational structure.

We calculate two **length** features. For each sentence, we derive a word-count feature normalized by the longest sentence in the conversation (*SLEN*) and a word-count feature normalized by the longest sentence in the turn (*SLEN2*). Sentence length has previously been found to be an effective feature in speech and text summarization (e.g. (Maskey and Hirschberg, 2005; Murray et al., 2005a; Galley, 2006)).

There are several **structural** features used, including position of the sentence in the turn (*TLOC*) and position of the sentence in the conversation (*CLOC*). We also include the time from the beginning of the conversation to the current turn (*TPOS1*) and from the current turn to the end of the conversation (*TPOS2*). Conversations in both modalities can be well-structured, with introductory turns, general discussion, and ultimate resolution or closure, and sentence informativeness might significantly correlate with this structure. We calculate two pause-style features: the time between the following turn and the current turn (*SPAU*), and the time between the current turn and previous turn (*PPAU*), both normalized by the overall length of the conversation. These features are based on the email and meeting transcript timestamps. We hypothesize that pause features may be useful if informative turns tend to elicit a large number of responses in a short period of time, or if they tend to quickly follow a preceding turn, to give two examples.

There are two features related to the conversation **participants** directly. One measures how dominant the current participant is in terms of words in the conversation (*DOM*), and the other is a binary feature indicating whether the current participant initiated the conversation (*BEGAUTH*), based simply on whether they were the first contributor. It is hypothesized that informative sentences may more often belong to participants who lead the conversation or have a good deal of dominance in the discussion.

There are several **lexical** features used in these experiments. For each unique word, we calculate two conditional probabilities. For each conversation participant, we calculate the probability of the participant given the word, estimating the probability from the actual term counts, and take the maximum of these conditional probabilities as our first term score, which we will call *Sprob*.

$$Sprob(t) = \max_S p(S|t)$$

where t is the word and S is a participant. For example, if the word *budget* is used ten times in total, with seven uses by participant A, three uses by participant B and no uses by the other participants, then the *Sprob* score for this term is 0.70. The intuition is that certain words will tend to be associated with one conversation participant more than the others, owing to varying interests and expertise between the people involved.

Using the same procedure, we calculate a score called *Tprob* based on the probability of each turn given the word.

$$Tprob(t) = \max_T p(T|t)$$

The motivating factor for this metric is that certain words will tend to cluster into a small number of turns, owing to shifting topics within a conversation.

Having derived *Sprob* and *Tprob*, we then calculate several sentence-level features based on these term scores. Each sentence has features related to max, $mean$ and sum of the term scores for the words in that sentence (*MXS*, *MNS* and *SMS* for *Sprob*, and *MXT*, *MNT* and *SMT* for *Tprob*). Using a vector representation, we calculate the cosine between the conversation preceding the given sentence and the conversation subsequent to the sentence, first using *Sprob* as the vector weights (*COS1*) and then using *Tprob* as the vector weights (*COS2*). This is motivated by the hypothesis that informative sentences might change the conversation in some fashion, leading to a low cosine between the preceding and subsequent portions. We similarly calculate two scores measuring the cosine between the current sentence and the rest of the converation, using each term-weight metric as vector weights (*CENT1* for *Sprob* and *CENT2* for *Tprob*). This measures

Feature ID	Description
MXS	max *Sprob* score
MNS	mean *Sprob* score
SMS	sum of *Sprob* scores
MXT	max *Tprob* score
MNT	mean *Tprob* score
SMT	sum of *Tprob* scores
TLOC	position in turn
CLOC	position in conv.
SLEN	word count, globally normalized
SLEN2	word count, locally normalized
TPOS1	time from beg. of conv. to turn
TPOS2	time from turn to end of conv.
DOM	participant dominance in words
COS1	cos. of conv. splits, w/ *Sprob*
COS2	cos. of conv. splits, w/ *Tprob*
PENT	entro. of conv. up to sentence
SENT	entro. of conv. after the sentence
THISENT	entropy of current sentence
PPAU	time btwn. current and prior turn
SPAU	time btwn. current and next turn
BEGAUTH	is first participant (0/1)
CWS	rough ClueWordScore
CENT1	cos. of sentence & conv., w/ *Sprob*
CENT2	cos. of sentence & conv., w/ *Tprob*

Table 1: Features Key

whether the candidate sentence is generally similar to the conversation overall.

There are three word entropy features, calculated using the formula

$$went(s) = \frac{\sum_{i=1}^{N} p(x_i) \cdot -\log(p(x_i))}{(\frac{1}{N} \cdot -\log(\frac{1}{N})) \cdot M}$$

where s is a string of words, x_i is a word type in that string, $p(x_i)$ is the probability of the word based on its normalized frequency in the string, N is the number of word types in the string, and M is the number of word tokens in the string.

Note that word entropy essentially captures information about type-token ratios. For example, if each word token in the string was a unique type then the word entropy score would be 1. We calculate the word entropy of the current sentence (*THISENT*), as well as the word entropy for the conversation up until the current sentence (*PENT*) and the word entropy for the conversation subsequent to the current sentence (*SENT*). We hypothesize that informative sentences themselves may have a diversity of word types, and that if they represent turning points in the conversation they may affect the entropy of the subsequent conversation.

Finally, we include a feature that is a rough approximation of the ClueWordScore (CWS) used by Carenini et al. (2007). For each sentence we remove stopwords and count the number of words that occur in other turns besides the current turn. The CWS is therefore a measure of conversation cohesion.

For ease of reference, we hereafter refer to this conversation features system as ConverSumm.

5 Comparison Summarization Systems

In order to compare the ConverSumm system with state-of-the-art systems for meeting and email summarization, respectively, we also present results using the features described by Murray and Renals (2008) for meetings and the features described by Rambow (2004) for email. Because the work by Murray and Renals used the same dataset, we can compare our scores directly. However, Rambow carried out summarization work on a different, unavailable email corpus, and so we re-implemented their summarization system for our current email data.

In their work on meeting summarization, Murray and Renals creating 700-word summaries of each meeting using several classes of features: prosodic, lexical, structural and speaker-related. While there are two features overlapping between our systems (word-count and speaker/participant dominance), their system is primarily domain-dependent in its use of prosodic features while our features represent a more general conversational view.

Rambow presented 14 features for the summarization task, including email-specific information such as the number of recipients, number of responses, and subject line overlap. There is again a slight overlap in features between our two systems, as we both include length and position of the sentence in the thread/conversation.

6 Results

Here we present, in turn, the summarization results for meeting and email data.

6.1 Meeting Summarization Results

Figure 1 shows the F statistics for each Conversumm feature in the meeting data, providing a measure of the usefulness of each feature in discriminating between the positive and negative classes. Some

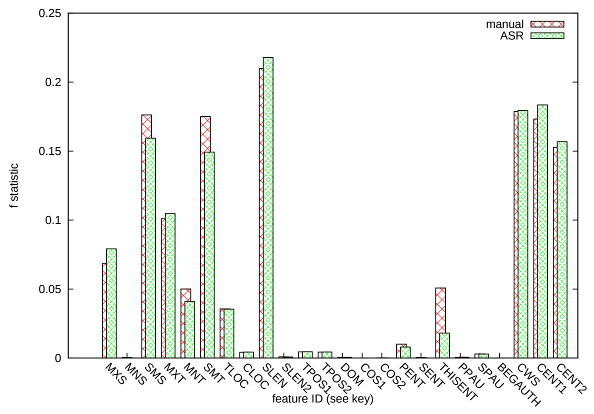

Figure 1: Feature F statistics for AMI meeting corpus

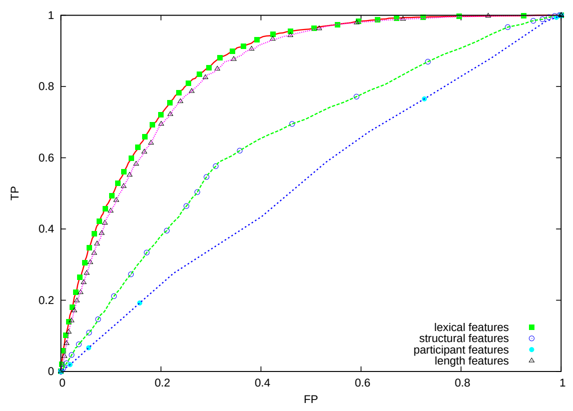
System	Weighted F-Score	AUROC
Speech - Man	0.23	0.855
Speech - ASR	0.24	0.850
Conv. - Man	0.23	0.852
Conv. - ASR	0.22	0.853

Table 2: Weighted F-Scores and AUROCs for Meeting Summaries

features such as participant dominance have very low F statistics because each sentence by a given participant will receive the same score; so while the feature itself may have a low score because it does not discriminate informative versus non-informative sentences on its own, it may well be useful in conjunction with the other features. The best individual ConverSumm features for meeting summarization are sentence length (SLEN), sum of $Sprob$ scores, sum of $Tprob$ scores, the simplified CWS score (CWS), and the two centroid measures (CENT1 and CENT2). The word entropy of the candidate sentence is very effective for manual transcripts but much less effective on ASR output. This is due to the fact that ASR errors can incorrectly lead to high entropy scores.

Table 2 provides the weighted f-scores for all summaries of the meeting data, as well as AUROC scores for the classifiers themselves. For our 700-word summaries, the Conversumm approach scores comparably to the speech-specific approach on both manual and ASR transcripts according to weighted f-score. There are no significant differences according to paired t-test. For the AUROC measures, there are again no significant differences between the conversation summarizers and speech-specific summarizers. The AUROC for the conversation system is slightly lower on manual transcripts and slightly higher when applied to ASR output.



Fea. Subset	AUROC
Structural	0.652
Participant	0.535
Length	0.837
Lexical	0.852

Figure 2: AUROC Values for Feature Subclasses, AMI Corpus

For all systems the weighted f-scores are somewhat low. This is partly owing to the fact that output summaries are very short, leading to high precision and low recall. The low f-scores are also indicative of the difficulty of the task. Human performance, gauged by comparing each annotator's summaries to the remaining annotators' summaries, exhibits an average weighted f-score of 0.47 on the same test set. The average kappa value on the test set is 0.48, showing the relatively low inter-annotator agreement that is typical of summarization annotation. There is no additional benefit to combining the conversational and speech-specific features. In that case, the weighted f-scores are 0.23 for both manual and ASR transcripts. The overall AUROC is 0.85 for manual transcripts and 0.86 for ASR.

We can expand the features analysis by considering the effectiveness of certain subclasses of features. Specifically, we group the summarization features into *lexical*, *structural*, *participant* and *length* features. Figure 2 shows the AUROCs for the feature subset classifiers, illustrating that the lexical subclass is very effective while the length features also constitute a challenging baseline. A weakness

System	Pyramid Precision	AUROC
Rambow	0.50	0.64
Conv.	0.46	0.75

Table 3: Pyramid Precision and AUROCs for Email Summaries

of systems that depend heavily on length features, however, is that recall scores tend to decrease because the extracted units are much longer - weighted recall scores for the 700 word summaries are significantly worse according to paired t-test ($p<0.05$) when using just length features compared to the full feature set.

6.2 Email Summarization Results

Figure 3 shows the F statistic for each ConverSumm feature in the email data.The two most useful features are sentence length and CWS. The *Sprob* and *Tprob* features rate very well according to the F statistic. The two centroid features incorporating *Sprob* and *Tprob* are comparable to one another and are very effective features as well.

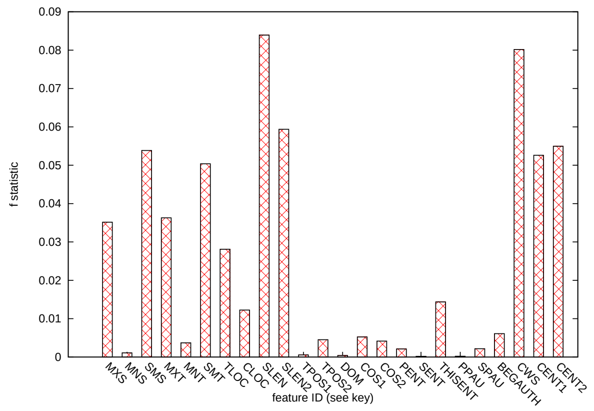


Figure 3: Feature F statistics for Enron email corpus

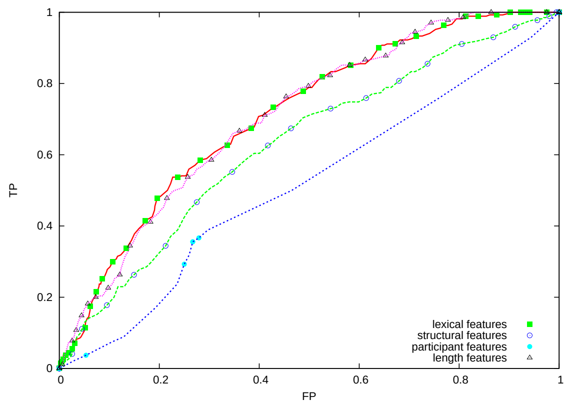
After creating 30% word compression summaries using both the ConverSumm and Rambow approaches, we score the 39 thread summaries using Pyramid Precision. The results are given in Table 3. On average, the Rambow system is slightly higher with a score of 0.50 compared with 0.46 for the conversational system, but there is no statistical difference according to paired t-test.

The average AUROC for the Rambow system is 0.64 compared with 0.75 for the ConverSumm system, with ConverSumm system significantly better according to paired t-test ($p<0.05$). Random classification performance would yield an AUROC of 0.5.



Fea. Subset	AUROC
Structural	0.63
Participant	0.51
Length	0.71
Lexical	0.71

Figure 4: AUROC Values for Feature Subclasses, Enron Corpus

Combining the Rambow and ConverSumm features does not yield any overall improvement. The Pyramid Precision score in that case is 0.47 while the AUROC is 0.74.

Figure 4 illustrates that the lexical and length features are the most effective feature subclasses, though the best results overall are derived from a combination of all feature classes.

7 Discussion

According to multiple evaluations, the ConverSumm features yield competitive summarization performance with the comparison systems. There is a clear set of features that are similarly effective in both domains, especially CWS, the centroid features, the $Sprob$ features, the $Tprob$ features, and sentence length. There are other features that are more effective in one domain than the other. For example, the BEGAUTH feature, indicating whether the current participant began the conversation, is more useful for emails. It seems that being the first person to speak in a meeting is not as significant as being the first person to email in a given thread. SLEN2, which normalizes sentence length by the longest sentence in the turn, also is much more effective for emails. The reason is that many meeting turns consist of a single, brief utterance such as "Okay, yeah."

The finding that the summary evaluations are not significantly worse on noisy ASR compared with manual transcripts has been previously attested (Valenza et al., 1999; Murray et al., 2005a), and it is encouraging that our ConverSumm features are similarly robust to this noisy data.

8 Conclusion

We have shown that a general conversation summarization approach can achieve results on par with state-of-the-art systems that rely on features specific to more focused domains. We have introduced a conversation feature set that is similarly effective in both the meetings and emails domains. The use of multiple summarization evaluation techniques confirms that the system is robust, even when applied to the noisy ASR output in the meetings domain. Such a general conversation summarization system is valuable in that it may save time and effort required to implement unique systems in a variety of conversational domains.

We are currently working on extending our system to other conversation domains such as chats, blogs and telephone speech. We are also investigating domain adaptation techniques; for example, we hypothesize that the relatively well-resourced domain of meetings can be leveraged to improve email results, and preliminary findings are encouraging.

Abstract

In this paper, we present an algorithm for learning a generative model of natural language sentences together with their formal meaning representations with hierarchical structures. The model is applied to the task of mapping sentences to hierarchical representations of their underlying meaning. We introduce dynamic programming techniques for efficient training and decoding. In experiments, we demonstrate that the model, when coupled with a discriminative reranking technique, achieves state-of-the-art performance when tested on two publicly available corpora. The generative model degrades robustly when presented with instances that are different from those seen in training. This allows a notable improvement in recall compared to previous models.

1 Introduction

To enable computers to understand natural human language is one of the classic goals of research in natural language processing. Recently, researchers have developed techniques for learning to map sentences to hierarchical representations of their underlying meaning (Wong and Mooney, 2006; Kate and Mooney, 2006).

One common approach is to learn some form of probabilistic grammar which includes a list of lexical items that models the meanings of input words and also includes rules for combining lexical meanings to analyze complete sentences. This approach performs well but is constrained by the use of a single, learned grammar that contains a fixed set of lexical entries and productions. In practice, such a grammar may lack the rules required to correctly parse some of the new test examples.

In this paper, we develop an alternative approach that learns a model which does not make use of an explicit grammar but, instead, models the correspondence between sentences and their meanings with a generative process. This model is defined over *hybrid trees* whose nodes include both natural language words and meaning representation tokens. Inspired by the work of Collins (2003), the generative model builds trees by recursively creating nodes at each level according to a Markov process. This implicit grammar representation leads to flexible learned models that generalize well. In practice, we observe that it can correctly parse a wider range of test examples than previous approaches.

The generative model is learned from data that consists of sentences paired with their meaning representations. However, there is no explicit labeling of the correspondence between words and meaning tokens that is necessary for building the hybrid trees. This creates a challenging, hidden-variable learning problem that we address with the use of an inside-outside algorithm. Specifically, we develop a dynamic programming parsing algorithm that leads to $O(n^3m)$ time complexity for inference, where n is the sentence length and m is the size of meaning structure. This approach allows for efficient training and decoding.

In practice, we observe that the learned generative models are able to assign a high score to the correct meaning for input sentences, but that this correct meaning is not always the highest scoring option.

To address this problem, we use a simple reranking approach to select a parse from a k-best list of parses. This pipelined approach achieves state-of-the-art performance on two publicly available corpora. In particular, the flexible generative model leads to notable improvements in recall, the total percentage of sentences that are correctly parsed.

2 Related Work

In Section 9, we will compare performance with the three existing systems that were evaluated on the same data sets we consider. SILT (Kate et al., 2005) learns deterministic rules to transform either sentences or their syntactic parse trees to meaning structures. WASP (Wong and Mooney, 2006) is a system motivated by statistical machine translation techniques. It acquires a set of synchronous lexical entries by running the IBM alignment model (Brown et al., 1993) and learns a log-linear model to weight parses. KRISP (Kate and Mooney, 2006) is a discriminative approach where meaning representation structures are constructed from the natural language strings hierarchically. It is built on top of SVM^{struct} with string kernels.

Additionally, there is substantial related research that is not directly comparable to our approach. Some of this work requires different levels of supervision, including labeled syntactic parse trees (Ge and Mooney, 2005; Ge and Mooney, 2006). Others do not perform lexical learning (Tang and Mooney, 2001). Finally, recent work has explored learning to map sentences to lambda-calculus meaning representations (Wong and Mooney, 2007; Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007).

3 Meaning Representation

We restrict our meaning representation (MR) formalism to a variable free version as presented in (Wong and Mooney, 2006; Kate et al., 2005).

A training instance consists of a natural language sentence (NL sentence) and its corresponding meaning representation structure (MR structure). Consider the following instance taken from the GEOQUERY corpus (Kate et al., 2005):

The NL sentence "`How many states do not have rivers ?`" consists of 8 words, including punctuation. The MR is a hierarchical tree structure, as shown in Figure 1.

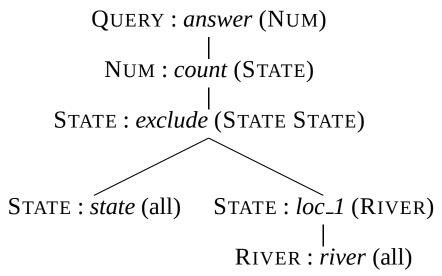

Figure 1: An example MR structure

Following an inorder traversal of this MR tree, we can equivalently represent it with the following list of *meaning representation productions* (MR productions):

(0)	QUERY	:	*answer* (NUM)
(1)	NUM	:	*count* (STATE)
(2)	STATE	:	*exclude* (STATE$_1$ STATE$_2$)
(3)	STATE	:	*state* (all)
(4)	STATE	:	*loc_1* (RIVER)
(5)	RIVER	:	*river* (all)

Each such MR production consists of three components: a *semantic category*, a *function symbol* which can be omitted (considered empty), and a list of *arguments*. An argument can be either a child semantic category or a constant. Take production (1) for example: it has a semantic category "NUM", a function symbol "*count*", and a child semantic category "STATE" as its only argument. Production (5) has "RIVER" as its semantic category, "*river*" as the function symbol, and "all" is a constant.

4 The Generative Model

We describe in this section our proposed generative model, which simultaneously generates a NL sentence and an MR structure.

We denote a single NL word as w, a contiguous sequence of NL words as $\mathbf{w}$, and a complete NL sentence as $\widehat{\mathbf{w}}$. In the MR structure, we denote a semantic category as $\mathcal{M}$. We denote a single MR production as m_a, or $\mathcal{M}_a : p_\alpha(\mathcal{M}_b, \mathcal{M}_c)$, where $\mathcal{M}_a$ is the semantic category for this production, p_α is the function symbol, and $\mathcal{M}_b, \mathcal{M}_c$ are the child semantic categories. We denote $\mathbf{m}_a$ as an MR structure rooted by an MR production m_a, and $\widehat{\mathbf{m}_a}$ an MR structure for a complete sentence rooted by an MR production m_a.

The model generates a *hybrid tree* that represents a sentence $\widehat{\mathbf{w}} = \mathbf{w}_1 \ldots \mathbf{w}_2 \ldots$ paired with an MR structure $\widehat{\mathbf{m}_a}$ rooted by m_a.

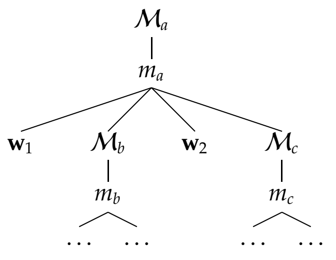

Figure 2: The generation process

Figure 2 shows part of a hybrid tree that is generated as follows. Given a semantic category $\mathcal{M}_a$, we first pick an MR production m_a that has the form $\mathcal{M}_a : p_\alpha(\mathcal{M}_b, \mathcal{M}_c)$, which gives us the function symbol p_α as well as the child semantic categories $\mathcal{M}_b$ and $\mathcal{M}_c$. Next, we generate the *hybrid sequence* of child nodes $\overline{\mathbf{w}_1\ \mathcal{M}_b\ \mathbf{w}_2\ \mathcal{M}_c}$, which consists of NL words and semantic categories.

After that, two child MR productions m_b and m_c are generated. These two productions will in turn generate other hybrid sequences and productions, recursively. This process produces a hybrid tree $\mathcal{T}$, whose nodes are either NL words or MR productions. Given this tree, we can recover a NL sentence $\mathbf{w}$ by recording the NL words visited in depth-first traversal order and can recover an MR structure $\mathbf{m}$ by following a tree-specific traversal order, defined by the hybrid-patterns we introduce below. Figure 3 gives a partial hybrid tree for the training example from Section 3. Note that the leaves of a hybrid tree are always NL tokens.

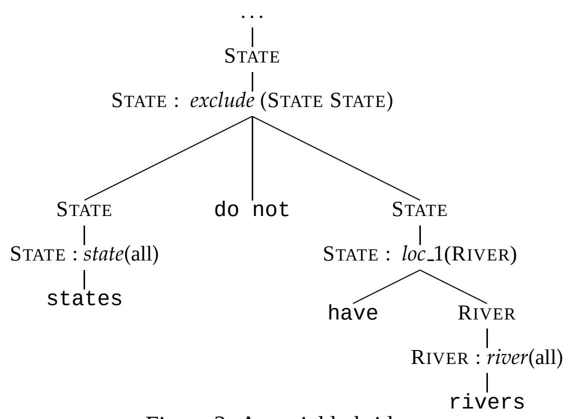

Figure 3: A partial hybrid tree

With several independence assumptions, the probability of generating $\langle\widehat{\mathbf{w}}, \widehat{\mathbf{m}}, \mathcal{T}\rangle$ is defined as:

$$\begin{aligned} P(\widehat{\mathbf{w}}, \widehat{\mathbf{m}}, \mathcal{T}) = P(\mathcal{M}_a) \times P(m_a|\mathcal{M}_a) \times P(\overline{\mathbf{w}_1\ \mathcal{M}_b\ \mathbf{w}_2\ \mathcal{M}_c}|m_a) \\ \times P(m_b|m_a, \text{arg} = 1) \times P(\ldots|m_b) \\ \times P(m_c|m_a, \text{arg} = 2) \times P(\ldots|m_c) \end{aligned} \quad (1)$$

where "arg" refers to the position of the child semantic category in the argument list.

Motivated by Collins' syntactic parsing models (Collins, 2003), we consider the generation process for a hybrid sequence from an MR production as a Markov process.

Given the assumption that each MR production has at most two semantic categories in its arguments (any production can be transformed into a sequence of productions of this form), Table 1 includes the list of all possible *hybrid patterns*.

# RHS	Hybrid Pattern	# Patterns
0	$m \to \mathbf{w}$	1
1	$m \to [\mathbf{w}]\mathcal{Y}[\mathbf{w}]$	4
2	$m \to [\mathbf{w}]\mathcal{Y}[\mathbf{w}]\mathcal{Z}[\mathbf{w}]$	8
	$m \to [\mathbf{w}]\mathcal{Z}[\mathbf{w}]\mathcal{Y}[\mathbf{w}]$	8

Table 1: A list of hybrid patterns, [] denotes optional

In this table, m is an MR production, $\mathcal{Y}$ and $\mathcal{Z}$ are respectively the first and second child semantic category in m's argument list. The symbol $\mathbf{w}$ refers to a contiguous sequence of NL words, and anything inside [] can be optionally omitted. The last row contains hybrid patterns that reflect reordering of one production's child semantic categories during the generation process. For example, consider the case that the MR production STATE : *exclude* (STATE$_1$ STATE$_2$) generates a hybrid sequence $\overline{\text{STATE}_1\ \texttt{do not}\ \text{STATE}_2}$, the hybrid pattern $m \to \mathcal{Y}\mathbf{w}\mathcal{Z}$ is associated with this generation step.

For the example hybrid tree in Figure 2, we can decompose the probability for generating the hybrid sequence as follows:

$$\begin{aligned} P(\overline{\mathbf{w}_1\ \mathcal{M}_b\ \mathbf{w}_2\ \mathcal{M}_c}|m_a) = P(m \to \mathbf{w}\mathcal{Y}\mathbf{w}\mathcal{Z}|m_a) \times P(\mathbf{w}_1|m_a) \\ \times P(\mathcal{M}_b|m_a, \mathbf{w}_1) \times P(\mathbf{w}_2|m_a, \mathbf{w}_1, \mathcal{M}_b) \\ \times P(\mathcal{M}_c|m_a, \mathbf{w}_1, \mathcal{M}_b, \mathbf{w}_2) \times P(\text{END}|m_a, \mathbf{w}_1, \mathcal{M}_b, \mathbf{w}_2, \mathcal{M}_c) \end{aligned} \quad (2)$$

Note that unigram, bigram, or trigram assumptions can be made here for generating NL words and semantic categories. For example, under a bigram assumption, the second to last term can be written as $P(\mathcal{M}_c|m_a, \mathbf{w}_1, \mathcal{M}_b, \mathbf{w}_2) \equiv P(\mathcal{M}_c|m_a, w_2^k)$, where w_2^k is the last word in $\mathbf{w}_2$. We call such additional information that we condition on, the *context*.

Note that our generative model is different from the synchronous context free grammars (SCFG) in a number of ways. A standard SCFG produces a correspondence between a pair of trees while our model produces a single hybrid tree that represents the correspondence between a sentence and a tree. Also, SCFGs use a finite set of context-free rewrite rules to define the model, where the rules are possibly weighted. In contrast, we make use of the more flexible Markov models at each level of the generative process, which allows us to potentially produce a far wider range of possible trees.

5 Parameter Estimation

There are three categories of parameters used in the model. The first category of parameters models the generation of new MR productions from their parent MR productions: *e.g.*, $P(m_b|m_a, \text{arg} = 1)$; the second models the generation of a hybrid sequence from an MR production: *e.g.*, $P(\mathbf{w}_1|m_a)$, $P(\mathcal{M}_b|m_a, \mathbf{w}_1)$; the last models the selection of a hybrid pattern given an MR production, *e.g.*, $P(m \to \mathbf{w}\mathcal{Y}|m_a)$. We will estimate parameters from all categories, with the following constraints:

1. $\sum_{m'} \rho(m'|m_j, \text{arg}{=}k){=}1$ for all j and $k = 1, 2$.

   These parameters model the MR structures, and can be referred to as *MR model parameters*.

2. $\sum_t \theta(t|m_j, \Lambda){=}1$ for all j, where t is a NL word, the "END" symbol, or a semantic category. Λ is the context associated with m_j and t.

   These parameters model the emission of NL words, the "END" symbol, and child semantic categories from an MR production. We call them *emission parameters*.

3. $\sum_r \phi(r|m_j) = 1$ for all j, where r is a hybrid pattern listed in Table 1.

   These parameters model the selection of hybrid patterns. We name them *pattern parameters*.

With different context assumptions, we reach different variations of the model. In particular, we consider three assumptions, as follows:

Model I We make the following assumption:

$$\theta(t_k|m_j, \Lambda) = P(t_k|m_j) \tag{3}$$

where t_k is a semantic category or a NL word, and m_j is an MR production.

In other words, generation of the next NL word depends on its direct parent MR production only. Such a *Unigram Model* may help in recall (the number of correct outputs over the total number of inputs), because it requires the least data to estimate.

Model II We make the following assumption:

$$\theta(t_k|m_j, \Lambda) = P(t_k|m_j, t_{k-1}) \tag{4}$$

where t_{k-1} is the semantic category or NL word to the left of t_k, *i.e.*, the previous semantic category or NL word.

In other words, generation of the next NL word depends on its direct parent MR production as well as the previously generated NL word or semantic category only. This model is also referred to as *Bigram Model*. This model may help in precision (the number of correct outputs over the total number of outputs), because it conditions on a larger context.

Model III We make the following assumption:

$$\theta(t_k|m_j, \Lambda) = \frac{1}{2} \times \Big(P(t_k|m_j) + P(t_k|m_j, t_{k-1})\Big) \tag{5}$$

We can view this model, called the *Mixgram Model*, as an interpolation between Model I and II. This model gives us a balanced score for both precision and recall.

5.1 Modeling Meaning Representation

The MR model parameters can be estimated independently from the other two. These parameters can be viewed as the "language model" parameters for the MR structure, and can be estimated directly from the corpus by simply reading off the counts of occurrences of MR productions in MR structures over the training corpus. To resolve data sparseness problem, a variant of the bigram Katz Back-Off Model (Katz, 1987) is employed here for smoothing.

5.2 Learning the Generative Parameters

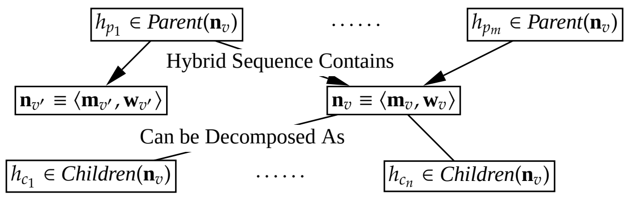
Learning the remaining two categories of parameters is more challenging. In a conventional PCFG parsing task, during the training phase, the correct correspondence between NL words and syntactic structures is fully accessible. In other words, there is a single deterministic derivation associated with each training instance. Therefore model parameters can be directly estimated from the training corpus by counting. However, in our task, the correct correspondence between NL words and MR structures is unknown. Many possible derivations could reach the same NL-MR pair, where each such derivation forms a hybrid tree.

The hybrid tree is constructed using hidden variables and estimated from the training set. An efficient inside-outside style algorithm can be used for model estimation, similar to that used in (Yamada and Knight, 2001), as discussed next.

5.2.1 The Inside-Outside Algorithm with EM

In this section, we discuss how to estimate the emission and pattern parameters with the Expectation Maximization (EM) algorithm (Dempster et al., 1977), by using an inside-outside (Baker, 1979) dynamic programming approach.

Denote $\mathbf{n}^i \equiv \langle \mathbf{m}^i, \mathbf{w}^i \rangle$ as the i-th training instance, where $\mathbf{m}^i$ and $\mathbf{w}^i$ are the MR structure and the NL sentence of the i-th instance respectively. We also denote $\mathbf{n}_v \equiv \langle \mathbf{m}_v, \mathbf{w}_v \rangle$ as an aligned pair of MR substructure and contiguous NL substring, where the MR substructure rooted by MR production m_v will correspond to (*i.e.*, hierarchically generate) the NL substring $\mathbf{w}_v$. The symbol h is used to denote a hybrid sequence, and the function *Parent*(h) gives the unique MR substructure-NL subsequence pair which can be decomposed as h. *Parent*($\mathbf{n}_v$) returns the set of all possible hybrid sequences under which the pair $\mathbf{n}_v$ can be generated. Similarly, *Children*(h) gives the NL-MR pairs that appear directly below the hybrid sequence h in a hybrid tree, and *Children*($\mathbf{n}$) returns the set of all possible hybrid sequences that $\mathbf{n}$ can be decomposed as. Figure 4 gives a packed tree structure representing the relations between the entities.



$h_{p_1} \in Parent(\mathbf{n}_v)$
......
$h_{p_m} \in Parent(\mathbf{n}_v)$
Hybrid Sequence Contains
$\mathbf{n}_{v'} \equiv \langle \mathbf{m}_{v'}, \mathbf{w}_{v'} \rangle$
$\mathbf{n}_v \equiv \langle \mathbf{m}_v, \mathbf{w}_v \rangle$
Can be Decomposed As
$h_{c_1} \in Children(\mathbf{n}_v)$
......
$h_{c_n} \in Children(\mathbf{n}_v)$

Figure 4: A packed tree structure representing the relations between hybrid sequences and NL-MR pairs

The formulas for computing inside and outside probabilities as well as the equations for updating parameters are given in Figure 5. We use a CKY-style parse chart for tracking the probabilities.

5.2.2 Smoothing

It is reasonable to believe that different MR productions that share identical function symbols are likely to generate NL words with similar distribution, regardless of semantic categories. For example,

The inside (β) probabilities are defined as

- If $\mathbf{n}_v \equiv \langle \mathbf{m}_v, \mathbf{w}_v \rangle$ is leaf
$$\beta(\mathbf{n}_v) = P(\mathbf{w}_v|\mathbf{m}_v) \tag{6}$$
- If $\mathbf{n}_v \equiv \langle \mathbf{m}_v, \mathbf{w}_v \rangle$ is not leaf
$$\beta(\mathbf{n}_v) = \sum_{h \in Children(\mathbf{n}_v)} \Big(P(h|\mathbf{m}_v) \times \prod_{\mathbf{n}_{v'} \in Children(h)} \beta(\mathbf{n}_{v'}) \Big) \tag{7}$$

The outside (α) probabilities are defined as

- If $\mathbf{n}_v \equiv \langle \mathbf{m}_v, \mathbf{w}_v \rangle$ is root
$$\alpha(\mathbf{n}_v) = 1 \tag{8}$$
- If $\mathbf{n}_v \equiv \langle \mathbf{m}_v, \mathbf{w}_v \rangle$ is not root
$$\alpha(\mathbf{n}_v) = \sum_{h \in Parent(\mathbf{n}_v)} \Big(\alpha\big(Parent(h)\big) \times P\big(h|Parent(h)\big) \times \prod_{\mathbf{n}_{v'} \in Children(h), v' \neq v} \beta(\mathbf{n}_{v'}) \Big) \tag{9}$$

Parameter Update

- Update the emission parameter
The count $c^i(t, m_v, \Lambda_k)$, where t is a NL word or a semantic category, for an instance pair $\mathbf{n}^i \equiv \langle \mathbf{m}^i, \mathbf{w}^i \rangle$:
$$c^i(t, m_v, \Lambda_k) = \frac{1}{\beta(\mathbf{n}^i)} \times \sum_{(t, m_v, \Lambda_k) \text{ in } h \in Children(m_v)} \Big(\alpha(\mathbf{n}^i_v) \times P(h|m_v) \times \prod_{\mathbf{n}^i_{v'} \in Children(h)} \beta(\mathbf{n}^i_{v'}) \Big)$$
The emission parameter is re-estimated as:
$$\theta'(t|m_v, \Lambda_k) = \frac{\sum_i c^i(t, m_v, \Lambda_k)}{\sum_{t'} \sum_i c^i(t', m_v, \Lambda_k)} \tag{10}$$
- Update the pattern parameter
The count $c^i(r, m_v)$, where r is a hybrid pattern, for an instance pair $\mathbf{n}^i \equiv \langle \mathbf{m}^i, \mathbf{w}^i \rangle$:
$$c^i(r, m_v) = \frac{1}{\beta(\mathbf{n}^i)} \times \sum_{(r, m_v) \text{ in } h \in Children(m_v)} \Big(\alpha(\mathbf{n}^i_v) \times P(h|m_v) \times \prod_{\mathbf{n}^i_{v'} \in Children(h)} \beta(\mathbf{n}^i_{v'}) \Big)$$
The pattern parameter is re-estimated as:
$$\phi'(r|m_v) = \frac{\sum_i c^i(r, m_v)}{\sum_{r'} \sum_i c^i(r', m_v)} \tag{11}$$

Figure 5: The inside/outside formulas as well as update equations for EM

RIVER : *largest* (RIVER) and CITY : *largest* (CITY) are both likely to generate the word "`biggest`".

In view of this, a smoothing technique is deployed. We assume half of the time words can be generated from the production's function symbol alone if it is not empty. Mathematically, assuming m_a with function symbol p_a, for a NL word or semantic category t, we have:

$$\theta(t|m_a,\Lambda) = \begin{cases} \theta_e(t|m_a,\Lambda) & \text{If } p_a \text{ is empty} \\ \big(\theta_e(t|m_a,\Lambda) + \theta_e(t|p_a,\Lambda)\big)/2 & \text{otherwise} \end{cases}$$

where θ_e models the generation of t from an MR production or its function symbol, together with the context Λ.

6 A Dynamic Programming Algorithm for Inside-Outside Computation

Though the inside-outside approach already employs packed representations for dynamic programming, a naive implementation of the inference algorithm will still require $O(n^6m)$ time for 1 EM iteration, where n and m are the length of the NL sentence and the size of the MR structure respectively. This is not very practical as in one of the corpora we look at, n and m can be up to 45 and 20 respectively.

In this section, we develop an efficient dynamic programming algorithm that enables the inference to run in $O(n^3m)$ time. The idea is as follows. Instead of treating each possible hybrid sequence as a separate rule, we efficiently aggregate the already computed probability scores for hybrid sequences that share identical hybrid patterns. Such aggregated scores can then be used for subsequent computations. By doing this, we can effectively avoid a large amount of redundant computations. The algorithm supports both unigram and bigram context assumptions. For clarity and ease of presentation, we primarily make the unigram assumption throughout our discussion.

We use $\beta(\mathbf{m}_v, \mathbf{w}_v)$ to denote the inside probability for $\mathbf{m}_v$-$\mathbf{w}_v$ pair, $b_r[\mathbf{m}_v, \mathbf{w}_v, c]$ to denote the aggregated probabilities for the MR sub-structure $\mathbf{m}_v$ to generate all possible hybrid sequences based on $\mathbf{w}_v$ with pattern r that covers its c-th child only. In addition, we use $\mathbf{w}_{(i,j)}$ to denote a subsequence of $\mathbf{w}$ with start index i (inclusive) and end index j (exclusive). We also use $\beta_r[\![\mathbf{m}_v, \mathbf{w}_v]\!]$ to denote the aggregated inside probability for the pair $\langle \mathbf{m}_v, \mathbf{w}_v \rangle$, if the hybrid pattern is restricted to r only. By definition we have:

$$\beta(\mathbf{m}_v, \mathbf{w}_v) = \sum_r \phi(r|m_v) \times \beta_r[\![\mathbf{m}_v, \mathbf{w}_v]\!] \times \theta(\mathsf{END}|m_v) \quad (12)$$

Relations between β_r and b_r can also be established. For example, if m_v has one child semantic category, we have:

$$\beta_{m\rightarrow \mathbf{w}\mathcal{Y}}[\![\mathbf{m}_v, \mathbf{w}_v]\!] = b_{m\rightarrow \mathbf{w}\mathcal{Y}}[\mathbf{m}_v, \mathbf{w}_v, 1] \quad (13)$$

For the case when m_v has two child semantic categories as arguments, we have, for example:

$$\beta_{m\rightarrow \mathbf{w}\mathcal{Y}\mathcal{Z}\mathbf{w}}[\![\mathbf{m}_v, \mathbf{w}_{(i,j)}]\!] = \sum_{i+2\le k\le j-2} b_{m\rightarrow \mathbf{w}\mathcal{Y}}[m_v, \mathbf{w}_{(i,k)}, 1] \times b_{m\rightarrow \mathcal{Y}\mathbf{w}}[m_v, \mathbf{w}_{(k,j)}, 2] \quad (14)$$

Note that there also exist relations amongst b terms for more efficient computation, for example:

$$b_{m\rightarrow \mathbf{w}\mathcal{Y}}[\mathbf{m}_v, \mathbf{w}_{(i,j)}, c] = \theta(w_i|m_v) \times \Big(b_{m\rightarrow \mathbf{w}\mathcal{Y}}[\mathbf{m}_v, \mathbf{w}_{(i+1,j)}, c] + b_{m\rightarrow \mathcal{Y}}[\mathbf{m}_v, \mathbf{w}_{(i+1,j)}, c]\Big) \quad (15)$$

Analogous but more complex formulas are used for computing the outside probabilities. Updating of parameters can be incorporated into the computation of outside probabilities efficiently.

7 Decoding

In the decoding phase, we want to find the optimal MR structure $\widehat{\mathbf{m}}^*$ given a new NL sentence $\widehat{\mathbf{w}}$:

$$\widehat{\mathbf{m}}^* = \arg\max_{\widehat{\mathbf{m}}} P(\widehat{\mathbf{m}}|\widehat{\mathbf{w}}) = \arg\max_{\widehat{\mathbf{m}}} \sum_{\mathcal{T}} P(\widehat{\mathbf{m}}, \mathcal{T}|\widehat{\mathbf{w}}) \quad (16)$$

where $\mathcal{T}$ is a possible hybrid tree associated with the $\widehat{\mathbf{m}}$-$\widehat{\mathbf{w}}$ pair. However, it is expensive to compute the summation over all possible hybrid trees. We therefore find the most likely hybrid tree instead:

$$\widehat{\mathbf{m}}^* = \arg\max_{\widehat{\mathbf{m}}} \max_{\mathcal{T}} P(\widehat{\mathbf{m}}, \mathcal{T}|\widehat{\mathbf{w}}) = \arg\max_{\widehat{\mathbf{m}}} \max_{\mathcal{T}} P(\widehat{\mathbf{w}}, \widehat{\mathbf{m}}, \mathcal{T}) \quad (17)$$

We have implemented an exact top-k decoding algorithm for this task. Dynamic programming techniques similar to those discussed in Section 6 can also be applied when retrieving the top candidates.

We also find the Viterbi hybrid tree given a NL-MR pair, which can be done in an analogous way. This tree will be useful for reranking.

8 Reranking and Filtering of Predictions

Due to the various independence assumptions we have made, the model lacks the ability to express some long range dependencies. We therefore post-process the best candidate predictions with a discriminative reranking algorithm.

Feature Type	Description	Example
1. Hybrid Rule	A MR production and its child hybrid form	f_1 : STATE : *loc_1*(RIVER) → `have` RIVER
2. Expanded Hybrid Rule	A MR production and its child hybrid form expanded	f_2 : STATE : *loc_1*(RIVER) → ⟨`have`, RIVER : *river*(all)⟩
3. Long-range Unigram	A MR production and a NL word appearing below in tree	f_3 : STATE : *exclude*(STATE STATE) → `rivers`
4. Grandchild Unigram	A MR production and its grandchild NL word	f_4 : STATE : *loc_1*(RIVER) → `rivers`
5. Two Level Unigram	A MR production, its parent production, and its child NL word	f_5 : ⟨RIVER : *river*(all), STATE : *loc_1*(RIVER)⟩ → `rivers`
6. Model Log-Probability	Logarithm of base model's joint probability	$\log\left(\widehat{P}(\mathbf{w}, \mathbf{m}, \mathcal{T})\right)$.

Table 2: All the features used. There is one feature for each possible combination, under feature type 1-5. It takes value 1 if the combination is present, and 0 otherwise. Feature 6 takes real values.

8.1 The Averaged Perceptron Algorithm with Separating Plane

The averaged perceptron algorithm (Collins, 2002) has previously been applied to various NLP tasks (Collins, 2002; Collins, 2001) for discriminative reranking. The detailed algorithm can be found in (Collins, 2002). In this section, we extend the conventional averaged perceptron by introducing an explicit separating plane on the feature space.

Our reranking approach requires three components during training: a **GEN** function that defines for each NL sentence a set of candidate hybrid trees; a single correct reference hybrid tree for each training instance; and a feature function Φ that defines a mapping from a hybrid tree to a feature vector. The algorithm learns a weight vector $\mathbf{w}$ that associates a weight to each feature, such that a score $\mathbf{w}\cdot\Phi(\mathcal{T})$ can be assigned to each candidate hybrid tree $\mathcal{T}$. Given a new instance, the hybrid tree with the highest score is then picked by the algorithm as the output.

In this task, the **GEN** function is defined as the output hybrid trees of the top-k (k is set to 50 in our experiments) decoding algorithm, given the learned model parameters. The correct reference hybrid tree is determined by running the Viterbi algorithm on each training NL-MR pair. The feature function is discussed in section 8.2.

While conventional perceptron algorithms usually optimize the accuracy measure, we extend it to allow optimization of the F-measure by introducing an explicit separating plane on the feature space that rejects certain predictions even when they score highest. The idea is to find a threshold b after $\mathbf{w}$ is learned, such that a prediction with score below b gets rejected. We pick the threshold that leads to the optimal F-measure when applied to the training set.

8.2 Features

We list in Table 2 the set of features we used. Examples are given based on the hybrid tree in Figure 3. Some of the them are adapted from (Collins and Koo, 2005) for a natural language parsing task. Features 1-5 are indicator functions (*i.e.,* it takes value 1 if a certain combination as the ones listed in Table 2 is present, 0 otherwise), while feature 6 is real valued. Features that do not appear more than once in the training set are discarded.

9 Evaluation

Our evaluations were performed on two corpora, GEOQUERY and ROBOCUP. The GEOQUERY corpus contains MR defined by a Prolog-based language used in querying a database on U.S. geography. The ROBOCUP corpus contains MR defined by a coaching language used in a robot coaching competition. There are in total 880 and 300 instances for the two corpora respectively. Standard 10-fold cross validations were performed and the micro-averaged results are presented in this section. To make our system directly comparable to previous systems, all our experiments were based on identical training and test data splits of both corpora as reported in the experiments of Wong and Mooney (2006).

9.1 Training Methodology

Given a training set, we first run a variant of IBM alignment model 1 (Brown et al., 1993) for 100 iterations, and then initialize Model I with the learned parameter values. This IBM model is a word-to-word alignment model that does not model word order, so we do not have to linearize the hierarchical MR structure. Given this initialization, we train Model I for 100 EM iterations and use the learned parameters to initialize Model II which is trained for another 100 EM iterations. Model III is simply an interpolation of the above two models. As for the reranking phase, we initialize the weight vector with the zero vector $\mathbf{0}$, and run the averaged perceptron algorithm for 10 iterations.

9.2 Evaluation Methodology

Following Wong (2007) and other previous work, we report performance in terms of *Precision* (percentage of answered NL sentences that are correct), *Recall* (percentage of correctly answered NL sentences, out of all NL sentences) and *F*-score (harmonic mean of *Precision* and *Recall*).

Again following Wong (2007), we define the correct output MR structure as follows. For the GEOQUERY corpus, an MR structure is considered correct if and only if it retrieves identical results as the reference MR structure when both are issued as queries to the underlying Prolog database. For the ROBOCUP corpus, an MR structure is considered correct if and only if it has the same string representation as the reference MR structure, up to reordering of children of MR productions whose function symbols are commutative, such as *and*, *or*, etc.

9.3 Comparison over Three Models

Model	GEOQUERY (880)			ROBOCUP (300)		
	Prec.	*Rec.*	*F*	*Prec.*	*Rec.*	*F*
I	81.3	77.1	79.1	71.1	**64.0**	67.4
II	**89.0**	76.0	82.0	**82.4**	57.7	**67.8**
III	86.2	**81.8**	**84.0**	70.4	63.3	66.7
I+R	87.5	80.5	83.8	79.1	67.0	72.6
II+R	**93.2**	73.6	82.3	**88.4**	56.0	68.6
III+R	89.3	**81.5**	**85.2**	82.5	**67.7**	**74.4**

Table 3: Performance comparison over three models (*Prec.*:precision, *Rec.*:recall, +R: with reranking)

We evaluated the three models, with and without reranking. The results are presented in Table 3. Comparing Model I and Model II, we noticed that for both corpora, Model I in general achieves better recall while Model II achieves better precision. This observation conforms to our earlier expectations. Model III, as an interpolation of the above two models, achieves a much better *F*-measure on GEOQUERY corpus. However, it is shown to be less effective on ROBOCUP corpus. We noticed that compared to the GEOQUERY corpus, ROBOCUP corpus contains longer sentences, larger MR structures, and a significant amount of non-compositionality. These factors combine to present a challenging problem for parsing with the generative model. Interestingly, although Model III fails to produce better best predictions for this corpus, we found that its top-*k* list contains a relatively larger number of correct predictions than Model I or Model II. This indicates the possibility of enhancing the performance with reranking.

The reranking approach is shown to be quite effective. We observe a consistent improvement in both precision and *F*-measure after employing the reranking phase for each model.

9.4 Comparison with Other Models

Among all the previous models, SILT, WASP, and KRISP are directly comparable to our model. They required the same amount of supervision as our system and were evaluated on the same corpora.

We compare our model with these models in Table 4, where the performance scores for the previous systems are taken from (Wong, 2007). For GEOQUERY corpus, our model performs substantially better than all the three previous models, with a notable improvement in the recall score. In fact, if we look at the recall scores alone, our best-performing model achieves a 6.7% and 9.8% absolute improvement over two other state-of-the-art models WASP and KRISP respectively. This indicates that overall, our model is able to handle over 25% of the inputs that could not be handled by previous systems. On the other hand, in terms of *F*-measure, we gain a 4.1% absolute improvement over KRISP, which leads to an error reduction rate of 22%. On the ROBOCUP corpus, our model's performance is also ranked the highest[1].

System	GEOQUERY (880)			ROBOCUP (300)		
	Prec.	*Rec.*	*F*	*Prec.*	*Rec.*	*F*
SILT	89.0	54.1	67.3	83.9	50.7	63.2
WASP	87.2	74.8	80.5	**88.9**	61.9	73.0
KRISP	**93.3**	71.7	81.1	85.2	61.9	71.7
Model III+R	89.3	**81.5**	**85.2**	82.5	**67.7**	**74.4**

Table 4: Performance comparison with other directly comparable systems

9.5 Performance on Other Languages

As a generic model that requires minimal assumptions on the natural language, our model is natural language independent and is able to handle various other natural languages than English. To validate this point, we evaluated our system on a subset of

[1]We are unable to perform statistical significance tests because the detailed performance for each fold of previously published research work is not available.

the GEOQUERY corpus consisting of 250 instances, with four different NL annotations.

As we can see from Table 5, our model is able to achieve performance comparable to WASP as reported by Wong (2007).

System	English			Spanish		
	Prec.	*Rec.*	*F*	*Prec.*	*Rec.*	*F*
WASP	95.42	70.00	80.76	91.99	72.40	81.03
Model III+R	91.46	72.80	**81.07**	95.19	79.20	**86.46**
System	**Japanese**			**Turkish**		
	Prec.	*Rec.*	*F*	*Prec.*	*Rec.*	*F*
WASP	91.98	74.40	**82.86**	96.96	62.40	75.93
Model III+R	87.56	76.00	81.37	93.82	66.80	**78.04**

Table 5: Performance on different natural languages for GEOQUERY-250 corpus

Our model is generic, which requires no domain-dependent knowledge and should be applicable to a wide range of different domains. Like all research in this area, the ultimate goal is to scale to more complex, open-domain language understanding problems. In future, we would like to create a larger corpus in another domain with multiple natural language annotations to further evaluate the scalability and portability of our approach.

10 Conclusions

We presented a new generative model that simultaneously produces both NL sentences and their corresponding MR structures. The model can be effectively applied to the task of transforming NL sentences to their MR structures. We also developed a new dynamic programming algorithm for efficient training and decoding. We demonstrated that this approach, augmented with a discriminative reranking technique, achieves state-of-the-art performance when tested on standard benchmark corpora.

In future, we would like to extend the current model to have a wider range of support of MR formalisms, such as the one with lambda-calculus support. We are also interested in investigating ways to apply the generative model to the inverse task: generation of a NL sentence that explains a given MR structure.

Learning with Compositional Semantics as Structural Inference for Subsentential Sentiment Analysis

Abstract

Determining the polarity of a sentiment-bearing expression requires more than a simple bag-of-words approach. In particular, words or constituents within the expression can interact with each other to yield a particular overall polarity. In this paper, we view such subsentential interactions in light of *compositional semantics*, and present a novel learning-based approach that incorporates structural inference motivated by compositional semantics into the learning procedure. Our experiments show that (1) simple heuristics based on compositional semantics can perform better than learning-based methods that do not incorporate compositional semantics (accuracy of 89.7% vs. 89.1%), but (2) a method that integrates compositional semantics into learning performs better than all other alternatives (90.7%). We also find that "content-word negators", not widely employed in previous work, play an important role in determining expression-level polarity. Finally, in contrast to conventional wisdom, we find that expression-level classification accuracy uniformly *decreases* as additional, potentially disambiguating, context is considered.

1 Introduction

Determining the polarity of sentiment-bearing expressions at or below the sentence level requires more than a simple bag-of-words approach. One of the difficulties is that words or constituents within the expression can interact with each other to yield a particular overall polarity. To facilitate our discussion, consider the following examples:

1: [I did [*not*]$^{\neg}$ have any [*doubt*]$^{-}$ about it.]$^{+}$
2: [The report [*eliminated*]$^{\neg}$ my [*doubt*]$^{-}$.]$^{+}$
3: [They could [*not*]$^{\neg}$ [*eliminate*]$^{\neg}$ my [*doubt*]$^{-}$.]$^{-}$

In the first example, "doubt" in isolation carries a negative sentiment, but the overall polarity of the sentence is positive because there is a *negator* "not", which flips the polarity. In the second example, both "eliminated" and "doubt" carry negative sentiment in isolation, but the overall polarity of the sentence is positive because "eliminated" acts as a negator for its argument "doubt". In the last example, there are effectively two negators – "not" and "eliminated" – which reverse the polarity of "doubt" twice, resulting in the negative polarity for the overall sentence.

These examples demonstrate that words or constituents interact with each other to yield the expression-level polarity. And a system that simply takes the majority vote of the polarity of individual words will not work well on the above examples. Indeed, much of the previous learning-based research on this topic tries to incorporate salient interactions by encoding them as features. One approach includes features based on *contextual valence shifters*[1] (Polanyi and Zaenen, 2004), which are words that affect the polarity or intensity of sentiment over neighboring text spans (e.g., Kennedy and Inkpen (2005), Wilson et al. (2005), Shaikh et al. (2007)). Another approach encodes frequent subsentential patterns (e.g., McDonald et al. (2007)) as features; these might indirectly capture some of the subsentential interactions that affect polarity. How-

[1]For instance, "never", "nowhere", "little", "most", "lack", "scarcely", "deeply".

ever, both types of approach are based on learning models with a flat bag-of-features: some structural information can be encoded as higher order features, but the final representation of the input is still a flat feature vector that is inherently too limited to adequately reflect the complex structural nature of the underlying subsentential interactions. (Liang et al., 2008)

Moilanen and Pulman (2007), on the other hand, handle the structural nature of the interactions more directly using the ideas from *compositional semantics* (e.g., Montague (1974), Dowty et al. (1981)). In short, *the Principle of Compositionality* states that the meaning of a compound expression is a function of the meaning of its parts and of the syntactic rules by which they are combined (e.g., Montague (1974), Dowty et al. (1981)). And Moilanen and Pulman (2007) develop a collection of composition rules to assign a sentiment value to individual expressions, clauses, or sentences. Their approach can be viewed as a type of structural inference, but their hand-written rules have not been empirically compared to learning-based alternatives, which one might expect to be more effective in handling some aspects of the polarity classification task.

In this paper, we begin to close the gap between learning-based approaches to expression-level polarity classification and those founded on compositional semantics: we present a novel learning-based approach that incorporates structural inference motivated by compositional semantics into the learning procedure.

Adopting the view point of compositional semantics, our working assumption is that the polarity of a sentiment-bearing expression can be determined in a two-step process: (1) assess the polarities of the constituents of the expression, and then (2) apply a relatively simple set of inference rules to combine them recursively. Rather than a rigid application of hand-written compositional inference rules, however, we hypothesize that an ideal solution to the expression-level polarity classification task will be a method that can exploit ideas from compositional semantics while providing the flexibility needed to handle the complexities of real-world natural language — exceptions, unknown words, missing semantic features, and inaccurate or missing rules. The learning-based approach proposed in this paper takes a first step in this direction.

In addition to the novel learning approach, this paper presents new insights for *content-word negators*, which we define as content words that can negate the polarity of neighboring words or constituents. (e.g., words such as "eliminated" in the example sentences). Unlike *function-word negators*, such as "not" or "never", content-word negators have been recognized and utilized less actively in previous work. (Notable exceptions include e.g., Niu et al. (2005), Wilson et al. (2005), and Moilanen and Pulman (2007).[2])

In our experiments, we compare learning- and non-learning-based approaches to expression-level polarity classification — with and without compositional semantics — and find that (1) simple heuristics based on compositional semantics outperform (89.7% in accuracy) other reasonable heuristics that do not incorporate compositional semantics (87.7%); they can also perform better than simple learning-based methods that do not incorporate compositional semantics (89.1%), (2) combining learning with the heuristic rules based on compositional semantics further improves the performance (90.7%), (3) content-word negators play an important role in determining the expression-level polarity, and, somewhat surprisingly, we find that (4) expression-level classification accuracy uniformly decreases as additional, potentially disambiguating, context is considered.

In what follows, we first explore heuristic-based approaches in §2, then we present learning-based approaches in §3. Next we present experimental results in §4, followed by related work in §5.

2 Heuristic-Based Methods

This section describes a set of heuristic-based methods for determining the polarity of a sentiment-bearing expression. Each assesses the polarity of the words or constituents using a polarity lexicon that indicates whether a word has positive or negative polarity, and finds negators in the given expression using a negator lexicon. The methods then infer the expression-level polarity using voting-based heuristics (§ 2.1) or heuristics that incorporate compositional semantics (§2.2). The lexicons are described

[2]See §5. Related Work for detailed discussion.

	VOTE	NEG(1)	NEG(N)	NEGEX(1)	NEGEX(N)	COMPO
type of negators	none	function-word		function-word & content-word		
maximum # of negations applied	0	1	n	1	n	n
scope of negators	N/A	over the entire expression				compositional

Table 1: Heuristic methods. (n refers to the number of negators found in a given expression.)

	Rules		Examples
1	Polarity(not_[arg1]) =	$\neg$ Polarity(arg1)	not [bad]$_{arg1}$.
2	Polarity([VP]_[NP]) =	Compose([VP], [NP])	[destroyed]$_{VP}$ [the terrorism]$_{NP}$.
3	Polarity([VP1]_to_[VP2]) =	Compose([VP1], [VP2])	[refused]$_{VP1}$ to [deceive]$_{VP2}$ the man.
4	Polarity([adj]_to_[VP]) =	Compose([adj], [VP])	[unlikely]$_{adj}$ to [destroy]$_{VP}$ the planet.
5	Polarity([NP1]_[IN]_[NP2]) =	Compose([NP1], [NP2])	[lack]$_{NP1}$ [of]$_{IN}$ [crime]$_{NP2}$ in rural areas.
6	Polarity([NP]_[VP]) =	Compose([VP], [NP])	[pollution]$_{NP}$ [has decreased]$_{VP}$.
7	Polarity([NP]_be_[adj]) =	Compose([adj], [NP])	[harm]$_{NP}$ is [minimal]$_{adj}$.

Definition of Compose(arg1, arg2)

For COMPOMC: (**COMPO**sition with **M**ajority **C**lass)	Compose(arg1, arg2) =
	 if (arg1 is a negator) then $\neg$ Polarity(arg2)
	 else if (Polarity(arg1) == Polarity(arg2)) then Polarity(arg1)
	 else the majority polarity of data

For COMPOPR: (**COMPO**sition with **PR**iority)	Compose(arg1, arg2) =
	 if (arg1 is a negator) then $\neg$ Polarity(arg2)
	 else Polarity(arg1)

Table 2: Compositional inference rules motivated by compositional semantics.

in §2.3.

2.1 Voting

We first explore five simple heuristics based on voting. VOTE is defined as the majority polarity vote by words in a given expression. That is, we count the number of positive polarity words and negative polarity words in a given expression, and assign the majority polarity to the expression. In the case of a tie, we default to the prevailing polarity of the data.

For NEG(1), we first determine the majority polarity vote as above, and then if the expression contains *any* function-word negator, flip the polarity of the majority vote once. NEG(N) is similar to NEG(1), except we flip the polarity of the majority vote n times after the majority vote, where n is the number of function-word negators in a given expression.

NEGEX(1) and NEGEX(N) are defined similarly as NEG(1) and NEG(N) above, except both function-word negators and content-word negators are considered as negators when flipping the polarity of the majority vote. See Table 1 for summary. Note that a word can be both a negator and have a negative prior polarity. For the purpose of voting, if a word is defined as a negator per the voting scheme, then that word does not participate in the majority vote.

For brevity, we refer to NEG(1) and NEG(N) collectively as NEG, and NEGEX(1) and NEGEX(N) collectively as NEGEX.

2.2 Compositional semantics

Whereas the heuristics above use voting-based inference, those below employ a set of hand-written rules motivated by compositional semantics. Table 2 shows the definition of the rules along with motivating examples. In order to apply a rule, we first detect a syntactic pattern (e.g., [destroyed]$_{VP}$ [the terrorism]$_{NP}$), then apply the *Compose* function as defined in Table 2 (e.g., Compose([destroyed], [the terrorism]) by rule #2).[3]

[3]Our implementation uses part-of-speech tags and function-words to coarsely determine the patterns. An implementation

Compose first checks whether the first argument is a negator, and if so, flips the polarity of the second argument. Otherwise, *Compose* resolves the polarities of its two arguments. Note that if the second argument is a negator, we do not flip the polarity of the first argument, because the first argument in general is not in the semantic scope of the negation.[4] Instead, we treat the second argument as a constituent with negative polarity.

We experiment with two variations of the *Compose* function depending on how conflicting polarities are resolved: COMPOMC uses a *Compose* function that defaults to the **M**ajority **C**lass of the polarity of the data,[5] while COMPOPR uses a *Compose* function that selects the polarity of the argument that has higher semantic **PR**iority. For brevity, we refer to COMPOPR and COMPOMC collectively as COMPO.

2.3 Lexicons

The polarity lexicon is initialized with the lexicon of Wilson et al. (2005) and then expanded using the General Inquirer dictionary.[6] In particular, a word contained in at least two of the following categories is considered as positive: POSITIV, PSTV, POSAFF, PLEASUR, VIRTUE, INCREAS, and a word contained in at least one of the following categories is considered as negative: NEGATIV, NGTV, NEGAFF, PAIN, VICE, HOSTILE, FAIL, ENLLOSS, WLBLOSS, TRANLOSS.

For the (function- and content-word) negator lexicon, we collect a handful of seed words as well as General Inquirer words that appear in either NOTLW or DECREAS category. Then we expand the list of content-negators using the synonym information of WordNet (Miller, 1995) to take a simple vote among senses.

based on parse trees might further improve the performance.

[4]Moilanen and Pulman (2007) provide more detailed discussion on the semantic scope of negations and the semantic priorities in resolving polarities.

[5]The majority polarity of the data we use for our experiments is negative.

[6]Available at http://www.wjh.harvard.edu/∼inquirer/. When consulting the General Inquirer dictionary, senses with less than 5% frequency and senses specific to an idiom are dropped.

3 Learning-Based Methods

While we expect that a set of hand-written heuristic rules motivated by compositional semantics can be effective for determining the polarity of a sentiment-bearing expression, we do not expect them to be perfect. Interpreting natural language is such a complex task that writing a perfect set of rules would be extremely challenging. Therefore, a more ideal solution would be a learning-based method that can exploit ideas from compositional semantics while providing the flexibility to the rigid application of the heuristic rules. To this end, we present a novel learning-based approach that incorporates inference rules inspired by compositional semantics into the learning procedure (§3.2). To assess the effect of compositional semantics in the learning-based methods, we also experiment with a simple classification approach that does not incorporate compositional semantics (§3.1). The details of these two approaches are elaborated in the following subsections.

3.1 Simple Classification (SC)

Given an expression x consisting of n words x_1, ..., x_n, the task is to determine the polarity $y \in \{positive, negative\}$ of x. In our simple binary classification approach, x is represented as a vector of features $\mathbf{f}(x)$, and the prediction y is given by $\text{argmax}_y \mathbf{w} \cdot \mathbf{f}(x, y)$, where $\mathbf{w}$ is a vector of parameters learned from training data. In our experiment, we use an online SVM algorithm called MIRA (Margin Infused Relaxed Algorithm) (Crammer and Singer, 2003)[7] for training.

For each x, we encode the following features:

- Lexical: We add every word x_i in x, and also add the lemma of x_i produced by the CASS partial parser toolkit (Abney, 1996).
- Dictionary: In order to mitigate the problem of unseen words in the test data, we add features that describe word categories based on the General Inquirer dictionary. We add this feature for each x_i that is not a stop word.
- Vote: We experiment with two variations of voting-related features: for SC-VOTE, we add

[7]We use the Java implementation of this algorithm available at http://www.seas.upenn.edu/∼strctlrn/StructLearn /StructLearn.html.

Simple Classification	Classification with Compositional Inference
$y \leftarrow \text{argmax}_y \text{ score}(y)$ $l \leftarrow \text{loss\_flat}(y^*, y)$ $\mathbf{w} \leftarrow \text{update}(\mathbf{w}, l, y^*, y)$	Find K best $\mathbf{z}$ and denote them as $\mathcal{Z} = \{\mathbf{z}^{(1)}, ..., \mathbf{z}^{(K)}\}$ $s.t. \forall\, i < j,\ \text{score}(\mathbf{z}^{(i)}) > \text{score}(\mathbf{z}^{(j)})$ $\mathbf{z}^{bad} \leftarrow \min_k \mathbf{z}^{(k)}\ s.t.\ \text{loss\_compo}(y^*, \mathbf{z}^{(k)}, x) > 0$ (if such $\mathbf{z}^{bad}$ not found in $\mathcal{Z}$, skip parameter update for this.) If $\text{loss\_compo}(y^*, \mathbf{z}^*, x) > 0$ $\mathbf{z}^{good} \leftarrow \min_k \mathbf{z}^{(k)}\ s.t.\ \text{loss\_compo}(y^*, \mathbf{z}^{(k)}, x) = 0$ $z^* \leftarrow \mathbf{z}^{good}$ (if such $\mathbf{z}^{good}$ not found in $\mathcal{Z}$, stick to the original z^*.) $l \leftarrow \text{loss\_compo}(y^*, \mathbf{z}^{bad}, x) - \text{loss\_compo}(y^*, \mathbf{z}^*, x)$ $\mathbf{w} \leftarrow \text{update}(\mathbf{w}, l, \mathbf{z}^*, \mathbf{z}^{bad})$
Definitions of score functions and loss functions	
$\text{score}(y) := \mathbf{w} \cdot \mathbf{f}(x, y)$ $\text{loss\_flat}(y^*, y) := \text{if } (y^* = y)\ 0 \text{ else } 1$	$\text{score}(\mathbf{z}) := \sum_i \text{score}(z_i) := \sum_i \mathbf{w} \cdot \mathbf{f}(x, z_i, i)$ $\text{loss\_compo}(y^*, \mathbf{z}, x) := \text{if } (y^* = \mathcal{C}(x, \mathbf{z}))\ 0 \text{ else } 1$

Figure 1: Training procedures. $y^* \in \{positive, negative\}$ denotes the true label for a given expression $x = x_1, ..., x_n$. $\mathbf{z}^*$ denotes the pseudo gold standard for hidden variables $\mathbf{z}$.

a feature that indicates the dominant polarity of words in the given expression, without considering the effect of negators. For SC-NEGEX, we count the number of content-word negators as well as function-word negators to determine whether the final polarity should be flipped. Then we add a conjunctive feature that indicates the dominant polarity together with whether the final polarity should be flipped. For brevity, we refer to SC-VOTE and SC-NEGEX collectively as SC.

Notice that in this simple binary classification setting, it is inherently difficult to capture the compositional structure among words in x, because $\mathbf{f}(x, y)$ is merely a flat bag of features, and the prediction is governed simply by the dot product of $\mathbf{f}(x, y)$ and the parameter vector w.

3.2 Classification with Compositional Inference (CCI)

Next, instead of determining y directly from x, we introduce hidden variables $\mathbf{z} = (z_1, ..., z_n)$ as intermediate decision variables, where $z_i \in \{positive, negative, negator, none\}$, so that z_i represents whether x_i is a word with positive/negative polarity, or a negator, or none of the above. For simplicity, we let each intermediate decision variable z_i (a) be determined independently from other intermediate decision variables, and (b) depend only on the input x, so that $z_i = \text{argmax}_{z_i} \mathbf{w} \cdot \mathbf{f}(x, z_i, i)$, where $\mathbf{f}(x, z_i, i)$ is the feature vector encoding around the ith word (described on the next page). Once we determine the intermediate decision variables, we apply the heuristic rules motivated by compositional semantics (from Table 2) in order to obtain the final polarity y of x. That is, $y = \mathcal{C}(x, \mathbf{z})$, where $\mathcal{C}$ is the function that applies the compositional inference, either COMPOPR or COMPOMC.

For training, there are two issues we need to handle: the first issue is dealing with the hidden variables z. Because the structure of compositional inference $\mathcal{C}$ does not allow dynamic programming, it is intractable to perform exact expectation-maximization style training that requires enumerating all possible values of the hidden variables $\mathbf{z}$. Instead, we propose a simple and tractable training

```
For each token $x_i$,
  if $x_i$ is a word in the negator lexicon
    then $z_i^* \leftarrow negator$
  else if $x_i$ is in the polarity lexicon as negative
    then $z_i^* \leftarrow negative$
  else if $x_i$ is in the polarity lexicon as positive
    then $z_i^* \leftarrow positive$
  else
    then $z_i^* \leftarrow none$
```

Figure 2: Constructing Soft Gold Standard $\mathbf{z}^*$

rule based on the creation of a *soft* gold standard for $\mathbf{z}$. In particular, we exploit the fact that in our task, we can automatically construct a reasonably accurate gold standard for $\mathbf{z}$, denoted as $\mathbf{z}^*$: as shown in Figure 2, we simply rely on the negator and polarity lexicons. Because $\mathbf{z}^*$ is not always correct, we allow the training procedure to replace $\mathbf{z}^*$ with potentially better assignments as learning proceeds: in the event that the soft gold standard $\mathbf{z}^*$ leads to an incorrect prediction, we search for an assignment that leads to a correct prediction to replace $\mathbf{z}^*$. The exact procedure is given in Figure 1, and will be discussed again shortly.

Figure 1 shows how we modify the parameter update rule of MIRA (Crammer and Singer, 2003) to reflect the aspect of compositional inference. In the event that the soft gold standard $\mathbf{z}^*$ leads to an incorrect prediction, we search for $\mathbf{z}^{good}$, the assignment with highest score that leads to a correct prediction, and replace $\mathbf{z}^*$ with $\mathbf{z}^{good}$. In the event of no such $\mathbf{z}^{good}$ being found among the K-best assignments of $\mathbf{z}$, we stick with $\mathbf{z}^*$.

The second issue is finding the assignment of $\mathbf{z}$ with the highest score$(\mathbf{z}) = \sum_i \mathbf{w} \cdot \mathbf{f}(x, z_i, i)$ that leads to an incorrect prediction $y = \mathcal{C}(x, \mathbf{z})$. Because the structure of compositional inference $\mathcal{C}$ does not allow dynamic programming, finding such an assignment is again intractable. We resort to enumerating only over K-best assignments instead. If none of the K-best assignments of $\mathbf{z}$ leads to an incorrect prediction y, then we skip the training instance for parameter update.

Features. For each x_i in x, we encode the following features:

- Lexical: We include the current word x_i as well as the lemma of x_i produced by CASS partial parser toolkit (Abney, 1996). We also add a boolean feature to indicate whether the current word is a stop word.
- Dictionary: In order to mitigate the problem with unseen words in the test data, we add features that describe word categories based on the General Inquirer dictionary. We add this feature for each x_i that is not a stop word. We also add a number of boolean features that provide following properties of x_i using the polarity lexicon and the negator lexicon:
  - whether x_i is a function-word negator
  - whether x_i is a content-word negator
  - whether x_i is a negator of any kind
  - the polarity of x_i according to Wilson et al. (2005)'s polarity lexicon
  - the polarity of x_i according to the lexicon derived from the General Inquirer dictionary
  - conjunction of the above two features
- Vote: We encode the same vote feature that we use for SC-NEGEX described in § 3.1.

As in the heuristic-based compositional semantics approach (§ 2.2), we experiment with two variations of this learning-based approach: CCI-COMPOPR and CCI-COMPOMC, whose compositional inference rules are COMPOPR and COMPOMC respectively. For brevity, we refer to both variations collectively as CCI-COMPO.

4 Experiments

The experiments below evaluate our heuristic- and learning-based methods for subsentential sentiment analysis (§ 4.1). In addition, we explore the role of context by expanding the boundaries of the sentiment-bearing expressions (§ 4.2).

4.1 Evaluation with given boundaries

For evaluation, we use the Multi-Perspective Question Answering (MPQA) corpus (Wiebe et al., 2005), which consists of 535 newswire documents manually annotated with phrase-level subjectivity information. We evaluate on all strong (i.e., intensity of expression is 'medium' or higher), sentiment-bearing (i.e., polarity is 'positive' or 'negative') expressions.[8] As a result, we can assume the boundaries of the expressions are given. Performance is reported using 10-fold cross-validation on 400 documents; a separate 135 documents were used as a development set. Based on pilot experiments on the development data, we set parameters for MIRA as follows: slack variable to 0.5, and the number of incorrect labels (constraints) for each parameter update to 1. The number of iterations (epochs) for training is set to 1 for simple classification, and to 4

[8]We discard expressions with confidence marked as 'uncertain'.

Heuristic-Based							Learning-Based			
VOTE	NEG (1)	NEG (N)	NEG EX (1)	NEG EX (N)	COMPO MC	COMPO PR	SC VOTE	SC NEG EX	CCI COMPO MC	CCI COMPO PR
86.5	82.0	82.2	87.7	87.7	89.7	89.4	88.5	89.1	90.6	90.7

Table 3: Performance (in accuracy) on MPQA dataset.

Data	Heuristic-Based							Learning-Based			
	VOTE	NEG (1)	NEG (N)	NEG EX (1)	NEG EX (N)	COMPO MC	COMPO PR	SC VOTE	SC NEG EX	CCI COMPO MC	CCI COMPO PR
[-0,+0]	86.5	82.0	82.2	87.7	87.7	89.7	89.4	88.5	89.1	90.6	90.7
[-1,+1]	86.4	81.0	81.2	87.2	87.2	89.3	89.0	88.3	88.4	89.5	89.4
[-5,+5]	85.9	79.0	79.4	85.7	85.6	88.2	88.0	86.4	87.1	88.7	88.7
[-∞,+∞]	85.3	75.8	76.9	83.9	83.9	87.0	86.9	85.8	85.8	87.3	87.5

Table 4: Performance (in accuracy) on MPQA data set with varying boundaries of expressions.

for classification with compositional inference. We use $K = 20$ for classification with compositional inference.

Results. Performance is reported in Table 3. Interestingly, the heuristic-based methods NEG ($\sim 82.2\%$) that only consider function-word negators perform even worse than VOTE (86.5%), which does not consider negators. On the other hand, the NEGEX methods (87.7%) that do consider content-word negators as well as function-word negators perform better than VOTE. This confirms the importance of content-word negators for determining the polarities of expressions. The heuristic-based methods motivated by compositional semantics COMPO further improve the performance over NEGEX, achieving up to 89.7% accuracy. In fact, these heuristics perform even better than the SC learning-based methods ($\sim 89.1\%$). This shows that heuristics that take into account the compositional structure of the expression can perform better than learning-based methods that do not exploit such structure.

Finally, the learning-based methods that incorporate compositional inference CCI-COMPO ($\sim 90.7\%$) perform better than all of the previous methods. The difference between CCI-COMPOPR (90.7%) and SC-NEGEX (89.1%) is statistically significant at the .05 level by paired t-test. The difference between COMPO and any other heuristic that is not based on computational semantics is also statistically significant. In addition, the difference between CCICOMPOPR (learning-based) and COMPOMC (non-learning-based) is statistically significant, as is the difference between NEGEX and VOTE.

4.2 Evaluation with noisy boundaries

One might wonder whether employing additional context outside the annotated expression boundaries could further improve the performance. Indeed, conventional wisdom would say that it is necessary to employ such contextual information (e.g., Wilson et al. (2005)). In any case, it is important to determine whether our results will apply to more real-world settings where human-annotated expression boundaries are not available.

To address these questions, we gradually relax our previous assumption that the exact boundaries of expressions are given: for each annotation boundary, we expand the boundary by x words for each direction, up to sentence boundaries, where $x \in \{1, 5, \infty\}$. We stop expanding the boundary if it will collide with the boundary of an expression with a different polarity, so that we can consistently recover the expression-level gold standard for evaluation. This expansion is applied to both the training and test data, and the performance is reported in Table 4. From this experiment, we make the following observations:

- Expanding the boundaries hurts the performance for any method. This shows that most of relevant context for judging the polarity is contained within the expression boundaries, and motivates the task of finding the boundaries of opinion expressions.

- The NegEx methods perform better than Vote only when the expression boundaries are reasonably accurate. When the expression boundaries are expanded up to sentence boundaries, they perform worse than Vote. We conjecture this is because the scope of negators tends to be limited to inside of expression boundaries.
- The Compo methods always perform better than any other heuristic-based methods. And their performance does not decrease as steeply as the NegEx methods as the expression boundaries expand. We conjecture this is because methods based on compositional semantics can handle the scope of negators more adequately.
- Among the learning-based methods, those that involve compositional inference (CCI-Compo) always perform better than those that do not (SC) for any boundaries. And learning with compositional inference tend to perform better than the rigid application of heuristic rules (Compo), although the relative performance gain decreases once the boundaries are relaxed.

5 Related Work

The task focused on in this paper is similar to that of Wilson et al. (2005) in that the general goal of the task is to determine the polarity in context at a sub-sentence level. However, Wilson et al. (2005) formulated the task differently by limiting their evaluation to individual words that appear in their polarity lexicon. Also, their approach was based on a flat bag of features, and only a few examples of what we call content-word negators were employed.

Our use of compositional semantics for the task of polarity classification is preceded by Moilanen and Pulman (2007), but our work differs in that we integrate the key idea of compositional semantics into learning-based methods, and that we perform empirical comparisons among reasonable alternative approaches. For comparison, we evaluated our approaches on the polarity classification task from SemEval-07 (Strapparava and Mihalcea, 2007). We achieve 88.6% accuracy with CompoPR, 90.1% with SCNegEx, and 87.6% with CCICompoMC.[9] There are a number of possible reasons for our lower performance vs. Moilanen and Pulman (2007) on this data set. First, SemEval-07 does not include a training data set for this task, so we use 400 documents from the MPQA corpus instead. In addition, the SemEval-07 data is very different from the MPQA data in that (1) the polarity annotation is given only at the sentence level, (2) the sentences are shorter, with simpler structure, and not as many negators as the MPQA sentences, and (3) there are many more instances with positive polarity than in the MPQA corpus.

Nairn et al. (2006) also employ a "polarity" propagation algorithm in their approach to the semantic interpretation of implicatives. However, their notion of polarity is quite different from that assumed here and in the literature on sentiment analysis. In particular, it refers to the degree of "commitment" of the author to the truth or falsity of a complement clause for a textual entailment task.

McDonald et al. (2007) use a structured model to determine the sentence-level polarity and the document-level polarity simultaneously. But decisions at each sentence level does not consider structural inference within the sentence.

Among the studies that examined content-word negators, Niu et al. (2005) manually collected a small set of such words (referred as "words that change phases"), but their lexicon was designed mainly for the medical domain and the type of negators was rather limited. Wilson et al. (2005) also manually collected a handful of content-word negators (referred as "general polarity shifters"), but not extensively. Moilanen and Pulman (2007) collected a more extensive set of negators semi-automatically using WordNet 2.1, but the empirical effect of such words was not explicitly investigated.

[9]For lack of space, we only report our performance on instances with strong intensities as defined in Moilanen and Pulman (2007), which amounts to only 208 test instances. The cross-validation set of MPQA contains $4.9k$ instances.

6 Conclusion

In this paper, we consider the task of determining the polarity of a sentiment-bearing expression, considering the effect of interactions among words or constituents in light of compositional semantics. We presented a novel learning-based approach that incorporates structural inference motivated by compositional semantics into the learning procedure. Our approach can be considered as a small step toward bridging the gap between computational semantics and machine learning methods. Our experimental results suggest that this direction of research is promising. Future research includes an approach that learns the compositional inference rules from data.

A Phrase-Based Alignment Model for Natural Language Inference

Bill MacCartney, Michel Galley, Christopher D. Manning
Natural Language Processing Group, Stanford University
{wcmac,mgalley,manning}@stanford.edu

Abstract

The alignment problem—establishing links between corresponding phrases in two related sentences—is as important in natural language inference (NLI) as it is in machine translation (MT). But the tools and techniques of MT alignment do not readily transfer to NLI, where one cannot assume semantic equivalence, and for which large volumes of bitext are lacking. We present a new NLI aligner, the MANLI system, designed to address these challenges. It uses a phrase-based alignment representation, exploits external lexical resources, and capitalizes on a new set of supervised training data. We compare the performance of MANLI to existing NLI and MT aligners on an NLI alignment task over the well-known Recognizing Textual Entailment data. We show that MANLI significantly outperforms existing aligners, achieving gains of 6.2% in F_1 over a representative NLI aligner and 10.5% over GIZA++.

1 Introduction

The problem of natural language inference (NLI) is to determine whether a natural-language hypothesis H can reasonably be inferred from a given premise text P. In order to recognize that *Kennedy was killed* can be inferred from *JFK was assassinated*, one must first recognize the correspondence between *Kennedy* and *JFK*, and between *killed* and *assassinated*. Consequently, most current approaches to NLI rely, implicitly or explicitly, on a facility for *alignment*—that is, establishing links between corresponding entities and predicates in P and H. Recent entries in the annual Recognizing Textual Entailment (RTE) competition (Dagan et al., 2005) have addressed the alignment problem in a variety of ways, though often without distinguishing it as a separate subproblem. Glickman et al. (2005) and Jijkoun and de Rijke (2005), among others, have explored approaches based on measuring the degree of lexical overlap between bags of words. While ignoring structure, such methods depend on matching each word in H to the word in P with which it is most similar—in effect, an alignment. At the other extreme, Tatu and Moldovan (2007) and Bar-Haim et al. (2007) have formulated the inference problem as analogous to proof search, using inferential rules which encode (among other things) knowledge of lexical relatedness. In such approaches, the correspondence between the words of P and H is implicit in the steps of the proof.

Increasingly, however, the most successful RTE systems have made the alignment problem explicit. Marsi and Krahmer (2005) and MacCartney et al. (2006) first advocated pipelined system architectures containing a distinct alignment component, a strategy crucial to the top-performing systems of Hickl et al. (2006) and Hickl and Bensley (2007). However, each of these systems has pursued alignment in idiosyncratic and poorly-documented ways, often using proprietary data, making comparisons and further development difficult.

In this paper we undertake the first systematic study of alignment for NLI. We propose a new NLI alignment system which uses a phrase-based representation of alignment, exploits external resources for knowledge of semantic relatedness, and capitalizes on the recent appearance of new supervised training data for NLI alignment. In addition, we examine the relation between NLI alignment and MT alignment, and investigate whether existing MT aligners can usefully be applied in the NLI setting.

2 NLI alignment vs. MT alignment

The alignment problem is familiar in machine translation (MT), where recognizing that *she came* is a good translation for *elle est venue* requires establishing a correspondence between *she* and *elle*, and between *came* and *est venue*. The MT community has developed not only an extensive literature on alignment (Brown et al., 1993; Vogel et al., 1996; Marcu and Wong, 2002; DeNero et al., 2006), but also standard, proven alignment tools such as GIZA++ (Och and Ney, 2003). Can off-the-shelf MT aligners be applied to NLI? There is reason to be doubtful. Alignment for NLI differs from alignment for MT in several important respects, including:

1. Most obviously, it is monolingual rather than cross-lingual, opening the door to utilizing abundant (monolingual) sources of information on semantic relatedness, such as WordNet.
2. It is intrinsically asymmetric: P is often much longer than H, and commonly contains phrases or clauses which have no counterpart in H.
3. Indeed, one cannot assume even approximate semantic equivalence—usually a given in MT. Because NLI problems include both valid and invalid inferences, the semantic content of H may diverge substantially from P. An NLI aligner must be designed to accommodate frequent unaligned words and phrases.
4. Little training data is available. MT alignment models are typically trained in unsupervised fashion, inducing lexical correspondences from massive quantities of sentence-aligned bitexts. While NLI aligners could in principle do the same, large volumes of suitable data are lacking. NLI aligners must therefore depend on smaller quantities of supervised training data, supplemented by external lexical resources. Conversely, while existing MT aligners can make use of dictionaries, they are not designed to harness other sources of information on degrees of semantic relatedness.

Consequently, the tools and techniques of MT alignment may not transfer readily to NLI alignment. We investigate the matter empirically in section 5.2.

3 Data

Until recently, research on alignment for NLI has been hampered by a paucity of high-quality, publicly available data from which to learn. Happily, that has begun to change, with the release by Microsoft Research (MSR) of human-generated alignment annotations (Brockett, 2007) for inference problems from the second Recognizing Textual Entailment (RTE2) challenge (Bar-Haim et al., 2006). To our knowledge, this work is the first to exploit this data for training and evaluation of NLI alignment models.

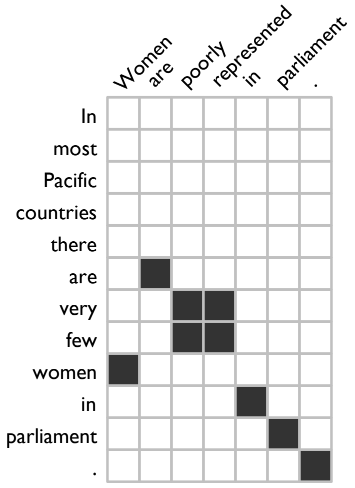

Figure 1: The MSR gold-standard alignment for problem 116 from the RTE2 development set.

The RTE2 data consists of a development set and a test set, each containing 800 inference problems. Each problem consists of a premise and a hypothesis. The premises contain 29 words on average; the hypotheses, 11 words. Each problem is marked as a valid or invalid inference (50% each); however, these annotations are ignored during alignment, since they would not be available during testing of a complete NLI system.

The MSR annotations use an alignment representation which is token-based, but many-to-many, and thus allows implicit alignment of multi-word phrases. Figure 1 shows an example in which *very few* has been aligned with *poorly represented*.

In the MSR data, every alignment link is marked as SURE or POSSIBLE. In making this distinction, the annotators have followed a convention common in MT, which permits alignment precision to be measured against both SURE and POSSIBLE links, while recall is measured against only SURE links. In this work, however, we have chosen to ignore POSSIBLE links, embracing the argument made by (Fraser and Marcu, 2007) that their use has impeded progress in MT alignment models, and that SURE-only annotation is to be preferred.

Each RTE2 problem was independently annotated by three people, following carefully designed annotation guidelines. Inter-annotator agreement was high: Brockett (2007) reports Fleiss' kappa[1] scores of about 0.73 ("substantial agreement") for mappings from H tokens to P tokens; and all three annotators agreed on $\sim$70% of proposed links, while at least two of three agreed on more than 99.7% of proposed links,[2] attesting to the high quality of the annotation data. For this work, we merged the three independent annotations, using majority rule,[3] to obtain a gold-standard annotation containing an average of 7.3 links per RTE problem.

4 The MANLI aligner

In this section, we describe the MANLI aligner, a new alignment system designed expressly for NLI alignment. The MANLI system consists of four elements: (1) a phrase-based representation of alignment, (2) a feature-based linear scoring function for alignments, (3) a decoder which uses simulated annealing to find high-scoring alignments, and (4) perceptron learning to optimize feature weights.

4.1 A phrase-based alignment representation

MANLI uses an alignment representation which is intrinsically phrase-based. (Following the usage common in MT, we use "phrase" to mean any contiguous span of tokens, not necessarily corresponding to a syntactic phrase.) We represent an alignment E between a premise P and a hypothesis H as a set of phrase edits $\{e_1, e_2, \ldots\}$, each belonging to one of four types:

- an EQ edit connects a phrase in P with an equal (by word lemmas) phrase in H
- a SUB edit connects a phrase in P with an unequal phrase in H
- a DEL edit covers an unaligned phrase in P
- an INS edit covers an unaligned phrase in H

For example, the alignment shown in figure 1 can be represented by the set $\{$DEL(*In*$_1$), DEL(*most*$_2$), DEL(*Pacific*$_3$), DEL(*countries*$_4$), DEL(*there*$_5$), EQ(*are*$_6$, *are*$_2$), SUB(*very*$_7$ *few*$_8$, *poorly*$_3$ *represented*$_4$), EQ(*women*$_9$, *Women*$_1$), EQ(*in*$_{10}$, *in*$_5$), EQ(*parliament*$_{11}$, *parliament*$_6$), EQ(.$_{12}$, .$_7$)$\}$.[4]

Alignments are constrained to be one-to-one at the phrase level: every token in P and H belongs to exactly one phrase, which participates in exactly one edit (possibly DEL or INS). However, the phrase representation permits alignments which are many-to-many at the token level. In fact, this is the chief motivation for the phrase-based representation: we can align *very few* and *poorly represented* as units, without being forced to make an arbitrary choice as to which word goes with which word. Moreover, our scoring function can make use of lexical resources which have information about semantic relatedness of multi-word phrases, not merely individual words.

About 23% of the MSR gold-standard alignments are not one-to-one (at the token level), and are therefore technically unreachable for MANLI, which is constrained to generate one-to-one alignments. However, by merging contiguous token links into phrase edits of size > 1, most MSR alignments (about 92%) can be straightforwardly converted into MANLI-reachable alignments. For the purpose of model training (but *not* for the evaluation described in section 5.4), we generated a version of the MSR data in which all alignments were converted to MANLI-reachable form.[5]

4.2 A feature-based scoring function

To score alignments, we use a simple feature-based linear scoring function, in which the score of an alignment is the sum of the scores of the edits it contains (including not only SUB and EQ edits, but also DEL and INS edits), and the score of an edit is the dot product of a vector encoding its features and a vector of weights. If E is a set of edits constituting

[1]Fleiss' kappa generalizes Cohen's kappa to the case where there are more than two annotators.

[2]The SURE/POSSIBLE distinction is taken as significant in computing all these figures.

[3]The handful of three-way disagreements were treated as POSSIBLE links, and thus were not used here.

[4]DEL and INS edits of size > 1 are possible in principle, but are not used in our training data.

[5]About 8% of the MSR alignments contain non-contiguous links, most commonly because P contains two references to an entity (e.g., *Christian Democrats* and *CDU*) which are both linked to a reference to the same entity in H (e.g., *Christian Democratic Union*). In such cases, one or more links must be eliminated to achieve a MANLI-reachable alignment. We used a string-similarity heuristic to break such conflicts, but were obliged to make an arbitrary choice in about 2% of cases.

an alignment, and $\mathbf{\Phi}$ is a vector of feature functions, the score s is given by:

$$s(E) = \sum_{e \in E} s(e) = \sum_{e \in E} \mathbf{w} \cdot \mathbf{\Phi}(e)$$

We'll explain how the feature weights $\mathbf{w}$ are set in section 4.4. The features used to characterize each edit are as follows:

Edit type features. We begin with boolean features encoding the type of each edit. We expect EQs to score higher than SUBs, and (since P is commonly longer than H) DELs to score higher than INSs.

Phrase features. Next, we have features which encode the sizes of the phrases involved in the edit, and whether these phrases are non-constituents (in syntactic parses of the sentences involved).

Lexical similarity feature. For SUB edits, a very important feature represents the lexical similarity of the substituends, as a real value in $[0, 1]$. This similarity score is computed as a max over a number of component scoring functions, some based on external lexical resources, including:

- various string similarity functions, of which most are applied to word lemmas
- measures of synonymy, hypernymy, antonymy, and semantic relatedness, including a widely-used measure due to Jiang and Conrath (1997), based on manually constructed lexical resources such as WordNet and NomBank
- a function based on the well-known distributional similarity metric of Lin (1998), which automatically infers similarity of words and phrases from their distributions in a very large corpus of English text

The ability to leverage external lexical resources—both manually and automatically constructed—is critical to the success of MANLI.

Contextual features. Even when the lexical similarity for a SUB edit is high, it may not be a good match. If P or H contains multiple occurrences of the same word—which happens frequently with function words, and occasionally with content words—lexical similarity may not suffice to determine the right match. To remedy this, we introduce contextual features for SUB and EQ edits. A real-valued *distortion* feature measures the difference between the relative positions of the substituends within their respective sentences, while boolean *matching neighbors* features indicate whether the tokens before and after the substituends are equal or similar.

```
Inputs
  • an alignment problem $\langle P, H \rangle$
  • a number of iterations $N$ (e.g. 100)
  • initial temperature $T_0$ (e.g. 40) and multiplier $r$ (e.g. 0.9)
  • a bound on edit size $max$ (e.g. 6)
  • an alignment scoring function, SCORE($E$)
Initialize
  • Let $E$ be an "empty" alignment for $\langle P, H \rangle$ (containing
    only DEL and INS edits, no EQ or SUB edits)
  • Set $\hat{E} = E$
Repeat for $i$ = 1 to $N$
  • Let $\{F_1, F_2, ...\}$ be the set of possible successors of $E$.
    To generate this set:
      – Consider every possible edit $f$ up to size $max$
      – Let $C(E, f)$ be the set of edits in $E$ which "conflict" with $f$
        (i.e., involve at least some of the same tokens as $f$)
      – Let $F = E \cup \{f\} \setminus C(E, f)$
  • Let $s(F)$ be a map from successors of $E$ to scores generated by SCORE
  • Set $p(F) = \exp s(F)$, and then normalize $p(F)$, transforming
    the score map to a probability distribution
  • Set $T_i = r \cdot T_{i-1}$
  • Set $p(F) = p(F)^{1/T_i}$, smoothing or sharpening $p(F)$
  • Renormalize $p(F)$
  • Choose a new value for $E$ by sampling from $p(F)$
  • If SCORE($E$) > SCORE($\hat{E}$), set $\hat{E}$ = $E$
Return $\hat{E}$
```

Figure 2: The MANLI-ALIGN algorithm

4.3 Decoding using simulated annealing

The problem of decoding—that is, finding a high-scoring alignment for a particular inference problem—is made more complex by our choice of a phrase-based alignment representation. For a model which uses a token-based representation (say, one which simply maps H tokens to P tokens), decoding is trivial, since each token can be aligned independently of its neighbors. (This is the case for the bag-of-words aligner described in section 5.1.) But with a phrase-based representation, things are more complicated. The segmentation into phrases is not given in advance, and every phrase pair considered for alignment must be consistent with its neighbors with respect to segmentation. Consequently, the decoding problem cannot be factored into a number of independent decisions.

To address this difficulty, we have devised a stochastic alignment algorithm, MANLI-ALIGN (figure 2), which uses a simulated annealing strategy. Beginning from an arbitrary alignment, we make a series of local steps, at each iteration sampling from a set of possible successors according to scores assigned by our scoring function. The sampling is controlled by a "temperature" which falls over time. At the beginning of the process, successors are sampled with nearly uniform probability, which helps to ensure that the space of possibilities is explored and local maxima are avoided. As the temperature falls, there is a ever-stronger bias toward high-scoring successors, so that the algorithm converges on a near-optimal alignment. Clever use of memoization helps to ensure that computational costs remain manageable. Using the parameter values suggested in figure 2, aligning an average RTE problem takes about two seconds.

While MANLI-ALIGN is not guaranteed to produce optimal alignments, there is reason to believe that it usually comes very close. After training, the alignment found by MANLI scored at least as high as the gold alignment for 99.6% of RTE problems.[6]

4.4 Perceptron learning

To tune the parameters **w** of the model, we use an adaptation of the averaged perceptron algorithm (Collins, 2002), which has proven successful on a range of NLP tasks. The algorithm is shown in figure 3. After initializing **w** to 0, we perform N training epochs. (Our experiments used $N = 50$.) In each epoch, we iterate through the training data, updating the weight vector at each training example according to the difference between the features of the target alignment and the features of the alignment produced by the decoder using the current weight vector. The size of the update is controlled by a learning rate which decreases over time. At the end of each epoch, the weight vector is normalized and stored. The final result is the average of the stored weight vectors, omitting vectors from a fixed number of epochs at the beginning of the run (which tend to be of poor quality). Using the parameter values suggested in figure 3, training runs on the RTE2 development set required about 20 hours.

```
Inputs
  • training problems $\langle P_j, H_j \rangle$, $j = 1..n$
  • corresponding gold-standard alignments $E_j$
  • a number of learning epochs $N$ (e.g. 50)
  • a "burn-in" period $N_0 < N$ (e.g. 10)
  • initial learning rate $R_0$ (e.g. 1) and multiplier $r$ (e.g. 0.8)
  • a vector of feature functions $\mathbf{\Phi}(E)$
  • an alignment algorithm ALIGN($P, H; \mathbf{w}$) which finds a
    good alignment for $\langle P, H \rangle$ using weight vector w
Initialize
  • Set $\mathbf{w} = 0$
Repeat for $i$ = 1 to $N$
  • Set $R_i = r \cdot R_{i-1}$, reducing the learning rate
  • Randomly shuffle the training problems
  • For $j$ = 1 to $n$:
      – Set $\hat{E}_j$ = ALIGN($P_j, H_j; \mathbf{w}$)
      – Set $\mathbf{w} = \mathbf{w} + R_i \cdot (\mathbf{\Phi}(E_j) - \mathbf{\Phi}(\hat{E}_j))$
  • Set $\mathbf{w} = \mathbf{w}/\|\mathbf{w}\|_2$ (L2 normalization)
  • Set $\mathbf{w}[i] = \mathbf{w}$, storing the weight vector for this epoch
Return an averaged weight vector:
  • $\mathbf{w}_{avg} = 1/(N - N_0) \sum_{i=N_0+1}^{N} \mathbf{w}[i]$
```

5 Evaluating aligners on MSR data

In this section, we describe experiments designed to evaluate the performance of various alignment systems on the MSR gold-standard data described in section 3. For each system, we report precision, recall, and F-measure (F_1).[7] Note that these are macro-averaged statistics, computed per problem by counting aligned token pairs,[8] and then averaged over all problems in a problem set.[9] We also re-

[6]This figure is based on the MANLI-reachable version of the gold-standard data described in section 4.1. For the raw gold-standard data, the figure is 88.1%. The difference is almost entirely attributable to unreachable gold alignments, which tend to score higher simply because they contain more edits (and because the learned weights are mostly positive).

[7]MT researchers conventionally report results in terms of alignment error rate (AER). Since we use only SURE links in the gold-standard data (see section 3), AER is equivalent to $1 - F_1$.

[8]For phrase-based alignments like those generated by MANLI, two tokens are considered to be aligned iff they are contained within phrases which are aligned.

[9]MT evaluations conventionally use micro-averaging, which gives greater weight to problems containing more aligned pairs. This makes sense in MT, where the purpose of alignment is to induce phrase tables. But in NLI, where the ultimate goal is to maximize the number of inference problems answered correctly, it is more fitting to give all problems equal weight, and so we macro-average. We have also generated all results using micro-averaging, and found that the relative comparisons are

port the exact match rate, that is, the proportion of problems in which the guessed alignment exactly matches the gold alignment. The results are summarized in table 1.

5.1 A robust baseline: the bag-of-words aligner

As a baseline, we use a simple alignment algorithm inspired by the lexical entailment model of Glickman et al. (2005), and similar to the simple heuristic model described in (Och and Ney, 2003). Each hypothesis word h is aligned to the premise word p to which it is most similar, according to a lexical similarity function $sim(p, h)$ which returns scores in $[0, 1]$. While Glickman et al. used a function based on web co-occurrence statistics, we use a much simpler function based on string edit distance:

$$sim(w_1, w_2) = 1 - \frac{dist(lem(w_1), lem(w_2))}{max(|lem(w_1)|, |lem(w_2)|)}$$

(Here $lem(w)$ denotes the lemma of word w; $dist()$ denotes Levenshtein string edit distance; and $|\cdot|$ denotes string length.)

This model can be easily extended to generate an alignment score, which will be of interest in section 6. We define the score for a specific hypothesis token h to be the log of its similarity with the premise token p to which it is aligned, and the score for the complete alignment of hypothesis H to premise P to be the sum of the scores of the tokens in H, weighted by *inverse document frequency* in a large corpus[10] (so that common words get less weight), and normalized by the length of H:

$$score(h|P) = \log \max_{p \in P} sim(p, h)$$

$$score(H|P) = \frac{1}{|H|} \sum_{h \in H} idf(h) \cdot score(h|P)$$

Despite the simplicity of this alignment model, its performance is fairly robust, with good recall. Its precision, however, its mediocre—chiefly because, by design, it aligns every h with some p. The model could surely be improved by allowing it to leave some H tokens unaligned, but this was not pursued.

not greatly affected.

[10]We use $idf(w) = \log(N/N_w)$, where N is the number of documents in the corpus, and N_w is the number of documents containing word w.

System	Data	P %	R %	F_1 %	E %

Table 1: Performance of various aligners on the MSR RTE2 alignment data. The columns show the data set used (800 problems each); average precision, recall, and F-measure; and the exact match rate (see text).

5.2 MT aligners: GIZA++ and Cross-EM

Given the importance of alignment for NLI, and the availability of standard, proven tools for MT alignment, an obvious question presents itself: why not use an off-the-shelf MT aligner for NLI? Although we have argued (section 2) that this is unlikely to succeed, to our knowledge, we are the first to investigate the matter empirically.[11]

The best-known MT aligner is undoubtedly GIZA++ (Och and Ney, 2003), which contains implementations of various IBM models (Brown et al., 1993), as well as the HMM model of Vogel et al. (1996). Most practitioners use GIZA++ as a black box, via the Moses MT toolkit (Koehn et al., 2007). We followed this practice, running with Moses' default parameters on the RTE2 data to obtain asymmetric word alignments in both directions (P-to-H and H-to-P). We then performed symmetrization using the well-known INTERSECTION heuristic.

Unsurprisingly, the out-of-the-box performance was quite poor, with most words aligned apparently at random. Precision was fair (72%) but recall was very poor (46%). Even equal words were usually not aligned—because GIZA++ is designed for cross-linguistic use, it does not consider word equality between source and target sentences. To remedy this, we supplied GIZA++ with a lexicon, using a trick

[11]However, Dolan et al. (2004) explore a closely-related topic: using an MT aligner to identify paraphrases.

common in MT: we supplemented the training data with synthetic data consisting of matched pairs of equal words. This gives GIZA++ a better chance of learning that, e.g., *man* should align with *man*. The result was a big boost in recall (+23%), and a smaller gain in precision. The results for GIZA++ shown in table 1 are based on using the lexicon and INTERSECTION. With these settings, GIZA++ properly aligned most pairs of equal words, but continued to align other words apparently at random.

Next, we compared the performance of INTERSECTION with other symmetrization heuristics defined in Moses—including UNION, GROW, GROW-DIAG, GROW-DIAG-FINAL (the default), and GROW-DIAG-FINAL-AND—and with asymmetric alignments in both directions. While all these alternatives achieved better recall than INTERSECTION, all showed substantially worse precision and F_1. On the RTE2 test set, the asymmetric alignment from H to P scored 68% in F_1; GROW scored 58%; and all other alternatives scored below 52%.

As an additional experiment, we tested the Cross-EM aligner (Liang et al., 2006) from the BerkeleyAligner package on the MSR data. While this aligner is in many ways simpler than GIZA++ (it lacks any model of fertility, for example), its method of jointly training two simple asymmetric HMM models has outperformed GIZA++ on standard evaluations of MT alignment. As with GIZA++, we experimented with a variety of symmetrization heuristics, and ran trials with and without a supplemental lexicon. The results were broadly similar: INTERSECTION greatly outperformed alternative heuristics, and using a lexicon provided a big boost (up to 12% in F_1). Under optimal settings, the Cross-EM aligner showed better recall and worse precision than GIZA++, with F_1 just slightly lower. Like GIZA++, it did well at aligning equal words, but aligned most other words at random.

The mediocre performance of MT aligners on NLI alignment comes as no surprise, for reasons discussed in section 2. Above all, the quantity of training data is simply too small for unsupervised learning to succeed. A successful NLI aligner will need to exploit supervised training data, and will need access to additional sources of knowledge about lexical relatedness.

5.3 The Stanford RTE aligner

A better comparison is thus to an alignment system expressly designed for NLI. For this purpose, we used the alignment component of the Stanford RTE system (Chambers et al., 2007). The Stanford aligner performs decoding and learning in a similar fashion to MANLI, but uses a simpler, token-based alignment representation, along with a richer set of features for alignment scoring. It represents alignments as an injective map from H tokens to P tokens. Phrase alignments are not directly representable, although the effect can be approximated by a pre-processing step which collapses multi-token named entities and certain collocations into single tokens. The features used for alignment scoring include not only measures of lexical similarity, but also syntactic features intended to promote the alignment of similar predicate-argument structures.

Despite this sophistication, the out-of-the-box performance of the Stanford aligner is mediocre, as shown in table 1. The low recall figures are particularly noteworthy. However, a partial explanation is readily available: by design, the Stanford system ignores punctuation.[12] Because punctuation tokens constitute about 15% of the aligned pairs in the MSR data, this sharply reduces measured recall. However, since punctuation matters little in inference, such recall errors probably should be forgiven. Thus, table 1 also shows adjusted statistics for the Stanford system in which all recall errors involving punctuation are (generously) ignored.

Even after this adjustment, the recall figures are unimpressive. Error analysis reveals that the Stanford aligner does a poor job of aligning function words. About 13% of the aligned pairs in the MSR data are matching prepositions or articles; the Stanford aligner misses about 67% of such pairs. (By contrast, MANLI misses only 10% of such pairs.) While function words matter less in inference than nouns and verbs, they are not irrelevant, and because sentences often contain multiple instances of a particular function word, matching them properly is by no means trivial. If matching prepositions and articles were ignored (in addition to punctuation), the gap in F_1 between the MANLI and Stanford systems

[12]In fact, it operates on a dependency-graph representation from which punctuation is omitted.

would narrow to about 2.8%.

Finally, the Stanford aligner is handicapped by its token-based alignment representation, often failing (partly or completely) to align multi-word phrases such as *peace activists* with *protesters*, or *hackers* with *non-authorized personnel*.

5.4 The MANLI aligner

As table 1 indicates, the MANLI aligner was found to outperform all other aligners evaluated on every measure of performance, achieving an F_1 score 10.5% higher than GIZA++ and 6.2% higher than the Stanford aligner (even with the punctuation correction).[13] MANLI achieved a good balance between precision and recall, and matched more than 20% of the gold-standard alignments exactly.

Three factors seem to have contributed most to MANLI's success. First, MANLI is able to outperform the MT aligners principally because it is able to leverage lexical resources to identify the similarity between pairs of words such as *jail* and *prison*, *prevent* and *stop*, or *injured* and *wounded*. Second, MANLI's contextual features enable it to do better than the Stanford aligner at matching function words, a weakness of the Stanford aligner discussed in section 5.3. Third, MANLI gains a marginal advantage because its phrase-based representation of alignment permits it to properly align phrase pairs such as *death penalty* and *capital punishment*, or *abdicate* and *give up*.

However, the phrase-based representation contributed far less than we had hoped. Setting MANLI's maximum phrase size to 1 (effectively, restricting it to token-based alignments) caused F_1 to fall by just 0.2%. We do not interpret this to mean that phrase alignments are not useful—indeed, about 2.6% of the links in the gold-standard data involve phrases of size > 1. Rather, we think it shows that we have failed to fully exploit the advantages of the phrase-based representation, chiefly because we lack lexical resources providing good information on similarity of multi-word phrases.

Error analysis suggests that there is ample room for improvement. A large proportion of recall errors (perhaps 40%) occur because the lexical similarity function assigns too low a value to pairs of words or phrases which are clearly similar, such as *conservation* and *protecting*, *server* and *computer networks*, *organization* and *agencies*, or *bone fragility* and *osteoporosis*. Better exploitation of lexical resources could help to reduce such errors. Another important category of recall errors (about 12%) result from the failure to identify one- and multi-word versions of the name of some entity, such as *Lennon* and *John Lennon*, or *Nike Inc.* and *Nike*. A special-purpose similarity function could help here. Note, however, that about 10% of recall errors are unavoidable, given our choice of alignment representation, since they involve cases where the gold standard aligns one or more tokens on one side to a non-contiguous set of tokens on the other side.

Precision errors may be harder to reduce. These errors are dominated by cases where we mistakenly align two equal function words (49% of precision errors), two forms of the verb *to be* (21%), two equal punctuation marks (7%), or two words or phrases of other types having equal lemmas (18%). Because such errors often occur because the aligner is forced to choose between nearly equivalent alternatives, they may be difficult to eliminate. The remaining 5% of precision errors result mostly from aligning words or phrases rightly judged to be highly similar, such as *expanding* and *increasing*, *labor* and *birth*, *figures* and *number*, or *223,000* and *220,000*.

6 Using alignment to predict RTE answers

In section 5, we evaluated the ability of aligners to recover gold-standard alignments. But since alignment is just one component of the NLI problem, we might also examine the impact of different aligners on the ability to recognize valid inferences. If a high-scoring alignment indicates a close correspondence between H and P, does this also indicate a valid inference? We have previously emphasized (MacCartney et al., 2006) that there is more to inferential validity than close lexical or structural correspondence: negations, modals, non-factive and implicative verbs, and other linguistic constructs can affect validity in ways hard to capture in alignment. Nevertheless, alignment score can be a strong predictor of inferential validity, and some NLI systems (e.g., (Glickman et al., 2005)) rely entirely on some measure of alignment quality to predict validity.

[13]Reported results for MANLI are averages over 10 runs.

System	data	acc %	avgP %
Bag-of-words aligner	dev	61.3	61.5
	test	57.9	58.9
Stanford RTE aligner	dev	63.1	64.9
	test	60.9	59.2
MANLI aligner	dev	59.3	69.0
(this work)	test	60.3	61.0
RTE2 entries (average)	test	58.5	59.1
LCC (Hickl et al., 2006)	test	75.4	80.8

Table 2: Performance of various aligners and complete RTE systems in predicting RTE2 answers. The columns show the data set used, accuracy, and average precision (the recommended metric for RTE2).

If an aligner generates real-valued alignment scores, we can use the RTE data to test its ability to predict inferential validity with the following simple method. For a given RTE problem, we predict YES (valid) if its alignment score[14] exceeds a threshold τ, and NO otherwise. We tune τ to maximize accuracy on the RTE2 development set, and then measure performance on the RTE2 test set using the same τ.

Table 2 shows results for several NLI aligners, along with some results for complete RTE systems, including the LCC system (the top performer at RTE2) and an average of all systems participating in RTE2. While none of the aligners rivals the performance of the LCC system, all achieve respectable results, and the Stanford and MANLI aligners outperform the average RTE2 entry. Thus, even if alignment quality does not determine inferential validity, many NLI systems could be improved by harnessing a well-designed NLI aligner.

7 Related work

Given the extensive literature on phrase-based MT, it may be helpful further to situate our phrase-based alignment model in relation to past work. The standard approach to training a phrase-based MT system is to apply phrase extraction heuristics using word-aligned training sets (Och and Ney, 2003; Koehn et al., 2007). Unfortunately, word alignment models assume that source words are individually translated into target words, which stands at odds with the key assumption in phrase-based systems that many translations are non-compositional. More recently, several works (Marcu and Wong, 2002; DeNero et al., 2006; Birch et al., 2006; DeNero and Klein, 2008) have presented more unified phrase-based systems that jointly align and weight phrases, though these systems have not come close to the state of the art when evaluated in terms of MT performance.

We would argue that previous work in MT phrase alignment is orthogonal to our work. In MANLI, the need for phrases arises when word-based representations are not appropriate for alignment (e.g., between *close down* and *terminate*), though longer phrases are not needed to achieve good alignment quality. In MT phrase alignment, it is beneficial to account for arbitrarily large phrases, since the larger contexts offered by these phrases can help realize more dependencies among translated words (e.g., word order, agreement, subcategorization). Perhaps because MT phrase alignment is dealing with much larger contexts, no existing work in MT phrase alignment (to our knowledge) directly models word insertions and deletions, as in MANLI. For example, in figure 1, MANLI can just skip *In most Pacific countries there*, while an MT phrase-based model would presumably align *In most Pacific countries there are* to *Women are*. Hence, previous work is of limited applicability to our problem.

8 Conclusion

While MT aligners succeed by unsupervised learning of word correspondences from massive amounts of bitext, NLI aligners are forced to rely on smaller quantities of supervised training data. With the MANLI system, we have demonstrated how to overcome this lack of data by utilizing external lexical resources, and how to gain additional power from a phrase-based representation of alignment.

[14]For good results, it may be necessary to normalize the alignment score. Scores from MANLI were normalized by the number of tokens in the problem. The Stanford aligner performs a similar normalization internally.

Attacking Decipherment Problems Optimally with Low-Order N-gram Models

Sujith Ravi and Kevin Knight

Abstract

We introduce a method for solving substitution ciphers using low-order letter n-gram models. This method enforces global constraints using integer programming, and it guarantees that no decipherment key is overlooked. We carry out extensive empirical experiments showing how decipherment accuracy varies as a function of cipher length and n-gram order. We also make an empirical investigation of Shannon's (1949) theory of uncertainty in decipherment.

1 Introduction

A number of papers have explored algorithms for automatically solving letter-substitution ciphers. Some use heuristic methods to search for the best deterministic key (Peleg and Rosenfeld, 1979; Ganesan and Sherman, 1993; Jakobsen, 1995; Olson, 2007), often using word dictionaries to guide that search. Others use expectation-maximization (EM) to search for the best probabilistic key using letter n-gram models (Knight et al., 2006). In this paper, we introduce an exact decipherment method based on integer programming. We carry out extensive decipherment experiments using letter n-gram models, and we find that our accuracy rates far exceed those of EM-based methods.

We also empirically explore the concepts in Shannon's (1949) paper on information theory as applied to cipher systems. We provide quantitative plots for uncertainty in decipherment, including the famous *unicity distance*, which estimates how long a cipher must be to virtually eliminate such uncertainty.

We find the ideas in Shannon's (1949) paper relevant to problems of statistical machine translation and transliteration. When first exposed to the idea of statistical machine translation, many people naturally ask: (1) how much data is needed to get a good result, and (2) can translation systems be trained without parallel data? These are tough questions by any stretch, and it is remarkable that Shannon was already in the 1940s tackling such questions in the realm of code-breaking, creating analytic formulas to estimate answers.

Our novel contributions are as follows:

- We outline an exact letter-substitution decipherment method which:
  - guarantees that no key is overlooked, and
  - can be executed with standard integer programming solvers
- We present empirical results for decipherment which:
  - plot search-error-free decipherment results at various cipher lengths, and
  - demonstrate accuracy rates superior to EM-based methods
- We carry out empirical testing of Shannon's formulas for decipherment uncertainty

2 Language Models

We work on letter substitution ciphers with spaces. We look for the key (among 26! possible ones) that, when applied to the ciphertext, yields the most English-like result. We take "English-like" to mean most probable according to some statistical language model, whose job is to assign some probability to any sequence of letters. According to a 1-gram model of English, the probability of a plaintext $p_1 ... p_n$ is given by:

$$P(p_1...p_n) = P(p_1) \cdot P(p_2) \cdot ... \cdot P(p_n)$$

That is, we obtain the probability of a sequence by multiplying together the probabilities of the individual letters that make it up. This model assigns a probability to any letter sequence, and the probabilities of all letter sequences sum to one. We collect letter probabilities (including space) from 50 million words of text available from the Linguistic Data Consortium (Graff and Finch, 1994). We also estimate 2- and 3-gram models using the same resources:

$$\begin{aligned} P(p_1...p_n) &= P(p_1 \mid START) \cdot P(p_2 \mid p_1) \cdot P(p_3 \mid p_2) \cdot \\ &\quad ... \cdot P(p_n \mid p_{n-1}) \cdot P(END \mid p_n) \end{aligned}$$

$$\begin{aligned} P(p_1...p_n) &= P(p_1 \mid START) \cdot P(p_2 \mid START\, p_1) \cdot \\ &\quad P(p_3 \mid p_1\, p_2) \cdot ... \cdot P(p_n \mid p_{n-2}\, p_{n-1}) \cdot \\ &\quad P(END \mid p_{n-1}\, p_n) \end{aligned}$$

Unlike the 1-gram model, the 2-gram model will assign a low probability to the sequence "ae" because the probability $P(e \mid a)$ is low. Of course, all these models are fairly weak, as already known by (Shannon, 1949). When we stochastically generate text according to these models, we get, for example:

1-gram: ... thdo detusar ii c ibt deg irn toihytrsen ...
2-gram: ... itariaris s oriorcupunond rke uth ...
3-gram: ... ind thnowelf jusision thad inat of ...
4-gram: ... rece bence on but ther servier ...
5-gram: ... mrs earned age im on d the perious ...
6-gram: ... a party to possible upon rest of ...
7-gram: ... t our general through approve the ...

We can further estimate the probability of a whole English sentence or phrase. For example, the probabilities of two plaintext phrases "het oxf" and "the fox" (which have the same letter frequency distribution) is shown below. The 1-gram model which counts only the frequency of occurrence of each letter in the phrase, estimates the same probability for both the phrases "het oxf" and "the fox", since the same letters occur in both phrases. On the other hand, the 2-gram and 3-gram models, which take context into account, are able to distinguish between the English and non-English phrases better, and hence assign a higher probability to the English phrase "the fox".

Model	P(het oxf)	P(the fox)
1-gram	1.83×10^{-9}	1.83×10^{-9}
2-gram	3.26×10^{-11}	1.18×10^{-7}
3-gram	1.89×10^{-13}	1.04×10^{-6}

Over a longer sequence X of length N, we can also calculate $-log_2(P(X))/N$, which (per Shannon) gives the compression rate permitted by the model, in bits per character. In our case, we get:[1]

1-gram: 4.19
2-gram: 3.51
3-gram: 2.93

3 Decipherment

Given a ciphertext $c_1...c_n$, we search for the key that yields the most probable plaintext $p_1...p_n$. There are 26! possible keys, too many to enumerate. However, we can still find the best one in a guaranteed fashion. We do this by taking our most-probable-plaintext problem and casting it as an integer programming problem.[2]

Here is a sample integer programming problem:

variables: x, y
minimize:
$$2x + y$$
subject to:
$$x + y < 6.9$$
$$y - x < 2.5$$
$$y > 1.1$$

We require that x and y take on integer values. A solution can be obtained by typing this integer program into the publicly available lp_solve program,

[1]Because spacing is fixed in our letter substitution ciphers, we normalize $P(X)$ by the sum of probabilities of all English strings that match the spacing pattern of X.

[2]For an overview of integer and linear programming, see for example (Schrijver, 1998).

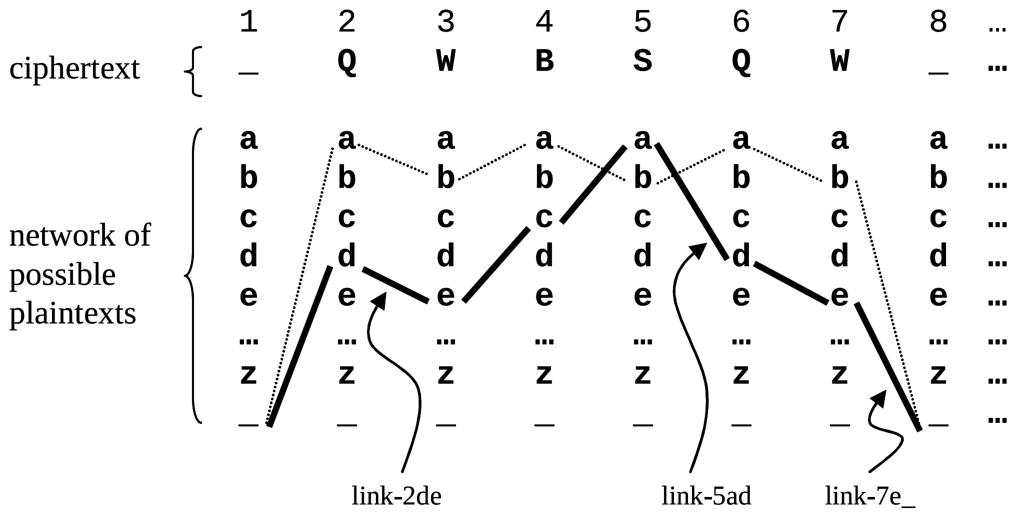

Figure 1: A decipherment network. The beginning of the ciphertext is shown at the top of the figure (underscores represent spaces). Any left-to-right path through the network constitutes a potential decipherment. The bold path corresponds to the decipherment "decade". The dotted path corresponds to the decipherment "ababab". Given a cipher length of n, the network has $27 \cdot 27 \cdot (n-1)$ links and 27^n paths. Each link corresponds to a named variable in our integer program. Three links are shown with their names in the figure.

or the commercially available $CPLEX$ program, which yields the result: $x = 4, y = 2$.

Suppose we want to decipher with a 2-gram language model, i.e., we want to find the key that yields the plaintext of highest 2-gram probability. Given the ciphertext $c_1...c_n$, we create an integer programming problem as follows. First, we set up a network of possible decipherments (Figure 1). Each of the $27 \cdot 27 \cdot (n-1)$ links in the network is a binary variable in the integer program—it must be assigned a value of either 0 or 1. We name these variables $link_{XYZ}$, where X indicates the column of the link's source, and Y and Z represent the rows of the link's source and destination (e.g. variables $link_{1aa}$, $link_{1ab}$, $link_{5qu}$, ...).

Each distinct left-to-right path through the network corresponds to a different decipherment. For example, the bold path in Figure 1 corresponds to the decipherment "decade". Decipherment amounts to turning some links "on" (assigning value 1 to the link variable) and others "off" (assigning value 0). Not all assignments of 0's and 1's to link variables result in a coherent left-to-right path, so we must place some "subject to" constraints in our integer program.

We observe that a set of variables forms a path if, for every node in columns 2 through $n-1$ of the network, the following property holds: the sum of the values of the link variables entering the node equals the sum of the link variables leaving the node. For nodes along a chosen decipherment path, this sum will be 1, and for others, it will be 0.[3] Therefore, we create one "subject to" constraint for each node ("_" stands for space). For example, for the node in column 2, row e we have:

subject to:

$$link_{1ae} + link_{1be} + link_{1ce} + ... + link_{1\_e}$$
$$= link_{2ea} + link_{2eb} + link_{2ec} + ... + link_{2e\_}$$

Now we set up an expression for the "minimize" part of the integer program. Recall that we want to select the plaintext $p_1...p_n$ of highest probability. For the 2-gram language model, the following are equivalent:

(a) Maximize $P(p_1...p_n)$

(b) Maximize $log_2\, P(p_1...p_n)$

(c) Minimize $-log_2\, P(p_1...p_n)$

(d) Minimize $-log_2\, [\ P(p_1 \mid START)$

[3]Strictly speaking, this constraint over nodes still allows multiple decipherment paths to be active, but we can rely on the rest of our integer program to select only one.

$$\begin{aligned} &\cdot P(p_2 \,|\, p_1) \\ &\cdot \;... \\ &\cdot P(p_n \,|\, p_{n-1}) \\ &\cdot P(END \,|\, p_n)\,] \end{aligned}$$

(e) Minimize
$$\begin{aligned} &-log_2\, P(p_1 \,|\, START) \\ &-log_2\, P(p_2 \,|\, p_1) \\ &-\; ... \\ &-log_2\, P(p_n \,|\, p_{n-1}) \\ &-log_2\, P(END \,|\, p_n) \end{aligned}$$

We can guarantee this last outcome if we construct our minimization function as a sum of $27 \cdot 27 \cdot (n-1)$ terms, each of which is a $link_{XYZ}$ variable multiplied by $-log_2 P(Z|Y)$:

Minimize
$$\begin{aligned} & link_{1aa} \cdot -log_2\, P(a \mid a) \\ &+ link_{1ab} \cdot -log_2\, P(b \mid a) \\ &+ link_{1ac} \cdot -log_2\, P(c \mid a) \\ &+ ... \\ &+ link_{5qu} \cdot -log_2\, P(u \mid q) \\ &+ ... \end{aligned}$$

When we assign value 1 to link variables along some decipherment path, and 0 to all others, this function computes the negative log probability of that path.

We must still add a few more "subject to" constraints. We need to ensure that the chosen path imitates the repetition pattern of the ciphertext. While the bold path in Figure 1 represents the fine plaintext choice "decade", the dotted path represents the choice "ababab", which is not consistent with the repetition pattern of the cipher "QWBSQW". To make sure our substitutions obey a consistent key, we set up $27 \cdot 27 = 729$ new key_{xy} variables to represent the choice of key. These new variables are also binary, taking on values 0 or 1. If variable key_{aQ} = 1, that means the key maps plaintext a to ciphertext Q. Clearly, not all assignments to these 729 variables represent valid keys, so we augment the "subject to" part of our integer program by requiring that for any letter x,

subject to:

$$\begin{aligned} & key_{xA} + key_{xB} + ... + key_{xZ} + key_{x\_} = 1 \\ & key_{Ax} + key_{Bx} + ... + key_{Zx} + key_{\_x} = 1 \end{aligned}$$

That is, every plaintext letter must map to exactly one ciphertext letter, and every ciphertext letter must map to exactly one plaintext letter. We also add a constraint to ensure that the ciphertext space character maps to the plaintext space character:

subject to:

$$key_{\_\_} = 1$$

Finally, we ensure that any chosen decipherment path of $link_{XYZ}$ variables is consistent with the chosen key. We know that for every node A along the decipherment path, exactly one active link has A as its destination. For all other nodes, zero active links lead in. Suppose node A represents the decipherment of ciphertext letter c_i as plaintext letter p_j—for all such nodes, we stipulate that the sum of values for $link_{(i-1)xp_j}$ (for all x) equals the value of $key_{p_j c_i}$. In other words, whether a node lies along the chosen decipherment path or not, the chosen key must support that decision.

Figure 2 summarizes the integer program that we construct from a given ciphertext $c_1...c_n$. The computer code that transforms any given cipher into a corresponding integer program runs to about one page. Variations on the decipherment network yield 1-gram and 3-gram decipherment capabilities. Once an integer program is generated by machine, we ask the commercially-available $CPLEX$ software to solve it, and then we note which key_{XY} variables are assigned value 1. Because $CPLEX$ computes the optimal key, the method is not fast—for ciphers of length 32, the number of variables and constraints encoded in the integer program (IP) along with average running times are shown below. It is possible to obtain less-than-optimal keys faster by interrupting the solver.

Model	**# of IP variables**	**# of IP constraints**	**Average running time**
1-gram	$1,755$	$1,083$	0.01 seconds
2-gram	$27,700$	$2,054$	50 seconds
3-gram	$211,600$	$27,326$	450 seconds

4 Decipherment Experiments

We create 50 ciphers each of lengths $2, 4, 8, ..., 256$. We solve these with 1-gram, 2-gram, and 3-gram language models. We record the average percentage of ciphertext tokens decoded incorrectly. 50% error means half of the ciphertext tokens are deciphered wrong, while 0% means perfect decipherment. Here

variables:

$link_{ipr}$ 1 if the *i*th cipher letter is deciphered as plaintext letter *p* AND the *(i+1)*th cipher letter is deciphered as plaintext letter *r*
0 otherwise

key_{pq} 1 if decipherment key maps plaintext letter *p* to ciphertext letter *q*
0 otherwise

minimize:

$\sum_{i=1}^{n-1} \sum_{p,r} link_{ipr} \cdot -log\ P(r|p)$ (2-gram probability of chosen plaintext)

subject to:

for all *p*: $\sum_r key_{pr} = 1$ (each plaintext letter maps to exactly one ciphertext letter)

for all *p*: $\sum_r key_{rp} = 1$ (each ciphertext letter maps to exactly one plaintext letter)

$key_{\_\ \_} = 1$ (cipher space character maps to plain space character)

for (*i=1...n-2*), for all *r*: $[\sum_p link_{ipr} = \sum_p link_{(i+1)rp}]$ (chosen links form a left-to-right path)

for (*i=1...n-1*), for all *p*: $\sum_r link_{irp} = key_{pc_{i+1}}$ (chosen links are consistent with chosen key)

Figure 2: Summary of how to build an integer program for any given ciphertext $c_1...c_n$. Solving the integer program will yield the decipherment of highest probability.

we illustrate some automatic decipherments with error rates:

42% error: the avelage ongrichman hal cy wiof a sevesonme qus antizexty that he buprk lathes we blung than soment - fotes mmasthes

11% error: the average englishman has so week a reference for antiality that he would rather be prong than recent - deter quarteur

2% error: the average englishman has so keep a reference for antiquity that he would rather be wrong than recent - peter mcarthur

0% error: the average englishman has so deep a reverence for antiquity that he would rather be wrong than recent - peter mcarthur

Figure 3 shows our automatic decipherment results. We note that the solution method is exact, not heuristic, so that decipherment error is not due to search error. Our use of global key constraints also leads to accuracy that is superior to (Knight et al., 2006). With a 2-gram model, their EM algorithm gives 10% error for a 414-letter cipher, while our method provides a solution with only 0.5% error. At shorter cipher lengths, we observe much higher improvements when using our method. For example, on a 52-letter textbook cipher, using a 2-gram model, the solution from our method resulted in 21% error as compared to 85% error given by the EM solution.

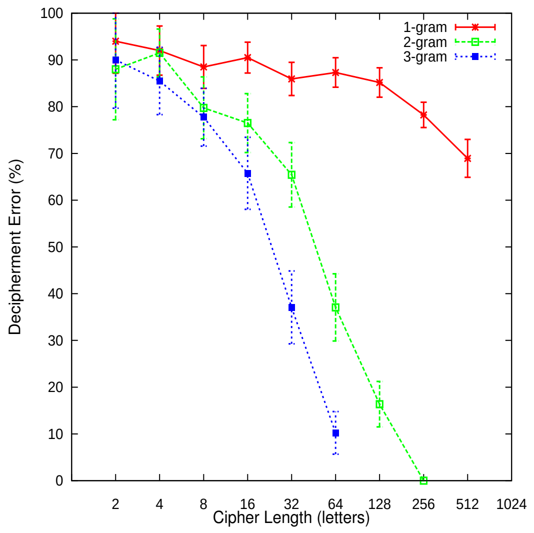

Figure 3: Average decipherment error using integer programming vs. cipher length, for 1-gram, 2-gram and 3-gram models of English. Error bars indicate 95% confidence intervals.

We see that deciphering with 3-grams works well on ciphers of length 64 or more. This confirms that such ciphers can be attacked with very limited knowledge of English (no words or grammar) and little custom programming.

The 1-gram model works badly in this scenario, which is consistent with Bauer's (2006) observation that for short texts, mechanical decryption on the basis of individual letter frequencies does not work. If we had infinite amounts of ciphertext and plaintext drawn from the same stochastic source, we would expect the plain and cipher frequencies to eventually line up, allowing us to read off a correct key from the frequency tables. The upper curve in Figure 3 shows that convergence to this end is slow.

5 Shannon Equivocation and Unicity Distance

Very short ciphers are hard to solve accurately. Shannon (1949) pinpointed an inherent difficulty with short ciphers, one that is independent of the solution method or language model used; the cipher itself may not contain enough information for its proper solution. For example, given a short cipher like $XYYX$, we can never be sure if the answer is *peep*, *noon*, *anna*, etc. Shannon defined a mathematical measure of our decipherment uncertainty, which he called *equivocation* (now called entropy).

Let C be a cipher, M be the plaintext message it encodes, and K be the key by which the encoding takes place. Before even seeing C, we can compute our uncertainty about the key K by noting that there are 26! equiprobable keys:[4]

$$\begin{aligned} H(K) &= -(26!) \cdot (1/26!) \cdot log_2\,(1/26!) \\ &= 88.4 \text{ bits} \end{aligned}$$

That is, any secret key can be revealed in 89 bits. When we actually receive a cipher C, our uncertainty about the key and the plaintext message is reduced. Shannon described our uncertainty about the plaintext message, letting m range over all decipherments:

$$\begin{aligned} H(M|C) &= \text{equivocation of plaintext message} \\ &= -\sum_m P(m|C) \cdot log_2\, P(m|C) \end{aligned}$$

[4](Shannon, 1948) The entropy associated with a set of possible events whose probabilities of occurrence are $p_1, p_2, ..., p_n$ is given by $H = -\sum_{i=1}^{n} p_i \cdot log_2(p_i)$.

$P(m|C)$ is probability of plaintext m (according to the language model) divided by the sum of probabilities of all plaintext messages that obey the repetition pattern of C. While integer programming gives us a method to find the most probable decipherment without enumerating all keys, we do not know of a similar method to compute a full equivocation without enumerating all keys. Therefore, we sample up to 100,000 plaintext messages in the neighborhood of the most probably decipherment[5] and compute $H(M|C)$ over that subset.[6]

Shannon also described $H(K|C)$, the *equivocation of key*. This uncertainty is typically larger than $H(M|C)$, because a given message M may be derived from C via more than one key, in case C does not contain all 26 letters of the alphabet.

We compute $H(K|C)$ by letting $r(C)$ be the number of distinct letters in C, and letting $q(C)$ be $(26 - r(C))!$. Letting i range over our sample of plaintext messages, we get:

$$\begin{aligned} H(K|C) &= \text{equivocation of key} \\ &= -\sum_i q(C) \cdot (P(i)/q(C)) \cdot log_2\,(P(i)/q(C)) \\ &= -\sum_i P(i) \cdot log_2\,(P(i)/q(C)) \\ &= -\sum_i P(i) \cdot (log_2\, P(i) - log_2\, q(C)) \\ &= -\sum_i P(i) \cdot log_2\, P(i) + \sum_i P(i) \cdot log_2\, q(C) \\ &= H(M|C) + log_2\, q(C) \end{aligned}$$

Shannon (1949) used analytic means to roughly sketch the curves for $H(K|C)$ and $H(M|C)$, which we reproduce in Figure 4. Shannon's curve is drawn for a human-level language model, and the y-axis is given in "decimal digits" instead of bits.

[5]The sampling used to compute $H(M|C)$ starts with the optimal key and expands out a frontier, by swapping letters in the key, and recursing to generate new keys (and corresponding plaintext message decipherments). The plaintext messages are remembered so that the frontier expands efficiently. The sampling stops if 100,000 different messages are found.

[6]Interestingly, as we grow our sample out from the most probable plaintext, we do not guarantee that any intermediate result is a lower bound on the equivocation. An example is provided by the growing sample (0.12, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01, 0.01), whose entropy steadily increases. However, if we add a 14th item whose $P(m)$ is 0.12, the entropy suddenly decreases from 2.79 to 2.78.

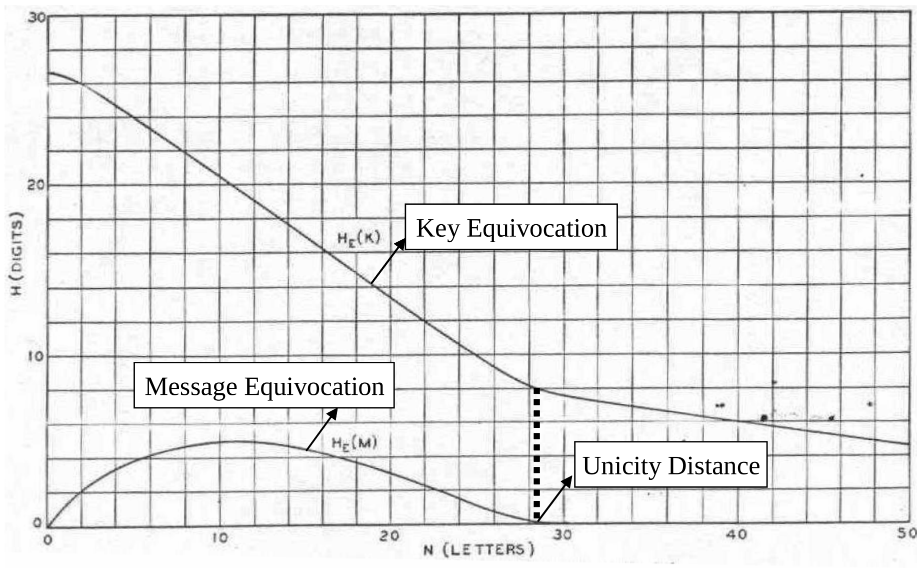

Figure 4: Equivocation for simple substitution on English (Shannon, 1949).

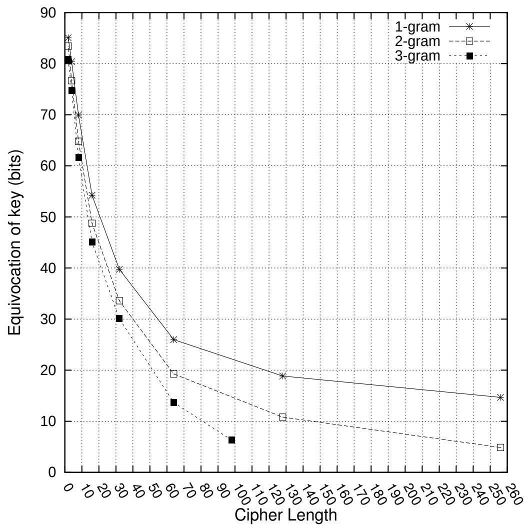

Figure 5: Average key equivocation observed (bits) vs. cipher length (letters), for 1-gram, 2-gram and 3-gram models of English.

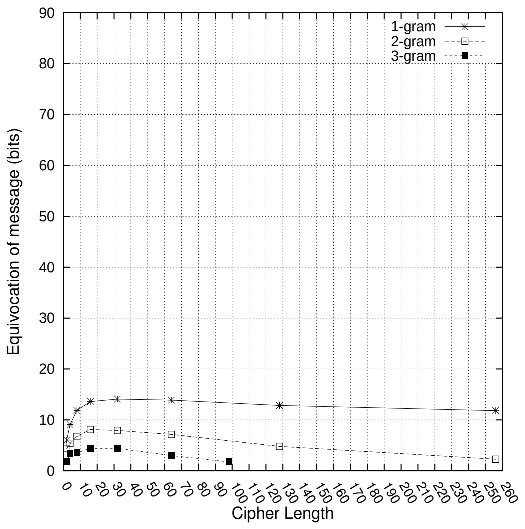

Figure 6: Average message equivocation observed (bits) vs. cipher length (letters), for 1-gram, 2-gram and 3-gram models of English.

For comparison, we plot in Figures 5 and 6 the average equivocations as we empirically observe them using our 1-, 2-, and 3-gram language models.

The shape of the key equivocation curve follows Shannon, except that it is curved from the start, rather than straight.

The message equivocation curve follows Shannon's prediction, rising then falling. Because very short ciphers have relatively few solutions (for example, a one-letter cipher has only 26), the overall uncertainty is not that great.[7] As the cipher gets longer, message equivocation rises. At some point, it then decreases, as the cipher begins to reveal its secret through patterns of repetition.

Shannon's analytic model also predicts a sharp decline of message equivocation towards zero. He

[7]Uncertainty is only loosely related to accuracy—even if we are quite certain about a solution, it may still be wrong.

defines the *unicity distance* (U) as the cipher length at which we have virtually no more uncertainty about the plaintext. Using analytic means (and various approximations), he gives:

$$U = H(K)/(A - B)$$

where:

A	=	bits per character of a 0-gram model (4.7)
B	=	bits per character of the model used to decipher

For a human-level language model ($B \sim 1.2$), he concludes $U \sim 25$, which is confirmed by practice. For our language models, the formula gives:

$$\begin{aligned} U &= 173 \text{ (1-gram)} \\ U &= 74 \text{ (2-gram)} \\ U &= 50 \text{ (3-gram)} \end{aligned}$$

These numbers are in the same ballpark as Bauer (2006), who gives 167, 74, and 59. We note that these predicted unicity distances are a bit too rosy, according to our empirical message equivocation curves. Our experience confirms this as well, as 1-gram frequency counts over a 173-letter cipher are generally insufficient to pin down a solution.

6 Conclusion

We provide a method for deciphering letter substitution ciphers with low-order models of English. This method, based on integer programming, requires very little coding and can perform an optimal search over the key space. We conclude by noting that English language models currently used in speech recognition (Chelba and Jelinek, 1999) and automated language translation (Brants et al., 2007) are much more powerful, employing, for example, 7-gram word models (not letter models) trained on trillions of words. Obtaining optimal keys according to such models will permit the automatic decipherment of shorter ciphers, but this requires more specialized search than what is provided by general integer programming solvers. Methods such as these should also be useful for natural language decipherment problems such as character code conversion, phonetic decipherment, and word substitution ciphers with applications in machine translation (Knight et al., 2006).

7 Acknowledgements

The authors wish to gratefully acknowledge Jonathan Graehl, for providing a proof to support the argument that taking a larger number of samples does not necessarily increase the equivocation. This research was supported by the Defense Advanced Research Projects Agency under SRI International's prime Contract Number NBCHD040058.

Abstract

To improve the Mandarin large vocabulary continuous speech recognition (LVCSR), a unified framework based approach is introduced to exploit multi-level linguistic knowledge. In this framework, each knowledge source is represented by a Weighted Finite State Transducer (WFST), and then they are combined to obtain a so-called analyzer for integrating multi-level knowledge sources. Due to the uniform transducer representation, any knowledge source can be easily integrated into the analyzer, as long as it can be encoded into WFSTs. Moreover, as the knowledge in each level is modeled independently and the combination is processed in the model level, the information inherently in each knowledge source has a chance to be thoroughly exploited. By simulations, the effectiveness of the analyzer is investigated, and then a LVCSR system embedding the presented analyzer is evaluated. Experimental results reveal that this unified framework is an effective approach which significantly improves the performance of speech recognition with a 9.9% relative reduction of character error rate on the HUB-4 test set, a widely used Mandarin speech recognition task.

1 Introduction

Language modeling is essential for large vocabulary continuous speech recognition (LVCSR), which aims to determine the prior probability of a supposed word string W, $p(W)$. Although the word-based n-gram language model remains the mainstream for most speech recognition systems, the utilization of linguistic knowledge is too limited in this model. Consequently, many researchers have focused on introducing more linguistic knowledge in language modeling, such as lexical knowledge , syntax and semantics of language (Wang and Vergyri, 2006; Wang et al., 2004; Charniak, 2001; Roark, 2001; Chelba, 2000; Heeman, 1998; Chelba et al., 1997).

Recently, structured language models have been introduced to make use of syntactic hierarchical characteristics (Roark, 2001; Charniak, 2001; Chelba, 2000). Nevertheless, the computational complexity of decoding will be heavily increased, as they are parser-based models. In contrast, the class-based language model groups the words that have similar functions of syntax or semantics into meaningful classes. As a result, it handles the questions of data sparsity and generalization of unseen event. In practice, the part-of-speech (POS) information, capturing the syntactic role of words, has been widely used in clustering words (Wang and Vergyri, 2006; Maltese et al., 2001; Samuelsson and Reichl, 1999). In Heeman's POS language model (Heeman, 1998), the joint probability of word sequence and associated POS sequence was estimated directly, which has been demonstrated to be superior to the conditional probability previously used in the class-based models (Johnson, 2001). Moreover, a SuperARV language model was presented (Wang and Harper, 2002), in which lexical features and syntactic constraints were tightly integrated into a linguistic structure of SuperARV serving as a class in the model. Thus, these knowledge was integrated in the representation level, and then the joint probabilities

[*]Corresponding author: Xihong Wu

of words and corresponding SuperARVs were estimated. However, in the class-based language models, words are taken as the model units, while other units smaller or larger than words are unfeasible for modeling simultaneously, such as the Chinese characters for Chinese names.

Usually, speech recognition systems can only recognize the words within a predefined dictionary. With the increase of unknown words, i.e., out-of-vocabulary (OOV) words, the performance will degrade dramatically. This is because not only those unknown words cannot be recognized correctly, but the words surrounding them will be affected. Thus, many efforts have been made to deal with the issue of OOV words (Martins et al., 2006; Galescu, 2003; Bazzi and Glass, 2001), and various model units smaller than words have been examined to recognize OOVs from speech, such as phonemes (Bazzi and Glass, 2000a), variable-length phoneme sequence (Bazzi and Glass, 2001), syllable (Bazzi and Glass, 2000b) and sub-word (Galescu, 2003). Since the proper name is a typical category of OOV words and usually takes a very large proportion among all kinds of OOV words, it has been specially addressed in (Hu et al., 2006; Tanigaki et al., 2000).

All those attempts mentioned above succeed in utilizing linguistic knowledge in language modeling in some degree respectively. In this study, a unified framework based approach, which aims to exploit information from multi-level linguistic knowledge, is presented. Here, the Weighted Finite State Transducer (WFST) turns to be an ideal choice for our purpose. WFSTs were formerly introduced to simplify the integration of models in speech recognition, including acoustic models, phonetic models and word n-gram (Mohri, 1997; Mohri et al., 2002). In recent years, the WFST has been successfully applied in several state-of-the-art speech recognition systems, such as systems developed by the AMI project (Hain et al., 2006), IBM (Saon et al., 2003) and AT&T (Mohri et al., 1996), and in various fields of natural language processing, such as smoothed n-gram model, partial parsing (Abney, 1996), named entities recognition (Friburger and Maurel, 2004), semantic interpretation (Raymond et al., 2006) and machine translation (Tsukada and Nagata, 2004). In (Takaaki Hori and Minami, 2003), the WFST has been further used for language model adaptation, where language models of different vocabularies that represented different styles were integrated through the framework of speech translation. In WFST-based systems, all of the models are represented uniformly by WFSTs, and the general composition algorithm (Mohri et al., 2000) combines these representations flexibly and efficiently. Thereby, rather than integrating the models step by step in decoding stage, a complete search network is constructed in advance. The combined WFST will be more efficient by optimizing with determinization, minimization and pushing algorithms of WFSTs (Mohri, 1997). Besides, the researches on optimizing the search space and improving WFST-based speech recognition has been carried out, especially on how to perform on-the-fly WFSTs composition more efficiently (Hori et al., 2007; Diamantino Caseiro, 2002).

In this study, we extend the linguistic knowledge used in speech recognition. As WFSTs provide a common and natural representation for lexical constraints, n-gram language model, Hidden Markov Model models and context-dependency, multi-level knowledge sources can be encoded into WFSTs under the uniform transducer representation. Then this group of WFSTs is flexibly combined together to obtain an analyzer representing knowledge of person and location names as well as POS information. Afterwards, the presented analyzer is incorporated into LVCSR to evaluate the linguistic correctness of recognition candidates by an n-best rescoring.

Unlike other methods, this approach holds two distinct features. Firstly, as all multi-level knowledge sources are modeled independently, the model units such as character, words, phrase, etc., can be chosen freely. Meanwhile, the integration of these information sources is conducted in the model level rather than the representation level. This setup will help to model each knowledge source sufficiently and may promote the accuracy of speech recognition. Secondly, under this unified framework, it is easy to combine additional knowledge source into the framework with the only requirement that the new knowledge source can be represented by WFSTs. Moreover, since all knowledge sources are finally represented by a single WFST, additional efforts are not required for decoding the new knowledge source.

The remainder of this paper is structured as follows. In section 2, we introduce our analyzer in detail, and incorporate it into a Mandarin speech recognition system. In section 3, the simulations are performed to evaluate the analyzer and test its effectiveness when being applied to LVCSR. The conclusion appears in section 4.

2 Incorporation of Multi-level linguistic knowledge in LVCSR

In this section, we start by giving a brief description on WFSTs. Then some special characteristics of Chinese are investigated, and the model units are fixed. Afterwards, each knowledge source is represented with WFSTs, and then they are combined into a final WFST, so-called analyzer. At last, this analyzer is incorporated into Mandarin LVCSR.

2.1 Weighted Finite State Transducers

The Weighted Finite State Transducer (WFST) is the generalization of the finite state automata, in which, besides of an input label, an output label and a weight are also placed on each transition. With these labels, a WFST is capable of realizing a weighted relation between strings. In our system, log probabilities are adopted as transition weights and the relation between two strings is associated with a weight indicating the probability of the mapping between them.

Given a group of WFSTs, each of which models a stage of a mapping cascade, the composition operation provides an efficient approach to combine them into a single one (Mohri et al., 2002; Mohri et al., 1996). In particular, for two WFSTs R and S, the composition $T = R^{o}S$ represents the composition of relations realized by R and S. The combination is performed strictly on R's output and S's input. It means for each path in T, mapping string r to string s, there must exist a path mapping r to some string t in R and a path mapping t to s in S. Decoding on the combined WFST enables to find the joint optimal results for multi-level weighted relations.

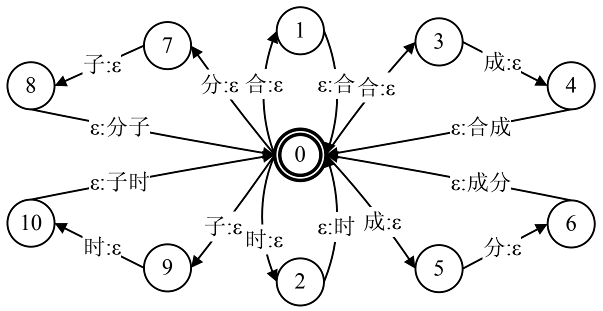
2.2 Model Unit Selection

This study primarily takes the person and location names as well as the POS information into account. To deal with Chinese OOV words, different from the western language in which the phoneme, syllable or sub-word are used as the model units (Bazzi and Glass, 2000a; Bazzi and Glass, 2000b; Galescu, 2003), Chinese characters are taken as the basic units. In general, a person name of Han nationality consists of a surname and a given name usually with one or two characters. Surnames commonly come from a fixed set that has been historically used. According to a recent investigation on surnames involving 296 million people, 4100 surnames are found, and 129 most used surnames account for 87% (conducted by the Institute of Genetics and Developmental Biology, Chinese Academy of Sciences). In contrast, the characters used in given names can be selected freely, and in many situations, some commonly used words may also appear in names, such as ”胜利” (victory) and ”长江” (the Changjiang River). Therefore, both Chinese characters and words are considered as model units in this study, and a word re-segmentation process on recognition hypotheses is necessary, where an n-gram language model based on word classes is adopted.

2.3 Representation and Integration of Multi-level Knowledge

In this work, we ignore the word boundaries of n-best hypotheses and perform a word re-segmentation for names recognition. Given an input Chinese character, it is encoded by a finite state acceptor FSA_{input}. For example, the input ”合成分子时” (while synthesizing molecule) is represented as in Figure 1(a). Then a dictionary is represented by a

(a)



(b)

Figure 1: (a) is an example of the FSA representing a given input; (b) is the FST representing a toy dictionary.

transducer with empty weights, denoted as FST_{dict}. Figure 1(b) illustrates a toy dictionary listed in Table 1, in which a successful path encodes a mapping from a Chinese character sequence to some word in the dictionary. In practice, all Chinese characters should appear in the dictionary for further incorporating models of names. Then the combination of FSA_{input} and FST_{dict}, $FST_{seg} = FSA_{input} \circ FST_{dict}$, will result in a WFST embracing all the possible candidate segmentations. Afterwards an n-gram language model based on word classes is used to weight the candidate segmentations. As in Figure 2, a toy bigram with three words is depicted by $WFST_{n-gram}$, and the word classes are defined in Table 2. Here, both in the training and test stages, the strings of numbers or letters in sentences are extracted according to the rules, and then substituted with the class tags, ”NUM” and ”LETTER” respectively. At the same time, the words, such as ”三月” and ”A型”, are replaced with ”NUM月” and ”LETTER型” in the dictionary. In addition, name classes, including ”CNAME”, ”TNAME” and ”LOC”, will be set according to names recognition.

Chinese Words	English Words
合成	synthesize
成分	element
分子	molecule
子时	the period of the day from 11 p.m.to l a.m.
合	together
时	present

Table 1: The Toy dictionary

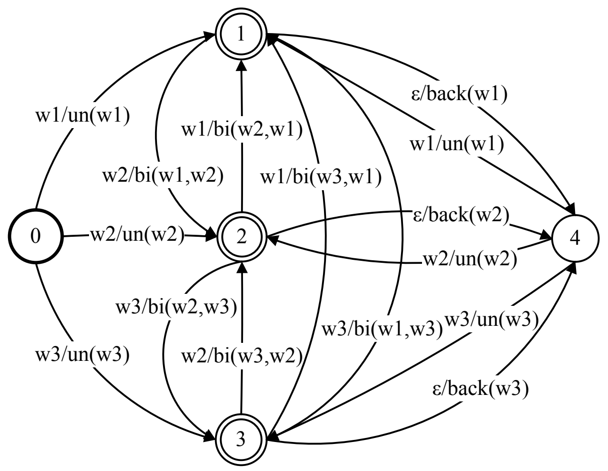


Figure 2: The WFST representing a toy bigram language model, in which $un(w1)$ denotes the unigram of $w1$; $bi(w1, w2)$ and $back(w1)$ respectively denotes the bigram of $w2$ and the backoff weight given the word history $w1$.

Classes	Description
w_i	Each word w_i listed in the dictionary
CNAME	Person names of Han nationality
TNAME	Translated person names
LOC	Location names
NUM	Number expressions
LETTER	Letter strings
NON	Other non Chinese character strings
BEGIN	Beginning of sentence
END	End of sentence

Table 2: The Definition of word classes

Hidden Markov Models (HMMs) are adopted both for names recognition and POS tagging. Here, each HMM is represented with two WFSTs. Taking the POS tagging as an example, the toy POS WFSTs with 3 different tags are illustrated in Figure 3. The emission probability of a word by a POS, ($P(word/pos)$), is represented as in Figure 3(a), and the bigram transition probabilities between POS tags are represented as in Figure 3(b), similar to the word n-gram. In terms of names recognition, the HMM states correspond to 30 role tags of names, some for model units of Chinese characters, such as surname, the first or second character of a given person name with two characters, the first or last character of a location name and so on, but others for model units of words, such as the word before or after a name, the words in a name and so on. When recognizing the person names, since there is a big difference between the translated names and the names of Han nationality, two types of person names are modeled separately, and substituted with two different class tags in the segmentation language model, as ”TNAME” and ”CNAME”. Some rules, which can be encoded into WFSTs, are responsible for the transformation from a role sequence to corresponding name class (for example, a role sequence might consist of the surname, the first character of the

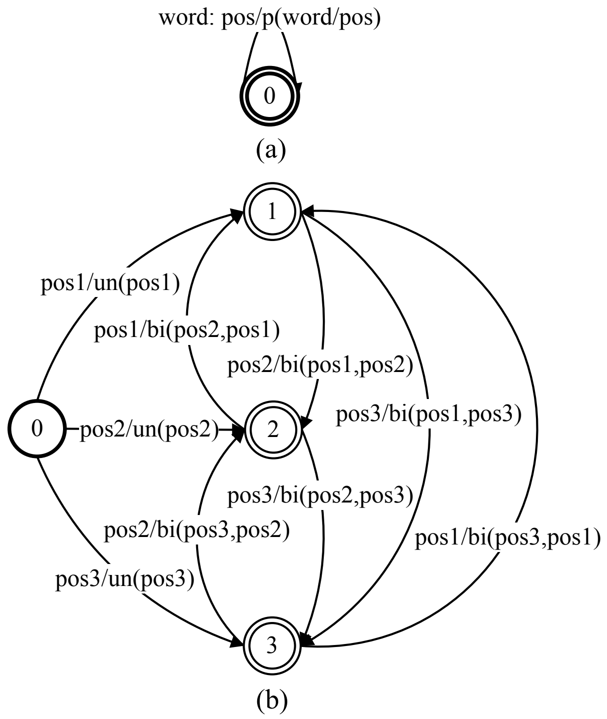

Figure 3: The toy POS WFSTs. (a) is the WFST representing the relationship between the word and the pos; (b) is the WFSA representing the bigram transition probabilities between POS tags

given name, and the second character of the given name, which will be transformed to "CNAME" in FST_{seg}). Hence, taking names recognition into account, a WFST, including all possible segmentations as well as recognized candidates of names, can be obtained as below, denoted as $WFST_{words}$:

$$FSA_{input} \circ FST_{dict} \circ WFST_{ne} \circ WFSA_{n-gram} \tag{1}$$

POS information is integrated as follows.

$$(\alpha * WFST_{words}) \circ WFST_{POS} \tag{2}$$

Consequently, the desired analyzer, a combined WFST that represents multi-level linguistic knowledge sources, has been obtained.

2.4 Incorporation in LVCSR

The presented analyzer models linguistic knowledge at different levels, which will be useful to find an optimal words sequence among a large number of speech recognition hypotheses. Thus in this research, the analyzer is incorporated after the first pass recognition, and the n-best hypotheses are reranked according to the total path scores adjusted with the analyzer scores as follows.

$$\hat{W} = \arg\max_{W} \left(\begin{array}{l} \log\left(P_{AM}\left(O|W\right)\right) \\ +\beta * \log\left(P_{LM}\left(W\right)\right) \\ +\gamma * \log\left(P_{Analyzer}\left(W\right)\right) \end{array} \right) \tag{3}$$

where $P_{AM}\left(O|W\right)$ and $P_{LM}\left(W\right)$ are the acoustic and language scores produced in first pass decoding, and $P_{Analyzer}\left(W\right)$ reflects the linguistic correctness of one hypothesis scored by the analyzer. Through the reranking paradigm, a new best sentence hypothesis is obtained.

3 Simulation

Under the unified framework, multi-level linguistic knowledge is represented by the analyzer as mentioned above. To guarantee the effectiveness of the introduced framework in integrating knowledge sources, the analyzer is evaluated in this section. Then the experiments using an LVCSR system in which the analyzer is embedded are performed.

3.1 Analyzer Evaluation

Considering the function of the analyzer, cascaded subtasks of word segmentation, names recognition and POS tagging can be processed jointly, while they are traditionally handled in a pipeline manner. Hence, a comparison between the analyzer and the pipeline system can be used to evaluate the effectiveness of the introduced framework for knowledge integration. As illustrated in Figure 4, two systems based on the presented analyzer and the pipeline manner are constructed respectively.

The evaluation data came from the People's Daily of China in 1998 from January to June (annotated by the Institute of Computational Linguistics of Peking University[1]), among which the January to May data was taken as the training set, and the June data was taken as the test set (consisted of 21,143 sentences and about 1.2 million words). The first two thousand sentences from the June data were extracted as the development set, used to fix the composition weight α in equation 2. A dictionary including about 113,000 words was extracted from the training data,

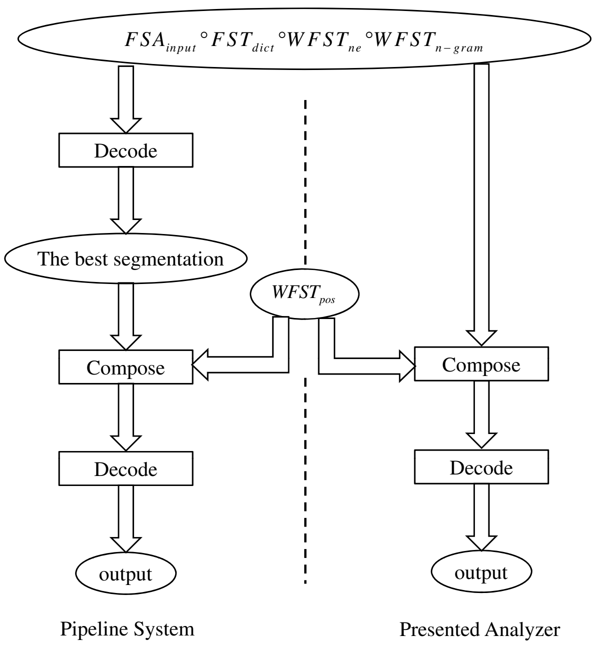

Figure 4: The pipeline system vs The analyzer

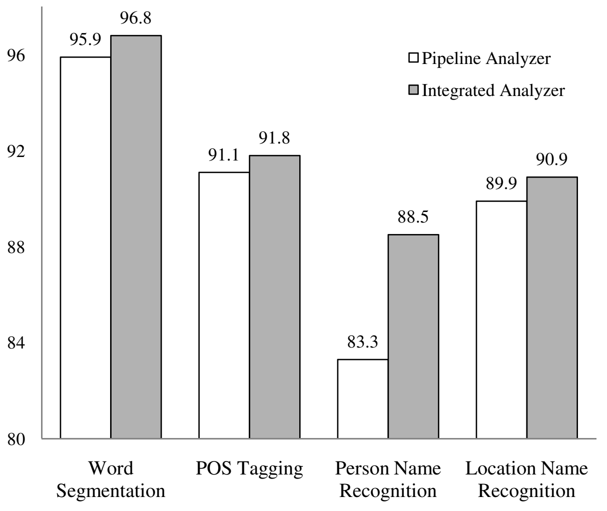

Figure 5: The Performance comparison between the pipeline system and the analyzer. The system performances are measured with the F1-score in the tasks of word segmentation, POS tagging, the person names recognition and the location names recognition.

in which a person or location name was accounted as a word in vocabulary, only when the number of its appearances was no less than three.

In Figure 5, the analyzer is compared with the pipeline system, where the analyzer outperforms the pipeline manner on all the subtasks in terms of $F1$-score metric. Furthermore to detect the differences, the statistical significance test using approximate randomization approach (Yeh, 2000) is done on the word segmentation results. Since there are more than 21,000 sentences in the test set, which is not appropriate for approximate randomization test, ten sets (500 sentences for each) are randomly selected from the test corpus. For each set, we run 1048576 shuffles twice and calculate the significance level p-value according to the shuffled results. It has been shown that all p-value are less than 0.001 on the ten sets. Accordingly the improvement is statistically significant. Actually, this significant improvement is reasonable, since the joint processing avoids error propagation and provides the opportunity of sharing information between different level knowledge sources. The superiority of this analyzer also shows that the integration of multi-level linguistic knowledge under the unified framework is effective, which may lead to improved LVCSR.

3.2 Experimental Setup for Mandarin Speech Recognition

In the baseline speech recognition system, the acoustic models consisted of context-dependent Initial-Final models, in which the left-to-right model topology was used to represent each unit. According to the phonetic structures, the number of states in each model was set to 2 or 3 for initials, and 4 or 5 for tonal finals. Each state was trained to have 32 Gaussian mixtures. The used 39-dimension feature vector comprised 12 MFCC coefficients, energy, and their first-order and second-order deltas. Since in this work we focused on modeling knowledge of language in Mandarin LVCSR, only clean male acoustic models were trained with a speech database that contained about 360 hours speech of over 750 male speakers. This training data was picked up from three continuous Mandarin speech corpora: the 863-I, 863-II and Intel corpora. The brief information about these three speech corpora was listed in Table 3. As in this work, the evaluation data was the 1997 HUB-4 Mandarin broadcast news evaluation data (HUB-4 test set), to better fit this task, the acoustic models were adapted by the approach of maximum a posterior (MAP) adaptation. The adaption data was drawn from the HUB4 training set, excluding the HUB-4 develop-

Corpus	Speakers	Amount of Speech (hours)
863-I (male)	83	56.67
863-II(male)	120	78.08
Intel (male)	556	227.30
total	759	362.05

Table 3: The information of the speech training data

ing set, where only the cleaned male speech data (data under condition f0 defined as (Doddington, 1996)) was used. The partition for the clean data was done with the acoustic segmentation software CMUseg_0.5[2] (Siegler et al., 1997), and finally 8.6 hours adaptation data was obtained.

The language model was a word-based trigram built on 60,000 words entries and trained with a corpus about 1.5 billion characters. The training set consisted of broadcast news data from the Xinhua News Agency released by LDC (Xinhua part of Chinese Gigaword), seven years data of People's Daily of China from 1995 to 2002 released by People's Daily Online[3], and some other data from news websites, such as yahoo, sina and so on.

In addition, the analyzer incorporated in speech recognition was trained with a larger corpus from People's Daily of China, including the data in 1998 from January to June and the data in 2000 from January to November (annotated by the Institute of Computational Linguistics of Peking University). The December data in 2000 was taken as the development set used to fix the composition weight α in equation 2.

3.3 Experimental Results

In our experiments, the clean male speech data from the Hub-4 test set was used, and 238 sentences were finally extracted for testing. The weight of the analyzer was empirically derived from the development set, including 649 clean male sentences from the devSet of HUB-4 Evaluation. The recognition results are shown in Table 4. The baseline system has a character error rate (CER) of 14.85%. When the analyzer is incorporated, a 9.9% relative reduction is achieved. Furthermore, we ran the statistical significance test to detect the performance improvement, in which the approximate randomization approach (Yeh, 2000) was modified to output the significance level, p-value, for the CER metric. The p-levels produced through two rounds of 1048576 shuffles are 0.0058 and 0.0057 respectively, both less than 0.01. Thus the performance improvement imposed by the utilization of the analyzer is statistically significant.

System	Err.	Sub.	Del.	Ins.
Baseline	14.85	13.02	0.76	1.07
Analyzer incorporation	13.38	11.78	1.00	0.60

Table 4: The Speech recognition results

4 Conclusion

Addressing the challenges of Mandarin large vocabulary continuous speech recognition task, within the unified framework of WFSTs, this study presents an analyzer integrating multi-level linguistic knowledge. Unlike other methods, model units, such as characters and words, can be chosen freely in this approach since multi-level knowledge sources are modeled independently. As a consequence, the final analyzer can be derived from the combination of better optimized models based on proper model units. Along with two level knowledge sources, i.e., the person and location names as well as the part-of-speech information, the analyzer is built and evaluated by a comparative simulation. Further evaluation is also conducted on an LVCSR system in which the analyzer is embedded. Experimental results consistently reveal that the approach is effective, and successfully improves the performance of speech recognition by a 9.9% relative reduction of character error rate on the HUB-4 test set. Also, the unified framework based approach provides a property of integrating additional linguistic knowledge flexibly, such as organization name and syntactic structure. Furthermore, the presented approach has a benefit of efficiency that additional efforts are not required for decoding as new knowledge comes, since all knowledge sources are finally encoded into a single WFST.

N-gram Weighting: Reducing Training Data Mismatch in Cross-Domain Language Model Estimation

Bo-June (Paul) Hsu, James Glass
MIT Computer Science and Artificial Intelligence Laboratory

{bohsu,glass}@csail.mit.edu

Abstract

In domains with insufficient matched training data, language models are often constructed by interpolating component models trained from partially matched corpora. Since the n-grams from such corpora may not be of equal relevance to the target domain, we propose an n-gram weighting technique to adjust the component n-gram probabilities based on features derived from readily available segmentation and metadata information for each corpus. Using a log-linear combination of such features, the resulting model achieves up to a 1.2% absolute word error rate reduction over a linearly interpolated baseline language model on a lecture transcription task.

1 Introduction

Many application domains in machine learning suffer from a dearth of matched training data. However, partially matched data sets are often available in abundance. Past attempts to utilize the mismatched data for training often result in models that exhibit biases not observed in the target domain. In this work, we will investigate the use of the often readily available data segmentation and metadata attributes associated with each corpus to reduce the effect of such bias. We will examine this approach in the context of language modeling for lecture transcription.

Compared with other types of audio data, lecture speech often exhibits a high degree of spontaneity and focuses on narrow topics with special terminologies (Glass et al., 2004). While we may have existing transcripts from general lectures or written text on the precise topic, training data that matches both the style and topic of the target lecture is often scarce. Thus, past research has investigated various adaptation and interpolation techniques to make use of partially matched corpora (Bellegarda, 2004).

Training corpora are often segmented into documents with associated metadata, such as title, date, and speaker. For lectures, if the data contains even a few lectures on linear algebra, conventional language modeling methods that lump the documents together will tend to assign disproportionately high probability to frequent terms like *vector* and *matrix*. Can we utilize the segmentation and metadata information to reduce the biases resulting from training data mismatch?

In this work, we present such a technique where we weight each n-gram count in a standard n-gram language model (LM) estimation procedure by a relevance factor computed via a log-linear combination of n-gram features. Utilizing features that correlate with the specificity of n-grams to subsets of the training documents, we effectively de-emphasize out-of-domain n-grams. By interpolating models, such as general lectures and course textbook, that match the target domain in complementary ways, and optimizing the weighting and interpolation parameters jointly, we allow each n-gram probability to be modeled by the most relevant interpolation component. Using a combination of features derived from multiple partitions of the training documents, the resulting weighted n-gram model achieves up to a 1.2% absolute word error rate (WER) reduction over a linearly interpolated baseline on a lecture transcription task.

2 Related Work

To reduce topic mismatch in LM estimation, we (2006) have previously assigned topic labels to each word by applying HMM-LDA (Griffiths et al., 2005) to the training documents. Using an ad hoc method to reduce the effective counts of n-grams ending on topic words, we achieved better perplexity and WER than standard trigram LMs. Intuitively, de-emphasizing such n-grams will lower the transition probability to out-of-domain topic words from the training data. In this work, we further explore this intuition with a principled feature-based model, integrated with LM smoothing and estimation to allow simultaneous optimization of all model parameters.

As Gao and Lee (2000) observed, even purported matched training data may exhibit topic, style, or temporal biases not present in the test set. To address the mismatch, they partition the training documents by their metadata attributes and compute a measure of the likelihood that an n-gram will appear in a new partitioned segment. By pruning n-grams with generality probability below a given threshold, the resulting model achieves lower perplexity than a count-cutoff model of equal size. Complementary to our work, this technique also utilizes segmentation and metadata information. However, our model enables the simultaneous use of all metadata attributes by combining features derived from different partitions of the training documents.

3 N-gram Weighting

Given a limited amount of training data, an n-gram appearing frequently in a single document may be assigned a disproportionately high probability. For example, an LM trained from lecture transcripts tends to assign excessive probability to words from observed lecture topics due to insufficient coverage of the underlying document topics. On the other hand, excessive probabilities may also be assigned to n-grams appearing consistently across documents with mismatched style, such as the course textbook in the written style. Traditional n-gram smoothing techniques do not address such issues of insufficient topic coverage and style mismatch.

One approach to addressing the above issues is to weight the counts of the n-grams according to the concentration of their document distributions. Assigning higher weights to n-grams with evenly spread distributions captures the style of a data set, as reflected across all documents. On the other hand, emphasizing the n-grams concentrated within a few documents focuses the model on the topics of the individual documents.

In theory, n-gram weighting can be applied to any smoothing algorithm based on counts. However, because many of these algorithms assume integer counts, we will apply the weighting factors to the smoothed counts, instead. For modified Kneser-Ney smoothing (Chen and Goodman, 1998), applying n-gram weighting yields:

$$p(w|h) = \frac{\beta(hw)\tilde{c}'(hw)}{\sum_w \beta(hw)\tilde{c}(hw)} + \alpha(h)p(w|h')$$

where $p(w|h)$ is the probability of word w given history h, $\tilde{c}$ is the adjusted Kneser-Ney count, $\tilde{c}'$ is the discounted count, β is the n-gram weighting factor, α is the normalizing backoff weight, and h' is the backoff history.

Although the weighting factor β can in general be any function of the n-gram, in this work, we will consider a log-linear combination of n-gram features, or $\beta(hw) = \exp(\mathbf{\Phi}(hw) \cdot \boldsymbol{\theta})$, where $\mathbf{\Phi}(hw)$ is the feature vector for n-gram hw and $\boldsymbol{\theta}$ specifies the parameter vector to be learned. To better fit the data, we allow independent parameter vectors $\boldsymbol{\theta}_o$ for each n-gram order o. Note that with $\beta(hw) = 1$, the model degenerates to the original modified Kneser-Ney formulation. Furthermore, β only specifies the relative weighting among n-grams with a common history h. Thus, scaling $\beta(hw)$ by an arbitrary function $g(h)$ has no effect on the model.

In isolation, n-gram weighting shifts probability mass from out-of-domain n-grams via backoff to the uniform distribution to improve the generality of the resulting model. However, in combination with LM interpolation, it can also distribute probabilities to LM components that better model specific n-grams. For example, n-gram weighting can de-emphasize off-topic and off-style n-grams from general lectures and course textbook, respectively. Tuning the weighting and interpolation parameters jointly further allows the estimation of the n-gram probabilities to utilize the best matching LM components.

3.1 Features

To address the issue of sparsity in the document topic distribution, we can apply n-gram weighting with features that measure the concentration of the n-gram distribution across documents. Similar features can also be computed from documents partitioned by their categorical metadata attributes, such as *course* and *speaker* for lecture transcripts. Whereas the features derived from the corpus documents should correlate with the topic specificity of the n-grams, the same features computed from the speaker partitions might correspond to the speaker specificity. By combining features from multiple partitions of the training data to compute the weighting factors, n-gram weighting allows the resulting model to better generalize across categories.

To guide the presentation of the n-gram features below, we will consider the following example partition of the training corpus. Words tagged by HMM-LDA as topic words appear in bold.

A B A	A **C** **C** A	**B** A B
B A **A** C	C B A	A B A
A C B	A A **C**	A **B** **B** A

One way to estimate the specificity of an n-gram across partitions is to measure the n-gram frequency f, or the fraction of partitions containing an n-gram. For instance, $f(\text{A}) = 3/3$, $f(\text{C}) = 2/3$. However, as the size of each partition increases, this ratio increases to 1, since most n-grams have a non-zero probability of appearing in each partition. Thus, an alternative is to compute the normalized entropy of the n-gram distribution across the S partitions, or $h = \frac{-1}{\log S} \sum_{s=1}^{S} p(s) \log p(s)$, where $p(s)$ is the fraction of an n-gram appearing in partition s. For example, the normalized entropy of the unigram C is $h(\text{C}) = \frac{-1}{\log 3}[\frac{2}{6} \log \frac{2}{6} + \frac{4}{6} \log \frac{4}{6} + 0] = .58$. N-grams clustered in fewer partitions have lower entropy than ones that are more evenly spread out.

Following (Hsu and Glass, 2006), we also consider features derived from the HMM-LDA word topic labels.[1] Specifically, we compute the empirical probability t that the target word of the n-gram is labeled as a topic word. In the example corpus, $t(\text{C}) = 3/6$, $t(\text{A C}) = 2/4$.

[1]HMM-LDA is performed using 20 states and 50 topics with a 3rd-order HMM. Hyperparameters are sampled with a log-normal Metropolis proposal. The model with the highest likelihood from among 10,000 iterations of Gibbs sampling is used.

Table 1: A list of n-gram weighting features. f: n-gram frequency, h: normalized entropy, t: topic probability.

All of the above features can be computed for any partitioning of the training data. To better illustrate the differences, we compute the features on a set of lecture transcripts (see Section 4.1) partitioned by lecture (doc), course, and speaker. Furthermore, we include the log of the n-gram counts c and random values between 0 and 1 as baseline features. Table 1 lists all the features examined in this work and their values on a select subset of n-grams.

3.2 Training

To tune the n-gram weighting parameters $\boldsymbol{\theta}$, we apply Powell's method (Press et al., 2007) to numerically minimize the development set perplexity (Hsu and Glass, 2008). Although there is no guarantee against converging to a local minimum when jointly tuning both the n-gram weighting and interpolation parameters, we have found that initializing the parameters to zero generally yields good performance.

4 Experiments

4.1 Setup

In this work, we evaluate the perplexity and WER of various trigram LMs trained with n-gram weighting on a lecture transcription task (Glass et al., 2007). The target data consists of 20 lectures from an introductory computer science course, from which we withhold the first 10 lectures for the development

Dataset	# Words	# Sents	# Docs
Textbook	131,280	6,762	271
Lectures	1,994,225	128,895	230
Switchboard	3,162,544	262,744	4,876
CS Dev	93,353	4,126	10
CS Test	87,527	3,611	10

Table 2: Summary of evaluation corpora.

	Perplexity		WER	
Model	Dev	Test	Dev	Test

+ W(h^{doc})	160.1	180.0	34.8%	36.8%

Table 3: Performance of n-gram weighting with a variety of Kneser-Ney settings. FixKN(d): Kneser-Ney with d fixed discount parameters. KN(d): FixKN(d) with tuned values. W(*feat*): n-gram weighting with *feat* feature.

set (CS Dev) and use the last 10 for the test set (CS Test). For training, we will consider the course textbook with topic-specific vocabulary (Textbook), numerous high-fidelity transcripts from a variety of general seminars and lectures (Lectures), and the out-of-domain LDC Switchboard corpus of spontaneous conversational speech (Switchboard) (Godfrey and Holliman, 1993). Table 2 summarizes all the evaluation data.

To compute the word error rate, we use a speaker-independent speech recognizer (Glass, 2003) with a large-margin discriminative acoustic model (Chang, 2008). The lectures are pre-segmented into utterances via forced alignment against the reference transcripts (Hazen, 2006). Since all the models considered in this work can be encoded as n-gram backoff models, they are applied directly during the first recognition pass instead of through a subsequent n-best rescoring step.

Model	Perplexity	WER
Lectures	189.3	36.9%
+ W(h^{doc})	187.8 (-0.8%)	36.6%
Textbook	326.1	43.1%
+ W(h^{doc})	317.5 (-2.6%)	43.1%
LI(Lectures + Textbook)	141.6	33.7%
+ W(h^{doc})	136.6 (-3.5%)	32.7%

Table 4: N-gram weighting with linear interpolation.

4.2 Smoothing

In Table 3, we compare the performance of n-gram weighting with the h^{doc} document entropy feature for various modified Kneser-Ney smoothing configurations (Chen and Goodman, 1998) on the Lectures dataset. Specifically, we considered varying the number of discount parameters per n-gram order from 1 to 10. The original and modified Kneser-Ney smoothing algorithms correspond to a setting of 1 and 3, respectively. Furthermore, we explored using both fixed parameter values estimated from n-gram count statistics and tuned values that minimize the development set perplexity.

In this task, while the test set perplexity tracks the development set perplexity well, the WER correlates surprisingly poorly with the perplexity on both the development and test sets. Nevertheless, n-gram weighting consistently reduces the absolute test set WER by a statistically significant average of 0.3%, according to the Matched Pairs Sentence Segment Word Error test (Pallet et al., 1990). Given that we obtained the lowest development set WER with the fixed 3-parameter modified Kneser-Ney smoothing, all subsequent experiments are conducted using this smoothing configuration.

4.3 Linear Interpolation

Applied to the Lectures dataset in isolation, n-gram weighting with the h^{doc} feature reduces the test set WER by 0.3% by de-emphasizing the probability contributions from off-topic n-grams and shifting their weights to the backoff distributions. Ideally though, such weights should be distributed to on-topic n-grams, perhaps from other LM components.

In Table 4, we present the performance of applying n-gram weighting to the Lectures and Textbook models individually versus in combination via linear interpolation (LI), where we optimize the n-gram

Model	Perplexity	WER
LI(Lectures + Textbook)	141.6	33.7%
+ W(*Random*)	141.5 (-0.0%)	33.7%
+ W($\log(c)$)	137.5 (-2.9%)	32.8%
+ W(f^{doc})	136.3 (-3.7%)	32.8%
+ W(f^{course})	136.5 (-3.6%)	32.7%
+ W(f^{speaker})	138.1 (-2.5%)	33.0%
+ W(h^{doc})	136.6 (-3.5%)	**32.7%**
+ W(h^{course}) ★	136.1 (-3.9%)	<u>32.7%</u>
+ W(h^{speaker})	138.6 (-2.1%)	33.1%
+ W(t^{doc})	**<u>134.8</u>** (-4.8%)	33.2%
+ W(t^{course})	136.4 (-3.6%)	33.1%
+ W(t^{speaker})	136.4 (-3.7%)	33.2%

Table 5: N-gram weighting with various features.

weighting and interpolation parameters jointly. The interpolated model with n-gram weighting achieves perplexity improvements roughly additive of the reductions obtained with the individual models. However, the 1.0% WER drop for the interpolated model significantly exceeds the sum of the individual reductions. Thus, as we will examine in more detail in Section 5.1, n-gram weighting allows probabilities to be shifted from less relevant n-grams in one component to more specific n-grams in another.

4.4 Features

With n-gram weighting, we can model the weighting function $\beta(hw)$ as a log-linear combination of any n-gram features. In Table 5, we show the effect various features have on the performance of linearly interpolating Lectures and Textbook. As the documents from the Lectures dataset is annotated with course and speaker metadata attributes, we include the n-gram frequency f, entropy h, and topic probability t features computed from the lectures grouped by the 16 unique courses and 299 unique speakers.[2]

In terms of perplexity, the use of the *Random* feature has negligible impact on the test set performance, as expected. On the other hand, the $\log(c)$ count feature reduces the perplexity by nearly 3%, as it correlates with the generality of the n-grams. By using features that leverage the information from document segmentation and associated metadata, we are generally able to achieve further perplexity reductions. Overall, the frequency and entropy features perform roughly equally. However, by considering information from the more sophisticated HMM-LDA topic model, the topic probability feature t^{doc} achieves significantly lower perplexity than any other feature in isolation.

In terms of WER, the *Random* feature again shows no effect on the baseline WER of 33.7%. However, to our surprise, the use of the simple $\log(c)$ feature achieves nearly the same WER improvement as the best segmentation-based feature, whereas the more sophisticated features computed from HMM-LDA labels only obtain half of the reduction even though they have the best perplexities.

When comparing the performance of different n-gram weighting features on this data set, the perplexity correlates poorly with the WER, on both the development and test sets. Fortunately, the features that yield the lowest perplexity and WER on the development set also yield one of the lowest perplexities and WERs, respectively, on the test set. Thus, during feature selection for speech recognition applications, we should consider the development set WER. Specifically, since the differences in WER are often statistically insignificant, we will select the feature that minimizes the sum of the development set WER and log perplexity, or cross-entropy.[3]

In Tables 5 and 6, we have underlined the perplexities and WERs of the features with the lowest corresponding development set values (not shown) and bolded the lowest test set values. The features that achieve the lowest combined cross-entropy and WER on the development set are starred.

4.5 Feature Combination

Unlike most previous work, n-gram weighting enables a systematic integration of features computed from multiple document partitions. In Table 6, we compare the performance of various feature combinations. We experiment with incrementally adding features that yield the lowest combined development set cross-entropy and WER. Overall, this metric appears to better predict the test set WER than either the development set perplexity or WER alone.

[2]Features that are not applicable to a particular corpus (e.g. h^{course} for Textbook) are removed from the n-gram weighting computation for that component. Thus, models with course and speaker features have fewer tunable parameters than the others.

[3]The choice of cross-entropy instead of perplexity is partially motivated by the linear correlation reported by (Chen and Goodman, 1998) between cross-entropy and WER.

Features	Perplexity	WER
h^{course}	136.1	32.7%
+ $\log(c)$	135.4 (-0.5%)	32.6%

Feature	Parameter Values
h^{doc}	$\boldsymbol{\theta}^{\mathsf{L}} = [3.42, 1.46, 0.12]$
	$\boldsymbol{\theta}^{\mathsf{T}} = [-0.45, -0.35, -0.73]$
	$[\lambda^{\mathsf{L}}, \lambda^{\mathsf{T}}] = [0.67, 0.33]$
t^{doc}	$\boldsymbol{\theta}^{\mathsf{L}} = [-2.33, -1.63, -1.19]$
	$\boldsymbol{\theta}^{\mathsf{T}} = [1.05, 0.46, 0.12]$
	$[\lambda^{\mathsf{L}}, \lambda^{\mathsf{T}}] = [0.68, 0.32]$

Table 8: N-gram weighting parameter values. $\boldsymbol{\theta}^{\mathsf{L}}$, $\boldsymbol{\theta}^{\mathsf{T}}$: parameters for each order of the Lectures and Textbook trigram models, λ^{L},λ^{T}: linear interpolation weights.

Using the combined feature selection technique, we notice that the greedily selected features tend to differ in the choice of document segmentation and feature type, suggesting that n-gram weighting can effectively integrate the information provided by the document metadata. By combining features, we are able to further reduce the test set WER by a statistically significant ($p < 0.001$) 0.2% over the best single feature model.

4.6 Advanced Interpolation

While n-gram weighting with all three features is able to reduce the test set WER by 1.2% over the linear interpolation baseline, linear interpolation is not a particularly effective interpolation technique. In Table 7, we compare the effectiveness of n-gram weighting in combination with better interpolation techniques, such as count merging (CM) (Bacchiani et al., 2006) and generalized linear interpolation (GLI) (Hsu, 2007). As expected, the use of more sophisticated interpolation techniques decreases the perplexity and WER reductions achieved by n-gram weighting by roughly half for a variety of feature combinations. However, all improvements remain statistically significant.

Although the WER reductions from better interpolation techniques are initially statistically significant, as we add features to n-gram weighting, the differences among the interpolation methods shrink significantly. With all three features combined, the test set WER difference between linear interpolation and generalized linear interpolation loses its statistical significance. In fact, we can obtain statistically the same WER of 32.4% using the simpler model of count merging and n-gram weighting with h^{course}.

5 Analysis

5.1 Weighting Parameters

To obtain further insight into how n-gram weighting improves the resulting n-gram model, we present in Table 8 the optimized parameter values for the linear interpolation model between Lectures and Textbook using n-gram weighting with h^{doc} and t^{doc} features. Using $\beta(hw) = \exp(\boldsymbol{\Phi}(hw) \cdot \boldsymbol{\theta})$ to model the n-gram weights, a positive value of θ_i corresponds to

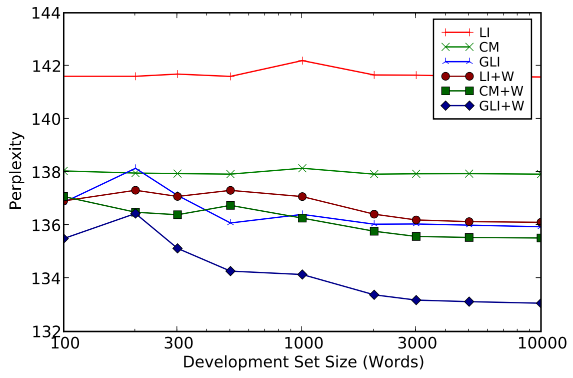

Figure 1: Test set perplexity vs. development set size.

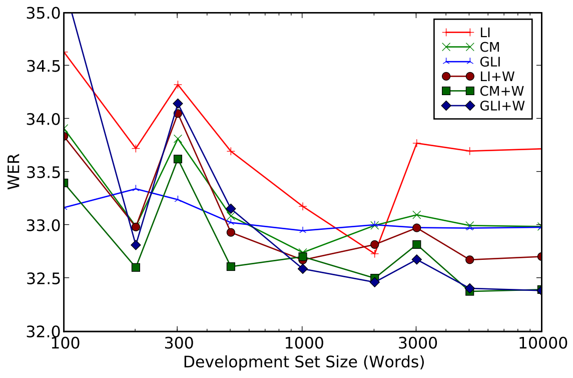

Figure 2: Test set WER vs. development set size.

increasing the weights of the i^{th} order n-grams with positive feature values.

For the h^{doc} normalized entropy feature, values close to 1 correspond to n-grams that are evenly distributed across the documents. When interpolating Lectures and Textbook, we obtain consistently positive values for the Lectures component, indicating a de-emphasis on document-specific terms that are unlikely to be found in the target computer science domain. On the other hand, the values corresponding to the Textbook component are consistently negative, suggesting a reduced weight for mismatched style terms that appear uniformly across textbook sections.

For t^{doc}, values close to 1 correspond to n-grams ending frequently on topic words with uneven distribution across documents. Thus, as expected, the signs of the optimized parameter values are flipped. By de-emphasizing topic n-grams from off-topic components and style n-grams from off-style components, n-gram weighting effectively improves the performance of the resulting language model.

5.2 Development Set Size

So far, we have assumed the availability of a large development set for parameter tuning. To obtain a sense of how n-gram weighting performs with smaller development sets, we randomly select utterances from the full development set and plot the test set perplexity in Figure 1 as a function of the development set size for various modeling techniques.

As expected, GLI outperforms both LI and CM. However, whereas LI and CM essentially converge in test set perplexity with only 100 words of development data, it takes about 500 words before GLI converges due to the increased number of parameters. By adding n-gram weighting with the h^{course} feature, we see a significant drop in perplexity for all models at all development set sizes. However, the performance does not fully converge until 3,000 words of development set data.

As shown in Figure 2, the test set WER behaves more erratically, as the parameters are tuned to minimize the development set perplexity. Overall, n-gram weighting decreases the WER significantly, except when applied to GLI with less than 1000 words of development data when the perplexity of GLI has not itself converged. In that range, CM with n-gram weighting performs the best. However, with more development data, GLI with n-gram weighting generally performs slightly better. From these results, we conclude that although n-gram weighting increases the number of tuning parameters, they are effective in improving the test set performance even with only 100 words of development set data.

5.3 Training Set Size

To characterize the effectiveness of n-gram weighting as a function of the training set size, we evaluate the performance of various interpolated models with increasing subsets of the Lectures corpus and the full Textbook corpus. Overall, every doubling of the number of training set documents decreases both the test set perplexity and WER by approximately 7 points and 0.8%, respectively. To better compare results, we plot the performance difference between various models and linear interpolation in Figures 3 and 4.

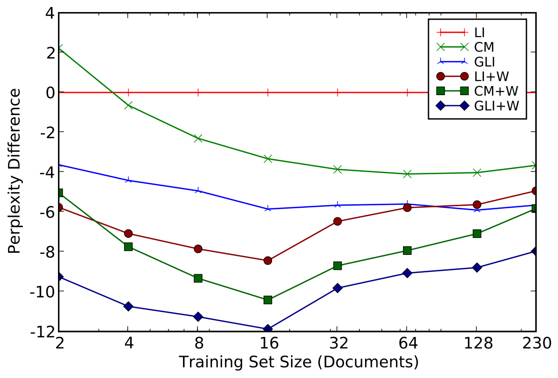

Figure 3: Test set perplexity vs. training set size.

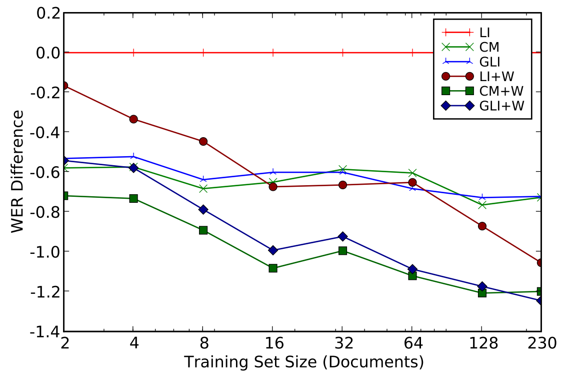

Figure 4: Test set WER vs. training set size.

Interestingly, the peak gain obtained from n-gram weighting with the h^{doc} feature appears at around 16 documents for all interpolation techniques. We suspect that as the number of documents initially increases, the estimation of the h^{doc} features improves, resulting in larger perplexity reduction from n-gram weighting. However, as the diversity of the training set documents increases beyond a certain threshold, we experience less document-level sparsity. Thus, we see decreasing gain from n-gram weighting beyond 16 documents.

For all interpolation techniques, even though the perplexity improvements from n-gram weighting decrease with more documents, the WER reductions actually increase. N-gram weighting showed statistically significant reductions for all configurations except generalized linear interpolation with less than 8 documents. Although count merging with n-gram weighting has the lowest WER for most training set sizes, GLI ultimately achieves the best test set WER with the full training set.

5.4 Training Corpora

In Table 9, we compare the performance of n-gram weighting with different combination of training corpora and interpolation techniques to determine its effectiveness across different training conditions. With the exception of interpolating Lectures and Switchboard using count merging, all other model combinations yield statistically significant improvements with n-gram weighting using h^{course}, t^{doc}, and f^{doc} features.

The results suggest that n-gram weighting with these features is most effective when interpolating

Model	L + T	L + S	T + S	L + T + S
LI	33.7%	36.7%	36.4%	33.6%
LI + W	32.5%	36.4%	35.7%	32.5%
CM	33.0%	36.6%	35.5%	32.9%
CM + W	32.4%	36.5%	35.4%	32.3%
GLI	33.0%	36.6%	35.7%	32.8%
GLI + W	32.4%	36.4%	35.3%	32.2%

Table 9: Test set WER with various training corpus combinations. L: Lectures, T: Textbook, S: Switchboard, W: n-gram weighting.

corpora that differ in how they match the target domain. Whereas the Textbook corpus is the only corpus with matching topic, both Lectures and Switchboard have a similar matching spoken conversational style. Thus, we see the least benefit from n-gram weighting when interpolating Lectures and Switchboard. By combining Lectures, Textbook, and Switchboard using generalized linear interpolation with n-gram weighting using h^{course}, t^{doc}, and f^{doc} features, we achieve our best test set WER of 32.2% on the lecture transcription task, a full 1.5% over the initial linear interpolation baseline.

6 Conclusion & Future Work

In this work, we presented the n-gram weighting technique for adjusting the probabilities of n-grams according to a set of features. By utilizing features derived from the document segmentation and associated metadata inherent in many training corpora, we achieved up to a 1.2% and 0.6% WER reduction over the linear interpolation and count merging baselines, respectively, using n-gram weighting on a lecture transcription task.

We examined the performance of various n-gram weighting features and generally found entropy-based features to offer the best predictive performance. Although the topic probability features derived from HMM-LDA labels yield additional improvements when applied in combination with the normalized entropy features, the computational cost of performing HMM-LDA may not justify the marginal benefit in all scenarios.

In situations where the document boundaries are unavailable or when finer segmentation is desired, automatic techniques for document segmentation may be applied (Malioutov and Barzilay, 2006). Synthetic metadata information may also be obtained via clustering techniques (Steinbach et al., 2000). Although we have primarily focused on n-gram weighting features derived from segmentation information, it is also possible to consider other features that correlate with n-gram relevance.

N-gram weighting and other approaches to cross-domain language modeling require a matched development set for model parameter tuning. Thus, for future work, we plan to investigate the use of the initial recognition hypotheses as the development set, as well as manually transcribing a subset of the test set utterances.

As speech and natural language applications shift towards novel domains with limited matched training data, better techniques are needed to maximally utilize the often abundant partially matched data. In this work, we examined the effectiveness of the n-gram weighting technique for estimating language models in these situations. With similar investments in acoustic modeling and other areas of natural language processing, we look forward to an ever increasing diversity of practical speech and natural language applications.

Availability An implementation of the n-gram weighting algorithm is available in the MIT Language Modeling (MITLM) toolkit (Hsu and Glass, 2008): http://www.sls.csail.mit.edu/mitlm/.

Complexity of finding the BLEU-optimal hypothesis in a confusion network

Gregor Leusch and **Evgeny Matusov** and **Hermann Ney**
RWTH Aachen University, Germany
{leusch,matusov,ney}@cs.rwth-aachen.de

Abstract

Confusion networks are a simple representation of multiple speech recognition or translation hypotheses in a machine translation system. A typical operation on a confusion network is to find the path which minimizes or maximizes a certain evaluation metric. In this article, we show that this problem is generally NP-hard for the popular BLEU metric, as well as for smaller variants of BLEU. This also holds for more complex representations like generic word graphs. In addition, we give an efficient polynomial-time algorithm to calculate unigram BLEU on confusion networks, but show that even small generalizations of this data structure render the problem to be NP-hard again.

Since finding the optimal solution is thus not always feasible, we introduce an approximating algorithm based on a multi-stack decoder, which finds a (not necessarily optimal) solution for n-gram BLEU in polynomial time.

1 Introduction

In machine translation (MT), confusion networks (CNs) are commonly used to represent alternative versions of sentences. Typical applications include translation of different speech recognition hypotheses (Bertoldi et al., 2007) or system combination (Fiscus, 1997; Matusov et al., 2006).

A typical operation on a given CN is to find the path which minimizes or maximizes a certain evaluation metric. This operation can be used in applications like Minimum Error Rate Training (Och, 2003), or optimizing system combination as described by Hillard et al. (2007). Whereas this is easily achievable for simple metrics like the *Word Error Rate* (WER) as described by Mohri and Riley (2002), current research in MT uses more sophisticated measures, like the BLEU score (Papineni et al., 2001). Zens and Ney (2005) first described this task on general word graphs, and sketched a complete algorithm for calculating the maximum BLEU score in a word graph. While they do not give an estimate on the complexity of their algorithm, they note that already a simpler algorithm for calculating the Position independent Error Rate (PER) has an exponential worst-case complexity. The same can be expected for their BLEU algorithm. Dreyer et al (2007) examined a special class of word graphs, namely those that denote constrained reorderings of single sentences. These word graphs have some properties which simplify the calculation; for example, no edge is labeled with the empty word, and all paths have the same length and end in the same node. Even then, their decoder does not optimize the true BLEU score, but an approximate version which uses a language-model-like unmodified precision. We give a very short introduction to CNs and the BLEU score in Section 2.

In Section 3 we show that finding the best BLEU score is an NP-hard problem, even for a simplified variant of BLEU which only scores unigrams and bigrams. The main reason for this problem to become NP-hard is that by looking at bigrams, we allow for one decision to also influence the following decision, which itself can influence the decisions after that. We also show that this also holds for unigram BLEU and the *position independent error rate* (PER) on a slightly augmented variant of CNs which allows for edges to carry multiple symbols. The concatenation of symbols corresponds to the interdependency of decisions in the case of bigram matches above.

NP-hard problems are quite common in machine translation; for example, Knight (1999) has shown that even for a simple form of statistical MT models, the decoding problem is NP-complete. More recently, DeNero and Klein (2008) have proven the NP-completeness of the phrase alignment problem.

But even a simple, common procedure as BLEU scoring, which can be performed in linear time on single sentences, becomes a potentially intractable problem as soon as it has to be performed on a slightly more powerful representation, such as confusion networks. This rather surprising result is the motivation of this paper.

The problem of finding the best unigram BLEU score in an unaugmented variant of CNs is not NP-complete, as we show in Section 4. We present an algorithm that finds such a unigram BLEU-best path in polynomial time.

An important corollary of this work is that calculating the BLEU-best path on general word graphs is also NP-complete, as CNs are a true subclass of word graphs. It is still desirable to calculate a "good" path in terms of the BLEU score in a CN, even if calculating the best path is infeasible. In Section 5, we present an algorithm which can calculate "good" solutions for CNs in polynomial time. This algorithm can easily be extended to handle arbitrary word graphs. We assess the algorithm experimentally on real-world MT data in Section 6, and draw some conclusions from the results in this article in Section 7.

2 Confusion networks

A *confusion network* (CN) is a word graph where each edge is labeled with exactly zero or one symbol, and each path from the start node to the end node visits each node of the graph in canonical order. Usually, we represent unlabeled edges by labeling them with the *empty word* ε.

Within this paper, we represent a CN by a list of lists of words $\{w_{i,j}\}$, where each $w_{i,j}$ corresponds to a symbol on an edge between nodes i and $i+1$. A *path* in this CN can be written as a string of integers, $a_1^n = a_1, \ldots, a_n$, such that the path is labeled $w_{1,a_1} w_{2,a_2} \ldots w_{n,a_n}$. Note that there can be a different number of possible words, j, for different positions i.

2.1 BLEU and variants

The BLEU score, as defined by Papineni et al. (2001), is the modified n-gram precision of a hypothesis, with $1 \leq n \leq N$, given a set of reference translations R. "Modified precision" here means that for each n-gram, its maximum number of occurrences within the reference sentences is counted, and only up to that many occurrences in the hypothesis are considered to be correct. The geometric mean over the precisions for all n is calculated, and multiplied by a *brevity penalty* bp. This brevity penalty is 1.0 if the hypothesis sentence is at least as long as the reference sentence (special cases occur if multiple reference sentences with different length exists), and less than 1.0 otherwise. The exact formulation can be found in the cited paper; for the proofs in our paper it is enough to note that the BLEU score is 1.0 exactly if all n-grams in the hypothesis occur at least that many times in a reference sentence, and if there is a reference sentence which is as long as or shorter than the hypothesis. Assuming that we can always provide a dummy reference sentence shorter than this length, we do not need to regard the brevity penalty in these proofs. Within the following proofs of NP-hardness, we will only require confusion networks (and word graphs) which do not contain empty words, and where all paths from the start node to the end node have the same length.

Usually, in the definition of the BLEU score, N is set to 4; within this article we denote this metric as 4BLEU. We can also restrict the calculations to unigrams only, which would be 1BLEU, or to bigrams and unigrams, which we denote as 2BLEU.

Similar to the 1BLEU metric is the Position independent Error Rate PER (Tillmann et al., 1997), which counts the number of substitutions, insertions, and deletions that have to be performed on the unigram counts to have the hypothesis counts match the reference counts. Unlike 1BLEU, for PER to be optimal (here, 0.0), the reference counts must match the candidate counts exactly.

Given a CN $\{w_{i,j}\}$ and a set of reference sentences R, we define the optimization problem

Definition 1 (CN-2BLEU-OPTIMIZE) *Among all paths a_1^I through the CN, what is the path with the highest 2BLEU score?*

Related to this is the decision problem

Definition 2 (CN-2BLEU-DECIDE) *Among all paths a_1^I through the CN, is there a path with a 2BLEU score of* 1.0*?*

Similarly we define CN-4BLEU-DECIDE, CN-PER-DECIDE, etc.

3 CN-2BLEU-DECIDE is NP-complete

We now show that CN-2BLEU-DECIDE is NP-complete. It is obvious that the problem is in NP: Given a path a_1^I, which is polynomial in size to the problem, we can decide in polynomial time whether a_1^I is a solution to the problem – namely by calculating the BLEU score. We now show that there is a problem known to be NP-complete which can be polynomially reduced to CN-2BLEU-DECIDE. For our proof, we choose 3SAT.

3.1 3SAT

Consider the following problem:

Definition 3 (3SAT) *Let $X = \{x_1, \dots, x_n\}$ be a set of Boolean variables, let $\mathcal{F} = \bigwedge_{i=1}^{k} (L_{i,1} \vee L_{i,2} \vee L_{i,3})$ be a Boolean formula, where each literal $L_{i,j}$ is either a variable x or its negate $\overline{x}$. Is there a assignment $\beta : X \to \{0, 1\}$ such that $\beta \models \mathcal{F}$? In other words, if we replace each x in $\mathcal{F}$ by $\beta(x)$, and each $\overline{x}$ by $1 - \beta(x)$, does $\mathcal{F}$ become true?*

It has been shown by Karp (1972) that 3SAT is NP-complete. Consequently, if for another problem in NP there is polynomial-size and -time reduction of an arbitrary instance of 3SAT to an instance of this new problem, this new problem is also NP-complete.

3.2 Reduction of 3SAT to CN-2BLEU-DECIDE

Let $\mathcal{F}$ be a Boolean formula in 3CNF, and let k be its size, as in Definition 3. We will now reduce it to a corresponding CN-2BLEU-DECIDE problem. This means that we create an alphabet Σ, a confusion network $\mathcal{C}$, and a set of reference sentences R, such that there is a path through $\mathcal{C}$ with a BLEU score of 1.0 exactly if $\mathcal{F}$ is solvable:

Create an alphabet Σ based on $\mathcal{F}$ as $\Sigma := \{x_1, \dots, x_n\} \cup \{\overline{x_1}, \dots, \overline{x_n}\} \cup \{\diamond\}$. Here, the x_i and $\overline{x_i}$ symbols will correspond to the variable with the same name or their negate, respectively, whereas $\diamond$ will serve as an "isolator symbol", to avoid unwanted bigram matches or mismatches between separate parts of the constructed CN or sentences.

Consider the CN $\mathcal{C}$ from Figure 1.

Consider the following set of reference sentences:

$$\begin{aligned} R := \{ & \diamond (x_1\diamond)^k (x_2\diamond)^k \dots (x_n\diamond)^k \\ & \diamond (\overline{x_1}\diamond)^k (\overline{x_2}\diamond)^k \dots (\overline{x_n}\diamond)^k, \\ & (x_1)^k \diamond (\overline{x_1})^k \diamond \dots (x_n)^k \diamond (\overline{x_n})^k \diamond (\diamond)^{k+n} \ \} \end{aligned}$$

where $(x)^k$ denotes k subsequent occurrences of x. Clearly, both $\mathcal{C}$ and R are of polynomial size in n and k, and can be constructed in polynomial time.

Then,

There is an assignment β such that $\beta \models \mathcal{F}$

$\Leftrightarrow$

There is a path a_1^I through $\mathcal{C}$ such that $\mathrm{BLEU}(a_1^I, R) = 1.0$.

Proof: "$\Rightarrow$"

Let β be an assignment under which $\mathcal{F}$ becomes true. Create a path a_1^I as follows: Within $\mathcal{A}$, for each set of edges $L_{i,1}$, $L_{i,2}$, $L_{i,3}$, choose the path through an x where $\beta(x) = 1$, or through an $\overline{x}$ where $\beta(x) = 0$. Note that there must be such an x, because otherwise the clause $L_{i,1} \vee L_{i,2} \vee L_{i,3}$ would not be true under β. Within $\mathcal{B}$, select the path always through x_i if $\beta(x_i) = 0$, and through $\overline{x_i}$ if $\beta(x_i) = 1$.

Then, a_1^I consists of, for each i,

- At most k occurrences of both x_i and $\overline{x_i}$
- At most k occurrences of each of the bigrams $x_i\diamond$, $\diamond x_i$, $\overline{x_i}\diamond$, $\diamond\overline{x_i}$, $x_i x_i$, and $\overline{x_i}\,\overline{x_i}$
- No other bigram than those listed above.

For all of these unigram and bigram counts, there is a reference sentence in R which contains at least as many of those unigrams/bigrams as the path. Thus, the unigram and bigram precision of a_1^I is 1.0. In addition, there is always a reference sentence whose length is shorter than that of a_1^I, such that the brevity penalty is also 1.0. As a result, $\mathrm{BLEU}(a_1^I, R) = 1.0$.

"$\Leftarrow$"

Let a_1^I be a path through $\mathcal{C}$ such that $BLEU(a_1^I, R) = 1.0$. Because there is no bigram $x_i\overline{x_i}$ or $\overline{x_i}x_i$ in R, we can assume that for each x_i, either only x_i edges, or only $\overline{x_i}$ edges appear in the $\mathcal{B}$ part of a_1^I, each at most k times. As no unigram x_i and $\overline{x_i}$ appears more than k times in R, we can assume that, if the $\overline{x_i}$ edges are passed in $\mathcal{B}$, then only the x_i edges are passed in $\mathcal{A}$, and vice versa. Now, create an assignment β as follows:

$$\beta := \begin{cases} 0 & \text{if } x_i \text{ edges are passed in } \mathcal{B} \\ 1 & \text{otherwise} \end{cases}$$

Then, $\beta \models \mathcal{F}$. Proof: Assume that $\mathcal{F}_\beta = 0$. Then there must be a clause i such that $L_{i,1} \vee L_{i,2} \vee L_{i,3} =$

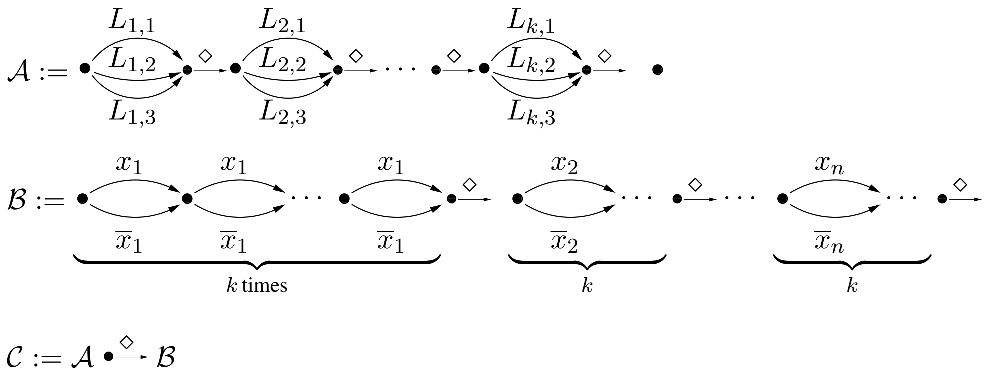

Figure 1: CN constructed from a 3SAT formula $\mathcal{F}$. $\mathcal{C}$ is the concatenation of the left part $\mathcal{A}$, and the right path $\mathcal{B}$, separated by an isolating $\diamond$.

0. At least one of the edges $L_{i,j}$ associated with the literals of this clause must have been passed by a_1^K in $\mathcal{A}$. This literal, though, can not have been passed in $\mathcal{B}$. As a consequence, $\beta(L_{i,j}) = 1$. But this means that $L_{i,1} \vee L_{i,2} \vee L_{i,3} = 1 \quad \rightsquigarrow$ contradiction.

Because CN-2BLEU-DECIDE is in NP, and we can reduce an NP-complete problem (3SAT) in polynomial time to a CN-2BLEU-DECIDE problem, this means that CN-2BLEU-DECIDE is NP-complete.

3.3 CN-4BLEU-DECIDE

It is straightforward to modify the construction above to create an equivalent CN-4BLEU-DECIDE problem instead: Replace each occurrence of the isolating symbol $\diamond$ in $\mathcal{A}, \mathcal{B}, \mathcal{C}, R$ by three consecutive isolating symbols $\diamond\diamond\diamond$. Then, everything said about unigrams still holds, and bi-, tri- and fourgrams are handled equivalently: Previous unigram matches on $\diamond$ correspond to uni-, bi-, and trigram matches on $\diamond$, $\diamond\diamond$, $\diamond\diamond\diamond$. Bigram matches on $x\diamond$ correspond to bi-, tri-, and fourgram matches on $x\diamond$, $x\diamond\diamond$, $x\diamond\diamond\diamond$, and similar holds for bigram matches $\overline{x}\diamond$, $\diamond x$, $\diamond\overline{x}$. Unigram matches x, $\overline{x}$, and bigram matches xx etc. stay the same. Consequently, CN-4BLEU-DECIDE is also an NP-complete problem.

3.4 CN*-1BLEU-DECIDE

Is it possible to get rid of the necessity for bigram counts in this proof? One possibility might be to look at slightly more powerful graph structures, CN*. In these graphs, each edge can be labeled by arbitrarily many symbols (instead of just zero or one). Then, consider a CN* graph $\mathcal{C}' := \mathcal{A}\bullet\xrightarrow{\diamond}\mathcal{B}'$, with $\mathcal{B}'$ as in Figure 2.

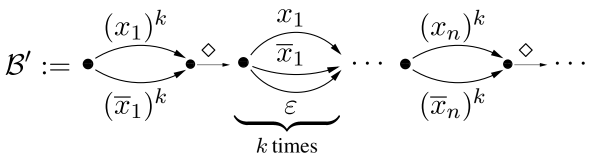

Figure 2: Right part of a CN* constructed from a 3SAT formula $\mathcal{F}$.

With

$$R' := \{(x_1)^k(\overline{x_1})^k \dots (x_n)^k(\overline{x_n})^k(\diamond)^k\}$$

we can again assume that either x_i or $\overline{x_i}$ appears k times in the $\mathcal{B}'$-part of a path a_1^K with $1BLEU(a_1^K, R') = 1.0$, and that for every solution β to $\mathcal{F}$ there is a corresponding path a_1^K through $\mathcal{C}'$ and vice versa. In this construction, we also have exact matches of the counts, so we can also use PER in the decision problem.

While CN* are generally not word graphs by themselves due to the multiple symbols on edges, it is straightforward to create an equivalent word graph from a given CN*, as demonstrated in Figure 3. Consequently, deciding unigram BLEU and unigram PER are NP-complete problems for general word graphs as well.

4 Solving CN-1BLEU-DECIDE in polynomial time

It is not a coincidence that we had to resort to bigrams or to edges with multiple symbols for NP-completeness: It turns out that CN-1BLEU-DECIDE, where the order of the words does not

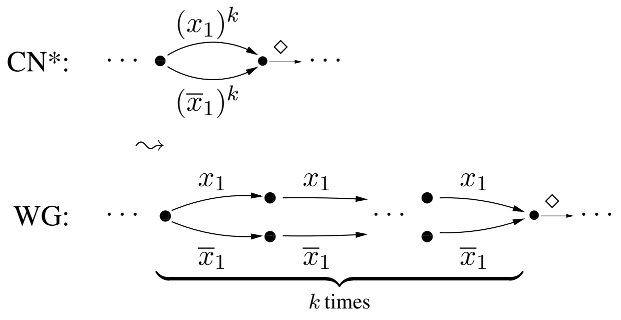

Figure 3: Construction of a word graph from a CN* as in $\mathcal{B}'$.

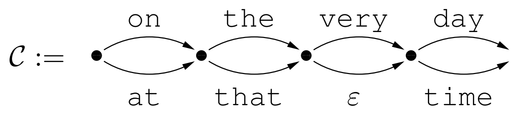
matter at all, can be decided in polynomial time using the following algorithm, which disregards a brevity penalty for the sake of simplicity:

Given a vocabulary X, a CN $\{w_{i,j}\}$, and a set of reference sentences R together with their unigram BLEU counts $c(x) : X \to \mathbb{N}$ and $C := \sum_{x \in X} c(x)$,

1. Remove all parts from w where there is an edge labeled with the empty word ε. This step will always increase unigram precision, and can not hurt any higher n-gram precision here, because $n = 1$. In the example in Figure 4, the edges labeled `very` and ε respectively are affected in this step.
2. Create nodes $A_0 := \{1, \dots, n\}$, one for each node with edges in the CN. In the example in Figure 5, the three leftmost column heads correspond to these nodes.
3. Create nodes $B := \{x.j \mid x \in X, 1 \le j \le c(x)\}$. In other words, create a unique node for each "running" word in R – e.g. if the first and second reference sentence contain x once each, and the third reference contains x twice, create exactly $x.1$ and $x.2$. In Figure 5, those are the row heads to the right.
4. Fill A with empty nodes to match the total length: $A := A_0 \cup \{\varepsilon.j \mid 1 \le j \le C - n\}$.
   If $n > C$, the BLEU precision can not be 1.0. The five rightmost columns in Figure 5 correspond to those.
5. Create edges
   $E := \{(i, w_{i,j}.k) \mid 1 \le i \le n, \text{ all } j, 1 \le c(w_{i,j})\}$ $\cup \{(i, \varepsilon.j) \mid 1 \le i \le n, \text{ all } j\}$. These edges are denoted as ○ or ● in Figure 5.



$R := \{$ `on the same day,`
`at the time and the day` $\}$

Figure 4: Example for CN-1BLEU-DECIDE.

○			○	○	●	○	○	`at`
		○	○	○	○	●	○	`time`
			○	○	○	○	●	`and`

Figure 5: Bipartite graph constructed to find the optimal 1BLEU path in Figure 4. One possible maximum bipartite matching is marked with ●.

6. Find the *maximum bipartite matching* M between A and B given E. Figure 5 shows such a matching with ●.
7. If all nodes in A and B are covered by M, then 1BLEU$(\{w_{i,j}\}, R) = 1.0$. The words that are matched to A_0 then form the solution path through $\{w_{i,j}\}$.

Figure 4 gives an example of a CN and a set of references R, for which the best 1BLEU path can be constructed by the algorithm above. The bipartite graph constructed in Step 1 to Step 4 for this example, given in matrix form, can be found in Figure 5.

Such a solution to Step 6, if found, corresponds exactly to a path through the confusion network with 1BLEU=1.0, and vice versa: for each position $1 \le i \le n$, the matched word corresponds to the word that is selected for the position of the path; "surplus" counts are matched with εs.

Step 6 can be performed in polynomial time (Hopcroft and Karp, 1973) $O((C+n)^{5/2})$; all other steps in linear time $O(C+n)$. Consequently, CN-1BLEU can be decided in polynomial time $O((C+n)^{5/2})$. Similarly, an actual optimum 1BLEU score can be calculated in $O((C+n)^{5/2})$.

It should be noted that the only alterations in the hypothesis length, and as a result the only alterations in the brevity penalty, will come from Step 1. Consequently, the brevity penalty can be taken into account as follows: Consider that there are M nodes with an empty edge in $\{w_{i,j}\}$. Instead of removing them in Step 1, keep them in, but for each $1 \leq m \leq M$, run through steps 2 to 6, but add m nodes $\varepsilon.1, \ldots, \varepsilon.m$ to B in Step 3, and add corresponding edges to these nodes to E in Step 5. After each iteration (which leads to a constant hypothesis length), calculate precision and brevity penalty. Select the best product of precision and brevity penalty in the end. The overall time complexity now is in $M \cdot O((C+n)^{5/2})$.

A PER score can be calculated in a similar fashion.

5 Finding approximating solutions for CN-4BLEU in polynomial time

Knowing that the problem of finding the BLEU-best path is an NP-complete problem is an unsatisfactory answer in practice – in many cases, having a good, but not necessarily optimum path is preferable to having no good path at all.

A simple approach would be to walk the CN from the start node to the end node, keeping track of n-grams visited so far, and choosing the word next which maximizes the n-gram precision up to this word. Track is kept by keeping n-gram count vectors for the hypothesis path and the reference sentences, and update those in each step.

The main problem with this approach is that often the local optimum is suboptimal on the global scale, for example if a word occurs on a later position again.

Zens and Ney (2005) on the other hand propose to keep all n-gram count vectors instead, and only recombine path hypotheses with identical count vectors. As they suspect, the search space can become exponentially large.

In this paper, we suggest a compromise between these two extremes, namely keeping active a sufficiently large number of "path hypotheses" in terms of n-gram precision, instead of only the first best, or of all. But even then, edges with empty words pose a problem, as stepping along an empty edge will never decrease the precision of the local path. In certain cases, steps along empty edges may affect the n-gram precision for higher n-grams. But this will only take effect after the next non-empty step, it does not influence the local decision in a node. Stepping along a non-empty edge will often decrease the local precision, though. As a consequence, a simple algorithm will prefer paths with shorter hypotheses, which leads to a suboptimal total BLEU score, because of the brevity penalty. One can counter this problem for example by using a brevity penalty already during the search. But this is problematic as well, because it is difficult to define a proper partial reference length in this case.

The approach we propose is to compare only partial path hypotheses with the same number of empty edges, and ending in the same position in the confusion network. This idea is illustrated in Figure 6: We compare only the partial precision of path hypotheses ending in the same node. Due to the simple nature of this search graph, it can easily be traversed in a left-to-right, top-to-bottom manner. With regard to a node currently being expanded, only the next node in the same row, and the corresponding columns in the next row need to be kept active. When implementing this algorithm, Hypotheses should be compared on the modified BLEUS precision by Lin and Och (2004) because the original BLEU precision equals zero as long as there are no higher n-gram matches in the partial hypotheses, which renders meaningful comparison hard or impossible.

In the rightmost column, all path hypotheses within a node have the same hypothesis length. Consequently, we can select the hypothesis with the best (brevity-penalized) BLEU score by multiplying the appropriate brevity penalty to the precision of the best path ending in each of these nodes. If we always expand all possible path hypotheses within the nodes, and basically run a full search, we will always find the BLEU-best path this way. From the proof above, it follows that the number of path hypothesis we would have to keep can become exponentially large. Fortunately, if a "good" solution is good enough, we do not have to keep all possible path hypotheses, but only the S best ones for a given constant S, or those with a precision not worse than c times the precision of the best hypothesis within the node. Assuming that adding and removing an element to/from a size-limited stack of size S takes time $O(\log S)$, that we allow at most E empty edges in a solution, and that there are j edges in each of the n positions, this algorithm has a time complexity of

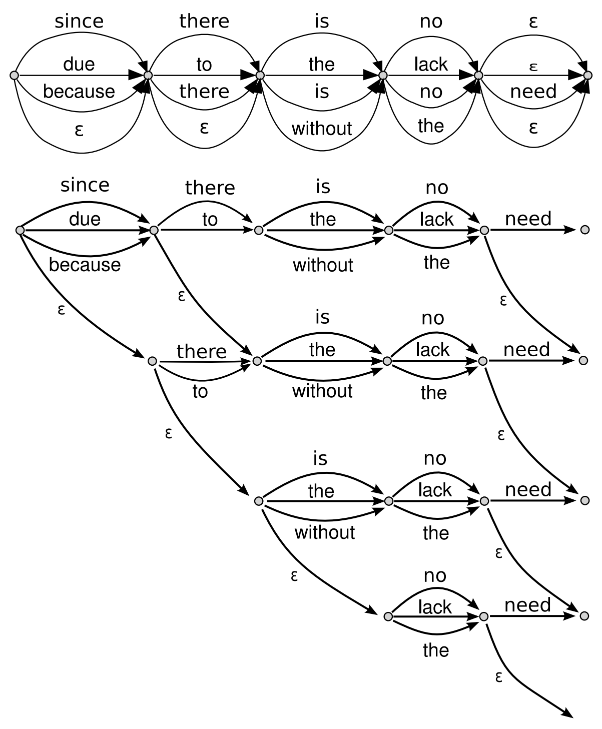

Figure 6: Principle of the multi-stack decoder used to find a path with a good BLEU score. The first row shows the original confusion network, the following rows show the search graph. Duplicate edges were removed, but no word was considered "unknown".

$O(E \cdot n \cdot j \cdot S \log S)$.

To reduce redundant duplicated path hypotheses, and by this to speed up the algorithm and reduce the risk that good path hypotheses are pruned, the confusion network should be *simplified* before the search, as shown in Figure 6:

1. Remove all words in the CN which do not appear in any reference sentence, if there at least one "known" non-empty word at the same position. If there is no such "known" word, replace them all by a single token denoting the "unknown word".

2. Remove all duplicate edges in a position, that is, if there are two or more edges carrying the same label in one position, remove all but one for them.

These two steps will keep at least one of the BLEU-best paths intact. But they can remove the average branching factor (j) of the CN significantly, which leads to a significantly lower number of duplicate path hypotheses during the search.

*average per sentence

Our algorithm can easily be extended to handle arbitrary word graphs instead of confusion networks. In this case, each "row" in Figure 6 will reflect the structure of the word graph instead of the "linear" structure of the CN.

While this algorithm searches for the best path for a single sentence only, a common task is to find the best BLEU score over a whole test set – which can mean suboptimal BLEU scores for individual sentences. This adds an additional combinatorial problem over the sentences to the actual decoding process. Both Zens and Ney (2005) and Dreyer et al (2007) use a greedy approach here; the latter estimated the impact of this to be insignificant in random sampling experiments. In our experiments, we used the per-sentence BLEUS score as (greedy) decision criterion, as this is also the pruning criterion. One possibility to adapt this approach to Zens's/Dreyer's greedy approach for system-level BLEU scores might be to initialize n-gram counts and hypothesis length not to zero at the beginning of each sentence, but to those of the corpus so far. But as this diverts from our goal to optimize the sentence-level scores, we have not implemented it so far.

6 Experimental assessment of the algorithm

The question arises how many path hypotheses we need to retain in each step to obtain optimal paths. To examine this, we created confusion networks out of the translations of the four best MT systems of

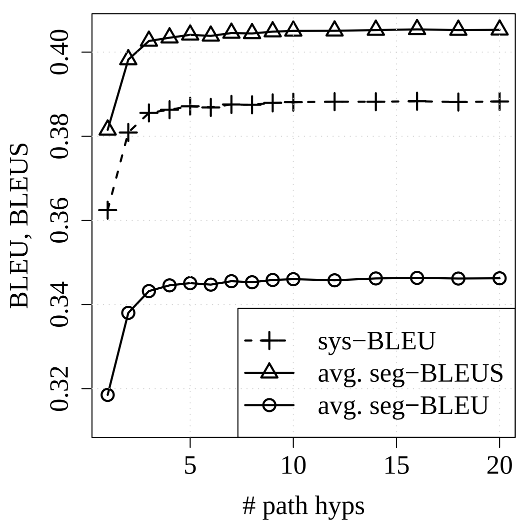

Figure 7: Average of the sentence-wise BLEU and BLEUS score and the system-wide BLEU score versus the number of path hypotheses kept per node during the search. NIST MT03 corpus.

the NIST 2003 and 2006 Chinese–English evaluation campaigns, as available from the Linguistic Data Consortium (LDC). The hypotheses of the best single system served as skeleton, those of the three remaining systems were reordered and aligned to the skeleton hypothesis. This corpus is described in Table 1. Figures 7 and 8 show the measured BLEU scores in three different definitions, versus the maximum number of path hypotheses that are kept in each node of the search graph. Shown are the average sentence-wise BLEUS score, which is what the algorithm actually optimizes, for comparison the average sentence-wise BLEU score, and the total document-wise BLEU score.

All scores increase with increasing number of retained hypotheses, but stabilize around a total of 15 hypotheses per node. The difference over a greedy approach, which corresponds to a maximum of one hypothesis per node if we leave out the separation by path length, is quite significant. No further improvements can be expected for a higher number of hypotheses, as experiments up to 100 hypotheses show.

7 Conclusions

In this paper, we showed that deciding whether a given CN contains a path with a BLEU score of 1.0 is an NP-complete problem for n-gram lengths ≥ 2. The problem is also NP-complete if we only look at unigram BLEU, but allow for CNs where edges may contain multiple symbols, or for arbitrary word graphs. As a corollary, any proposed algorithm to find the path with an optimal BLEU score in a CN, even more in an arbitrary word graph, which runs in worst case polynomial time can only deliver an approximation[1].

We gave an efficient polynomial time algorithm for the simplest variant, namely deciding on a unigram BLEU score for a CN. This algorithm can easily be modified to decide on the PER score as well, or to calculate an actual unigram BLEU score for the hypothesis CN.

Comparing these results, we conclude that the ability to take bi- or higher n-grams into account, be it in the scoring (as in 2BLEU), or in the graph structure (as in CN*), is the key to render the problem NP-hard. Doing so creates long-range dependencies, which oppose local decisions.

We also gave an efficient approximating algorithm for higher-order BLEU scores. This algorithm is based on a multi-stack decoder, taking into account the empty arcs within a path. Experimental results on real-world data show that our method is indeed able to find paths with a significantly better

[1]provided that $P \neq NP$, of course.

BLEU score than that of a greedy search. The resulting BLEUS score stabilizes already on a quite restricted search space, showing that despite the proven NP-hardness of the exact problem, our algorithm can give useful approximations in reasonable time. It is yet an open problem in how far the problems of finding the best paths regarding a sentence-level BLEU score, and regarding a system-level BLEU score correlate. Our experiments here suggest a good correspondence.

Abstract

While phrase-based statistical machine translation systems currently deliver state-of-the-art performance, they remain weak on word order changes. Current phrase reordering models can properly handle swaps between adjacent phrases, but they typically lack the ability to perform the kind of long-distance re-orderings possible with syntax-based systems. In this paper, we present a novel hierarchical phrase reordering model aimed at improving non-local reorderings, which seamlessly integrates with a standard phrase-based system with little loss of computational efficiency. We show that this model can successfully handle the key examples often used to motivate syntax-based systems, such as the rotation of a prepositional phrase around a noun phrase. We contrast our model with reordering models commonly used in phrase-based systems, and show that our approach provides statistically significant BLEU point gains for two language pairs: Chinese-English (+0.53 on MT05 and +0.71 on MT08) and Arabic-English (+0.55 on MT05).

1 Introduction

Statistical phrase-based systems (Och and Ney, 2004; Koehn et al., 2003) have consistently delivered state-of-the-art performance in recent machine translation evaluations, yet these systems remain weak at handling word order changes. The re-ordering models used in the original phrase-based systems penalize phrase displacements proportionally to the amount of nonmonotonicity, with no consideration of the fact that some words are far more likely to be displaced than others (e.g., in English-to-Japanese translation, a verb should typically move to the end of the clause).

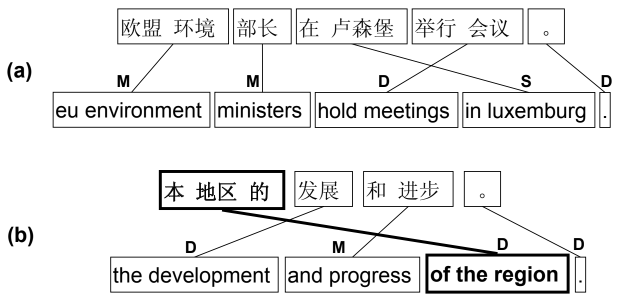

Figure 1: Phase orientations (monotone, swap, discontinuous) for Chinese-to-English translation. While previous work reasonably models phrase reordering in simple examples (a), it fails to capture more complex reorderings, such as the swapping of "of the region" (b).

Recent efforts (Tillman, 2004; Och et al., 2004; Koehn et al., 2007) have directly addressed this issue by introducing lexicalized reordering models into phrase-based systems, which condition reordering probabilities on the words of each phrase pair. These models distinguish three orientations with respect to the previous phrase—monotone (*M*), swap (*S*), and discontinuous (*D*)—and as such are primarily designed to handle *local* re-orderings of neighboring phrases. Fig. 1(a) is an example where such a model effectively swaps the prepositional phrase *in Luxembourg* with a verb phrase, and where the noun *ministers* remains in monotone order with respect to the previous phrase *EU environment*.

While these lexicalized re-ordering models have shown substantial improvements over unlexicalized phrase-based systems, these models only have a limited ability to capture sensible long distance re-orderings, as can be seen in Fig. 1(b). The phrase *of the region* should swap with the rest of the noun phrase, yet these previous approaches are unable to model this movement, and assume the orientation of this phrase is discontinuous (*D*). Observe that, in a shortened version of the same sentence (without *and progress*), the phrase orientation would be different (*S*), even though the shortened version has essentially the same sentence structure. Coming from the other direction, such observations about phrase reordering between different languages are precisely the kinds of facts that parsing approaches to machine translation are designed to handle and do successfully handle (Wu, 1997; Melamed, 2003; Chiang, 2005).

In this paper, we introduce a novel orientation model for phrase-based systems that aims to better capture long distance dependencies, and that presents a solution to the problem illustrated in Fig. 1(b). In this example, our reordering model effectively treats the adjacent phrases *the development* and *and progress* as one single phrase, and the displacement of *of the region* with respect to this phrase can be treated as a swap. To be able identify that adjacent blocks (e.g., *the development* and *and progress*) can be merged into larger blocks, our model infers binary (non-linguistic) trees reminiscent of (Wu, 1997; Chiang, 2005). Crucially, our work distinguishes itself from previous hierarchical models in that it does not rely on any cubic-time parsing algorithms such as CKY (used in, e.g., (Chiang, 2005)) or the Earley algorithm (used in (Watanabe et al., 2006)). Since our reordering model does not attempt to resolve natural language ambiguities, we can effectively rely on (linear-time) shift-reduce parsing, which is done jointly with left-to-right phrase-based beam decoding and thus introduces no asymptotic change in running time. As such, the hierarchical model presented in this paper maintains all the effectiveness and speed advantages of statistical phrase-based systems, while being able to capture some key linguistic phenomena (presented later in this paper) which have motivated the development of parsing-based approaches. We also illustrate this with results that are significantly better than previous approaches, in particular the lexical reordering models of Moses, a widely used phrase-based SMT system (Koehn et al., 2007).

This paper is organized as follows: the training of lexicalized re-ordering models is described in Section 3. In Section 4, we describe how to combine shift-reduce parsing with left-to-right beam search phrase-based decoding with the same asymptotic running time as the original phrase-based decoder. We finally show in Section 6 that our approach yields results that are significantly better than previous approaches for two language pairs and different test sets.

2 Lexicalized Reordering Models

We compare our re-ordering model with related work (Tillman, 2004; Koehn et al., 2007) using a log-linear approach common to many state-of-the-art statistical machine translation systems (Och and Ney, 2004). Given an input sentence **f**, which is to be translated into a target sentence **e**, the decoder searches for the most probable translation $\hat{\mathbf{e}}$ according to the following decision rule:

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}} \left\{ p(\mathbf{e}|\mathbf{f}) \right\} \quad (1)$$

$$= \arg\max_{\mathbf{e}} \left\{ \sum_{j=1}^{J} \lambda_j h_j(\mathbf{f},\mathbf{e}) \right\} \quad (2)$$

$h_j(\mathbf{f},\mathbf{e})$ are J arbitrary feature functions over sentence pairs. These features include lexicalized re-ordering models, which are parameterized as follows: given an input sentence **f**, a sequence of target-language phrases $\mathbf{e} = (\overline{e}_1,\ldots,\overline{e}_n)$ currently hypothesized by the decoder, and a phrase alignment $\mathbf{a} = (a_1,\ldots,a_n)$ that defines a source $\overline{f}_{a_i}$ for each translated phrase $\overline{e}_i$, these models estimate the probability of a sequence of orientations $\mathbf{o} = (o_1,\ldots,o_n)$

$$p(\mathbf{o}|\mathbf{e},\mathbf{f}) = \prod_{i=1}^{n} p(o_i|\overline{e}_i,\overline{f}_{a_i},a_{i-1},a_i), \quad (3)$$

where each o_i takes values over the set of possible orientations $\mathscr{O} = \{M,S,D\}$.[1] The probability is conditioned on both a_{i-1} and a_i to make sure that the label o_i is consistent with the phrase alignment. Specifically, probabilities in these models can be

[1]We note here that the parameterization and terminology in (Tillman, 2004) is slightly different. We purposely ignore these differences in order to enable a direct comparison between Tillman's, Moses', and our approach.

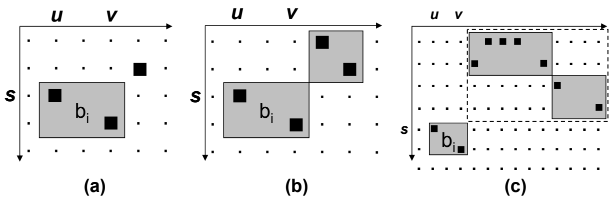

Figure 2: Occurrence of a swap according to the three orientation models: word-based, phrase-based, and hierarchical. Black squares represent word alignments, and gray squares represent blocks identified by phrase-extract. In (a), block $b_i = (e_i, f_{a_i})$ is recognized as a swap according to all three models. In (b), b_i is not recognized as a swap by the word-based model. In (c), b_i is recognized as a swap only by the hierarchical model.

greater than zero only if one of the following conditions is true:

- $o_i = M$ and $a_i - a_{i-1} = 1$
- $o_i = S$ and $a_i - a_{i-1} = -1$
- $o_i = D$ and $|a_i - a_{i-1}| \neq 1$

At decoding time, rather than using the log-probability of Eq. 3 as single feature function, we follow the approach of Moses, which is to assign three distinct parameters $(\lambda_m, \lambda_s, \lambda_d)$ for the three feature functions:

- $f_m = \sum_{i=1}^{n} \log p(o_i = M | \ldots)$
- $f_s = \sum_{i=1}^{n} \log p(o_i = S | \ldots)$
- $f_d = \sum_{i=1}^{n} \log p(o_i = D | \ldots)$.

There are two key differences between this work and previous orientation models (Tillman, 2004; Koehn et al., 2007): (1) the estimation of factors in Eq. 3 from data; (2) the segmentation of **e** and **f** into phrases, which is static in the case of (Tillman, 2004; Koehn et al., 2007), while it is dynamically updated with hierarchical phrases in our case. These differences are described in the two next sections.

3 Training

We present here three approaches for computing $p(o_i|\overline{e}_i, \overline{f}_{a_i}, a_{i-1}, a_i)$ on word-aligned data using relative frequency estimates. We assume here that phrase $\overline{e}_i$ spans the word range $s, \ldots, t$ in the target sentence **e** and that the phrase $\overline{f}_{a_i}$ spans the range

Orientation Model	$o_i = M$	$o_i = S$	$o_i = D$
word-based (Moses)	0.1750	0.0159	0.8092
phrase-based	0.3192	0.0704	0.6104
hierarchical	0.4878	0.1004	0.4116

Table 1: Class distributions of the three orientation models, estimated from 12M words of Chinese-English data using the grow-diag alignment symmetrization heuristic implemented in Moses, which is similar to the 'refined' heuristic of (Och and Ney, 2004).

$u, \ldots, v$ in the source sentence **f**. All phrase pairs in this paper are extracted with the phrase-extract algorithm (Och and Ney, 2004), with maximum length set to 7.

Word-based orientation model: This model analyzes word alignments at positions $(s-1, u-1)$ and $(s-1, v+1)$ in the alignment grid shown in Fig. 2(a). Specifically, orientation is set to $o_i = M$ if $(s-1, u-1)$ contains a word alignment and $(s-1, v+1)$ contains no word alignment. It is set to $o_i = S$ if $(s-1, u-1)$ contains no word alignment and $(s-1, v+1)$ contains a word alignment. In all other cases, it is set to $o_i = D$. This procedure is exactly the same as the one implemented in Moses.[2]

Phrase-based orientation model: The model presented in (Tillman, 2004) is similar to the word-based orientation model presented above, except that it analyzes adjacent phrases rather than specific word alignments to determine orientations. Specifically, orientation is set to $o_i = M$ if an adjacent phrase pair lies at $(s-1, u-1)$ in the alignment grid. It is set to S if an adjacent phrase pair covers $(s-1, v+1)$ (as shown in Fig. 2(b)), and is set to D otherwise.

Hierarchical orientation model: This model analyzes alignments beyond adjacent phrases. Specifically, orientation is set to $o_i = M$ if the phrase-extract algorithm is able to extract a phrase pair at $(s-1, u-1)$ given no constraint on maximum phrase length. Orientation is S if the same is true at $(s-1, v+1)$, and orientation is D otherwise.

Table 1 displays overall class distributions according to the three models. It appears clearly that occurrences of M and S are too sparsely seen in the word-based model, which assigns more than 80% of its

Table 2: Monotone and swap probabilities for specific phrases according to the three models (word, phrase, and hierarchical). To ensure probabilities are representative, we only selected phrase pairs that occur at least 100 times in the training data.

probability mass to D. Conversely, the hierarchical model counts considerably less discontinuous cases, and is the only model that accounts for the fact that real data is predominantly monotone.

Since D is a rather uninformative default category that gives no clue how a particular phrase should be displaced, we will also provide MT evaluation scores (in Section 6) for a set of classes that distinguishes between left and right discontinuity $\{M, S, D_l, D_r\}$, a choice that is admittedly more linguistically motivated.

Table 2 displays orientation probabilities for concrete examples. Each example was put under one of the four categories that linguistically seems the best match, and we provide probabilities for that category according to each model. Note that, while we have so far only discussed left-to-right reordering models, it is also possible to build right-to-left models by substituting a_{i-1} with a_{i+1} in Eq. 3. Examples for right-to-left models appear in the second half of the table. The table strongly suggests that the hierarchical model more accurately determines the orientation of phrases with respect to large contextual blocks. In Examples 1 and 2, the hierarchical model captures the fact that coordinated clauses almost always remain in the same order, and that words should generally be forbidden to move from one side of "and" to the other side, a constraint that is difficult to enforce with the other two reordering models. In Example 4, the first two models completely ignore that "he said" sometimes rotates around its neighbor clause.

4 Decoding

Computing reordering scores during decoding with word-based[3] and phrase-based models (Tillman, 2004) is trivial, since they only make use of local information to determine the orientation of a new incoming block b_i. For a left-to-right ordering model, b_i is scored based on its orientation with respect to b_{i-1}. For instance, if b_i has a swap orientation with respect to the previous phrase in the current translation hypothesis, feature $p(o_i = S|\ldots)$ becomes active.

Computing lexicalized reordering scores with the hierarchical model is more complex, since the model must identify contiguous blocks—monotone or swapping—that can be merged into hierarchical blocks. The employed method is an instance of the well-known shift-reduce parsing algorithm, and relies on a stack (S) of foreign substrings that have already been translated. Each time the decoder adds a new block to the current translation hypothesis, it shifts the source-language indices of the block onto S, then repeatedly tries reducing the top two elements of S if they are contiguous.[4] This parsing algorithm was first applied in computational geometry to identify convex hulls (Graham, 1972), and its running time was shown to be linear in the length of the sequence (a proof is presented in (Huang et al., 2008), which applies the same algorithm to the binarization of SCFG rules).

Figure 3 provides an example of the execution of this algorithm for the translation output shown in Figure 4, which was produced by a decoder incorporating our hierarchical reordering model. The decoder successively pushes source-language spans [1], [2], [3], which are successively merged into [1-3], and all correspond to monotone orientations.

[3]We would like to point out an inconsistency in Moses between training and testing. Despite the fact that Moses estimates a word-based orientation model during training (i.e., it analyzes the orientation of a given phrase with respect to adjacent word alignments), this model is then treated as a phrase-based orientation model during testing (i.e., as a model that orients phrases with respect to other phrases).

[4]It is not needed to store target-language indices onto the stack, since the decoder proceeds left to right, and thus successive blocks are always contiguous with respect to the target language.

Target phrase	Source	Op.	o_i	Stack

issue	[8]	R,R	M	[6-7], [9-12], [1-3]
in the near future	[4-5]	R,R	S	[6-12], [1-3]
.	[13]	R,A	M	[1-12]

Figure 3: The application of the shift-reduce parsing algorithm for identifying hierarchical blocks. This execution corresponds to the decoding example of Figure 4. Operations (Op.) include shift (S), reduce (R), and accept (A). The source and stack columns contain source-language spans, which is the only information needed to determine whether two given blocks are contiguous. o_i is the label predicted by the hierarchical model by comparing the current block to the hierarchical phrase that is at the top of the stack.

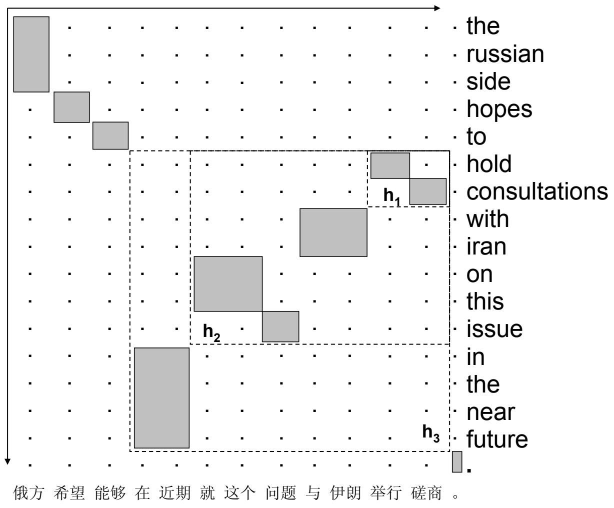

Figure 4: Output of our phrase-based decoder using the hierarchical model on a sentence of MT06. Hierarchical phrases h_1 and h_2 indicate that *with Iran* and *in the near future* have a swap orientation. h_3 indicates that "*to*" and "." are monotone. In this particular example, distortion limit was set to 10.

It then encounters a discontinuity that prevents the next block [11] from being merged with [1-3]. As the decoder reaches the last words of the sentence (*in the near future*), [4-5] is successively merged with [6-12], then [1-3], yielding a stack that contains only [1-12].

A nice property of this parsing algorithm is that it does not worsen the asymptotic running time of beam-search decoders such as Moses (Koehn, 2004a). Such decoders run in time $O(n^2)$, where n is the length of the input sentence. Indeed, each time a partial translation hypothesis is expanded into a longer one, the decoder must perform an $O(n)$ operation in order to copy the coverage set (indicating which foreign words have already been translated) into the new hypothesis. Since this copy operation must be executed $O(n)$ times, the overall time complexity is quadratic. The incorporation of the shift-reduce parser into such a decoder does not worsen overall time complexity: whenever the decoder expands a given partial translation into a longer hypothesis, it simply copies its stack into the newly created hypothesis (similarly to copying the coverage vector, this is an $O(n)$ operation). Hence, the incorporation of the hierarchical models described in the paper into a phrase-based decoder preserves the $O(n^2)$ running time. In practice, we observe based on a set of experiments for Chinese-English and Arabic-English translation that our phrase-based decoder is on average only 1.35 times slower when it is running using hierarchical reordering features and the shift-reduce parser.

We finally note that the decoding algorithm presented in this section can only be applied left-to-right if the decoder itself is operating left-to-right. In order to predict orientations relative to the right-to-left hierarchical reordering model, we must resort to approximations at decoding time. We experimented with different approximations, and the one that worked best (in the experiments discussed in Section 6) is described as follows. First, we note that an analysis of the alignment grid often reveals that certain orientations are impossible. For instance, the block *issue* in Figure 4 can only have discontinuous orientation with respect to what comes next in English, since words surrounding the Chinese phrase have already been translated. When several hierarchical orientations are possible according to the alignment grid, we choose according to the following order of preference: (1) monotone, (2) swap, (3) discontinuous. For instance, in the case of *with iran* in Figure 4, only swap and discontinuous orientations are possible (monotone orientation is impossible because of the block *hold consultations*), hence we give preference to swap. This prediction turns out to be the correct one according to the decoding steps that complete the alignment grid.

5 Discussion

We now analyze the system output of Figure 4 to further motivate the hierarchical model, this time from the perspective of the decoder. We first observe that the prepositional phrase *in the future* should rotate around a relatively large noun phrase headed by *consultations*. Unfortunately, localized reordering models such as (Tillman, 2004) have no means of identifying that such a displacement is a swap (S). According to these models, the orientation of *in the future* with respect to what comes previously is discontinuous (D), which is an uninformative fall-back category. By identifying h_2 (*hold ... issue*) as a hierarchical block, the hierarchical model can properly determine that the block *in the near future* should have a swap orientation.[5] Similar observations can be made regarding blocks h_1 and h_3, which leads our model to predict either monotone orientation (between h_3 and "*to*" and between h_3 and ".") or swap orientation (between h_1 and *with Iran*) while local models would predict discontinuous in all cases.

Another benefit of the hierarchical model is that its representation of phrases remains the same during both training and decoding, which is not the case for word-based and phrase-based reordering models. The deficiency of these local models lies in the fact that blocks handled by phrase-based SMT systems tend to be long at training time and short at test time, which has adverse consequences on non-hierarchical reordering models. For instance, in Figure 4, the phrase-based reordering model categorizes the block *in the near future* as discontinuous, though if the sentence pair had been a training example, this block would count as a swap because of the extracted phrase *on this issue*.

6 Results

In our experiments, we use a re-implementation of the Moses decoder (Koehn et al., 2007). Except for lexical reordering models, all other features are standard features implemented almost exactly as in Moses: four translation features (phrase-based translation probabilities and lexically-weighted probabilities), word penalty, phrase penalty, linear distortion, and language model score. We experiment with two language pairs: Chinese-to-English (C-E) and Arabic-to-English (A-E). For C-E, we trained translation models using a subset of the Chinese-English parallel data released by LDC (mostly news, in particular FBIS and Xinhua News). This subset comprises 12.2M English words, and 11M Chinese words. Chinese words are segmented with a conditional random field (CRF) classifier that conforms to the Chinese Treebank (CTB) standard. The training set for our A-E systems also includes mostly news parallel data released by LDC, and contains 19.5M English words, and 18.7M Arabic tokens that have been segmented using the Arabic Treebank (ATB) (Maamouri et al., 2004) standard.[6]

For our language model, we trained a 5-gram model using the Xinhua and AFP sections of the Gigaword corpus (LDC2007T40), in addition to the target side of the parallel data. For both C-E and A-E, we manually removed documents of Gigaword that were released during periods that overlap with those of our development and test sets. The language model was smoothed with the modified Kneser-Ney algorithm, and we kept only trigrams, 4-grams, and 5-grams that respectively occurred two, three, and three times in the training data.

Parameters were tuned with minimum error-rate training (Och, 2003) on the NIST evaluation set of 2006 (MT06) for both C-E and A-E. Since MERT is prone to search errors, especially with large numbers of parameters, we ran each tuning experiment four times with different initial conditions. This precaution turned out to be particularly important in the case of the combined lexicalized reordering models (the combination of phrase-based and hierarchical discussed later), since MERT must optimize up to 26 parameters at once in these cases.[7] For testing,

[5]Note that the hierarchical phrase *hold ... issue* is not a well-formed syntactic phrase – i.e., it neither matches the bracketing of the verb phrase *hold ... future* nor matches the noun phrase *consultations ... issue* – yet it enables sensible reordering.

[6]Catalog numbers for C-E: LDC2002E18, LDC2003E07, LDC2003E14, LDC2005E83, LDC2005T06, LDC2006E26, and LDC2006E8. For A-E: LDC2007E103, LDC2005E83, LDC2006E24, LDC2006E34, LDC2006E85, LDC2006E92, LDC2007E06, LDC2007E101, LDC2007E46, LDC2007E86, and LDC2008E40.

[7]We combine lexicalized reordering models by simply treating them as distinct features, which incidentally increases the number of model parameters that must be tuned with MERT.

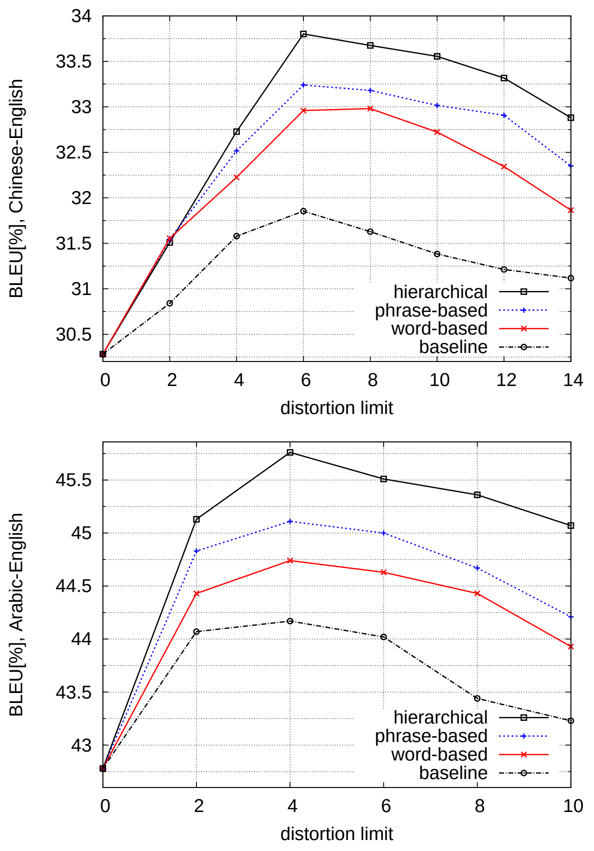

Figure 5: Performance on the Chinese-English and Arabic-English development sets (MT06) with increasing distortion limits for all lexicalized reordering models discussed in the paper. Our novel hierarchical model systematically outperforms all other models for distortion limit equal to or greater than 4. The baseline is Moses with no lexicalized reordering model.

we used the NIST evaluation sets of 2005 and 2008 (MT05 and MT08) for Chinese-English, and the test set of 2005 (MT05) for Arabic-English.

Statistical significance is computed using the approximate randomization test (Noreen, 1989), whose application to MT evaluation (Riezler and Maxwell, 2005) was shown to be less sensitive to type-I errors (i.e., incorrectly concluding that improvement is significant) than the perhaps more widely used bootstrap resampling method (Koehn, 2004b).

Tuning set performance is shown in Figure 5. Since this paper studies various ordering models, it is interesting to first investigate how the distortion limit affects performance.[8] As has been shown in previous work in Chinese-English and Arabic-English translation, limiting phrase displacements to six source-language words is a reasonable choice. For both C-E and A-E, the hierarchical model is significantly better ($p \leq .05$) than either other models for distortion limits equal to or greater than 6 (except for distortion limit 12 in the case of C-E). Since a distortion limit of 6 works reasonably well for both language pairs and is the default in Moses, we used this distortion limit value for all test-set experiments presented in this paper.

LEXICALIZED REORDERING	MT06	MT05	MT08
none	31.85	29.75	25.22
word-based	32.96	31.45	25.86
phrase-based	33.24	31.23	26.01
hierarchical	33.80**	32.20**	26.38
phrase-based + hierarchical	33.86**	32.85**	26.53*

Table 3: BLEU[%] scores (uncased) for Chinese-English and the orientation categories $\{M,S,D\}$. Maximum distortion is set to 6 words, which is the default in Moses. The stars at the bottom of the tables indicate when a given hierarchical model is significantly better than all local models for a given development or test set (*: significance at the .05 level; **: significance at the .01 level).

LEXICALIZED REORDERING	MT06	MT05	MT08
phrase-based	33.79	32.32	26.32
hierarchical	34.01	32.35	26.58
phrase-based + hierarchical	34.36**	32.33	27.03**

Table 4: BLEU[%] scores (uncased) for Chinese-English and the orientation categories $\{M,S,D_l,D_r\}$. Since the distinction between these four categories is not available in Moses, hence we have no baseline results for this case. Maximum distortion is set to 6 words.

Our main results for Chinese-English are shown in Table 3. It appears that hierarchical models provide significant gains over all non-hierarchical models. Improvements on MT06 and MT05 are very significant ($p \leq .01$). In the case of MT08, significant improvement is reached through the combination of both phrase-based and hierarchical models. We often observe substantial gains when we combine such models, presumably because we get the benefit of identifying both local and long-distance swaps.

Since most orientations in the phrase-based model are discontinuous, it is reasonable to ask whether

[8]Note that we ran MERT separately for each distinct distortion limit.

LEXICALIZED REORDERING	MT06	MT05
none	44.03	54.87
word-based	44.64	54.96
phrase-based	45.01	55.09
hierarchical	45.51*	55.50*
phrase-based + hierarchical	45.64**	56.01**

Table 5: BLEU[%] scores (uncased) for Arabic-English and the reordering categories $\{M,S,D\}$.

LEXICALIZED REORDERING	MT06	MT05
phrase-based	44.74	55.52
hierarchical	45.53**	56.02**
phrase-based + hierarchical	45.63**	56.07**

Table 6: BLEU[%] scores (uncased) for Arabic-English and the reordering categories $\{M,S,D_l,D_r\}$.

the relatively poor performance of the phrase-based model is the consequence of an inadequate set of orientation labels. To try to answer this question, we use the set of orientation labels $\{M,S,D_l,D_r\}$ described in Section 3. Results for this different set of orientations are shown in Table 4. While the phrase-based model appears to benefit more from the distinction between left- and right-discontinuous, systems that incorporate hierarchical models remain the most competitive overall: their best performance on MT06, MT05, and MT08 are respectively 34.36, 32.85, and 27.03. The best non-hierarchical models achieve only 33.79, 32.32, and 26.32, respectively. All these differences (i.e., .57, .53, and .71) are statistically significant at the .05 level.

Our results for Arabic-English are shown in Tables 5 and 6. Similarly to C-E, we provide results for two orientation sets: $\{M,S,D\}$ and $\{M,S,D_l,D_r\}$. We note that the four-class orientation set is overall less effective for A-E than for C-E. This is probably due to the fact that there is less probability mass in A-E assigned to the D category, and thus it is less helpful to split the discontinuous category into two.

For both orientation sets, we observe in A-E that the hierarchical model significantly outperforms the local ordering models. Gains provided by the hierarchical model are no less significant than for Chinese-to-English. This positive finding is perhaps a bit surprising, since Arabic-to-English translation generally does not require many word order changes compared to Chinese-to-English translation, and this translation task so far has seldom benefited from hierarchical approaches to MT. In our case, one possible explanation is that Arabic-English translation is benefiting from the fact that orientation predictions of the hierarchical model are consistent across training and testing, which is not the case for the other ordering models discussed in this paper (see Section 4). Overall, hierarchical models are the most effective on the two sets: their best performances on MT06 and MT05 are respectively 45.64 and 56.07. The best non-hierarchical models obtain only 45.01 and 55.52 respectively for the same sets. All these differences (i.e., .63 and .55) are statistically significant at the .05 level.

7 Conclusions and Future Work

In this paper, we presented a lexicalized orientation model that enables phrase movements that are more complex than swaps between adjacent phrases. This model relies on a hierarchical structure that is built as a by-product of left-to-right phrase-based decoding without increase of asymptotic running time. We show that this model provides statistically significant improvements for five NIST evaluation sets and for two language pairs. In future work, we plan to extend the parameterization of our models to not only predict phrase orientation, but also the length of each displacement as in (Al-Onaizan and Papineni, 2006). We believe such an extension would improve translation quality in the case of larger distortion limits. We also plan to experiment with discriminative approaches to estimating reordering probabilities (Zens and Ney, 2006; Xiong et al., 2006), which could also be applied to our work. We think the ability to condition reorderings on any arbitrary feature functions is also very effective in the case of our hierarchical model, since information encoded in the trees would seem beneficial to the orientation prediction task.

Abstract

Traditionally, statistical machine translation systems have relied on parallel bi-lingual data to train a translation model. While bi-lingual parallel data are expensive to generate, monolingual data are relatively common. Yet monolingual data have been under-utilized, having been used primarily for training a language model in the target language. This paper describes a novel method for utilizing monolingual target data to improve the performance of a statistical machine translation system on news stories. The method exploits the existence of comparable text—multiple texts in the target language that discuss the same or similar stories as found in the source language document. For every source document that is to be translated, a large monolingual data set in the target language is searched for documents that might be comparable to the source documents. These documents are then used to adapt the MT system to increase the probability of generating texts that resemble the comparable document. Experimental results obtained by adapting both the language and translation models show substantial gains over the baseline system.

1 Introduction

While the amount of parallel data available to train a statistical machine translation system is sharply limited, vast amounts of monolingual data are generally available, especially when translating to languages such as English. Yet monolingual data are generally only used to train the language model of the translation system. Previous work (Fung and Yee, 1998; Rapp, 1999) has sought to learn new translations for words by looking at comparable, but not parallel, corpora in multiple languages and analyzing the co-occurrence of words, resulting in the generation of new word-to-word translations.

More recently, Resnik and Smith (2003) and Munteanu and Marcu (2005) have exploited monolingual data in both the source and target languages to find document or sentence pairs that appear to be parallel. This newly discovered bilingual data can then be used as additional training data for the translation system. Such methods generally have a very low yield leaving vast amounts of data that is only used for language modeling.

These methods rely upon comparable corpora, that is, multiple corpora that are of the same general genre. In addition to this, documents can be comparable—two documents that are both on the same event or topic. Comparable documents occur because of the repetition of information across languages, and in the case of news data, on the fact that stories reported in one language are often reported in another language. In cases where no direct translation can be found for a source document, it is often possible to find documents in the target language that are on the same story, or even on a related story, either in subject matter or historically. Such documents can be classified as comparable to the original source document. Phrases within this comparable document are likely to be translations of phrases in the source document, even if the documents themselves are not parallel.

Figure 1 shows an excerpt of the reference translation of an Arabic document, and figure 2 shows a

Cameras are flashing and reporters are following up, for Hollywood star Angelina Jolie is finally talking to the public after a one-month stay in India, but not as a movie star. The Hollywood actress, goodwill ambassador of the United Nations high commissioner for refugees, met with the Indian minister of state for external affairs, Anand Sharma, here today, Sunday, to discuss issues of refugees and children. **...** Jolie, accompanied by her five-year-old son, Maddox, visited the refugee camps that are run by the Khalsa Diwan Society for social services and the high commissioner for refugees Saturday afternoon after she arrived in Delhi. Jolie has been in India since October 5th shooting the movie "A Mighty Heart," which is based on the life of Wall Street Journal correspondent Daniel Pearl, who was kidnapped and killed in Pakistan. Jolie plays the role of Pearl's wife, Mariane.

Figure 1: Excerpt of Example Reference Translation of an Arabic Source Document

Actress Angelina Jolie hopped onto a crowded Mumbai commuter train Monday to film a scene for a movie about slain journalist Daniel Pearl, who lived and worked in India's financial and entertainment capital. Hollywood actor Dan Futterman portrays Pearl and Jolie plays his wife Mariane in the "A Mighty Heart" co-produced by Plan B, a production company founded by Brad Pitt and his ex-wife, actress Jennifer Aniston. Jolie and Pitt, accompanied by their three children – Maddox, 5, 18-month-old Zahara and 5-month-old Shiloh Nouvel – arrived in Mumbai on Saturday from the western Indian city Pune where they were shooting the movie for nearly a month. **...**

Figure 2: Excerpt of Example Comparable Document

comparable passage.[1] In this case, the two new stories are not translations of each other and were not reported at the same time—the comparable passage being an older news story—but both discuss actress Angelina Jolie's visit to India. Many phrases and words are shared between the two, including: the name of the movie, the name and relationship of the actress' character, the name and age of her son and many others. Such a pairing is extremely comparable, although even less related document pairs could easily be considered comparable.

We seek to take advantage of these comparable documents to inform the translation of the source document. This can be done by augmenting the major components of the statistical translation system: the Language Model and the Translation Model. This work is in the same tradition as Kim and Khudanpur (2003), Zhao et al. (2004), and Kim (2005). Kim (2005) used large amounts of comparable data to adapt language models on a document-by-document basis, while Zhao et al. (2004) used comparable data to perform sentence level adaptation of the language model. These adapted language models were shown to improve performance for both automatic speech recognition as well as machine translation.

In addition to language model adaptation we also modify the translation model, adding additional translation rules that enable the translation of new words and phrases in both the source and target languages, as well as increasing the probability of existing translation rules. Translation adaptation using the translation system's own output, known as Self-Training (Ueffing, 2006) has previously shown gains by augmenting the translation model with additional translation rules. In that approach however, the translation model was augmented using parallel data, rather than comparable data, by interpolating a translation model trained using the system output with the original translation model.

Translation model adaptation using comparable out-of-domain parallel data, rather than monolingual data was shown by Hildebrand et al. (2005) to yield significant gains over a baseline system. The translation model was adapted by selecting comparable sentences from parallel corpora for each of the sentences to be translated. In addition to selecting out-of-domain data to adapt the translation model, comparable data selection techniques have been used to select and weight portions of the existing training data for the translation model to improve translation performance (Lu et al., 2007).

The research presented in this paper utilizes a different approach to translation model adaptation using comparable monolingual text rather than parallel text, exploiting data that would otherwise be unused

[1]This is an actual source document from the tuning set used in our experiments, and the first of a number of similar passages found by the comparable text selection system described in section 2.

for estimating the translation model. In addition, this data also informs the translation system by interpolating the original language model with a new language model trained from the same comparable documents.

We discuss the selection of comparable text for model adaptation in section 2. In sections 3.1 and 3.2, we describe the model adaptation for the language model and translation model, respectively. Experimental results describing the application of model adaptation to a hierarchical Arabic-to-English MT system are presented in section 4. Finally we draw conclusions in sections 5.

2 Comparable Text Selection

Comparable text is selected for every source document from a large monolingual corpus in the target language. In practice, one could search the World Wide Web for documents that are comparable to a set of source documents, but this approach presents problems for ensuring the quality of the retrieved documents. The experiments in this paper use comparable text selected from a collection of English news texts. Because these texts are all fluent English, and of comparable genre to the test set, they are also used for training the standard language model training.

The problem of selecting comparable text has been widely studied in the information retrieval community and cross-lingual information retrieval (CLIR) (Oard and Dorr, 1998; Levow et al., 2005) has been largely successful at the task of selecting comparable or relevant documents in one language given a query in another language. We use CLIR to select a ranked list of documents in our target language, English in the experiments described in this paper, for each source document, designated as the query in the CLIR framework, that we wish to translate.

The CLIR problem can be framed probabilistically as: Given a query Q, find a document D that maximizes the equation $\Pr(D \text{ is rel}|Q)$. This equation can be expanded using Bayes' Law as shown in equation 1. The prior probability of a document being relevant can be viewed as uniform, and thus in this work, we assume $\Pr(D \text{ is rel})$ is a constant.[2]

[2]In fact, it can be beneficial to use features of the document to estimate $\Pr(D \text{ is rel})$ (Miller and Schwartz, 1998) but we have not explored that here.

The $\Pr(Q)$ is constant across all documents. Therefore finding a document to maximize $\Pr(D \text{ is rel}|Q)$ is equivalent to finding a document that maximizes $\Pr(Q|D \text{ is rel})$.

$$\Pr(D \text{ is rel}|Q) = \frac{\Pr(D \text{ is rel}) \Pr(Q|D \text{ is rel})}{\Pr(Q)} \tag{1}$$

A method of calculating the probability of a query given a document was proposed by (Xu et al., 2001)[3] and is shown in Equation 2. In this formulation, each foreign word, f, in the query is generated from the foreign vocabulary with probability α and from the English document with probability $1 - \alpha$, where α is a constant.[4] The probability of f being generated by the general foreign vocabulary, F, is $\Pr(f|F) = \mathit{freq}(f, F)/|F|$, the frequency of the word f in the vocabulary divided by the size of the vocabulary. The probability of the word being generated by the English document is the sum of the probabilities of it being generated by each English word, e, in the document which is the frequency of the English word in the document, ($\Pr(e|D) = \mathit{freq}(e, D)/|D|$) multiplied by the probability of the translation of the English word to the foreign word, $\Pr(f|e)$.

$$\Pr(Q|D) = \prod_{f \in Q} (\alpha \Pr(f|F) + (1 - \alpha) \sum_e \Pr(e|D) \Pr(f|e)) \tag{2}$$

This formulation favors longer English documents over shorter English documents. In addition, many documents cover multiple stories and topics. For the purposes of adaptation, shorter, fully comparable documents are preferred to longer, only partially comparable documents. We modify the CLIR system by taking the 1000 highest ranked target language documents found by the CLIR system for each source document, and dividing them into overlapping passages of approximately 300 words.[5] Sen-

[3]Xu et al. (2001) formulated this for the selection of foreign documents given an English query. We reverse this to select English documents given a foreign query.

[4]As in Xu et al. (2001), a value of 0.3 was used for α.

[5]The length of 300 was chosen as this was approximately the same length as the source documents.

tence boundaries are preserved when creating passages, insuring that the text is fluent within each passage. These passages are then scored again by the CLIR system, resulting in a list of passages of about 300 words each for each source document. Finally, we select the top N passages to be used for adaptation.

The N passages selected by this method are not guaranteed to be comparable and are often largely unrelated to the story or topic in the source document. We shall refer to the set of passages selected by the CLIR system as the *bias text* to differentiate it from comparable text, as the adaptation methods will use this text to *bias* the MT system so that its output will be more similar to the bias text.

While we have not conducted experiments using other CLIR systems, the adaptation methods presented in this paper could be applied without modification using another CLIR system, as the adaptation method treats the CLIR system as a black box. With the exception of running a second pass of CLIR, we use the algorithm of Xu et al. (2001) without any significant modification, including the use of a stop word list for both the English and foreign texts. The parameters for $\Pr(f|F)$ and $\Pr(f|e)$ were estimated using the same parallel data that our translation system was trained on.

The bias text selected for a source document is used to adapt the language model (described in section 3.1) and the translation model (described in section 3.2) when translating that source document.

3 Model Adaptation

We use the same bias text to adapt both the language model and the translation model. For language model adaptation, we increase the probability of the word sequences in the bias text, and for translation model adaptation we use additional phrasal translation rules. The adaptations can be done independently and while they can augment each other when used together, this is not required. It is not necessary to use the same number of passages for both forms of adaptation, although doing so makes it more likely both that the English side of the new translation rule will be assigned a high probability by the adapted language model, and that the translation model produces the English text to which the language model has been adapted. Bias text that is used by one adaptation but not the other will receive no special treatment by the other model. This could result in new translation rules that produce text to which the language assigns low probability, or it could result in the language model being able to assign a high probability to a good English translation that cannot be produced by the translation model due to a lack of necessary translation rules.

While both adaptation methods are integrated into a hierarchical translation model (Chiang, 2005), they are largely implementation independent. Language model adaptation could be integrated into any statistical machine translation that uses a language model over words, while translation model adaptation could be added to any statistical machine translation that can utilize phrasal translation rules.

3.1 Language Model Adaptation

For every source document, we estimate a new language model, the *bias language model*, from the corresponding bias text. Since this bias text is short, the corresponding bias language model is small and specific, giving high probabilities to those phrases that occur in the bias text. The bias language model is interpolated with the *generic language model* that would otherwise be used for translation if no LM adaptation was used. The new bias language model is of the same order as the generic language model, so that if a trigram language model is used for the MT decoding, then the biased language model will also be a trigram language model. The bias language model is created using the same settings as the generic language model. In our particular implementation however, the generic language model uses Kneser-Ney smoothing, while the biased language model uses Witten-Bell smoothing due to implementation limitations. In principle the biased language model can be smoothed in the same manner as the generic language model.

We interpolate the bias language model and the generic language model as shown in equation 3, where $\Pr_g$ and $\Pr_b$ are the probabilities from the generic language model and the bias language model, respectively. A constant interpolation weight, λ is used to weight the two probabilities for all documents. While a value for λ could be chosen that minimizes perplexity on a tuning set, in a similar fashion to Kim (2005), it is unclear that such a weight would be ideal when the interpolated language model is used as part of a statistical translation system. In practice we have observed that weights other than one that minimizes perplexity, typically a lower weight, can yield better translation results on the tuning set.

$$\Pr(e) = (1 - \lambda) \Pr_g(e) + \lambda \Pr_b(e) \tag{3}$$

The resulting interpolated language model is then used in place of the generic language model in the translation process, increasing the probability that the translation output will resemble the bias text. It is important to note that, unlike the translation model adaptation described in section 3.2, no new information is added to the system with language model adaptation. Because the bias text is extracted from the same monolingual corpus that the generic language model was estimated from, all of the word sequences used for training the bias language model were also used for training the generic language model. Language model adaptation only increases the weight of the portion of the language model data that was selected as comparable.

3.2 Translation Model Adaptation

It is frequently the case in machine translation that unknown words or phrases are present in the source document, or that the known translations of source words are based on a very small number of occurrences in the training data. In other cases, translations may be known for individual words in the source document, but not for longer phrases. Translation model adaptation seeks to generate new phrasal translation rules for these source words and phrases. The bias text for a source document may, if comparable, contain a number of English words and phrases that are the English side of these desired rules.

Because the source data and the bias text are not translations of each other and are not sentence aligned, conventional alignment tools, such as GIZA++ (Och and Ney, 2000), cannot be used to align the source and bias text. Because the passages in the bias text are not translations of the source document, it will always be the case that portions of the source document have no translation in the bias text, and portions of the bias text have no translation in the source document. In addition a phrase in one of these texts might have multiple, differing translations in the other text.

Unlike language model adaptation, the entirety of the bias text is not used for translation adaptation. We extract those phrases that occur in at least M of the passages in the bias texts. A phrase is only counted once for every passage in which it occurs, so that repeated use of a phrase within a passage does not affect whether it used to generate new rules. Typically, passages selected by the CLIR tend to be very similar to each other if they are comparable to the source document and are very different from each other if they are not comparable to the source document. Phrases that are identical across passages are the ones that are most likely to be comparable, whereas a phrase or word that occurs in only one passage is likely to be present only by chance or if the passage it is in is not comparable. Filtering the target phrases to those that occur in multiple passages therefore serves not only to reduce the total number of rules, but also to filter out phrases from passages that are not comparable.

For each phrase in the source document we generate a new translation to each of the phrases selected from the bias text, and assign it a low uniform probability.[6] For each translation rule we also have a lexical translation probability that we estimate correctly from the trained word model. These new rules are then added to the phrase table of the existing translation model when translating the source document. Rather than adding probability to the existing generic rules, the new rules are marked as bias rules by the system and given their own feature weight. While the vast majority of these rules are incorrect translations, these incorrect rules will be naturally biased against by the translation system. If the source side of a translation already has a number of observed translations, then the low probability of the new bias rule will cause it to not be selected by the translation system. If the new translation rules would produce garbled English, then it will be biased against by the language model. When this is combined with the language model adapta-

[6]A probability of 1/700 is arbitrarily used for the bias rules although it is then weighted by the bias translation rule weight.

tion, a natural pressure is exerted to use the bias rules for source phrases primarily when it would cause the output to look more like the bias text.

4 Experimental Results

We evaluated the performance of language and translation model adaptation with our translation system on two conditions, the details of which are presented in section 4.1. One condition involved a small amount of parallel training, such as one might find when translating a less commonly taught language (LCTL). The other condition involved the full amount of training available for Arabic-to-English translation. In the case of LCTLs we expect our translation model to have the most deficiencies and be most in need of additional translation rules. So, it is under such a condition we would expect the translation model adaptation to be the most beneficial. We evaluate the system's performance under this condition in section 4.2. The effectiveness of this technique on state-of-the-art systems, and its efficiency when used with a well trained generic translation model is presented in section 4.3.

4.1 Implementation Details

Both language-model and translation-model adaptation are implemented on top of a hierarchical Arabic-to-English translation system with string-to-dependency rules as described in Shen et al. (2008). While generalized rules are generated from the parallel data, rules generated by the translation model adaptation are not generalized and are used only as phrasal rules. A trigram language model was used during decoding, and a 5-gram language model was used to re-score the n-best list after decoding. In addition to the features described in Shen et al. (2008), a new feature is added to the model for the bias rule weight, allowing the translation system to effectively tune the probability of the rules added by translation model adaptation in order to improve performance on the tuning set.

Bias texts were selected from three monolingual corpora: the English Gigaword corpus (2,793,350,201 words), the FBIS corpus (28,465,936 words), and a collection of news archive data collected from the websites of various online, public news sites (828,435,409 words). All three corpora were also part of the generic language model training data. Language model adaptation on both the trigram and 5-gram language models used 10 comparable passages with an interpolation weight of 0.1. Translation model adaptation used 10 comparable passages for the bias text and a value of 2 for M.

Each selected passage contains approximately 300 words, so in the case where 10 comparable passages are used to create a bias text, the resulting text will be 3000 words long on average. The language models created using these bias texts are very specific giving large probability to n-gram sequences seen in those texts.

The construction of the bias texts increases the overall run-time of the translation system, although in practice this is a small expenditure. The most intensive portion is the initial indexing of the monolingual corpus, but this is only required once and can be reused for any subsequent test set that is evaluated. This index can then be quickly searched for comparable passages. When considering research environments, test sets are used repeatedly and bias texts only need to be built once per set, making the building cost negligible. Otherwise, the time required to build the bias text is still small compared to the actual translation time.

All conditions were optimized using BLEU (Papineni et al., 2002) and evaluated using both BLEU and Translation Edit Rate (TER) (Snover et al., 2006). BLEU is an accuracy measure, so higher values indicate better performance, while TER is an error metric, so lower values indicate better performance. Optimization was performed on a tuning set of newswire data, comprised of portions of MTEval 2004, MTEval 2005, and GALE 2007 newswire development data, a total of 48921 words of English in 1385 segments and 173 documents. Results were measured on the NIST MTEval 2006 Arabic Evaluation set, which was 55578 words of English in 1797 segments and 104 documents. Four reference translations were used for scoring each translation.

Parameter optimization method was done using n-best optimization, although the adaptation process is not tied to this method. The MT decoder is run on the tuning set generating an n-best list (where $n = 300$), on which all of the translation features (including bias rule weights) are optimized using

Powell's method. These new weights are then used to decode again, repeating the whole process, using a cumulative n-best list. This continues for several iterations until performance on the tuning set stabilizes. The resulting feature weights are used when decoding the test set. A similar, but simpler, method is used to determine the feature weights after 5-gram rescoring. This n-best optimization method has subtle implications for translation model adaptation. In the first iteration, few bias rules are used in decoding the 300-best, and those that are used frequently help, although the overall gain is small due to the small number of bias rules used. This causes the optimizer to greatly increase the weight of the bias rules, causing the decoder to overuse the bias rules in the next iteration causing a sharp decrease in translation quality. Several iterations are needed for the cumulative n-best to achieve sufficient diversity and size to assign a weight for the bias translation rules that results in an increase in performance over the baseline. Alternative optimization methods could likely circumvent this process. Language model adaptation does not suffer from this phenomenon.

4.2 Less Commonly Taught Language Simulation

In order to better examine the nature of translation model adaptation, we elected to work with a translation model that was trained on only 5 million words of parallel Arabic-English text. Limiting the translation model training in this way simulates the problem of translating less commonly taught languages (LCTL) where less parallel text is available, a situation that is not the case for Arabic. Since the model is trained on less parallel data, it is lacking a large number of translation rules, which is expected to be addressed by the translation model adaptation. By working in an environment with a more deprived baseline translation model, we are giving the translation model adaptation more room to assist.

The experiments described below use a 5 million word Arabic parallel text corpus constructed from the LDC2004T18 and LDC2006E25 corpora. The full monolingual English data were used for the language model and for selection of comparable documents. Unless otherwise specified no language model adaptation was used.

We first establish an upper limit on the gain using translation model adaptation, using the reference data to adapt the translation system. These reference data can be considered to be extremely comparable, better than could ever be hoped to gain by comparable document selection. We first aligned this data using GIZA++ to the source data, simulating the ideal case where we can perfectly determine which source words translate to which comparable words. Because our translation model adaptation system assigns uniform probability to all bias rules, we ignore the correct rule probabilities that we could extract from word alignment and assign uniform probability to all of the bias translation rules. As expected, this gives a large gain over the baseline.

We also examine limiting these new translation rules to those rules whose target side occurs in the top 100 passages selected by CLIR, thus minimizing the adaption to those rules that it theoretically could learn from the bias text. On average, 50% of the rules were removed by this filtering, resulting in a corresponding 50% decrease in the gain over the baseline. The results of these experiments and an unadapted baseline are shown in table 1.

Test Set	TM Adaptation	TER	BLEU
Tune	None	0.4984	0.4080
	Aligned Reference	0.3692	0.5841
	Overlapping Only	0.4179	0.5138
MT06	None	0.5516	0.3468
	Aligned Reference	0.4517	0.5216
	Overlapping Only	0.4899	0.4335

Table 1: LCTL Aligned Reference Adaptation Results

The fair translation model adaptation system, however, does not align source phrases to the correct bias text phrases in such a fashion, and instead aligns all source words to all target words. To investigate the effect of this over production of rules, we again used the reference translations as if they were comparable data, but we ignored the alignments learned by GIZA++, and instead allowed all source phrases to translate to all English phrases in the reference text, with uniform probability. This still shows large gains in translation quality over the baseline, as measured by TER and BLEU. Again, we also examined limiting the text used for translation model adaptation to those phrases that occur in both the reference text and the top 100 comparable passages selected the CLIR system. While this decreased performance, the system still performs significantly better than the baseline, as shown in the following table 2.

Test Set	TM Adaptation	TER	BLEU
Tune	None	0.4984	0.4080
	Unaligned Ref.	0.4492	0.4566
	Overlapping Only	0.4808	0.4313
MT06	None	0.5516	0.3468
	Unaligned Ref.	0.5254	0.3990
	Overlapping Only	0.5390	0.3695

Table 2: LCTL Unaligned Reference Adaptation Results

Applying translation model and language model adaptation fairly, using only bias text from the comparable data selection, yields smaller gains on both the tuning and MT06 sets, as shown in table 3. The combination of language-model and translation-model adaptation exceeds the gains that would be achieved over the baseline by either method separately.

Test Set	Adaptation	TER	BLEU
Tune	None	0.4984	0.4080
	LM	0.4922	0.4140
	TM	0.4916	0.4169
	LM & TM	0.4888	0.4244
MT06	None	0.5516	0.3468
	LM	0.5559	0.3490
	TM	0.5545	0.3478
	LM & TM	0.5509	0.3536

Table 3: LCTL Fair Adaptation Results

4.3 Full Parallel Training Results

While the simulation described in section 4.2 used only 5 million words of parallel training, 230 million words of parallel data from 18.5 million segments were used for training the full Arabic-to-English translation system. This parallel data includes the LDC2007T08 ”ISI Arabic-English Automatically Extracted Parallel Text” corpus (Munteanu and Marcu, 2007), which was created from monolingual corpora in English and Arabic using the algorithm described in Munteanu and Marcu (2005), as the techniques used in that work are separate and independent from the adaptation methods we describe in this paper.[7] Language model adaptation and translation model adaptation were applied both independently and jointly to the translation system, and the results were evaluated against an unadapted baseline, as shown in table 4.

While gains from language model adaptation were substantial on the tuning set, on the MT06 test set they are reduced to a 0.65% gain on BLEU and a negligible improvement in TER. The translation model adaptation performs better with 1.37% improvement in BLEU and a 0.26% improvement in TER. This gain increases to a 2.07% improvement in BLEU and a 0.64% improvement in TER when language adaptation is used in conjunction with the translation model adaptation, showing the importance of using both adaptation methods. While it could be expected that a more heavily trained translation model might not require the benefit of language and translation model adaptation, a more substantial gain over the baseline can be seen when both forms of adaptation are used than in the case with less parallel training—a difference of 2.07% BLEU versus 0.68% BLEU.

Test Set	Adaptation	TER	BLEU
Tune	None	0.4339	0.4661
	LM	0.4227	0.4857
	TM	0.4351	0.4657
	LM & TM	0.4245	0.4882
MT06	None	0.5146	0.3852
	LM	0.5140	0.3917
	TM	0.5120	0.3989
	LM & TM	0.5082	0.4059

Table 4: Full Training Adaptation Results

Of the comparable passages selected by the CLIR system for the MT06 test set in the full training experiment, 16.3% were selected from the News

[7]The two methods are not directly comparable, and so we do not make any attempt to do so. Munteanu and Marcu (2005) creates new parallel corpora from two monolingual corpora. This new parallel data is generally applicable for training a translation model but does not target any particular test set. Our adaptation method does not generate new parallel data, but creates a new specific translation model for a test document that is being translated.

Archive corpus, 81.2% were selected from the English GigaWord corpus and 2.5% were selected from the FBIS corpus. A slightly different distribution was found for the Tuning set, where 17.8% of the passages were selected from the News Archive corpus, 77.1% were selected from the English GigaWord corpus, and 5.1% were selected from the FBIS corpus.

5 Discussion

The reuse of a monolingual corpus that was already used by a translation system for language model training to perform both language and translation model adaptation shows large gains over an unadapted baseline. By leveraging off of a CLIR system, which itself contains no information not already given to the translation system,[8] potentially comparable passages can be found which allow improved translation. Surprisingly, these gains are largest when the baseline model is better trained, indicating that a strong reliance of the adaptation on the existing models.

One explantation for these counter-intuitive results–larger gains in the full training scenario versus the LCTL scenario–is that the lexical probabilities are better estimated in the former case. The bias rules all have equal translation probability and only vary in probability according to the lexical probability of the rules. Better estimates of these lexical probabilities may enable the translation system to more clearly distinguish between helpful and harmful bias rules.

There are many clear directions for the improvement of these methods. The current adaptation method does not utilize the probabilities from the CLIR system and treats the top-ranked passages all as equally comparable regardless of the probability assigned. Variable weighting of passages could prove beneficial to both language model adaptation, where the passages could be weighted proportionally to the probability of the passage being relevant, and translation model adaptation, where the requirement on repetition of phrases across passages could be weighted, as could the probability of the new rules produced by the translation system. In addition, the CLIR score, among other possible features such as phrase overlap, could be used to determine those documents where no comparable passage could be detected and where it would be beneficial to not adapt the models.

[8]The probabilistic parameters of the CLIR system are estimated from the same parallel corpora that is used to train the generic translation model.

A clear limitation of using comparable documents to adapt the language and translation model is that comparable documents must be found. For many source documents, none of the top passages found by the CLIR system were comparable. We suspect that while this will always occur to some extent, this becomes more common as the monolingual data becomes less like the source data, such as when there is a large time gap between the two. The full extent of this and the effect of the level of document comparability on translation remains an open question. In addition, while newswire is an excellent source of comparable text, it is unclear how well this method can be used on newsgroups or spoken data, where the fluency of the source text is diminished. When translating news stories, this technique is not limited to major news events. While many of the events discussed in the source data receive world-wide attention, many are local events that are unreported in the English comparable data used in our experiments. Events of a similar nature or events involving many of the same people often do occur in the English comparable data, allowing improvement even when the stories are quite different.

The adaptation methods described in this paper are not limited to a particular framework of statistical machine translation, but have applicability to any statistical machine translation system that uses a language model or translation rules.

Sparse Multi-Scale Grammars for Discriminative Latent Variable Parsing

Slav Petrov and **Dan Klein**

Abstract

We present a discriminative, latent variable approach to syntactic parsing in which rules exist at multiple scales of refinement. The model is formally a latent variable CRF grammar over trees, learned by iteratively splitting grammar productions (not categories). Different regions of the grammar are refined to different degrees, yielding grammars which are three orders of magnitude smaller than the single-scale baseline and 20 times smaller than the split-and-merge grammars of Petrov et al. (2006). In addition, our discriminative approach integrally admits features beyond local tree configurations. We present a multi-scale training method along with an efficient CKY-style dynamic program. On a variety of domains and languages, this method produces the best published parsing accuracies with the smallest reported grammars.

1 Introduction

In latent variable approaches to parsing (Matsuzaki et al., 2005; Petrov et al., 2006), one models an observed treebank of coarse *parse* trees using a grammar over more refined, but unobserved, *derivation* trees. The parse trees represent the desired output of the system, while the derivation trees represent the typically much more complex underlying syntactic processes. In recent years, latent variable methods have been shown to produce grammars which are as good as, or even better than, earlier parsing work (Collins, 1999; Charniak, 2000). In particular, in Petrov et al. (2006) we exhibited a very accurate category-splitting approach, in which a coarse initial grammar is refined by iteratively splitting each grammar category into two subcategories using the EM algorithm. Of course, each time the number of grammar categories is doubled, the number of binary productions is increased by a factor of eight. As a result, while our final grammars used few categories, the number of total active (non-zero) productions was still substantial (see Section 7). In addition, it is reasonable to assume that some generatively learned splits have little discriminative utility. In this paper, we present a discriminative approach which addresses both of these limitations.

We introduce *multi-scale* grammars, in which some productions reference fine categories, while others reference coarse categories (see Figure 2). We use the general framework of *hidden variable CRFs* (Lafferty et al., 2001; Koo and Collins, 2005), where gradient-based optimization maximizes the likelihood of the observed variables, here parse trees, summing over log-linearly scored derivations. With multi-scale grammars, it is natural to refine *productions* rather than categories. As a result, a category such as NP can be complex in some regions of the grammar while remaining simpler in other regions. Additionally, we exploit the flexibility of the discriminative framework both to improve the treatment of unknown words as well as to include *span features* (Taskar et al., 2004), giving the benefit of some input features integrally in our dynamic program. Our multi-scale grammars are 3 orders of magnitude smaller than the fully-split baseline grammar and 20 times smaller than the generative split-and-merge grammars of Petrov et al. (2006).

In addition, we exhibit the best parsing numbers on several metrics, for several domains and languages.

Discriminative parsing has been investigated before, such as in Johnson (2001), Clark and Curran (2004), Henderson (2004), Koo and Collins (2005), Turian et al. (2007), Finkel et al. (2008), and, most similarly, in Petrov and Klein (2008). However, in all of these cases, the final parsing performance fell short of the best generative models by several percentage points or only short sentences were used. Only in combination with a generative model was a discriminative component able to produce high parsing accuracies (Charniak and Johnson, 2005; Huang, 2008). Multi-scale grammars, in contrast, give higher accuracies using smaller grammars than previous work in this direction, outperforming top generative models in grammar size and in parsing accuracy.

2 Latent Variable Parsing

Treebanks are typically not annotated with fully detailed syntactic structure. Rather, they present only a coarse trace of the true underlying processes. As a result, learning a grammar for parsing requires the estimation of a more highly articulated model than the naive CFG embodied by such treebanks. A manual approach might take the category NP and subdivide it into one subcategory NPˆS for subjects and another subcategory NPˆVP for objects (Johnson, 1998; Klein and Manning, 2003). However, rather than devising linguistically motivated features or splits, latent variable parsing takes a fully automated approach, in which each symbol is split into unconstrained subcategories.

2.1 Latent Variable Grammars

Latent variable grammars augment the treebank trees with latent variables at each node. This creates a set of (exponentially many) *derivations* over split categories for each of the original *parse trees* over unsplit categories. For each observed category A we now have a set of latent subcategories A_x. For example, NP might be split into NP$_1$ through NP$_8$.

The parameters of the refined productions $A_x \rightarrow B_y\ C_z$, where A_x is a subcategory of A, B_y of B, and C_z of C, can then be estimated in various ways; past work has included both generative (Matsuzaki et al., 2005; Liang et al., 2007) and discriminative approaches (Petrov and Klein, 2008). We take the discriminative log-linear approach here. Note that the comparison is only between estimation methods, as Smith and Johnson (2007) show that the model classes are the same.

2.2 Log-Linear Latent Variable Grammars

In a log-linear latent variable grammar, each production $r = A_x \rightarrow B_y\ C_z$ is associated with a multiplicative weight ϕ_r (Johnson, 2001; Petrov and Klein, 2008) (sometimes we will use the log-weight θ_r when convenient). The probability of a derivation t of a sentence w is proportional to the product of the weights of its productions r:

$$P(t|w) \propto \prod_{r \in t} \phi_r$$

The score of a parse T is then the sum of the scores of its derivations:

$$P(T|w) = \sum_{t \in T} P(t|w)$$

3 Hierarchical Refinement

Grammar refinement becomes challenging when the number of subcategories is large. If each category is split into k subcategories, each (binary) production will be split into k^3. The resulting memory limitations alone can prevent the practical learning of highly split grammars (Matsuzaki et al., 2005). This issue was partially addressed in Petrov et al. (2006), where categories were repeatedly split and some splits were re-merged if the gains were too small. However, while the grammars are indeed compact at the (sub-)category level, they are still dense at the production level, which we address here.

As in Petrov et al. (2006), we arrange our subcategories into a hierarchy, as shown in Figure 1. In practice, the construction of the hierarchy is tightly coupled to a split-based learning process (see Section 5). We use the naming convention that an original category A becomes A_0 and A_1 in the first round; A_0 then becoming A_{00} and A_{01} in the second round, and so on. We will use $\hat{x} \succ x$ to indicate that the subscript or subcategory x is a refinement of $\hat{x}$.[1] We

[1] Conversely, $\hat{x}$ is a coarser version of x, or, in the language of Petrov and Klein (2007), $\hat{x}$ is a projection of x.

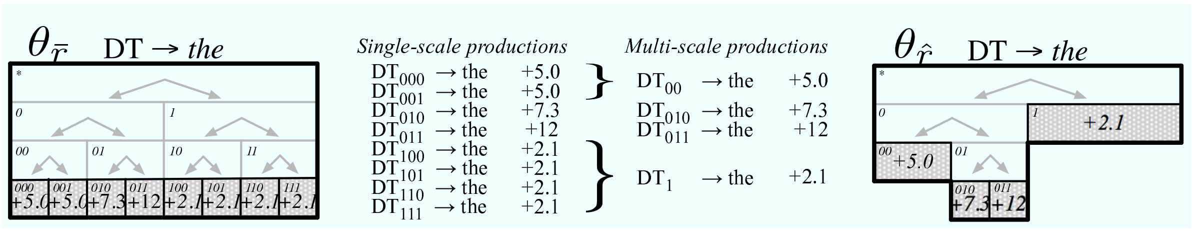

Figure 1: Multi-scale refinement of the $DT \rightarrow the$ production. The multi-scale grammar can be encoded much more compactly than the equally expressive single scale grammar by using only the shaded features along the fringe.

will also say that $\hat{x}$ dominates x, and $\overline{x}$ will refer to fully refined subcategories. The same terminology can be applied to (binary) productions, which split into eight refinements each time the subcategories are split in two.

The core observation leading to multi-scale grammars is that when we look at the refinements of a production, many are very similar in weight. It is therefore advantageous to record productions only at the level where they are distinct from their children in the hierarchy.

4 Multi-Scale Grammars

A multi-scale grammar is a grammar in which some productions reference fine categories, while others reference coarse categories. As an example, consider the multi-scale grammar in Figure 2, where the NP category has been split into two subcategories (NP_0, NP_1) to capture subject and object distinctions. Since *it* can occur in subject and object position, the production NP $\rightarrow$ *it* has remained unsplit. In contrast, in a single-scale grammar, two productions $\mathrm{NP}_0 \rightarrow$ *it* and $\mathrm{NP}_1 \rightarrow$ *it* would have been necessary. We use * as a wildcard, indicating that NP_* can combine with any other NP, while NP_1 can only combine with other NP_1. Whenever subcategories of different granularity are combined, the resulting constituent takes the more specific label.

In terms of its structure, a multi-scale grammar is a set of productions over varyingly refined symbols, where each production is associated with a weight. Consider the refinement of the production shown in Figure 1. The original unsplit production (at top) would naively be split into a tree of many subproductions (downward in the diagram) as the grammar categories are incrementally split. However, it may be that many of the fully refined productions share the same weights. This will be especially common in the present work, where we go out of our way to achieve it (see Section 5). For example, in Figure 1, the productions $\mathrm{DT}_x \rightarrow$ *the* have the same weight for all categories DT_x which refine DT_1.[2] A multi-scale grammar can capture this behavior with just 4 productions, while the single-scale grammar has 8 productions. For binary productions the savings will of course be much higher.

In terms of its semantics, a multi-scale grammar is simply a compact encoding of a fully refined latent variable grammar, in which identically weighted refinements of productions have been collapsed to the coarsest possible scale. Therefore, rather than attempting to control the degree to which categories are split, multi-scale grammars simply encode productions at varying scales. It is hence natural to speak of refining productions, while considering the categories to exist at all degrees of refinement. Multi-scale grammars enable the use of coarse (even unsplit) categories in some regions of the grammar, while requiring very specific subcategories in others, as needed. As we will see in the following, this flexibility results in a tremendous reduction of grammar parameters, as well as improved parsing time, because the vast majority of productions end up only partially split.

Since a multi-scale grammar has productions which can refer to different levels of the category hierarchy, there must be constraints on their coherence. Specifically, for each fully refined production, exactly one of its dominating coarse productions must be in the grammar. More formally, the multi-scale grammar partitions the space of fully refined base rules such that each $\overline{r}$ maps to a unique

[2]We define dominating productions and refining productions analogously as for subcategories.

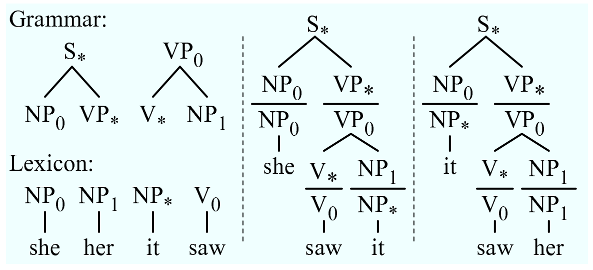

Figure 2: In multi-scale grammars, the categories exist at varying degrees of refinement. The grammar in this example enforces the correct usage of *she* and *her*, while allowing the use of *it* in both subject and object position.

dominating rule $\hat{r}$, and for all base rules $\overline{r}'$ such that $\hat{r} \succ \overline{r}'$, $\overline{r}'$ maps to $\hat{r}$ as well. This constraint is always satisfied if the multi-scale grammar consists of fringes of the production refinement hierarchies, indicated by the shading in Figure 1.

A multi-scale grammar straightforwardly assigns scores to derivations in the corresponding fully refined single scale grammar: simply map each refined derivation rule to its dominating abstraction in the multi-scale grammar and give it the corresponding weight. The fully refined grammar is therefore trivially (though not compactly) reconstructable from its multi-scale encoding.

It is possible to directly define a derivational semantics for multi-scale grammars which does not appeal to the underlying single scale grammar. However, in the present work, we use our multi-scale grammars only to compute expectations of the underlying grammars in an efficient, implicit way.

5 Learning Sparse Multi-Scale Grammars

We now consider how to discriminatively learn multi-scale grammars by iterative splitting productions. There are two main concerns. First, because multi-scale grammars are most effective when many productions share the same weight, sparsity is very desirable. In the present work, we exploit L_1-regularization, though other techniques such as structural zeros (Mohri and Roark, 2006) could also potentially be used. Second, training requires repeated parsing, so we use coarse-to-fine chart caching to greatly accelerate each iteration.

5.1 Hierarchical Training

We learn discriminative multi-scale grammars in an iterative fashion (see Figure 1). As in Petrov et al. (2006), we start with a simple X-bar grammar from an input treebank. The parameters θ of the grammar (production log-weights for now) are estimated in a log-linear framework by maximizing the penalized log conditional likelihood $\mathcal{L}_{cond} - R(\theta)$, where:

$$\begin{aligned} \mathcal{L}_{cond}(\theta) &= \log \prod_i \mathrm{P}(T_i|w_i) \\ R(\theta) &= \sum_r |\theta_r| \end{aligned}$$

We directly optimize this non-convex objective function using a numerical gradient based method (LBFGS (Nocedal and Wright, 1999) in our implementation). To handle the non-diferentiability of the L_1-regularization term $R(\theta)$ we use the orthant-wise method of Andrew and Gao (2007). Fitting the log-linear model involves the following derivatives:

$$\frac{\partial \mathcal{L}_{cond}(\theta)}{\partial \theta_r} = \sum_i \Big(\mathbb{E}_\theta \left[f_r(t) | T_i \right] - \mathbb{E}_\theta [f_r(t) | w_i] \Big)$$

where the first term is the expected count f_r of a production r in derivations corresponding to the correct parse tree T_i and the second term is the expected count of the production in all derivations of the sentence w_i. Note that r may be of any scale. As we will show below, these expectations can be computed exactly using marginals from the chart of the inside/outside algorithm (Lari and Young, 1990).

Once the base grammar has been estimated, all categories are split in two, meaning that all binary productions are split in eight. When splitting an already refined grammar, we only split productions whose log-weight in the previous grammar deviates from zero.[3] This creates a refinement hierarchy over productions. Each newly split production r is given a unique feature, as well as inheriting the features of its parent productions $\hat{r} \succ r$:

$$\phi_r = \exp \Big(\sum_{\hat{r} \succ r} \theta_{\hat{r}} \Big)$$

The parent productions $\hat{r}$ are then removed from the grammar and the new features are fit as described

[3] L_1-regularization drives more than 95% of the feature weights to zero in each round.

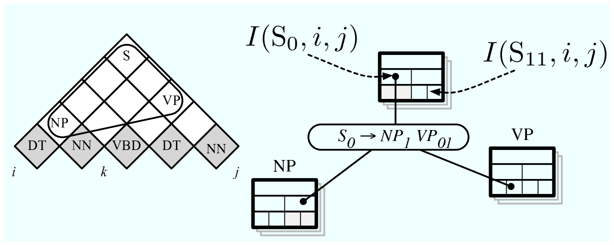

Figure 3: A multi-scale chart can be used to efficiently compute inside/outside scores using productions of varying specificity.

above. We detect that we have split a production too far when all child production features are driven to zero under L_1 regularization. In such cases, the children are collapsed to their parent production, which forms an entry in the multi-scale grammar.

5.2 Efficient Multi-Scale Inference

In order to compute the expected counts needed for training, we need to parse the training set, score all derivations and compute posteriors for all subcategories in the refinement hierarchy. The inside/outside algorithm (Lari and Young, 1990) is an efficient dynamic program for summing over derivations under a context-free grammar. It is fairly straightforward to adapt this algorithm to multi-scale grammars, allowing us to sum over an exponential number of derivations *without* explicitly reconstructing the underlying fully split grammar.

For single-scale latent variable grammars, the inside score $I(A_{\overline{x}}, i, j)$ of a fully refined category $A_{\overline{x}}$ spanning $\langle i, j\rangle$ is computed by summing over all possible productions $\overline{r} = A_{\overline{x}} \rightarrow B_{\overline{y}}\ C_{\overline{z}}$ with weight $\phi_{\overline{r}}$, spanning $\langle i, k\rangle$ and $\langle k, j\rangle$ respectively:[4]

$$I(A_{\overline{x}}, i, j) = \sum_{\overline{r}} \phi_{\overline{r}} \sum_{k} I(B_{\overline{y}}, i, k) I(C_{\overline{z}}, k, j)$$

Note that this involves summing over *all* relevant fully refined grammar productions.

The key quantities we will need are marginals of the form $I(A_x, i, j)$, the sum of the scores of all fully refined derivations rooted at any $A_{\overline{x}}$ dominated by A_x and spanning $\langle i, j\rangle$. We define these marginals in terms of the standard inside scores of the most refined subcategories $A_{\overline{x}}$:

$$I(A_x, i, j) = \sum_{\overline{x} \prec x} I(A_{\overline{x}}, i, j)$$

When working with multi-scale grammars, we expand the standard three-dimensional chart over spans and grammar categories to store the scores of all subcategories of the refinement hierarchy, as illustrated in Figure 3. This allows us to compute the scores more efficiently by summing only over rules $\hat{r} = A_{\hat{x}} \rightarrow B_{\hat{y}}\ C_{\hat{z}} \succ \overline{r}$:

$$\begin{aligned}
I(A_{\overline{x}}, i, j) &= \sum_{\hat{r}} \sum_{\overline{r} \prec \hat{r}} \phi_{\overline{r}} \sum_{k} I(B_{\overline{y}}, i, k) I(C_{\overline{z}}, k, j) \\
&= \sum_{\hat{r}} \phi_{\hat{r}} \sum_{\overline{r} \prec \hat{r}} \sum_{k} I(B_{\overline{y}}, i, k) I(C_{\overline{z}}, k, j) \\
&= \sum_{\hat{r}} \phi_{\hat{r}} \sum_{\overline{y} \prec \hat{y}} \sum_{\overline{z} \prec \hat{z}} \sum_{k} I(B_{\overline{y}}, i, k) I(C_{\overline{z}}, k, j) \\
&= \sum_{\hat{r}} \phi_{\hat{r}} \sum_{k} \sum_{\overline{y} \prec \hat{y}} I(B_{\overline{y}}, i, k) \sum_{\overline{z} \prec \hat{z}} I(C_{\overline{z}}, k, j) \\
&= \sum_{\hat{r}} \phi_{\hat{r}} \sum_{k} I(B_{\hat{y}}, i, k) I(C_{\hat{z}}, k, j)
\end{aligned}$$

Of course, some of the same quantities are computed repeatedly in the above equation and can be cached in order to obtain further efficiency gains. Due to space constraints we omit these details, and also the computation of the outside score, as well as the handling of unary productions.

5.3 Feature Count Approximations

Estimating discriminative grammars is challenging, as it requires repeatedly taking expectations over all parses of all sentences in the training set. To make this computation practical on large data sets, we use the same approach as Petrov and Klein (2008). Therein, the idea of coarse-to-fine parsing (Charniak et al., 1998) is extended to handle the repeated parsing of the same sentences. Rather than computing the entire coarse-to-fine history in every round of training, the pruning history is cached between training iterations, effectively avoiding the repeated calculation of similar quantities and allowing the efficient approximation of feature count expectations.

[4]These scores lack any probabilistic interpretation, but can be normalized to compute the necessary expectations for training (Petrov and Klein, 2008).

6 Additional Features

The discriminative framework gives us a convenient way of incorporating additional, overlapping features. We investigate two types of features: unknown word features (for predicting the part-of-speech tags of unknown or rare words) and span features (for determining constituent boundaries based on individual words and the overall sentence shape).

6.1 Unknown Word Features

Building a parser that can process arbitrary sentences requires the handling of previously unseen words. Typically, a classification of rare words into word classes is used (Collins, 1999). In such an approach, the word classes need to be manually defined *a priori*, for example based on discriminating word shape features (suffixes, prefixes, digits, etc.).

While this component of the parsing system is rarely talked about, its importance should not be underestimated: when using only one unknown word class, final parsing performance drops several percentage points. Some unknown word features are universal (e.g. digits, dashes), but most of them will be highly language dependent (prefixes, suffixes), making additional human expertise necessary for training a parser on a new language. It is therefore beneficial to automatically learn what the discriminating word shape features for a language are. The discriminative framework allows us to do that with ease. In our experiments we extract prefixes and suffixes of length ≤ 3 and add those features to words that occur 25 times or less in the training set. These unknown word features make the latent variable grammar learning process more language independent than in previous work.

6.2 Span Features

There are many features beyond local tree configurations which can enhance parsing discrimination; Charniak and Johnson (2005) presents a varied list. In reranking, one can incorporate any such features, of course, but even in our dynamic programming approach it is possible to include features that decompose along the dynamic program structure, as shown by Taskar et al. (2004). We use non-local *span features*, which condition on properties of input spans (Taskar et al., 2004). We illustrate our span features with the following example and the span $\langle 1, 4 \rangle$:

$$_0 \text{“} \ _1 [\, \textit{Yes} \ _2 \text{”} \ _3 \, , \,] \ _4 \textit{he} \ _5 \textit{said} \ _6 \, . \ _7$$

We first added the following lexical features:

- the first (*Yes*), last (*comma*), preceding (“) and following (*he*) words,
- the word pairs at the left edge $\langle$“,*Yes*$\rangle$, right edge $\langle$*comma,he*$\rangle$, inside border $\langle$*Yes,comma*$\rangle$ and outside border $\langle$“,*he*$\rangle$.

Lexical features were added for each span of length three or more. We used two groups of span features, one for natural constituents and one for synthetic ones.[5] We found this approach to work slightly better than anchoring the span features to particular constituent labels or having only one group.

We also added shape features, projecting the sentence to abstract shapes to capture global sentence structures. Punctuation shape replaces every non-punctuation word with `x` and then further collapses strings of `x` to `x+`. Our example becomes `#‘‘x’’,x+.#`, and the punctuation feature for our span is `‘‘[x’’,]x`. Capitalization shape projects the example sentence to `#.X..xx.#`, and `.[X..]x` for our span. Span features are a rich source of information and our experiments should be seen merely as an initial investigation of their effect in our system.

7 Experiments

We ran experiments on a variety of languages and corpora using the standard training and test splits, as described in Table 1. In each case, we start with a completely unannotated X-bar grammar, obtained from the raw treebank by a simple right-branching binarization scheme. We then train multi-scale grammars of increasing latent complexity as described in Section 5, directly incorporating the additional features from Section 6 into the training procedure. Hierarchical training starting from a raw treebank grammar and proceeding to our most refined grammars took three days in a parallel implementation using 8 CPUs. At testing time we marginalize out the hidden structure and extract the tree with the highest number of expected correct productions, as in Petrov and Klein (2007).

[5]Synthetic constituents are nodes that are introduced during binarization.

Table 1: Corpora and standard experimental setups.

We compare to a baseline of discriminatively trained latent variable grammars (Petrov and Klein, 2008). We also compare our discriminative multi-scale grammars to their generative split-and-merge cousins, which have been shown to produce the state-of-the-art figures in terms of accuracy and efficiency on many corpora. For those comparisons we use the grammars from Petrov and Klein (2007).

7.1 Sparsity

One of the main motivations behind multi-scale grammars was to create compact grammars. Figure 4 shows parsing accuracies vs. grammar sizes. Focusing on the grammar size for now, we see that multi-scale grammars are extremely compact - even our most refined grammars have less than 50,000 active productions. This is 20 times smaller than the generative split-and-merge grammars, which use explicit category merging. The graph also shows that this compactness is due to controlling production sparsity, as the single-scale discriminative grammars are two orders of magnitude larger.

7.2 Accuracy

Figure 4 shows development set results for English. In terms of parsing accuracy, multi-scale grammars significantly outperform discriminatively trained single-scale latent variable grammars and perform on par with the generative split-and-merge grammars. The graph also shows that the unknown word and span features each add about 0.5% in final parsing accuracy. Note that the span features improve the performance of the unsplit baseline grammar by 8%, but not surprisingly their contribution gets smaller when the grammars get more refined. Section 8 contains an analysis of some of the learned features, as well as a comparison between discriminatively and generatively trained grammars.

[6]See Gildea (2001) for the exact setup.

[7]This setup contains only sentences without annotation errors, as in (Arun and Keller, 2005).

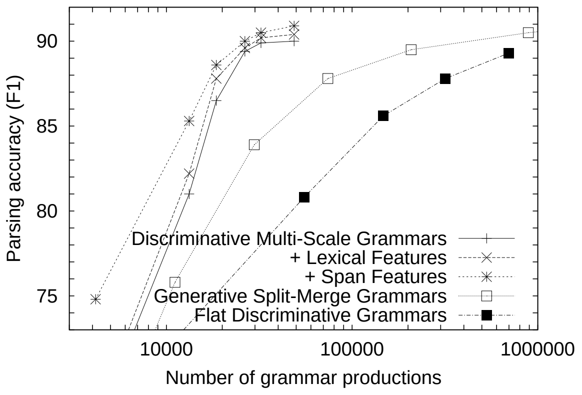

Figure 4: Discriminative multi-scale grammars give similar parsing accuracies as generative split-merge grammars, while using an order of magnitude fewer rules.

7.3 Efficiency

Petrov and Klein (2007) demonstrates how the idea of coarse-to-fine parsing (Charniak et al., 1998; Charniak et al., 2006) can be used in the context of latent variable models. In coarse-to-fine parsing the sentence is rapidly pre-parsed with increasingly refined grammars, pruning away unlikely chart items in each pass. In their work the grammar is projected onto coarser versions, which are then used for pruning. Multi-scale grammars, in contrast, do not require projections. The refinement hierarchy is built in and can be used directly for coarse-to-fine pruning. Each production in the grammar is associated with a set of hierarchical features. To obtain a coarser version of a multi-scale grammar, one therefore simply limits which features in the refinement hierarchy can be accessed. In our experiments, we start by parsing with our coarsest grammar and allow an additional level of refinement at each stage of the pre-parsing. Compared to the generative parser of Petrov and Klein (2007), parsing with multi-scale grammars requires the evaluation of 29% fewer productions, decreasing the average parsing time per sentence by 36% to 0.36 sec/sentence.

Table 2: Our final test set parsing accuracies compared to the best previous work on English, French and German.

7.4 Final Results

For each corpus we selected the grammar that gave the best performance on the development set to parse the final test set. Table 2 summarizes our final test set performance, showing that multi-scale grammars achieve state-of-the-art performance on most tasks. On WSJ-English, the discriminative grammars perform on par with the generative grammars of Petrov et al. (2006), falling slightly short in terms of F1, but having a higher exact match score. When trained on WSJ-English but tested on the Brown corpus, the discriminative grammars clearly outperform the generative grammars, suggesting that the highly regularized and extremely compact multi-scale grammars are less prone to overfitting. All those methods fall short of reranking parsers like Charniak and Johnson (2005) and Huang (2008), which, however, have access to many additional features, that cannot be used in our dynamic program.

When trained on the French and German treebanks, our multi-scale grammars achieve the best figures we are aware of, without any language specific modifications. This confirms that latent variable models are well suited for capturing the syntactic properties of a range of languages, and also shows that discriminative grammars are still effective when trained on smaller corpora.

8 Analysis

It can be illuminating to see the subcategories that are being learned by our discriminative multi-scale grammars and to compare them to generatively estimated latent variable grammars. Compared to the generative case, the lexical categories in the discriminative grammars are substantially less refined. For example, in the generative case, the nominal categories were fully refined, while in the discriminative case, fewer nominal clusters were heavily used. One reason for this can be seen by inspecting the first two-way split in the NNP tag. The generative model split into initial NNPs (*San, Wall*) and final NNPs (*Francisco, Street*). In contrast, the discriminative split was between organizational entities (*Stock, Exchange*) and other entity types (*September, New, York*). This constrast is unsurprising. Generative likelihood is advantaged by explaining lexical choice – *New* and *York* occur in very different slots. However, they convey the same information about the syntactic context above their base NP and are therefore treated the same, discriminatively, while the systematic attachment distinctions between temporals and named entities are more predictive.

Analyzing the syntactic and semantic patterns learned by the grammars shows similar trends. In Table 3 we compare the number of subcategories in the generative split-and-merge grammars to the average number of features per unsplit production with that phrasal category as head in our multi-scale grammars after 5 split (and merge) rounds. These quantities are inherently different: the number of features should be roughly cubic in the number of subcategories. However, we observe that the numbers are very close, indicating that, due to the sparsity of our productions, and the efficient multi-scale encoding, the number of grammar parameters grows linearly in the number of subcategories. Furthermore, while most categories have similar complexity in those two cases, the complexity of the two most refined phrasal categories are flipped. Generative grammars split NPs most highly, discrimina-

	NP	VP	PP	S	SBAR	ADJP	ADVP	QP	PRN
Generative subcategories	32	24	20	12	12	12	8	7	5
Discriminative production parameters	19	32	20	14	14	8	7	9	6

Table 3: Complexity of highly split phrasal categories in generative and discriminative grammars. Note that subcategories are compared to production parameters, indicating that the number of parameters grows cubicly in the number of subcategories for generative grammars, while growing linearly for multi-scale grammars.

Adverbs	-ly	-mal	-ent
Numbers	-ty	-zig	—

Table 4: Automatically learned suffixes with the highest weights for different languages and part-of-speech tags.

tive grammars split the VP. This distinction seems to be because the complexity of VPs is more syntactic (e.g. complex subcategorization), while that of NPs is more lexical (noun choice is generally higher entropy than verb choice).

It is also interesting to examine the automatically learned word class features. Table 4 shows the suffixes with the highest weight for a few different categories across the three languages that we experimented with. The learning algorithm has selected discriminative suffixes that are typical derviational or inflectional morphemes in their respective languages. Note that the highest weighted suffixes will typically not correspond to the most common suffix in the word class, but to the most discriminative.

Finally, the span features also exhibit clear patterns. The highest scoring span features encourage the words between the last two punctuation marks to form a constituent (excluding the punctuation marks), for example `,[x+].` and `:[x+].` Words between quotation marks are also encouraged to form constituents: ``` ``[x+]'' ``` and ``` x[``x+'']x ```. Span features can also discourage grouping words into constituents. The features with the highest negative weight involve single commas: `x[x,x+]`, and `x[x+,x+]x` and so on (indeed, such spans were structurally disallowed by the Collins (1999) parser).

9 Conclusions

Discriminatively trained multi-scale grammars give state-of-the-art parsing performance on a variety of languages and corpora. Grammar size is dramatically reduced compared to the baseline, as well as to methods like split-and-merge (Petrov et al., 2006). Because fewer parameters are estimated, multi-scale grammars may also be less prone to overfitting, as suggested by a cross-corpus evaluation experiment. Furthermore, the discriminative framework enables the seamless integration of additional, overlapping features, such as span features and unknown word features. Such features further improve parsing performance and make the latent variable grammars very language independent.

Our parser, along with trained grammars for a variety of languages, is available at http://nlp.cs.berkeley.edu.

Abstract

We show that jointly parsing a bitext can substantially improve parse quality on both sides. In a maximum entropy bitext parsing model, we define a distribution over source trees, target trees, and node-to-node alignments between them. Features include monolingual parse scores and various measures of syntactic divergence. Using the translated portion of the Chinese treebank, our model is trained iteratively to maximize the marginal likelihood of training tree pairs, with alignments treated as latent variables. The resulting bitext parser outperforms state-of-the-art monolingual parser baselines by 2.5 F_1 at predicting English side trees and 1.8 F_1 at predicting Chinese side trees (the highest published numbers on these corpora). Moreover, these improved trees yield a 2.4 BLEU increase when used in a downstream MT evaluation.

1 Introduction

Methods for machine translation (MT) have increasingly leveraged not only the formal machinery of syntax (Wu, 1997; Chiang, 2007; Zhang et al., 2008), but also linguistic tree structures of either the source side (Huang et al., 2006; Marton and Resnik, 2008; Quirk et al., 2005), the target side (Yamada and Knight, 2001; Galley et al., 2004; Zollmann et al., 2006; Shen et al., 2008), or both (Och et al., 2003; Aue et al., 2004; Ding and Palmer, 2005). These methods all rely on automatic parsing of one or both sides of input bitexts and are therefore impacted by parser quality. Unfortunately, parsing general bitexts well can be a challenge for newswire-trained treebank parsers for many reasons, including out-of-domain input and tokenization issues.

On the other hand, the presence of translation pairs offers a new source of information: bilingual constraints. For example, Figure 1 shows a case where a state-of-the-art English parser (Petrov and Klein, 2007) has chosen an incorrect structure which is incompatible with the (correctly chosen) output of a comparable Chinese parser. Smith and Smith (2004) previously showed that such bilingual constraints can be leveraged to transfer parse quality from a resource-rich language to a resource-impoverished one. In this paper, we show that bilingual constraints and reinforcement can be leveraged to substantially improve parses on both sides of a bitext, even for two resource-rich languages.

Formally, we present a log-linear model over triples of source trees, target trees, and node-to-node tree alignments between them. We consider a set of core features which capture the scores of monolingual parsers as well as measures of syntactic alignment. Our model conditions on the input sentence pair and so features can and do reference input characteristics such as posterior distributions from a word-level aligner (Liang et al., 2006; DeNero and Klein, 2007).

Our training data is the translated section of the Chinese treebank (Xue et al., 2002; Bies et al., 2007), so at training time correct trees are observed on both the source and target side. Gold tree alignments are not present and so are induced as latent variables using an iterative training procedure. To make the process efficient and modular to existing monolingual parsers, we introduce several approximations: use of k-best lists in candidate generation, an adaptive bound to avoid considering all k^2 combinations, and Viterbi approximations to alignment posteriors.

Figure 1: Two possible parse pairs for a Chinese-English sentence pair. The parses in a) are chosen by independent monolingual statistical parsers, but only the Chinese side is correct. The gold English parse shown in b) is further down in the 100-best list, despite being more consistent with the gold Chinese parse. The circles show where the two parses differ. Note that in b), the ADVP and PP nodes correspond nicely to Chinese tree nodes, whereas the correspondence for nodes in a), particularly the SBAR node, is less clear.

We evaluate our system primarily as a parser and secondarily as a component in a machine translation pipeline. For both English and Chinese, we begin with the state-of-the-art parsers presented in Petrov and Klein (2007) as a baseline. Joint parse selection improves the English trees by 2.5 F_1 and the Chinese trees by 1.8 F_1. While other Chinese treebank parsers do not have access to English side translations, this Chinese figure does outperform all published monolingual Chinese treebank results on an equivalent split of the data.

As MT motivates this work, another valuable evaluation is the effect of joint selection on downstream MT quality. In an experiment using a syntactic MT system, we find that rules extracted from joint parses results in an increase of 2.4 BLEU points over rules extracted from independent parses.[1] In sum, jointly parsing bitexts improves parses substantially, and does so in a way that that carries all the way through the MT pipeline.

2 Model

In our model, we consider pairs of sentences (s, s'), where we use the convention that unprimed variables are source domain and primed variables are target domain. These sentences have parse trees t (respectively t') taken from candidate sets T (T'). Non-terminal nodes in trees will be denoted by n (n') and we abuse notation by equating trees with their node sets. Alignments a are simply at-most-one-to-one matchings between a pair of trees t and t' (see Figure 2a for an example). Note that we will also mention *word* alignments in feature definitions; a and the unqualified term *alignment* will always refer to node alignments. Words in a sentence are denoted by v (v').

[1]It is anticipated that in some applications, such as tree transducer extraction, the alignments themselves may be of value, but in the present work they are not evaluated.

Our model is a general log-linear (maximum entropy) distribution over triples (t, a, t') for sentence pairs (s, s'):

$$\mathrm{P}(t, a, t|s, s') \propto \exp(w^\top \phi(t, a, t'))$$

Features are thus defined over (t, a, t') triples; we discuss specific features below.

3 Features

To use our model, we need features of a triple (t, a, t') which encode both the monolingual quality of the trees as well as the quality of the alignment between them. We introduce a variety of features in the next sections.

3.1 Monolingual Features

To capture basic monolingual parse quality, we begin with a single source and a single target feature whose values are the log likelihood of the source tree t and the target tree t', respectively, as given by our baseline monolingual parsers. These two features are called SOURCELL and TARGETLL respectively. It is certainly possible to augment these simple features with what would amount to monolingual reranking features, but we do not explore that option here. Note that with only these two features, little can be learned: all positive weights w cause the jointly optimal parse pair (t, t') to comprise the two top-1 monolingual outputs (the baseline).

3.2 Word Alignment Features

All other features in our model reference the entire triple (t, a, t'). In this work, such features are defined over aligned node pairs for efficiency, but generalizations are certainly possible.

Bias: The first feature is simply a bias feature which has value 1 on each aligned node pair (n, n'). This bias allows the model to learn a general preference for denser alignments.

Alignment features: Of course, some alignments are better than others. One indicator of a good node-to-node alignment between n and n' is that a good word alignment model thinks that there are many word-to-word alignments in their bispan. Similarly, there should be few alignments that violate that bispan. To compute such features, we define $a(v, v')$ to be the posterior probability assigned to the word alignment between v and v' by an independent word aligner.[2]

Before defining alignment features, we need to define some additional variables. For any node $n \in t$ ($n' \in t'$), the inside span $i(n)$ ($i(n')$) comprises the input tokens of s (s') dominated by that node. Similarly, the complement, the outside span, will be denoted $o(n)$ ($o(n')$), and comprises the tokens not dominated by that node. See Figure 2b,c for examples of the resulting regions.

$$\begin{aligned}
\textsc{InsideBoth} &= \sum_{v \in i(n)} \sum_{v' \in i(n')} a(v, v') \\
\textsc{InSrcOutTrg} &= \sum_{v \in i(n)} \sum_{v' \in o(n')} a(v, v') \\
\textsc{InTrgOutSrc} &= \sum_{v \in o(n)} \sum_{v' \in i(n')} a(v, v')
\end{aligned}$$

[2]It is of course possible to learn good alignments using lexical indicator functions or other direct techniques, but given our very limited training data, it is advantageous to leverage counts from an unsupervised alignment system.

Hard alignment features: We also define the hard versions of these features, which take counts from the word aligner's hard top-1 alignment output δ:

$$\begin{aligned}
\textsc{HardInsideBoth} &= \sum_{v \in i(n)} \sum_{v' \in i(n')} \delta(v, v') \\
\textsc{HardInSrcOutTrg} &= \sum_{v \in i(n)} \sum_{v' \in o(n')} \delta(v, v') \\
\textsc{HardInTrgOutSrc} &= \sum_{v \in o(n)} \sum_{v' \in i(n')} \delta(v, v')
\end{aligned}$$

Scaled alignment features: Finally, undesirable larger bispans can be relatively sparse at the word alignment level, yet still contain many good word alignments simply by virtue of being large. We therefore define a scaled count which measures density rather than totals. The geometric mean of span lengths was a superior measure of bispan "area" than the true area because word-level alignments tend to be broadly one-to-one in our word alignment model.

$$\begin{aligned}
\textsc{ScaledInsideBoth} &= \frac{\textsc{InsideBoth}}{\sqrt{|i(n)| \cdot |i(n')|}} \\
\textsc{ScaledInSrcOutTrg} &= \frac{\textsc{InSrcOutTrg}}{\sqrt{|i(n)| \cdot |o(n')|}} \\
\textsc{ScaledInTrgOutSrc} &= \frac{\textsc{InTrgOutSrc}}{\sqrt{|o(n)| \cdot |i(n')|}}
\end{aligned}$$

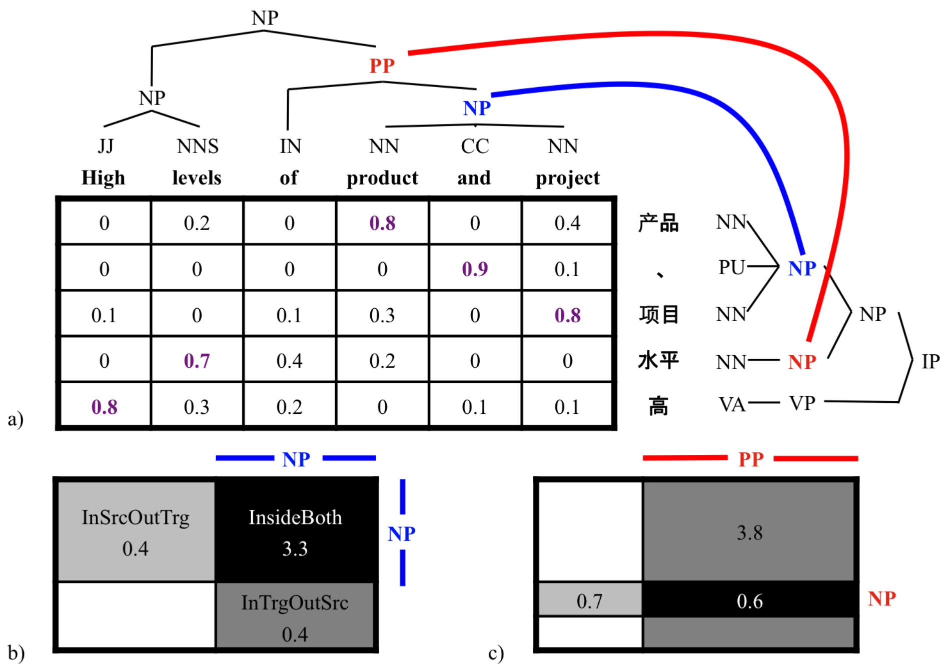
Head word alignment features: When considering a node pair (n, n'), especially one which dominates a large area, the above measures treat all spanned words as equally important. However, lexical heads are generally more representative than other spanned words. Let h select the headword of a node according to standard head percolation rules (Collins, 2003; Bikel and Chiang, 2000).

$$\begin{aligned}
\textsc{AlignHeadWord} &= a(h(n), h(n')) \\
\textsc{HardAlignHeadWord} &= \delta(h(n), h(n'))
\end{aligned}$$

3.3 Tree Structure Features

We also consider features that measure correspondences between the tree structures themselves.

Span difference: We expect that, in general, aligned nodes should dominate spans of roughly the same length, and so we allow the model to learn to



0	0.2	0	**0.8**	0	0.4	产品

0.8	0.3	0.2	0	0.1	0.1	高

Figure 2: a) An example of a legal alignment on a Chinese-English sentence fragment with one good and one bad node pair, along with sample word alignment posteriors. Hard word alignments are bolded. b) The word alignment regions for the good NP-NP alignment. InsideBoth regions are shaded in black, InSrcOutTrg in light grey, and InTrgOutSrc in grey. c) The word alignment regions for the bad PP-NP alignment.

penalize node pairs whose inside span lengths differ greatly.

$$\text{SPANDIFF} = ||i(n)| - |i(n')||$$

Number of children: We also expect that there will be correspondences between the rules of the CFGs that generate the trees in each language. To encode some of this information, we compute indicators of the number of children c that the nodes have in t and t'.

$$\text{NUMCHILDREN}\langle|c(n)|, |c(n')|\rangle = 1$$

Child labels: In addition, we also encode whether certain label pairs occur as children of matched nodes. Let $c(n, \ell)$ select the children of n with label ℓ.

$$\text{CHILDLABEL}\langle\ell, \ell'\rangle = |c(n, \ell)| \cdot |c(n', \ell')|$$

Note that the corresponding "self labels" feature is not listed because it arises in the next section as a typed variant of the bias feature.

3.4 Typed vs untyped features

For each feature above (except monolingual features), we create label-specific versions by conjoining the label pair $(\ell(n), \ell(n'))$. We use both the typed and untyped variants of all features.

4 Training

Recall that our data condition supplies sentence pairs (s, s') along with gold parse pairs (g, g'). We do not observe the alignments a which link these parses. In principle, we want to find weights which maximize the marginal log likelihood of what we do observe given our sentence pairs:[3]

$$w^* = \arg\max_w \sum_a \text{P}(g, a, g'|s, s', w) \quad (1)$$

$$= \arg\max_w \frac{\sum_a exp(w^\top \phi(g, a, g'))}{\sum_{(t,t')} \sum_a exp(w^\top \phi(t, a, t'))} \quad (2)$$

There are several challenges. First, the space of symmetric at-most-one-to-one matchings is #P-hard

[3]In this presentation, we only consider a single sentence pair for the sake of clarity, but our true objective was multiplied over all sentence pairs in the training data.

to sum over exactly (Valiant, 1979). Second, even without matchings to worry about, standard methods for maximizing the above formulation would require summation over pairs of trees, and we want to assume a fairly generic interface to independent monolingual parsers (though deeper joint modeling and/or training is of course a potential extension). As we have chosen to operate in a reranking mode over monolingual k-best lists, we have another issue: our k-best outputs on the data which trains our model may not include the gold tree pair. We therefore make several approximations and modifications, which we discuss in turn.

4.1 Viterbi Alignments

Because summing over alignments a is intractable, we cannot evaluate (2) or its derivatives. However, if we restrict the space of possible alignments, then we can make this optimization more feasible. One way to do this is to stipulate in advance that for each tree pair, there is a canonical alignment $a_0(t, t')$. Of course, we want a_0 to reflect actual correspondences between t and t', so we want a reasonable definition that ensures the alignments are of reasonable quality. Fortunately, it turns out that we can efficiently optimize a given a fixed tree pair and weight vector:

$$\begin{aligned} a^* &= \arg\max_a \mathrm{P}(a|t, t', s, s', w) \\ &= \arg\max_a \mathrm{P}(t, a, t'|s, s', w) \\ &= \arg\max_a \exp(w^\top \phi(t, a, t')) \end{aligned}$$

This optimization requires only that we search for an optimal alignment. Because all our features can be factored to individual node pairs, this can be done with the Hungarian algorithm in cubic time.[4] Note that we do not enforce any kind of domination consistency in the matching: for example, the optimal alignment might in principle have the source root aligning to a target non-root and vice versa.

We then define $a_0(t, t')$ as the alignment that maximizes $w_0^\top \phi(t, a, t')$, where w_0 is a fixed initial weight vector with a weight of 1 for InsideBoth, -1 for InSrcOutTrg and InTrgOutSrc, and 0 for all other features. Then, we simplify (2) by fixing the alignments a_0:

$$w^* = \arg\max_w \frac{exp(w^\top \phi(g, a_0(g, g'), g'))}{\sum_{(t,t')} exp(w^\top \phi(t, a_0(t, t'), t'))} \quad (3)$$

This optimization has no latent variables and is therefore convex and straightforward. However, while we did use this as a rapid training procedure during development, fixing the alignments a priori is both unsatisfying and also less effective than a procedure which allows the alignments a to adapt during training.

Again, for fixed alignments a, optimizing w is easy. Similarly, with a fixed w, finding the optimal a for any particular tree pair is also easy. Another option is therefore to use an iterative procedure that alternates between choosing optimal alignments for a fixed w, and then reoptimizing w for those fixed alignments according to (3). By iterating, we perform the following optimization:

$$w^* = \arg\max_w \frac{\max_a exp(w^\top \phi(g, a, g'))}{\sum_{(t,t')} \max_a exp(w^\top \phi(t, a, t'))} \quad (4)$$

Note that (4) is just (2) with summation replaced by maximization. Though we do not know of any guarantees for this EM-like algorithm, in practice it converges after a few iterations given sufficient training data. We initialize the procedure by setting w_0 as defined above.

4.2 Pseudo-gold Trees

When training our model, we approximate the sets of all trees with k-best lists, T and T', produced by monolingual parsers. Since these sets are not guaranteed to contain the gold trees g and g', our next approximation is to define a set of *pseudo-gold trees*, following previous work in monolingual parse reranking (Charniak and Johnson, 2005). We define $\hat{T}$ ($\hat{T}'$) as the F_1-optimal subset of T (T'). We then modify (4) to reflect the fact that we are seeking to maximize the likelihood of trees in this subset:

$$w^* = \arg\max_w \sum_{(t,t') \in (\hat{T}, \hat{T}')} \mathrm{P}(t, t'|s, s', w) \quad (5)$$

where $\mathrm{P}(t, t'|s, s', w) =$

$$\frac{\max_a \exp(w^\top \phi(t, a, t'))}{\sum_{(\bar{t},\bar{t}') \in (T,T')} \max_a \exp(w^\top \phi(\bar{t}, a, \bar{t}'))} \quad (6)$$

[4]There is a minor modification to allow nodes not to match. Any alignment link which has negative score is replaced by a zero-score link, and any zero-score link in the solution is considered a pair of unmatched nodes.

4.3 Training Set Pruning

To reduce the time and space requirements for training, we do not always use the full k-best lists. To prune the set T, we rank all the trees in T from 1 to k, according to their log likelihood under the baseline parsing model, and find the rank of the least likely pseudo-gold tree:

$$r^* = \min_{t \in \hat{T}} rank(t)$$

Finally, we restrict T based on rank:

$$T_{pruned} = \{t \in T | rank(t) \leq r^* + \epsilon\}$$

where ϵ is a free parameter of the pruning procedure. The restricted set T'_{pruned} is constructed in the same way. When training, we replace the sum over all tree pairs in (T, T') in the denominator of (6) with a sum over all tree pairs in $(T_{pruned}, T'_{pruned})$.

The parameter ϵ can be set to any value from 0 to k, with lower values resulting in more efficient training, and higher values resulting in better performance. We set ϵ by empirically determining a good speed/performance tradeoff (see §6.2).

5 Joint Selection

At test time, we have a weight vector w and so selecting optimal trees for the sentence pair (s, s') from a pair of k best lists, (T, T') is straightforward. We just find:

$$\begin{aligned}(t^*, t'^*) &= \underset{(t,t') \in (T,T')}{\arg\max} \max_a \mathrm{P}(t, a, t' | s, s', w) \\ &= \underset{(t,t') \in (T,T')}{\arg\max} \max_a w^\top \phi(t, a, t')\end{aligned}$$

Note that with no additional cost, we can also find the optimal alignment between t^* and t'^*:

$$a^* = \arg\max_a w^\top \phi(t^*, a, t'^*)$$

5.1 Test Set Pruning

Because the size of (T, T') grows as $O(k^2)$, the time spent iterating through all these tree pairs can grow unreasonably long, particularly when reranking a set of sentence pairs the size of a typical MT corpus. To combat this, we use a simple pruning technique to limit the number of tree pairs under consideration.

	Training	Dev	Test
Articles	1-270	301-325	271-300
Ch Sentences	3480	352	348
Eng Sentences	3472	358	353
Bilingual Pairs	2298	270	288

Table 1: Sentence counts from bilingual Chinese treebank corpus.

To prune the list of tree pairs, first we rank them according to the metric:

$$w_{\textsc{SourceLL}} \cdot \textsc{SourceLL} + w_{\textsc{TargetLL}} \cdot \textsc{TargetLL}$$

Then, we simply remove all tree pairs whose ranking falls below some empirically determined cutoff. As we show in §6.3, by using this technique we are able to speed up reranking by a factor of almost 20 without an appreciable loss of performance.

6 Statistical Parsing Experiments

All the data used to train the joint parsing model and to evaluate parsing performance were taken from articles 1-325 of the Chinese treebank, which all have English translations with gold-standard parse trees. The articles were split into training, development, and test sets according to the standard breakdown for Chinese parsing evaluations. Not all sentence pairs could be included for various reasons, including one-to-many Chinese-English sentence alignments, sentences omitted from the English translations, and low-fidelity translations. Additional sentence pairs were dropped from the training data because they had unambiguous parses in at least one of the two languages. Table 1 shows how many sentences were included in each dataset.

We had two training setups: rapid and full. In the rapid training setup, only 1000 sentence pairs from the training set were used, and we used fixed alignments for each tree pair rather than iterating (see §4.1). The full training setup used the iterative training procedure on all 2298 training sentence pairs.

We used the English and Chinese parsers in Petrov and Klein (2007)[5] to generate all k-best lists and as our evaluation baseline. Because our bilingual data is from the Chinese treebank, and the data

[5]Available at http://nlp.cs.berkeley.edu.

typically used to train a Chinese parser contains the Chinese side of our bilingual training data, we had to train a new Chinese grammar using only articles 400-1151 (omitting articles 1-270). This modified grammar was used to generate the k-best lists that we trained our model on. However, as we tested on the same set of articles used for monolingual Chinese parser evaluation, there was no need to use a modified grammar to generate k-best lists at test time, and so we used a regularly trained Chinese parser for this purpose.

We also note that since all parsing evaluations were performed on Chinese treebank data, the Chinese test sentences were in-domain, whereas the English sentences were very far out-of-domain for the Penn Treebank-trained baseline English parser. Hence, in these evaluations, Chinese scores tend to be higher than English ones.

Posterior word alignment probabilities were obtained from the word aligner of Liang et al. (2006) and DeNero and Klein (2007)[6], trained on approximately 1.7 million sentence pairs. For our alignment model we used an HMM in each direction, trained to agree (Liang et al., 2006), and we combined the posteriors using DeNero and Klein's (2007) soft union method.

Unless otherwise specified, the maximum value of k was set to 100 for both training and testing, and all experiments used a value of 25 as the ϵ parameter for training set pruning and a cutoff rank of 500 for test set pruning.

6.1 Feature Ablation

To verify that all our features were contributing to the model's performance, we did an ablation study, removing one group of features at a time. Table 2 shows the F_1 scores on the bilingual development data resulting from training with each group of features removed.[7] Note that though head word features seemed to be detrimental in our rapid training setup, earlier testing had shown a positive effect, so we reran the comparison using our full training setup, where we again saw an improvement when including these features.

[6] Available at http://nlp.cs.berkeley.edu.

[7] We do not have a test with the basic alignment features removed because they are necessary to compute $a_0(t, t')$.

Table 3: Training set pruning study. F_1 on dev set after training with different values of the ϵ parameter for training set pruning.

6.2 Training Set Pruning

To find a good value of the ϵ parameter for training set pruning we tried several different values, using our rapid training setup and testing on the dev set. The results are shown in Table 3. We selected 25 as it showed the best performance/speed tradeoff, on average performing as well as if we had done no pruning at all, while requiring only a quarter the memory and CPU time.

6.3 Test Set Pruning

We also tried several different values of the rank cutoff for test set pruning, using the full training setup

Cutoff	Ch F_1	Eng F_1	Tot F_1	Time (s)

100	86.71	79.37	92.23	84.73
150	86.67	79.47	92.49	85.17

Table 5: Sensitivity to k study. Joint parsing and oracle F_1 obtained on dev set using different maximum values of k when generating baseline k-best lists.

and testing on the dev set. The results are in Table 4. For F_1 evaluation, which is on a very small set of sentences, we selected 500 as the value with the best speed/performance tradeoff. However, when reranking our entire MT corpus, we used a value of 200, sacrificing a tiny bit of performance for an extra factor of 2 in speed.[8]

6.4 Sensitivity to k

Since our bitext parser currently operates as a reranker, the quality of the trees is limited by the quality of the k-best lists produced by the baseline parsers. To test this limitation, we evaluated performance on the dev set using baseline k-best lists of varying length. Training parameters were fixed (full training setup with $k = 100$) and test set pruning was disabled for these experiments. The results are in Table 5. The relatively modest gains with increasing k, even as the oracle scores continue to improve, indicate that performance is limited more by the model's reliance on the baseline parsers than by search errors that result from the reranking approach.

6.5 Final Results

Our final evaluation was done using the full training setup. Here, we report F_1 scores on two sets of data. First, as before, we only include the sentence pairs from our bilingual corpus to fully demonstrate the gains made by joint parsing. We also report scores on the full test set to allow easier comparison with past work on Chinese parsing. For the latter evaluation, sentences that were not in the bilingual corpus were simply parsed with the baseline parsers. The results are in Table 6. Joint parsing improves F_1 by 2.5 points on out-of-domain English sentences and by 1.8 points on in-domain Chinese sentences; this represents the best published Chinese treebank parsing performance, even after sentences that lack a translation are taken into account.

[8]Using a rank cutoff of 200, the reranking step takes slightly longer than serially running both baseline parsers, and generating k-best lists takes slightly longer than getting 1-best parses, so in total, joint parsing takes about 2.3 times as long as monolingual parsing. With a rank cutoff of 500, total parsing time is scaled by a factor of around 3.8.

7 Machine Translation

To test the impact of joint parsing on syntactic MT systems, we compared the results of training an MT system with two different sets of trees: those produced by the baseline parsers, and those produced by our joint parser. For this evaluation, we used a syntactic system based on Galley et al. (2004) and Galley et al. (2006), which extracts tree-to-string transducer rules based on target-side trees. We trained the system on 150,000 Chinese-English sentence pairs from the training corpus of Wang et al. (2007), and used a large (close to 5 billion tokens) 4-gram lan-

BLEU	18.7	**21.1**	18.8

Table 7: MT comparison on a syntactic system trained with trees output from either baseline monolingual parsers or our joint parser. To facilitate relative comparison, the Moses (Koehn et al., 2007) number listed reflects the default Moses configuration, including its full distortion model, and standard training pipeline.

guage model for decoding. We tuned and evaluated BLEU (Papineni et al., 2001) on separate held-out sets of sentences of up to length 40 from the same corpus. The results are in Table 7, showing that joint parsing yields a BLEU increase of 2.4.[9]

8 Conclusions

By jointly parsing (and aligning) sentences in a translation pair, it is possible to exploit mutual constraints that improve the quality of syntactic analyses over independent monolingual parsing. We presented a joint log-linear model over source trees, target trees, and node-to-node alignments between them, which is used to select an optimal tree pair from a k-best list. On Chinese treebank data, this procedure improves F_1 by 1.8 on Chinese sentences and by 2.5 on out-of-domain English sentences. Furthermore, by using this joint parsing technique to preprocess the input to a syntactic MT system, we obtain a 2.4 BLEU improvement.

Abstract

Statistical parsers have become increasingly accurate, to the point where they are useful in many natural language applications. However, estimating parsing accuracy on a wide variety of domains and genres is still a challenge in the absence of gold-standard parse trees.

In this paper, we propose a technique that automatically takes into account certain characteristics of the domains of interest, and accurately predicts parser performance on data from these new domains. As a result, we have a cheap (no annotation involved) and effective recipe for measuring the performance of a statistical parser on any given domain.

1 Introduction

Statistical natural language parsers have recently become more accurate and more widely available. As a result, they are being used in a variety of applications, such as question answering (Hermjakob, 2001), speech recognition (Chelba and Jelinek, 1998), language modeling (Roark, 2001), language generation (Soricut, 2006) and, most notably, machine translation (Charniak et al., 2003; Galley et al., 2004; Collins et al., 2005; Marcu et al., 2006; Huang et al., 2006; Avramidis and Koehn, 2008). These applications are employed on a wide range of domains and genres, and therefore the question of how accurate a parser is on the domain and genre of interest becomes acute. Ideally, one would want to have available a recipe for precisely answering this question: "given a parser and a particular domain of interest, how accurate are the parse trees produced?" The only recipe that is implicitly given in the large literature on parsing to date is to have human annotators build parse trees for a sample set from the domain of interest, and consequently use them to compute a PARSEVAL (Black et al., 1991) score that is indicative of the intrinsic performance of the parser. Given the wide range of domains and genres for which NLP applications are of interest, combined with the high expertise required from human annotators to produce parse tree annotations, this recipe is, albeit precise, too expensive. The other recipe that is currently used on a large scale is to measure the performance of a parser on existing treebanks, such as WSJ (Marcus et al., 1993), and assume that the accuracy measure will carry over to the domains of interest. This recipe, albeit cheap, cannot provide any guarantee regarding the performance of a parser on a new domain, and, as experiments in this paper show, can give wrong indications regarding important decisions for the design of NLP systems that use a syntactic parser as an important component.

This paper proposes another method for measuring the performance of a parser on a given domain that is both cheap and effective. It is a fully automated procedure (no expensive annotation involved) that uses properties of both the domain of interest and the domain on which the parser was trained in order to measure the performance of the parser on the domain of interest. It is, in essence, a solution to the following prediction problem:

Input: (1) a statistical parser and its training data, (2) some chunk of text from a new domain or genre

Output: an estimate of the accuracy of the parse trees produced for that chunk of text

Accurate estimations for this prediction problem will allow a system designer to make the right decisions for the given domain of interest. Such decisions include, but are not restricted to, the choice of the parser, the choice of the training data, the choice of how to implement various components such as the treatment of unknown words, etc. Altogether, a correct estimation of the impact of such decisions on the resulting parse trees can guide a system designer in a hill-climbing scenario for which an extrinsic metric (such as the impact on the overall quality of the system) is usually too expensive to be employed often enough. To provide an example, a machine translation engine that requires parse trees as training data in order to learn syntax-based translation rules (Galley et al., 2006) needs to employ a syntactic parser as soon as the training process starts, but it can take up to hundreds and even thousands of CPU hours (for large training data sets) to train the engine before translations can be produced and measured. Although a real estimate of the impact of a parser design decision in this scenario can only be gauged from the quality of the translations produced, it is impractical to create such estimates for each design decision. On the other hand, estimates using the solution proposed in this paper can be obtained fast, before submitting the parser output to a costly training procedure.

2 Related Work and Experimental Framework

There have been previous studies which explored the problem of automatically predicting the task difficulty for various NLP applications. (Albrecht and Hwa, 2007) presented a regression based method for developing automatic evaluation metrics for machine translation systems without directly relying on human reference translations. (Hoshino and Nakagawa, 2007) built a computer-adaptive system for generating questions to teach English grammar and vocabulary to students, by predicting the difficulty level of a question using various features. There have been a few studies of English parser accuracy in domains/genres other than WSJ (Gildea, 2001; Bacchiani et al., 2006; McClosky et al., 2006), but in order to make measurements for such studies, it is necessary to have gold-standard parses in the non-WSJ domain of interest.

Gildea (2001) studied how well WSJ-trained parsers do on the Brown corpus, for which a gold standard exists. He looked at sentences with 40 words or less. (Bacchiani et al., 2006) carried out a similar experiment on sentences of all lengths, and (McClosky et al., 2006) report additional results. The table below shows results from our own measurements of Charniak parser[1] (Charniak and Johnson, 2005) accuracy (F-measure on sentences of all lengths), which are consistent with these studies. For the Brown corpus, the test set was formed from every tenth sentence in the corpus (Gildea, 2001).

Training Set	**Test Set**	**Sent. count**	**Charniak accuracy**
WSJ sec. 02-21 (39,832 sent.)	WSJ sec. 24	1308	90.48
	WSJ sec. 23	2343	91.13
	Brown-test	2186	86.34

Here we investigate algorithms for predicting the accuracy of a parser $\mathcal{P}$ on sentences, chunks of sentences, and whole corpora. We also investigate and contrast several scenarios for prediction: (1) the predictor looks at the input text only, (2) the predictor looks at the input text and the output parse trees of $\mathcal{P}$, and (3) the predictor looks at the input text, the output parse trees of $\mathcal{P}$, and the outputs of other programs, such as the output parse trees of a different parser $\mathcal{P}_{ref}$ used as a reference. Under none of these scenarios is the predictor allowed to look at gold-standard parses in the new domain/genre.

The intuition behind what we are trying to achieve here can be compared to an analogous task—trying to assess the performance of a median student from a math class on a given test, without having access to the answer sheet. Looking at the test only, we could probably tell whether the test looks hard or not, and therefore whether the student will do well or not. Looking at the student's answers will likely give us an even better idea of the performance. Finally, the answers of a second student with similar proficiency will provide even better clues: if the students agree on every answer, then they probably both did well, but if they disagree frequently, then they (and hence our student) probably did not do as well.

Our first experiments are concerned with validating the idea itself: can a predictor be trained such

[1]Downloaded from *ftp.cs.brown.edu/pub/nlparser/reranking-parserAug06.tar.gz* in February, 2007.

that it predicts the same F-scores as the ones obtained using gold-trees? We first validate this using the WSJ corpus itself, by dividing the WSJ treebank into several sections:

1. *Training* (WSJ section 02-21). The parser $\mathcal{P}$ is trained on this data.

2. *Development* (WSJ section 24). We use this data for training our predictor.

3. *Test* (WSJ section 23). We use this data for measuring our predictions. For each test sentence, we compute (1) the PARSEVAL F-measure score using the test gold standard, and (2) our predicted F-measure. We report the correlation coefficient (r) between the actual F-scores and our predicted F-scores. We will also use a root-mean-square error (rms error) metric to compare actual and predicted F-scores.

Section 3 describes the features used by our predictor. Given these features, as well as actual F-scores computed for the development data, we use supervised learning to set the feature weights. To this end, we use SVM-Regression[2] (Smola and Schoelkopf, 1998) with an RBF kernel, to learn the feature weights and build our predictor system.[3] We validate the accuracy of the predictor trained in this fashion on both WSJ (Section 4) and the Brown corpus (Section 5).

3 Features Used for Predicting Parser Accuracy

3.1 Text-based Features

One hypothesis we explore is that (all other things being equal) longer sentences are harder to parse correctly than shorter sentences. When exposed to the development set, SVM-Regression learns weights to best predict F-scores using the values for this feature corresponding to each sentence in the corpus.

Does the predicted F-score correlate with actual F-score on a sentence by sentence basis? There was a positive but weak correlation:

Feature set	**dev (r)**	**test (r)**
Length	0.13	0.19

Another hypothesis is that the parser performance is influenced by the number of UNKNOWN words in the sentence to be parsed, i.e., the number of words in the test sentence that were never seen before in the training set. Training the predictor with this feature produces a positive correlation, slightly weaker compared to the Length feature.

Feature set	**dev (r)**	**test (r)**
UNK	0.11	0.11

Unknown words are not the only ones that can influence the performance of a parser. Rare words, for which statistical models do not have reliable estimates, are also likely to impact parsing accuracy. To test this hypothesis, we add a language model perplexity–based (LM-PPL) feature. We extract the yield of the training trees, on which we train a trigram language model.[4] We compute the perplexity of each test sentence with respect to this language model, and use it as feature in our predictor system. Note that this feature is meant as a refinement of the previous UNK feature, in the sense that perplexity numbers are meant to signal the occurrence of unknown words, as well as rare (from the training data perspective) words. However, the correlation we observe for this feature is similar to the correlation observed for the UNK feature, which seems to suggest that the smoothing techniques used by the parsers employed in these experiments lead to correct treatment of the rare words.

Feature set	**dev (r)**	**test (r)**
LM-PPL	0.11	0.10

We also look at the possibility of automatically detecting certain "cue" words that are appropriate for our prediction problem. That is, we want to see if we can detect certain words that have a discriminating power in deciding whether parsing a sentence that contains them is difficult or easy. To this end, we use a subset of the development data, which contains the 200 best-parsed and 200 worst-parsed sentences (based on F-measure scores). For each word in the development dataset, we compute the information gain (IG) (Yang and Pedersen, 1997) score for that word with respect to the best/worst parsed

[2]Weka software (http://www.cs.waikato.ac.nz/ml/weka/)

[3]We compared a few regression algorithms like SVM-Regression (using different kernels and parameter settings) and Multi-Layer Perceptron (neural networks) – we trained the algorithms separately on dev data and picked the one that gave the best cross-validation accuracy (F-measure).

[4]We trained using the SRILM language modeling toolkit, with default settings.

dataset. These words are then ranked by their IG scores, and the top 100 words are included as lexical features in our predictor system. As expected, the correlation on the development set is quite high (given that these lexical cues are extracted from this particular set), but a positive correlation holds for the test set as well.

Feature set	dev (r)	test (r)
lexCount100	0.43	0.18

3.2 Parser $\mathcal{P}$–based Features

Besides exploiting the information present in the input text, we can also inspect the output tree of the parser $\mathcal{P}$ for which we are interested in predicting accuracy. We create a rootSYN feature based on the syntactic category found at the root of the output tree ("is it S?", "is it FRAG?"). We also create a puncSYN feature based on the number of words labeled as punctuation tags (based on the intuition that heavy use of punctuation can be indicative of the difficulty of the input sentences), and a labelSYN feature in which we bundled together information regarding the number of internal nodes in the parse tree output that have particular labels ("how many nodes are labeled with PP?"). In our predictor, we use 72 such labelSYN features corresponding to all the syntactic labels found in the parse tree output for the development set. The test set correlation given by the rootSYN and the labelSYN features are higher than some of the text-based features, whereas the puncSYN feature seems to have little discriminative power.

Feature set	dev (r)	test (r)
rootSYN	0.21	0.17
puncSYN	0.09	0.01
labelSYN	0.33	0.28

3.3 Reference Parser $\mathcal{P}_{ref}$–based Features

In addition to the text-based features and parser $\mathcal{P}$–based features, we can bring in an additional parser $\mathcal{P}_{ref}$ whose output is used as a reference against which the output of parser $\mathcal{P}$ is measured. For the reference parser feature, our goal is to measure how similar/different are the results from the two parsers. We find that if the parses are similar, they are more likely to be right. In order to compute similarity, we can compare the constituents in the two parse trees from $\mathcal{P}$ and $\mathcal{P}_{ref}$, and see how many constituents match. This is most easily accomplished by considering $\mathcal{P}_{ref}$ to be a "gold standard" (even though it is not necessarily a correct parse) and computing the F-measure score of parser $\mathcal{P}$ against $\mathcal{P}_{ref}$. We use this F-measure score as a feature for prediction.

For the experiments presented in this section we use as $\mathcal{P}_{ref}$, the parser from (Bikel, 2002). Intuitively, the requirement for choosing parser $\mathcal{P}_{ref}$ in conjunction with parser $\mathcal{P}$ seems to be that they are different enough to produce non-identical trees when presented with the same input, and at the same time to be accurate enough to produce reliable parse trees. The choice of $\mathcal{P}$ as (Charniak and Johnson, 2005) and $\mathcal{P}_{ref}$ as (Bikel, 2002) fits this bill, but many other choices can be made regarding $\mathcal{P}_{ref}$, such as (Klein and Manning, 2003; Petrov and Klein, 2007; McClosky et al., 2006; Huang, 2008). We leave the task of creating features based on the consensus of multiple parsers as future work.

The correlation given by the reference parser–based feature $\mathcal{P}_{ref}$ on the test set is the highest among all the features we explored.

Feature set	dev (r)	test (r)
$\mathcal{P}_{ref}$	0.40	0.36

3.4 The Aggregated Power of Features

The table below lists all the individual features we have described in this section, sorted according to the correlation value obtained on the test set.

Feature set	dev (r)	test (r)
$\mathcal{P}_{ref}$	0.40	0.36
labelSYN	0.33	0.28
lexCount500	0.56	0.23
lexBool500	0.58	0.20
lexCount1000	0.67	0.20
lexBool1000	0.58	0.20
Length	0.13	0.19
lexCount100	0.43	0.18
lexBool100	0.43	0.18
rootSYN	0.21	0.17
UNK	0.11	0.11
LM-PPL	0.11	0.10
puncSYN	0.09	0.01

Note how the lexical features tend to over-fit the development data—the words were specifically chosen for their discriminating power on that particular set. Hence, adding more lexical features to the predictor system improves the correlation on development (due to over-fitting), but it does not produce consistent improvement on the test set. However,

Method (using 3 features: Length, UNK, $\mathcal{P}_{ref}$)	**# of random restarts**	**dev (r)**
SVM Regression		**0.42**
Maximum Correlation Training (MCT)	1	0.138
	5	0.136
	10	0.166
	25	0.178
	100	0.232
	1000	0.27
	10,000	0.401

Table 1: Comparison of correlation (r) obtained using MCT versus SVM-Regression on development corpus.

there is some indication that the counts of the lexical features are important, and count-based lexical features tend to have similar or better performance compared to their boolean-based counterparts.

Since these features measure different but overlapping pieces of the information available, it is to be expected that some of the feature combinations would provide better correlation that the individual features, but the gains are not strictly additive. By taking the individual features that provide the best discriminative power, we are able to get a correlation score of 0.42 on the test set.

Feature set	**dev (r)**	**test (r)**
$\mathcal{P}_{ref}$ + labelSYN + Length + lexCount100 + rootSYN + UNK + LM-PPL	0.55	0.42

3.5 Optimizing for Maximum Correlation

If our goal is to obtain the highest correlations with the F-score measure, is SVM regression the best method? Liu and Gildea (2007) recently introduced Maximum Correlation Training (MCT), a search procedure that follows the gradient of the formula for correlation coefficient (r). We implemented MCT, but obtained no better results. Moreover, it required many random re-starts just to obtain results comparable to SVM regression (Table 1).

4 Predicting Accuracy on Multiple Sentences

The results for the scenario presented in Section 3 are encouraging, but other scenarios are also important from a practical perspective. For instance, we are interested in predicting the performance of a particular parser not on a sentence-by-sentence basis, but for a representative chunk of sentences from the new domain. In order to predict the F-measure on multiple sentences, we modify our feature set to generate information on a whole chunk of sentences rather than a single sentence. Predicting the correlation at chunk level is, not unexpectedly, an easier problem than predicting correlation at sentence level, as the results in the first two columns of Table 2 show.

Sentences in chunk (n)	**WSJ-test (r)**	**WSJ-test (rms error)**
1	0.42	0.098
20	0.61	0.026
50	0.62	0.019
100	0.69	0.015
500	0.79	0.011

Table 2: Performance of predictor on n-sentence chunks from WSJ-test (Correlation and rms error between actual/predicted accuracies).

For 100-sentence chunks, we also plot the predicted accuracies versus actual accuracies for the WSJ-test set in Figure 1. This scatterplot brings to light an artifact of using correlation metric (r) for evaluating our predictor's performance. Although our objective is to improve correlation between actual and predicted F-scores, the correlation metric (r) does not tell us directly how well the predictor is doing. In Figure 1, the system predicts that on an average, most sentence chunks can be parsed with an accuracy of 0.9085 (which is the mean predicted F-score on WSJ-test). But the range of predictions from our system [0.89,0.92] is smaller than the actual F-score range [0.86,0.95]. Hence, even though the correlation scores are high, this does not necessarily mean that our predictions are on target. An additional metric, *root-mean-square (rms) error*, which measures the distance between actual and predicted F-measures, can be used to gauge the quality of our predictions. For a particular chunk-size, lowering the *rms error* translates into aligning the points of a scatterplot as the one in Figure 1, closer to the x=y line, implying that the predictor is getting better at exactly predicting the F-score values. The third column in Table 2 shows the rms error for our predictor at different chunk sizes. The results using this metric also show that the prediction problem becomes easier as the chunk size increases.

Assuming that we have the test set of WSJ section 23, but without the gold-standard trees, how can we get an approximation for the overall accuracy of a parser $\mathcal{P}$ on this test set? One possibility, which we use here as a baseline, is to compute the F-score on a set for which we do have gold-standard trees. If we use our development set (WSJ section

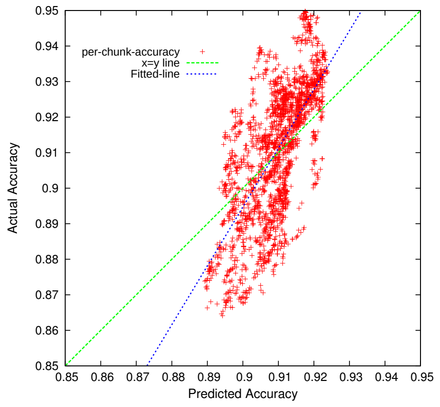

Figure 1: Plot showing Actual vs. Predicted accuracies for WSJ-test (100-sentence chunks). Each plot point represents a 100-sentence chunk. *(rms error = 0.015)*

System	F-measure
Charniak F-measure on WSJ-dev (baseline)	90.48 (f_d)
Predictor (feature weights set with WSJ-dev)	**90.85** (f_p)
Actual Charniak accuracy	91.13 (f_t)

Table 3: Comparing Charniak parser accuracy (from different systems) on entire WSJ-test corpus

24) for this purpose, and (Charniak and Johnson, 2005) as the parser $\mathcal{P}$, the baseline is an F-score of 90.48 (f_d), which is the actual Charniak parser accuracy on WSJ section 24. Instead, if we run our predictor on the test set (a single chunk containing all the sentences in the test set), it predicts an F-score of 90.85 (f_p). These two predictions are listed as the first two rows in Table 3. Of course, having the actual gold-standard trees for WSJ section 23 helps us decide which prediction is better: the actual accuracy of the Charniak parser on WSJ section 23 is an F-score of 91.13 (f_t), which makes our prediction better than the baseline.

4.1 Shifting Predictions to Match Actual Accuracy

We correctly predict (in Table 3) that the WSJ-test is easier to parse than the WSJ-dev (90.85 > 90.48). However, our predictor is too conservative—the WSJ-test is actually even easier to parse (91.13 > 90.85). We can fix this by shifting the mean predicted F-score (which is equal to f_p) further away from the dev F-measure (f_d), and closer to the actual F-measure (f_t). This is achieved by shifting all the individual predictions by a certain amount as shown below.

Let p be an individual prediction from our system.

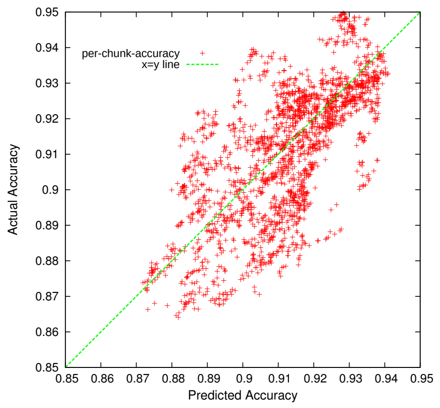

Figure 2: Plot showing Actual vs. Adjusted Predicted accuracies *(shifting with $\alpha = 0.757$, skewing with $\beta = 1.0$)* for WSJ-test (100-sentence chunks). *(rms error = 0.014)*

The shifted prediction p' is given by:

$$p' = p + \alpha(f_p - f_d) \qquad (1)$$

We can tune α to make the new mean prediction (f'_p) to be equal to the actual F-measure (f_t).

$$f'_p = f_p + \alpha(f_p - f_d) \qquad (2)$$

$$\alpha = \frac{f_t - f_p}{f_p - f_d} \qquad (3)$$

Using the F-score values from Table 3, we get an $\alpha = 0.757$ and an exact prediction of 91.13. Of course, this is because we tune on test, so we need to validate this idea on a new test set to see if it leads to improved predictions (Section 5).

4.2 Skewing to Widen Prediction Range

Our predictor is also too conservative about its *distribution* (see Figure 1). It knows (roughly) which chunks are easier to parse and which are harder, but its range of predictions is lower than the range of actual F-measure scores.

We can skew individual predictions so that sentences predicted to be easy are re-predicted to be even easier (and those that are hard to be even harder). For each prediction p' (from Equation 1), we compute

$$p'' = p' + \beta(p' - f'_p) \qquad (4)$$

We simply set β to 1.0, doubling the distance of each prediction p' (in Equation 1) from the (adjusted) mean prediction f'_p, to obtain the skewed prediction p''.

Figure 2 shows how the points representing 100-sentence chunks in Figure 1 look after the predictions have been shifted ($\alpha = 0.757$) and skewed ($\beta = 1.0$). These two operations have the desired effect of changing the range of predictions from [0.89,0.92] to [0.87,0.94], much closer to the actual

Sentences in chunk (n)	WSJ-test (rms error)	Brown-test Prediction (rms error)	Brown-test Adjusted Prediction (rms error)
1	0.098	0.129	0.139
20	0.026	0.039	0.036
50	0.019	0.032	0.029
100	0.015	0.025	0.020
500	0.011	0.038	0.024

Table 4: Performance of predictor on n-sentence chunks from WSJ-test and Brown-test (rms error between actual/predicted accuracies).

range of [0.86,0.95]. The points in the new plot (Figure 2) also align closer to the "x=y" line than in the original graph (Figure 1). The rms error also drops from 0.015 to 0.014 (7% relative reduction), showing that the predictions have improved.

Since we use the WSJ-test corpus to tune the parameter values for shifting and skewing, we need to apply our predictor on a different test set to see if we get similar improvements by using these techniques, which we do in the next section.

5 Predicting Accuracy on the Brown Corpus

The Brown corpus represents a genuine challenge for our predictor, as it presents us with the opportunity to test the performance of our predictor in an out-of-domain scenario. Our predictor, trained on WSJ data, is now employed to predict the performance of a WSJ-trained parser $\mathcal{P}$ on the Brown-test corpus. As in the previous experiments, we use (Charniak and Johnson, 2005) trained on WSJ sections 02-21 as parser $\mathcal{P}$. The feature weights for our predictor are again trained on section 24 of WSJ, and the shifting and skewing parameters ($\alpha = 0.757$, $\beta = 1.0$) are determined using section 23 of WSJ.

The results on the Brown-test, both the original predictions and after they have been adjusted (shifted/skewed), are shown in Table 4, at different level of chunking. For chunks of size n > 1, the shifting and skewing techniques help in lowering the rms error. On 100-sentence chunks from the Brown test, shifting and skewing ($\alpha = 0.757$, $\beta = 1.0$) leads to a 20% relative reduction in the rms error.

In a similar vein with the evaluation done in Section 4, we are interested in estimating the overall accuracy of a WSJ-trained parser $\mathcal{P}$ given an out-of-domain set such as the Brown test set (for which, at least for now, we do not have access to gold-standard trees). If we use (Charniak and Johnson, 2005) as parser $\mathcal{P}$, a cheap and readily-available answer is to approximate the performance using the Charniak parser performance on WSJ section 23, which has an F-score of 91.13. Another cheap and readily-available answer is to take the Charniak parser performance on WSJ section 24 with an F-score of 90.48. Table 5 lists these baselines, along with the prediction made by our system when using a single chunk containing all the sentences in the Brown test set (both base predictions and adjusted predictions, i.e. shifting using $\alpha = 0.757$). Again, having gold-standard trees for the Brown test set helps us decide which prediction is better. Our predictions are much closer to the actual Charniak parser performance on the Brown-test set, with the adjusted prediction at 86.96 compared to the actual F-score of 86.34.

System	F-measure
Baseline1 (F-measure on WSJ sec. 23)	91.13
Baseline2 (F-measure on WSJ sec. 24)	90.48
Predictor (base)	88.48
Adjusted Predictor (shifting using $\alpha = 0.757$)	**86.96**
Actual accuracy	86.34

Table 5: Charniak parser accuracy on entire Brown-test corpus

6 Ranking Parser Performance

One of the main goals for computing F-score figures (either by traditional PARSEVAL evaluation against gold standards or by methods such as the one proposed in this paper) is to compare parsing accuracy when confronted with a choice between various parser deployments. Not only are there many parsing techniques available (Collins, 2003; Charniak and Johnson, 2005; Petrov and Klein, 2007; McClosky et al., 2006; Huang, 2008), but recent annotation efforts in providing training material for statistical parsing (LDC, 2005; LDC, 2006a; LDC, 2006b; LDC, 2006c; LDC, 2007) have compounded the difficulty of the choices ("Do I parse using parser X?", "Do I train parser X using the treebank Y or Z?"). In this section, we show how our predictor can provide guidance when dealing with some of these choices, namely the choice of the training material to use with a statistical parser, prior to its application in an NLP task.

For the experiments reported in this paper, we use as parser $\mathcal{P}$, our in-house implementation of the Collins parser (Collins, 2003), to which various speed-related enhancements (Goodman, 1997) have been applied. This choice has been made to better reflect a scenario in which parser $\mathcal{P}$ would be used in a data-intensive application such as syntax-driven machine translation, in which the parser must be able to run through hundreds of millions of training words in a timely manner. We use the more accurate, but slower Charniak parser (Charniak and Johnson, 2005) as the reference parser $\mathcal{P}_{ref}$ in our predictor (see Section 3.3). In order to predict the Collins-style parser behavior on the ranking task, we use the same predictor model (including feature weights and adjustment parameters) that was used for predicting Charniak parser behavior on the Brown corpus (Section 5).

We compare three training scenarios that make for three different parsers:

(1) P_{WSJ} - trained on sections 02-21 of WSJ.

(2) P_{News} - trained on the union of the English Chinese Translation Treebank (LDC, 2007) (news stories from Xinhua News Agency translated from Chinese into English) and the English Newswire Translation Treebank (LDC, 2005; LDC, 2006a; LDC, 2006b; LDC, 2006c) (An-Nahar new stories translated from Arabic into English).

(3) $\text{P}_{WSJ-News}$ - trained on the union of all the above training material.

When comparing the performance of these three parsers on a development set from WSJ (section 0), we get the following F-scores.[5]

Parser	**WSJ (sec. 0) Accuracy (F-scores)**
P_{WSJ}	88.25
P_{News}	83.00
$\text{P}_{WSJ-News}$	88.00

Consider now that we are interested in comparing the parsing accuracy of these parsers on a domain completely different from WSJ. The ranking P_{WSJ}>$\text{P}_{WSJ-News}$>P_{News}, given by the evaluation above, provides some guidance, but is this guidance accurate? The intuition here is that the information that we already have about the new domain of interest (which implicitly appears in texts extracted from this domain), can be used to better guide this decision. Our predictor is able to capitalize on this information, and provide domain-informed guidance for choosing the most accurate parser to use with the new data, which in this case relates to choosing the best training strategy for the parser $\mathcal{P}$. If we consider as our domain of interest, news stories from Xinhua News Agency, then using our predictor on a chunk of 1866 sentences from this domain gives the F-scores shown in the second column of Table 6.

[5]Because of tokenization differences between the different treebanks involved in these experiments, we have to adopt a tokenization scheme different from the one used in the Penn Treebank, and therefore the F-scores, albeit in the same range, are not directly comparable with the ones in the parsing literature.

Parser	**Xinhua News Prediction (F-scores)**	**Xinhua News Accuracy (F-scores)**
P_{WSJ}	85.1	79.14
P_{News}	87.0	84.84
$\text{P}_{WSJ-News}$	89.4	85.14

Table 6: Performance of predictor on the Xinhua News domain, compared with actual F-scores.

As with the previous experiments, we can compute the actual PARSEVAL F-scores (using gold-standard) for this particular 1866-sentence test set, as it happens to be part of the English Chinese Translation Treebank (LDC, 2007). These F-score figures are shown in the third column of Table 6. As these results show, for this particular domain the correct ranking is $\text{P}_{WSJ-News}$>P_{News}>P_{WSJ}, which is exactly the ranking predicted by our method, without the aid of gold-standard trees.

We observe that even though the system predicts the ranking correctly, the predictions in the Xinhua News domain might not be as accurate in comparison to the predictions on Brown corpus (predicted F-score = 86.96, actual F-score = 86.34). One possible reason for this lower accuracy is that we use the same prediction model without optimizing for the particular parser on which we wish to make predictions. Still, the model was able to make distinctions between multiple parsers for the ranking task correctly, and decide the best parser to use with the given data. We believe this to be useful in typical NLP applications which use parsing as a component, and where making the right choice between different parsers can affect the end-to-end accuracy of the system.

7 Conclusion

The steady advances in statistical parsing over the last years have taken this technology to the point where it is accurate enough to be useful in a variety of natural language applications. However, due to large variations in the characteristics of the domains for which these applications are developed, estimating parsing accuracy becomes more involved than simply taking for granted accuracy estimates done on a certain well-studied domain, such as WSJ. As the results in this paper show, it is possible to take into account these variations in the domain characteristics (encoded in our predictor as text-based, syntax-based, and agreement-based features)—to make better predictions about the accuracy of certain statistical parsers (and under different training scenarios), instead of relying on accuracy estimates done on a standard domain. We have provided a mechanism to incorporate these domain variations for making predictions about parsing accuracy, without the costly requirement of creating human annotations for each of the domains of interest. The experiments shown in the paper were limited to readily available statistical parsers (which are widely deployed in a number of applications), and certain domains/genres (because of ready access to gold-standard data on which we could verify predictions). However, the features we use in our predictor are independent of the particular type of parser or domain, and the same technique could be applied for making predictions on other parsers as well.

There are many avenues for future work opened up by the work presented here. The accuracy of the predictor can be further improved by incorporating more complex syntax-based features and multiple-agreement features. Moreover, rather than predicting an intrinsic metric such as the PARSEVAL F-score, the metric that the predictor learns to predict can be chosen to better fit the final metric on which an end-to-end system is measured, in the style of (Och, 2003). The end-result is a finely-tuned tool for predicting the impact of various parser design decisions on the overall quality of a system.

A Structured Vector Space Model for Word Meaning in Context

Abstract

We address the task of computing vector space representations for the meaning of word occurrences, which can vary widely according to context. This task is a crucial step towards a robust, vector-based compositional account of sentence meaning. We argue that existing models for this task do not take syntactic structure sufficiently into account.

We present a novel *structured vector space* model that addresses these issues by incorporating the selectional preferences for words' argument positions. This makes it possible to integrate syntax into the computation of word meaning in context. In addition, the model performs at and above the state of the art for modeling the contextual adequacy of paraphrases.

1 Introduction

Semantic spaces are a popular framework for the representation of word meaning, encoding the meaning of lemmas as high-dimensional vectors. In the default case, the components of these vectors measure the co-occurrence of the lemma with context features over a large corpus. These vectors are able to provide a robust model of *semantic similarity* that has been used in NLP (Salton et al., 1975; McCarthy and Carroll, 2003; Manning et al., 2008) and to model experimental results in cognitive science (Landauer and Dumais, 1997; McDonald and Ramscar, 2001). Semantic spaces are attractive because they provide a model of word meaning that is independent of dictionary senses and their much-discussed problems (Kilgarriff, 1997; McCarthy and Navigli, 2007).

In a default semantic space as described above, each vector represents one *lemma*, averaging over all its possible usages (Landauer and Dumais, 1997; Lund and Burgess, 1996). Since the meaning of words can vary substantially between occurrences (e.g., for polysemous words), the next necessary step is to characterize the meaning of individual *words in context*.

There have been several approaches in the literature (Smolensky, 1990; Schütze, 1998; Kintsch, 2001; McDonald and Brew, 2004; Mitchell and Lapata, 2008) that compute meaning in context from lemma vectors. Most of these studies phrase the problem as one of vector composition: The meaning of a target occurrence a in context b is a single new vector c that is a function (for example, the centroid) of the vectors: $c = a \odot b$.

The context b can consist of as little as one word, as shown in Example (1). In (1a), the meaning of *catch* combined with *ball* is similar to *grab*, while in (1b), combined with *disease*, it can be paraphrased by *contract*. Conversely, verbs can influence the interpretation of nouns: In (1a), *ball* is understood as a spherical object, and in (1c) as a dancing event.

(1) a. catch a ball
  b. catch a disease
  c. attend a ball

In this paper, we argue that models of word meaning relying on this procedure of vector composition are limited both in their scope and scalability. The underlying shortcoming is a failure to consider *syntax* in two important ways.

The syntactic relation is ignored. The first problem concerns the manner of vector composition, which ignores the relation between the target a and its context b. This relation can have a decisive influence on their interpretation, as Example (2) shows:

(2) a. a horse draws
 b. draw a horse

In (2a), the meaning of the verb *draw* can be paraphrased as *pull*, while in (2b) it is similar to *sketch*. This difference in meaning is due to the difference in relation: in (2a), *horse* is the subject, while in (2b) it is the object. On the modeling side, however, a vector combination function that ignores the relation will assign the same representation to (2a) and (2b). Thus, existing models are systematically unable to capture this class of phenomena.

Single vectors are too weak to represent phrases. The second problem arises in the context of the important open question of how semantic spaces can "scale up" to provide interesting meaning representations for entire sentences. We believe that the current vector composition methods, which result in a single vector c, are not informative enough for this purpose. One proposal for "scaling up" is to straightforwardly interpret $c = a \odot b$ as the *meaning of the phrase* $a + b$ (Kintsch, 2001; Mitchell and Lapata, 2008). The problem is that the vector c can only encode a fixed amount of structural information if its dimensionality is fixed, but there is no upper limit on sentence length, and hence on the amount of structure to be encoded. It is difficult to conceive how c could encode *deeper* semantic properties, like predicate-argument structure (distinguishing "dog bites man" and "man bites dog"), that are crucial for sentence-level semantic tasks such as the recognition of textual entailment (Dagan et al., 2006). An alternative approach to sentence meaning would be to use the vector space representation only for representing word meaning, and to represent sentence structure separately. Unfortunately, present models cannot provide this grounding either, since they compute a single vector c that provides the same representations for *both* the meanings of a and b in context.

In this paper, we propose a new, *structured vector space* model for word meaning (SVS) that addresses these problems. A SVS representation of a lemma comprises several vectors representing the word's lexical meaning as well as the *selectional preferences* that it has for its argument positions. The meaning of word a in context b is computed by combining a with b's selectional preference vector specific to the relation between a and b, addressing the first problem above. In an expression $a + b$, the meanings of a and b in this context are computed as two separate vectors a' and b'. These vectors can then be combined with a representation of the structure's expression (e.g., a parse tree), to address the second problem discussed above. We test the SVS model on the task of recognizing contextually appropriate paraphrases, finding that SVS performs at and above the state-of-the-art.

Plan of the paper. Section 2 reviews related work. Section 3 presents the SVS model for word meaning in context. Sections 4 to 6 relate experiments on the paraphrase appropriateness task.

2 Related Work

In this section we give a short overview over existing vector space based approaches to computing word meaning in context.

General context effects. The first category of models aims at integrating the widest possible range of context information without recourse to linguistic structure. The best-known work in this category is Schütze (1998). He first computes "first-order" vector representations for word meaning by collecting co-occurrence counts from the entire corpus. Then, he determines "second-order" vectors for individual word instances in their context, which is taken to be a simple surface window, by summing up all first-order vectors of the words in this context. The resulting vectors form sense clusters.

McDonald and Brew (2004) present a similar model. They compute the expectation for a word w_i in a sequence by summing the first-order vectors for the words w_1 to w_{i-1} and showed that the distance between expectation and first-order vector for w_i correlates with human reading times.

Predicate-argument combination. The second category of prior studies concentrates on contexts consisting of a single word only, typically modeling the combination of a predicate p and an argument a. Kintsch (2001) uses vector representations of p and a to identify the set of words that are similar to both p and a. After this set has been narrowed down in a self-inhibitory network, the meaning of the predicate-argument combination is obtained by computing the centroid of its members' vectors. The procedure does not take the relation between p and a into account.

Mitchell and Lapata (2008) propose a framework to represent the meaning of the combination $p + a$ as a function f operating on four components:

$$c = f(p, a, R, K) \quad (3)$$

R is the relation holding between p and a, and K additional knowledge. This framework allows sensitivity to the relation. However, the concrete instantiations that Mitchell and Lapata consider disregards K and R, thus sharing the other models' limitations. They focus instead on methods for the direct combination of p and a: In a comparison between component-wise addition and multiplication of p and a, they find far superior results for the multiplication approach.

Tensor product-based models. Smolensky (1990) uses tensor product to combine two word vectors a and b into a vector c representing the expression $a+b$. The vector c is located in a very high-dimensional space and is thus capable of encoding the structure of the expression; however, this makes the model infeasible in practice, as dimensionality rises with every word added to the representation. Jones and Mewhort (2007) represent lemma meaning by using circular convolution to encode n-gram co-occurrence information into vectors of fixed dimensionality. Similar to Brew and McDonald (2004), they predict most likely next words in a sequence, without taking syntax into account.

Kernel methods. One of the main tests for the quality of models of word meaning in context is the ability to predict the appropriateness of paraphrases in given a context. Typically, a paraphrase applies only to some senses of a word, not all, as can be seen in the paraphrases "grab" and "contract" of "catch". Vector space models generally predict paraphrase appropriateness based on the similarity between vectors. This task can also be addressed with kernel methods, which project items into an implicit feature space for efficient similarity computation. Consequently, vector space methods and kernel methods have both been used for NLP tasks based on similarity, notably Information Retrieval and Textual Entailment. Nevertheless, they place their emphasis on different types of information. Current kernels are mostly tree kernels that compare syntactic structure, and use semantic information mostly for smoothing syntactic similarity (Moschitti and Quarteroni, 2008). In contrast, vector-space models focus on the interaction between the lexical meaning of words in composition.

3 A structured vector space model for word meaning in context

In this section, we define the structured vector space (SVS) model of word meaning.

The main intuition behind our model is to view the interpretation of a word in context as guided by *expectations about typical events.* For example, in (1a), we assume that upon hearing the phrase "catch a ball", the hearer will interpret the meaning of "catch" to match *typical actions that can be performed with a ball.* Similarly, the interpretation of "ball" will reflect the hearer's expectations about *typical things that can be caught.* This move to include typical arguments and predicates into a model of word meaning can be motivated both on cognitive and linguistic grounds.

In cognitive science, the central role of expectations about typical events for human language processing is well-established. Expectations affect reading times (McRae et al., 1998), the interpretation of participles (Ferretti et al., 2003), and sentence processing generally (Narayanan and Jurafsky, 2002; Padó et al., 2006). Expectations exist both for verbs and nouns (McRae et al., 1998; McRae et al., 2005).

In linguistics, expectations, in the form of *selectional restrictions* and *selectional preferences*, have long been used in semantic theories (Katz and Fodor, 1964; Wilks, 1975), and more recently induced from corpora (Resnik, 1996; Brockmann and Lapata, 2003). Attention has mostly been limited to selectional preferences of verbs, which have been used for example for syntactic disambiguation (Hindle and Rooth, 1993), word sense disambiguation (McCarthy and Carroll, 2003) and semantic role labeling (Gildea and Jurafsky, 2002). Recently, a vector-spaced model of selectional preferences has been proposed that computes the typicality of an argument simply through similarity to previously seen arguments (Erk, 2007; Padó et al., 2007).

We first present the SVS model of word meaning

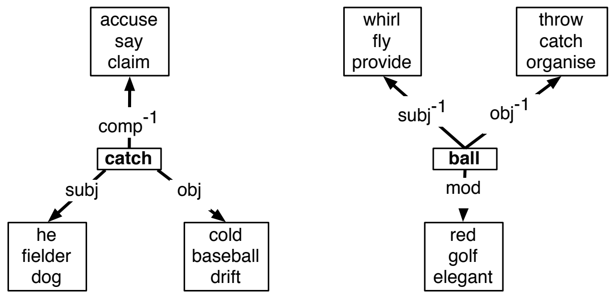

Figure 1: Structured meaning representations for noun *ball* and verb *catch*: lexical information plus expectations

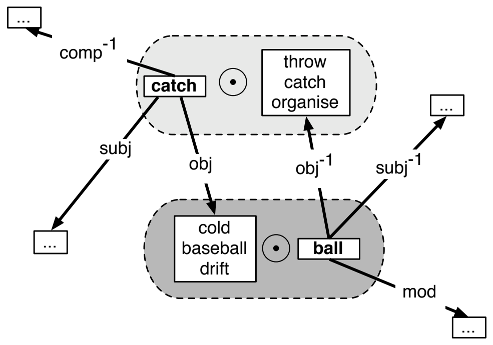

Figure 2: Combining predicate and argument via relation-specific semantic expectations

that integrates lexical information with selectional preferences. Then, we show how the SVS model provides a new way of computing meaning in context.

Representing lemma meaning. We abandon the traditional choice of representing word meaning as a single vector. Instead, we encode each word as a combination of (a) one vector that models the *lexical* meaning of the word, and (b) a set of vectors, each of which represents the *semantic expectations/selectional preferences* for one particular relation that the word supports.[1]

The idea is illustrated in Fig. 1. In the representation of the verb *catch*, the central square stands for the lexical vector of *catch* itself. The three arrows link it to *catch*'s preferences for its subjects ($subj$), its objects (obj), and for verbs for which it appears as a complement ($comp^{-1}$). The figure shows the selectional preferences as word lists for readability; in practice, each selectional preference is a single vector (cf. Section 4). Likewise, *ball* is represented by one vector for *ball* itself, one for *ball*'s preferences for its modifiers (mod), one vector for the verbs of which it is a subject ($subj^{-1}$), and one for the verbs of which is an object (obj^{-1}).

This representation includes selectional preferences (like $subj$, obj, mod) exactly parallel to *inverse* selectional preferences ($subj^{-1}$, obj^{-1}, $comp^{-1}$). To our knowledge, preferences of the latter kind have not been studied in computational linguistics. However, their existence is supported in psycholinguistics by priming effects from nouns to typical verbs (McRae et al., 2005).

Formally, let D be a vector space (the set of possible vectors), and let $\mathcal{R}$ be some set of relation labels. In the *structured vector space (*SVS*)* model, we represent the meaning of a lemma w as a triple

$$w = (v, R, R^{-1})$$

where $v \in D$ is a lexical vector describing the word w itself, $R : \mathcal{R} \to D$ maps each relation label onto a vector that describes w's selectional preferences, and $R^{-1} : \mathcal{R} \to D$ maps from role labels to vectors describing inverse selectional preferences of w. Both R and R^{-1} are partial functions. For example, the direct object preference would be undefined for intransitive verbs.

Computing meaning in context. The SVS model of lemma meaning permits us to compute the meaning of a word a in the context of another word b in a new way, via their selectional preferences. Let (v_a, R_a, R_a^{-1}) and (v_b, R_b, R_b^{-1}) be the representations of the two words, and let $r \in \mathcal{R}$ be the relation linking a to b. Then, we define the meaning of a and b in this context as a pair (a', b') of vectors, where a' is the meaning of a in the context of b, and b' the meaning of b in the context of a:

$$\begin{aligned} a' &= \left(v_a \odot R_b^{-1}(r), R_a - \{r\}, R_a^{-1}\right) \\ b' &= \left(v_b \odot R_a(r), R_b, R_b^{-1} - \{r\}\right) \end{aligned} \quad (4)$$

where $v_1 \odot v_2$ is a direct vector combination function as in traditional models, e.g. addition or component-wise multiplication. If either $R_a(r)$ or $R_b^{-1}(r)$ are not defined, the combination fails. Afterwards, the argument position r is considered filled, and is deleted from R_a and R_b^{-1}.

[1]We do not commit to a particular set of relations; see the discussion at the end of this section.

Figure 2 illustrates this procedure on the representations from Figure 1. The dotted lines indicate that the lexical vector for *catch* is combined with the inverse object preference of *ball*. Likewise, the lexical vector for *ball* is combined with the object preference vector of *catch*.

Note that our procedure for computing meaning in context can be expressed within the framework of Mitchell and Lapata (Eq. (3)). We can encode the expectations of a and b as additional knowledge K. The combined representation c is the pair (a', b') that is computed according to our model (Eq. (4)).

The SVS scheme we have proposed incorporates syntactic information in a more general manner than previous models, and thus addresses the issues we have discussed in Section 1. Since the representation retains individual selectional preferences for all relations, combining the same words through different relations can (and will in general) result in different adapted representations. For instance, in the case of Example (2), we would expect the inverse subject preference of *horse* ("things that a horse typically does") to push the lexical vector of *draw* into the direction of *pulling*, while its inverse object preference ("things that are done to horses") suggest a different interpretation.

Rather than yielding a single, joint vector for the whole expression, our procedure for computing meaning in context results in one context-adapted meaning representation per word, similar to the output of a WSD system. As a consequence, our model can be combined with any formalism representing the structure of an expression. (The formalism used then determines the set $\mathcal{R}$ of relations.) For example, combining SVS with a dependency tree would yield a tree in which each node is labeled by a SVS tuple that represents the word's meaning in context.

4 Experimental setup

This section provides the background to the following experimental evaluation of SVS, including parameters used for computing the SVS representations that will be used in the experiments.

4.1 Experimental rationale

In this paper, we evaluate the SVS model against the task of predicting, given a predicate-argument pair, how appropriate a paraphrase (of either the predicate or the argument) is in that context. We perform two experiments that both use the paraphrase task, but differ in their emphasis. Experiment 1 replicates an existing evaluation against human judgments. This evaluation uses synthetic dataset, limited to one particular construction, and constructed to provide maximally distinct paraphrase candidates. Experiment 2 considers a broader class of constructions along with annotator-generated paraphrase candidates that are not screened for distinctness. In both experiments, we compare the SVS model against the state-of-the-art model by Mitchell and Lapata 2008 (henceforth M&L; cf. Sec. 2 for model details).

4.2 Parameter choices

Vector space. In our parameterization of the vector space, we largely follow M&L because their model has been rigorously evaluated and found to outperform a range of other models.

Our first space is a traditional "bag-of-words" vector space (BOW, (Lund and Burgess, 1996)). For each pair of a target word and context word, the BOW space records a function of their co-occurrence frequency within a surface window of size 10. The space is constructed from the British National Corpus (BNC), and uses the 2,000 most frequent context words as dimensions.

We also consider a "dependency-based" vector space (SYN, (Padó and Lapata, 2007)). In this space, target and context words have to be linked by a "valid" dependency path in a dependency graph to count as co-occurring.[2] This space was built from BNC dependency parses obtained from Minipar (Lin, 1993).

For both spaces, we used pre-experiments to compare two methods for the computation of vector components, namely raw co-occurrence counts, the standard model, and the pointwise mutual information (PMI) definition employed by M&L.

Selectional preferences. We use a simple, knowledge-lean representation for selectional preferences inspired by Erk (2007), who models selectional preference through similarity to seen filler vectors $\vec{v}_a$: We compute the selectional preference vector for word b and relation r as the weighted

[2]More specifically, we used the minimal context specification and plain weight function. See Padó and Lapata (2007).

centroid of seen filler vectors $\vec{v}_a$. We collect seen fillers from the Minipar-parse of the BNC.

Let $f(a, r, b)$ denote the frequency of a occurring in relation r to b in the parsed BNC, then

$$R_b(r)_{\text{SELPREF}} = \sum_{a:f(a,r,b)>0} f(a, r, b) \cdot \vec{v}_a \quad (5)$$

We call this base model SELPREF. We will also study two variants of SELPREF, based on two different hypotheses about what properties of the selectional preferences are particularly important for meaning adaption. The first model aims specifically at alleviating noise introduced by infrequent fillers, a common problem in data-driven approaches. It only uses fillers seen more often than a threshold θ. We call this model SELPREF-CUT:

$$R_b(r)_{\text{SELPREF-CUT}} = \sum_{a:f(a,r,b)>\theta} f(a, r, b) \cdot \vec{v}_a \quad (6)$$

Our second variant again aims at alleviating noise, but noise introduced by low-valued dimensions rather than infrequent fillers. It achieves this by taking each component of the selectional preference vector to the nth power. In this manner, dimensions with high counts are further inflated, while dimensions with low counts are depressed.[3] This model, SELPREF-POW, is defined as follows: If $R_b(r)_{\text{SELPREF}} = \langle v_1, \ldots, v_m \rangle$,

$$R_b(r)_{\text{SELPREF-POW}} = \langle v_1^n, \ldots, v_m^n \rangle \quad (7)$$

The inverse selectional preferences R_b^{-1} are defined analogously for all three model variants. We instantiate the vector combination function $\odot$ as component-wise multiplication, following M&L.

Baselines and significance testing. All tasks that we consider below involve judgments for the meaning of a word a in the context of a word b. A first baseline that every model must beat is simply using the original vector for a. We call this baseline "target only". Since we assume that the selectional preferences of b model the expectations for a, we use b's selectional preference vector for the given relation as a second baseline, "selpref only".

[3]Since we focus on the size-invariant cosine similarity, the use of this model does not require normalization.

verb	subject	landmark	sim	judgment
slump	shoulder	slouch	high	7
slump	shoulder	decline	low	2
slump	value	slouch	low	3
slump	value	decline	high	7

Figure 3: Experiment 1: Human similarity judgements for subject-verb pair with high- and low-similarity landmarks

Differences between the performance of models were tested for significance using a stratified shuffling-based randomization test (Yeh, 2000).[4].

5 Exp. 1: Predicting similarity ratings

In our first experiment, we attempt to predict human similarity judgments. This experiment is a replication of the evaluation of M&L on their dataset[5].

Dataset. The M&L dataset comprises a total of 3,600 human similarity judgements for 120 experimental items. Each item, as shown in Figure 3, consists of an intransitive verb and a subject noun that are combined with a "landmark", a synonym of the verb that is chosen to be either similar or dissimilar to the verb in the context of the given subject.

The dataset was constructed by extracting pairs of subjects and intransitive verbs from a parsed version of the BNC. Each item was paired with two landmarks, chosen to be as dissimilar as possible according to a WordNet similarity measure. All nouns and verbs were subjected to a pretest, where only those with highly significant variations in human judgments across landmarks were retained.

For each item of the final dataset, judgements on a 7-point scale were elicited. For example, judges considered the compatible landmark "slouch" to be much more similar to "shoulder slumps" than the incompatible landmark "decline". In Figure 3, the column *sim* shows whether the experiment designers considered the respective landmark to have high or low similarity to the verb, and the column *judgment* shows a participant's judgments.

Experimental procedure. We used cosine to compute similarity to the lexical vector of the landmark.

[4]The software is available at `http://www.nlpado.de/~sebastian/sigf.html`.

[5]We thank J. Mitchell and M. Lapata for providing their data.

Model	high	low	ρ

Upper bound	–	–	0.4

Table 1: Experiment 1: Mean cosine similarity for items with high- and low-similarity landmarks; correlation with human judgements (ρ). (**: p $<$ 0.01)

"Target only" compares the landmark against the lexical vector of the verb, and "selpref only" compares it to the noun's $subj^{-1}$ preference. For the M&L model, the comparison is to the combined lexical vectors of verb and noun. For our models SELPREF, SELPREF-CUT and SELPREF-POW, we combine the verb's lexical vector with the $subj^{-1}$ preference of the noun. We used a held-out dataset of 10% of the data to optimize the parameters of θ of SELPREF-CUT and n of SELPREF-POW. Vectors with PMI components could model the data, while raw frequency components could not; we report only the former.

We use the same two evaluation scores as M&L: The first score is the average similarity to compatible landmarks (high) and incompatible landmarks (low). The second is Spearman's ρ, a nonparametric correlation coefficient. We compute ρ between individual human similarity scores and our predictions. Based on agreement between human judges, M&L estimate an upper bound ρ of 0.4 for the dataset.

Results and discussion. Table 1 shows the results of Exp. 1 on the test set. In the upper half (BOW), we replicate M&L's main finding that simple component-wise multiplication of the predicate and argument vectors results in a highly significant correlation of $\rho = 0.2$, significantly outperforming both baselines. It is interesting, though, that the $subj^{-1}$ preference itself ("Selpref only") is already highly significantly correlated with the human judgments.

A comparison of the upper half (BOW) with the lower half (SYN) shows that the dependency-based space generally shows better correlation with human judgements. This corresponds to a beneficial effect of syntactic information found for other applications of semantic spaces (Lin, 1998; Padó and Lapata, 2007).

All instances of the SELPREF model show highly significant correlations. SELPREF and SELPREF-CUT show very similar performance. They do better than both baselines in the BOW space; however, in the cleaner SYN space, their performance is numerically lower than using selectional preferences only ($\rho = 0.13$ vs. 0.16). SELPREF-POW is always significantly better than SELPREF and SELPREF-CUT, and shows the best result of all tested models ($\rho = 0.27$, BOW space). The performance is somewhat lower in the SYN space ($\rho = 0.22$). However, this difference, and the difference to the best M&L model at $\rho = 0.24$, are not statistically significant.

The SVS model computes meaning in context by combining a word's lexical representation with the preference vector of its context. In this, it differs from previous models, including that by M&L, which used what we have been calling "direct combination". So it is important to ask to what extent this difference in method translate to a difference in predictions. We analyzed this by measuring the similarity by the nouns' lexical vectors, used by direct combination methods, and their inverse subject preferences, which SVS uses. The result is shown in the first column in Table 2, computed as mean cosine similarities and standard deviations between noun vectors and selectional preferences. The table shows that these vectors have generally low similarity, which is further

Model	lex. vector	obj^{-1} selpref
SELPREF	0.23 (0.09)	0.88 (0.07)
SELPREF-CUT (10)	0.20 (0.10)	0.72 (0.18)
SELPREF-POW (30)	0.03 (0.08)	0.52 (0.48)

Table 2: Experiment 1: Average similarity (and standard deviation) between the inverse subject preferences of a noun and (left) its lexical vector and (right) inverse object preferences vector (cosine similarity in SYN space)

reduced by applying cutoff and potentiation. Thus, the predictions of SVS will differ from those of direct combination models like M&L.

A related question is whether syntax-aware vector combination makes a difference: Does the model encode different expectations for different syntactic relations (cf. Example 2)? The second column of Table 2 explores this question by comparing inverse selectional preferences for the subject and object slots. We observe that the similarity is very high for raw preferences, but becomes lower when noise is eliminated. Since the SELPREF-POW model performed best in our evaluation, we read this as evidence that potentiation helps to suppress noise introduced by mis-identified subject and object fillers.

In Experiment 1, all experimental items were verbs, which means that all disambiguation was done through inverse selectional preferences. As inverse selectional preferences are currently largely unexplored, it is interesting to note that the evidence that they provide for the paraphrase task is as strong as that of the context nouns themselves.

6 Exp. 2: Ranking paraphrases

This section reports on a second, more NLP-oriented experiment whose task is to distinguish between appropriate and inappropriate paraphrases on a broader range of constructions.

Dataset. For this experiment, we use the SemEval-1 *lexical substitution* (lexsub) dataset (McCarthy and Navigli, 2007), which contains 10 instances each of 200 target words in sentential contexts, drawn from Sharoff's (2006) English Internet Corpus. Contextually appropriate paraphrases for each instance of each target word were elicited from up to 6 participants. Fig. 4 shows two instances for the verb *to work*. The distribution over paraphrases can be seen as a characterization of the target word's meaning in each context.

Experimental procedure. In this paper, we predict appropriate paraphrases solely on the basis of a single context word that stands in a direct predicate-argument relation to the target word. We extracted all instances from the lexsub test data with such a relation. After parsing all sentences with verbal and nominal targets with Minipar, this resulted in three

Sentence	Substitutes
By asking people who **work** there, I have since determined that he didn't. (# 2002)	be employed 4; labour 1
Remember how hard your ancestors **worked**. (# 2005)	toil 4; labour 3; task 1

Figure 4: Lexical substitution example items for "work"

sets of sentences: (a), target intransitive verbs with noun subjects (V-SUBJ, 48 sentences); (b), target transitive verbs with noun objects (V-OBJ, 213 sent.); and (c), target nouns occurring as objects of verbs (N-OBJ, 102 sent.).[6] Note that since we use only part of the lexical substitution dataset in this experiment, a direct comparison with results from the SemEval task is not possible.

As in the original SemEval task, we phrase the task as a ranking problem. For each target word, the paraphrases given for all 10 instances are pooled. The task is to rank the list for each item so that appropriate paraphrases (such as "be employed" for # 2002) rank higher than paraphrases not given (e.g., "toil").

Our model ranks paraphrases by their similarity to the following combinations (Eq. (4)): for V-SUBJ, verb plus the noun's $subj^{-1}$ preferences; for V-OBJ, verb plus the noun's obj^{-1} preferences; and for N-OBJ, the noun plus the verb's obj preferences. Our comparison model, M&L, ranks all paraphrases by their similarity to the direct noun-verb combination.

To avoid overfitting, we consider only the two models that performed optimally in in the SYN space in Experiment 1 (SELPREF-POW with n=30 and M&L). However, since we found that vectors with raw frequency components could model the data, while PMI components could not, we only report the former.

For evaluation, we adopt the SemEval "out of ten" precision metric $\mathrm{P_{OOT}}$. It uses the model's ten top-ranked paraphrases as its guesses for appropriate paraphrases. Let G_i be the gold paraphrases for item i, M_i the model's top ten paraphrases for i, and $f(s,i)$ the frequency of s as paraphrase for i:

$$\mathrm{P_{OOT}} = 1/|I| \sum_i \frac{\sum_{s \in M_i \cap G_i} f(s,i)}{\sum_{s \in G_i} f(s,i)} \qquad (8)$$

McCarthy and Navigli propose this metric for the

[6]The specification of this dataset will be made available.

Model	V-SUBJ	V-OBJ	N-OBJ
Target only	47.9	47.4	49.6
Selpref only	54.8	51.4	55.0
M&L	50.3	52.0	53.4
SELPREF-POW, n=30	**63.1**	**55.8**	**56.9**

Table 3: Experiment 2: Mean "out of ten" precision (P_{OOT})

dataset for robustness. Due to the sparsity of paraphrases, a metric that considers fewer guesses leads to artificially low results when a "good" paraphrase was not mentioned by the annotators by chance but is ranked highly by a model.

Results and discussion. Table 6 shows the mean out-of-ten precision for all models. The behavior is fairly uniform across all three datasets. Unsurprisingly, "target only", which uses the same ranking for all instances of a target, yields the worst results.[7]

M&L's direct combination model outperforms "target only" significantly ($p < 0.05$). However, on both the V-SUBJ and the N-OBJ the "selpref only" baseline does better than direct combination. The best results on all datasets are obtained by SELPREF-POW. The difference between SELPREF-POW and the "target only" baseline is highly significant ($p < 0.01$). The difference to M&L's model is significant at $p = 0.05$.

We interpret these results as encouraging evidence for the usefulness of selectional preferences for judging substitutability in context. Knowledge about the selectional preferences of a single context word can already lead to a significant improvement in precision. We find this overall effect even though the word is not informative in all cases. For instance, the subject of item 2002 in Fig. 4, "who", presumably helps little in determining the verb's context-adapted meaning.

It is interesting that the improvement of SELPREF-POW over "selpref only" is smallest for the N-OBJ dataset (1.9% P_{OOT}). N-OBJ uses selectional preferences for nouns that may fill the direct object position, , while V-SUBJ and V-OBJ use inverse selectional preferences for verbs (cf. the two graphs in Fig. 1).

[7]"Target only" still does very much better than a random baseline, which performs at 22% P_{OOT}.

7 Conclusion

In this paper, we have considered semantic space models that can account for the meaning of word occurrences in context. Arguing that existing models do not sufficiently take syntax into account, we have introduced the new structured vector space (SVS) model of word meaning. In addition to a vector representing a word's lexical meaning, it contains vectors representing the word's selectional preferences. These selectional preferences play a central role in the computation of meaning in context.

We have evaluated the SVS model on two datasets on the task of predicting the felicitousness of paraphrases in given contexts. On the M&L dataset, SVS outperforms the state-of-the-art model of M&L, though the difference is not significant. On the Lexical Substitution dataset, SVS significantly outperforms the state-of-the-art. This is especially interesting as the Lexical Substitution dataset, in contrast to the M&L data, uses "realistic" paraphrase candidates that are not necessarily maximally distinct.

The most important limitation of the evaluation that we have given in this paper is that we have only considered single words as context. Our next step will be to integrate information from multiple relations (such as both the subject and object positions of a verb) into the computation of context-specific meaning. Our eventual aim is a model that can give a compositional account of a word's meaning in context, where all words in an expression disambiguate one another according to the relations between them.

We will explore the usability of vector space models of word meaning in NLP applications, formulated as the question of how to perform inferences on them in the context of the Textual Entailment task (Dagan et al., 2006). Paraphrase-based inference rules play a large role in several recent approaches to Textual Entailment (e.g. Szpektor et al (2008)); appropriateness judgments of paraphrases in context, the task of Experiments 1 and 2 above, can be viewed as testing the applicability of these inferences rules.

Abstract

We consider a parsed text corpus as an instance of a labelled directed graph, where nodes represent words and weighted directed edges represent the syntactic relations between them. We show that graph walks, combined with existing techniques of supervised learning, can be used to derive a task-specific word similarity measure in this graph. We also propose a new *path-constrained* graph walk method, in which the graph walk process is guided by high-level knowledge about meaningful edge sequences (paths). Empirical evaluation on the task of named entity coordinate term extraction shows that this framework is preferable to vector-based models for small-sized corpora. It is also shown that the path-constrained graph walk algorithm yields both performance and scalability gains.

1 Introduction

Graph-based similarity measures have been used for a variety of language processing applications. In this paper we assume directed graphs, where typed nodes denote entities and labelled directed and weighted edges denote the relations between them. In this framework, graph walks can be applied to draw a measure of similarity between the graph nodes. Previous works have applied graph walks to draw a notion of semantic similarity over such graphs that were carefully designed and manually tuned, based on WordNet reations (Toutanova et al., 2004; Collins-Thompson and Callan, 2005; Hughes and Ramage, 2007).

While these and other researchers have used WordNet to evaluate similarity between words, there has been much interest in extracting such a measure from text corpora (e.g., (Snow et al., 2005; Padó and Lapata, 2007)). In this paper, we suggest processing dependency parse trees within the general framework of directed labelled graphs. We construct a graph that directly represents a corpus of structured (parsed) text. In the suggested graph scheme, nodes denote words and weighted edges represent the dependency relations between them. We apply graph walks to derive an inter-word similarity measure. We further apply learning techniques, adapted to this framework, to improve the derived corpus-based similarity measure.

The learning methods applied include existing learning techniques, namely edge weight tuning, where weights are associated with the edge types, and discriminative reranking of graph nodes, using features that describe the possible paths between a graph node and the initial "query nodes" (Minkov and Cohen, 2007).

In addition, we outline in this paper a novel method for learning *path-constrained* graph walks. While reranking allows use of high-level features that describe properties of the traversed paths, the suggested algorithm incorporates this information in the graph walk process. More specifically, we allow the probability flow in the graph to be conditioned on the history of the walk. We show that this method results in improved performance as it directs probability flow to meaningful paths. In addition, it leads

[*]Current address: Nokia Research Center Cambridge, Cambridge, MA 02142, USA.

to substantial gains in terms of runtime performance.

The graph representation and the set of learning techniques suggested are empirically evaluated on the task of *coordinate term* extraction[1] from small to moderately sized corpora, where we compare them against vector-based models, including a state-of-the-art syntactic distributional similarity method (Padó and Lapata, 2007). It is shown that the graph walk based approach gives preferable results for the smaller datasets (and comparable otherwise), where learning yields significant gains in accuracy.

There are several contributions of this paper. First, we represent dependency-parsed corpora within a general graph walk framework, and derive inter-word similarity measures using graph walks and learning techniques available in this framework. To our knowledge, the application of graph walks to parsed text in general, and to the extraction of coordinate terms in particular, is novel. Another main contribution of this paper is the path-constrained graph walk variant, which is a general learning technique for calculating the similarity between graph nodes in directed and labelled graphs.

Below we first outline our proposed scheme for representing a dependency-parsed text corpus as a graph, and provide some intuitions about the associated similarity metric (Section 2). We then give an overview of the graph-walk based similarity metric (Section 3), as well as the known edge weight tuning and reranking learning techniques (Section 4). We next present the proposed algorithm of path-constrained graph walks (Section 5). The paper proceeds with a review of related work (Section 6), a discussion of the coordinate term extraction task, empirical evaluation and our conclusions (Sections 7-9).

2 Representing a Corpus as a Graph

A typed dependency parse tree consists of directed links between words, where dependencies are labelled with the relevant grammatical relation (e.g., *nominal subject*, *indirect object* etc.). We suggest representing a text corpus as a connected graph of dependency structures, according to the scheme shown in Figure 1. The graph shown in the figure

[1]In particular, we focus on the extraction of named entity classes.

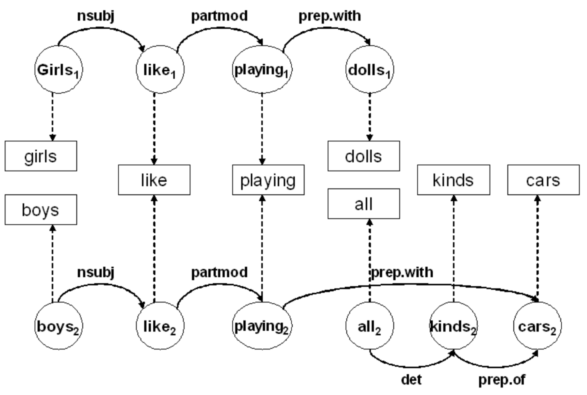

Figure 1: The suggested graph schema, demonstrated for a two-sentence corpus.

includes the dependency analysis of two sentences: “boys like playing with all kinds of cars”, and “girls like playing with dolls”. In the graph, each word mention is represented as a node, which includes the index of the sentence in which it appears, as well as its position within the sentence. Word mentions are marked as circles in the figure. The “type” of each word – henceforth a *term* node – is denoted by a square in the figure. Each word mention is linked to the corresponding term; for example, the nodes “like$_1$” and “like$_2$” represent distinct word mentions and both nodes are linked to the *term* “like”. For every edge in the graph, we add another edge in the opposite direction (not shown in the figure); for example, an inverse edge exists from “like$_1$” to “girls$_1$” with an edge labelled as “nsubj-inv”. The resulting graph is highly interconnected and cyclic.

We will apply graph walks to derive an extended measure of similarity, or relatedness, between word *terms* (as defined above). For example, starting from the term “girls”, we will reach the semantically related term “boys” via the following two paths:

(1) girls $\xrightarrow{mention}$ girls1 $\xrightarrow{nsubj}$ like1 $\xrightarrow{as-term}$ like $\xrightarrow{mention}$ like2 $\xrightarrow{nsubj-inverse}$ boys2 $\xrightarrow{as-term}$ boys

(2) girls $\xrightarrow{mention}$ girls1 $\xrightarrow{nsubj}$ like1 $\xrightarrow{partmod}$ playing1 $\xrightarrow{as-term}$ playing $\xrightarrow{mention}$ playing2 $\xrightarrow{partmod-inverse}$ like2 $\xrightarrow{nsubj-inverse}$ boys2 $\xrightarrow{as-term}$ boys .

Intuitively, in a graph representing a large corpus, terms that are more semantically related will be linked by a larger number of connecting paths. In addition, shorter connecting paths may be in general more meaningful. In the next section we show that the graph walk paradigm addresses both of these requirements. Further, different edge types, as well as the paths traversed, are expected to have varying importance in different types of word similarity (for example, verbs and nouns are associated with different connectivity patterns). These issues are addressed using learning.

3 Graph Walks and Similarity Queries

This section provides a quick overview of the graph walk induced similarity measure. For details, the reader is referred to previous publications (e.g., (Toutanova et al., 2004; Minkov and Cohen, 2007)).

In summary, similarity between two nodes in the graph is defined by a weighted graph walk process, where an edge of type ℓ is assigned an edge weight, θ_ℓ, determined by its type.[2] The transition probability of reaching node y from node x over a single time step, $Pr(x \longrightarrow y)$, is defined as the weight of their connecting edge, θ_l, normalized by the total outgoing weight from x. Given these transition probabilities, and starting from an initial distribution V_q of interest (a *query*), we perform a graph walk for a finite number of steps K. Further, at each step of the walk, a proportion γ of the probability mass at every node is emitted. Thus, this model applies exponential decay on path length. The final probability distribution of this walk over the graph nodes, which we denote as R, is computed as follows: $R = \sum_{i=1}^{K} \gamma^i V_q \mathbf{M}^i$, where M is the transition matrix.[3] The answer to a query, V_q, is a list of nodes, ranked by the scores in the final distribution R. In this multi-step walk, nodes that are reached from the query nodes by many shorter paths will be assigned a higher score than nodes connected over fewer longer paths.

4 Learning

We consider a supervised setting, where we are given a dataset of example queries and labels over the graph nodes, indicating which nodes are relevant to which query. For completeness, we describe here two methods previously described by Minkov and Cohen (Minkov and Cohen, 2007): a hill-climbing method that tunes the graph weights; and a reranking method. We also specify the feature set to be used by the reranking method in the domain of parsed text.

4.1 Weight Tuning

There are several motivations for learning the graph weights Θ in this domain. First, some dependency relations – foremost, *subject* and *object* – are in general more salient than others (Lin, 1998; Padó and Lapata, 2007). In addition, dependency relations may have varying importance per different notions of word similarity (e.g., noun vs. verb similarity (Resnik and Diab, 2000)). Weight tuning allows the adaption of edge weights to each *task* (i.e., distribution of queries).

The weight tuning method implemented in this work is based on an error backpropagation hill climbing algorithm (Diligenti et al., 2005). The algorithm minimizes the following cost function:

$$E = \frac{1}{N} \sum_{z \in N} e_z = \frac{1}{N} \sum_{z \in N} \frac{1}{2} (p_z - p_z^{Opt})^2$$

where e_z is the error for a target node z defined as the squared difference between the final score assigned to z by the graph walk, p_z, and some ideal score according to the example's labels, p_z^{Opt}.[4] Specifically, p_z^{Opt} is set to 1 in case that the node z is relevant or 0 otherwise. The error is averaged over a set of example instantiations of size N. The cost function is minimized by gradient descent where the derivative of the error with respect to an edge weight θ_ℓ is derived by decomposing the walk into single time steps, and considering the contribution of each node traversed to the final node score.

4.2 Node Reranking

Reranking of the top candidates in a ranked list has been successfully applied to multiple NLP tasks (Collins, 2002; Collins and Koo, 2005). In essence, discriminative reranking allows the re-ordering of results obtained by methods that perform some form of local search, using features that encode higher level information.

[2]In this paper, we consider either uniform edge weights; or, learn the set of weights Θ from examples.

[3]We tune K empirically and set $\gamma = 0.5$, as in (Minkov and Cohen, 2007).

[4]For every example query, a handful of the retrieved nodes are considered, including both relevant and irrelevant nodes.

A number of features describing the set of paths from V_q can be conveniently computed in the process of executing the graph walk, and it has been shown that reranking using these features can improve results significantly. It has also been shown that reranking is complementary to weight tuning (Minkov and Cohen, 2007), in the sense that the two techniques can be usefully combined by tuning weights, and then reranking the results.

In the reranking approach, for every training example i ($1 \leq i \leq N$), the reranking algorithm is provided with the corresponding output ranked list of l_i nodes. Let z_{ij} be the output node ranked at rank j in l_i, and let $p_{z_{ij}}$ be the probability assigned to z_{ij} by the graph walk. Each output node z_{ij} is represented through m features, which are computed by pre-defined feature functions $f_1, \ldots, f_m$. The *ranking function* for node z_{ij} is defined as:

$$F(z_{ij}, \bar{\alpha}) = \alpha_0 log(p_{z_{ij}}) + \sum_{k=1}^{m} \alpha_k f_k(z_{ij})$$

where $\bar{\alpha}$ is a vector of real-valued parameters. Given a new test example, the output of the model is the output node list reranked by $F(z_{ij}, \bar{\alpha})$. To learn the parameter weights $\bar{\alpha}$, we here applied a boosting method (Collins and Koo, 2005) (see also (Minkov et al., 2006)).

4.2.1 Features

We evaluate the following feature templates. *Edge label sequence* features indicate whether a particular sequence of edge labels ℓ_i occurred, in a particular order, within the set of paths leading to the target node z_{ij}. *Lexical unigram* feature indicate whether a word mention whose lexical value is t_k was traversed in the set of paths leading to z_{ij}. Finally, the *Source-count* feature indicates the number of different source query nodes that z_{ij} was reached from. The intuition behind this last feature is that nodes linked to multiple query nodes, where applicable, are more relevant. For example, for the query term "girl" in the graph depicted in Figure 1, the target node "boys" is described by the features (denoted as *feature-name.feature-value*): *sequence.nsubj.nsubj-inv* (where *mention* and *as-term* edges are omitted) , *lexical.'"like"* etc.

In this work, the features encoded are binary. However, features can be assugned numeric weights that corresponds to the probability of the indicator being true for any path between x and z_{ij} (Cohen and Minkov, 2006).

5 Path-Constrained Graph Walk

While node reranking allows the incorporation of high-level features that describe the traversed paths, it is desirable to incorporate such information earlier in the graph walk process. In this paper, we suggest a variant of a graph-walk, which is *constrained* by path information. Assume that preliminary knowledge is available that indicates the probability of reaching a relevant node after following a particular edge type sequence (path) from the query distribution V_q to some node x. Rather than fix the edge weights Θ, we can evaluate the weights of the outgoing edges from node x dynamically, given the history of the walk (the path) up to this node. This should result in gains in accuracy, as paths that lead mostly to irrelevant nodes can be eliminated in the graph walk process. In addition, scalability gains are expected, for the same reason.

We suggest a path-constrained graph walk algorithm, where path information is maintained in a compact path-tree structure constructed based on training examples. Each vertex in the path tree denotes a particular walk history. In applying the graph walk, the nodes traversed are represented as a set of node pairs, comprised of the graph node and the corresponding vertices in the path tree. The outgoing edge weights from each node pair will be estimated according to the respective vertex in the path tree. This approach needs to address two subtasks: learning of the path-tree; and updating of the graph walk paradigm to co-sample from the graph and the path tree. We next describe these two components in detail.

The Path-Tree

We construct a path-tree T using a training set of N example queries. Let a *path* p be a sequence of $k < K$ edge types (where K is the maximum number of graph walk steps). For each training example, we recover all of the connecting paths leading to the top M (correct and incorrect) nodes. We consider only acyclic paths. Let each path p be associated with its count, within the paths leading to the correct nodes, denoted as C_p^+. Similarly, the

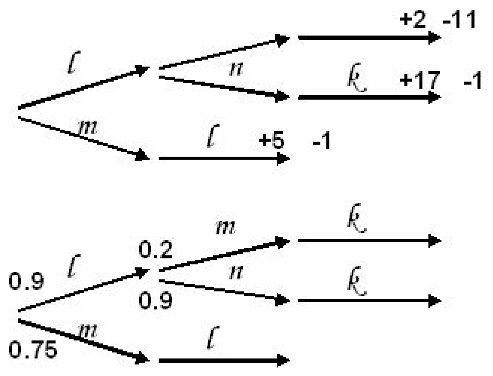

Figure 2: An example path-tree.

count within paths leading to the negatively labelled nodes is denoted C_p^-. The full set of paths observed is then represented as a tree.[5] The leaves of the tree are assigned a Laplace-smoothed probability: $Pr(p) = \frac{C_p^+ + 1}{C_p^+ + C_p^- + 2}$.

Given path probabilities, they are propagated backwards to all tree vertices, applying the MAX operator.[6] Consider the example given in Figure 2. The path-tree in the figure includes three paths (constructed from edge types k, l, m, n). The top part of the figure gives the paths' associated counts, and the bottom part of the figure gives the derived outgoing edge probabilities at each vertex. This path-tree specifies, for example, that given an edge of type l was traversed from the root, the probability of reaching a correct target node is 0.9 if an edge of type n is followed, whereas the respective probability if an edge of type m is followed is estimated at a lower 0.2.

A Concurrent Graph-walk

Given a generated path tree, we apply *path-constrained* graph walks that adhere both to the topology of the graph G, and to the path tree T. Walk histories of each node x visited in the walk are compactly represented as pairs $< t, x >$, where t denotes the relevant vertex in the path tree. For example, suppose that after one walk step, the maintained node-history pairs include $< T(l), x_1 >$ and $< T(m), x_2 >$. If x_3 is reached in the next walk step

[5]The conversion to a tree is straight-forward, where identical path prefixes are merged.

[6]Another possibility is to average the downstream cumulative counts at each vertex. The MAX operation gave better results in our experiments.

```
Given: graph $G$, path-tree $T$, query distribution $V_0$, number of steps $K$
Initialize: for each $x_i \in V_0$, assign a pair $< root(T), x_i >$
Repeat for steps $k = 0$ to $K$:
For each $< t_i, x_i > \in V_k$:
Let $L$ be the set of outgoing edge labels from $x_i$, in $G$.
For each $l_m \in L$:
For each $x_j \in G$ s.t., $x_i \xrightarrow{l_m} x_j$, add $< t_j, x_j >$ to $V_{k+1}$, where $t_j \in T$, s.t. $t_i \xrightarrow{l_m} t_j$, with probability $Pr(x_i|V_k) \times Pr(l_m|t_i, T)$. (The latter probabilities should be normalized with respect to $x_i$.)
If $t_i$ is a terminal node in $T$, emit $x_i$ with probability $Pr(x_i|V_k) \times Pr(t_i|T)$.
```

Figure 3: Pseudo-code for path-constrained graph walk

from both x_1 and x_2 over paths included in the path-tree, it will be represented by multiple node pairs, e.g., $< T(l \rightarrow n), x_3 >$ and $< T(m \rightarrow l, x_3 >$. A pseudo-code for a path-constrained graph walk is given in Figure 3. It is straight-forward to discard paths in T that are associated with a lower probability than some threshold. A threshold of 0.5, for example, implies that only paths that led to a majority of positively labelled nodes in the training set are followed.

6 Related Work

Graph walks over typed graphs have been applied to derive semantic similarity for NLP problems using WordNet as a primary information source. For instance, Hughes and Ramage (2007) constructed a graph which represented various types of word relations from WordNet, and compared random-walk similarity to similarity assessments from human-subject trials. Random-walk similarity has also been used for lexical smoothing for prepositional word attachment (Toutanova et al., 2004) and query expansion (Collins-Thompson and Callan, 2005). In contrast to these works, our graph representation describes parsed text and has not been (consciously) engineered for a particular task. Instead, we include learning techniques to optimize the graph-walk based similarity measure. The learning methods described in this paper can be readily applied to other directed and labelled entity-relation graphs.[7]

The graph representation described in this paper is perhaps most related to syntax-based vector space models, which derive a notion of semantic similarity from statistics associated with a parsed corpus (Grefenstette, 1994; Lin, 1998; Padó and Lapata, 2007). In most cases, these models construct vectors to represent each word w_i, where each element in the vector for w_i corresponds to particular "context" c, and represents a count or an indication of whether w_i occurred in context c. A "context" can refer to simple co-occurrence with another word w_j, to a particular syntactic relation to another word (e.g., a relation of "direct object" to w_j), etc. Given these word vectors, inter-word similarity is evaluated using some appropriate similarity measure for the vector space, such as cosine vector similarity, or *Lin's similarity* (Lin, 1998).

Recently, Padó and Lapata (Padó and Lapata, 2007) have suggested an extended syntactic vector space model called *dependency vectors*, in which rather than simple counts, the components of a word vector of contexts consist of *weighted scores*, which combine both co-occurrence frequency and the importance of a context, based on properties of the connecting dependency paths. They considered two different weighting schemes: a *length* weighting scheme, assigning lower weight to longer connecting paths; and an *obliqueness* weighting hierarchy (Keenan and Comrie, 1977), assigning higher weight to paths that include grammatically salient relations. In an evaluation of word pair similarity based on statistics from a corpus of about 100 million words, they show improvements over several previous vector space models. Below we will compare our framework to that of Padó and Lapata. One important difference is that while Padó and Lapata make manual choices (regarding the set of paths considered and the weighting scheme), we apply learning to adjust the analogous parameters.

7 Extraction of Coordinate Terms

We evaluate the text representation schema and the proposed set of graph-based similarity measures on the task of *coordinate term* extraction. In particular, we evaluate the extraction of named entities, including *city names* and *person names* from newswire data, using word similarity measures. Coordinate terms reflect a particular type of word similarity (relatedness), and are therefore an appropriate test case for our framework. While coordinate term extraction is often addressed by a rule-based (templates) approach (Hearst, 1992), this approach was designed for very large corpora such as the Web, where the availability of many redundant documents allows use of high-precision and low-recall rules. In this paper we focus on relatively small corpora. Small limited text collections may correspond to documents residing on a personal desktop, email collections, discussion groups and other specialized sets of documents.

The task defined in the experiments is to retrieve a ranked list of city or person names given a small set of seeds. This task is implemented in the graph as a query, where we let the query distribution V_q be uniform over the given seeds (and zero elsewhere). Ideally, the resulting ranked list will be populated with many additional city, or person, names.

We compare graph walks to *dependency vectors* (DV) (Padó and Lapata, 2007),[8] as well as to a vector-based bag-of-words co-occurrence model. DV is a state-of-the-art syntactic vector-based model (see Section 6). The co-occurrence model represents a more traditional approach, where text is processed as a stream rather than syntactic structures. In applying the vector-space based methods, we compute a similarity score between *every* candidate from the corpus and each of the query terms, and then average these scores (as the query distributions are uniform) to construct a ranked list. For efficiency, in the vector-based models we limit the considered set of candidates to named entities. Similarly, the graph walk results are filtered to include named entities.[9]

Corpora. As the experimental corpora, we use the training set portion of the MUC-6 dataset (MUC, 1995) as well as articles from the Associated Press (AP) extracted from the AQUAINT corpus (Bilotti

[7]We refer the reader to the TextGraph workshop proceedings, http://textgraphs.org.

[8]We used the code from http://www.coli.uni-saarland.de/ pado/dv.html, and converted the underlying syntactic patterns to the Stanford dependency parser conventions.

[9]In general, graph walk results can be filtered by various word properties, e.g., capitalization pattern, or part-of-speech.

Corpus	*words*	*nodes*	*edges*	*unique NEs*
MUC	140K	82K	244K	3K
MUC+AP	2,440K	1,030K	3,550K	36K

Table 1: Corpus statistics

et al., 2007), all parsed using the Stanford dependency parser (de Marneffe et al., 2006).[10] The MUC corpus provides true named entity tags, while the AQUAINT corpus includes automatically generated, noisy, named entity tags. Statistics on the experimental corpora and their corresponding graph representation are detailed in Table 1. As shown, the MUC corpus contains about 140 thousand words, whereas the MUC+AP experimental corpus is substantially larger, containing about 2.5 million words.

We generated 10 queries, each comprised of 4 city names selected randomly according to the distribution of city name mentions in MUC-6. Similarly, we generated a set of 10 queries that include 4 person names selected randomly from the MUC corpus. (The MUC corpus was appended to AP, so that the same query sets are applicable in both cases.) For each task, we use 5 queries for training and tuning and the remaining queries for testing.

8 Experimental Results

Experimental setup. We evaluated cross-validation performance over the training queries in terms of mean average precision for varying walk lengths K. We found that beyond $K = 6$ improvements were small (and in fact deteriorated for $K = 9$). We therefore set $K = 6$. Weight tuning was trained using the training queries and two dozens of target nodes overall. In reranking, we set a feature count cutoff of 3, in order to avoid over-fitting. Reranking was applied to the top 200 ranked nodes output by the graph walk using the tuned edge weights. Finally, path-trees were constructed using the top 20 correct nodes and 20 incorrect nodes retrieved by the uniformly weighted graph walk. In the experiments, we apply a threshold of 0.5 to the path constrained graph walk method.

We note that for learning, true labels were used for the fully annotated MUC corpus (we hand labelled all of the named entities of type location in the corpus as to whether they were city names). However, noisy negative examples were considered for the larger automatically annotated AP corpus. (Specifically, for cities, we only considered city names included in the MUC corpus as correct answers.)

A co-occurrence vector-space model was applied using a window of two tokens to the right and to the left of the focus word. Inter-word similarity was evaluated in this model using cosine similarity, where the underlying co-occurrence counts were normalized by log-likelihood ratio (Padó and Lapata, 2007). The parameters of the DV method were set based on a cross validation evaluation (using the MUC+AP corpus). The *medium* set of dependency paths and the *oblique* edge weighting scheme were found to perform best. We experimented with cosine as well as Lin similarity measure in combination with the dependency vectors representation. Finally, given the large number of candidates in the MUC+AP corpus (Table 1), we show the results of applying the considered vector-space models to the top, high-quality, entities retrieved with reranking for this corpus.[11]

Test set results. Figure 4 gives results for the city name (top) and the person name (bottom) extraction tasks. The left part of the figure shows results using the MUC corpus, and its right part – using the MUC+AP corpus. The curves show precision as a function of rank in the ranked list, up to rank 100. (For this evaluation, we hand-labeled all the top-ranked results as to whether they are city names or person names.) Included in the figure are the curves of the graph-walk method with uniform weights (G:Uw), learned weights (G:Lw), graph-walk with reranking (Rerank) and a path-constrained graph-walk (PCW). Also given are the results of the co-occurrence model (CO), and the syntactic vector-space DV model, using the Lin similarity measure (DV:Lin). Performance of the DV model using cosine similarity was found comparable or inferior to using the Lin measure, and is omitted from the figure for clarity.

Several trends can be observed from the results. With respect to the graph walk methods, the graph walk using the learned edge weights consistently outperforms the graph walk with uniform weights. Reranking and the path-constrained graph walk,

[10]http://nlp.stanford.edu/software/lex-parser.shtml; sentences longer than 70 words omitted.

[11]We process the union of the top 200 results per each query.

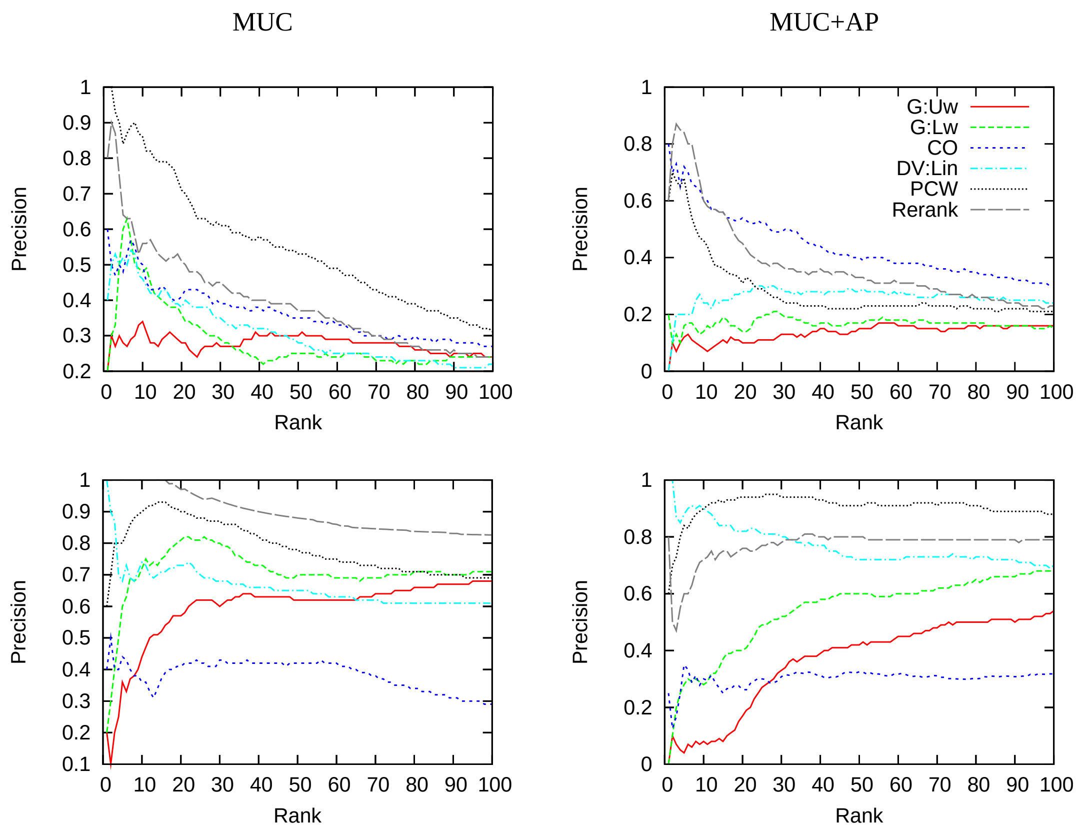

Figure 4: Test results: Precision at the top 100 ranks, for the city name extraction task (top) and person name extraction task (bottom).

however, yield superior results. Both of these learning methods utilize a richer set of features than the graph walk and weight tuning, which can consider only local information. In particular, while the graph walk paradigm assigns lower importance to longer connecting paths (as described in Section 3), reranking and the path-constrained walker allow to discard short yet irrelevant paths, and by that eliminate noise at the top ranks of the retrieved list. In general, the results show that edge sequences carry additional meaning compared with the individual edge label segments traversed.

Out of the vector-based models, the co-occurrence model is preferable for the city name extraction task, and the syntactic dependency vectors model gives substantially better performance for person name extraction. We conjecture that city name mentions are less structured in the underlying text. In addition, the syntactic weighting scheme of the DV model is probably not optimal for the case of city names. For example, a *conjunction* relation was found highly indicative for city names (see below). However, this relation is not emphasized by the DV weighting schema. As expected, the performance of the vector-based models improves for larger corpora (Terra and Clarke, 2003). These models demonstrate good performance for the larger MUC+AP corpus, but only mediocre performance for the smaller MUC corpus.

Contrasting the graph-based methods with the vector-based models, the difference in performance in favor of reranking and PCW, especially for the smaller corpus, can be attributed to two factors. The first factor is learning, which optimizes performance for the underlying data. A second factor is the incorporation of non-local information, encoding properties of the traversed paths.

Models. Following is a short description of the models learned by the different methods and tasks. Weight tuning assigned high weights to edge types such as *conj-and*, *prep-in* and *prep-from*, *nn*, *appos* and *amod* for the city extraction task. For per-

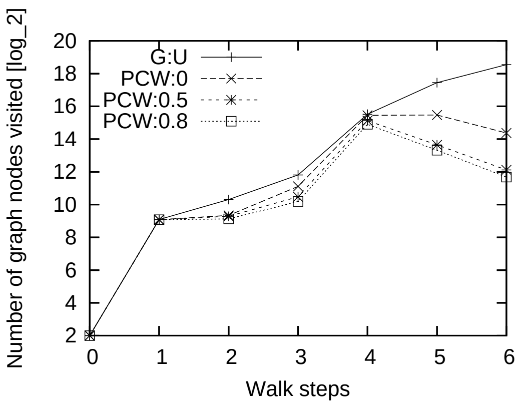

Figure 5: The graph walk exponential spread is bounded by the path constrained walk.

son extraction, prominent edge types included *subj*, *obj*, *poss* and *nn*. (The latter preferences are similar to the linguistically motivated weights of DV.) High weight features assigned by reranking for city name extraction included, for example, lexical features such as "based" and "downtown", and edge bigrams such as "prep-in-Inverse→conj-and" or "nn-Inverse→nn". Positive highly predictive paths in the constructed path tree included many symmetric paths, such as ...→conj_andInverse...→.conj_and..., ...→prep_inInverse...→.prep_in..., for the city name extraction task.

Scalability. Figure 5 shows the number of graph nodes maintained in each step of the graph walk (logarithm scale) for a typical city extraction query and the MUC+AP corpus. As shown by the solid line, the number of graph nodes visited using the weighted graph walk paradigm grows exponentially with the length of the walk. Applying a path-constrained walk with a threshold of 0 (PCW:0) reduces the maximal number of nodes expanded (as paths not observed in the training set are discarded). As shown, increasing the threshold leads to significant gains in scalability. Overall, query processing time averaged at a few minutes, using a commodity PC.

9 Conclusion and Future Directions

In this paper we make several contributions. First, we have explored a novel but natural representation for a corpus of dependency-parsed text, as a labelled directed graph. We have evaluated the task of coordinate term extraction using this representation, and shown that this task can be performed using similarity queries in a general-purpose graph-walk based query language. Further, we have successfully applied learning techniques that tune weights assigned to different dependency relations, and re-score candidates using features derived from the graph walk.

Another orthogonal contribution of this paper is a path-constrained graph walk variant, where the graph walk is guided by high level knowledge about meaningful paths, learned from training examples. This method was shown to yield improved performance for the suggested graph representation, and improved scalability compared with the local graph walk. The method is general, and can be readily applied in similar settings.

Empirical evaluation of the coordinate term extraction task shows that the graph-based framework performs better than vector-space models for the smaller corpus, and comparably otherwise. Overall, we find that the suggested model is suitable for deep (syntactic) processing of small specialized corpora. In preliminary experiments where we evaluated this framework on the task of extracting general word synonyms, using a relatively large corpus of 15 million words, we found the graph-walk performance to be better than DV using cosine similarity measures, but second to DV using Lin's similarity measure. While this set of results is incomplete, we find that it is consistent with the results reported in this paper.

The framework presented can be enhanced in several ways. For instance, WordNet edges and morphology relations can be readily encoded in the graph. We believe that this framework can be applied for the extraction of more specialized notions of word relatedness, as in relation extraction (Bunescu and Mooney, 2005). The path-constrained graph walk method proposed may be enhanced by learning edge probabilities, using a rich set of features. We are also interested in exploring a possible relation between the path-constrained walk approach and reinforcement learning.

A graph-theoretic model of lexical syntactic acquisition

Hinrich Schütze and Michael Walsh
Institute for Natural Language Processing
University of Stuttgart, Germany
{hs999,walsh}@ifnlp.org

Abstract

This paper presents a graph-theoretic model of the acquisition of lexical syntactic representations. The representations the model learns are non-categorical or graded. We propose a new evaluation methodology of syntactic acquisition in the framework of exemplar theory. When applied to the CHILDES corpus, the evaluation shows that the model's graded syntactic representations perform better than previously proposed categorical representations.

1 Introduction

In recent years, exemplar theory has had great explanatory success in phonetics. Exemplar theory posits that linguistic production and perception are not mediated via abstract categories, but that instead each production and perception of a linguistic unit is stored and retained. Linguistic inference then directly operates on these stored *exemplars*. In this paper, we propose a new approach to lexical syntactic acquisition in the framework of exemplar theory.

Our approach uses an evaluation measure that is different from previous work. Lexical syntactic acquisition is most often evaluated with respect to standard syntactic categories like verb and noun. Our first contribution in this paper is that we instead evaluate learned representations in the context of a syntactic task. This task is the determination of an aspect of grammaticality that we call *local syntactic coherence*.

Our second contribution is a *graph-theoretic model of the acquisition of lexical syntactic representations* that is more rigorous than previous heuristic proposals. The graph-theoretic model can learn both categorical and non-categorical (or graded) representations. The model is also a unified framework for syntagmatic and paradigmatic relations (as will be discussed below), and for lower-order syntactic relations (those that can be directly observed from the input) and higher-order syntactic relations (those that require some generalization from what is directly observable).

Redington et al. (1998) give an influential account of the acquisition of lexical syntactic representations in which a standard syntactic category like verb or noun is assigned to each word. Our third contribution is to show that, in the context of acquisition, *graded representations are superior to standard categorical representations* in supporting judgments of local syntactic coherence. A graded representation formalism is one that, for any two words, can represent a third word whose syntactic properties are intermediate between the two words (Manning and Schütze, 1999).

Clearly exemplar theory is not the only framework in which lexical acquisition has been explored. Gleitman (1990) for example argues for syntactic bootstrapping to infer lexical semantics, work not at odds with our own (see discussion on the role of semantics below). Our argument for the importance of distributional evidence does not call into question the large body of work in child language acquisition that demonstrates that "part of the capacity to learn languages must be 'innate' " (Gleitman and Newport, 1995). Tabula rasa learning is not possible. Our goal is not to show that language acquisition proceeds with a minimum of inductive bias. Rather, we attempt to formalize one aspect of language acquisition, the use of distributional information.

The paper is organized as follows. Section 2 motivates the exemplar-theoretic approach by reviewing its success in phonetics. Section 3 defines local syntactic coherence, which is the basis for a new evaluation methodology for the acquisition of lexical representations. Section 4 develops the graph-theoretic model. Section 5 compares graded and categorical representations for the task of inferring local syntactic coherence. Section 6 presents our evaluation. Sections 7 and 8 discuss related and future work, and present our conclusions.

2 Exemplar theory

The general idea of research into exemplars in speech production and perception is that encountered items (segments, words, sentences etc.) are stored in great detail in memory along with rich linguistic and extra-linguistic context information. These exemplars are organized into clouds of memory traces with similar traces lying close to each other while dissimilar traces are more distant. A number of such models have had great success in accounting for production and perception phenomena in phonetics. E.g., Johnson (1997) offers an exemplar model which challenges the notion that speech is perceived through a process of normalization whereby a speaker-specific representation is mapped or normalized into a speaker-neutral categorical abstraction. Johnson's model successfully treats aspects of vowel perception, sex identification, and speaker variability. Crucially, no normalization of percepts into categorical representations takes place. The correct identification of phonemes and words in his model is a function of direct comparison to richly detailed exemplars stored in memory. Other examples of exemplar-theoretic phonetic accounts include (Goldinger, 1997), (Pierrehumbert, 2001), and our own work (Schütze et al., 2007). Exemplar theory's success in phonetics motivates us to investigate its use as a model for local syntactic phenomena.

3 Local syntactic coherence

In the context sequence model for exemplar-theoretic phonetics (Wade et al., 2008), we represent speech using amplitude envelopes derived from the acoustic signal and then compute similarity as the integral over the correlation of the two acoustic signals.

For the syntactic level, we need a representation that has two key properties of the representation we use in phonetics in order to support an exemplar-theoretic account. First, the representation must be directly derivable from the perceived input. In particular, it cannot rely on the results of any disambiguation that would occur either as part of exemplar-theoretic perception or in further downstream processing. Second, it must support similarity computations. Accordingly, we first motivate the representation we use and then introduce a similarity measure on these representations.

Representation. There are two main sources[1] of directly observable information about the syntactic properties of words: semantic cues (e.g., things are often referred to with nouns) and the neighbors of a word in sentences that it is used in. In this paper, we only consider the second source of information for acquisition, lexical neighbors.[2] We further limit ourselves to the immediate left and right lexical neighbors (see discussion in Section 7).

When using lexical neighbors as the basis of representation, we have to make a basic choice as to whether we look at left and right neighbors separately or whether we only look at the "correlated" neighborhood information of left and right neighbors jointly. Our approach is based on the first alternative: we separate the processing of left and right neighbors. We do this for two reasons. First, generalization improves and model complexity decreases if left-neighbor information and right-neighbor information are looked at separately. E.g., the right neighbors of *to*, *might* and *not* are similar because all three words can be followed by base verbs like *dance*: *to dance*, *might dance*, *(might) not dance*. But their left neighbors are very different.

Second, exemplar-theoretic similarity is best defined at the smallest possible scale in order to allow optimal matching between parts of the stimulus and parts of memory. In phonetics, we use a time scale of 10s of milliseconds or even less. Conceivably, one could also use segments (e.g., consonants and vowels) as the smallest unit; however, this would presume a segmented signal. And segmentation is part of the perception task we want to explain in the first place.

Separating left and right neighbors – which amounts to looking at left and right local contexts of each word separately – is the smallest scale we can operate at when doing syntactic matching. We

[1]A comprehensive account of acquisition must also include morphology. See Christiansen et al. (2004).

[2]Psycholinguistic evidence for the importance of neighbor information for learning categories includes (Mintz, 2002).

choose this small scale for the same reasons as we choose a small scale in phonetics: to ensure maximum flexibility when matching parts of the stimulus with exemplars in memory. Using words, bigrams or larger units would reduce the flexibility in matching and require a larger amount of experience (or training data) to learn a particular generalization.

We refer to the representations of left and right contexts of a given word as *half-words*. In other words, we split a word into two entities, a left half-word that characterizes its behavior to the left and a right half-word that characterizes its behavior to the right. Thus left-context and right-context components of the representation of a given focus word are defined, where a left (right) half-word consists of a probability distribution over all words that occur to the left (right) of the focus word and the dimensionality of the vector for each word is dependent on the number of distinct neighbors (left and right). For example, having experienced *take doll* twice and *drop doll* once, then the left context distribution, or left half-word of *doll*, *doll*$_l$, is $P(\text{take}) = 2/3, P(\text{drop}) = 1/3$. By extension, the phrase *take the doll* is represented as the following six half-words: *take*$_l$, *take*$_r$, *the*$_l$, *the*$_r$, *doll*$_l$, and *doll*$_r$.

Distance measure. The basic intuition behind local syntactic coherence is that an important component of syntactic wellformedness – and a component that is of particular importance in acquisition – is whether a similar sequence has already been stored as grammatical in memory. The same way that a phonetic signal that is well-formed in a particular language has many similar exemplars in memory, a syntactic sequence should also be licensed by similar, previously perceived sequences in memory. To operationalize this notion, we need to be able to compute the similarity or distance between an input stimulus and exemplars in memory. We do this by first defining a distance measure for sequences of fixed length.

The distance Δ between two sequences of half-words $< g_1, \ldots, g_n >$ and $< h_1, \ldots, h_n >$ is defined to be the sum of the distances of their half-words:
$\Delta(<g_1, \ldots, g_n>,<h_1, \ldots, h_n>) = \sum_{i=1}^{n} \Delta(g_i, h_i)$
This definition presupposes a definition of the distance of two half-words which will be given below.

We then call a sequence of n half-words $g_1, \ldots, g_n$ *locally coherent* if there is a sequence $h_1, \ldots, h_n$ in memory with $\Delta(< g_1, \ldots, g_n >, < h_1, \ldots, h_n >) < \theta$ where θ is a parameter.

Finally, we define a sentence to be *locally n-coherent* if all of its subsequences of length n are locally coherent.

The graph-theoretic model that is introduced in the next section will be evaluated with respect to how well it captures local syntactic coherence. This enables us to evaluate the model with respect to a task as opposed to its ability to reproduce a particular linguistic representation of syntactic categories.[3] Obviously, the notion of local syntactic coherence only captures some aspects of syntax – e.g., it does not capture long-distance dependencies. However, it is a plausible component of syntactic competence and a plausible intermediate step in the acquisition of syntax.

4 Graph-theoretic model

We briefly review the structuralist notions of syntagmatic and paradigmatic relationships that have been frequently used in prior work in NLP (e.g., (Church et al., 1994)). De Saussure defined a syntagmatic relationship between two words as their contiguous occurrence in a sentence and a paradigmatic relationship as mutual substitutability (de Saussure, 1962) (although he used the term *rapport associatif* instead of *paradigmatic*). E.g., *brown* and *dog* stand in a syntagmatic relationship with each other in the phrase *brown dog*; *brown* and *black* stand in a paradigmatic relationship with each other with respect to the position between *the* and *dog* in the phrase *the X dog*. De Saussure's conceptualization of syntactic relationships captures the fact that both admissible *neighbors* and admissible *substitutes* in language are an important part of the characterization of the syntactic properties of a word.

We formalize the two relations as *distributions over words*, where we assume a vocabulary $\{w_1, \ldots, w_V\}$ and V is the number of words in the vocabulary.

We denote the *left syntagmatic distribution* of w_i

[3]Freudenthal et al. (2004) have much the same motivation in introducing an evaluation measure of syntactic acquisition based on chunking.

by $p_{i,s,l,m}$ where i is the vocabulary index of w_i, s stands for *syntagmatic*, l for *left* and m is the order of the distribution as discussed below. Intuitively, $p_{i,s,l,m}(w_j)$ is the probability that word w_j occurs to the left of w_i. Similarly, for the *left paradigmatic distribution* of w_i, $p_{i,p,l,m}(w_j)$ is the probability that w_j can be substituted for w_i without changing local syntactic coherence as far as the context to the left is concerned. Note that we distinguish between left and right paradigmatic distributions. A word w_j can be a perfect substitute for w_i as far as the context to the left is concerned, but a very unlikely substitute as far as the context to the right is concerned. E.g., in the phrase *She loves her job*, the word *him* is a good left-context substitute for *her*, but a terrible right-context substitute for *her*.

We will now show how the syntagmatic/paradigmatic (henceforth: syn/para) distributions are defined iteratively, based on the bigram distribution p_{ww}, and grounded by defining $p_{i,p,l,1}$ and $p_{i,p,r,1}$.

$p_{ww}(w_iw_j)$ is the probability that the bigram w_iw_j occurs, that is, that w_i and w_j occur next to each other (and in that order). We define the $V \times V$ *joint probability matrix* J by $J_{ij} = p_{ww}(w_iw_j)$.

Denote by N the diagonal $V \times V$ matrix that contains in N_{ii} the reciprocal of $p_w(w_i)$ where p_w is the marginal distribution of p_{ww}:

$$\sum_{j=1}^{V} p_{ww}(w_iw_j) = \sum_{j=1}^{V} p_{ww}(w_jw_i) = p_w(w_i) = \frac{1}{N_{ii}}$$

The conditional probability p_{left} of the following word and the conditional probability p_{right} of the preceding word can be computed by multiplying (the transpose of) J and N: $p_{\text{left}}(w_i|w_j) = p_{ww}(w_iw_j)/p_w(w_j) = (JN)_{ij}$; and $p_{\text{right}}(w_i|w_j) = (J^TN)_{ij}$.

The "grounding" paradigmatic distributions of order 1 are defined as follows.

$$p_{i,p,l,1}(w_j) = p_{i,p,r,1}(w_j) = \begin{cases} 0 & \text{if } w_i \neq w_j \\ 1 & \text{if } w_i = w_j \end{cases}$$

In other words, each word has only one perfect left / right substitute and that perfect substitute is itself. We define the syn/para distributions of higher order recursively:

$$p_{i,s,l,m} = JNp_{i,p,l,m} \qquad (1)$$

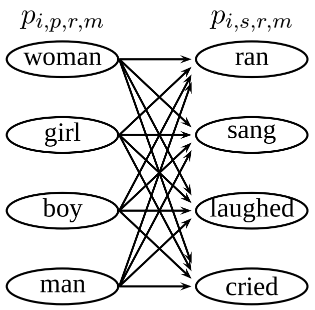

Figure 1: The distribution of typical right neighbors (the right syntagmatic distribution $p_{i,s,r,m}$) is computed from the distribution of typical "right substitutes" (the right paradigmatic distribution $p_{i,p,r,m}$).

$$p_{i,p,l,m} = J^TNp_{i,s,l,m-1} \qquad (2)$$
$$p_{i,s,r,m} = J^TNp_{i,p,r,m} \qquad (3)$$
$$p_{i,p,r,m} = JNp_{i,s,r,m-1} \qquad (4)$$

Basic matrix arithmetic shows that $p_{i,s,l,1}$ is simply $p_{\text{left}}(.|w_i)$ and $p_{i,s,r,1}$ is $p_{\text{right}}(.|w_i)$.

For higher orders, the principle underlying Eq.s 1–4 is that when moving from left to right, we use p_{right} (that is, J^TN), the conditional distribution that characterizes right neighbors; when moving from right to left, we use p_{left} (that is, JN), the conditional distribution that characterizes left neighbors. This is graphically shown in Fig. 1.

As illustrated by Fig. 1, the underlying graph for $p_{i,s,r,m}$ and $p_{i,p,r,m}$ is a weighted bipartite directed graph that connects the vocabulary on the left with the vocabulary on the right. A directed edge from w_i on the left to w_j on the right is weighted with $p_{ww}(w_iw_j)/p_w(w_i)$. A directed edge from w_j on the right to w_i on the left (not shown) is weighted with $p_{ww}(w_iw_j)/p_w(w_j)$.

Eq.s 1–4 define four Markov chains:

$$p_{i,s,l,m} = (JNJ^TN)p_{i,s,l,m-1} \qquad (5)$$
$$p_{i,p,l,m} = (J^TNJN)p_{i,p,l,m-1} \qquad (6)$$
$$p_{i,s,r,m} = (J^TNJN)p_{i,s,r,m-1} \qquad (7)$$
$$p_{i,p,r,m} = (JNJ^TN)p_{i,p,r,m-1} \qquad (8)$$

It is easy to see that p_w is a stationary distribution for Eq. 1–4. Writing $\vec{x}$ for p_w, we have:

$$(JN\vec{x})_i = \sum_{j=1}^{V} \frac{p_{ww}(w_iw_j)}{p_w(w_j)} p_w(w_j) = p_w(w_i) = x_i$$

$$(J^TN\vec{x})_i = \sum_{j=1}^{V} \frac{p_{ww}(w_jw_i)}{p_w(w_j)} p_w(w_j) = p_w(w_i) = x_i$$

Hence, p_w is a solution for Eq.s (5)–(8).

The series converge if JNJ^TN and J^TNJN are ergodic, i.e., if the chain is aperiodic and irreducible (Kemeny and Snell, 1976). Observe that for many simple probabilistic context-free grammars (PCFGs) the series in Eq. 1–4 will *not* converge. For simple PCFGs, the alternation between syntagmatic and paradigmatic distributions is periodic. E.g., if inflected verb forms only occur after nouns and nouns only before inflected verb forms, then the right syntagmatic distributions of nouns will have non-zero activation only for verbs and the right paradigmatic distributions of nouns will have non-zero activation only for nouns, thus preventing convergence.[4]

The key difference between a simple PCFG and natural language is ambiguity and noise. Because of ambiguity and noise, JNJ^TN and J^TNJN are likely to be ergodic – there is always a small non-zero probability that two words can occur next to each other. Ambiguity and noise have the same effect as teleportation for PageRank (Brin and Page, 1998) in the sense that we can jump from each word to each other word with non-zero probability.

Assuming that the Markov chains are ergodic, all four converge to p_w: $p_{i,p,r,\infty} = p_{i,p,l,\infty} = p_{i,s,r,\infty} = p_{i,s,l,\infty} = p_w$, for $1 \leq i \leq V$.

Thus, in this formalization, given enough iterations, syntagmatic and paradigmatic distributions of words eventually all become identical with the prior distribution p_w. This is surprising because linguistically and computationally syntagmatic and paradigmatic relations are fundamentally different.

However, on closer inspection, we observe that limiting the number of iterations is often beneficial when computing solutions to a problem iteratively. E.g., the expectation-maximization algorithm is often stopped early because results close to convergence are worse than results obtained after a small number of iterations. From the point of view of modeling human language acquisition, early stopping is perhaps also more realistic since humans are unlikely to perform a large number of iterations.

[4]However, non-ergodicity of JN does not imply non-ergodicity of JNJ^TN and J^TNJN, so Eq. (5)–(8) can converge even for non-ergodic JN.

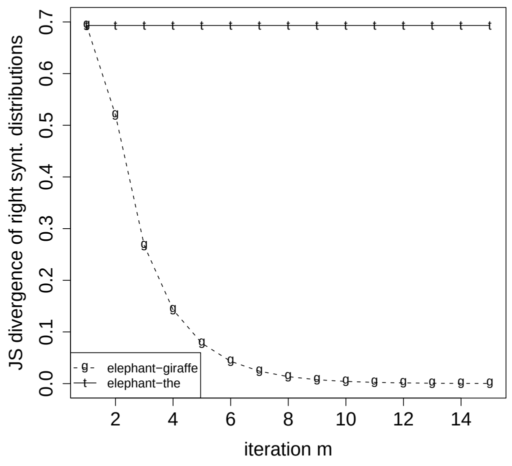

Figure 2: The distance between *elephant* and *giraffe* (measured by the Jensen-Shannon divergence) is accurately represented after a number of iterations. The words *elephant* and *the* retain their large distance.

Example 1. For the following matrix J

$$\left(\begin{array}{cccc} & w_1 & w_2 & w_3 \\ w_1 & 82/1002 & 77/1002 & 112/1002 \\ w_2 & 90/1002 & 18/1002 & 107/1002 \\ w_3 & 99/1002 & 120/1002 & 297/1002 \end{array}\right)$$

we get $p_{1,s,r,1} = (0.31, 0.28, 0.41)$ by computing the product $J^TNp_{1,p,r,1}$. E.g., $p_{1,s,r,1}(w_2) = p_{ww}(w_1w_2)/p_w(w_1) \cdot 1.0 = 77/(82+77+112) \approx 0.28$.

By iteration $m = 4$, the series $p_{i,s,r,m}$ (Eq. (7)) and $p_{i,p,r,m}$ (Eq. (8)) have converged to:
$p_{i,s,r,m} = p_{i,p,r,m} = (0.2704, 0.2145, 0.5149)$
for all three words w_i. One can easily verify that this is p_w. E.g., $p_w(w_1) = (82+90+99)/1002 = (82+77+112)/1002 \approx 0.27045$.

Example 2. We computed 15 iterations of syn/para distributions for the corpus: *The giraffe ran. An elephant fell. The man ran. An aunt fell. The man slept. The aunt slept.* Fig. 2 shows that the distance between the right syntagmatic distributions of *elephant* and *giraffe* is large for $m = 1$. The reason is that the two words have no right neighbors in common. The right neighbors of the two words are *ran* and *fell*. Although *ran* and *fell* have no left neighbors in common, their left neighbors have a right neighbor in common: the word *slept*. This indirect similarity information is exploited to deduce by iteration

15 that the two words are very similar with respect to their right syntactic context. In contrast, no such inference, even a very indirect one, is possible for the right contexts of *elephant* and *the*. Consequently, the distance between the two distributions remains high and unchanged with higher iterations.

In this case, the Markov chain is not ergodic and the syntagmatic and paradigmatic series (Eq.s (5)–(8)) do not converge to p_w.

5 Experimental evaluation

Recall from Section 3 that our evaluation task is to discriminate sentences that exhibit local coherence from those that do not; that sentences are represented as sequences of half-words; that syntactic coherence of a sentence is defined as all subsequences of a given length n exhibiting local coherence; and that a subsequence is locally coherent if its distance from a sequence in memory is less than θ.

These definitions can be applied to the graph model as follows. A left half-word is a left syntagmatic (or paradigmatic) distribution and a right half-word is a right syntagmatic (or paradigmatic) distribution. We compute the distance of two half-words either as the Jensen-Shannon (JS) divergence (Lin, 1991) or as $(1 - \cos(\alpha))$. JS divergence is more appropriate for the comparison of probability distributions. But the cosine is more efficient when a sparse vector is compared to a dense vector.[5] We therefore employ the cosine for the compute-intensive experiments in Section 6.

The baseline representation is the categorical representation proposed by Redington et al. (1998). A difficulty in replicating their experiments is that they use hierarchical agglomerative clustering (HAC), which eventually agglomerates all words in a single category. To circumvent the need for a stopping criterion, we represent each word as the temporal sequence of clusters it occurred in during agglomeration and define the distance of two words as the agglomeration step in which the two words are joined in a cluster. E.g., given the agglomeration sequences $\{1\}, \{1, 2\}, \{1, 2, 4\}, \{1, 2, 3, 4\}$ for w_1 and $\{4\}, \{4\}, \{1, 2, 4\}, \{1, 2, 3, 4\}$ for w_4, the distance between w_1 and w_4 is 3 since they are joined in step 3 when cluster $\{1, 2, 4\}$ is created.

For both graded (graph-theoretic) and categorical (cluster-based) representations, we need to set the parameter θ that is the boundary between locally coherent and locally incoherent sentences. This parameter gives rise to a precision-recall tradeoff. A small θ will impose strict requirements on which sequences in memory match, resulting in false negative decisions for local grammaticality. A large θ will incorrectly judge many locally incoherent sequences to be grammatical.

We will pick the optimal θ in both cases. For categorical representations, this amounts to selecting the HAC dendrogram with optimal performance. The experiment below evaluates whether grammatical and ungrammatical sentences are well separated by the proposed measure.[6]

Experiment on CHILDES. We used the well-known CHILDES database (MacWhinney, 2000), a corpus of conversations between young children and their playmates, siblings, and caretakers. In order to avoid mixing varieties of English (e.g., British English vs. American English), we selected the largest homogeneous subcorpus of CHILDES, the Manchester corpus. It contains roughly 350,000 sentences and 1.5 million words. This is a conservative estimate of the amount of child-directed speech a child would receive annually (Redington et al., 1998). All names in the corpus (i.e., all capitalized words) were replaced with a special word "_n_". A boundary symbol "_b_" was introduced to separate sentences. The representation of the corpus is then a concatenation of all its sentences. The vocabulary consists of $V = 8601$ words.

Construction of the evaluation set. We tested the ability of the two models to distinguish locally coherent vs. incoherent sentences by selecting 100 *unattested* sentences from the corpus, which were not used to train the model. We only selected unattested sentences that were not a substring of a sentence in the training corpus since, presumably, any substring of a sentence in the training corpus is locally coherent. A further constraint was that the

[5]This is so because, when computing the cosine, we can ignore all dimensions where one of the two vectors has a zero value.

[6]This evaluation of "separation" is not directly an evaluation of classification performance, but more similar to an evaluation of ranking using AUC or an evaluation of clustering using a measure like purity.

unattested sentence was not allowed to contain a word that did not occur in the training corpus, the rationale being that we want to address the problem of local coherence for known words only since unknown words present special challenges. Finally, we ensured that each unattested sentence contained a word that occurred in only one sentence type in the training corpus. In early experiments, we found that local grammatical inference for frequent words is easy as there is redundant evidence available that characterizes legal syntactic environments for frequent words. Since rare words are a key challenge in syntactic acquisition, we only selected sentences as unattested sentences that contained at least one rare word (where a rare word is defined as a word that occurs once in the training set).

100 ungrammatical sentences were generated by randomly selecting and concatenating words from the vocabulary. Ungrammatical sentences were matched in length to unattested sentences, so that both sets contained the same number of sentences of a given length. As with unattested sentences, ungrammatical sentences that were substrings of sentences in the training corpus were eliminated. As there are many more infrequent words than frequent words in the vocabulary, the construction ensured that, as with unattested sentences, infrequent words were overrepresented in ungrammatical sentences.

To summarize, our setup consists of 348,463 training sentences, 100 unattested grammatical sentences and 100 ungrammatical sentences.

The task of discriminating the 100 unattested from the 100 ungrammatical sentences cannot be solved perfectly as CHILDES contains ungrammatical sentences, a few of which were randomly selected as unattested sentences (e.g., *yes pleas*, which is missing the final letter). Similarly, one or two of the automatically generated ungrammatical sentences were actually grammatical.

Since the test set does not consist of a random sample of sentences, performance on the test set is not a direct indicator of the percentage of sentences that the model can correctly discriminate in a child's typical input. A large proportion of sentences in child input are simple 1-word, 2-word, and 3-word sentences that even simplistic models can evaluate with high accuracy. However, the test set is appropriate for a comparative evaluation of graded and categorical syntactic representations in language acquisition, which is one of the goals of the paper. Difficult sentences (those with rare words and greater length) are overrepresented in the test set as the discrimination of short sentences containing only frequent words can easily be done by simplistic models. Thus, a test set of "easy" sentences would not distinguish good models from bad models.

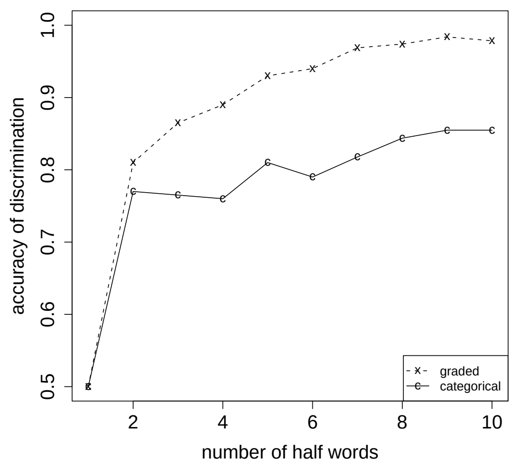

Figure 3: Accuracy of discrimination between grammatical and ungrammatical sentences for graded and categorical representations.

Discrimination experiment. In order to train the graph model, the entries of matrix J were estimated using maximum likelihood based on the training corpus. $p_{i,s,l,1}$ and $p_{i,s,r,1}$ were then computed for all 8601 words. Replicating (Redington et al., 1998), the most frequent 1000 words were clustered (using single-link HAC, Manning and Schütze (1999)). For each remaining word w, the closest neighbor w' in the 1000 most frequent words was determined and w was then assigned to the cluster of w'.

Fig. 3 shows the performance of graded and categorical representations for different subsequence sizes n. To compute the accuracy for each n, the θ with optimal discrimination performance was chosen (for both graded and categorical).

For a subsequence of size $n = 1$, the performance is 0.5 in both cases since the 200-sentence test set does not contain unknown words. So for every half-word, there is a sequence of one half-word in the training corpus with distance 0. Thus, all sentences get the same local coherence scores, both for graded and categorical representations.

This argument does not apply to $n = 2$ since we earlier defined a sentence to be locally coherent if all of its subsequences are coherent. While subsequences of 2 half-words that are part of the *same* word have local coherence score 0, this is not true of subsequences of 2 half-words that are part of *different* words, e.g., the subsequence <*black*$_r$,*dog*$_l$> in *black dog*. If *black dog* does not occur in the training set, then its local coherence score is > 0.

The main result of the experiment is that except for n=1 ($p = 1$) and n=2 ($p = 0.39$) the differences between categorical and graded representations are significant (χ^2 test, $p < 0.05$ for $3 \leq n \leq 10$). This is evidence that graded representations are more accurate when determining local syntactic coherence and grammaticality than categorical representations.

The experimental results demonstrate that, for syntagmatic distributions of order 1, graded representations discriminate locally coherent vs. incoherent sentences better than categorical representations. We attribute this to the ability of exemplar theory to incorporate rich context information into discrimination decisions. This is of particular importance for ambiguous words. Categorical representations of ambiguous words are problematic because they are either too similar or not similar enough to the two alternatives. E.g., if a word with a verb/noun ambiguity is represented as one of the alternatives, say, as a verb, then subsequences containing its noun use will no longer be similar to other subsequences with nouns. If a special conflation category noun/verb is introduced, then we are faced with the same problem: subsequences containing the noun/verb category are not similar to subsequences containing either non-ambiguous verbs or non-ambiguous nouns.

6 Higher-order distributions

The main motivation for higher-order distributions is that syntagmatic vectors of order 1 do not perform well for some infrequent words. In the elephant/giraffe example above, the distance between the two words is close to maximum for order 1 representations because each occurs only once, in entirely different contexts. As we showed in Fig. 2, higher-order representations address this problem because they exploit indirect evidence about the syntactic properties of words.

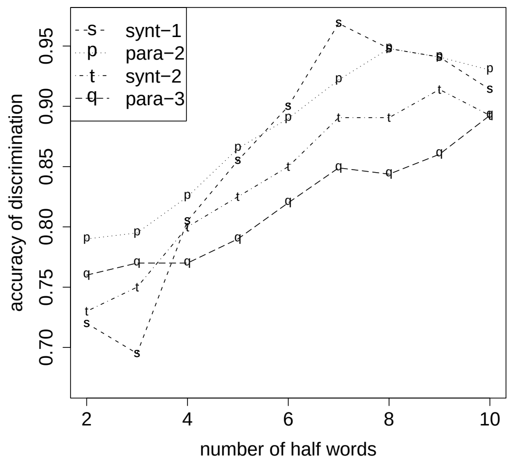

Figure 4: Accuracy of discrimination between grammatical and ungrammatical sentences of the exemplar-based method for different orders. Key: synt = syntagmatic, para = paradigmatic; s is of order 1; p and t are of order 2; q is of order 3.

To evaluate higher-order representations on CHILDES, we used the same setup as before, but computed several additional iterations. We also limited the experiments to a subset consisting of 60,000 words of the Manchester corpus. It contains only V=1666 different words, which reduces the storage requirements for the syn/para distributions (which is $2 \cdot V^2$ for each order) and the cost of the matrix multiplications. We also used $(1 - \cos(\alpha))$ instead of JS divergence as distance measure.

The results of the experiment are shown in Fig. 4. Higher-order representations are clearly superior for short subsequences, especially for $n = 2$ and $n = 3$ (and up to 5 half-words when comparing synt-1 and para-2). However, for long subsequences, there is no consistent difference between the syntagmatic distribution of order 1 (synt-1) and higher order distributions. Apparently, the generalized information available in higher orders is not helpful in local grammatical inference if long contexts are considered.

We were surprised that the best-performing distribution for short sequences is para-2 (paradigmatic distribution of order 2), not a higher order distribution. E.g., para-3 performs worse than para-2.

We would expect the performance to decrease with higher order eventually since the distributions converge towards p_w. The fact that this happens so early in this experiment merits further investigation.

7 Related work

Data-oriented parsing (Bod et al., 2003) shares basic assumptions about linguistic inference with exemplar-based theory, but it does not model or use the similarity between input and stored exemplars. Previous work on exemplar theory in syntax (Abbot-Smith and Tomasello, 2006; Bybee, 2006; Hay and Bresnan, 2006) has not been computational or formal. Previous work on non-categorical representations of words has viewed these representations as an intermediate step for arriving at categorical parts of speech (Redington et al., 1998; Schütze, 1995; Clark, 2003). Consequently, all of these papers evaluate their results by comparing induced categories to gold-standard parts of speech.

Redington et al. (1998) did not find a difference in categorization accuracy between simple syntagmatic representation and those using non-adjacent words.

The BEAGLE model (Jones and Mewhort, 2007), and related work (Sahlgren et al., 2008), merges co-occurrence information and word order information into a single composite vector through a process of vector convolution. Our model differs in that it explicitly captures the recursive relationship between the orders in a unified framework.

Previous graph-theoretic work (Biemann, 2006) uses order 1 representations. Several papers have looked at higher-order representations, but have not examined the equivalence of syn/para distributions when formalized as Markov chains (Schütze and Pedersen, 1993; Lund and Burgess, 1996; Edmonds, 1997; Rapp, 2002; Biemann et al., 2004; Lemaire and Denhière, 2006). Toutanova et al. (2004) found that their graph model of predicate argument structure deteriorated after a small number of iterations of the random walk, similar to our findings.

8 Conclusions and Future Work

In this paper, we have presented a graph-theoretic model of the acquisition of lexical syntactic representations and a new exemplar-based evaluation of lexical syntactic acquisition. When applied to the CHILDES corpus, the evaluation shows that the graded syntactic representations learned by the model perform significantly better than previously proposed categorical representations. An initial evaluation of high-order representations showed little improvement over low-order representations.

In future work, we intend to investigate the influence of noise and ambiguity on the quality of the representations in order to characterize when higher order representations improve generalization and exemplar-theoretic inference. We also want to address that the model as it currently stands is trained under the false assumption that the training input is grammatical. Ungrammatical test input which matches a learned ungrammatical sequence will be deemed grammatical. Future work will examine how to best treat this challenge, e.g., by using an estimation of density instead of the simplistic "1 nearest neighbor" distance used here.

The most important future work concerns class-based language models. The cognitive-linguistic tradition we have mainly addressed in this paper has focused on the task of learning traditional parts of speech and has usually not discussed the relevance of language models to acquisition. If, as we have argued, instead of learning traditional parts of speech the focus should be on performance in particular language processing tasks (like grammaticality judgments), then language models are the natural competing account that we must compare our work to. Of particular relevance are class-based language models (e.g., (Saul and Pereira, 1997; Brown et al., 1992)). In ongoing work, we are attempting to show that the exemplar-theoretic model performs better on grammaticality judgments than class-based language models.

Abstract

Question classification plays an important role in question answering. Features are the key to obtain an accurate question classifier. In contrast to Li and Roth (2002)'s approach which makes use of very rich feature space, we propose a compact yet effective feature set. In particular, we propose head word feature and present two approaches to augment semantic features of such head words using WordNet. In addition, Lesk's word sense disambiguation (WSD) algorithm is adapted and the depth of hypernym feature is optimized. With further augment of other standard features such as unigrams, our linear SVM and Maximum Entropy (ME) models reach the accuracy of 89.2% and 89.0% respectively over a standard benchmark dataset, which outperform the best previously reported accuracy of 86.2%.

1 Introduction

An important step in question answering (QA) and other dialog systems is to classify the question to the anticipated type of the answer. For example, the question of *Who discovered x-rays* should be classified into the type of human (individual). This information would narrow down the search space to identify the correct answer string. In addition, this information can suggest different strategies to search and verify a candidate answer. For instance, the classification of question *What is autism* to a definition type question would trigger the search strategy specific for definition type (e.g., using predefined templates like: *Autism is ...* or *Autism is defined as...*). In fact, the combination of QA and the named entity recognition is a key approach in modern question answering systems (Voorhees and Dang, 2005).

The question classification is by no means trivial: Simply using question wh-words can not achieve satisfactory results. The difficulty lies in classifying the *what* and *which* type questions. Considering the example *What is the capital of Yugoslavia*, it is of location (city) type, while *What is the pH scale* is of definition type. Considering also examples (Li and Roth, 2006) *What tourist attractions are there in Reims*, *What are the names of the tourist attractions in Reims*, *What do most tourists visit in Reims*, *What attracts tourists to Reims*, and *What is worth seeing in Reims*, all these reformulations are of the same answer type of location. Different wording and syntactic structures make it difficult for classification.

Many QA systems used manually constructed sets of rules to map a question to a type, which is not efficient in maintain and upgrading. With the increasing popularity of statistical approaches, machine learning plays a more and more important role in this task. A salient advantage of machine learning approach is that one can focus on designing insightful features, and rely on learning process to efficiently and effectively cope with the features. In addition, a learned classifier is more flexible to reconstruct than a manually constructed system because it can be trained on a new taxonomy in a very short time. Earlier question classification work includes Pinto et al. (2002) and Radev et at. (2002), in which language model and Rappier rule learning were employed respectively. More recently, Li and Roth (2002) have developed a machine learning approach which uses the SNoW learning architecture (Khardon et al.,

Proceedings of the 2008 Conference on Empirical Methods in Natural Language Processing, pages 927–936,
Honolulu, October 2008. ©2008 Association for Computational Linguistics

1999). They have compiled the UIUC question classification dataset [1] which consists of 5500 training and 500 test questions. The questions in this dataset are collected from four sources: 4,500 English questions published by USC (Hovy et al., 2001), about 500 manually constructed questions for a few rare classes, 894 TREC 8 and TREC 9 questions, and also 500 questions from TREC 10 which serve as the test dataset. All questions in the dataset have been manually labeled by them according to the coarse and fine grained categories as shown in Table 3, with coarse classes (in bold) followed by their fine class refinements. In addition, the table shows the distribution of the 500 test questions over such categories. Li and Roth (2002) have made use of lexical words, part of speech tags, chunks (non-overlapping phrases), head chunks (the first noun chunk in a question) and named entities. They achieved 78.8% accuracy for 50 fine grained classes. With a hand-built dictionary of semantically related words, their system is able to reach 84.2%.

The UIUC dataset has laid a platform for the follow-up research. Hacioglu and Ward (2003) used linear support vector machines with question word bigrams and error-correcting output to obtain accuracy of 80.2% to 82.0%. Zhang and Lee (2003) used linear SVMs with all possible question word grams, and obtained accuracy of 79.2%. Later Li and Roth (2006) used more semantic information sources including named entities, WordNet senses, class-specific related words, and distributional similarity based categories in question classification task. With all these semantic features plus the syntactic ones, their model was trained on 21'500 questions and was able to achieve the best accuracy of 89.3% on a test set of 1000 questions (taken from TREC 10 and TREC 11) for 50 fine classes. Most recently, Krishnan et al. (2005) used a short (typically one to three words) subsequence of question tokens as features for question classification. Their model can reach the accuracy of 86.2% using UIUC dataset over fine grained question categories, which is the highest reported accuracy on UIUC dataset.

In contrast to Li and Roth (2006)'s approach which makes use of a very rich feature set, we propose to use a compact yet effective feature set. In particular, we propose head word feature and present two approaches to augment semantic features of such head words using WordNet. In addition, Lesk's word sense disambiguation (WSD) algorithm is adapted and the depth of hypernym feature is optimized. With further augment of other standard features such as unigrams, we can obtain accuracy of 89.2% using linear SVMs, or 89.0% using ME for 50 fine classes.

2 Classifiers

In this section, we briefly present two classifiers, support vector machines and maximum entropy model, which will be employed in our experiments. These two classifiers perform roughly identical in the question classification task.

2.1 Support Vector Machines

Support vector machine (Vapnik, 1995) is a useful technique for data classification. Given a training set of instance-labeled pairs $(\mathbf{x}_i, y_i)$, $i = 1, \ldots, l$ where $\mathbf{x}_i \in R^n$ and $\mathbf{y} \in \{1, -1\}^l$, the support vector machines (SVM) require the solution of the following optimization problem: $\min_{\mathbf{w},b,\xi} \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l}\xi_i$ subject to $y_i(\mathbf{w}^T\phi(\mathbf{x}_i) + b) \geq 1 - \xi_i$ and $\xi_i \geq 0$. Here training vectors $\mathbf{x}_i$ are mapped into a higher (maybe infinite) dimensional space by the function ϕ. Then SVM finds a linear separating hyperplane with the maximal margin in this higher dimensional space. $C > 0$ is the penalty parameter of the error term. Furthermore, $K(\mathbf{x}_i, \mathbf{x}_j) \equiv \phi(\mathbf{x}_i)^T\phi(\mathbf{x}_i)$ is called the kernel function. There are four basic kernels: linear, polynomial, radial basis function, and sigmoid. In the question classification context, $\mathbf{x}_i$ is represented by a set of binary features, for instance, the presence or absence of particular words. $y_i \in \{1, -1\}$ indicates wether a question is of a particular type or not. Due to the large number of features in question classification, one may not need to map data to a higher dimensional space. It has been commonly accepted that the linear kernel of $K(\mathbf{x}_i, \mathbf{x}_j) = {\mathbf{x}_i}^T\mathbf{x}_i$ is good enough for question classification. In this paper, we adopt the LIBSVM (Chang and Lin, 2001) implementation in our experiments.

2.2 Maximum Entropy Models

Maximum entropy (ME) models (Berger et al., 1996; Manning and Klein, 2003), also known as log-linear and exponential learning models, provide a general purpose machine learning technique for classification and prediction which has been successfully applied to natural language processing including part of speech tagging, named entity recognition etc. Maximum entropy models can integrate features from many heterogeneous information sources for classification. Each feature corresponds to a constraint on the model. In the context of question classification, a sample feature could be the presence of a particular word associated with a particular question type. The maximum entropy model is the model with maximum entropy of all models that satisfy the constraints. In this paper, we adopt Stanford Maximum Entropy (Manning and Klein, 2003) implementation in our experiments.

3 Features

Each question is represented as a bag of features and is feeded into classifiers in training stage. We present five binary feature sets, namely question wh-word, head word, WordNet semantic features for head word, word grams, and word shape feature. The five feature sets will be separately used by the classifiers to determine their individual contribution. In addition, these features are used in an incremental fashion in our experiments.

3.1 Question wh-word

The wh-word feature is the question wh-word in given questions. For example, the wh-word of question *What is the population of China* is *what*. We have adopted eight question wh-words, namely *what*, *which*, *when*, *where*, *who*, *how*, *why*, and *rest*, with *rest* being the type does not belong to any of the previous type. For example, the question *Name a food high in zinc* is a *rest* type question.

3.2 Head Word

Li and Roth (2002;2006) used head chunks as features. The first noun chunk and the first verb chunk after the question word in a sentence are defined as head chunks in their approach. Krishnan et al. (2005) used one contiguous span of tokens which is denoted as the *informer span* as features. In both approaches, noisy information could be introduced. For example, considering the question of *What is a group of turkeys called*, both the head chunk and informer span of this question is *group of turkeys*. The word of *turkeys* in the chunk (or span) contributes to the classification of type ENTY:animal if the hypernyms of WordNet are employed (as described in next section). However, the extra word *group* would introduce ambiguity to misclassify such question into HUMAN:group, as all words appearing in chunk are treated equally. To tackle this problem, we propose the feature of *head word*, which is one single word specifying the object that the question seeks. In the previous example *What is a group of turkeys called*, the head word is exactly *turkeys*. In doing so, no misleading word *group* is augmented. Another example is *George Bush purchased a small interest in which baseball team*. The head chunk, informer span and head word are *baseball team*, *baseball team* and *team* respectively. The extra word *baseball* in the head chunk and informer span may lead the question misclassified as ENTY:sport rather than HUM:group. In most cases, the head chunk or informer span include head words. The head chunk feature or informer span feature would be beneficiary so long as the useful information plays a stronger role than the misleading one. Nevertheless, this is not as effective as the introduction of one head word.

To obtain the head word feature, a syntactic parser is required. A syntactic parser is a model that outputs the grammatical structure of given sentences. There are accurate parsers available such as Chaniak parser (Charniak and Johnson, 2005), Stanford parser (Klein and Manning, 2003) and Berkeley parser (Petrov and Klein, 2007), among which we use the Berkeley parser [2] to help identify the head word. Figure 1 shows two example parse trees for questions *What year did the Titanic sink* and *What is the sales tax in Minnesota* respectively.

Collins rules (Collins, 1999) can be applied to parse trees to extract the syntactic head words. For example, the WHNP phrase (Wh-noun phrase) in the top of Figure 1 takes its WP child as its head word, thus assigning the word *what* (in the bracket) which is associated with WP tag to the syntactic head word of WHNP phrase. Such head word assignment is carried out from the bottom up and the word *did* is extracted as the head word of the whole question. Similarly, the word *is* is extracted as the

[2] available at http://nlp.cs.berkeley.edu/Main.html#parsing

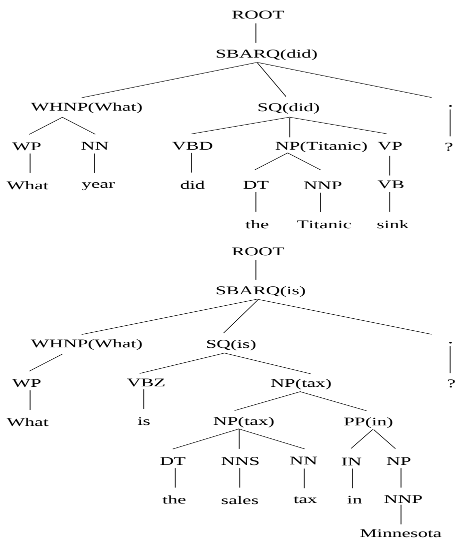

Figure 1: Two example parse trees and their head words assignment

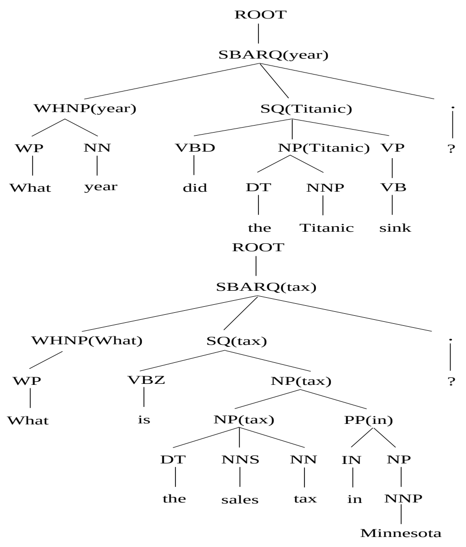

Figure 2: Two example parse trees and their revised head words assignment

syntactic head word in the bottom of Figure 1.

Collins head words finder rules have been modified to extract semantic head word (Klein and Manning, 2003). To better cover the question sentences, we further re-define the semantic head finder rules to fit our needs. In particular, the rules to find the semantic head word of phrases SBARQ (Clause introduced by subordinating conjunction), SQ (subconstituent of SBARQ excluding wh-word or wh-phrase), VP (verb phrase) and SINV (declarative sentence with subject-aux inversion) are redefined, with the head preference of noun or noun phrase rather than verb or verb phrase. The new head word assignments for the previous two examples are shown in Figure 2.

If the head word is any of *name*, *type* or *kind* etc, post fix is required to identify the real head word if necessary. In particular, we compile a tree pattern as shown in the left of Figure 3. If this pattern is matched against a given parse question parse tree, the head word is re-assigned to the head word of NP node in the tree pattern. For example, the initial head word extracted from parse tree of question *What is the proper name for a female walrus* is *name*. As such parse tree (as shown partially in the right of Figure 3) matches the compiled tree pattern, the post operation shall fix it to *walrus*, which is the head word of the NP in the tree pattern. This post fix helps classify the question to ENTY:animal.

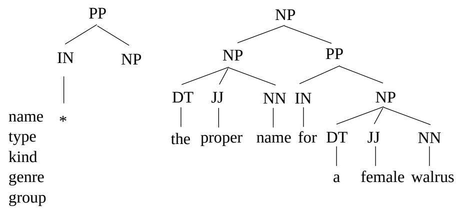

Figure 3: Post fix for the head word assignment

In addition to the question head word as described above, we introduce a few regular expression patterns to help question head word identification. Note that these patterns depend on the question type taxonomy as shown in Table 3. For example, considering the questions of *What is an atom* and *What are invertebrates*, the head word of *atom* and *invertebrates* do not help classify such questions to DESC:def. To resolve this, we create a binary feature using a string regular expression which begins with *what is/are* and follows by an optional *a*, *an*, or *the* and then follows by one or two words. If a question matches this regular expression, a binary feature (a placeholder word is used in implementation, for instance DESC:def_1 in this case) would be inserted to the feature set of the question. This feature, if it is beneficial, would be picked up by the classifiers (SVMs or MEs) in training. We list all regular expression patterns which are used in our experiments as following:

DESC:def pattern 1 The question begins with *what is/are* and follows by an optional *a*, *an*, or *the* and then follows by one or two words.

DESC:def pattern 2 The question begins with *what do/does* and ends with *mean*.

ENTY:substance pattern The question begins with *what is/are* and ends with *composed of/made of/made out of*.

DESC:desc pattern The question begins with *what does* and ends with *do*.

ENTY:term The question begins with *what do you call*.

DESC:reason pattern 1 The question begins with *what causes/cause*.

DESC:reason pattern 2 The question begins with *What is/are* and ends with *used for*.

ABBR:exp pattern The question begins with *What does/do* and ends with *stand for*.

HUM:desc pattern The question begins with *Who is/was* and follows by a word starting with a capital letter.

It is worth noting that all these patterns serve as feature generators for given questions: the feature becomes active if the pattern matches the questions. The algorithm to extract question head word is shown in Algorithm 1. There is no head word returned for *when*, *where* or *why* type questions, as these hw-words are informative enough; the inclusion of other words would introduce noisy information. If the question is of type *how*, the word following *how* is returned as head word. The patterns are then attempted to match the question if it is of type *what* or *who*. If there is a match, the placehold word for such pattern (e.g., *HUM:desc* for HUM:desc pattern) is returned as head word. If none of the above condition is met, the candidate head word is extracted from the question parse tree using the redefined head finder rules. Such extracted head word is returned only if it has noun or noun phrase tag; otherwise the first word which has noun or noun phrase tag is returned. The last step is a back up plan in case none of the previous procedure happens.

Algorithm 1 Question head word extraction

```
Require: Question $q$
Ensure: Question head word
 1: if $q$.type == $when|where|why$ then
 2:     return null
 3: end if
 4: if $q$.type == how then
 5:     return the word following word "how"
 6: end if
 7: if $q$.type == what then
 8:     for any aforementioned regular expression $r$ (except HUM:desc pattern) do
 9:         if($q$ matches $r$)
10:         return $r$.placehold-word
11:     end for
12: end if
13: if $q$.type == who && $q$ matches HUM:desc pattern then
14:     return "HUM:desc"
15: end if
16: String $candidate$ = head word extracted from question parse tree
17: if $candidate$.tag starts with NN then
18:     return $candidate$
19: end if
20: return the first word whose tag starts with NN
```

3.3 WordNet Semantic Feature

WordNet (Fellbaum, 1998) is a large English lexicon in which meaningfully related words are connected via cognitive synonyms (synsets). The WordNet is a useful tool for word semantics analysis and has been widely used in question classification (Krishnan et al., 2005; Schlaefer et al., 2007). A natural way to use WordNet is via hypernyms: Y is a hypernym of X if every X is a (kind of) Y. For example, the question of *What breed of hunting dog did the Beverly Hillbillies own* requires the knowledge of *animal* being the hypernym of *dog*. In this paper, we propose two approaches to augment WordNet semantic features, with the first augmenting the hypernyms of head words as extracted in previous section directly, and the second making use of a WordNet similarity package (Seco et al., 2004), which implicitly employs the structure of hypernyms.

3.3.1 Direct Use of Hypernyms

In WordNet, senses are organized into hierarchies with hypernym relationships, which provides a natural way to augment hypernyms features from the original head word. For example, the hierarchies for a noun sense of domestic dog is described as: *dog* → *domestic animal* → *animal*, while another noun sense (a dull unattractive unpleasant girl or woman) is organized as *dog* → *unpleasant woman* → *unpleasant person*. In addition, a verb sense of dog is organized as *dog* → *pursue* → *travel*. In our first approach, we attempt to directly introduce hypernyms for the extracted head words. The augment of hypernyms for given head word can introduce useful information, but can also bring noise if the head word or the sense of head word are not correctly identified. To resolve this, three questions shall be addressed: 1) which part of speech senses should be augmented? 2) which sense of the given word is needed to be augmented? and 3) how many depth are required to tradeoff the generality (thus more informative) and the specificity (thus less noisy). The first question can be answered by mapping the Penn Treebank part of speech tag of the given head word to its WordNet part of speech tag, which is one of POS.NOUN, and POS.ADJECTIVE, POS.ADVERB and POS.VERB. The second question is actually a word sense disambiguation (WSD) problem. The Lesk algorithm (Lesk, 1986) is a classical algorithm for WSD. It is based on the assumption that words in a given context will tend to share a common topic. A basic implementation of the The Lesk algorithm is described as following:

1. Choosing pairs of ambiguous words within a context
2. Checks their definitions in a dictionary
3. Choose the senses as to maximize the number of common terms in the definitions of the chosen words

In our head word sense disambiguation, the context words are words (except the head word itself) in the question, and the dictionary is the gloss of a sense for a given word. Algorithm 2 shows the adapted Lesk algorithm which is employed in our system. Basically, for each sense of given head word, this

Algorithm 2 Head word sense disambiguation

```
Require: Question $q$ and its head word $h$
Ensure: Disambiguated sense for $h$
 1: int $count$ = 0
 2: int $maxCount$ = -1
 3: sense $optimum$ = null
 4: for each sense $s$ for $h$ do
 5:     $count$ = 0
 6:     for each context word $w$ in $q$ do
 7:         int $subMax$ = maximum number of common words in $s$
            definition (gloss) and definition of any sense of $w$
 8:         count = count + sumMax
 9:     end for
10:     if $count > maxCount$ then
11:         $maxCount = count$
12:         $optimum = s$
13:     end if
14: end for
15: return $optimum$
```

algorithm computes the maximum number of common words between gloss of this sense and gloss of any sense of the context words. Among all head word senses, the sense which results in the maximum common words is chosen as the optimal sense to augment hypernyms later. Finally the third question is answered via trail and error based on evaluating randomly generated 10% data from the training dataset. Generally speaking, if the identification of the head word is not accurate, it would brings significant noisy information. Our experiments show that the use of depth six produces the best results over the validation dataset. This indirectly proves that our head word feature is very accurate: the hypernyms introduction within six depths would otherwise pollute the feature space.

3.3.2 Indirect Use of Hypernyms

In this approach, we make use of the WordNet Similarity package (Seco et al., 2004), which implicitly employs WordNet hypernyms. In particular, for a given pair of words, the WordNet similarity package models the length of path traveling from one word to the other over the WordNet network. It then computes the semantic similarity based on the path. For example, the similarity between *car* and *automobile* is 1.0, while the similarity between *film* and *audience* is 0.38. For each question, we use the WordNet similarity package to compute the similarity between the head word of such question and each description word in a question categorization. The description words for a question category are a few words (usually one to three) which explain the semantic meaning of such a question category [3]. For example, the descriptions words for category ENTY:dismed are *diseases* and *medicine*. The question category which has the highest similarity to the head word is marked as a feature. This is equal to a mini question classifier. For example, as the head word *walrus* of question *What is the proper name for a female walrus* has the highest similarity measure to *animals*, which is a description word of category ENTY:animal, thus the ENTY:animal is inserted into the feature set of the given question.

3.4 N-Grams

An N-gram is a sub-sequence of N words from a given question. Unigram forms the bag of words feature, and bigram forms the pairs of words feature, and so forth. We have considered unigram, bigram, and trigram features in our experiments. The reason to use such features is to provide word sense

[3]available at http://12r.cs.uiuc.edu/∼cogcomp/Data/QA/QC/definition.html

disambiguation for questions such as *How long did Rip Van Winkle sleep*, as *How long* (captured by wh-word and head word features) could refer to either NUM:dist or NUM:period. The word feature of *sleep* help determine the NUM:period classification.

3.5 Word Shape

Word shape in a given question may be useful for question classification. For instance, the question *Who is Duke Ellington* has a mixed shape (begins a with capital letter and follows by lower case letters) for *Duke*, which roughly serves as a named entity recognizer. We use five word shape features, namely all upper case, all lower case, mixed case, all digits, and other. The experiments show that this feature slightly boosts the accuracy.

4 Experimental Results

We designed two experiments to test the accuracy of our classifiers. The first experiment evaluates the individual contribution of different feature types to question classification accuracy. In particular, the SVM and ME are trained from the UIUC 5500 training data using the following feature sets: 1) wh-word + head word, 2) wh-word + head word + direct hypernym, 3) wh-wod + head word + indirect hypernym, 4) unigram, 5) bigram, 6) trigram, and 7) word shape. We set up the tests of 1), 2) and 3) due to the fact that wh-word and head word can be treated as a unit, and hypernym depends on head word. In the second experiment, feature sets are incrementally feeded to the SVM and ME. The parameters for both SVM and ME classifiers (e.g., the C in the SVM) are all with the default values. In order to facilitate the comparison with previously reported results, the question classification performance is measured by accuracy, i.e., the proportion of the correctly classified questions among all test questions.

4.1 Individual Feature Contribution

Table 1 shows the question classification accuracy of SVM and ME using individual feature sets for 6 coarse and 50 fine classes. Among all feature sets, wh-word + head word proves to be very informative for question classification. Our first WordNet semantic feature augment, the inclusion of direct hypernym, can further boost the accuracy in the fine classes for both SVM and ME, up to four per-

Table 1: Question classification accuracy of SVM and ME using individual feature sets for 6 and 50 classes over UIUC dataset

		6 class		50 class	
		SVM	ME	SVM	ME
wh-word + head word		92.0	92.2	81.4	82.0
wh-word +	depth=1	92.0	91.8	84.6	84.8
head word +	depth = 3	92.0	92.2	85.4	85.4
direct hypernym	depth = 6	92.6	91.8	85.4	85.6
wh-word + head		91.8	92.0	83.2	83.6
+ indirect hypernym					
unigram		88.0	86.6	80.4	78.8
bigram		85.6	86.4	73.8	75.2
trigram		68.0	57.4	39.0	44.2
word shape		18.8	18.8	10.4	10.4

cent. This phenomena conforms to Krishnan et al. (2005) that WordNet hypernym benefits mainly on the 50 fine classes classification. Li and Roth (2006) made use of semantic features including named entities, WordNet senses, class-specific related words, and distributional similarity based categories. Their system managed to improve around 4 percent with the help of those semantic features. They reported that WordNet didn't contribute much to the system, while our results show that the WordNet significantly boosts the accuracy. The reason may be that their system expanded the hypernyms for each word in the question, while ours only expanded the head word. In doing so, the augmentation does not introduce much noisy information. Notice that the inclusion of various depth of hypernyms results in different accuracy. The depth of six brings the highest accuracy of 85.4% and 85.6% for SVM and ME under 50 classes, which is very competitive to the previously reported best accuracy of 86.2% (Krishnan et al., 2005).

Our second proposed WordNet semantic feature, the indirect use of hypernym, does not perform as good as the first approach; it only contributes the accuracy gain of 1.8 and 1.6 in the fine classes for SVM and ME respectively. The reason may be two fold: 1) the description words (usually one to three words) of question categories are not representative enough, and 2) the indirect use of hypernyms via the WordNet similarity package is not as efficient as direct use of hypernyms.

Among the surface words features, unigram feature perform the best with accuracy of 80.4% for SVM under 50 classes, and 88.0% for SVM under 6 classes. It is not surprising that the word shape feature only achieves small gain in question classification, as the use of five shape type does not provide enough information for question classification. However, this feature is treated as an auxiliary one to boost a good classifier, as we will see in the second experiment.

4.2 Incremental Feature Contribution

Based on the individual feature contribution, we then trained the SVMs and MEs using wh-word, head word, direct hypernyms (with depth 6) of head word, unigram, and word shape incrementally. Table 2 shows the question classification accuracy (broken down by question types) of SVM and ME for 6 coarse and 50 fine classes. As can be seen, the main difficulty for question classification lies in the *what* type questions. SVM and ME perform roughly identical if they use the same features. For both SVM and ME, the baseline using the wh-head word and head word results in 81.4% and 82.0% respectively for 50 fine class classification (92.0% and 92.2% for 6 coarse classes). The incremental use of hypernym feature within 6 depths boost about four percent for both SVM and ME under 50 classes, while slight gain or slight loss for SVM and ME for 6 coarse classes. The further use of unigram feature leads to another three percent gain for both SVM and ME in 50 classes. Finally, the use of word shape leads to another 0.6% accuracy increase for both SVM and ME in 50 classes. The best accuracy achieved for 50 classes is 89.2% for SVM and 89.0% for ME. For 6 coarse classes, SVM and ME achieve the best accuracy of 93.4% and 93.6% respectively.

Our best result feature space only consists of 13'697 binary features and each question has 10 to 30 active features. Compared to the over feature size of 200'000 in Li and Roth (2002), our feature space is much more compact, yet turned out to be more informative as suggested by the experiments.

Note that if we replace the bigram with unigram, SVM and ME achieve the overall accuracy of 88.4% and 88.0% respectively for 50 fine classes, and the use of trigram leads SVM and ME to 86.6% and 86.8% respectively. The inclusion of unigram, bigram and trigram together won't boost the accuracy, which reflects the fact that the bigram and trigram features cannot bring more information given that unigram, wh-word and head word features are present. This is because the useful information which are supposed to be captured by bigram or trigram are effectively captured by wh-word and head word features. The unigram feature thus outperforms bigram and trigram due to the fact that it is less sparse. In addition, if we replace the indirect use of hypernym with the direct use of hypernym, the overall accuracy is 84.6% and 84.8% for SVM and ME respectively. All these experiments conform to the individual features contributions as shown in Table 1.

For a better understanding of the error distribution with respect to the 50 question categories, Table 3 shows the precision and recall for each question type in the best result (89.2%) using SVM. It is not surprising that some of the categories are more difficult to predict such as ENTY:other and ENTY:product, while others are much easier such as HUMAN:individual, since the former are more semantically ambiguous than the latter.

Table 3: Precision and recall for fine grained question categories

lenge questions. For instance, the question *What is the proper name for a female walrus* has been correctly classified as ENTY:animal. However, it still has nearly ten percent error rate for 50 fine classes. The reason is three fold: 1) there are inherently ambiguity in classifying a question. For instance, the question *What is mad cow disease*, it could be either of type DESC:def or ENTY:dismed; 2) there are inconsistent labeling in the training data and test data. For instance, *What is the population of Kansas* is labeled with the type NUM:other while *What is the population of Arcadia , Florida* is labeled with type NUM:count. Another example, *What county is Chicago in* is labeled with type LOC:other while *What county is Phoenix , AZ in* is labeled with type LOC:city; and 3) The parser can produce incorrect parse tree which would result in wrong head word extraction. For instance, the head word extracted from *What is the speed hummingbirds fly* is *hummingbirds* (the correct one should be *speed*), thus leading to the incorrect classification of ENTY:animal (rather than the correct NUM:speed).

5 Conclusion

In contrast to Li and Roth (2006)'s approach which makes use of very rich feature space, we proposed a compact yet effective feature set. In particular, we proposed head word feature and presented two approaches to augment semantic features of such head words using WordNet. In addition, Lesk's word sense disambiguation algorithm was adapted and the depth of hypernym feature was optimized through cross validation, which was to introduce useful information while not bringing too much noise. With further augment of wh-word, unigram feature, and word shape feature, we can obtain accuracy of 89.2% using linear SVMs, or 89.0% using ME for 50 fine classes.

Abstract

An increasingly popular method for finding information online is via the Community Question Answering (CQA) portals such as Yahoo! Answers, Naver, and Baidu Knows. Searching the CQA archives, and ranking, filtering, and evaluating the submitted answers requires intelligent processing of the questions and answers posed by the users. One important task is automatically detecting the question's *subjectivity orientation*: namely, whether a user is searching for subjective or objective information. Unfortunately, real user questions are often vague, ill-posed, poorly stated. Furthermore, there has been little labeled training data available for real user questions. To address these problems, we present *CoCQA*, a co-training system that exploits the association between the questions and contributed answers for question analysis tasks. The co-training approach allows *CoCQA* to use the effectively unlimited amounts of *unlabeled* data readily available in CQA archives. In this paper we study the effectiveness of *CoCQA* for the question subjectivity classification task by experimenting over thousands of real users' questions.

1 Introduction

Automatic question answering (QA) has been one of the long-standing goals of natural language processing, information retrieval, and artificial intelligence research. For a natural language question we would like to respond with a specific, accurate, and complete answer that addresses the question. Although much progress has been made, answering complex, opinion, and even many factual questions automatically is still beyond the current state-of-the-art. At the same time, the rise of popularity in social media and collaborative content creation services provides a promising alternative to web search or completely automated QA. The explicit support for social interactions between participants, such as posting comments, rating content, and responding to questions and comments makes this medium particularly amenable to Question Answering. Some very successful examples of Community Question Answering (CQA) sites are Yahoo! Answers[1] and Naver[2], and Baidu Knows[3]. Yahoo! Answers alone has already amassed hundreds of millions of answers posted by millions of participants on thousands of topics.

The questions posted to such CQA portals are typically complex, subjective, and rely on human interpretation to understand the corresponding information need. At the same time, the questions are also usually ill-phrased, vague, and often *subjective* in nature. Hence, analysis of the questions (and of the corresponding user intent) in this setting is a particularly difficult task. At the same time, CQA content incorporates the relationships between questions and the corresponding answers. Because of the various incentives provided by the CQA sites, answers posted by users tend to be, at least to some degree, responsive to the question. This observation suggests investigating whether the relation-

[1] http://answers.yahoo.com
[2] http://www.naver.com
[3] http://www.baidu.com

ship between questions and answers can be exploited to improve automated analysis of the CQA content and the user intent behind the questions posted.

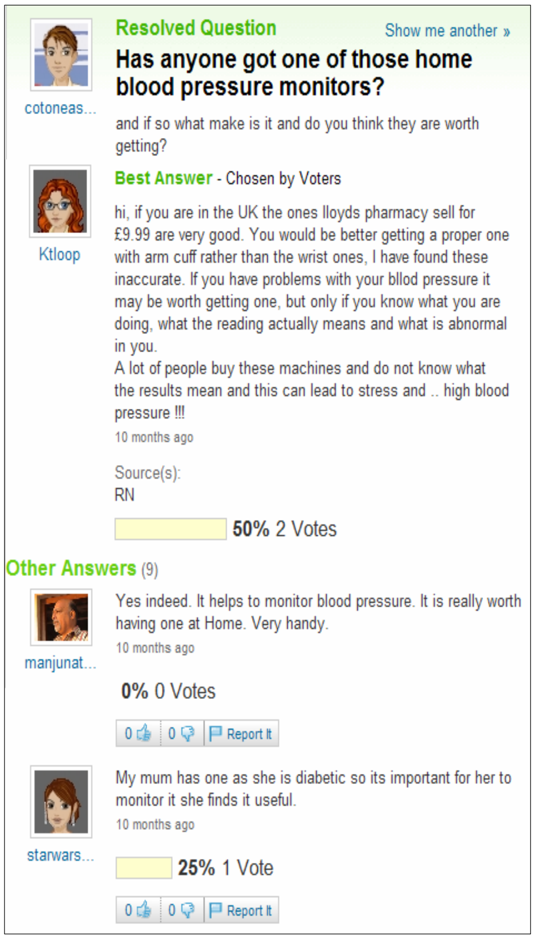
To this end, we exploit the ideas of *co-training*, a general semi-supervised learning approach naturally applicable to cases of complementary views on a domain, for example, web page links and content (Blum and Mitchell, 1998). In our setting, we focus on the complimentary views for a question, namely the text of the question and the text of the associated answers.

As a concrete case-study of our approach we focus on one particularly important aspect of intent detection: the *subjectivity orientation*. We attempt to predict whether a question posted in a CQA site is subjective or objective. Objective questions are expected to be answered with reliable or authoritative information, typically published online and possibly referenced as part of the answer, whereas subjective questions seek answers containing private states, e.g. personal opinions, judgment, experiences. If we could automatically predict the orientation of a question, we would be able to better rank or filter the answers, improve search over the archives, and more accurately identify similar questions. For example, if a question is objective, we could try to find a few highly relevant articles as references, whereas if a question is subjective, useful answers are not expected to be found in authoritative sources and tend to rank low with current question answering and CQA search techniques. Finally, learning how to identify question orientation is a crucial component of inferring user intent, a long-standing problem in web information access settings.

In particular, we focus on the following research questions:

- Can we utilize the inherent structure of the CQA interactions and use the unlimited amounts of *unlabeled* data to improve classification performance, and/or reduce the amount of manual labeling required?

- Can we automatically predict question subjectivity in Community Question Answering – and which features are useful for this task in the real CQA setting?



Resolved Question

cotoneas...

Has anyone got one of those home blood pressure monitors?

and if so what make is it and do you think they are worth getting?

Ktloop

Best Answer - Chosen by Voters

hi, if you are in the UK the ones lloyds pharmacy sell for £9.99 are very good. You would be better getting a proper one with arm cuff rather than the wrist ones, I have found these inaccurate. If you have problems with your bllod pressure it may be worth getting one, but only if you know what you are doing, what the reading actually means and what is abnormal in you.
A lot of people buy these machines and do not know what the results mean and this can lead to stress and .. high blood pressure !!!

Figure 1: Example question (Yahoo! Answers)

The rest of the paper is structured as follows. We first overview the community question answering setting, and state the question orientation classification problem, which we use as the motivating application for our system, more precisely. We then introduce our *CoCQA* system for semi-supervised classification of questions and answers in CQA communities (Section 3). We report the results of our experiments over thousands of real user questions in Section 4, showing the effectiveness of our approach. Finally, we review related work in Section 5, and discuss our conclusions and future work in Section 6.

2 Question Orientation in CQA

We first briefly describe the essential features of question answering communities such as Yahoo! Answers or Naver. Then, we formally state the problem addressed in this paper, and the features used for this setting.

2.1 Community Question Answering

Online social media content and associated services comprise one of the fastest growing segments on the Web. The explicit support for social interactions between participants, such as posting comments, rating content, and responding to questions and comments makes the social media unique. Question answering has been particularly amenable to social media by directly connecting information seekers with the community members willing to share the information. Yahoo! Answers, with millions of users and hundreds of millions of answers for millions of questions is a very successful implementation of CQA.

For example, consider two example user-contributed questions, objective and subjective respectively:

> **`Q1: What's the difference between chemotherapy and radiation treatments?`**
>
> **`Q2: Has anyone got one of those home blood pressure monitors?`** `and if so what make is it` *`and do you think they are worth getting`*`?`

Figure 1 shows an example of community interactions in Yahoo! Answers around the question Q2 above. A user posted the question in the *Health* category of the site, and was able to obtain 10 responses from other users. Eventually, the asker chooses the best answer. Failing that, as shown in the example, the best answer can also be chosen according to the votes from other users. Many of the interactions depend on the perceived goals of the asker: if the participants interpret the question as subjective, they will tend to share their experiences and opinions, and if they interpret the question as objective, they may still share their experiences but may also provide more factual information.

2.2 Problem Definition

We now state our problem of question orientation more precisely. We consider question orientation from the perspective of user goals: authors of objective questions request authoritative, objective information (e.g., published literature or expert opinion), whereas authors of subjective questions seek opinions or judgments of other users in the community. We state our problem as follows.

> **Question Subjectivity Problem:** *Given a question Q in a question answering community, predict whether Q has objective or subjective orientation, based on question and answer text as well as the user and community feedback.*

3 *CoCQA*: A Co-Training Framework over Questions and Answers

In the CQA setting we could easily obtain thousands or millions of unlabeled examples from the online CQA archives. On the other hand, it is difficult to create a labeled dataset with a reasonable size, which could be used to train a perfect classifier to analyze questions from different domains and sub-domains. Therefore, semi-supervised learning (Chapelle et al., 2006) is a natural approach for this setting.

Intuitively, we can consider the text of the question itself or answers to it. In other words, we have multiple (at least two) natural views of the data, which satisfies the conditions of the co-training approach (Blum and Mitchell, 1998). In *co-training*, two separate classifiers are trained on two sets of features, respectively. By automatically labeling the unlabeled examples, these two classifiers iteratively "teach" each other by giving their partners a newly labeled data that they can predict with high confidence. Based on the original co-training algorithm in (Blum and Mitchell, 1998) and other implementations, we develop our algorithm *CoCQA* shown in Figure 2.

At Steps 1 and 2, the *K* examples are coming from different feature spaces, and each category (for example, *Subjective* and *Objective*) has top K_j most confident examples chosen, where K_j corresponds to the distribution of class in the current set of labeled examples L. *CoCQA* will terminate when the increments of both classifiers are less than a specified threshold *X* or the maximum number of iterations are exceeded. Following the co-training approach, we include the most confidently predicted examples as additional "labeled" data. The SVM output margin value was used to estimate confidence; alternative

```
Input:
  • $F_Q$ and $F_A$ are Question and Answer feature views
  • $C_Q$ and $C_A$ are classifiers trained on $F_Q$ and $F_A$ respectively
  • L is a set of labeled training examples
  • U is a set of unlabeled examples
  • $K$: Number of unlabeled examples to choose on each iteration
  • $X$: the threshold for increment
  • $R$: the maximal number of iterations
Algorithm CoCQA
1. Train $C_Q,0$ on L: $F_Q$, and record resulting $ACC_Q,0$
2. Train $C_A,0$ on L: $F_A$, and record resulting $ACC_A,0$
3. for j=1 to $R$ do:
     Use $C_Q,j-1$ to predict labels for U and choose
         top $K$ items with highest confidence $\rightarrow E_{Q,},j-1$
     Use $C_A,j-1$ to predict labels for U and choose
         top $K$ items with highest confidence $\rightarrow E_{A,},j-1$
     Move examples $E_{Q,},j-1 \cup E_{A,},j-1 \rightarrow$ L
     Train $C_Q,j$ on L: $F_Q$ and record training $ACC_Q,j$
     Train $C_A,j$ on L: $F_A$ and record training $ACC_A,j$
     if $Max(\Delta ACC_Q,j, \Delta ACC_A,j) < X$ break

4. return final classifiers $C_Q,j \rightarrow C_Q$ and $C_A,j \rightarrow C_A$
```

Figure 2: Algorithm CoCQA: A co-training algorithm for exploiting redundant feature sets in community question answering.

methods (including reliability of this confidence prediction) could further improve performance, and we will explore these issues in future work. Finally, the next question is how to estimate classification performance with training data. For each pass, we randomly split the original training data into *N* folds (N=10 in our experiments), and keep one part for validation and the rest, augmented with the newly added examples, as the expanded training set.

After *CoCQA* terminates, we obtain two classifiers. When a new example arrives, we will classify it with these two classifiers based on both of the feature sets, and combine the predictions of these two classifiers. We explored two strategies to make the final decision based on the confidence values given by two classifiers:

- Choose the class with higher confidence
- Multiply the confidence values, and choose the class that has the highest product.

We found the second heuristic to be more effective than the first in our experiments. As the base classifier we use SVM in the current implementation, but other classifiers could be incorporated as well.

4 Experimental Evaluation

We experiment with supervised and semi-supervised methods on a relatively large data set from Yahoo! Answers.

4.1 Datasets

To our knowledge, there is no standard dataset of real questions and answers posted by online users, labeled for subjectivity orientation. Hence, we had to create a dataset ourselves. To create our dataset, we downloaded more than 30,000 resolved questions from each of the following top-level categories of Yahoo! Answers: Arts, Education, Health, Science, and Sports. We randomly chose 200 questions from each category to create a raw dataset with 1,000 questions total. Then, we labeled the dataset with annotators from the Amazon's Mechanical Turk service[4].

For annotation, each question was judged by 5 Mechanical Turk workers who passed a qualification test of 10 questions (labeled by ourselves) with at least 9 of them correctly marked. The qualification test was required to ensure that the raters were sufficiently competent to make reasonable judgments. We grouped the tasks into 25 question batches, where the whole batch was submitted as the Mechanical Turk's Human Intelligence Task (HIT). The batching of questions was done to easily detect the "random" ratings produced by irresponsible workers. That is, each worker rated a batch of 25 questions.

While precise definition of subjectivity is elusive, we decided to take the practical perspective, namely the "majority" interpretation. The annotators were instructed to guess orientation according to how the question would be answered by most people. We did not deal with multi-part questions: if any part of question was subjective, the whole question was labeled as subjective. The gold standard was thus derived with the majority strategy, followed by manual inspection as a "sanity check". At this stage we removed 22 questions with undeterminable meaning, including gems such as "`Upward Soccer`

[4] http://www.mturk.com

`Shorts?`"[5] and "`1+1=?fdgdgdfg?`"[6]. Finally, we create a labeled dataset consisting of 978 resolved questions, available online[7].

	Num. of SUB. Q	*Num. of OBJ. Q*	*Total Num.*	*Annotator agreement*
Arts	137 (70%)	58 (30%)	195	0.841
Education	127 (64%)	70 (36%)	197	0.716
Health	125 (64%)	69 (36%)	194	0.833
Science	103 (52%)	94 (48%)	197	0.618
Sports	154 (79%)	41 (21%)	195	0.877
Total	**646 (66%)**	**332 (34%)**	**978**	**0.777**

Table 1: Labeled dataset statistics.

Table 1 reports the statistics of the annotated dataset. The overall inter-annotator percentage agreement between Mechanical Turk workers and final annotation is 0.777, indicating that the task is difficult, but feasible for humans to annotate manually.

The statistics of our labeled sample show that the vast majority of the questions in all categories except for Science are subjective in nature. The relatively high ratio of subjective questions in the Science category is surprising. However, we find that users often post polemics and statements instead of questions, using CQA as a forum to share their opinions on controversial topics. Overall, we were struck by the expressed need in Subjective information, even for categories such as Health and Education, where objective information would intuitively seem more desirable.

4.2 Features Used in Experiments

For the subjectivied experiments to follow, we attempt to capture the linguistic characteristics identified in previous work (Section 5) in a lightweight and robust manner, due to the informal and noisy nature of CQA. In particular, we use the following feature classes, computed separately over question and answer content:

- Character 3-grams
- Words
- Word with Character 3-grams
- Word n-grams (n<=3, i.e. W_i, W_iW_{i+1}, $W_iW_{i+1}W_{i+2}$)
- Word and POS n-gram (n<=3, i.e. W_i, W_iW_{i+1}, W_i POS_{i+1}, POS_iW_{i+1}, POS_iPOS_{i+1}, etc.).

We use the character 3-grams features to overcome spelling errors and problems of ill-formatted or ungrammatical questions, and the POS information to capture common patterns across domains, as words, especially the content words, are quite diverse in different topical domains. For word and character 3-gram features, we consider two different versions: case-sensitive and case-insensitive. Case-insensitive features are assumed to be helpful for mitigating negative effects of ill-formatted text.

Moreover, we experimented with three term weighting schemes: Binary, TF, and TF*IDF. Term frequency (TF) exhibited better performance in our development experiments, so we use this weighting scheme for all the experiments in Section 4. Regarding features: both words and structure of the text (e.g., word order) can be used to infer subjectivity. Therefore, the features we employ, such as words and word n-grams, are expected to be useful as a (coarse) proxy to grammatical and phrase features. Unlike traditional work on news-like text, the text of CQA and has poor spelling, grammar, and heavily uses non-standard abbreviations, hence our decision to use character n-grams.

4.3 Experimental Setting

Metrics: Since the prediction on both subjective questions and objective questions is equally important, we use the **macro-averaged F1** measure as the evaluation metric. This is computed as the macro average of F1 measures computed for the *Subjective* and *Objective* classes individually. The **F1** measure for either class is computed as $\frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$.

Methods compared: We compare our approach with both the base supervised learning, as well as *GE*, a state-of-the-art semi-supervised method:

- ***Supervised***: we use the LibSVM implementation (Chang and Lin, 2001) with linear kernel.

[5]http://answers.yahoo.com/question/?qid=20060829074901AADBRJ4
[6] http://answers.yahoo.com/question/?qid=1006012003651
[7] Available at http://ir.mathcs.emory.edu/datasets/.

- ***GE***: This is a state-of-the-art semi-supervised learning algorithm, Generalized Expectation (GE), introduced in (McCallum et al., 2007) that incorporates model expectations into the objective functions for parameter estimation.
- ***CoCQA***: Our method (Section 3).

For semi-supervised learning experiments, we selected a random subset of 2,000 unlabeled questions for each of the topical categories, for the total of 10,000 unlabeled questions.

4.4 Experimental Results

First we report the performance of our *Supervised* baseline system with a variety of features, reporting the average results of 5-fold cross validation. Then we investigate the performance to our new *CoCQA* framework under a variety of settings.

4.4.1 Supervised Learning

Table 2 reports the classification performance for varying units of representation (e.g., question text vs. answer text) and the varying feature sets. We used case-insensitive features and TF (term frequency within the text unit) as feature weights, as these two settings achieved the best results in our development experiments. The rows show performance considering only the question text (**question)**, the best answer (**best_ans**), text of all answers to a question (**all_ans**), the text of the question and the best answer (**q_bestans**), and the text of the question with all answers (**q_allans**), respectively. In particular, using the words in the question alone achieves F1 of 0.717, compared to using words in the question and the best answers text (F1 of 0.695). For comparison, a naïve baseline that always guesses the majority class (*Subjective*) obtains F1 of 0.398.

With character 3-gram, our system achieves performance comparable with words as features, but combining them together does not improve performance. We observe a slight gain with more complicated features, e.g. word n-gram, or word and POS n-grams, but the gain is not significant, and hence not worth the increased complexity of the feature generation. Finally, combining question text with answer text does not improve performance.

Interestingly, the best answer itself is not as effective as the question for subjectivity analysis, nor is using all of the answers submitted. One possible reason is that approximately 40% of the best answers were chosen by the community and not the asker herself, are hence not necessarily representative of the asker intent.

Feature set / Unit	Char 3-gram	Word	Word+ Char 3-gram	Word n-gram (n<=3)	Word POS n-gram (n<=3)
question	0.700	**0.717**	0.694	0.716	0.720
best_ans	0.587	0.597	0.578	0.580	0.565
all_ans	0.603	0.628	0.607	0.648	0.630
q_bestans	0.681	**0.695**	0.662	0.687	0.712
q_allans	0.679	0.677	0.676	0.708	0.689
Naïve (majority class) baseline:			0.398		

Table 2. Performance of predicting question orientation on the mixed dataset with varying feature sets (Supervised).

Table 3 reports the supervised subjectivity classification performance for each question category with word features. The overall classification results are significantly lower compared to training and testing on the mixture of the questions drawn from all categories, likely caused by the small amount of labeled training data for each category. Another possibility is that the subjectivity clues are not topical and hence are not category dependent, with the possible exception of the questions in the Health domain.

Category	Arts	Edu.	Health	Science	Sports
F1	0.448	0.572	**0.711**	0.647	0.441

Table 3. Experiment results on sub-categories with supervised SVM (q_bestans features).

As words are simple and effective features in this experiment, we will use them in the subsequent experiments. Furthermore, the feature set using the words in the question with best answer together (**q_bestans**) exhibit higher performance than question with all answers (**q_allans**). Thus, we will only consider questions and best answers in the following experiments with GE and *CoCQA*.

4.4.2 Semi-Supervised Learning

We now focus on investigating the effectiveness of *CoCQA*, our co-training-based framework for community question answering analysis. Table 4 summarizes the main results of this section. The values for *CoCQA* are derived with the parameter settings: K=100, *X*=0.001. These optimal settings are chosen after comprehensive experiments with different combinations, described later in this section. *GE* does not exhibit a significant improvement over *Supervised*. In contrast, *CoCQA* performs significantly better than the purely supervised method, with F1 of 0.745 compared to the F1 of 0.717 for *Supervised*. While it may seem surprising that a semi-supervised method outperforms a supervised one, note that we use all of the available *labeled* data as provided to the Supervised method, as well as a large amount of *unlabeled* data, that is ultimately responsible for the performance improvement.

Features / Method	Question	Question+ Best Answer
Supervised	0.717	0.695
GE	0.712 (-0.7%)	0.717 (+3.2%)
CoCQA	0.731 (+1.9%)	**0.745** (+7.2%)

Table 4. Performance of *CoCQA*, *GE*, and *Supervised* with the same feature and data settings.

As an added advantage, *CoCQA* approach is also practical. In a realistic application, we have two different situations: offline and online. With online processing, we may not have best answers available to predict question's orientation, whereas we can employ information from best answers in offline setting. Co-training is a solution that is applicable to both situations. With *CoCQA*, we have two classifiers using the question text and the best answer text, respectively. We can use both of them to obtain better results in the offline setting, while in online setting, we can use the text of the question alone. In contrast, *GE* may not have this flexibility.

We now analyze the performance of *CoCQA* under a variety of settings to derive optimal parameters and to better understand the performance. Figure 3 reports the performance of *CoCQA* with varying the *K* parameter from 20 to 200. In this experiment, we fix *X* to be 0.001. The combination of question and best answer is superior to that of question and all answers. When *K* is 100, the system obtains the best result, 0.745.

Figure 4 reports the number of co-training iterations needed to converge to optimal performance. After 13 iterations (and 2500 unlabeled examples added), *CoCQA* achieves optimal performance, and eventually terminates after an additional 3 iterations. While a validation set should have been used for *CoCQA* parameter tuning, Figures 3 and 4 indicate that *CoCQA* is not sensitive to the specific parameter settings. In particular, we observe that any *K* is greater than 100, and for any number of iterations *R* is greater than 10, *CoCQA* exhibits in effectively equivalent performance.

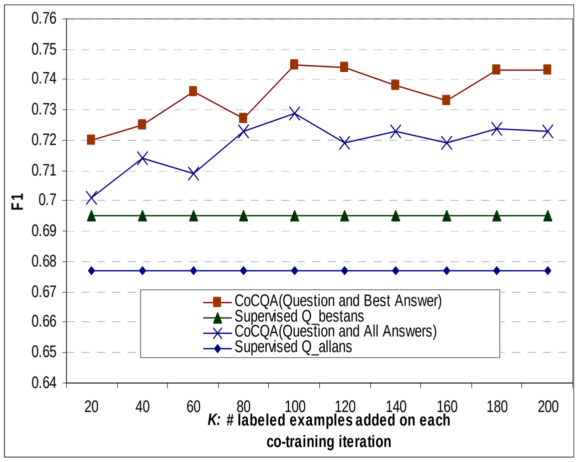

Figure 3: Performance of CoCQA for varying the *K* (number of examples added on each iteration of co-training).

Figure 5 reports the performance of *CoCQA* for varying the number of labeled examples from 50 to 400 (that is, up to 50% of the available labeled training data). Note that for this comparison we use the same feature sets (words in question and best answer text), but using only the (varying) fractions of the manually labeled data. Surprisingly, *CoCQA* exhibits comparable performance of F1=0.685 with only 200 labeled examples are used, compared to the F1=0.695 for *Supervised* with all 800 labeled training examples on this feature set. In other words, *CoCQA* is able to achieve comparable performance to supervised SVM with only one quarter of the labeled training data.

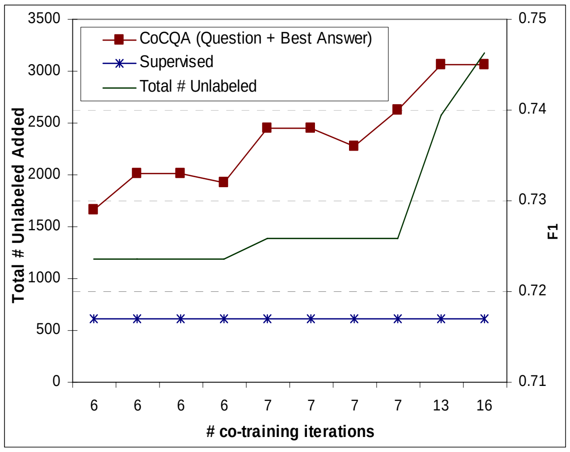

Figure 4: Performance and the *total* number of unlabeled examples added for varying number of co-training iterations (*K*=100, using *q_bestans* features)

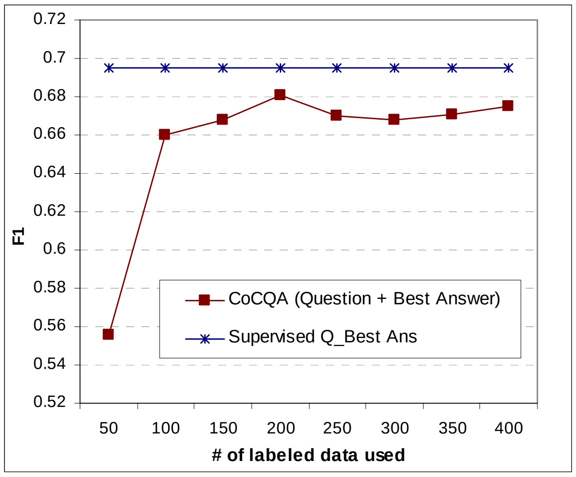

Figure 5: Performance of *CoCQA* with varying number of labeled examples used, compared to *Supervised* method, on same features.

5 Related Work

Question analysis, especially question classification, has been long studied in the question answering research community. However, most of the previous research primarily considered factual questions, with the notable exception of the most recent TREC opinion QA track. Furthermore, the questions were specifically designed for benchmark evaluation. A related thread of research considered deep analysis of the questions (and corresponding sentences) by manually classifying questions along several orientation dimensions, notably (Stoyanov et al., 2005). In contrast, our work focuses on analyzing real user questions posted in a question answering community. These questions are often complex or subjective, and are typically difficult to answer automatically as the question author probably was not able to find satisfactory answers with quick web search.

Automatic complex question answering has been an active area of research, ranging from simple modification to factoid QA techniques (e.g., Soricut and Brill, 2003) to knowledge intensive approaches for specific domains (e.g., Harabagiu et al. 2001, Fushman and Lin 2007). However, the technology does not yet exist to automatically answer open-domain complex and subjective questions. While there has been some recent research (e.g., Agichtein et al. 2008, Bian et al. 2008) on retrieving high quality answers from CQA archives, the subjectivity orientation of the questions has not been considered as a feature for ranking.

A related corresponding problem is complex QA evaluation. Recent efforts at automatic evaluation show that even for well-defined, objective, complex questions, evaluation is extremely labor-intensive and introduces many challenges (Lin and Fushman 2006, Lin and Zhang 2007). As part of our contribution we showed that it is feasible to use the Amazon Mechanical Turk service for evaluation by combining large degree of annotator redundancy (5 annotators per question) with more sparse but higher-quality expert annotation.

The problem of automatic subjective question answering has recently started to be addressed in the question answering community, most recently as the first opinion QA track in (Dang et al., 2007). Unlike the controlled TREC opinion track (introduced in 2007), many of the questions in Yahoo! Answers community are inherently subjective, complex, ill-formed, or all of the above. To our knowledge, this paper is the first large-scale study of subjective/objective orientation of information needs, and certainly the first in the CQA environment.

A closely related research thread is subjectivity analysis at document and sentence level. For example, reference (Yu, H., and Hatzivassiloglou, V. 2003; Somasundaran et al. 2007) attempted to classify sentences into those reporting facts or opinions. Also related is research on sentiment analysis (e.g., Pang et al., 2004) where the goal is to classify a sentence or text fragment as being overall positive or negative. More generally, (Wiebe et al. 2004) and subsequent work focused on the analysis of subjective language in narrative text, primarily news. Our problem is quite different in the sense that we are trying to identify the orientation of a *question*. Nevertheless, our baseline method is similar to the methods and features used for sentiment analysis, and one of our contributions is evaluating the usefulness of the established features and techniques to the new CQA setting.

In order to predict question orientation, we build on co-training, one of the known semi-supervised learning techniques. Many models and techniques have been proposed for classification, including support vector machines, decision tree based techniques, boosting-based techniques, and many others. We use LIBSVM (Chang and Lin, 2001) as a robust implementation of SVM algorithms.

In summary, while we draw on many techniques in question answering, natural language processing, and text classification, our work differs from previous research in that a) develop a novel co-training based algorithm for question and answer classification; b) we address a relatively new problem of *automatic* question subjectivity prediction; c) demonstrate the effectiveness of our techniques in the new CQA setting and d) explore the characteristics unique to CQA – while showing good results for a quite difficult task.

6 Conclusions

We presented *CoCQA*, a co-training framework for modeling the textual interactions in question answer communities. Unlike previous work, we have focused on real user questions (often noisy, ungrammatical, and vague) submitted in Yahoo! Answers, a popular community question answering portal. We demonstrated *CoCQA* for one particularly important task of automatically identifying question subjectivity orientation, showing that *CoCQA* is able to exploit the structure of questions and corresponding answers. Despite the inherent difficulties of subjectivity analysis for real user questions, we have shown that by applying *CoCQA* to this task we can significantly improve prediction performance, and substantially reduce the size of the required training data, while outperforming a general state-of-the-art semi-supervised algorithm that does not take advantage of the CQA characteristics.

In the future we plan to explore more sophisticated features such semantic concepts and relationships (e.g., derived from WordNet or Wikipedia), and richer syntactic and linguistic information. We also plan to explore related variants of semi-supervised learning such as co-boosting methods to further improve classification performance. We will also investigate other applications of our co-training framework to tasks such as sentiment analysis in community question answering and similar social media content.

Acknowledgments

This research was partially supported by the Emory University Research Committee (URC) grant, and by the Emory College Seed grant. We thank the Yahoo! Answers team for providing access to the Answers API, and anonymous reviewers for their excellent suggestions.

Abstract

This paper explores the use of set expansion (SE) to improve question answering (QA) when the expected answer is a list of entities belonging to a certain class. Given a small set of seeds, SE algorithms mine textual resources to produce an extended list including additional members of the class represented by the seeds. We explore the hypothesis that a noise-resistant SE algorithm can be used to extend candidate answers produced by a QA system and generate a new list of answers that is better than the original list produced by the QA system. We further introduce a hybrid approach which combines the original answers from the QA system with the output from the SE algorithm. Experimental results for several state-of-the-art QA systems show that the hybrid system performs better than the QA systems alone when tested on list question data from past TREC evaluations.

1 Introduction

Question answering (QA) systems are designed to retrieve precise answers to questions posed in natural language. A *list question* expects a list as its answer, e.g. *Name the coffee-producing countries in South America*. The ability to answer list questions has been tested as part of the yearly TREC QA evaluation (Dang et al., 2006; Dang et al., 2007). This paper focuses on the use of *set expansion* to improve list question answering. A set expansion (SE) algorithm receives as input a few members of a class or set, and mines various textual resources (e.g. web pages) to produce an extended list including additional members of the class or set that are not in the input. A well-known online SE system is Google Sets[1]. This system is publicly accessible, but since it is a proprietary system that might be changed at any time, its results cannot be replicated reliably. We explore the hypothesis that a SE algorithm, when carefully designed to handle noisy inputs, can be applied to the output from a QA system to produce an overall list of answers for a given question that is better than the answers produced by the QA system itself. We propose to exploit large, redundant sources of structured and/or semi-structured data and use linguistic analysis to seed a shallow analysis of these sources. This is a hard problem since the linguistic evidence used as seeds is noisy. More precisely, we combine the QA system Ephyra (Schlaefer et al., 2007) with the SE system SEAL (Wang and Cohen, 2007) to create a hybrid approach that performs better than either system by itself when tested on data from the TREC 13-15 evaluations. In addition, we apply our SE algorithm to answers generated by the five QA systems that performed the best on the list questions in the TREC 15 evaluation and report improvements in F_1 scores for four of these systems.

Section 2 of the paper gives an overview of the QA and SE systems used for our experiments. Section 3 describes how the SE system was adapted to deal with noisy seeds produced by QA systems, and Section 4 presents the details of the experimental design. Experimental results are discussed in Section 5, and the paper concludes in Section 6 with a discussion of planned future work.

2 System Overview

2.1 Ephyra Question Answering System

Ephyra (Schlaefer et al., 2006; Schlaefer et al., 2007) is a QA system that has been evaluated in the TREC QA track (Dang et al., 2006; Dang et al., 2007). The system combines three answer extraction techniques for factoid and list questions: (1) an answer type classification approach; (2) a syntactic pattern learning and matching approach; and (3) a semantic extractor that uses a semantic role labeling system. The answer type based extractor classifies questions by their answer types and extracts candidates of the expected types. The Ephyra pattern matching approach learns textual patterns that relate question key terms to possible answers and applies these patterns to candidate sentences to extract factoid answers. The semantic approach generates a semantic representation of the question that is based on predicate-argument structures and extracts answer candidates from similar structures in the corpus. The source code of the answer extractors is included in OpenEphyra, an open source release of the system.[2]

The answer candidates from these extractors are combined and ranked by a statistical answer selection framework (Ko et al., 2007), which estimates the probability of an answer based on a number of answer validation and similarity features. Validation features use resources such as gazetteers and Wikipedia to verify an answer, whereas similarity features measure the syntactic and semantic similarity to other candidates, e.g. using string distance measures and WordNet relations.

2.2 Set Expander for Any Language (SEAL)

Set expansion (SE) refers to expanding a given partial set of objects into a more complete set. SEAL[3] (Wang and Cohen, 2007) is a SE system which accepts input elements (seeds) of some target set S_t and automatically finds other probable elements of S_t in semi-structured documents such as web pages. SEAL also works on unstructured text, but its extraction mechanism benefits from structuring elements such as HTML tags. The algorithm is independent of the human language from which the seeds are taken, and also independent of the markup language used to annotate the documents. Examples of SEAL's input and output are shown in Figure 1.

	English	Chinese	Japanese
input seed	Amazing Race	豬血糕	ドラえもん
	Survivor	臭豆腐	ハローキティ
output	Big Brother	蘿蔔糕	アンパンマン
	The Mole	蚵仔煎	シナモロール
	The Apprentice	肉圓	ウルトラマン
	Project Runway	滷肉飯	スヌーピー
	The Bachelor	春捲	くまのプーさん

Figure 1: Examples of SEAL's input and output. English entities are reality TV shows, Chinese entities are popular Taiwanese food, and Japanese entities are famous cartoon characters.

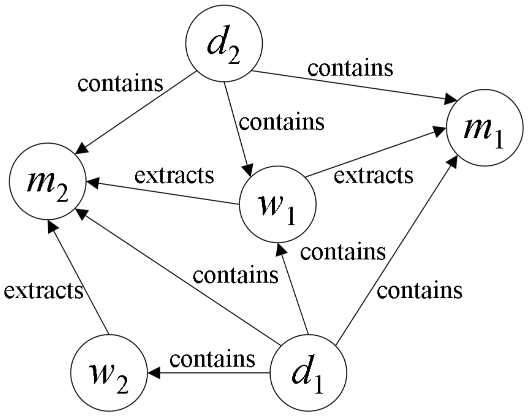

Figure 2: An example graph constructed by SEAL. Every edge from node x to y actually has an inverse relation edge from node y to x that is not shown here (e.g. m_1 *is extracted by* w_1).

In more detail, SEAL comprises three major components: the Fetcher, the Extractor, and the Ranker. The *Fetcher* focuses on retrieving web pages. The URLs of the web pages come from top results retrieved from Google and Yahoo! using the concatenation of all seeds as the query. The *Extractor* automatically constructs page-specific extraction rules, or *wrappers*, for each page that contains the seeds. Every wrapper is defined by two character strings, which specify the left-context and right-context necessary for an entity to be extracted from a page. These strings are chosen to be maximally-long contexts that bracket at least one occurrence of every seed string on a page. Most of the wrappers con-

[2]http://www.ephyra.info/

[3]http://rcwang.com/seal

tain HTML tags, which illustrates the importance of structuring information in the source documents. All entity mentions bracketed by these contextual strings derived from a particular page are extracted from the same page. Finally, the *Ranker* builds a graph, and then ranks the extracted mentions globally based on the weights computed by performing a random graph walk.

An example graph is shown in Figure 2, where each node d_i represents a document, w_i a wrapper, and m_i an extracted entity mention. The graph models the relationship between documents, wrappers, and mentions. In order to measure the relative importance of each node within the graph, the Ranker performs a graph walk until all node weights converge. The idea is that nodes are weighted higher if they are connected to many other highly weighted nodes.

We apply this SE algorithm to answer candidates for list questions generated by Ephyra and other TREC QA systems to find additional instances of correct answers that were not in the original candidate set.

3 Proposed Approach

SEAL was originally designed to handle only relevant input seeds. When provided with a mixture of relevant and irrelevant answers from a QA system, the performance would suffer. In this section, we propose three modifications to SEAL to improve its ability to handle noisy input seeds.

3.1 Aggressive Fetcher

For each expansion, SEAL's fetcher concatenates all seeds and sends them as one query to the search engines. However, when the seeds are noisy, the documents fetched are constrained by the irrelevant seeds, which decreases the chance of finding good documents. To overcome this problem, we designed an *aggressive fetcher* (AF) that increases the chance of composing queries containing only relevant seeds. It sends a two-seed query for every possible pair of seeds to the search engines. If there are n input seeds, then the total number of queries sent would be $\binom{n}{2}$. For example, suppose SEAL is given a set of noisy seeds: *Boston*, *Seattle* and *Carnegie-Mellon* (assuming *Carnegie-Mellon* is irrelevant), then by using AF, one query will contain only relevant seeds (as shown in Table 1). The documents are then collected and sent to SEAL's extractor for learning wrappers.

	Queries	Quality
-AF	#1: Boston Seattle Carnegie-Mellon	Low
+AF	#1: Boston Seattle	High
	#2: Boston Carnegie-Mellon	Low
	#3: Seattle Carnegie-Mellon	Low

Table 1: Example queries and their quality given the seeds *Boston*, *Seattle* and *Carnegie-Mellon*, where *Carnegie-Mellon* is assumed to be irrelevant.

3.2 Lenient Extractor

SEAL's extractor requires the longest common contexts to bracket at least one instance of every seed per web page. However, when seeds are noisy, such common contexts usually do not exist or are too short to be useful. To solve this problem, we propose a *lenient extractor* (LE) which only requires the contexts to bracket at least one instance of *a minimum of two* seeds, instead of *every* seed. This increases the chance of finding longest common contexts that bracket only relevant seeds. For instance, suppose SEAL is given the seeds from the previous example (*Boston*, *Seattle* and *Carnegie-Mellon*) and the passage below. Then the extractor would learn the wrappers shown in Table 2.

"While attending a hearing in Boston City Hall, Alan, a professor at Boston University, met Tina, his former student at Seattle University, who is studying at Carnegie-Mellon University Art School and will be working in Seattle City Hall."

	Learned Wrappers
-LE	#1: `at [...] University`
+LE	#1: `at [...] University`
	#2: `in [...] City Hall`

Table 2: Wrappers learned by SEAL's extractor when given the passage in Section 3.2 and the seeds *Boston*, *Seattle* and *Carnegie-Mellon*.

As illustrated, with lenient extraction, SEAL is now able to learn the second wrapper because it brackets one instance of at least two seeds (*Boston* and *Seattle*). This can be very helpful if the list question is asking for city names rather than university names. The extractor then uses these wrappers to extract additional answer candidates, by searching for other strings that fit into the placeholders of the wrappers. Note that the example was simplified for ease of presentation. The wrappers are actually character-based (as opposed to word-based) and are likely to contain HTML tags when generated from real web pages.

3.3 Hinted Expander

Most QA systems use keywords from the question to guide the retrieval of relevant documents and the extraction of answer candidates. We believe these keywords are also important for SEAL to identify additional instances of correct answers. For example, if the seeds are *George Washington*, *John Adams*, and *Thomas Jefferson*, then without using any context from the question, SEAL would output a mixture of founding fathers and presidents of the U.S.A. To solve this problem, we devised a *hinted expansion* (HE) technique that utilizes the context given in the question to constrain SEAL's search space on the Web. This is achieved by appending keywords from the question to every query that is sent to the search engines. The rationale is that the retrieved documents will also match the keywords, which may increase the chance of finding those documents that contain our desired set of answers.

4 Experimental Design

We conducted experiments in two phases. In the first phase, we evaluated the SE approach by applying SEAL to answers generated by Ephyra. In the second phase, we evaluated the approach by applying SEAL to the output from QA systems that performed the best on the list questions in the TREC 15 evaluation. In both phases, the answers found by SEAL were retrieved from the Web instead of the AQUAINT newswire corpus used in the TREC evaluations. However, we rejected answers if they could only be found in the Web and not in the AQUAINT corpus to avoid an unfair advantage over the QA systems: TREC participants were allowed to extract candidates from the Web (or any other source), but they had to identify a supporting document in the AQUAINT corpus for each answer and thus could not return answers that were not covered by the corpus.

Preliminary experiments showed that we can obtain a good balance between the amount and quality of the documents fetched by using only rare question terms as hint words. In particular, we select the three question words that occur least frequently in a sample of the AQUAINT corpus as hints. The candidate answers were evaluated by using the answer keys, composed of regular expression patterns, obtained from the TREC website. We did not extend the patterns with additional correct answers found in our experiments. These answer keys were not officially used in the TREC evaluation; thus the baseline scores we computed for Ephyra and other QA systems in our experiments are slightly different from those officially reported.

4.1 Ephyra

We evaluated our SE approach on Ephyra using the list questions from TREC 13, 14, and 15 (55, 93, and 89 questions, respectively). For each question, the top four answer candidates from Ephyra were given as input seeds to SEAL. Initial experiments showed that by adding additional seeds, the effectiveness of our approach can be improved at the expense of a longer runtime.

We report both mean average precision (MAP) and F_1 scores. For the F_1 scores, we drop answer candidates with low confidence scores by applying a relative cut-off threshold: an answer candidate is dropped if the ratio of its confidence score and the score of the top answer is below a threshold. An optimal threshold for a question is a threshold that maximizes the F_1 score for that particular question.

For each TREC dataset, we conducted three experiments: (1) evaluation of answer candidates using MAP; (2) evaluation using average F_1 with an optimal threshold for each question; and (3) evaluation using average F_1 with thresholds trained by 5-fold cross validation. For each of those 5-fold validations, only one threshold was determined for all questions in the training folds.

	Ephyra	**Ephyra's Top 4 Ans.**	**SEAL**	**SEAL+LE**	**SEAL+LE +AF**	**SEAL+LE +AF+HE**
TREC 13	25.95%	21.39%	23.76%	31.43%	34.22%	35.26%
TREC 14	14.45%	8.71%	14.47%	17.04%	16.58%	18.82%
TREC 15	13.42%	9.02%	13.17%	16.87%	17.12%	18.95%

Table 4: Average F_1 of Ephyra, its top four answers, and various SEAL configurations when using an optimal threshold for each question.

4.2 Top QA Systems

We evaluated two SE approaches, SEAL and Google Sets, on the five QA systems that performed the best on the list questions in TREC 15. For each question, the top four answer candidates[4] from those systems were given as input seeds to SEAL and Google Sets. Unlike the candidates found by Ephyra, these candidates were provided without confidence scores; hence, we assumed they all have a score of 1.0. In our experiments with SEAL, we first determined a single threshold that optimizes the average of the F_1 scores of the top five systems in both TREC 13 and 14. We then obtained evaluation results for the top systems in TREC 15 by using this trained threshold. When performing hinted expansion, the keywords (or hint words) for each question were extracted by Ephyra's question analysis component. In our experiments with Google Sets, we requested *Small Sets* of items and again measured the performance in terms of F_1 scores. We also tried requesting *Large Sets* but the results were worse.

5 Results and Discussion

In Tables 3 and 4, we present evaluation results for all answers from Ephyra, only the top four answers, and various configurations of SEAL using the top four answers as seeds. Table 3 shows the MAP for each dataset (TREC 13, 14, and 15), and Table 4 shows for each dataset the average F_1 score when using optimal per-question thresholds. The results indicate that SEAL achieves the best performance when configured with all three proposed extensions. In terms of MAP, the best-configured SEAL improves the quality of the input answers (relatively) by 65%, 116%, 110% for each dataset respectively, and improves Ephyra's overall performance by 36%, 30%, 41%. In terms of optimal F_1, SEAL improves the quality of the input answers by 55%, 77%, 76% and Ephyra's overall performance by 14%, 9%, 14% respectively. These results illustrate that a SE system is capable of improving a QA system's performance on list questions, if we know how to select good thresholds.

In practice, the thresholds are unknown and must be estimated from a training set. Table 5 shows evaluation results using 5-fold cross validation for each dataset (TREC 13, 14, and 15) independently, and the combination of all three datasets (All). For each validation, we determine the threshold that maximizes the F_1 score on the training folds, and we also determine the F_1 score on the test fold by applying the trained threshold. We repeat this validation for each of the five test folds and present the average threshold and F_1 score for each configuration and dataset. The F_1 scores give an estimate of the performance on unseen data and allow a fair com-

Table 6: Average F_1 of the QA systems, their top four answers, Google Sets, the best-configured SEAL, the hybrid system, and their relative improvements over the QA systems.

parison across systems. Here, we also introduce a hybrid system (Hybrid) that intersects the answers found by both systems by multiplying their probabilistic scores.

Tables 3, 4, and 5 show that the effectiveness of the SE approach depends on the quality of the initial answer candidates. The improvements are most apparent for the TREC 13 dataset, where Ephyra has a much higher performance compared to TREC 14 and 15. However, the best-configured SEAL did not improve the F_1 score on TREC 14, as reported in Table 5. We suspect that this is due to the comparatively low quality of Ephyra's top four answers for this dataset. The experiments also illustrate that by intersecting the answer candidates found by Ephyra and SEAL, we can eliminate poor answer candidates and partially compensate for the low precision of Ephyra on the harder TREC datasets. However, this comes at the expense of a lower recall, which slightly hurts the performance on the comparatively easier TREC 13 questions. We also evaluated Google Sets on top four answers from Ephyra for TREC 13-15 and obtained F_1 scores of 12%, 11%, and 9% respectively (compared to 29%, 17%, and 16% for our hybrid approach with trained thresholds).

Table 6 shows F_1 scores for the SE approach applied to the output from the five QA systems with the highest performance on the list questions in TREC 15. Again, Hybrid intersects the answers found by the QA system and SEAL by multiplying their confidence scores. Two thresholds were trained separately on the top five systems in both TREC 13 and 14; one for SEAL (0.2376) and another for Hybrid (0.2463). As shown, the performance of Google Sets is worse than SEAL and Hybrid, but better than the top four answers on average. We believe our SE system outperforms Google Sets because we have methods to handle noisy inputs (i.e. AF, LE) and a method for guiding the SE algorithm to search in the right space on the Web (i.e. HE).

The results show that both SEAL and Hybrid are capable of improving four out of the five systems. We observed that one reason why SEAL did not improve "lccPA06" was the incompleteness of the answer keys. Table 7 shows one of many examples where SEAL was penalized for finding additional correct answers. As illustrated, Hybrid improved all systems except "NUSCHUAQA1". The reason is that even though SEAL improved the baseline, their overlapping answer set is too small; thus hurting the recall of Hybrid substantially. Unfortunately, Question 154.6: Name titles of movies, other than "Superman" movies, that Christopher Reeve acted in.

lccPA06 (F_1: 75%)	SEAL+LE+AF+HE (F_1: 40%)
+Rear Window	+Rear Window
+The Remains of the Day	+The Remains of the Day
+Snakes and Ladders	-The Bostonians
-Superman	-Somewhere in Time
	-Village of the Damned
	-In the Gloaming

Table 7: Example of SEAL being penalized for finding correct answers (all are correct except the last one). Answers found in the answer keys are marked with "+". All four answers from "lccPA06" were used as seeds.

Question 170.6: What are the titles of songs written by John Prine?

NUSCHUAQA1 (F_1: 25%)	SEAL+LE+AF+HE (F_1: 44%)
+I Just Want to Dance With You	+I Just Want to Dance With You
-Titled In Spite of Ourselves	+Christmas in Prison
+Christmas in Prison	+Sam Stone
-Grammy - Winning	-Grandpa was a Carpenter
	-Sabu Visits the Twin Cities Alone
	+Angel from Montgomery

Table 8: Example demonstrating SEAL's ability to handle noisy input seeds. All four answers from "NUSCHUAQA1" were used as seeds. Again, SEAL is penalized for finding correct answers (all answers are correct).

for the top TREC 15 systems we only had access to the answers that were actually submitted by the participants, whereas for Ephyra we could utilize the entire list of generated answer candidates, including those that fell below the cutoff threshold for list questions. Nevertheless, the hybrid approach could improve the baseline by more than 2% on average in terms of F_1 score. Table 8 shows that the best-configured SEAL is capable of expanding only the relevant seeds even when given a set of noisy seeds. Neither Google Sets nor the original SE algorithm without the proposed extensions could expand these seeds with additional candidates.

On average, SEAL required about 5 seconds for querying the search engines, 10 seconds for crawling the Web, 20 seconds for extracting answer candidates from the web pages, and 5 seconds for ranking the candidates. Note that the SE system has not been optimized extensively. The runtime of the web page retrieval step and much of the search is due to network latency and can be reduced if the search is performed locally.

6 Conclusion and Future Work

We have shown that our SE approach is capable of improving the performance of QA systems on list questions by utilizing only their top four answer candidates as seeds. We have also illustrated a feasible and effective method for integrating a SE approach into any QA system. We would like to emphasize that for each of the experiments we conducted, all that the SE system received as input were the top four noisy answers from a QA system and three keywords from the TREC questions. We have shown that higher quality candidates support more effective set expansion. In the future, we will investigate how to utilize more answer candidates from the QA system and determine the minimal quality of those candidates required for SE approach to make an improvement.

We have also shown that, in terms of F_1 scores with trained thresholds, the hybrid method improves the Ephyra QA system on all datasets and also improves four out of the five systems that performed the best on the list questions in TREC 15. However, the final list of answers only comprises candidates found by both the QA system and the SE algorithm. In future experiments, we will investigate other methods of merging answer candidates, such as taking the union of answers from both systems. We expect further improvements from adding candidates that are found only by the QA system, but it is unclear how the confidence measures from the two systems can be combined effectively.

We would also like to emphasize that the SE approach is entirely language independent, and thus can be readily applied to answer candidates in other languages. In future experiments, we will investigate its performance on question answering tasks in languages such as Chinese and Japanese.

As pointed out previously, the performance of the SE approach highly depends on the accuracy of the seeds. However, QA systems are usually not optimized to provide few high-precision results, but treat precision and recall as equally important. This leaves room for further improvements, e.g. by applying stricter answer validation techniques to the seeds used for SE.

We also plan to analyze the effectiveness of our approach across different question types and evaluate it on more complex questions such as the rigid list questions in the new TAC QA evaluation, which ask for opinion holders and subjects.

Abstract

We describe an approach for acquiring the domain-specific dialog knowledge required to configure a task-oriented dialog system that uses human-human interaction data. The key aspects of this problem are the design of a dialog information representation and a learning approach that supports capture of domain information from in-domain dialogs. To represent a dialog for a learning purpose, we based our representation, the *form-based dialog structure representation*, on an observable structure. We show that this representation is sufficient for modeling phenomena that occur regularly in several dissimilar task-oriented domains, including information-access and problem-solving. With the goal of ultimately reducing human annotation effort, we examine the use of unsupervised learning techniques in acquiring the components of the form-based representation (i.e. task, subtask, and concept). These techniques include statistical word clustering based on mutual information and Kullback-Liebler distance, TextTiling, HMM-based segmentation, and bisecting *K*-mean document clustering. With some modifications to make these algorithms more suitable for inferring the structure of a spoken dialog, the unsupervised learning algorithms show promise.

1 Introduction

In recent dialog management frameworks, such as *RavenClaw* (Bohus and Rudnicky, 2003) and *Collagen* (Rich et al., 2001), domain-dependent components of a dialog manager are clearly separated from domain-independent components. This separation allows rapid development of a dialog management module in a new task-oriented domain as dialog system developers can focus only on specifying domain-specific dialog information (e.g. the *Dialog Task Specification* in RavenClaw and *Task Models* in Collagen) while general dialog behaviors (e.g. turn-taking, confirmation mechanism, and generic help) are provided by the framework. For task-oriented domains, the domain-specific dialog information is equivalent to task-specific information. Examples of the task-specific information are steps in a task and domain keywords.

Specifying task-specific knowledge by hand is still a time consuming process (Feng et al., 2003). Furthermore, the hand-crafted knowledge may not reflect users' perceptions of a task (Yankelovich, 1997). To reduce the subjectivity of system developers, recorded conversations of humans performing a similar task as a target dialog system have been used to help the developers design the task specification. Nevertheless, analyzing a corpus of dialogs by hand requires a great deal of human effort (Bangalore et al., 2006). This paper investigates the feasibility of automating this dialog analysis process through a machine-learning approach. By inferring the task-specific dialog information automatically from human-human interaction data, the knowledge engineering effort could be reduced as the developers need to only revise learned information rather than analyzing a large amount of data.

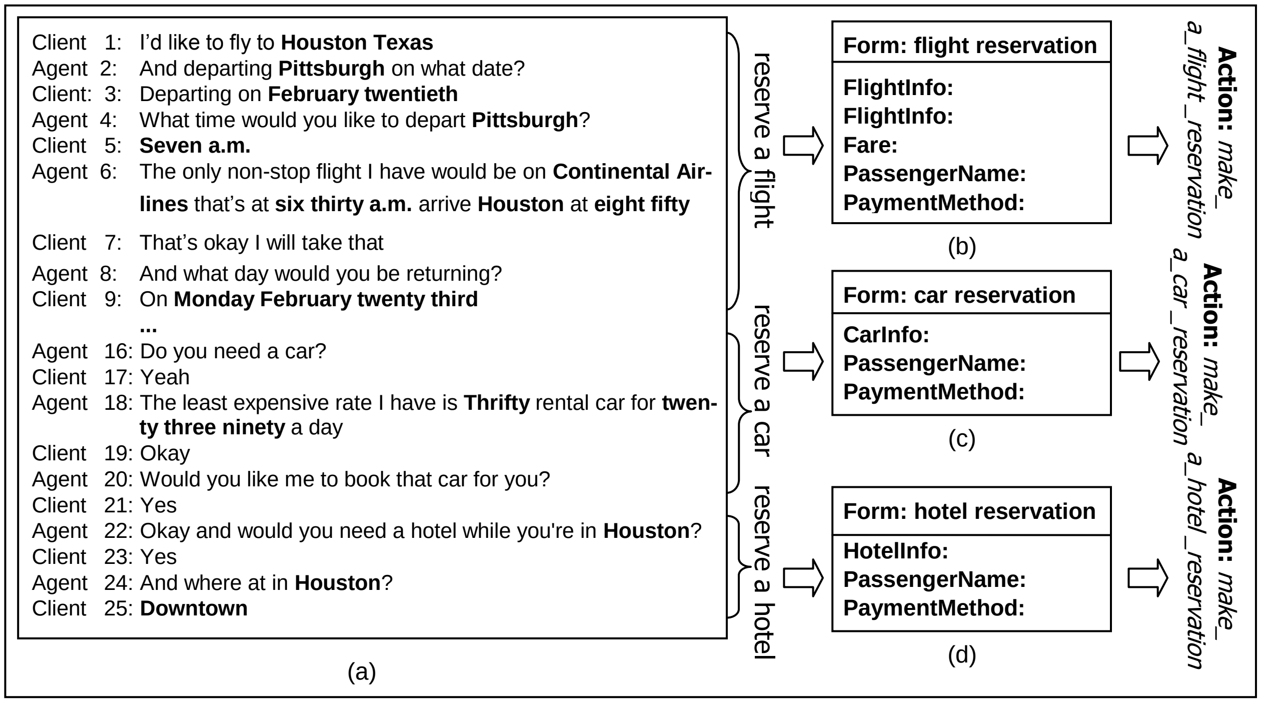
Acquiring the task-specific knowledge from a corpus of human-human dialogs is considered a knowledge acquisition process, where the target task structure has not yet been specified but will be explored from data before a dialog system is built. This is contrasted with a dialog structure recognition process (Alexandersson and Reithinger, 1997;

Bangalore et al., 2006; Hardy et al., 2004), where pre-specified dialog structure components are recognized as a dialog progresses.

We use an unsupervised learning approach in our knowledge acquisition process as it can freely explore the structure in the data without any influence from human supervision. Woszczyna and Waibel (1994) showed that when modeling a dialog state transition diagram from data an unsupervised approach outperformed a supervised one as it better reflects the characteristic of the data. It is also interesting to see how well a machine-learning approach can perform on the problem of task-specific knowledge acquisition when no assumption about the domain is made and no prior knowledge is used.

Examination of task-oriented human-human dialogs show that task-specific information can be observed in dialog transcription; therefore, it should be feasible to be infer it through an unsupervised learning approach. Figure 1 (a) shows a dialog in an air travel domain. This dialog is organized into three parts according to the three steps (i.e. reserve a flight, reserve a car, reserve a hotel) required to accomplish the task, creating a travel itinerary. Domain keywords (highlighted in bold) required to accomplish each step are clearly communicated.

To infer task-specific knowledge from data using an unsupervised learning approach, two problems need to be addressed: 1) choosing an appropriate dialog representation that captures observable task-specific knowledge in a dialog, and 2) developing an unsupervised learning approach that infers the task-specific knowledge modeled by this representation from in-domain human-human dialogs. The first problem is discussed in Section 3 where a *form-based dialog structure representation* is proposed. After describing the definition of each component in the form-based dialog structure representation, examples of how a domain expert models the task-specific information in a dialog with the form-based representation are given Section 3.1. Then the annotation experiment which was used to verify that the form-based representation can be understood and applied by other human annotators is discussed in Section 3.2. For the second problem, we modify existing unsupervised learning approaches to make them suitable for inferring the structure of a spoken dialog. Section 4 describes these modifications and their performances when inferring the components of the form-based dialog structure representation from interaction data.



Client 1: I'd like to fly to **Houston Texas**
Agent 2: And departing **Pittsburgh** on what date?
Client: 3: Departing on **February twentieth**
Agent 4: What time would you like to depart **Pittsburgh**?
Client 5: **Seven a.m.**
Agent 6: The only non-stop flight I have would be on **Continental Airlines** that's at **six thirty a.m.** arrive **Houston** at **eight fifty**
Client 7: That's okay I will take that
Agent 8: And what day would you be returning?
Client 9: On **Monday February twenty third**
...
Agent 16: Do you need a car?
Client 17: Yeah
Agent 18: The least expensive rate I have is **Thrifty** rental car for **twenty three ninety** a day
Client 19: Okay
Agent 20: Would you like me to book that car for you?
Client 21: Yes
Agent 22: Okay and would you need a hotel while you're in **Houston**?
Client 23: Yes
Agent 24: And where at in **Houston**?

2 Related Work

Automatic task-specific knowledge acquisition for configuring a dialog system is a relatively new research area. Supervised learning approaches were used to acquire a task model for a collaborative agent (Garland et al., 2001) and task-specific information for a customer care service (Feng et al., 2003). These supervised algorithms were trained on rich knowledge sources (examples described in a specific annotation language and a well-organized website respectively) annotated by domain experts. In contrast, the unsupervised conceptual clustering algorithm in DIA-MOLE (Möller, 1998) requires no additional human annotation to infer a set of domain-specific dialog acts from in-domain dialogs. The motivation behind the use of an unsupervised approach is similar to ours, to reduce human effort in creating a new dialog system.

3 Form-based Dialog Structure Representation

Many models have been proposed to account for the structure of a human-human conversation. Many such models focus on other aspects of a dialog such as coordinated activities, i.e. turn-taking and grounding, (Traum and Hinkelman, 1992) and regular patterns in the dialog (Carletta et al., 1997) rather than the domain-specific information communicated by participants. More complicated dialog representations (Grosz and Sidner, 1986; Litman and Allen, 1987) model several aspects of a dialog including domain-specific information. However, additional components in these models, such as beliefs and intentions, are difficult to observe directly from a conversation and, as for the current technology, may not be learnable through an unsupervised learning approach.

Since the task-specific information that we would like to model will be used for configuring a dialog system, we can view this information from a dialog system perspective. Our dialog representation is based on *form*, a data representation used in a form-based (or frame-based) dialog system. A form is a simple representation that captures necessary task-specific information communicated through dialog. This information is observable from dialog transcription (see below) and thus could be inferred through an unsupervised learning approach.

Typically, a form corresponds to a database query form while slots in the form represent search criteria. Nevertheless, a form can represent related pieces of information required to perform any domain action not just a database query action. With this more general definition of a form, a *form-based dialog structure representation* can be applied to various types of task-oriented domains where dialog participants have to gather pieces of information, analogous to search criteria, through dialog in order to perform domain actions that fulfill a dialog goal. Chotimongkol (2008) provided examples of these domains, for instance, meeting (Banerjee and Rudnicky, 2006) and flight simulation control (Gorman et al., 2003).

In the form-based dialog structure representation, task-specific information in each dialog is organized into a three-level structure of concept, subtask and task. A *concept* is a word or a group of words which captures a piece of information required to perform a domain action. A *subtask* is a subset of a dialog which contains sufficient concepts to execute a domain action that advances a dialog toward its goal. A *task* is a subset of a dialog (usually the entire dialog) which contains all the subtasks that belong to the same goal. A subtask can also be considered as a step in a task. In terms of representation, a task is represented by a set of forms, one for each of its subtasks. A concept is a slot in a form.

To model the structure of a dialog in a new domain with the form-based dialog structure representation, a list of tasks, subtasks, and concepts in that domain has to be specified. This list is considered a domain-specific tagset. The form-based dialog structure framework only provides the definitions of these components (i.e. task, subtask, and concept), which can be regarded as meta-tags and are domain-independent. A list of tasks, subtasks, and concepts can be identified manually as shown in Section 3.1 or automatically through a machine-learning approach as discussed in Section 4. Section 3.1 illustrates how a domain expert models the task-specific information in two task-oriented domains, air travel planning (information-accessing) and map reading (problem-solving), with the form-based representation. These examples also show that the form-based dialog structure representation is sufficient for modeling task-specific information in dissimilar domains.

Nonetheless, by focusing on observable task-specific information and describing this information using a simple model, the form-based dialog structure representation cannot model the information that is not clearly expressed in a dialog. Example of such information in an air travel domain is the pickup date of a car rental which may not be discussed in a dialog as it can be inferred from the arrival date of the corresponding flight. Furthermore, the form-based representation is not well suited for modeling a complex dialog that has a dynamic structure such as a tutoring dialog.

3.1 Dialog Structure Modeling Examples

Figure 1 illustrates how a dialog in the air travel domain (Eskenazi et al., 1999) can be represented with the form-based dialog structure representation. A dialog in this domain usually has a single goal, to create an air-travel itinerary which may include hotel and car reservations. Thus, the entire dialog corresponds to one task. The dialog in Figure 1 (a) contains three subtasks, one for each ***make_•_reservation*** action. The forms that represent these subtasks are shown in Figure 1 (b) – (d). Each form contains a set of concepts necessary for making the corresponding reservation. For a display purpose, the values of these slots are omitted.

A subtask can be further decomposed. For example, to reserve a round trip ticket, two database lookup actions, one for each leg, are required. A **reserve_flight** subtask in Figure 1 is decomposed into two **query_flight_info** subtasks. The corresponding forms of these subtasks are illustrated in Figure 2. Each **FlighInfo** concept in the flight reservation form is a result of a database lookup action that corresponds to each flight query form.

Form: flight query
DepartCity: Pittsburgh **ArriveCity:** Houston **ArriveState:** Texas **DepartDate:** February twentieth **DepartTime:** seven a.m.

Form: flight query
DepartCity: Houston **ArriveCity:** Pittsburgh **DepartDate:** Monday February twenty third **DepartTime:** five p.m.

Form: flight reservation
FlightInfo: **Airline:** Continental **DepartTime:** six thirty a.m. **ArriveCity:** Houston **ArriveTime:** eight fifty **FlightInfo:** **Airline:** Continental **DepartCity:** Houston **DepartTime:** six forty p.m. **ArriveCity:** Pittsburgh **ArriveTime:** ten twenty p.m **Fare:** four hundred dollars **Name:** **PaymentMethod:**

Figure 2: An example of subtask decomposition

Figure 3 show a dialog in the map reading domain (Anderson et al., 1991) and its corresponding form-based dialog structure representation. The goal of a dialog in this domain is to have a route follower draw a route on his/her map according to a description given by a route giver. Since drawing an entire route involves several drawing strokes, a **draw_a_route** task is divided into several **draw_a_segment** subtasks, one for each ***drawing*** action. This action required a set of concepts that describe a segment as shown in a segment description form. Since the landmarks on the giver's map can be different from those in the follower's map, the participants have to explicitly define the **Location** of a mismatched **Landmark** before using it in a segment description. In this case **grounding** becomes another subtask and can be represented by a form. This type of grounding is not necessary in the air travel domain.

		…
Giver	3:	right, **below the start** do you have a **missionary camp**?
Follower	4:	yeah.
Giver	5:	okay, well if you take it from **the start** just run horizontally.
Follower	6:	uh-huh.
Giver	7:	to the **left** for about **an inch**.
Follower	8:	right.
Giver	9:	then go **down** along **the side of the missionary camp**.
		….

Form: grounding
Landmark: missionary camp **Location:** below the start

Form: segment description
StartLocation: the start **Direction:** left **Distance:** an inch **EndLocation:**

Figure 3: An example of a dialog in the map reading domain and its corresponding form-based representation

3.2 Annotation Experiment

The goal of this annotation experiment is to verify that the form-based dialog structure framework can be understood by human annotators other than its developers, and that they can consistently apply the framework to model task-specific information in a dialog. In this experiment, each annotator had to design a form-based dialog structure representation for a given task-oriented domain by specifying a hierarchical structure of tasks, sub-tasks and concepts in that domain. Note that we are interested in the process of designing a domain-specific tagset from the definitions of task, subtask, and concept provided by the framework, not in the process of using an existing tagset to annotate data (see for example (Carletta et al., 1997)). The description of the framework is provided in annotation guidelines along with examples from the domains that were not used in the experiment.

The experimental procedure is as follows: the subjects first developed their own tagset according to the guidelines by analyzing a set of in-domain dialogs, and then annotate those dialogs with the tagset they had designed. To obtain enough annotated instances for each dialog structure component and to make the annotation simple, the dialog structure annotation part of the experiment was divided into two sub-parts: concept annotation and task/sub-task annotation. Two domains were used in the experiment, air travel planning and map reading. Four subjects were assigned to each domain. None had used the scheme previously. The average number of tags that each subject annotated is shown in the first row of Table 1.

Since some variations in tagset designs are acceptable as long as they conform to the guidelines, each subject's annotation is judged against the guidelines rather than one specific reference annotation. An annotation instance is marked as incorrect only when it does not conform to the guidelines. Each subject's annotation was evaluated by both a coding scheme expert and by other subjects. *Accuracy* is computed from the expert's judgment while *acceptability* is computed from peers' judgments. Acceptability scores shown in Table 1 were averaged from all other subjects in the same group. Please note that the result presented in this table should not be compared to the results from machine-learning approaches presented in Table 2 and Table 3 as the evaluation procedures and data sets are different.

Measure	**Air Travel**		**Map Reading**	
	C	**T**	**C**	**T**
Number of tags	178.8	50.5	347.8	60.8
Accuracy (%)	96.5	89.7	89.0	65.2
Acceptability (%)	95.6	81.1	94.9	84.5

Table 1: Accuracy and acceptability on concept annotation (C), and task/subtask annotation (T)

Both accuracy and acceptability are high for all annotation tasks except for the accuracy of task/subtask annotation in the map reading domain. Most of the errors come from the annotation of the **grounding** subtasks. Since its corresponding action is quite difficult to observe, subjects may not have a concrete definition of **grounding** and were more likely to produce errors. In addition, they were less critical when judging other subjects' annotations. Consistency in applying the form-based dialog structure representation shows that the representation is unambiguous and could potentially be identified through a machine-learning approach.

When comparing among components, concepts were annotated more consistently than tasks and subtasks in terms of both accuracy and acceptability. One possible reason is that, a concept is easier to observe as its unit is smaller than a task or a subtask. Moreover, dialog participants have to clearly communicate the concepts in order to execute a domain action. The subjects usually agreed on tasks and top-level subtasks, but did not quite agree on low-level subtasks. The low-level subtasks are correlated with the implementation of a dialog system; hence, the designs of these subtasks are more subjective and likely to be different.

4 Learning Approaches

This section describes machine-learning approaches for inferring the task-specific information modeled by the form-based dialog structure representation from human-human conversations. Specifically, the learning approach has to infer a list of tasks, sub-tasks and concepts in a given domain from in-domain dialogs similar to what a human does in Section 3. To make the problem tractable, components in the form-based representation are acquired separately. For most task-oriented dialogs that we encountered, each dialog corresponds to one task. Hence, the learning effort can be focused on identifying concept and subtask. Since we can only observe instances or values of these components in a dialog, we have to first identify these instances and then make a generalization for its type. For instant, to infer that there is a concept **City** in the air travel domain, a set of city names has to be identified and grouped together.

To identify a set of domain concepts from the transcription of in-domain dialogs, we follow the algorithm described in (Chotimongkol and Rudnicky, 2002). This algorithm utilizes an unsupervised clustering algorithm which clusters words based on context similarity, e.g. mutual information-based and Kullback-Liebler-based clustering, since the members of the same domain concept are usually used in similar contexts in a particular domain. Examples of the clusters obtained from the KL-based clustering algorithm are shown in Figure 4. These clusters represent **Hour**, **RentalCompany**, and **City** respectively. Underlined cluster members belong to other concepts. The clustering algorithm can identify all 12 members of **Hour** and about half of **RentalCompany**. In the third cluster, some airport names got merged with city names because they occur in quite similar context.

Figure 4: Learned concepts in the air travel domain

The rest of this section describes an approach for identifying subtasks and their corresponding forms in a given domain. We decided to simplify the form-learning problem by first segmenting a dialog into form-filling episodes (which are equivalent to sub-tasks), then grouping the ones that correspond to the same form together so that we can determine a set of necessary slots in each form from the concepts present in its corresponding cluster. We further simplify the problem by concentrating on the domains that have only one top-level task (though in principle the approach can be extended to the domains that have multiple top-level tasks). Since we utilize well-known unsupervised algorithms, only the modifications which are applied to make these algorithms suitable for inferring the structure of a spoken dialog are discussed.

Two unsupervised discourse segmentation algorithms are investigated: TextTiling (Hearst, 1997) and Hidden Markov Modeling (Barzilay and Lee, 2004). These algorithms only recover the sequence of subtasks but not the hierarchical structure of subtasks similar to Bangalore et al.'s (2006) chunk-based model. Nevertheless, this simplification is sufficient when a subtask is embedded at the beginning or the end of the higher-level subtask which is the case for most embedded structures we have found. Both algorithms, while performing well with expository text, require modifications when applying to a fine-grained segmentation problem of spoken dialogs. In WSJ text, the average topic length is 428 words (Beeferman et al., 1999) while in the air travel domain the average subtask length is 84 words (10 utterances).

For TextTiling, the modifications include a distance weight and a data-driven stop word list. For the subtasks that are much shorter than the average length, distant words in the context window can be irrelevant. A *distance weight* demotes the importance of the context word that is far away from the considered boundary by giving it a lower weight. A manually prepared stop word list, containing common words, may not be suitable for every application domain. We propose a novel approach that determines a list of stop words directly from word distribution in each data set. TextTiling assumes that words that occur regularly throughout a dialog are not informative. However, the regularity of a particular word is determined from its distribution over the dialog rather than from its frequency. A high frequency word is useful if its instances occur only in a specific location. For example, the word "delta" which occurs many times in a **reserve_flight** subtask but does not occur in other subtasks is undoubtedly useful for determining subtask boundaries while the word "you" which can occur anywhere in a dialog is not useful. Specifically, a *regularity count* of word *w* is defined as the number of sliding context windows in the similarity score calculation of TextTiling that contain the word *w* in each dialog. A *data-driven stop word list* contains words that have a regularity count greater than a pre-defined threshold.

For HMM-based segmentation, we modified Barzilay and Lee's (2004) content models by using larger text spans when inducing the HMM states. HMM states are created automatically by clustering similar text spans together. When using an utterance as a text span, it may not contain enough information to indicate its relevant subtask as some utterances in a task-oriented dialog are very short and can occur in any subtask (e.g. acknowledgements and yes/no responses). Larger text spans, reference topics, were used in (Yamron et al., 1998). Nevertheless, this approach requires true segment boundaries. To eliminate the need of annotated data in our algorithm, HMM states are induced from predicted segments generated by TextTiling instead.

After segmenting all dialogs into sequences of subtasks, the bisecting *K*-means clustering algorithm (Steinbach et al., 2000) is used to group the segments that belong to the same type of subtask together as they represent the same form type. The clustering is done based on cosine similarity between segments. This unsupervised clustering algorithm is also used to infer a set of HMM states in the HMM-based segmentation described above.

Words are used as features for both segmentation and clustering algorithms. If a set of domain concepts has already been identified, we can use this information to enhance the features. When concept annotation is available, we can incorporate a concept label into a representation of a concept word. A *Label+Word* representation joins a word string and its label and can help disambiguate between similar words that belong to different concepts. For instance, "one" in "that one" is not the same token as "**[Hour]:**one". A *Label* representation, on the other hand, only represents a concept word by its label. This representation is based on the assumption that a list of concepts occurring in one subtask is distinguishable from a list of concepts occurring in other subtasks regardless of the values of the concepts; hence, a concept label is more informative than its value. This representation provides an abstraction over all different values of the same concept type. For example, **[Airline]:**northwest and **[Airline]:**delta are represented with the same token **[Airline]**. In all experiments, concept labels are provided by a domain expert as we assume that a set of domain concepts has already been identified.

4.1 Dialog Segmentation Results

To evaluate dialog segmentation performance, we compare predicted boundaries against subtask boundaries annotated by a domain expert. Subtask boundaries could occur only at utterance boundaries. Two metrics are used: P_k (Beeferman et al., 1999) and concept-based f-measure (C. F-1). P_k measures the probability of misclassifying two utterances that are *k* utterances apart as belonging to the same sub-task or different sub-tasks. *k* is set to half the average sub-task length. *C. F-1* is a modification of the standard f-measure (a harmonic mean of precision and recall) that gives credit to some near misses. Since the segmented dialogs will later be used to identify a set of forms and their associated slots, the segment that contains the same set of concepts as the reference segment is acceptable even if its boundaries are slightly different from the reference. For this reason, a near-miss counts as a match if there is no concept between the near-miss boundary and the reference boundary.

We evaluated the proposed dialog segmentation algorithms with 24 dialogs from the air travel domain and 20 dialogs from the map reading domain. The window size for TextTiling was set to 4 utterances. The cut-off threshold for choosing subtask boundaries was set to $\mu - \sigma/2$; where μ is the mean of the *depth scores* (Hearst, 1997), the relative change in word co-occurrence similarities on both sides of a candidate boundary, in each dialog and σ is their standard deviation. We found that a small window size and a low cut-off threshold are more suitable for identifying fine-grained segments as in the case of subtasks. However, we also found that TextTiling is quite robust as varying these two parameters doesn't severely degrade its performance (Chotimongkol, 2008). The threshold for selecting data-driven stop words was set to $\mu + 2*\sigma$; where μ is the mean of the regularity counts of all the words in a given dialog and σ is their standard deviation. The performance of TextTiling and HMM-based segmentation algorithm is shown in Table 2.

Augmented TextTiling, which uses a data-driven stop word list, distance weights, and the *Label+Word* representation, performed significantly better than the baseline in both domains. Each of these augmenting techniques can on their own improve segmentation performance but not significantly. Unsurprisingly, the proposed regularity counts discover stop words that are specific to spoken dialogs, but are absent from the hand-crafted list[1], e.g. “okay” and “yeah”.

Algorithm	Air Travel		Map Reading	
	P_k	C. F-1	P_k	C. F-1
TextTiling (baseline)	0.387	0.621	0.412	0.396
TextTiling (augmented)	0.371	0.712	0.384	0.464
HMM-based (utterance)	0.398	0.624	0.392	0.436
HMM-based (segment)	0.385	0.698	0.355	0.507
HMM-based (segment + Label representation)	0.386	0.706	0.250	0.686

Table 2: Dialog segmentation results

For HMM-based segmentation, the segmentation result obtained when modeling the HMM states from predicted subtasks generated by TextTiling (4th row) is better than the result obtained when modeling the HMM states from utterances (3rd row). Predicted segments provide more context to the clustering algorithm that induces the HMM states. As a result a more robust state representation is obtained. A more efficient clustering algorithm can also improve the performance of the HMM-based segmentation algorithm since it provides a state representation that better differentiates among dialog segments which belong to dissimilar subtasks. When the *Label* representation which yielded a better subtask clustering result (see Section 4.2) was used, HMM-based segmentation produced a better result (5th row) especially in the map reading domain. These numbers may appear modest compared to the numbers obtained when segmenting expository text. However, predicting the boundaries of fine-grained subtasks is more difficult even with a supervised learning approach (Arguello and Rosé, 2006). Our results are comparable to Arguello and Rosé’s (2006) results.

Between the two segmentation algorithms, the HMM-based algorithm performed slightly worse than TextTiling in the air travel domain but performed significantly better in the map reading domain. The HMM-based algorithm can identify more boundaries between fine-grained subtasks, which occur more often in the map reading domain. TextTiling, which relies on local lexical cohesion, is unlikely to find two significant drops in lexical similarity that are only a couple of utterances apart, and thus fails to detect boundaries of short segments. However, HMM-based segmentation misses more boundaries between two subtask occurrences of the same type, which occurs more often in the air travel domain, as they are usually represented by the same state.

[1] http://search.cpan.org/~creamyg/Lingua-StopWords-0.08/lib/Lingua/StopWords.pm.

4.2 Subtask Clustering Results

We evaluated the subtask clustering algorithm on the same data set used in the dialog segmentation evaluation. Table 3 presents the quality score (QS) for each clustering result. These QSs were obtained by comparing the output clusters against a set of reference subtasks. See (Chotimongkol and Rudnicky, 2002) for the definition of QS.

Feature Representation	Air Travel	Map Reading
Label+Word (oracle)	0.738	0.791
Label+Word	0.577	0.675
Label	0.601	0.823

Table 3: Subtask clustering results

When predicted segments were clustered, the quality of the output (2nd row) is not as good as when the reference segments were used (1st row) as inaccurate segment boundaries affected the performance of the clustering algorithm. However, the qualities of subtasks that occur frequently are not much different. In terms of feature representation, the clustering algorithm that uses the *Label* representation achieved better performance in both domains. When the sets of concepts in all of the subtasks are disjoint, the clustering algorithm that uses the *Label* representation can achieve a very good result as in the map reading domain. This result is even better than the result obtained when the reference segments were clustered by the algorithm that uses the *Label+Word* representation. These results demonstrate that an appropriate feature representation provides more useful information to the clustering algorithm than accurate segment boundaries. However, when the subtasks contain overlapping sets of concepts as in the air travel domain, the performance gain obtained from the *Label* representation is quite small.

Figure 5 shows four types of forms in the air travel domain that were acquired by the proposed form identification approach. The slot names are taken from concept labels. The number in parentheses is slot frequency in the corresponding cluster. The underlined slots are the ones that belong to other forms. Some slots in the car query form are missing as some instances of its corresponding subtask get merged into other clusters.

4.3 Discussions on Learning Approaches

The results presented in the previous sections show that existing unsupervised learning algorithms are able to identify components of the form-based dialog structure representation.. However, some modifications are required to make these algorithms more suitable for inferring the structure of a spoken dialog. The advantages of different learning algorithms can be combined to improve performance. For example, TextTiling and HMM-based segmentation are good at detecting different types of boundaries; therefore, combining the predictions made by both algorithms could improve segmentation performance. Additional features such as prosodic features could also be useful.

Subsequent steps in the learning process are subjected to propagation errors. However, the proposed learning algorithms, which are based on generalization of recurring patterns, are able to learn from inaccurate information given that the number of errors is moderate, so that there are enough correct examples to learn from. Given redundant information in dialog corpora, a domain knowledge acquisition process does not require high learning accuracy and an unsupervised learning approach is reasonable. The overall quality of the learning result is acceptable. The proposed unsupervised learning approach can infer much useful task-specific dialog information needed for automatically configuring a task-oriented dialog system from data.

5 Conclusion and Future Directions

To represent a dialog for a learning purpose, we based our representation, the form-based dialog structure representation, on observable information. Components of the form-based representation can be acquired with acceptable accuracy from observable structures in dialogs without requiring human supervision. We show that this dialog representation can capture task-specific information in dissimilar domains. Additionally, it can be understood and applied by annotators other than the developers.

Our investigation shows that it is feasible to automatically acquire the domain-specific dialog information necessary for configuring a task-oriented dialog system from a corpus of in-domain dialogs. This corpus-based approach could potentially reduce human effort in dialog system development. A limitation of this approach is that it can discover only information present in the data. For instance, the corpus-based approach cannot identify city names absent in the corpus while a human developer would know to include these. Revision may be required to make learned information more accurate and complete before deployment; we expect that this effort would be less than the one required for manual analysis. A detailed evaluation of correction effort would be desirable.

In this paper, task-specific knowledge was acquired from in-domain dialogs without using any prior knowledge about the domain. In practice, existing knowledge sources about the world and the domain, such as WordNet, could be used to improve learning. Some human supervision can be valuable particularly in the form of semi-supervised learning and active learning. In particular a process that integrates human input at appropriate times (for example seeding or correction) is likely to be part of a successful approach.

huerta@us.ibm.com

Abstract

We introduce the relative rank differential statistic which is a non-parametric approach to document and dialog analysis based on word frequency rank-statistics. We also present a simple method to establish semantic saliency in dialog, documents, and dialog segments using these word frequency rank statistics. Applications of our technique include the dynamic tracking of topic and semantic evolution in a dialog, topic detection, automatic generation of document tags, and new story or event detection in conversational speech and text. Our approach benefits from the robustness, simplicity and efficiency of non-parametric and rank based approaches and consistently outperformed term-frequency and TF-IDF cosine distance approaches in several experiments conducted.

1 Background

Existing research in dialog analysis has focused on several specific problems including dialog act detection (e.g., Byron and Heeman 1998), segmentation and chunking (e.g., Hearst 1993), topic detection (e.g., Zimmerman et al 2005), distillation and summarization (e.g., Mishne et al 2005) etc. The breath of this research reflects the increasing importance that dialog analysis has for multiple domains and applications. While historically, dialog analysis research has initially leveraged the corresponding techniques originally intended for textual document analysis, techniques tailored specifically for dialog processing eventually should be able to address the sparseness, noise, and time considerations intrinsic to dialog and conversations.

The approach proposed in this paper focuses on the relative change of rank ordering of words occurring in a conversation according to their frequencies. Our approach emphasizes relatively *improbable* terms by focusing on terms that are relatively unlikely to appear frequently and thus weighting their change in rank more once they are observed. Our technique achieves this in a non-parametric fashion without explicitly computing probabilities, without the assumption of an underlying distribution, and without the computation of likelihoods.

In general, non-parametric approaches to data analysis are well known and present several attractive characteristics (as a general reference see Hollander and Wolfe 1999). Non-parametric approaches require few assumptions about the data analyzed and can present computational advantages over parametric approaches especially when the underlying distributions of the data are not normal. In specific, our approach uses rank order statistics of word-feature frequencies to compute a relative rank-differential statistic.

This paper is organized as follows: in Section 2 we introduce and describe our basic approach (the relative rank differential RRD function and its sorted list). In Section 3 we address the temporal nature of dialogs and describe considerations to dynamically update the RRD statistics in an on-line fashion especially for the case of shifting temporal windows of analysis. In Section 4 we relate the RRD approach to relevant existing and previous dialog and text analysis approaches. In Section 5 we illustrate the usefulness of our metric by analyzing a set of conversations in various ways using the RRD. Specifically, in that section we will empirically demonstrate its robustness to noise and data sparseness compared to the popular term frequency and TF-IDF cosine distance approaches in a dialog classification task. And finally, in Section 6, we present some concluding remarks and future directions

2 The Relative Rank Differential

Let $d^u = \{d_1{}^u, d_2{}^u, d_3{}^u ...\}$ denote the ranked dictionary of a language (i.e., the ordered list of words sorted in decreasing order of frequency). The superscript *u* denotes that this ranked list is based on the *universal* language. Specifically, the word $d_i{}^u$ is the i^{th} entry in d^u if its frequency of occurrence in the language denoted by $f(d_i{}^u)$ is larger than $f(d_j{}^u)$ for every j where $i < j$ (for notational simplicity we assume that no two words share the same frequency). In the case where want to relax this assumption we simply allow $i < j$ when $f(d_i^u) = f(d_j{}^u)$ as long as d_i^u precedes $d_j{}^u$ lexicographically, or under any other desired precedence criteria. For d^u we assume that $f(d_i^u) > 0$ for every entry (i.e., each word has been observed at least once in the language).

Similarly, let now $d^S = \{d_1{}^S, d_2{}^S, d_3{}^S ...\}$ denote the corresponding ranked dictionary for a dialog, or dialog segment, S (ordered, as in the case of the language dictionary, in decreasing order of frequency)[1]. The superscript S denotes that this ranked list is based on the dialog *S*. The word $d_i{}^S$ is the i^{th} entry in d^s if its frequency of occurrence in the conversation segment *S* denoted by $f(d_i{}^S)$ is larger than $f(d_j{}^S)$ for every j where $i < j$. In this case we allow $f(d_i{}^S) \geq 0$ for every i so that the cardinality of d^u is the same as d^s.

Let $r_d(w)$ denote the rank of word w in the ranked dictionary d so that, for example, $r_{d^u}(d_i^u) = i$.

Based now on a dialog segment and a universal language, any given word w will be associated with a rank in d^u (the universal ranked dictionary) and a rank in d^s, the dialog segment ranked dictionary.

Let us define now for every word the relative rank differential (RRD) function or statistic[2] given by:

$$c_{d^s, d^u}(w) = \frac{\left| r_{d^u}(w) - r_{d^s}(w) \right|}{\left(r_{d^u}(w) \right)^{\alpha}}$$

The relative rank-differential is the ratio of the absolute difference (or change) in rank between the word's original position in the universal dictionary and the segment s. The exponent α in the denominator allows us to emphasize or deemphasize changes in terms according to their position or rank in the language (or universal) dictionary. Typically we will want to increase the denominator's value (i.e., deemphasize) for terms that have very low frequency (and their rank value in the universal dictionary is large) so that only relatively big changes in rank will result in substantial values of this function.

When alpha is zero, the RRD focuses on every word identically as we consider only the absolute change in rank. For alpha equal to 1.0 the relative change in rank gets scaled down linearly according to its rank, while for alphas larger than 1.0 the numerator will scale down or reduce to a larger extent the value of relative rank differential for words that have large rank value.

Based on each word's relative rank differential we can compute the ranked list of words sorted in decreasing order by their corresponding value of relative rank differential. Let this sorted list of words be denoted by $R(d^u, d^S) = \{w_1, w_2, ...\}$. So that $c(w_i)$ is larger than $c(w_j)$[3] for every j where $i < j$.

We now provide some intuition on the ranked RRD lists and the RRD function. The ranked dictionary of a language contains information

[1] We only consider at this point the case in which both speakers' parts in a dialog interaction are considered jointly (i.e., single channel), however, our method can be easily extended to separate conversation channels. Also, for simplicity we consider at this point only words (or phrases) as features.

[2] For brevity, we refer to the Relative Rank Differential of a word given two utterances as a *statistic*. It is not, strictly speaking, a metric or a distance, but rather a function.

[3] For simplicity, c is written without subscripts when these are apparent from the context.

about the frequency of all words in a language (i.e., across the universe of conversations) while the segment counterpart pertains a single conversation or segment thereof. The relative rank differential tells us how different a word is ranked in a conversation segment from the universal language, but this difference is normalized by the universal rank of the word. Intuitively, and especially when alpha equals 1.0, the RRD denotes some sort of percent change in rank. This also means that this function is less sensitive to small changes in frequency in the case of frequent words and to small changes in rank in case of infrequent words. Finally, the sorted list $R(d^u, d^S)$ contains in order of importance the most relatively salient terms of a dialog segment, as measured by relative changes or differences in rank.

3 Collecting Rank Statistics

We now discuss how to extend the metrics described in the previous section to consider finite-time sliding windows of analysis, that is, we describe how to update rank statistics, specifically the ranked lists and relative rank differential information for every feature in an on-line fashion. This is useful when tracking the evolution of single dialogs, when focusing the analysis to span shorter regions, as well as to supporting dynamic real-time analytics of large number of dialogs.

To approach this, we decompose the *word events* (words as they occur in time) into arriving and departing events. An arriving event at time *t* is a word that is covered by the analysis window at its specific time as the finite length window slides in time, and a departing word at time *t* is a feature that stops falling within the window of analysis. For simplicity, and without loss of generality, we now assume that we are performing the analysis in real time and that the sliding window of analysis spans from current time *t* back to *(t-T)*, where *T* is the length of the window of analysis.

An arriving word at current time *t* falls into our current window of analysis and thus needs to be processed. To account for these events efficiently, we need a new structure: the temporal event *FIFO* list (i.e., a queue where events get registered) that keeps track of events as they arrive in time. As an event (word w_t) arrives it is registered and processed as follows:

1. Find the corresponding identifier of w_t in the universal ranked dictionary and add it as d_i^u at the end of the temporal event list together with its time stamp.
2. The corresponding entry in d^s, the ranked segment dictionary, is located through an index list that maps $d_i^u \rightarrow d_k^s$ and the segment frequency associated is incremented $f(d_k^s) = f(d_k^s) + 1$
3. Verify if the rank of the feature needs to be updated in the segment rank list. In other words evaluate whether $f(d_{k-1}^s) > f(d_k^s)$ still holds true after the update. If this is not true then shift feature up in the rank list (to a higher rank) and shift down the predecessor feature in the rank list. In this single shift-up-down operation, update the index list and the value of *k*.
4. For every feature shifted down in 3 down re-compute the relative rank differential RRD function and verify if its position needs to be modified in $R(d^u, d^S)$ (a second index list is needed to compute this efficiently).
5. Repeat step 3 iteratively until feature is not able to push up any further in the ranked list.

The process for dealing with departing events is quite similar to the arriving process just described. Of course, as the analysis window slides in time, it is necessary to keep track of the temporal event FIFO list to make sure that the events at the top are removed as soon as they fall out of the analysis window. The process is then:

1. The departing event is identified and its corresponding identifier in the universal ranked dictionary d_i^u is removed from the top of the temporal event list.
2. Its location in d^s the ranked segment dictionary is located through the index list. The corresponding segment frequency associated is decreased as follows: $f(d_k^s) = f(d_k^s) - 1$.
3. Verify if the rank of the feature needs to be updated in the segment rank list. In other

words evaluate if $f(d^s_{k+1}) < f(d^s_k)$ still holds true after the update. If not shift feature down in rank (to a lower rank, denoting less frequent occurrence) and shift the successor feature up in the rank list. In this single shift up-down operation, update the index list and the value of k.

4. For every feature shifted up in step 3 recompute the relative rank differential and verify if its location needs to be modified in $R(d^u, d^S)$
5. Repeat step 3 until the feature is not able to shift down any further in the ranked list.

The procedures just described are efficiently implementable as they simply identify entries in rank lists through index lists, update values by incrementing and decrementing variables, and performed some localized and limited re-sorting. Additionally, simple operations like adding data at the end and removing data at the beginning of the FIFO list are needed making it altogether computationally inexpensive.

4 Related Techniques

Our work relates to several existing techniques as follows. Many techniques of text and dialog analysis utilize a word frequency vector based approach (e.g., Chu-Carroll et al 1999) in which lexical features counts (term frequencies) are used to populate the vector. Sometimes the term frequency is normalized by document size and weighted by the inverse document frequency (TF-IDF). The TF-IDF and TF metrics are the base of other approaches like discriminative classification (Kuo and Lee 2003; and Li and Huerta 2004), Text Tilling or topic chains (Hearst 1993; Zechner 2001), and latent semantic indexing (Landauer et al 1998). Ultimately, these types of approaches are the foundation of complex classification and document understanding systems which use these features together with possibly more sophisticated classification algorithms (e.g., D'Avanzo et al 2007).

When using TF and TF-IDF approaches, it is important to notice that by normalizing the term frequency by the document length, TF-based approaches are effectively equivalent to estimation of a multinomial distribution. The variance of the estimate will be larger as the number of observations decreases. Recently, approaches that explicitly establish this parametric assumption and perform parameter inference have been presented in (Blei et al 2003). This work is an example of the potential complexity associated when performing parameter inference.

The area of adaptation of frequency parameters for ASR, specifically the work of (Church 2000), is relevant to our work in the sense that both approaches emphasize the importance of and present a method to update the lexical or semantic feature statistics on-line.

In the area of non-parametric processing of dialog and text, the work of (Huffaker et al 2006), is very close to the work in this paper as it deals with non-parametric statistics of the word frequencies (rank of occurrences) and uses the Spearman's Correlation Coefficient. Our work differs from this approach in two ways: first, the Relative Rank Differential tells us about the relative change in rank (while SCC focuses in the absolute change) and secondly, from the ranked RDD list, we can identify the saliency of each term (as opposed to simply computing the overall similarity between two passages).

5 Experiments

In order to illustrate the application of the RRD statistic, we conducted two sets of experiments based on conversations recorded in a large customer contact center for an American car manufacturer. In the first group of experiments we took a corpus of 258 hand transcribed dialogs and conducted classification experiments using the basic RRD statistic as feature. We compared its performance against term frequency and TF-IDF based cosine distance approaches. The second set of experiments is based on ASR transcribed speech and for this we used a second corpus consisting of a set of 44 conversations spanning over 3 hours of conversational speech.

In the first set of experiments we intend to illustrate two things: first the usefulness of RRD as a feature in terms of representational accuracy and second, its robustness to noise and data sparseness compared to other popular features. In the second set of experiments we illustrate the versatility and potential of our technique to be applied in dialog-oriented analysis.

5.1 RRD for Dialog matching

For this set of experiments we used a corpus of 258 hand transcribed conversations. Each dialog was treated like a single document. Using the set of dialogs we constructed different query vectors and affected these queries using various noise conditions, and then we utilized these vectors to perform a simple document query classification experiment. We measured the cosine distance between the noisy query vector and the document vector of each document in this corpus. A noisy query is constructing by adding zero mean additive gaussian noise to the query vector with amplitude proportional to the value of a parameter *N* and with floor value of zero to avoid negative valued features. We allow, in these experiments, for counts to have non-integer values; as the dialog becomes larger, the Gaussian assumption holds true due to the Central Limit Theorem, independently of the actual underlying distribution of the noise source. This distortion is intended to mimic the variation between two similar dialogs (or utterances) that are essentially similar, except for a additive zero mean random changes. A good statistic should be able to show robustness to these types of distortions. A correct match is counted when the closest match for each query is the generating document.

	N=0.0	N=.05	N=0.1	N=0.2	N=0.4
TF-cosine	99.6	98.0	84.9	60.0	32.5
TF-IDF cosine	99.6	99.6	97.3	88.0	67.4
RRD-dot	99.6	99.6	97.6	91.8	70.9

Table 1. Query match accuracy for 3 features under several query noise conditions.

Table 1 shows the percent correct matches for the TF, TF-IDF and Relative Rank Differential features, under various levels of query noise. As we can see, in clean conditions the accuracy of the 3 features is quite high but as the noise conditions increase the accuracy of the 3 techniques decreases substantially. However, the TF feature is much more sensitive to noise than the other two techniques. We can see that our technique is better than both TF and TF-IDF in noisy conditions.

We also conducted experiments to test the comparative robustness or the RRD feature to query data sparseness. To measure this, we evaluated the accuracy in query-document match when using a random *subset* of the document as query. Figure 1 show the results of this experiment using the RRD feature, the Term Frequency, and the TF-IDF feature vectors. We can see that with as little as 5% of the document size as query, the RRD achieves close to 90% accuracy while the TF-IDF feature needs up to 20% to achieve the same performance, and the TF counts only need close to 70%.

These results empirically demonstrate that RRD statistics are more robust to noise and to term coverage sparseness than TF and TF-IDF.

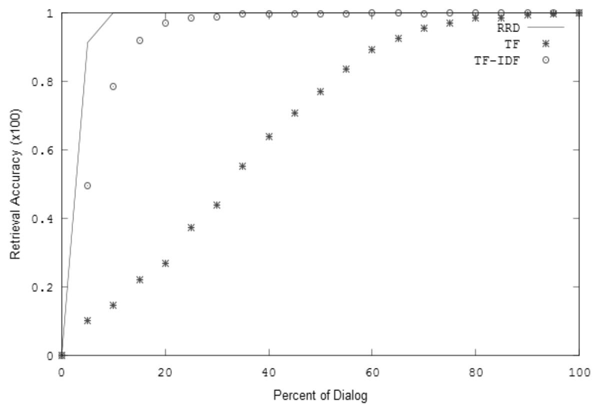

Figure1. Query match accuracy for 3 feature types under various query data sparseness conditions

5.2 ASR Based experiments

For the experiments of this section we used 44 dialogs. Manual transcriptions for these 44 conversations were obtained in order to evaluate the speech recognition accuracy. While we could have used the manual transcripts to perform the analysis, the results reported here are based on the recognition output. The reason for using ASR transcripts as opposed to human transcription is that we wanted to evaluate how useful our approach would be in a real ASR based solution dealing with large amounts of noisy data at this level of ASR error.

Each dialog was recorded in two separate channels (one for the agent and one for the customer) and automatically transcribed separately using a large vocabulary two-stage automatic speech recognizer system. In the first stage, a speaker independent recognition pass is performed after which the resulting hypothesis is used to compensate and adapt feature and models. Using the adapted feature and models the second stage recognition is performed. After recognition, the single best hypothesis with time stamps for the agent and customer are weaved back together.

The overall Word Error Rate is about 24% and varies significantly between the set of agents and the set of customers (the set of agents being more accurate).

The universal dictionary we used consists exclusively of the words occurring in the corpus which total 2046 unique words. Call length ranged from just less than 1 minute to more than 20 minutes with most of the calls lasting between 2 and 3 minutes. The corpus consists of close to 30k tokens and does not distinguish between agent channel and customer channel. A universal dictionary of ranked words is built from the set of dialogs and each dialog is treated as a segment.

Dialog Tagging and Topic Saliency

In this analysis we look at complete dialogs. A useful application of the methods we describe in this work is to identify and separate calls that are interesting from non-interesting calls[4], furthermore, one could also be interested in singling out which specific terms make this dialog salient. An application of this approach is the automatic generation of tags (e.g., social-network style of document tagging). In our approach, we will identify calls whose top entries in their sorted relative rank differential lists are above a certain threshold and deem these calls as semantically salient.

We now describe in detail how an interesting call can be distinguished from a non-interesting call using the relative rank differential statistic.

Figure 2 below shows the ranked dictionary $d^S = \{d_1^S, d_2^S, d_3^S ...\}$ (i.e., the universal rank id's as a function of their observed ranks) and Figure 3 shows the plot of the sorted relative rank differential list $R(d^u, d^S)$ for when the segment corresponds to an interesting call (as defined above).

The chosen call, specifically shows as topic AIRBAG deployment in the context of a car accident.

Specifically, Figure 2 shows the corresponding rank in the universal ranked dictionary versus the rank in the dialog or segment. We can see that the right-most part of the plot is largely monotonic, meaning that most entries of lesser frequency occur in the same ranked order both in the universal and the specific dialog (including zero times for the segment), while a subset across the whole range of the universal dictionary were substantially relocated up in the rank (i.e., occurred more frequently in the dialog than in the language). If the plot was a single straight line each word would have the same rank both in the language and in the dialog.

We argue that while the terms of interest lie in that subset of interest in the graph (the terms whose rank increased substantially), not all of those words are equally interesting or important and rather than simply looking at absolute changes in rank we focus on the relative-rank differential RRD metric. Thus, Figure 3 shows the sorted values of the relative rank differential list (with $\alpha = 1.3$). The top entries and their rank in the universal dictionary (in parentheses) are: AIRBAGS (253), AS (55), FRONT (321), DEPLOY (369), SIDE (279), ACCIDENT (687). As we can see, the top entries are distributed across a broad range of ranks in the universal dictionary and relate to the topic of the conversation, which from the top ranked entries are evidently the deployment of front and side airbags during an accident, and thus, for this call were able to identify its semantic saliency from the corpus of conversations.

Other interesting or salient calls also showed a similar this profile in the RRD curve.

The question now is what the behavior of our approach for uninteresting calls is. We repeated the procedure above for a call which we deemed semantically un-interesting (i.e., dealing with a common topic like call transfer and other routine procedures). Figure 4 shows the sorted relative rank differential values and, especially when compared with Figure 2, we see a large monotonic component on the higher ranked terms and not so marked discontinuities in the low and mid-range part of the curve.

We computed the relative rank differential RRD metric for each feature similarly as with the interesting call, and ranked the words based on these values. The distribution of the ranked values is shown in Figure 5. The resulting words with top values are CLEAR (1113), INFORMATION (122) BUYING (1941), and CLEARLY (1910). From these words we cannot really tell what is the specific topic of the conversation is as easily as with

[4] For the purpose of this work, we simply define as an *interesting call* a call that deals with an infrequent or rare topic which influences the distribution of keywords and key-phrases. Examples of calls in our domain meeting this criterion are calls dealing with accidents and airbags.

the interesting call. More importantly, we can now compare Figures 3 and 5 and see that the highest relative rank differential value of the top entry in Figure 3 (larger than 10) is significantly larger than the largest relative rank differential value in Figure 5 (just above 7) reflecting the fact that the relative rank differential metric could be a useful parameter in evaluating semantic saliency of a segment using a static threshold. As an interesting point, conceivably the highly ranked features based on RRD could reflect language utilization idiosyncrasies.

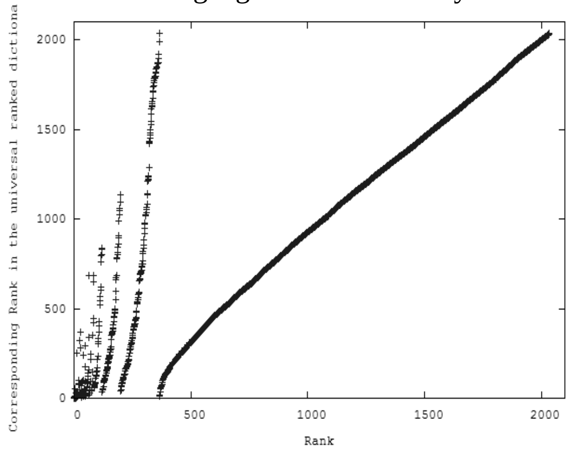

Figure 2. Ranked dictionary entry vs Universal Rank for a salient call

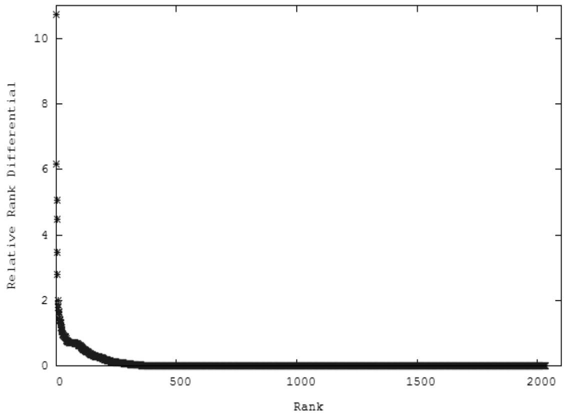

Figure 3. Sorted relative rank differential values of $R(d^u, d^S)$ for a semantically salient call.

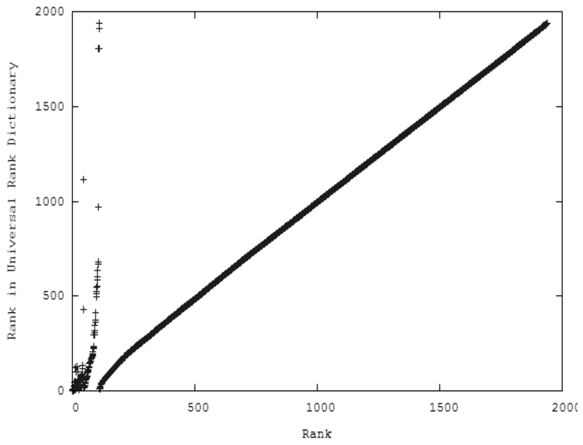

Figure 4. Ranked dictionary entry vs Universal Rank for a non-salient call

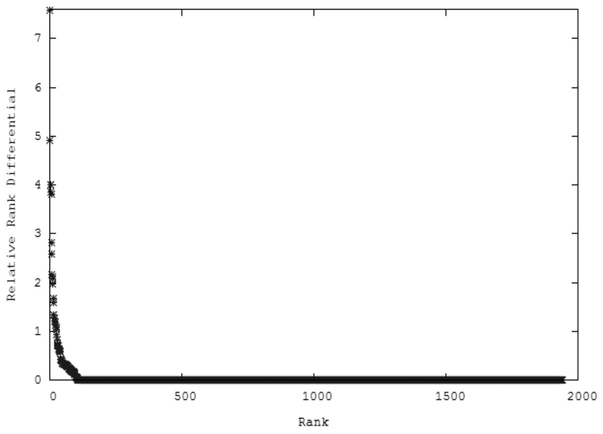

Figure 5. Sorted relative rank differential values of $R(d^u, d^S)$ for a non-interesting (semantically non-salient) call.

6 Conclusions

In this paper we presented a novel non parametric rank-statistics based method for the semantic analysis of conversations and dialogs. Our method is implementable in segment-based or dialog-based modalities, as well as in batch form and in on-line or dynamic form. Applications of our method include topic detection, event tracking, story/topic monitoring, new-event detection, summarization, information filtering, etc. Because our approach is based on non-parametric statistics it has favorable intrinsic benefits, like making no assumptions about the underlying data, which makes it suitable for the use of both lexical semantic features as well as classifier-based semantic features. Furthermore, our approach could, in the future, benefit from classical non-parametric approaches like block-treatment analysis etc.

We demonstrated that our approach is as effective in query classification as TF and TF-IDF in low noise and no noise (i.e., distortion) conditions, and consistently better than those techniques in noisy conditions. We also found RRD to be more robust to query data sparseness than TF and TF-IDF. These results provide a motivation to combine our statistic with other techniques like topic chains, textilling, latent semantic indexing, and discriminant classification approaches; specifically RRD could replace TF and TF-IDF based features.

Future work could focus on applying ranking statistics to techniques for mining and tracking temporal and time-changing parameters in conjunction with techniques like (Agrawal and Srikant 1995; Pratt 2001; Last et al 2001).

Another area of possible future work is the detection and separation of multiple underlying trends in dialogs. Our approach is also suited for the analysis of large streams of real time conversations, and this is a very important area of focus as presently more and more conversational data gets generated through channels like chat, mobile telephony, VoIP etc.

tsolorio,yangl@hlt.utdallas.edu

Abstract

Predicting possible code-switching points can help develop more accurate methods for automatically processing mixed-language text, such as multilingual language models for speech recognition systems and syntactic analyzers. We present in this paper exploratory results on learning to predict potential code-switching points in Spanish-English. We trained different learning algorithms using a transcription of code-switched discourse. To evaluate the performance of the classifiers, we used two different criteria: 1) measuring precision, recall, and F-measure of the predictions against the reference in the transcription, and 2) rating the naturalness of artificially generated code-switched sentences. Average scores for the code-switched sentences generated by our machine learning approach were close to the scores of those generated by humans.

1 Introduction

Multilingual speakers often switch back and forth between languages when speaking or writing, mostly in informal settings. The mixing of languages involves very elaborated patterns and forms and we usually use the term Code-Switching (CS) to encompass all of them (Lipski, 1978). Before the Internet era, CS was mainly used in its spoken form. But with so many different informal interaction settings, such as chats, forums, blogs, and web sites like Myspace and Facebook, CS is being used more and more in written form. For English and Spanish, CS has taken a step further. It has become a hallmark of the chicano culture as it is evident by the growing number of chicano writers publishing work in Spanish-English CS.

We have not completely discovered the process of human language acquisition, especially dual language acquisition. Findings in linguistics, sociolinguistics, and psycholinguistics show that the production of code-switched discourse requires a very sophisticated knowledge of the languages being mixed. Some theories suggest bilingual speakers might have a third grammar for processing this type of discourse. The general agreement regarding CS is that switches do not take place at random and instead it is possible to identify rules that bilingual speakers adhere to.

Understanding the CS process can lead to accurate methods for the automatic processing of bilingual discourse, and corpus-driven studies about CS can also inform linguistic theories. In this paper we present exploratory work on learning to predict CS points using a machine learning approach. Such an approach can be used to reduce perplexity of language models for bilingual discourse. We believe that CS behavior can be learned by a classifier and the results presented in this paper support our belief.

One of the difficult aspects of trying to predict CS points is how to evaluate the performance of the learner since switching is intrinsically motivated and there are no forced switches (Sankoff, 1998b). Therefore, standard classification measures for this task such as precision, recall, F-measure, or accuracy, are not the best approach for measuring the effectiveness of a CS predictor. To complement the evaluation of our approach, we designed a task involving human judgements on the naturalness of automatically generated code-switched sentences. Both evaluations yielded encouraging results.

The next section discusses theories explaining the CS production process. Then in Section 3 we present our framework for learning to predict CS points. Section 4 discusses the empirical evaluation of the classifiers compared to the human reference. In Section 5 we present results of human evaluations on automatically generated code-switched sentences. Section 6 describes previous work related to the processing of code-switched text. Finally, we conclude in Section 7 with a summary of our findings and directions for future work.

2 Bilingual Discourse

The combination of languages can be considered to be a continuous spectrum where on each end of the spectrum we have one of the standard languages and no blending. As one moves closer to the middle of the spectrum the amount and complexity of the blending pattern increases. The blending pattern most widely known, and studied, is code-switching, which refers to the mixing of words from two languages, but the words themselves do not suffer any syntactic or phonological alterations. The CS points can lie at sentence boundaries, but very often we will also observe CS inside sentences. According to (Sankoff, 1998b; Poplack, 1980; Lipski, 1978) when CS is used inside a sentence, it can only happen at syntactic boundaries shared by both languages, and the resulting monolingual fragments will conform to the grammar of the corresponding language. In this CS theory the relationship between both languages is symmetric –lexical items from one language can be replaced by the corresponding items in the second language and vice versa. Another prevalent linguistic theory argues the contrary: there is an asymmetric relation where the changes can occur only in one direction, which reflects the existence of a Matrix Language (ML), the dominant language, and an Embedded Language (EL), or subordinate language (Joshi, 1982). The Matrix Language Frame model, proposed and extended by Scotton-Myers, supports this asymmetric relation theory. This formalism prescribes that content morphemes can come from the ML or the EL, whereas late system morphemes, the elements that indicate grammatical relations, can only be provided by the ML (Myers-Scotton, 1997).

Until an empirical evaluation is carried out on large representative samples of discourse involving a large number of different speakers, and different language-pairs, the production of CS discourse will not be explained satisfactorily. The goal of this work is to move closer to a better understanding of CS by learning from corpora to predict possible CS points.

3 Learning When To Code-Switch

3.1 The English-Spanish Code-Switched Data Set

We recorded a conversation among three English-Spanish bilingual speakers that code-switch regularly when speaking to each other. The conversation lasts for about 40 minutes (∼8k words, 922 sentences). It was manually transcribed and annotated with Part-of-Speech (POS) tags. A total of 239 switches were identified manually. English is the predominant language used, with a total of 576 monolingual sentences. We refer to this transcription as the Spanglish data set. We are currently in the process of collecting new transcriptions of this conversation in order to measure inter annotator agreement.

3.2 Approach

Machine learning algorithms have proven to be surprisingly good at language processing tasks, including optical character recognition, text classification, named entity extraction, and many more. The premise of our paper is that machine learning algorithms can also be successful at learning how to code-switch as well as humans. At the very least we want to provide encouraging evidence that this is possible. To the best of our knowledge, there is no previous work related to the problem of automatically predicting CS points. Our machine learning framework then is inspired by existing theories of CS and existing work on part-of-speech tagging code-switched text (Solorio and Liu, 2008).

In our approach, each word boundary is a potential point for switching – an instance of the learning task. It should be noted that we can only rely on the history of words preceding potential CS points in or-

der to extract meaningful features. Otherwise, if we look also into the future, we could just do language identification to extract the CS points. However, our goal is to provide methods that can be used in real time applications, where we do not have access to observations beyond the point of interest. Another restriction we imposed on the method is related to the size of the context used. A sentence can be code-switched in different ways, with all different versions adhering to the CS "grammar". The number of permissible CS sentences grows almost exponentially with the length of the sentence[1]. By limiting the length of the context to at most two words we are trying to avoid some sort of over fitting by having the model making assumptions over the interaction of the two languages that will be too weak, or speaker-dependent.

Previous studies have identified several socio-pragmatic functions of code-switching. The most common include direct quotation, emphasis, clarification, parenthetical comments, tags, and trigger switches. Other characteristics relevant to CS behavior are the topic being discussed, the speakers involved, the setting where the conversation is taking place, and the level of familiarity between the speakers. Having encoded information regarding the CS function and the aforementioned relevant factors might help in predicting upcoming CS points. However, annotating this information in the transcription can be time consuming and very often this information is not readily available. Therefore, at the expense of making this task even more difficult, we decided against trying to include this type of information and include only lexical and syntactic features, to evaluate a practical and cost effective method for this task. Table 1 shows the list of features. All of these features are associated with word w_n, the word immediately preceding boundary n. Feature 1 is the word form[2]. Feature 2 is language identification. If the production of CS discourse adheres to the matrix language frame model, then knowledge of the language can potentially be a good source of information. Feature 3 is the gold-standard POS tag. We also include as a feature the position of the word relative to the phrase constituent using a Beginning-Inside-Outside (BIO) scheme. For instance, the word at the beginning of the verb phrase will be labeled as B, the following words inside this verb phrase will be tagged as I, and words that were not identified as part of a phrase constituent were labeled as O. This chunking information was extracted using the English and Spanish versions of FreeLing[3]. We did not measure accuracy on the chunking information. Features 5 to 9 were generated by tagging the Spanglish conversation using the Spanish and the English versions of the Tree Tagger (Schmid, 1994). Attributes 5 to 7 are extracted from the English version, which include the POS tag, the confidence, and the lemma for that word. Similarly, features 8 to 10 were taken from the Spanish monolingual tree tagger. Features from the monolingual taggers will have some noisy labels when tagging fragments of the other language. However, considering that our feature set is small we want to explore if adding these features, which include the lemmas and probability estimates, can contribute to the learning task.

We also explored using a larger context. In this case, we extract the same features shown in Table 1 for the two words preceding the word boundary, resulting in 20 attributes representing each instance.

Evaluation for this task is not straightforward. Within a sentence, there are several CS points that will result in a natural sounding code-switched sentence, but none of these CS points are mandatory.

[1]Almost exponentially because not all sentences will be considered grammatical.

[2]Strictly speaking these should be called tokens, not words since punctuation marks are considered as well.

[3]http://garraf.epsevg.upc.es/freeling/

CS has a lot to do with the speaker's preferences, the topic being discussed, and the background of the participants involved. Using the standard approach for measuring performance of classifiers can be misleading, especially if the reference data set is small and/or has only a small number of speakers. It is unrealistic to just consider F-measure, or accuracy, as truthfully reflecting how well the learners generalize to the task. Therefore, we evaluated the classifier's performance using two different criteria, which are discussed in the next sections.

4 Evaluation 1: Using the Reference Data Set

This is the standard evaluation of machine learning classifiers. We randomly divided the data into sentences and grouped them into 10 subsets to perform a cross-validation. Tables 2 and 3 show results for Naive Bayes (NB) and Value Feature Interval (VFI) (Demiroz and Guvenir, 1997). Using WEKA (Witten and Frank, 1999), we experimented with different subsets of the attributes and two context windows: using only the preceding word and using the previous two words. The results presented here are overall averages of 10-fold cross validation. We also report standard deviations. It should be noted that the Spanglish data set is highly imbalanced, around 96% of the instances belong to the negative class. Therefore, our comparisons are based on Precision, Recall, and F-measure, leaving accuracy aside, since a weak classifier predicting that all instances belong to the negative class will reach an accuracy of 96%.

The performance measures shown on Tables 2 and 3 show that NB outperforms VFI in most of the configurations tested. In particular, NB yields the best results when using a 1 word context with no lexical forms nor lemmas as attributes (see Table 2 row 3). This is a fortunate finding –for most practical problems there will always be words in the test set that have not been observed in the training set. For our small Spanglish data set that will certainly be the case. In contrast, VFI achieves higher F-measures when using a context of two words and all the features are used.

Analyzing the predictions of the learners we noted that the NB classifier is heavily biased by the language attribute, close to 80% of the positive predictions made by NB are after seeing a word in Spanish. This preference seems to support the assumption of the asymmetry between the two languages and the existence of an ML[4]. This however is not the case for VFI, only a little over 50% of the positive predictions belong to this scenario. Another interesting finding is the learner's tendency to predict a code-switch after observing words like "Yeah", "anyway", "no", and "shower". The first two seem to fit the pattern of idiomatic expressions. According to Montes-Alcalá this type of CS includes linguistic routines and fillers that are difficult to translate accurately (Montes-Alcalá, 2007), which might be the case of "anyway", and unconscious changes, which can explain the case of "Yeah". The case of "shower" and "no" are more difficult to explain, they might be overfitting patterns from the learners. We also found out that VFI learned to predict that a CS will take place right after seeing the sequence of words *le dije* (I said). This sequence of words is frequently used when the speaker is about to quote his/herself, and this quotation is one of the well-documented CS functions (Montes-Alcalá, 2007).

A greedy search approach for attribute selection using WEKA showed that out of the 20 attributes (when using a two word context), the subset with the highest predictive value included the language identification for word w_{n-1} and w_{n-2}, the confidence threshold from the English tagger for word w_{n-2}, the lemma from the Spanish Tree tagger for w_{n-1}, and the lexical form of the word w_{n-1}. We expected the chunk information to be useful and this does not seem to be the case. Another unexpected outcome is that higher F-measures are reached by adding features generated by the monolingual Tree taggers. Even though these features are noisy, they still carry useful information.

We only show results from NB and VFI. Initial experiments with a subset of the data showed that these algorithms were the most promising for this task. They both yielded higher F-measures, even when compared against Support Vector Machines (SVMs), C4.5, and neural networks. On this experiment all the discriminative classifiers reached a classification accuracy close to 96%, but an F-

[4]We remind the reader that in this paper ML stands for Matrix Language.

Columns P, R, and F_1, show precision, recall, and F-measure, respectively. Numbers in parenthesis show standard deviations. The row marked with a '*' shows the configuration used for the generation of CS sentences presented in Section 5.

measure on the positive class of around 0%. NB and VFI estimate predictions for each class separately, which makes them robust to imbalanced data sets. In addition, generative models are known to be better for smaller data sets since they reach their higher asymptotic error much faster than discriminative models (Ng and Jordan, 2002). This might explain why Naive Bayes outperformed strong classifiers such as SVMs by a large margin.

The overall prediction performance is not very high. However, we should remark that for this particular task expecting a high F-measure is unrealistic. Consider for example, a case where the learners predict a CS point where the speaker decided not to switch, this does not imply that particular point is not a good CS point. And similarly, if the classifier missed an existing CS point in the reference data set the resulting sentence might still be grammatical and natural sounding. This motivated the use of an alternative evaluation, which we discuss below.

5 Evaluation 2: Using Human Evaluators

The goal of this evaluation is to explore how humans perceive our automatically generated CS sentences, and in particular, how do they compare to the original sentences and to the randomly generated ones. We selected 30 spontaneous and naturally occurring CS sentences from different sources. Some of them were selected from the Spanglish Times Magazine[5], some others from blogs found in (Montes-Alcalá, 2007). Other sentences were taken from a paper discussing CS on e-mails (Montes-Alcalá, 2005). All of the sentences are true occurrences of written CS, from speakers different from the ones in the Spanglish data set. The sentences were translated to standard English and Spanish and were manually aligned. We will use this parallel set of sentences to predict CS points with our models. Based on the model predictions we will generate code-switched sentences by combining monolingual fragments.

It should be noted that the Spanglish data set is a transcription of spoken CS. In contrast, this new evaluation set contains only written CS. Recent studies suggest written CS will adhere to the rules of spoken CS (Montes-Alcalá, 2005), but there is still some controversy on this issue. From our perspective, both samples come from informal conversational interactions. It is expected that both will have similar patterns and therefore will provide a good source for our evaluation.

5.1 Automatically Generated Code-Switching Sentences

In this subsection we describe how to generate code-switched sentences randomly and with the learned models described in the previous sections. For the

Table 3: Prediction results of CS points with VFI using different features. The notation on this table is the same as in Table 2

classifier-based approach, we POS tagged each parallel set of sentences, with the monolingual English and Spanish Tree Taggers, and we extracted the same set of features described shown in Table 1. We decided to train the models with a context size of one word, even though both learners reached higher F-measures when using a two-word context. This decision was based on the observation that having a two-word context will pose restrictions on possible CS points, since we would not be able to switch unless we have inserted into the sentence at least two tokens from the same language.

We trained the NB and VFI models with the Spanglish data set (using features 2–6, 8, and 9, see Table 1) and generated CS predictions for each parallel file. A code-switched sentence is generated by adding the first token of the sentence in language 1 (L1), and continue adding more tokens from L1 until a CS point is found. When a CS prediction is found, the following tokens are selected from the second language (L2), and we continue adding tokens from L2 until the classifier has predicted a change. Different versions of the sentences are generated by changing the definition of L1 and L2.

For the randomly generated CS sentences, switching decisions are made randomly with a probability proportional to the positive predictions made by the classifiers (in this case NB). That is, for the Spanish sentences switch points are predicted randomly with a 30% chance of switching while for English switch points are predicted with a 10% chance.

Generator	Average Score
Human	3.64
NB	3.33
Random	2.68
VFI	2.50

Table 4: Average score of 18 judges over the set of 28 code-switched sentences rated.

In total we generated 180 CS sentences: 30 sentences per generator scheme (we have three generators: NB, VFI, and random), and two versions from each generator corresponding to the two possible configurations of L1-L2 (Spanish-English, English-Spanish). We noticed that in some cases same sentences are generated by different methods and sometimes there are no switches. We narrowed down the sentences by randomly choosing the combination of L1-L2 for each generator. This reduced the number of sentences from having 6 versions, to having only 3 versions of each sentence. From the resulting 30 sets, we removed 2 sets because one or more of the generator schemes produced a monolingual sentence. Therefore, we used 28 sets for human evaluations.

5.2 Human Evaluation Results

We had a total of 18 subjects participating in the experiment. All of them identified themselves as being able to read and write Spanish and English, and the majority of them said to have used CS at least some times. We showed to the human subjects the 28 sets of sentences. This time we included the original version of the sentence. Therefore, each judge was given 4 versions of each of the 28 code-switched sentences: the one generated from NB predictions, the one from VFI, the randomly generated, and the original one. Then we asked them to rate each sentence with a number from 1 to 5 indicating how natural and human-like the sentence sounds. A rating of 5 means that they strongly agree, 4 means they agree, 3 not sure, 2 disagree, 1 strongly disagree.

The average results are presented in Table 4. The sentences generated by NB were scored considerably higher than those from VFI and random, and closer to the human sentences. According to the paired t-test the difference between the NB score and the random one is significant (p=0.01). However the average score for VFI is lower than random. More experiments are needed to see if by choosing the setting where VFI had the highest F-measure would make a difference in this respect. Overall the subjects rated the human-generated CS sentences lower than what we were expecting, although it is clear that they consider these sentences more natural sounding than the rest. This low rating might be related to the attitude several evaluators expressed toward CS. In the evaluation form we asked the judges to express their opinion on CS and several of them indicated feelings along the lines of “we shouldn’t code-switch”.

There are several ways in which two parallel sentences can be combined in CS, and possibly several will sound natural, but from our results, it is clear that the NB algorithm was indeed able to generate a human-like CS behavior that was successfully differentiated from randomly-generated sentences.

By looking at the set of automatically generated code-switched sentences, we realized that the majority of the sentences are grammatical and natural sounding. We believe that for a large number of the sentences it would be hard for a human to distinguish the sentences that were automatically generated from the human-generated ones. One of the give away clues is when a multi-word expression is CS, or a tag line. Table 5 shows three examples from the sentences evaluated. In the table there is an example in sentence 1c where the noun phrase is code-switched, the sentence is grammatical according to Spanish rules, but it sounds very odd to have the noun *carta* followed by the adjective in English, “astrological”. Other interesting features are present in example 3 where for the same noun phrase “produce section” we have both, the female marking determiner *la* and the masculine *el*. The same thing happens for the noun phrase “check-out line”. We would need to have a larger occurrence of these instances in our test set to determine if on average one form is preferred over the other.

In another experiment, we measured the prediction performance of NB and VFI on the 30 code-switched sentences used in this part of the evaluation. The best results, an F-measure of 0.418, were achieved by NB when a context of 1 word was used, and no words, nor lemmas were included as features. This is the same setting used for the generation process. In contrast, VFI reached an F-measure of 0.351 on this same setting. 30 sentences represent a very small dataset but the results are very promising since the speakers are different in the training and testing dataset. Moreover, these results support the claim that written and spoken CS obey similar rules.

6 Related Work

There is little prior work on computational linguistic approaches to code-switched discourse. Most of the previous work includes formalisms to parsing and generating mixed sentences, for example for Marathi and English (Joshi, 1982), or Hindi and English (Goyal et al., 2003). Sankoff proposed a production model of bilingual discourse that accounts for the equivalence constraint and the unpredictability of code-switching (Sankoff, 1998a). His real-time production model draws on the alternation of fragments from two virtual monolingual sentences. But no statistical assessment has been conducted on real corpora.

Another related work deals with language identification on English-Maltese code-switched SMS messages (Rosner and Farrugia, 2007). What the authors found to work best for language identification in this noisy domain is a combination of a bigram Hidden Markov Model, trained on language transitions, and a trigram character Markov Model for handling unknown words.

Me confirmó Juan que fue muy obvio, y no solamente en la produce section, *también en el* check-out line.
3e. English version:
Juan confirmed me that it was very obvious, and not only on the produce section, in the check-out line as well.

Table 5: Examples of automatically generated CS sentences.

7 Conclusions

We presented preliminary results on learning to predict CS points with machine learning. One of the possible applications of our method involves fine-tuning the weights in a multilingual language model, for instance, as part of a speech recognizer for Spanglish. With this in mind, we restricted the possible features in the learning scenario allowing only lexical and syntactic features that could be automatically generated from the text. Empirical evaluations on a Spanglish conversation showed that Naive Bayes and VFI can predict with acceptable F-measures possible CS points, considering the difficulty of the task. Prediction of CS points can help improve multilingual language models.

Evaluation of our approach cannot be done based only on the gold-standard set since there is no single right answer in this task. Therefore, we complemented the evaluation by involving judgements from bilingual speakers. We generated CS sentences by taking the predictions from the classifiers to merge parallel sentences. On average, the sentences generated from the NB model were rated closer to the original sentences, and a lot higher than the ones from a random generator. Most of the sentences sounded human-like. But because the process is automatic we did find some awkward constructions, for example plural vs singular noun-verb agreement, or multi-word phrases that were code-switched in the middle. Perhaps a multi-word recognition feature could improve results.

One of the advantages of technological development and economic globalization is that more people from different regions of the world with different cultures, and therefore, different languages will be in closer contact. As a result, code-switching will become more popular. It is important to start addressing this type of bilingual communication from a computational linguistics point of view. This work is one of the few attempts to fill the gap.

Some directions for future work include: exploring the extent to which our results can be improved by including a multi-word expression recognition system. We also want to investigate the integration of our approach to multilingual language models and move beyond CS to address other deeper linguistic phenomena. Lastly, we would like to explore similar approaches in other popular language combinations.

Abstract

Knowing the degree of antonymy between words has widespread applications in natural language processing. Manually-created lexicons have limited coverage and do not include most semantically contrasting word pairs. We present a new automatic and empirical measure of antonymy that combines corpus statistics with the structure of a published thesaurus. The approach is evaluated on a set of closest-opposite questions, obtaining a precision of over 80%. Along the way, we discuss what humans consider antonymous and how antonymy manifests itself in utterances.

1 Introduction

Native speakers of a language intuitively recognize different **degrees of antonymy**—whether two words are strongly antonymous (*hot–cold, good–bad, friend–enemy*), just semantically contrasting (*enemy–fan, cold–lukewarm, ascend–slip*) or not antonymous at all (*penguin–clown, cold–chilly, boat–rudder*). Over the years, many definitions of antonymy have been proposed by linguists (Cruse, 1986; Lehrer and Lehrer, 1982), cognitive scientists (Kagan, 1984), psycholinguists (Deese, 1965), and lexicographers (Egan, 1984), which differ from each other in small and large respects. In its strictest sense, antonymy applies to gradable adjectives, such as *hot–cold* and *tall–short*, where the two words represent the two ends of a semantic dimension. In a broader sense, it includes other adjectives, nouns, and verbs as well (*life–death, ascend–descend, shout–whisper*). In its broadest sense, it applies to any two words that represent contrasting meanings. We will use the term **degree of antonymy** to encompass the complete semantic range—a combined measure of the contrast in meaning conveyed by two words and the tendency of native speakers to call them opposites. The higher the degree of antonymy between a target word pair, the greater the semantic contrast between them and the greater their tendency to be considered antonym pairs by native speakers.

Automatically determining the degree of antonymy between words has many uses including detecting and generating paraphrases (*The dementors **caught** Sirius Black / Black could **not escape** the dementors*) and detecting contradictions (Marneffe et al., 2008; Voorhees, 2008) (*Kyoto has a predominantly **wet** climate / It is mostly **dry** in Kyoto*). Of course, such “contradictions” may be a result of differing sentiment, new information, non-coreferent mentions, or genuinely contradictory statements. Antonyms often indicate the discourse relation of contrast (Marcu and Echihabi, 2002). They are also useful for detecting humor (Mihalcea and Strapparava, 2005), as satire and jokes tend to have contradictions and oxymorons. Lastly, it is useful to know which words are semantically contrasting to a target word, even if simply to filter them out. For example, in the automatic creation of a thesaurus it is necessary to distinguish near-synonyms from word pairs that are semantically contrasting. Measures of distributional similarity fail to do so. Detecting antonymous words is not sufficient to solve most of these problems, but it remains a crucial, and largely unsolved, component.

Lexicons of pairs of words that native speakers consider antonyms have been created for certain languages, but their coverage has been limited. Further, as each term of an antonymous pair can have many semantically close terms, the contrasting word pairs far outnumber those that are commonly considered antonym pairs, and they remain unrecorded. Even though a number of computational approaches have been proposed for semantic closeness, and some for hypernymy–hyponymy (Hearst, 1992), measures of antonymy have been less successful. To some extent, this is because antonymy is not as well understood as other classical lexical-semantic relations.

We first very briefly summarize insights and intuitions about this phenomenon, as proposed by linguists and lexicographers (Section 2). We discuss related work (Section 3). We describe the resources we use (Section 4) and present experiments that examine the manifestation of antonymy in text (Sections 5 and 6). We then propose a new empirical approach to determine the degree of antonymy between two words (Section 7). We compiled a dataset of 950 closest-opposite questions, which we used for evaluation (Section 8). We conclude with a discussion of the merits and limitations of this approach and outline future work.

2 The paradoxes of antonymy

Antonymy, like synonymy and hyponymy, is a lexical-semantic relation that, strictly speaking, applies to two **lexical units**—combinations of surface form and word sense. (That said, for simplicity and where appropriate we will use the term "antonymous words" as a proxy for "antonymous lexical units".) However, accepting this leads to two interesting and seemingly paradoxical questions (described below in the two subsections).

2.1 Why are some pairs better antonyms?

Native speakers of a language consider certain contrasting word pairs to be antonymous (for example, *large–small*), and certain other seemingly equivalent word pairs as less so (for example, *large–little*). A number of reasons have been suggested: (1) Cruse (1986) observes that if the meaning of the target words is completely defined by one semantic dimension and the words represent the two ends of this semantic dimension, then they tend to be considered antonyms. We will refer to this semantic dimension as the **dimension of opposition**. (2) If on the other hand, as Lehrer and Lehrer (1982) point out, there is more to the meaning of the antonymous words than the dimension of opposition—for example, more semantic dimensions or added connotations—then the two words are not so strongly antonymous. Most people do not think of *chubby* as a direct antonym of *thin* because it has the additional connotation of being cute and informal. (3) Cruse (1986) also postulates that word pairs are not considered strictly antonymous if it is difficult to identify the dimension of opposition (for example, *city–farm*). (4) Charles and Miller (1989) claim that two contrasting words are identified as antonyms if they occur together in a sentence more often than chance. However, Murphy and Andrew (1993) claim that the greater-than-chance co-occurrence of antonyms in sentences is because together they convey contrast well, which is rhetorically useful, and not really the reason why they are considered antonyms in the first place.

2.2 Are semantic closeness and antonymy opposites?

Two words (more precisely, two lexical units) are considered to be close in meaning if there is a lexical-semantic relation between them. Lexical-semantic relations are of two kinds: **classical** and **non-classical**. Examples of classical relations include synonymy, hyponymy, troponymy, and meronymy. Non-classical relations, as pointed out by Morris and Hirst (2004), are much more common and include concepts pertaining to another concept (*kind, chivalrous, formal* pertaining to *gentlemanly*), and commonly co-occurring words (for example, problem–solution pairs such as *homeless, shelter*). Semantic distance (or closeness) in this broad sense is known as semantic relatedness. Two words are considered to be **semantically similar** if they are associated via the synonymy, hyponymy–hypernymy, or the troponymy relation. So terms that are semantically similar (*plane–glider, doctor–surgeon*) are also semantically related, but terms that are semantically related may not always be semantically similar (*plane–sky, surgeon–scalpel*).

Antonymy is unique among these relations because it simultaneously conveys both a sense of closeness and of distance (Cruse, 1986). Antonymous concepts are semantically related but not semantically similar.

3 Related work

Charles and Miller (1989) proposed that antonyms occur together in a sentence more often than chance. This is known as the **co-occurrence hypothesis**. They also showed that this was empirically true for four adjective antonym pairs. Justeson and Katz (1991) demonstrated the co-occurrence hypothesis for 35 prototypical antonym pairs (from an original set of 39 antonym pairs compiled by Deese (1965)) and also for an additional 22 frequent antonym pairs. All of these pairs were adjectives. Fellbaum (1995) conducted similar experiments on 47 noun, verb, adjective, and adverb pairs (noun–noun, noun–verb, noun–adjective, verb–adverb and so on) pertaining to 18 concepts (for example, *lose(v)–gain(n)* and *loss(n)–gain(n)*, where *lose(v)* and *loss(n)* pertain to the concept of "failing to have/maintain"). However, non-antonymous semantically related words such as hypernyms, holonyms, meronyms, and near-synonyms also tend to occur together more often than chance. Thus, separating antonyms from them has proven to be difficult.

Lin et al. (2003) used patterns such as "from *X* to *Y*" and "either *X* or *Y*" to separate antonym word pairs from distributionally similar pairs. They evaluated their method on 80 pairs of antonyms and 80 pairs of synonyms taken from the *Webster's Collegiate Thesaurus* (Kay, 1988). In this paper, we propose a method to determine the degree of antonymy between any word pair and not just those that are distributionally similar. Turney (2008) proposed a uniform method to solve word analogy problems that require identifying synonyms, antonyms, hypernyms, and other lexical-semantic relations between word pairs. However, the Turney method is supervised whereas the method proposed in this paper is completely unsupervised.

Harabagiu et al. (2006) detected antonyms for the purpose of identifying contradictions by using WordNet chains—synsets connected by the hypernymy–hyponymy links and exactly one antonymy link. Lucerto et al. (2002) proposed detecting antonym pairs using the number of words between two words in text and also cue words such as *but*, *from*, and *and*. Unfortunately, they evaluated their method on only 18 word pairs. Neither of these methods determines the degree of antonymy between words and they have not been shown to have substantial coverage. Schwab et al. (2002) create "antonymous vector" for a target word. The closer this vector is to the context vectors of the other target word, the more antonymous the two target words are. However, the antonymous vectors are manually created. Further, the approach is not evaluated beyond a handful of word pairs.

Work in sentiment detection and opinion mining aims at determining the polarity of words. For example, Pang, Lee and Vaithyanathan (2002) detect that adjectives such as *dazzling*, *brilliant*, and *gripping* cast their qualifying nouns positively whereas adjectives such as *bad*, *cliched*, and *boring* portray the noun negatively. Many of these gradable adjectives have antonyms. but these approaches do not attempt to determine pairs of positive and negative polarity words that are antonyms.

4 Resources

4.1 Published thesauri

Published thesauri, such as the *Roget's* and *Macquarie*, divide the vocabulary into about a thousand **categories**. Words within a category tend to be near-synonymous or semantically similar. One may also find antonymous and semantically related words in the same category, but this is rare. The intuition is that words within a category represent a coarse concept. Words with more than one meaning may be found in more than one category; these represent its coarse senses. Within a category, the words are grouped into **paragraphs**. Words in the same paragraph tend to be closer in meaning than those in different paragraphs. We will take advantage of the structure of the thesaurus in our approach.

4.2 WordNet

Unlike the traditional approach to antonymy, WordNet encodes antonymy as a lexical relationship—a relation between two words (not concepts) (Gross et al., 1989). Even though a synset (a WordNet concept) may be represented by more than one word, individual words across synsets are marked as (direct) antonyms. Gross et al. argue that other words in the synsets form "indirect antonyms".

Even after including the indirect antonyms, WordNet's coverage is limited. As Marcu and Echihabi (2002) point out, WordNet does not encode antonymy across part-of-speech (for example, *legally–embargo*). Further, the noun–noun, verb–verb, and adjective–adjective antonym pairs of WordNet largely ignore near-opposites as revealed by our experiments (Section 8 below). Also, WordNet (or any other manually-created repository of antonyms for that matter) does not encode the *degree* of antonymy between words. Nevertheless, we investigate the usefulness of WordNet as a source of seed antonym pairs for our approach.

4.3 Co-occurrence statistics

The **distributional hypothesis of closeness** states that words that occur in similar contexts tend to be semantically close (Firth, 1957). Distributional measures of distance, such as those proposed by Lin (1998), quantify how similar the two sets of contexts of a target word pair are. Equation 1 is a modified form of Lin's measure that ignores syntactic dependencies and hence it estimates semantic relatedness rather than semantic similarity:

$$Lin(w_1,w_2) = \frac{\sum_{w \in T(w_1) \cap T(w_2)} (I(w_1,w) + I(w_2,w))}{\sum_{w' \in T(w_1)} I(w_1,w') + \sum_{w'' \in T(w_2)} I(w_2,w'')} \quad (1)$$

Here w_1 and w_2 are the target words; $I(x,y)$ is the pointwise mutual information between x and y; and $T(x)$ is the set of all words y that have positive pointwise mutual information with the word x ($I(x,y) > 0$).

Mohammad and Hirst (2006) showed that these distributional word-distance measures perform poorly when compared with WordNet-based concept-distance measures. They argued that this is because the word-distance measures clump together the contexts of the different senses of the target words. They proposed a way to obtain distributional distance between word *senses*, using any of the distributional measures such as *cosine* or that proposed by Lin, and showed that this approach performed markedly better than the traditional *word-distance* approach. They used thesaurus categories as very coarse word senses. Equation 2 shows how Lin's formula is used to determine distributional distance between two thesaurus categories c_1 and c_2:

$$Lin(c_1,c_2) = \frac{\sum_{w \in T(c_1) \cap T(c_2)} (I(c_1,w) + I(c_2,w))}{\sum_{w' \in T(c_1)} I(c_1,w') + \sum_{w'' \in T(c_2)} I(c_2,w'')} \quad (2)$$

Here $T(c)$ is the set of all words w that have positive pointwise mutual information with the thesaurus category c ($I(c,w) > 0$). We adopt this method for use in our approach to determine word-pair antonymy.

5 The co-occurrence hypothesis of antonyms

As a first step towards formulating our approach, we investigated the co-occurrence hypothesis on a significantly larger set of antonym pairs than those studied before. We randomly selected a thousand antonym pairs (nouns, verbs, and adjectives) from WordNet and counted the number of times (1) they occurred individually and (2) they co-occurred in the same sentence within a window of five words, in the *British National Corpus (BNC)* (Burnard, 2000). We then calculated the mutual information for each of these word pairs and averaged it. We randomly generated another set of a thousand word pairs, without regard to whether they were antonymous or not, and used it as a control set. The average mutual information between the words in the antonym set was 0.94 with a standard deviation of 2.27. The average mutual information between the words in the control set was 0.01 with a standard deviation of 0.37. Thus antonymous word pairs occur together much more often than chance irrespective of their intended senses ($p < 0.01$). Of course, a number of non-antonymous words also tend to co-occur more often than chance—commonly known as collocations. Thus, strong co-occurrence is not a sufficient condition for detecting antonyms, but these results show that it can be a useful cue.

6 The substitutional and distributional hypotheses of antonyms

Charles and Miller (1989) also proposed that in most contexts, antonyms may be interchanged. The meaning of the utterance will be inverted, of course, but the sentence will remain grammatical and linguistically plausible. This came to be known as the **substitutability hypothesis**. However, their experiments did not support this claim. They found that given a sentence with the target adjective removed, most people did not confound the missing word with its antonym. Justeson and Katz (1991) later showed that in sentences that contain both members of an antonymous adjective pair, the target adjectives do indeed occur in similar syntactic structures at the phrasal level. From this (and to some extent from the co-occurrence hypothesis), we can derive the **distributional hypothesis of antonyms**: antonyms occur in similar contexts more often than non-antonymous words.

We used the same set of one thousand antonym pairs and one thousand control pairs as in the previous experiment to gather empirical proof of the distributional hypothesis. For each word pair from the antonym set, we calculated the distributional distance between each of their senses using Mohammad and Hirst's (2006) method of concept distance along with the modified form of Lin's (1998) distributional measure (equation 2). The distance between the closest senses of the word pairs was averaged for all thousand antonyms. The process was then repeated for the control set.

The control set had an average semantic closeness of 0.23 with a standard deviation of 0.11 on a scale from 0 (unrelated) to 1 (identical). On the other hand, antonymous word pairs had an average semantic closeness of 0.30 with a standard deviation of 0.23.[1] This demonstrates that relative to other word pairs, antonymous words tend to occur in similar contexts ($p < 0.01$). However, near-synonymous and similar word pairs also occur in similar contexts. (the distributional hypothesis of closeness). Thus, just like the co-occurrence hypothesis, occurrence in similar contexts is not sufficient, but rather yet another useful cue towards detecting antonyms.

[1]It should be noted that absolute values in the range between 0 and 1 are meaningless by themselves. However, if a set of word pairs is shown to consistently have higher values than another set, then we can conclude that the members of the former set tend to be semantically closer than those of the latter.

7 Our approach

We now present an empirical approach to determine the degree of antonymy between words. In order to maximize applicability and usefulness in natural language applications, we model the broad sense of antonymy. Given a target word pair, the approach determines whether they are antonymous or not, and if they are antonymous whether they have a high, medium, or low degree of antonymy. More precisely, the approach presents a way to determine whether one word pair is more antonymous than another.

The approach relies on the structure of the published thesaurus as well as the co-occurrence and distributional hypotheses. As mentioned earlier, a thesaurus organizes words in sets representing concepts or categories. We first determine pairs of thesaurus categories that are contrasting in meaning (Section 7.1). We then use the co-occurrence and distributional hypotheses to determine the degree of antonymy (Section 7.2).

7.1 Detecting contrasting categories

We propose two ways of detecting thesaurus category pairs that represent contrasting concepts (we will call these pairs **contrasting categories**): (1) using a seed set of antonyms and (2) using a simple heuristic that exploits how thesaurus categories are ordered.

7.1.1 Seed sets

Affix-generated seed set Antonym pairs such as *hot–cold* and *dark–light* occur frequently in text, but in terms of type-pairs they are outnumbered by those created using affixes, such as *un-* (*clear–unclear*) and *dis-* (*honest–dishonest*). Further, this phenomenon is observed in most languages (Lyons, 1977).

Table 1 lists sixteen morphological rules that tend to generate antonyms in English. These rules were applied to each of the words in the *Macquarie Thesaurus* and if the resulting term was also a valid word in the thesaurus, then the word-pair was added to the **affix-generated seed set**. These sixteen rules generated 2,734 word pairs. Of course, not all of them are antonymous, for example *sect–insect* and *coy–decoy*. However, these are relatively few in

w_1	w_2	**example pair**	w_1	w_2	**example pair**	w_1	w_2	**example pair**
X	*ab*X	*normal–abnormal*	X	*mis*X	*fortune–misfortune*	*im*X	*ex*X	*implicit–explicit*
X	*anti*X	*clockwise–anticlockwise*	X	*non*X	*aligned–nonaligned*	*in*X	*ex*X	*introvert–extrovert*
X	*dis*X	*interest–disinterest*	X	*un*X	*biased–unbiased*	*up*X	*down*X	*uphill–downhill*
X	*im*X	*possible–impossible*	*l*X	*ill*X	*legal–illegal*	*over*X	*under*X	*overdone–underdone*
X	*in*X	*consistent–inconsistent*	*r*X	*ir*X	*regular–irregular*	X*less*	X*ful*	*harmless–harmful*
X	*mal*X	*adroit–maladroit*						

Table 1: Sixteen affix rules to generate antonym pairs. Here 'X' stands for any sequence of letters common to both words w_1 and w_2.

number and were found to have only a small impact on the results.

WordNet seed set We compiled a list of 20,611 semantically contrasting word pairs from WordNet. If two words from two synsets in WordNet are connected by an antonymy link, then every possible word pair across the two synsets was considered to be semantically contrasting. A large number of them include multiword expressions. For only 10,807 of the 20,611 pairs were both words found in the *Macquarie Thesaurus*—the vocabulary used for our experiments. We will refer to them as the **WordNet seed set**.

Then, given these two seed sets, if any word in thesaurus category C_1 is antonymous to any word in category C_2 as per a seed antonym pair, then the two categories are marked as contrasting. It should be noted, however, that the seed antonym pair may be antonymous only in certain senses. For example, consider the antonym pair *work–play*. Here, *play* is antonymous to *work* only in its ACTIVITY FOR FUN sense and not its DRAMA sense. In such cases, we employ the distributional hypothesis of closeness: two words are antonymous to each other in those senses which are closest in meaning to each other. Since the thesaurus category pertaining to WORK is relatively closer in meaning to the ACTIVITY FOR FUN sense than the DRAMA sense, those two categories will be considered contrasting and not the categories pertaining to WORK and DRAMA.

If no word in C_1 is antonymous to any word in C_2, then the categories are considered not contrasting. As the seed sets, both automatically generated and manually created, are relatively large in comparison to the total number of categories in the *Macquarie Thesaurus* (812), this simple approach has reasonable coverage and accuracy.

7.1.2 Order of thesaurus categories

Most published thesauri are ordered such that contrasting categories tend to be adjacent. This is not a hard-and-fast rule, and often a category may be contrasting in meaning to several other categories. Further, often adjacent categories are not semantically contrasting. However, since this was an easy-enough heuristic to implement, we investigated the usefulness of considering adjacent categories as contrasting. We will refer to this as the **adjacency heuristic**.

7.2 Determining the degree of antonymy

Once we know which category pairs are contrasting (using the methods from the previous subsection), we determine the *degree* of antonymy between the two categories (Section 7.2.1). The aim is to assign contrasting category pairs a non-zero value signifying the degree of contrast. In turn, we will use that information to determine the degree of antonymy between any word pair whose members belong to two contrasting categories (Sections 7.2.2 and 7.2.3).

7.2.1 Category level

Using the distributional hypothesis of antonyms, we claim that the degree of antonymy between two *contrasting* concepts (thesaurus categories) is directly proportional to the distributional closeness of the two concepts. In other words, the more the words representing two contrasting concepts occur in similar contexts, the more the two concepts are considered to be antonymous.

Again we used Mohammad and Hirst's (2006) method along with Lin's (1998) distributional measure to determine the distributional closeness of two thesaurus concepts. Co-occurrence statistics required for the approach were computed from the

BNC. Words that occurred within a window of 5 words were considered to co-occur.

7.2.2 Lexical unit level

Recall that strictly speaking, antonymy (like other lexical-semantic relations) applies to lexical units (a combination of surface form and word sense). If two words are used in senses pertaining to contrasting categories (as per the methods described in Section 7.1), then we will consider them to be antonymous (degree of antonymy is greater than zero). If two words are used in senses pertaining to non-contrasting senses, then we will consider them to be not antonymous (degree of antonymy is equal to 0).

If the target words belong to the same thesaurus paragraphs as any of the seed antonyms linking the two contrasting categories, then the words are considered to have a high degree of antonymy. This is because words that occur in the same thesaurus paragraph tend to be semantically very close in meaning. Relying on the co-occurrence hypothesis, we claim that for word pairs listed in contrasting categories, the greater their tendency to co-occur in text, the higher their degree of antonymy. We use mutual information to capture the tendency of word–word co-occurrence.

If the target words do not both belong to the same paragraphs as a seed antonym pair, but occur in contrasting categories, then the target words are considered to have a low or medium degree of antonymy (less antonymous than the word pairs discussed above). Such word pairs that have a higher tendency to co-occur are considered to have a medium degree of antonymy, whereas those that have a lower tendency to co-occur are considered to have a low degree of antonymy.

Co-occurrence statistics for this purpose were collected from the *Google n-gram corpus* (Brants and Franz, 2006).[2] Words that occurred within a window of 5 words were considered to be co-occurring.

7.2.3 Word level

Even though antonymy applies to pairs of word and sense combinations, most available texts are not sense-annotated. If antonymous occurrences are to be exploited for any of the purposes listed in the beginning of this paper, then the text must be sense disambiguated. However, word sense disambiguation is a hard problem. Yet, and to some extent because unsupervised word sense disambiguation systems perform poorly, much can be gained by using simple heuristics. For example, it has been shown that cohesive text tends to have words that are close in meaning rather than unrelated words. This, along with the distributional hypothesis of antonyms, and the findings by Justeson and Katz (1991) (antonymous concepts tend to occur more often than chance in the same sentence), suggests that if we find a word pair in a sentence such that two of its senses are strongly contrasting (as per the algorithm described in Section 7.2.2), then it is probable that the two words are used in those contrasting senses.

8 Evaluation

8.1 Task and data

In order to best evaluate a computational measure of antonymy, we need a task that not only requires knowing whether two words are antonymous but also whether one word pair is more antonymous than another pair. Therefore, we evaluated our system on a set of closest-opposite questions. Each question has one target word and five alternatives. The objective is to identify that alternative which is the closest opposite of the target. For example, consider:

adulterate: a. *renounce* b. *forbid*
c. *purify* d. *criticize* e. *correct*

Here the target word is *adulterate*. One of the alternatives provided is *correct*, which as a verb has a meaning that contrasts with that of *adulterate*; however, *purify* has a greater degree of antonymy with *adulterate* than *correct* does and must be chosen in order for the instance to be marked as correctly answered. This evaluation is similar to how others have evaluated semantic distance algorithms on TOEFL synonym questions (Turney, 2001), except that in those cases the system had to choose the alternative which is *closest* in meaning to the target.

We looked on the World Wide Web for large sets of closest antonym questions. We found two independent sets of questions designed to prepare stu-

[2]We used the *Google n-gram corpus* is created from a text collection of over 1 trillion words. We intend to use the same corpus (and not the *BNC*) to determine semantic distance as well, in the near future.

	development data			**test data**		
	P	R	F	P	R	F
a. random baseline	0.20	0.20	0.20	0.20	0.20	0.20
b. affix-generated seeds only	0.72	0.53	0.61	0.71	0.51	0.60
c. WordNet seeds only	0.79	0.52	0.63	0.75	0.50	0.60

Table 2: Results obtained on closest-opposite questions.

dents for the Graduate Record Examination.[3] The first set consists of 162 questions. We used this set to develop our approach and will refer to it as the *development set*. Even though the algorithm does not have any tuned parameters per se, the development set helped determine which cues of antonymy were useful and which were not. The second set has 1208 closest-opposite questions. We discarded questions that had a multiword target or alternative. After removing duplicates we were left with 950 questions, which we used as the unseen *test set*.

Interestingly, the data contains many instances that have the same target word used in different senses. For example:

(1) ***obdurate:***	a. *meager*	b. *unsusceptible*
c. *right*	d. *tender*	e. *intelligent*
(2) ***obdurate:***	a. *yielding*	b. *motivated*
c. *moribund*	d. *azure*	e. *hard*
(3) ***obdurate:***	a. *transitory*	b. *commensurate*
c. *complaisant*	d. *similar*	e. *uncommunicative*

In (1), *obdurate* is used in the HARDENED IN FEELINGS sense and the closest opposite is *tender*. In (2), it is used in the RESISTANT TO PERSUASION sense and the closest opposite is *yielding*. In (3), it is used in the PERSISTENT sense and the closest opposite is *transitory*.

The datasets also contain questions in which one or more of the alternatives is a near-synonym of the target word. For example:

astute:	a. *shrewd*	b. *foolish*
c. *callow*	d. *winning*	e. *debating*

Observe that *shrewd* is a near-synonym of *astute*. The closest-opposite of *astute* is *foolish*. A manual check of a randomly selected set of 100 test-set questions revealed that, on overage, one in four had a near-synonym as one of the alternative.

[3]Both datasets are apparently in the public domain and will be made available on request.

8.2 Experiments

We used the algorithm proposed in Section 7 to automatically solve the closest-opposite questions. Since individual words may have more than one meaning, we relied on the hypothesis that the intended sense of the alternatives are those which are most antonymous to one of the senses of the target word. (This follows from the discussion earlier in Section 7.2.3.) So for each of the alternatives we used the target word as context (but not the other alternatives). We think that using a larger context to determine antonymy will be especially useful when the target words are found in sentences and natural text—something we intend to explore in the future.

Table 2 presents results obtained on the development and test data using different combinations of the seed sets and the adjacency heuristic. If the system did not find any evidence of antonymy between the target and any of its alternatives, then it refrained from attempting that question. We therefore report precision (number of questions answered correctly / number of questions attempted), recall (number of questions answered correctly / total number of questions), and F-score values ($2 \times P \times R/(P+R)$).

Observe that all results are well above the random baseline of 0.20 (obtained when a system randomly guesses one of the five alternatives to be the answer). Also, using only the small set of sixteen affix rules, the system performs almost as well as when it uses 10,807 WordNet antonym pairs. Using both the affix-generated and the WordNet seed sets, the system obtains markedly improved precision and coverage. Using only the adjacency heuristic gave best precision values (upwards of 0.8) with substantial coverage (attempting close to half the questions). However, best overall performance was obtained using both seed sets and the adjacency heuristic (F-score of 0.7).

8.3 Discussion

These results show that, to some degree, the automatic approach does indeed mimic human intuitions of antonymy. In tasks that require higher precision, using only the adjacency heuristic is best, whereas in tasks that require both precision and coverage, the seed sets may be included. Even when both seed sets were included, only four instances in the development set and twenty in the test set had target–answer pairs that matched a seed antonym pair. For all remaining instances, the approach had to generalize to determine the closest opposite. This also shows that even the seemingly large number of direct and indirect antonyms from WordNet (more than 10,000) are by themselves insufficient.

The comparable performance obtained using the affix rules alone suggests that even in languages without a wordnet, substantial accuracies may be achieved. Of course, improved results when using WordNet antonyms as well suggests that the information they provide is complementary.

Error analysis revealed that at times the system failed to identify that a category pertaining to the target word contrasted with a category pertaining to the answer. Additional methods to identify seed antonym pairs will help in such cases. Certain other errors occurred because one or more alternatives other than the official answer were also antonymous to the target. For example, the system chose *accept* as the opposite of *chasten* instead of *reward*.

9 Conclusion

We have proposed an empirical approach to antonymy that combines corpus co-occurrence statistics with the structure of a published thesaurus. The method can determine the degree of antonymy or contrast between any two thesaurus categories (sets of words representing a coarse concept) and between any two word pairs. We evaluated the approach on a large set of closest-opposite questions wherein the system not only identified whether two words are antonymous but also distinguished between pairs of antonymous words of different degrees. It achieved an F-score of 0.7 in this task where the random baseline was only 0.2. When aiming for high precision it scores over 0.8, but there is some drop in the number of questions attempted. In the process of developing this approach we validated the co-occurrence hypothesis proposed by Charles and Miller (1989) on a large set of 1000 noun, verb, and adjective pairs. We also gave empirical proof that antonym pairs tend to be used in similar contexts—the distributional hypothesis for antonyms.

Our future goals include porting this approach to a cross-lingual framework in order to determine antonymy in a resource-poor language by combining its text with a thesaurus from a resource-rich language. We will use antonym pairs to identify contrast relations between sentences to in turn improve automatic summarization. We also intend to use the approach proposed here in tasks where keyword matching is especially problematic, for example, separating paraphrases from contradictions.

Abstract

Some phrases can be interpreted either idiomatically (figuratively) or literally in context, and the precise identification of idioms is indispensable for full-fledged natural language processing (NLP). To this end, we have constructed an idiom corpus for Japanese. This paper reports on the corpus and the results of an idiom identification experiment using the corpus. The corpus targets 146 ambiguous idioms, and consists of 102,846 sentences, each of which is annotated with a literal/idiom label. For idiom identification, we targeted 90 out of the 146 idioms and adopted a word sense disambiguation (WSD) method using both common WSD features and idiom-specific features. The corpus and the experiment are the largest of their kind, as far as we know. As a result, we found that a standard supervised WSD method works well for the idiom identification and achieved an accuracy of 89.25% and 88.86% with/without idiom-specific features and that the most effective idiom-specific feature is the one involving the adjacency of idiom constituents.

1 Introduction

Some phrases like *kick the bucket* are ambiguous with regard to whether they carry literal or idiomatic meaning in a certain context. This ambiguity needs to be resolved in the same manner as ambiguous words that have been dealt with in the WSD literature. We term the resolution of the literal/idiomatic ambiguity as idiom identification, hereafter.

Idiom identification is classified into two kinds; one is for idiom types and the other is for idiom tokens. With the former, phrases that *can* be interpreted as idioms are found in text corpora, typically for compiling idiom dictionaries. On the other hand, the latter helps identify a phrase in context as a true idiom or a phrase that should be interpreted literally (a literal phrase, henceforth). In this paper, we deal with the latter, i.e., idiom token identification.

Despite the recent enthusiasm for multiword expressions (MWEs) (Grégoire et al., 2007; Grégoire et al., 2008), the idiom token identification is in an early phase of its development. Given that many NLP tasks like machine translation or parsing have been developed as a result of the availability of language resources, idiom token identification should also be developed when adequate idiom resources are provided. To this end, we have constructed a Japanese idiom corpus. We have also conducted an idiom identification experiment using the corpus that we hope will be a good reference point for future studies on the task. We drew on a standard WSD framework with machine learning exploiting both features commonly used in the WSD studies and idiom-specific features. This paper reports in detail the corpus and the result of the experiment; herein, it must be noted that to the best of our knowledge, the corpus and the experiment are the largest ever of their kind.

We only deal with the ambiguity between literal and idiomatic interpretations. However, some phrases have two or more idiomatic meanings without context. For example, a Japanese idiom *te-o dasu* (hand-ACC stretch)[1] can be interpreted as ei-

[1]ACC is the accusative case marker. Likewise we use the following notation in this paper; NOM for the nominative case

ther "punch," "steal" or "make moves on." This kind of ambiguity should be placed on the agenda.

We do not tackle the problem of what constitutes the notion of "idiom." We simply regard phrases listed in Sato (2007) as idioms.

The reminder of this paper is organized as follows. In §2 we present related works. §3 shows the target idioms. After the idiom corpus is described in §4, we detail our idiom identification method and experiment in §5. Finally §6 concludes the paper.

2 Related Work

There have only been a few works on the construction of an idiom corpus. In this regard, Birke and Sarkar (2006) and Cook et al. (2008) are notable exceptions. Birke and Sarkar (2006) automatically constructed a corpus of English idiomatic expressions (words that can be used non-literally). They targeted 50 expressions and collected about 6,600 examples. They call the corpus TroFi Example Base, which is available on the Web.[2] Cook et al. (2008) compiled a corpus of English verb-noun combinations (VNCs) tokens. Their corpus deals with 53 VNC expressions and consists of about 3,000 example sentences. Like ours, they assigned each example with a label indicating whether an expression in the example is used literally or idiomatically. Our corpus can be regarded as the Japanese idiom counterpart of these works. However, note that our corpus targets 146 idioms and consists of as many as 102,846 example sentences. Another exception is Tsuchiya et al. (2006), who manually constructed an example database of Japanese compound functional expressions named MUST. They provide it on the Web.[3] Some of the compound functional expressions in Japanese are ambiguous like idioms are.[4]

marker, DAT for the dative case marker, and GEN for the genitive case marker. FROM and TO stand for the Japanese counterparts of *from* and *to*. NEG represents a verbal negation morpheme.

[2]http://www.cs.sfu.ca/~anoop/students/jbirke/

[3]http://nlp.iit.tsukuba.ac.jp/must/

[4]For example, *(something)-ni-atatte* ((something)-DAT-run.into) means either "run into (something)" or "on the occasion of (something)." The former is the literal interpretation and the latter is the idiomatic interpretation of the compound functional expression.

The SAID dataset[5] provides data about the syntactic flexibility of English idioms. It does not concern itself with idiom token identification. However, as in Hashimoto et al. (2006b), Hashimoto et al. (2006a) and Cook et al. (2007) among others, the syntactic behavior of idioms is an important clue to idiom token identification.

Previous studies have mostly focused on the idiom type identification (Lin, 1999; Krenn and Evert, 2001; Baldwin et al., 2003; Shudo et al., 2004; Fazly and Stevenson, 2006). However, there has been a growing interest in idiom token identification in recent times (Katz and Giesbrecht, 2006; Hashimoto et al., 2006b; Hashimoto et al., 2006a; Birke and Sarkar, 2006; Cook et al., 2007). Katz and Giesbrecht (2006) compared the word vector of an idiom in context and that of the constituent words of the idiom using LSA in order to determine if the expression is idiomatic. Hashimoto et al. (2006b) and Hashimoto et al. (2006a) (HSU henceforth) focused their attention on the differences in grammatical constraints imposed on idioms and their literal counterparts such as the possibility of passivization, and developed handcrafted rules for Japanese idiom identification. Although their task is exactly the same as ours and we draw on the grammatical knowledge provided by them, the scale of their experiment is very small, since only 108 sentences were used for idiom identification in their paper. Further, unlike HSU, we employ matured WSD technologies. Cook et al. (2007) (CFS henceforth) propose an unsupervised method for English on the basis of the observation that idioms tend to be expressed in a small number of fixed forms.

These studies used only the characteristics of idioms (or MWEs). On the other hand, we exploit a WSD method, for which there have been many studies and matured technologies, in addition to the characteristics of idioms. Birke and Sarkar (2006) also used WSD. However, they employed an unsupervised method, while ours is a completely supervised one.

Apart from idioms, Uchiyama et al. (2005) conducted the token classification of Japanese compound verbs exploiting supervised method.

3 Target Idioms

For this study, we selected 146 idioms through the following procedure. ① We extracted basic idioms from Sato (2007). Sato compiled about 3,600 basic idioms of Japanese from five books: two dictionaries for elementary school, two idiom dictionaries, and one linguistics book on idioms. We extracted those idioms that were described in more than two of these five books. The total number of such idioms added up to 926. ② From among these idioms, we chose ambiguous ones.[6] As a result, 146 idioms were selected.

As for ②, sometimes it is not trivial to determine if an idiom is ambiguous or not. Some idioms are rarely interpreted literally, while others, in all likelihood, take on the literal meaning. Is it meaningful to regard them as ambiguous and deal with them in this study? If not, how does one assuredly distinguish truly ambiguous idioms from those that are mostly interpreted either literally or figuratively? This can only be done if there is an accurate idiom identification system.

After all, we asked two native speakers of Japanese (Group A) to classify idioms into two classes: 1) truly ambiguous ones and 2) completely unambiguous or practically unambiguous ones. On the basis of the classification, one of the authors made final judgments.

To verify how stable this ambiguity endorsement was, we asked another two other native speakers of Japanese (Group B) to perform the same task and calculated the Kappa statistic between the two speakers. First, we sampled 101 idioms from the 926 chosen earlier. Then, the two members of Group B classified the sampled idioms into the two classes. The Kappa statistic was found to be 0.6576, which indicates middling stability.

Tables 2 and 3 list some of the target idioms.

4 Idiom Corpus

4.1 Corpus Specification

The corpus is designed for the idiom token identification task. That is, each example sentence in the corpus is annotated with a label that indicates whether the corresponding phrase in the example is used as an idiom or a literal phrase. We call the former the positive example and the latter the negative example. More specifically, the corpus consists of lines that each represent one example. A line consists of four fields as follows: $\boxed{1}$ **Label** indicates whether the example is positive or negative. Label *i* is used for positive examples and *l* for negative ones. $\boxed{2}$ **ID** denotes the idiom that is included in the example. In this study, each idiom has a unique number, which is based on Sato (2007). $\boxed{3}$ **Lemma** also shows the idiom in the example. We assigned each idiom its canonical (or standard) form on the basis of Sato (2007). $\boxed{4}$ **Example** is the example itself.

Given below is a sample of a negative example of *goma-o suru* (sesame-ACC crush) 'flatter'.

- *l*␣1417␣ごまをする␣すり鉢でごまをすり ···

The third field is the lemma of the idiom. The last one is the example that says 'crushing sesame in a mortar...'

Before working on the corpus construction, we prepared a reference by which human annotators could consistently distinguish between the literal and figurative meanings of idioms. To be more precise, this reference specified literal and idiomatic meanings for each idiom like dictionaries do. For example, the entry for *goma-o suru* in the reference is as follows.

Idiom:	To flatter people.
Literal:	To crush sesame.

As for the corpus size, we continued to annotate examples for each idiom, regardless of the proportion of idioms and literal phrases, until the total number of examples for each idiom reached 1,000.[7] In the case of a shortage of original data, we annotated as many examples as possible. The original data were sourced from the Japanese Web corpus (Kawahara and Kurohashi, 2006).

4.2 Corpus Construction

We constructed the corpus in the following manner: ❶ From the Web corpus, we collected example sentences that contained one of our target idioms whichever meaning (positive or negative) they

[6]Some idioms like *by and large* do not have a literal meaning. They are not dealt with in this paper.

[7]For idioms that we sampled for preliminary annotation, we annotated more than 1,000 examples.

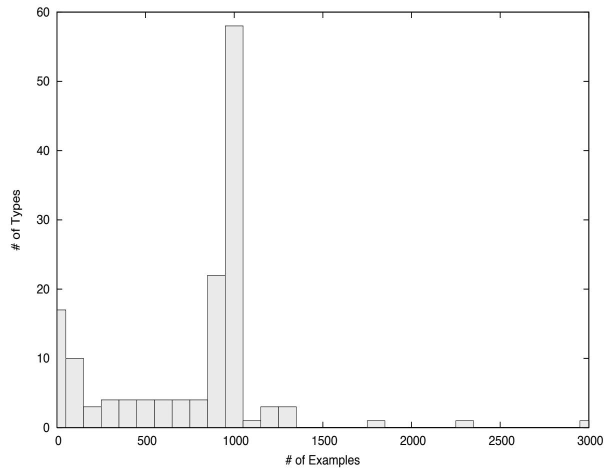

Figure 1: Distribution of the number of examples

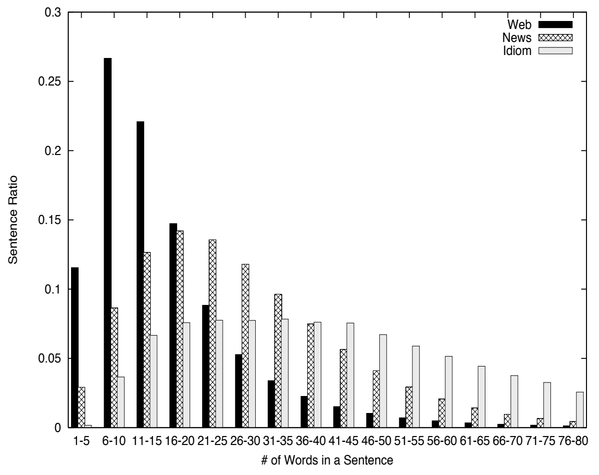

Figure 2: Distribution of sentence length

take on. Concretely speaking, we automatically collected sentences in which constituent words of one of our targets appeared in a canonical dependency relationship by using KNP[8], a Japanese dependency parser. ❷ We classified the collected examples as positive and negative. This was done by human annotators and was based on the reference to distinguish the two meanings. For annotation, longer examples were given higher priority than shorter examples. Note that we discarded examples that were collected by mistake due to dependency parsing errors and those that lacked a context that could help them be interpreted correctly.

This was done by the two members of Group A and took 230 hours.

4.3 Status of Corpus

The corpus consists of 102,846 examples.[9] Figure 1 shows the distribution of the number of examples. For 68 idioms, we annotated more than 1,000 examples. However, we annotated less than 100 examples for 17 idioms because of inadequate original data.

The average number of words in a sentence is 46. `Idiom` in Figure 2 shows the distribution of sentence length (the number of words) in the corpus. `Web` and `News` indicate the sentence length in the Web and a newspaper corpora, respectively. This is drawn from Kawahara and Kurohashi (2006). As you see, our corpus contains many more long sentences. This is because longer sentences were given priority for annotation, as stated in §4.2. Figure 3 shows the longest and shortest examples each for literal and idiomatic meanings of *goma-o suru* drawn from the corpus.

To determine how consistent the positive/negative annotation is across different human annotators, we sampled 1,421 examples from the corpus, asked the two members of Group B to do the same annotation, and calculated the Kappa statistic between the two. The value was 0.8519, which indicates very high agreement.

The corpus is available on the Web.[10] Currently we provide the list of the basic Japanese idioms we are dealing with, the idiom corpus, and the vector representation data used for the idiom identification experiment. The corpus is protected under the BSD license.

5 Idiom Identification Experiment

5.1 Method of Idiom Identification

We adopted a standard WSD method using machine learning. More specifically, we used SVM (Vapnik, 1995) with a quadratic kernel implemented in TinySVM.[11] The features we used are classified into either those that have been commonly used in WSD on the lines of Lee and Ng (2002) (LN hereafter),

[8]http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp.html

[9]Note that the figures reported here are for the corpus of the 2008-06-25 version and will be slightly changed over time.

[10]http://openmwe.sourceforge.jp/

[11]http://www.chasen.org/~taku/software/TinySVM/

- ただし、１５６２年にグレシャムは１５６２年に、同一の額面価値で流通する素材価値を異にする２種類の貨幣が存在すると劣悪な貨幣が流通に残り、優良な貨幣は駆逐されるという「グレシャムの法則」を発表していることから、女衒がしたたかであったように、ＩＴ興行師もメーカーに**ごまをすり**、政府の省庁にこびを売り、知性が無くても生命力だけで、目新しい言葉のつまみ食いで、悪毒、図々しく、虚勢で生き続けることだろう。
  (But I suspect that the show managers of IT ventures will remain sly and audacious, and survive by **flattering** manufacturers, bending over themselves to accede to the demands of governmental agencies, and talking glibly about buzz terms, without intelligence but with vitality, just like the brokers of prostitutes in the Edo period were, because Gresham's law of 1562 says that any circulating currency consisting of both good and bad money quickly becomes dominated by the bad money.)
- 上に**ごまをする**小役人タイプ。
  (Just like a pretty official **flattering** his boss.)

- 煮た大豆をつぶすには、ミンチみたいな器具があればいいのですが、ない　場合は、**ごまをする**もので潰すか、もっと簡単な方法としては、ビニール　袋に大豆を入れ、封をしてタオルをかけてその上から瓶でこするようにす　るといいでしょう。
  (In order to mash boiled soybeans, it is the best to use a meat chopper, but if you don't have one, use the thing to **crush sesame**, or put them into a plastic bag, cover it with a towel, then mash it with a glass bottle, which is easier.)
- **ごまをすり**調味料とあえる
  (**Crushing sesame**, then adding seasonings to it.)

Figure 3: The longest and shortest examples for both literal and idiomatic meanings of *goma-o suru*

or those that have been designed for Japanese idiom identification proposed by HSU.[12]

- Common WSD Features

  f1: POS of three words on the left side of idiom and three words on the right side

  f2: Local collocations

  f3: Single words in the surrounding context

  f4a: Lemma of the rightmost word among those words that are the dependents of the leftmost constituent word of idiom[13]

  f4b: POS of the rightmost word among those words that are the dependents of the leftmost constituent word of idiom

  f5a: Lemma of the word which the rightmost constituent word of idiom is the dependent of

  f5b: POS of the word which the rightmost constituent word of idiom is the dependent of

  f6: Hypernyms of words in the surrounding context

  f7: Domains of words (Hashimoto and Kurohashi, 2007; Hashimoto and Kurohashi, 2008) in the surrounding context

- Idiom-Specific Features

  f8: Adnominal modification flag

  f9: Topic case marking flag

  f10: Voice alternation flag

  f11: Negation flag

  f12: Volitional modality flag

  f13: Adjacency flag

We used JUMAN,[14] a morphological analyzer of Japanese, and KNP to extract these features.

[12]Remember that HSU implemented them in handcrafted rules. We adapted them to a machine learning framework.

[13]Note that Japanese is a head final language.

[14]`http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman.html`

f2 and **f3** are the same as those described in LN. But **f1** is slightly different in that we did not use the P_0 of LN. **f4** and **f5** roughly correspond to the syntactic relations of LN. We adapted it to Japanese idioms along with some simplifications. In the case of the example of *mune-o utu* (chest-ACC hit) 'impress' below,[15] **f4** is the POS and lemma of *tyousyu* and **f5** corresponds to those of *uta*.[16]

- tyousyu-no **mune-o** **utu** utukusi uta
  audience-GEN **chest-ACC** **hit** beautiful song
  'A beautiful song that **impresses** the audience'

f6 and **f7** are available from JUMAN's output. For example, the hypernym of *tyousyu* (audience) is `human` and its domain is `culture/media`. Those of *uta* (song) are `abstract-thing` and `culture/recreation`. They are not used in LN, but they are known to be useful for WSD (Tanaka et al., 2007; Magnini et al., 2002).

f8 indicates whether a nominal constituent of an idiom, if any, undergoes adnominal modification. **f9** indicates whether one of Japanese topic case markers is attached to a nominal constituent of an idiom, if any. **f10** is turned on when a passive or causative suffix is attached to a verbal constituent of an idiom, if any.[17] **f11** and **f12** are similar to **f10**. The former is used for negated forms and the latter for volitional modality suffixes of a predicate part of an idiom, if any.[18] Volitional modality includes expressions like order, request, permission, prohibition, and volition. Finally, **f13** indicates whether the constituents of an idiom is adjacent to each other.

As discussed in HSU, the idiom-specific features are effective to distinguish idioms from literal phrases. For example, the idiom *goma-o suru* does not allow adnominal modification, while its literal counterpart does. Similarly, the idiom *mune-o utu* cannot take volitional modality unlike its literal counterpart.

[15]The arrows indicate dependency relations.

[16]Functional words attaching to either the **f4** word or the **f5** word are ignored. In the example, *no* (GEN) is ignored.

[17]Passivization is indicated by the suffix *(r)are* in Japanese. But the same suffix is also used for honorification, potentials and spontaneous potentials. Since it is beyond the current technology, we gave up distinguishing them.

[18]Note that **f10**, **f11** and **f12** are applied to only those idioms that can be used as predicates.

5.2 Experimental Condition

In the experiment, we dealt with 90 idioms for which more than 50 examples for both idiomatic and literal usages were available.[19] We conducted experiments for each idiom.

The performance measure is the accuracy.

$$\text{Accuracy} = \frac{\text{\# of examples correctly identified}}{\text{\# of all example}}$$

The baseline system uniformly regards all examples as either positive or negative depending on which is more dominant in the idiom corpus. Naturally, this is prepared for each idiom.

$$\text{Baseline} = \frac{\max(\text{\# of positive, \# of negative})}{\text{\# of all example}}$$

The accuracy and the baseline accuracy for each idiom are calculated in a 10-fold cross validation style; we split examples of an idiom into 10 pieces in advance of the experiment.

Also, we calculated the overall accuracy and baseline accuracy from the individual results. We summed up all accuracy scores of all the 90 idioms and then divided it by 90, which is called the macro-average. We did this for the baseline accuracy, too.

Another performance measure is the relative error reduction (RER).[20]

$$\text{RER} = \frac{\text{ER of baseline} - \text{ER of system}}{\text{ER of baseline}}$$

The overall RER is calculated from the overall accuracy and baseline by the above formula.

5.3 Experimental Result

Table 1 shows the overall performance. The first column is the baseline accuracy (%). The second column is the accuracy (%) and relative error reduction (%) of the system without the idiom-specific features. The third column is those of the system with the idiom features. Tables 2 and 3 show the individual results of the 90 idioms. The first column shows

[19]Some examples were unavailable due to the feature extraction failure. Thus, examples used for the experiment are fewer in number than those included in the corpus.

[20]ER stands for Error Rate in the formula.

Table 2: Individual Results (1/2)

Type	Base	(Pos ; Neg)	w/o I (RER)	w/ I (RER)
青筋を立てる (blue.vein-ACC emerge) ‘burst a blood vessel’	83.38	(286 ; 57)	86.32 (17.68)	**86.61 (19.45)**
あぐらをかく (sit cross-legged) ‘rest on one’s laurels’	62.45	(587 ; 353)	92.66 (80.45)	**92.87 (81.02)**
足が付く (leg-NOM attach) ‘find a clue to solving a case’	72.21	(184 ; 478)	77.20 (17.96)	**79.62 (26.68)**
足が出る (leg-NOM go.out) ‘run over the budget’	77.59	(188 ; 651)	92.61 (67.01)	**93.08 (69.13)**
足元を見る (one’s feet-ACC look.down) ‘see someone coming’	57.53	(420 ; 310)	**85.89 (66.77)**	85.75 (66.45)
足を洗う (leg-ACC wash) ‘wash one’s hands of ...’	68.47	(632 ; 291)	92.65 (76.68)	92.65 (76.69)
足を伸ばす (leg-ACC stretch) ‘go a little further’	80.24	(727 ; 179)	95.26 (76.03)	**95.38 (76.59)**
頭が痛い (head-NOM ache) ‘harass oneself about ...’	57.87	(158 ; 217)	83.94 (61.89)	83.94 (61.89)
頭を抱える (head-ACC fold) ‘tear one’s hair out’	87.28	(796 ; 116)	91.35 (31.99)	91.35 (31.99)
頭をもたげる (head-ACC lift) ‘rear its head’	83.14	(804 ; 163)	93.40 (60.83)	**93.50 (61.45)**
脂が乗る (fat-NOM put.on) ‘warm up to one’s work’	83.69	(196 ; 1006)	92.94 (56.69)	92.94 (56.69)
油を売る (oil-ACC sell) ‘shoot the breeze’	86.67	(507 ; 78)	92.63 (44.70)	92.63 (44.70)
油を絞る (oil-ACC squeeze) ‘rake someone over the coals’	66.83	(69 ; 139)	84.64 (53.71)	**86.14 (58.23)**
網を張る (net-ACC spread) ‘wait expectantly’	70.10	(366 ; 858)	**81.28 (37.41)**	80.96 (36.31)
息が詰まる (breath-NOM choke.up) ‘stifling’	71.61	(681 ; 270)	**79.82 (28.91)**	79.50 (27.80)
一から十まで (one-FROM ten-TO) ‘all without exception’	92.00	(770 ; 67)	93.48 (18.51)	93.48 (18.51)
色を失う (color-ACC lose) ‘turn pale’	73.32	(262 ; 720)	84.23 (40.91)	84.23 (40.91)
腕が上がる (arm-NOM go.up) ‘develop one’s skill’	57.06	(481 ; 362)	84.47 (63.85)	**88.75 (73.80)**
尾を引く (tail-ACC pull) ‘have a lasting effect’	87.72	(843 ; 118)	93.14 (44.15)	**93.35 (45.84)**
顔を出す (face-ACC present) ‘show up’	84.48	(697 ; 128)	88.60 (26.49)	**88.82 (27.93)**
肩を並べる (shoulder-ACC juxtapose) ‘on a par’	89.38	(842 ; 100)	**93.20 (35.97)**	93.10 (34.97)
角が取れる (corner-NOM remove) ‘become mature’	57.45	(370 ; 274)	**78.35 (49.13)**	78.04 (48.39)
唇をかむ (lip-ACC bite) ‘bite one’s lip’	70.89	(587 ; 241)	78.40 (25.78)	**79.36 (29.10)**
口を切る (mouth-ACC cut) ‘break the ice’	51.50	(210 ; 223)	**84.83 (68.73)**	83.69 (66.36)
口をとがらせる (mouth-ACC sharpen) ‘pout’	86.33	(663 ; 105)	**87.61 (9.40)**	87.35 (7.47)
首が回らない (neck-NOM turn-NEG) ‘up to one’s neck’	66.63	(619 ; 310)	**86.41 (59.28)**	86.22 (58.71)
首を切る (neck-ACC cut) ‘give the axe’	53.90	(449 ; 384)	**89.93 (78.15)**	89.80 (77.88)
首をひねる (neck-ACC twist) ‘think hard’	93.16	(885 ; 65)	**94.11 (13.85)**	93.79 (9.23)
事によると (thing-DAT depend) ‘perhaps’	67.15	(231 ; 113)	96.50 (89.35)	**97.35 (91.94)**
ごまをする (sesame-ACC crush) ‘flatter’	50.29	(87 ; 88)	**92.75 (85.42)**	90.99 (81.88)
背を向ける (back-ACC train) ‘turn one’s back’	66.70	(597 ; 298)	89.06 (67.14)	89.06 (67.14)
血が通う (blood-NOM flow) ‘humane’	50.18	(422 ; 419)	82.41 (64.70)	**83.24 (66.37)**
宙に浮く (midair-DAT float) ‘’	58.07	(382 ; 529)	88.03 (71.46)	**88.69 (73.03)**
土が付く (dirt-NOM attach) ‘be defeated in sumo wrestling’	72.66	(70 ; 186)	**79.48 (24.97)**	78.76 (22.33)
手が届く (hand-NOM reach) ‘afford’ ‘reach an age’ ‘attentive’	80.76	(470 ; 112)	87.66 (35.85)	87.66 (35.85)
手がない (hand-NOM there.isn’t) ‘have no remedy’	86.94	(799 ; 120)	92.61 (43.38)	**92.83 (45.06)**
手が離れる (hand-NOM get.away) ‘get one’s work done’	53.49	(360 ; 414)	**92.37 (83.59)**	92.36 (83.57)
手に乗る (hand-DAT ride) ‘fall into someone’s trap’	61.05	(372 ; 583)	92.86 (81.68)	**93.49 (83.30)**
手を入れる (hand-DAT insert) ‘obtain’	53.21	(373 ; 328)	93.44 (85.99)	**93.59 (86.29)**
手を掛ける (hand-ACC hang) ‘give a lot of care’	70.57	(241 ; 578)	91.19 (70.04)	**91.31 (70.46)**
手を切る (hand-ACC cut) ‘break away’	57.85	(468 ; 341)	91.08 (78.83)	91.08 (78.83)
手を取る (hand-ACC take) ‘give every possible help (to learn)’	88.89	(91 ; 728)	**92.74 (34.67)**	92.62 (33.56)
手を握る (hand-ACC grasp) ‘conclude an alliance’	90.51	(73 ; 696)	**95.44 (51.93)**	95.17 (49.16)
手を延ばす (hand-ACC stretch) ‘extend one’s business’	89.55	(95 ; 814)	94.01 (42.69)	**94.22 (44.72)**
手を広げる (hand-ACC open.up) ‘extend one’s business’	70.52	(579 ; 242)	89.17 (63.26)	**90.15 (66.57)**
手を回す (hand-ACC turn) ‘take measures’	68.86	(246 ; 544)	93.04 (77.64)	**93.92 (80.49)**
峠を越す (mountain.pass-ACC go.over) ‘get over the hump’	72.18	(685 ; 264)	89.28 (61.46)	**89.49 (62.23)**
泥を塗る (mud-ACC daub) ‘drag someone through mud’	74.38	(543 ; 187)	91.64 (67.38)	**91.92 (68.45)**
波に乗る (wave-DAT ride) ‘catch a wave’	86.23	(783 ; 125)	**93.05 (49.55)**	92.94 (48.74)
熱が冷める (heat-NOM get.cool) ‘fever goes down’	89.90	(890 ; 100)	92.02 (21.00)	**92.22 (23.00)**
熱を上げる (heat-ACC raise) ‘go ape’	92.52	(903 ; 73)	94.50 (26.45)	**94.71 (29.21)**
熱を入れる (heat-ACC feed.in) ‘enthuse’	85.06	(723 ; 127)	90.71 (37.80)	**91.76 (44.88)**
根を下ろす (root-ACC take.down) ‘take root’	85.83	(824 ; 136)	93.23 (52.21)	93.23 (52.21)
根を張る (root-ACC spread) ‘take root’	60.00	(564 ; 376)	87.66 (69.15)	87.66 (69.15)
バスに乗り遅れる (bus-DAT miss) ‘miss the boat’	76.97	(199 ; 665)	90.50 (58.74)	**92.36 (66.81)**
バトンを渡す (baton-ACC give) ‘have someone succeed his position’	65.33	(471 ; 250)	81.70 (47.23)	**82.25 (48.81)**
鼻息が荒い (nasal.breathing-NOM heavy) ‘full of big talk’	52.77	(286 ; 256)	75.33 (47.77)	**76.62 (50.50)**
鼻が高い (nose-NOM high) ‘proud’	50.27	(659 ; 652)	81.01 (61.81)	**82.30 (64.42)**
鼻を折る (nose-ACC break) ‘humble (someone)’	56.60	(69 ; 90)	69.58 (29.91)	**74.92 (42.20)**
鼻を鳴らす (nose-ACC make.a.sound) ‘make light of ...’	55.72	(536 ; 426)	80.79 (56.63)	**81.21 (57.57)**
腹を割る (belly-ACC cut) ‘have a heart-to-heart talk’	95.62	(1265 ; 58)	96.68 (24.16)	96.68 (24.16)
歯を食い縛る (teeth-ACC clench) ‘grit one’s teeth’	65.54	(194 ; 102)	**71.97 (18.66)**	71.63 (17.66)
人を食う (human-ACC eat) ‘look down on someone’	74.95	(727 ; 243)	87.01 (48.15)	87.01 (48.15)
火花を散らす (spark-ACC spread) ‘fight heatedly’	75.99	(728 ; 230)	89.57 (56.56)	**89.68 (57.00)**

Table 3: Individual Results (2/2)

Type	Base	(Pos ; Neg)	w/o I (RER)	w/ I (RER)
筆を入れる (painting.brush-ACC add) ‘correct (writings or paintings)’	75.80	(213 ; 68)	83.99 (33.84)	**84.70 (36.79)**

実を結ぶ (fruit-ACC bear) ‘bear fruit’	89.39	(826 ; 98)	**95.79 (60.33)**	95.68 (59.31)
胸が痛む (chest-NOM ache) ‘suffer heartache’	93.59	(876 ; 60)	95.82 (34.78)	**95.93 (36.46)**
胸が膨らむ (chest-NOM expand) ‘feel one’s heart leap’	55.58	(338 ; 423)	94.08 (86.68)	**94.48 (87.57)**
胸を打つ (chest-ACC hit) ‘impress’	92.39	(801 ; 66)	96.45 (53.34)	**96.68 (56.39)**
芽が出る (germ-NOM come.out) ‘close to making the top’	56.57	(377 ; 491)	91.33 (80.03)	**91.55 (80.55)**
目がない (eye-NOMthere.isn’t) ‘have a passion for ...’	91.81	(829 ; 74)	**95.70 (47.47)**	95.25 (42.05)
メスを入れる (scalpel-ACC insert) ‘take drastic measures’	88.96	(741 ; 92)	96.28 (66.30)	96.28 (66.30)
目に入る (eye-DAT enter) ‘catch sight of ...’	84.76	(623 ; 112)	90.22 (35.79)	**91.16 (41.97)**
目を覆う (eye-ACC cover) ‘be in a shambles’	87.24	(725 ; 106)	91.45 (32.99)	**92.06 (37.72)**
目を覚ます (eye-ACC awake) ‘snap out of ..’	83.26	(118 ; 587)	87.92 (27.85)	**88.64 (32.12)**
目をつぶる (eye-ACC close) ‘turn a blind eye’	70.13	(533 ; 227)	90.26 (67.40)	90.26 (67.40)
目を細くする (eye-ACC thin) ‘one’s eyes light up’	53.44	(115 ; 132)	**75.20 (46.74)**	75.11 (46.54)
指をくわえる (finger-ACC suck) ‘look enviously’	92.50	(876 ; 71)	**95.68 (42.41)**	95.58 (41.09)
弓を引く (bow-ACC draw) ‘defy’	88.06	(138 ; 1018)	**95.51 (62.41)**	95.43 (61.68)

Table 1: Overall Result

Base	w/o I (RER)	w/ I (RER)
72.92	88.86 (58.87)	89.25 (60.30)

the target idioms. The second column shows baseline accuracy (%) and the numbers of positive and negative examples for each idiom. The accuracy (%) and relative error reduction (%) of the system without the idiom-specific features are described in the third column. The fourth column is those of the system with the idiom features. Bold face indicates a better performance.

All in all, we see relatively high baseline performances. Nevertheless, both systems outperformed the baseline. Especially, the system without the idiom-specific features has a noticeable lead over the baseline, showing that WSD technologies are effective in the idiom identification. Incorporating the idiom features into the system improved the overall performance, which is statistically significant (McNemar test, $p<0.01$). But performances of some idioms slightly degraded by the incorporation of the idiom features.

Table 4: Overall Results without Using One of the Idiom Features

Feature Type	Acc
All	89.25
−f8 (w/o Adnominal modification flag)	89.24
−f9 (w/o Topic case marking flag)	89.22
−f10 (w/o Voice alternation flag)	89.15
−f11 (w/o Negation flag)	89.17
−f12 (w/o Volitional modality flag)	89.19
−f13 (w/o Adjacency flag)	89.09

Table 4 shows overall results without using one of the idiom features.[21] As you see, the adjacency flag (f13) contributes to idiom identification accuracy the most.[22] On the other hand, the adnominal modification flag (f8) contributes to the task only slightly.[23]

[21]The first row shows the result with all idiom features used, just for ease of reference.

[22]Note that greater performance drop indicates greater contribution.

[23]This result is inconsistent with the result obtained in HSU, where they reported that grammatical constraints involving adnominal modification was most effective. This inconsistency might be attributed to the differences of datasets being used for idiom identification experiment. HSU used only 108 sentences

Table 5: Results reported in CFS

	Accu	RER
Baseline	61.9	—
Unsupervised	72.4	27.6
Supervised	76.2	37.5

Table 5 shows the results reported in CFS. Their baseline system regards all instances as idioms. The performance of the supervised one is obtained by the method of Katz and Giesbrecht (2006). Though we cannot simply compare this with our results due to the difference in experimental conditions, this implies that our WSD-based method was equally good or possibly better than their methods that are tailored to MWEs.

6 Conclusion

In this paper, we reported on the idiom corpus we have constructed and the idiom identification experiment using the corpus.

As mentioned in §4.3, some idioms are short of examples in the current idiom corpus. We plan to collect more examples by using different characters. In the Japanese language, there are basically three character systems: Hiragana, Katakana, and Chinese characters. Thus, you can write an idiom in different characters. For example, *mune-o utu* (chest-ACC hit) 'impress' can be either 胸を打つ or 胸をうつ.

In spite of its imperfection, we are sure that we can learn a lot about the idiom identification from the corpus, since, as far as we know, it is the largest-ever one, and so is the idiom identification experiment reported in §5.

Also, we showed that a standard supervised WSD method works well for the idiom identification. Our system achieved the accuracy of 89.25% and 88.86% with/without idiom-specific features.

Though we dealt with as many as 90 idioms, practical NLP systems are required to deal with many more idioms. Toward a scalable idiom identification, we have to develop an unsupervised or semi-supervised method. The unsupervised method of Birke and Sarkar (2006) requires WordNet. Fortunately, the Japanese WordNet is now available (Isahara et al., 2008), thus we can try their method. Also, CFS propose a language-independent unsupervised method. These could be of help.

At any rate, our idiom corpus will play an important role in the development of unsupervised or semi-supervised methods, and the experimental results obtained in this study will be a good reference point to evaluate those methods.

for the experiment, while 75,011 sentences were used for our experiment. Also, the dataset of HSU came from newspaper articles, while our dataset came from the web.

Acknowledgments

This work was conducted as a part of the collaborative research project of Kyoto University and NTT Communication Science Laboratories.

The work was supported from NTT Communication Science Laboratories and JSPS Grants-in-Aid for Young Scientists (B) 19700141.

We would like to thank the members of the collaborative research group of Kyoto University and NTT Communication Science Laboratories and Francis Bond for their stimulating discussion. Our thanks go as well to Prof. Sato Satoshi, who kindly gave us the list of basic idioms of Japanese.

Abstract

The accuracy of current word sense disambiguation (WSD) systems is affected by the fine-grained sense inventory of WordNet as well as a lack of training examples. Using the WSD examples provided through OntoNotes, we conduct the first large-scale WSD evaluation involving hundreds of word types and tens of thousands of sense-tagged examples, while adopting a coarse-grained sense inventory. We show that though WSD systems trained with a large number of examples can obtain a high level of accuracy, they nevertheless suffer a substantial drop in accuracy when applied to a different domain. To address this issue, we propose combining a domain adaptation technique using feature augmentation with active learning. Our results show that this approach is effective in reducing the annotation effort required to adapt a WSD system to a new domain. Finally, we propose that one can maximize the dual benefits of reducing the annotation effort while ensuring an increase in WSD accuracy, by only performing active learning on the set of most frequently occurring word types.

1 Introduction

In language, many words have multiple meanings. The process of identifying the correct meaning, or sense of a word in context, is known as word sense disambiguation (WSD). WSD is one of the fundamental problems in natural language processing and is important for applications such as machine translation (MT) (Chan et al., 2007a; Carpuat and Wu, 2007), information retrieval (IR), etc.

WSD is typically viewed as a classification problem where each ambiguous word is assigned a sense label (from a pre-defined sense inventory) during the disambiguation process. In current WSD research, WordNet (Miller, 1990) is usually used as the sense inventory. WordNet, however, adopts a very fine level of sense granularity, thus restricting the accuracy of WSD systems. Also, current state-of-the-art WSD systems are based on supervised learning and face a general lack of training data.

To provide a standardized test-bed for evaluation of WSD systems, a series of evaluation exercises called SENSEVAL were held. In the English all-words task of SENSEVAL-2 and SENSEVAL-3 (Palmer et al., 2001; Snyder and Palmer, 2004), no training data was provided and systems must tag all the content words (noun, verb, adjective, and adverb) in running English texts with their correct WordNet senses. In SENSEVAL-2, the best performing system (Mihalcea and Moldovan, 2001) in the English all-words task achieved an accuracy of 69.0%, while in SENSEVAL-3, the best performing system (Decadt et al., 2004) achieved an accuracy of 65.2%. In SemEval-2007, which was the most recent SENSEVAL evaluation, a similar English all-words task was held, where systems had to provide the correct WordNet sense tag for all the verbs and head words of their arguments in running English texts. For this task, the best performing system (Tratz et al., 2007) achieved an accuracy of 59.1%. Results of these evaluations showed that state-of-the-art English all-words WSD systems performed with an accuracy of 60%–70%, using the fine-grained sense inventory of WordNet.

The low level of performance by these state-of-the-art WSD systems is a cause for concern, since WSD is supposed to be an enabling technology to be incorporated as a module into applications such as MT and IR. As mentioned earlier, one of the major reasons for the low performance is that these evaluation exercises adopted WordNet as the reference sense inventory, which is often too fine-grained. As an indication of this, inter-annotator agreement (ITA) reported for manual sense-tagging on these SENSEVAL English all-words datasets is typically in the mid-70s. To address this issue, a coarse-grained English all-words task (Navigli et al., 2007) was conducted during SemEval-2007. This task used a coarse-grained version of WordNet and reported an ITA of around 90%. We note that the best performing system (Chan et al., 2007b) of this task achieved a relatively high accuracy of 82.5%, highlighting the importance of having an appropriate level of sense granularity.

Another issue faced by current WSD systems is the lack of training data. We note that the top performing systems mentioned in the previous paragraphs are all based on supervised learning. With this approach, however, one would need to obtain a corpus where each ambiguous word occurrence is manually annotated with the correct sense, to serve as training data. Since it is time consuming to perform sense annotation of word occurrences, only a handful of sense-tagged corpora are publicly available. Among the existing sense-tagged corpora, the SEMCOR corpus (Miller et al., 1994) is one of the most widely used. In SEMCOR, content words have been manually tagged with WordNet senses. Current supervised WSD systems (which include all the top-performing systems in the English all-words task) usually rely on this relatively small manually annotated corpus for training examples, and this has inevitably affected the accuracy and scalability of current WSD systems.

Related to the problem of a lack of training data for WSD, there is also a lack of *test* data. Having a large amount of test data for evaluation is important to ensure the robustness and scalability of WSD systems. Due to the expensive process of manual sense-tagging, the SENSEVAL English all-words task evaluations were conducted on relatively small sets of evaluation data. For instance, the evaluation data of SENSEVAL-2 and SENSEVAL-3 English all-words task consists of 2,473 and 2,041 test examples respectively. In SemEval-2007, the fine-grained English all-words task consists of only 465 test examples, while the SemEval-2007 coarse-grained English all-words task consists of 2,269 test examples.

Hence, it is necessary to address the issues of sense granularity, and the lack of both training and test data. To this end, a recent large-scale annotation effort called the OntoNotes project (Hovy et al., 2006) was started. Building on the annotations from the Wall Street Journal (WSJ) portion of the Penn Treebank (Marcus et al., 1993), the project added several new layers of semantic annotations, such as coreference information, word senses, etc. In its first release (LDC2007T21) through the Linguistic Data Consortium (LDC), the project manually sense-tagged more than 40,000 examples belonging to hundreds of noun and verb types with an ITA of 90%, based on a coarse-grained sense inventory, where each word has an average of only 3.2 senses. Thus, besides providing WSD examples that were sense-tagged with a high ITA, the project also addressed the previously discussed issues of a lack of training and test data.

In this paper, we use the sense-tagged data provided by the OntoNotes project to investigate the accuracy achievable by current WSD systems when adopting a coarse-grained sense inventory. Through our experiments, we then highlight that domain adaptation for WSD is an important issue as it substantially affects the performance of a state-of-the-art WSD system which is trained on SEMCOR but evaluated on sense-tagged examples in OntoNotes. To address this issue, we then show that by combining a domain adaptation technique using feature augmentation with active learning, one only needs to annotate a small amount of in-domain examples to obtain a substantial improvement in the accuracy of the WSD system which is previously trained on out-of-domain examples.

The contributions of this paper are as follows. To our knowledge, this is the first large-scale WSD evaluation conducted that involves hundreds of word types and tens of thousands of sense-tagged examples, and that is based on a coarse-grained sense inventory. The present study also highlights the practical significance of domain adaptation in word sense disambiguation in the context of a large-scale empirical evaluation, and proposes an effective method to address the domain adaptation problem.

In the next section, we give a brief description of our WSD system. In Section 3, we describe experiments where we conduct both training and evaluation using data from OntoNotes. In Section 4, we investigate the WSD performance when we train our system on examples that are gathered from a different domain as compared to the OntoNotes evaluation data. In Section 5, we perform domain adaptation experiments using a recently introduced feature augmentation technique. In Section 6, we investigate the use of active learning to reduce the annotation effort required to adapt our WSD system to the domain of the OntoNotes data, before concluding in Section 7.

2 The WSD System

For the experiments reported in this paper, we follow the supervised learning approach of (Lee and Ng, 2002), by training an individual classifier for each word using the knowledge sources of local collocations, parts-of-speech (POS), and surrounding words.

For local collocations, we use 11 features: $C_{-1,-1}$, $C_{1,1}$, $C_{-2,-2}$, $C_{2,2}$, $C_{-2,-1}$, $C_{-1,1}$, $C_{1,2}$, $C_{-3,-1}$, $C_{-2,1}$, $C_{-1,2}$, and $C_{1,3}$, where $C_{i,j}$ refers to the ordered sequence of tokens in the local context of an ambiguous word *w*. Offsets *i* and *j* denote the starting and ending position (relative to *w*) of the sequence, where a negative (positive) offset refers to a token to its left (right). For parts-of-speech, we use 7 features: P_{-3}, P_{-2}, P_{-1}, P_0, P_1, P_2, P_3, where P_0 is the POS of *w*, and P_{-i} (P_i) is the POS of the *i*th token to the left (right) of *w*. For surrounding words, we consider all unigrams (single words) in the surrounding context of *w*. These words can be in a different sentence from *w*. For our experiments reported in this paper, we use support vector machines (SVM) as our learning algorithm, which was shown to achieve good WSD performance in (Lee and Ng, 2002; Chan et al., 2007b).

3 Training and Evaluating on OntoNotes

The annotated data of OntoNotes is drawn from the Wall Street Journal (WSJ) portion of the Penn Treebank corpus, divided into sections 00-24. These WSJ documents have been widely used in various NLP tasks such as syntactic parsing (Collins, 1999) and semantic role labeling (SRL) (Carreras and Marquez, 2005). In these tasks, the practice is to use documents from WSJ sections 02-21 as training data and WSJ section 23 as test data. Hence for our experiments reported in this paper, we follow this convention and use the annotated instances from WSJ sections 02-21 as our training data, and instances in WSJ section 23 as our test data.

Table 1: Size of the sense-tagged data in the various WSJ sections.

As mentioned in Section 1, the OntoNotes data provided WSD examples for a large number of nouns and verbs, which are sense-tagged according to a coarse-grained sense inventory. In Table 1, we show the amount of sense-tagged data available from OntoNotes, across the various WSJ sections.[1] In the table, for each WSJ section, we list the number of word types, the number of sense-tagged examples, and the cumulative count on the number of

[1]We removed erroneous examples which were simply tagged with 'XXX' as sense-tag, or tagged with senses that were not found in the sense-inventory provided. Also, since we will be comparing against training on SEMCOR later (which was tagged using WordNet senses), we removed examples tagged with OntoNotes senses which were not mapped to WordNet senses. On the whole, about 7% of the original OntoNotes examples were removed as a result.

sense-tagged examples. From the table, we see that sections 02-21, which will be used as training data in our experiments, contain a total of slightly over 31,000 sense-tagged examples.

Using examples from sections 02-21 as training data, we trained our WSD system and evaluated on the examples from section 23. In our experiments, if a word type in section 23 has no training examples from sections 02-21, we randomly select an OntoNotes sense as the answer. Using these experimental settings, our WSD system achieved an accuracy of 89.1%. We note that this accuracy is much higher than the 60%–70% accuracies achieved by state-of-the-art English all-words WSD systems which are trained using the fine-grained sense inventory of WordNet. Hence, this highlights the importance of having an appropriate level of sense granularity.

Besides training on the entire set of examples from sections 02-21, we also investigated the performance achievable from training on various subsections of the data and show these results as "ON" in Figure 1. From the figure, we see that WSD accuracy increases as we add more training examples.

The fact that current state-of-the-art WSD systems are able to achieve a high level of performance is important, as this means that WSD systems will potentially be more usable for inclusion in end-applications. For instance, the high level of performance by syntactic parsers allows it to be used as an enabling technology in various NLP tasks. Here, we note that the 89.1% WSD accuracy we obtained is comparable to state-of-the-art syntactic parsing accuracies, such as the 91.0% performance by the statistical parser of Charniak and Johnson (2005).

4 Building WSD Systems with Out-of-Domain Data

Although our WSD system had achieved a high accuracy of 89.1%, this was achieved by training on a large amount (about 31,000) of manually sense annotated examples from sections 02-21 of the OntoNotes data. Further, all these training data and test data are gathered from the same domain of WSJ. In reality, however, since manual sense annotation is time consuming, it is not feasible to collect such a large amount of manually sense-tagged data for every domain of interest. Hence, in this section, we investigate the performance of our WSD system when it is trained on out-of-domain data.

In the English all-words task of the previous SENSEVAL evaluations (SENSEVAL-2, SENSEVAL-3, SemEval-2007), the best performing English all-words task systems with the highest WSD accuracy were trained on SEMCOR (Mihalcea and Moldovan, 2001; Decadt et al., 2004; Chan et al., 2007b). Hence, we similarly trained our WSD system on SEMCOR and evaluated on section 23 of the OntoNotes corpus. For those word types in section 23 which do not have training examples from SEMCOR, we randomly chose an OntoNotes sense as the answer. In training on SEMCOR, we have also ensured that there is a domain difference between our training and test data. This is because while the OntoNotes data was gathered from WSJ, which contains mainly business related news, the SEMCOR corpus is the sense-tagged portion of the Brown Corpus (BC), which is a mixture of several genres such as scientific texts, fictions, etc.

Evaluating on the section 23 test data, our WSD system achieved only 76.2% accuracy. Compared to the 89.1% accuracy achievable when we had trained on examples from sections 02-21, this is a substantially lower and disappointing drop of performance and motivates the need for domain adaptation.

The need for domain adaptation is a general and important issue for many NLP tasks (Daume III and Marcu, 2006). For instance, SRL systems are usually trained and evaluated on data drawn from the WSJ. In the CoNLL-2005 shared task on SRL (Carreras and Marquez, 2005), however, a task of training and evaluating systems on different domains was included. For that task, systems that were trained on the PropBank corpus (Palmer et al., 2005) (which was gathered from the WSJ), suffered a 10% drop in accuracy when evaluated on test data drawn from BC, as compared to the performance achievable when evaluated on data drawn from WSJ. More recently, CoNLL-2007 included a shared task on dependency parsing (Nivre et al., 2007). In this task, systems that were trained on Penn Treebank (drawn from WSJ), but evaluated on data drawn from a different domain (such as chemical abstracts and parent-child dialogues) showed a similar drop in performance. For research involving training and eval-

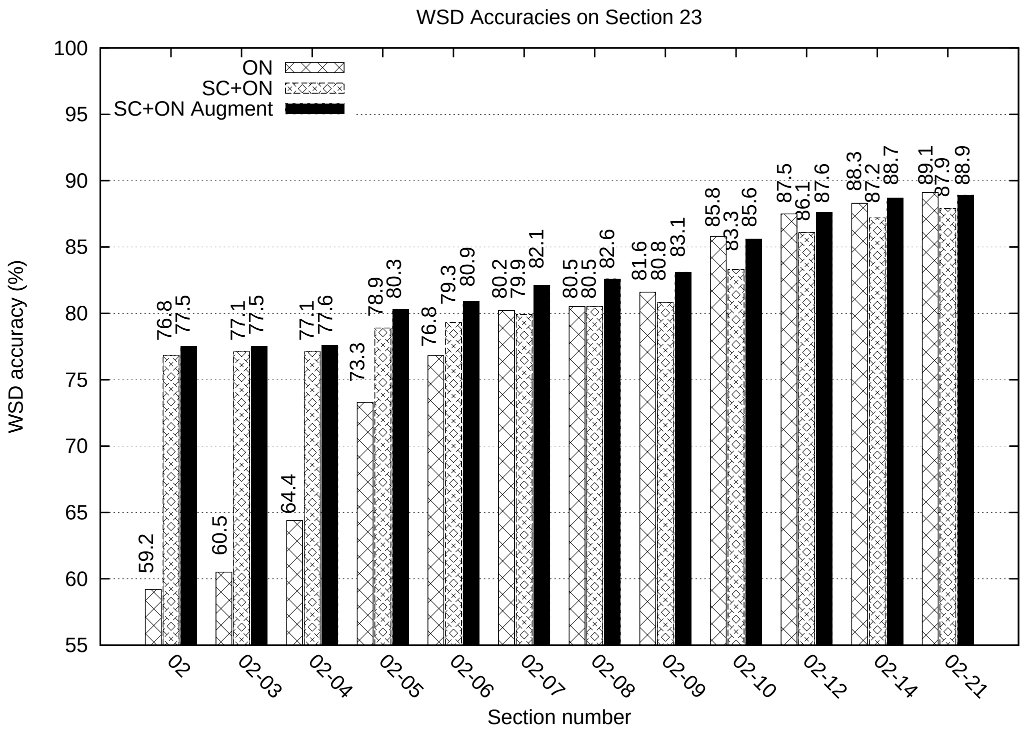

Figure 1: WSD accuracies evaluated on section 23, using SEMCOR and different OntoNotes sections as training data. ON: only OntoNotes as training data. SC+ON: SEMCOR and OntoNotes as training data, SC+ON Augment: Combining SEMCOR and OntoNotes via the Augment domain adaptation technique.

uating WSD systems on data drawn from different domains, several prior research efforts (Escudero et al., 2000; Martinez and Agirre, 2000) observed a similar drop in performance of about 10% when a WSD system that was trained on the BC part of the DSO corpus was evaluated on the WSJ part of the corpus, and vice versa.

In the rest of this paper, we perform domain adaptation experiments for WSD, focusing on domain adaptation methods that use in-domain annotated data. In particular, we use a feature augmentation technique recently introduced by Daume III (2007), and active learning (Lewis and Gale, 1994) to perform domain adaptation of WSD systems.

5 Combining In-Domain and Out-of-Domain Data for Training

In this section, we will first introduce the AUGMENT technique of Daume III (2007), before showing the performance of our WSD system with and without using this technique.

5.1 The AUGMENT technique for Domain Adaptation

The AUGMENT technique introduced by Daume III (2007) is a simple yet very effective approach to performing domain adaptation. This technique is applicable when one has access to training data from the source domain and a small amount of training data from the target domain.

The technique essentially augments the feature space of an instance. Assuming $\boldsymbol{x}$ is an instance and its original feature vector is $\Phi(\boldsymbol{x})$, the augmented feature vector for instance $\boldsymbol{x}$ is

$$\Phi'(\boldsymbol{x}) = \begin{cases} <\Phi(\boldsymbol{x}), \Phi(\boldsymbol{x}), \mathbf{0}> & \text{if } \boldsymbol{x} \in D_s \\ <\Phi(\boldsymbol{x}), \mathbf{0}, \Phi(\boldsymbol{x})> & \text{if } \boldsymbol{x} \in D_t \end{cases},$$

where $\mathbf{0}$ is a zero vector of size $|\Phi(\boldsymbol{x})|$, D_s and D_t are the sets of instances from the source and target domains respectively. We see that the technique essentially treats the first part of the augmented feature space as holding general features that are not meant to be differentiated between different domains. Then, different parts of the augmented feature space are reserved for holding source domain specific, or target domain specific features. Despite its relative simplicity, this AUGMENT technique has been shown to outperform other domain adaptation techniques on various tasks such as named entity recognition, part-of-speech tagging, etc.

5.2 Experimental Results

As mentioned in Section 4, training our WSD system on SEMCOR examples gave a relatively low accuracy of 76.2%, as compared to the 89.1% accuracy obtained from training on the OntoNotes section 02-21 examples. Assuming we have access to some in-domain training data, then a simple method to potentially obtain better accuracies is to train on both the out-of-domain and in-domain examples. To investigate this, we combined the SEMCOR examples with various amounts of OntoNotes examples to train our WSD system and show the resulting "SC+ON" accuracies obtained in Figure 1. We also performed another set of experiments, where instead of simply combining the SEMCOR and OntoNotes examples, we applied the AUGMENT technique when combining these examples, treating SEMCOR examples as out-of-domain (source domain) data and OntoNotes examples as in-domain (target domain) data. We similarly show the resulting accuracies as "SC+ON Augment" in Figure 1.

Comparing the "SC+ON" and "SC+ON Augment" accuracies in Figure 1, we see that the AUGMENT technique *always* helps to improve the accuracy of our WSD system. Further, notice from the first few sets of results in the figure that when we have access to limited in-domain training examples from OntoNotes, incorporating additional out-of-domain training data from SEMCOR (either using the strategies "SC+ON" or "SC+ON Augment") achieves better accuracies than "ON". Significance tests using one-tailed paired t-test reveal that these accuracy improvements are statistically significant at the level of significance 0.01 (all significance tests in the rest of this paper use the same level of significance 0.01). These results validate the contribution of the SemCor examples. This trend continues till the result for sections 02-06.

The right half of Figure 1 shows the accuracy trend of the various strategies, in the unlikely event that we have access to a large amount of in-domain training examples. Although we observe that in this scenario, "ON" performs better than "SC+ON", "SC+ON Augment" continues to perform better than "ON" (where the improvement is statistically significant) till the result for sections 02-09. Beyond that, as we add more OntoNotes examples, significance testing reveals that the "SC+ON Augment" and "ON" strategies give comparable performance. This means that the "SC+ON Augment" strategy, besides giving good performance when one has few in-domain examples, does continue to perform well even when one has a large number of in-domain examples.

```
$D_S \leftarrow$ the set of SEMCOR training examples
$D_A \leftarrow$ the set of OntoNotes sections 02-21 examples
$D_T \leftarrow$ empty
while $D_A \neq \phi$
    $p_{min} \leftarrow \infty$
    $\Gamma \leftarrow$ WSD system trained on $D_S$ and $D_T$ using AUGMENT technique
    for each $d \in D_A$ do
        $\widehat{s} \leftarrow$ word sense prediction for $d$ using $\Gamma$
        $p \leftarrow$ confidence of prediction $\widehat{s}$
        if $p < p_{min}$ then
            $p_{min} \leftarrow p$, $d_{min} \leftarrow d$
        end
    end
    $D_A \leftarrow D_A - \{d_{min}\}$
    provide correct sense $s$ for $d_{min}$ and add $d_{min}$ to $D_T$
end
```

Figure 2: The active learning algorithm.

6 Active Learning with AUGMENT Technique

So far in this paper, we have seen that when we have access to some in-domain examples, a good strategy is to combine the out-of-domain and in-domain examples via the AUGMENT technique. This suggests that when one wishes to apply a WSD system to a new domain of interest, it is worth the effort to annotate a small number of examples gathered from the new domain. However, instead of randomly selecting in-domain examples to annotate, we could use active learning (Lewis and Gale, 1994) to help select in-domain examples to annotate. By doing so, we could minimize the manual annotation effort needed.

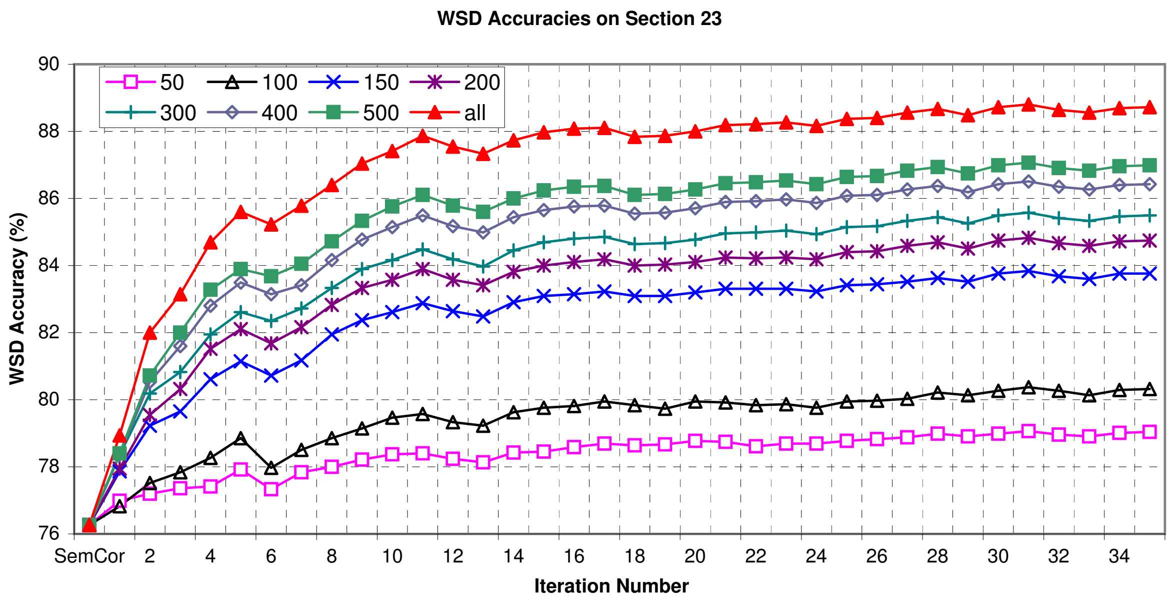

Figure 3: Results of applying active learning with the AUGMENT technique on different number of word types. Each curve represents the adaptation process of applying active learning on a certain number of most frequently occurring word types.

In WSD, several prior research efforts have successfully used active learning to reduce the annotation effort required (Zhu and Hovy, 2007; Chan and Ng, 2007; Chen et al., 2006; Fujii et al., 1998). With the exception of (Chan and Ng, 2007) which tried to adapt a WSD system trained on the BC part of the DSO corpus to the WSJ part of the DSO corpus, the other researchers simply applied active learning to reduce the annotation effort required and did not deal with the issue of adapting a WSD system to a new domain. Also, these prior research efforts only experimented with a few word types. In contrast, we perform active learning experiments on the hundreds of word types in the OntoNotes data, with the aim of adapting our WSD system trained on SEMCOR to the WSJ domain represented by the OntoNotes data.

For our active learning experiments, we use the *uncertainty sampling* strategy (Lewis and Gale, 1994), as shown in Figure 2. For our experiments, the SEMCOR examples will be our initial set of training examples, while the OntoNotes examples from sections 02-21 will be used as our pool of adaptation examples, from which we will select examples to annotate via active learning. Also, since we have found that the AUGMENT technique is useful in increasing WSD accuracy, we will apply the AUGMENT technique during each iteration of active learning to combine the SEMCOR examples and the selected adaptation examples.

As shown in Figure 2, we train an initial WSD system using only the set D_S of SEMCOR examples. We then apply our WSD system on the set D_A of OntoNotes adaptation examples. The example in D_A which is predicted with the lowest confidence will be removed from D_A and added to the set D_T of in-domain examples that have been selected via active learning thus far. We then use the AUGMENT technique to combine the set of examples in D_S and D_T to train a new WSD system, which is then applied again on the set D_A of remaining adaptation examples, and this active learning process continues until we have used up all the adaptation examples. Note that because we are using OntoNotes sections 02-21 (which have already been sense-tagged beforehand) as our adaptation data, the annotation of the selected example during each active learning iteration is simply simulated by referring to its tagged sense.

6.1 Experimental Results

As mentioned earlier, we use the examples in OntoNotes sections 02-21 as our adaptation examples during active learning. Hence, we perform active learning experiments on *all* the word types that have sense-tagged examples from OntoNotes sections 02-21, and show the evaluation results on OntoNotes section 23 as the topmost "all" curve in Figure 3. Since our aim is to reduce the human annotation effort required in adapting a WSD system to a new domain, we may not want to perform active learning on all the word types in practice. Instead, we can maximize the benefits by performing active learning only on the more frequently occurring word types. Hence, in Figure 3, we also show via various curves the results of applying active learning only to various sets of word types, according to their frequency, or number of sense-tagged examples in OntoNotes sections 02-21. Note that the various accuracy curves in Figure 3 are plotted in terms of evaluation accuracies over all the test examples in OntoNotes section 23, hence they are directly comparable to the results reported thus far in this paper. Also, since the accuracies for the various curves stabilize after 35 active learning iterations, we only show the results of the first 35 iterations.

From Figure 3, we note that by performing active learning on the set of 150 most frequently occurring word types, we are able to achieve a WSD accuracy of 82.6% after 10 active learning iterations. Note that in Section 4, we mentioned that training only on the out-of-domain SEMCOR examples gave an accuracy of 76.2%. Hence, we have gained an accuracy improvement of 6.4% (82.6% − 76.2%) by just using 1,500 in-domain OntoNotes examples. Compared with the 12.9% (89.1% − 76.2%) improvement in accuracy achieved by using all 31,114 OntoNotes sections 02-21 examples, we have obtained half of this maximum increase in accuracy, by requiring only about 5% (1,500/31,114) of the total number of sense-tagged examples. Based on these results, we propose that when there is a need to apply a previously trained WSD system to a different domain, one can apply the AUGMENT technique with active learning on the most frequent word types, to greatly reduce the annotation effort required while obtaining a substantial improvement in accuracy.

7 Conclusion

Using the WSD examples made available through OntoNotes, which are sense-tagged according to a coarse-grained sense inventory, we show that our WSD system is able to achieve a high accuracy of 89.1% when we train and evaluate on these examples. However, when we apply a WSD system that is trained on SEMCOR, we suffer a substantial drop in accuracy, highlighting the need to perform domain adaptation. We show that by combining the AUGMENT domain adaptation technique with active learning, we are able to effectively reduce the amount of annotation effort required for domain adaptation.

Abstract

Bootstrapping has a tendency, called *semantic drift*, to select instances unrelated to the seed instances as the iteration proceeds. We demonstrate the semantic drift of bootstrapping has the same root as the topic drift of Kleinberg's HITS, using a simplified graph-based reformulation of bootstrapping. We confirm that two graph-based algorithms, the von Neumann kernels and the regularized Laplacian, can reduce semantic drift in the task of word sense disambiguation (WSD) on Senseval-3 English Lexical Sample Task. Proposed algorithms achieve superior performance to *Espresso* and previous graph-based WSD methods, even though the proposed algorithms have less parameters and are easy to calibrate.

1 Introduction

In recent years machine learning techniques become widely used in natural language processing (NLP). These techniques offer various ways to exploit large corpora and are known to perform well in many tasks. However, these techniques often require tagged corpora, which are not readily available to many languages. So far, reducing the cost of human annotation is one of the important problems for building NLP systems.

To mitigate the problem of hand-tagging resources, semi(or minimally)-supervised and unsupervised techniques have been actively studied. Hearst (1992) first presented a bootstrapping method which requires only a small amount of instances (seed instances) to start with, but can easily multiply the number of tagged instances with minimal human annotation cost, by iteratively applying the following phases: pattern induction, pattern ranking/selection, and instance extraction. Bootstrapping has been widely adopted in NLP applications such as word sense disambiguation (Yarowsky, 1995), named entity recognition (Collins and Singer, 1999) and relation extraction (Riloff and Jones, 1999; Pantel and Pennacchiotti, 2006).

However, it is known that bootstrapping often acquires instances not related to seed instances. For example, consider the task of collecting the names of common tourist sites from web corpora. Given words like "Geneva" and "Bali" as seed instances, bootstrapping would eventually learn *generic patterns* such as "pictures" and "photos," which also co-occur with many other unrelated instances. The subsequent iterations would likely acquire frequent words that co-occur with these generic patterns, such as "Britney Spears." This phenomenon is called *semantic drift* (Curran et al., 2007).

A straightforward approach to avoid semantic drift is to terminate iterations before hitting generic patterns, but the optimal number of iterations is task dependent and is hard to come by. The recently proposed *Espresso* (Pantel and Pennacchiotti, 2006) algorithm incorporates sophisticated scoring functions to cope with generic patterns, but as Komachi and Suzuki (2008) pointed out, Espresso still shows semantic drift unless iterations are terminated appropriately.

Another deficiency in bootstrapping is its sensitivity to many parameters such as the number of seed instances, the stopping criterion of iteration, the number of instances and patterns selected on each iteration, and so forth. These parameters also need to be calibrated for each task.

In this paper, we present a graph-theoretic analysis of Espresso-like bootstrapping algorithms. We argue that semantic drift is inherent in these algorithms, and propose to use two graph-based algorithms that are theoretically less prone to semantic drift, as an alternative to bootstrapping.

After a brief review of related work in Section 2, we analyze in Section 3 a bootstrapping algorithm (*Simplified Espresso*) which can be thought of as a degenerate version of Espresso. Simplified Espresso is simple enough to allow an algebraic treatment, and its equivalence to Kleinberg's HITS algorithm (Kleinberg, 1999) is shown. An implication of this equivalence is that semantic drift in this bootstrapping algorithm is essentially the same phenomenon as topic drift observed in link analysis. Another implication is that semantic drift is inevitable in Simplified Espresso as it converges to the same score vector regardless of seed instances.

The original Espresso also suffers from the same problem as its simplified version does. It incorporates heuristics not present in Simplified Espresso to reduce semantic drift, but these heuristics have limited effect as we demonstrate in Section 3.3.

In Section 4, we propose two graph-based algorithms to reduce semantic drift. These algorithms are used in link analysis community to reduce the effect of topic drift. In Section 5 we apply them to the task of word sense disambiguation on Senseval-3 Lexical Sample Task and verify that they indeed reduce semantic drift. Finally, we conclude our work in Section 6.

2 Related Work

2.1 Overview of Bootstrapping

Bootstrapping (or self-training) is a general framework for reducing the requirement of manual annotation. Hearst (1992) described a bootstrapping procedure for extracting words in hyponym (*is-a*) relation, starting with three manually given lexico-syntactic patterns.

The idea of learning with a bootstrapping method was adopted for many tasks. Yarowsky (1995) presented an unsupervised WSD system which rivals supervised techniques. Abney (2004) presented a thorough discussion on the Yarowsky algorithm. He extended the original Yarowsky algorithm to a new family of bootstrapping algorithms that are mathematically well understood.

Li and Li (2004) proposed a method called *Bilingual Bootstrapping*. It makes use of a translation dictionary and a comparable corpus to help disambiguate word senses in the source language, by exploiting the asymmetric many-to-many sense mapping relationship between words in two languages.

Curran et al. (2007) presented an algorithm called *Mutual Exclusion Bootstrapping*, which minimizes semantic drift using mutual exclusion between semantic classes of learned instances. They prepared a list of so-called *stop classes* similar to a stop word list used in information retrieval to help bound the semantic classes. Stop classes are sets of terms known to cause semantic drift in particular semantic classes. However, stop classes vary from task to task and domain to domain, and human intervention is essential to create an effective list of stop classes.

A major drawback of bootstrapping is the lack of principled method for selecting optimal parameter values (Ng and Cardie, 2003; Banko and Brill, 2001). Also, there is an issue of generic patterns which deteriorates the quality of acquired instances. Previously proposed bootstrapping algorithms differ in how they deal with the problem of semantic drift. We will take recently proposed Espresso algorithm as the example to explain common configuration for bootstrapping in detail.

2.2 The Espresso Algorithm

Pantel and Pennachiotti (2006) proposed a bootstrapping algorithm called Espresso to learn binary semantic relations such as *is-a* and *part-of* from a corpus. What distinguishes Espresso from other bootstrapping algorithms is that it benefits from generic patterns by using a principled measure of instance and pattern reliability. The key idea of Espresso is recursive definition of pattern-instance scoring metrics. The reliability scores of pattern p and instance i, denoted respectively as $r_\pi(p)$ and

$r_\iota(i)$, are given as follows:

$$r_\pi(p) = \frac{\sum_{i \in I} \frac{pmi(i,p)}{\max\ pmi} r_\iota(i)}{|I|} \quad (1)$$

$$r_\iota(i) = \frac{\sum_{p \in P} \frac{pmi(i,p)}{\max\ pmi} r_\pi(p)}{|P|} \quad (2)$$

where

$$pmi(i,p) = \log_2 \frac{|i,p|}{|i,*||*,p|} \quad (3)$$

is pointwise mutual information between i and p, P and I are sets of patterns and instances, and $|P|$ and $|I|$ are the numbers of patterns and instances, respectively. $|i,*|$ and $|*,p|$ are the frequencies of pattern p and instance i in a given corpus, respectively, and $|i,p|$ is the frequency of pattern p which co-occurs with instance i. $\max\ pmi$ is a maximum value of the pointwise mutual information over all instances and patterns. The intuition behind these definitions is that a reliable pattern co-occurs with many reliable instances, and a reliable instance co-occurs with many reliable patterns.

Espresso and other bootstrapping methods iterate the following three phases: *pattern induction, pattern ranking/selection, and instance extraction.*

We describe these phases below, along with the parameters that controls each phase.

Phase 1. Pattern Induction Induce patterns from a corpus given seed instances. Patterns may be surface text patterns, lexico-syntactic patterns, and/or just features.

Phase 2. Pattern Ranking/Selection Create a pattern ranker from a corpus using instances as features and select patterns which co-occur with seed instances for the next instance extraction phase. The main issue here is to avoid ranking generic patterns high and to choose patterns with high relatedness to the seed instances. Parameters and configurations: (a) *a pattern scoring metrics* and (b) *the number of patterns to use for extraction of instances*.

Phase 3. Instance Extraction Select high-confidence instances to the seed instance set. It is desirable to keep only high-confidence instances at this phase, as they are used as seed instances for the next iteration. Optionally, instances can be cumulatively obtained on each iteration to retain highly relevant instances learned in early iterations. Parameters and configurations: (c) *instance scoring metrics*, (d) *whether to retain extracted instances on each iteration or not*, and (e) *the number of instances to pass to the next iteration*.

```
input:
    seed vector $\mathbf{i}_0$
    pattern-instance co-occurrence matrix $M$
output:
    instance and pattern score vectors $\mathbf{i}$ and $\mathbf{p}$

1:  $\mathbf{i} = \mathbf{i}_0$
2:  loop
3:      $\mathbf{p} \leftarrow M\mathbf{i}$
4:      Normalize $\mathbf{p}$
5:      $\mathbf{i} \leftarrow M^T\mathbf{p}$
6:      Normalize $\mathbf{i}$
7:      if $\mathbf{i}$ and $\mathbf{p}$ have both converged then
8:          return $\mathbf{i}$ and $\mathbf{p}$
9:      end if
10: end loop
```

Figure 1: A simple bootstrapping algorithm

Bootstrapping iterates the above three phases several times until stopping criteria are met. Acquired instances tend to become noisy as the iteration proceeds, so it is important to terminate before semantic drift occurs. Thus, we have another configuration: (f) *stopping criterion*.

Espresso uses Equations (1) for (a) and (2) for (c) respectively, whereas other parameters rely on the tasks and need calibration. Even though Espresso greatly improves recall while keeping high precision by using these pattern and instance scoring metrics, Komachi and Suzuki (2008) observed that extracted instances matched against generic patterns may become erroneous after tens of iterations, showing the difficulty of applying bootstrapping methods to different domains.

3 Analysis of an Espresso-like Bootstrapping Algorithm

3.1 Simplified Espresso

Let us consider a simple bootstrapping algorithm illustrated in Figure 1, in order to elucidate the cause of semantic drift.

As before, let $|I|$ and $|P|$ be the numbers of instances and patterns, respectively. The algorithm takes a seed vector $\mathbf{i}_0$, and a pattern-instance co-occurrence matrix M as input. $\mathbf{i}_0$ is a $|I|$-dimensional vector with 1 at the position of seed instances, and 0 elsewhere. M is a $|P| \times |I|$-matrix whose (p, i)-element $[M]_{pi}$ holds the (possibly reweighted) number of co-occurrence of pattern p and instance i in the corpus. If both $\mathbf{i}$ and $\mathbf{p}$ have converged, the algorithm returns the pair of $\mathbf{i}$ and $\mathbf{p}$ as output.

This algorithm, though simple, can encode Espresso's update formulae (1) and (2) as Steps 3 through 6 if we pose

$$[M]_{pi} = \frac{pmi(i, p)}{\max pmi}, \tag{4}$$

and normalize $\mathbf{p}$ and $\mathbf{i}$ in Steps 4 and 6 by

$$\mathbf{p} \leftarrow \mathbf{p}/|I| \quad \text{and} \quad \mathbf{i} \leftarrow \mathbf{i}/|P|, \tag{5}$$

respectively.

This specific instance of the algorithm of Figure 1, obtained by specialization through Equations (4) and (5), will be henceforth referred to as *Simplified Espresso*. Indeed, it is an instance of the original Espresso in which the iteration is not terminated until convergence, all instances are carried over to the next iteration, and instances are not cumulatively learned.

3.2 Simplified Espresso as Link Analysis

Let n denote the number of times Steps 2–10 are iterated. Plugging (4) and (5) into Steps 3–6, we see that the score vector of instances after the nth iteration is

$$\mathbf{i}_n = A^n \mathbf{i}_0 \tag{6}$$

where

$$A = \frac{1}{|I||P|} M^T M. \tag{7}$$

Suppose matrix A is irreducible; i.e., the graph induced by taking A as the adjacency matrix is connected. If n is increased and $\mathbf{i}_n$ is normalized on each iteration, $\mathbf{i}_n$ tends to the principal eigenvector of A. This implies that no matter what seed instances are input, the algorithm will end up with the same ranking of instances, if it is run until convergence. Because $A = \frac{M^T M}{|I||P|}$, the principal eigenvector of A is identical to the authority vector of HITS (Kleinberg, 1999) algorithm run on the graph induced by M. [1] This similarity of Equations (1), (2) and HITS is not discussed in (Pantel and Pennacchiotti, 2006).

As a consequence of the above discussion, semantic drift in simplified Espresso seems to be inevitable as the iteration proceeds, since the principal eigenvector of A need not resemble seed vector $\mathbf{i}_0$. A similar phenomenon is reported for HITS and is known as *topic drift*, in which pages of the dominant topic are ranked high regardless of the given query. (Bharat and Henzinger, 1998)

Unlike HITS and Simplified Espresso, however, Espresso and other bootstrapping algorithms (Yarowsky, 1995; Riloff and Jones, 1999), incorporate heuristics so that only patterns and instances with high confidence score are carried over to the next iteration.

3.3 Convergence Process of Espresso

To investigate the effect of semantic drift on Espresso with and without the heuristics of selecting the most confident instances on each iteration (i.e., the original Espresso and Simplified Espresso of Section 3.2), we apply them to the task of word sense disambiguation of word "bank" in the Senseval-3 Lexical Sample (S3LS) Task data.[2] There are 394 instances of word "bank" and their occurring context in this dataset, and each of them is annotated with its true sense. Of the ten senses of *bank,* the most frequent is the bank as in "bank of the river." We use the standard training-test split provided with the data set.

We henceforth denote Espresso with the following filtering strategy as *Filtered Espresso* to stress the distinction from Simplified Espresso. For Filtered Espresso, we cleared all but the 100 top-scoring instances in the instance vector on each iteration, and the number of non-zeroed instance scores

[1] As long as the relative magnitude of the components of vector $\mathbf{i}_n$ is preserved, the vector can be normalized in any way on each iteration. Hence HITS and Simplified Espresso use different normalization but both converge to the principal eigenvector of A.

[2] http://www.senseval.org/senseval3/data.html

grows by 100 on each iteration. On the other hand, we cleared all but the 20 top-scoring patterns in the pattern vector on each iteration, and the number of non-zeroed pattern scores grows by 1 on each iteration following (Pantel and Pennacchiotti, 2006).[3] The values of other parameters (b), (d), (e) and (f) remains the same as those for simplified Espresso in Section 3.1.

The task of WSD is to correctly predict the senses of test instances whose true sense is hidden from the system, using training data and their true senses. To predict the sense of a given instance i, we apply k-nearest neighbor algorithm.

Given a test instance i, its sense is predicted with the following procedure:

1. Compute the instance-pattern matrix M from the entire set of instances. We defer the details of this step to Section 5.2.
2. Run Simplified- and Filtered Espresso using the given instance i as the only seed instance.
3. After the termination of the algorithm, select k training instances with the highest scores in the score vector $\mathbf{i}$ output by the algorithm.
4. Since the selected k instances are training instances, their true senses are accessible. Choose the majority sense s from these k instances, and output s as the prediction for the given instance i. When there is a tie, output the sense of the instance with the highest score in $\mathbf{i}$. Note that only Step 4 uses sense information.

Figure 2 shows the convergence process of Simplified- and Filtered Espresso. X-axis indicates the number of bootstrapping iterations and Y-axis indicates the recall, which in this case equals precision, as the coverage is 100% in all cases.

[3]We conducted preliminary experiment to find these parameters to maximize the performance of Filtered Espresso. (These numbers are different from the original Espresso (Pantel and Pennacchiotti, 2006).) The number of initial patterns is relatively large because of a data sparseness problem in WSD, unlike relation extraction and named entity recognition. Also, WSD basically uses more features than relation extraction and thus it is hard to determine the stopping criterion based on the number and scores of patterns, as (Pantel and Pennacchiotti, 2006) does.

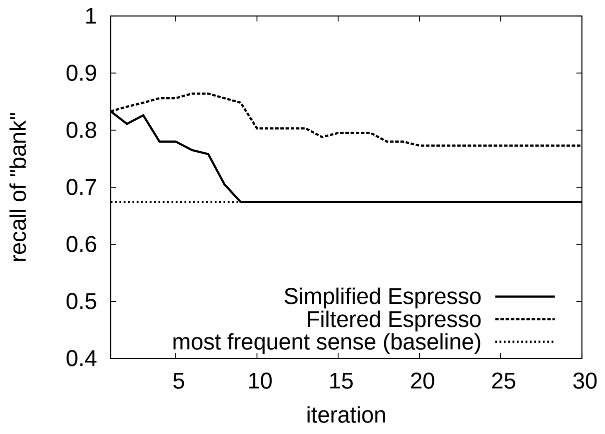

Figure 2: Recall of Simplified- and Filtered Espresso

Simplified Espresso tends to select the most frequent sense as the iteration proceeds, and after nine iterations it selects the most frequent sense ("the bank of the river") regardless of the seed instances. As expected from the discussion in Section 3.2, generic patterns gradually got more weight and semantic drift occurred in later iterations. Indeed, the ranking of the instances after convergence was identical to the HITS authority ranking computed from instance-pattern matrix M (i.e., the ranking induced by the dominant eigenvector of $M^T M$).

On the other hand, Filtered Espresso suffers less from semantic drift. The final recall achieved was 0.773 after convergence on the 20th iteration, outperforming the most-frequent sense baseline by 0.10. However, a closer look reveals that the filtering heuristics is limited in effectiveness.

Figure 3 plots the learning curve of Filtered Espresso on the set of test instances. We show recall ($\frac{|correct\ instances|}{|total\ true\ instances|}$) of each sense to see how Filtered Espresso tends to select the most frequent sense. If semantic drift takes place, the number of instances predicted as the most frequent sense should increase as the iteration proceeds, resulting in increased recall on the most frequent sense and decreased recall on other senses. Figure 3 exactly exhibit this trend, meaning that Filtered Espresso is not completely free from semantic drift. Figure 2 also shows that the recall of Filtered Espresso starts to decay after the seventh iteration.

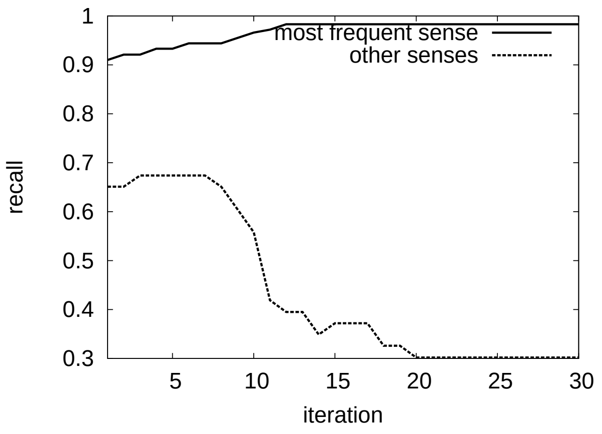

Figure 3: Recall of Filtered Espresso on the instances having "bank of the river" and other senses

4 Two Graph-based Algorithms for Exploiting Generic Patterns

We explore two graph-based methods which have the advantage of Espresso to harness the property of generic patterns by the mutual recursive definition of instance and pattern scores. They also have less parameters than bootstrapping, and are less prone to semantic drift.

4.1 Von Neumann Kernel

Kandola et al. (2002) proposed the *von Neumann kernels* for measuring similarity of documents using words. If we apply the von Neumann kernels to the pattern-instance co-occurrence matrix instead of the document-word matrix, the relative importance of an instance to seed instances can be estimated.

Let $A = M^T M$ be the instance similarity matrix obtained from pattern-instance matrix M, and λ be the principal eigenvalue of A. The *von Neumann kernel matrix* K_β with diffusion factor β $(0 \leq \beta < \lambda^{-1})$ is defined as follows:

$$K_\beta \;=\; A \sum_{n=0}^{\infty} \beta^n A^n = A(I - \beta A)^{-1}. \quad (8)$$

The similarity between two instances i, j is given by the (i, j) element of K_β. Hence, the i-th column vector can be used as the score vector for seed instance i.

Ito et al. (2005) showed that the von Neumann kernels represent a mixture of the co-citation relatedness and Kleinberg's HITS importance. They compute the weighted sum of all paths between two nodes in the co-citation graph induced by $A = M^T M$. The $(M^T M)^n$ term of smaller n corresponds to the relatedness to the seed instances, and the $(M^T M)^n$ term of larger n corresponds to HITS importance. The von Neumann kernels calculate the weighted sum of $(M^T M)^n$ from $n = 1$ to ∞, and therefore smaller diffusion factor β results in ranking by relatedness, and larger β returns ranking by HITS importance.

In NLP literature, Schütze (1998) introduced the notion of first- and second-order co-occurrence. First-order co-occurrence is a context which directly co-occurs with a word, whereas second-order co-occurrence is a context which occurs with the (contextual) words that co-occur with a word. Higher-order co-occurrence information is less sparse and more robust than lower-order co-occurrence, and thus is useful for a proximity measure.

Given these definitions, we see that the $(M^T M)^n$ term of smaller n corresponds to lower-order co-occurrence, which is accurate but sparse, and the $(M^T M)^n$ term of larger n corresponds to higher-order co-occurrence, which is dense but possibly giving too much weight on unrelated instances extracted by generic patterns.

As a result, it is expected that setting diffusion factor β to a small value prevents semantic drift and also takes higher order pattern vectors into account. We verify this claim in Section 5.3.

4.2 Regularized Laplacian Kernel

The von Neumann kernels can be regarded as a mixture of relatedness and importance, and diffusion factor β controls the trade-off between relatedness and importance. In practice, however, setting the right parameter value becomes an issue. We solve this problem by the regularized Laplacian (Smola and Kondor, 2003; Chebotarev and Shamis, 1998), which are stable across diffusion factors and can safely benefit from generic patterns.

Let G be a weighted undirected graph whose adjacency (weight) matrix is a symmetric matrix A. The (combinatorial) graph Laplacian L of a graph G is defined as follows:

$$L = D - A \quad (9)$$

where D is a diagonal matrix, and the ith diagonal

Table 1: Recall of predicted labels of *bank*

algorithm	MFS	others
Simplified Espresso	100.0	0.0
Filtered Espresso	100.0	30.2
Filtered Espresso (optimal stopping)	94.4	67.4
von Neumann kernels	92.1	65.1
regularized Laplacian	92.1	62.8

element $[D]_{ii}$ is given by

$$[D]_{ii} = \sum_j [A]_{ij}. \tag{10}$$

Here, $[A]_{ij}$ stands for the (i, j) element of A. By replacing A with $-L$ in Equation (8) and deleting the first A, we obtain a *regularized Laplacian kernel* [4].

$$R_\beta = \sum_{n=0}^{\infty} \beta^n (-L)^n = (I + \beta L)^{-1} \tag{11}$$

Again, $\beta(\geq 0)$ is called the diffusion factor.

Both the regularized Laplacian and the von Neumann kernels compute all the possible paths in a graph, and consequently they can calculate influence between nodes in a long distance in the graph. Also, Equations (9) and (10) show that the negative Laplacian $-L$ can be regarded as a modification to the graph G with the weight of self-loops re-weighted to negative values. In this modified graph, if an instance co-occurs with a pattern which also co-occurs with a large number of other instances, a self-loop of a node in the instance similarity graph induced by $M^T M$ will receive a higher negative weight. In other words, instances co-occurring with generic patterns will get less weight in the regularized Laplacian than in the von Neumann kernels.

5 Experiments and Results

5.1 Experiment 1: Reducing Semantic Drift

We test the von Neumann kernels and the regularized Laplacian on the same task as we used in Section 3.3; i.e., word sense disambiguation of word "bank." During the training phase, a pattern-instance matrix M was constructed using the training and testing data from Senseval-3 Lexical Sample (S3LS) Task. The (i, j) element of M of both kernels is set to pointwise mutual information of a pattern i and an instance j, just the same as in Espresso. Recall is used in evaluation.[5] The diffusion parameter β is set to 10^{-5} and 10^{-2} for the von Neumann kernels and the regularized Laplacian, respectively.

Table 1 illustrates how well the proposed methods reduce semantic drift, just the same as the experiment of Figure 3 in Section 3.3. We evaluate the recall on predicting the most frequent sense (MFS) and the recall on predicting other less frequent senses (others). For Filtered Espresso, two results are shown: the result on the seventh iteration, which maximizes the performance (Filtered Espresso (optimal stopping)), and the one after convergence. As in Section 3.3, if semantic drift occurs, recall of prediction on the most frequent sense increases while recall of prediction on other senses declines. Even Filtered Espresso was affected by semantic drift, which is again a consequence of the inherent graphical nature of Espresso-like bootstrapping algorithms. On the other hand, both proposed methods succeeded to balance the most frequent sense and other senses. Filtered Espresso at the optimal number of iterations achieved the best performance. Nevertheless, the number of iterations has to be estimated separately.

5.2 Experiment 2: WSD Benchmark Data

We conducted experiments on the task of word sense disambiguation of S3LS data, this time not just on the word "bank" but on all target nouns in the data, following (Agirre et al., 2006). We used two types of patterns.

Unordered single words (bag-of-words) We used all single words (unigrams) in the provided context from S3LS data sets. Each word in the context constructs one pattern. The pattern corresponding to a word w is set to 1 if it appears in the context of instance i. Words were lowercased and pre-processed with the Porter Stemmer[6].

[4]It has been reported that normalization of A improves performance in application (Johnson and Zhang, 2007), so we normalize L by $L = I - D^{-\frac{1}{2}} A D^{-\frac{1}{2}}$.

[5]Again, recall equals precision in this case as the coverage is 100% in all cases.

Table 2: Comparison of WSD algorithms

algorithm	Recall
most frequent sense	54.5
HyperLex (Véronis, 2004)	64.6
PageRank (Agirre et al., 2006)	64.5
Simplified Espresso	44.1
Filtered Espresso	46.9
Filtered Espresso (optimal stopping)	66.5
von Neumann kernels ($\beta = 10^{-5}$)	**67.2**
regularized Laplacian ($\beta = 10^{-2}$)	67.1

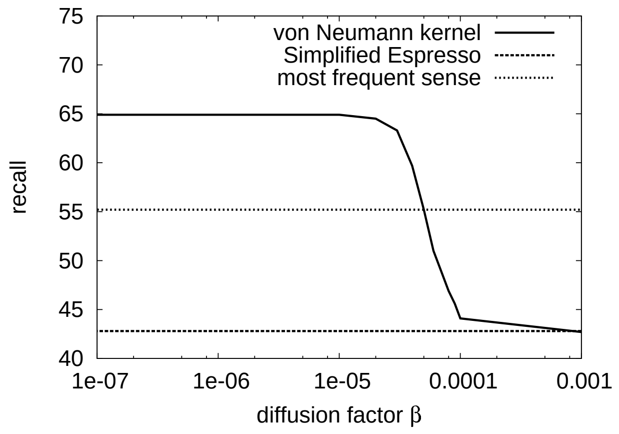

Figure 4: Recall of the von Neumann kernels with a different diffusion factor β on S3LS WSD task

Local collocations A local collocation refers to the ordered sequence of tokens in the local, narrow context of the target word. We allowed a pattern to have wildcard expressions like "sale of * *interest* in * *" for the target word *interest*. We set the window size to ± 3 by a preliminary experiment.

We report the results of Filtered Espresso both after convergence, and with its optimal number of iterations to show the upper bound of its performance.

Table 2 compares proposed methods with Espresso with various configurations. The proposed methods outperform by a large margin the most frequent sense baseline and both Simplified- and Filtered Espresso. This means that the proposed methods effectively prevent semantic drift.

Also, Filtered Espresso without early stopping shows more or less identical performance to Simplified Espresso. It is implied that the heuristics of filtering and early stopping is a crucial step not to select generic patterns in Espresso, and the result is consistent with the experiment of convergence process of Espresso in Section 3.3.

Filtered Espresso halted after the seventh iteration (Filtered Espresso (optimal stopping)) is comparable to the proposed methods. However, in bootstrapping, not only the number of iterations but also a large number of parameters must be adjusted for each task and domain. This shortcoming makes it hard to adapt bootstrapping in practical cases. One of the main advantages of the proposed methods is that they have only one parameter β and are much easier to tune.

It is suggested in Sections 3.3 and 4.1 that Espresso and the von Neumann kernel with large β converge to the principal eigenvector of A, though the result does not seem to support this claim (both Simplified- and Filtered Espresso are 10 points lower than the most frequent sense baseline). The reason seems to be because Espresso and the von Neumann kernels use pointwise mutual information as a weighting factor so that the principal eigenvector of A may not always represent the most frequent sense.[7]

We also show the results of previous graph-based methods (Agirre et al., 2006), based on HyperLex (Véronis, 2004) and PageRank (Brin and Page, 1998). The experimental set-up is the same as ours in that they do not use the sense tags of training corpus to construct a co-occurrence graph, and they use the sense tags of all the S3LS training corpus for mapping senses to clusters. However, these methods have seven parameters to tune in order to achieve the best performance, and hence are difficult to optimize.

5.3 Experiment 3: Sensitivity to a Different Diffusion Factor

Figure 4 shows the performance of the von Neumann kernels with a diffusion factor β. As expected, smaller β leads to relatedness to seed instances, and larger β asymptotically converges to the HITS authority ranking (or equivalently, Simplified

[7]A similar but more extreme case is described in (Ito et al., 2005) in which the use of a normalized weight matrix M results in an unintuitive principal eigenvector.

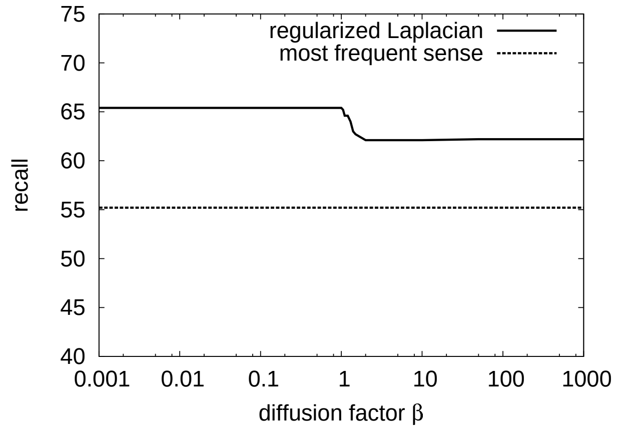

Figure 5: Recall of the regularized Laplacian with a different diffusion factor β on S3LS WSD task

Espresso).

One of the disadvantages of the von Neumann kernels over the regularized Laplacian is their sensitivity to parameter β. Figure 5 illustrates the performance of the regularized Laplacian with a diffusion factor β. The regularized Laplacian is stable for various values of β, while the von Neumann kernels change their behavior drastically depending on the value of β. However, β in the von Neumann kernels is upper-bounded by the reciprocal $1/\lambda$ of the principal eigenvalue of A, and the derivatives of kernel matrices with respect to β can be used to guide systematic calibration of β (see (Ito et al., 2005) for detail).

6 Conclusion and Future Work

This paper gives a graph-based analysis of semantic drift in Espresso-like bootstrapping algorithms. We indicate that semantic drift in bootstrapping is a parallel to topic drift in HITS. We confirm that the von Neumann kernels and the regularized Laplacian reduce semantic drift in the Senseval-3 Lexical Sample task. Our proposed methods have only one parameters and are easy to calibrate.

Beside the regularized Laplacian, many other kernels based on the eigenvalue regularization of the Laplacian matrix have been proposed in machine learning community (Kondor and Lafferty, 2002; Nadler et al., 2006; Saerens et al., 2004). One such kernel is the commute-time kernel (Saerens et al., 2004) defined as the pseudo-inverse of Laplacian. Despite having no parameters at all, it has been reported to perform well in many collaborative filtering tasks (Fouss et al., 2007). We plan to test these kernels in our task as well.

Another research topic is to investigate other semi-supervised learning techniques such as co-training (Blum and Mitchell, 1998). As we have described in this paper, self-training can be thought of a graph-based algorithm. It is also interesting to analyze how co-training is related to the proposed algorithm.

Bootstrapping algorithms have been used in many NLP applications. Two major tasks of bootstrapping are word sense disambiguation and named entity recognition. In named entity recognition task, instances are usually retained on each iteration and added to seed instance set. This seems to be because named entity recognition suffers from semantic drift more severely than word sense disambiguation. Even though this problem setting is different from ours, it needs to be verified that the graph-based approaches presented in this paper are also effective in named entity recognition.

Abstract

Web-search queries are known to be short, but little else is known about their structure. In this paper we investigate the applicability of part-of-speech tagging to typical English-language web search-engine queries and the potential value of these tags for improving search results. We begin by identifying a set of part-of-speech tags suitable for search queries and quantifying their occurrence. We find that proper-nouns constitute 40% of query terms, and proper nouns and nouns together constitute over 70% of query terms. We also show that the majority of queries are noun-phrases, not unstructured collections of terms. We then use a set of queries manually labeled with these tags to train a Brill tagger and evaluate its performance. In addition, we investigate classification of search queries into grammatical classes based on the syntax of part-of-speech tag sequences. We also conduct preliminary investigative experiments into the practical applicability of leveraging query-trained part-of-speech taggers for information-retrieval tasks. In particular, we show that part-of-speech information can be a significant feature in machine-learned search-result relevance. These experiments also include the potential use of the tagger in selecting words for omission or substitution in query reformulation, actions which can improve recall. We conclude that training a part-of-speech tagger on labeled corpora of queries significantly outperforms taggers based on traditional corpora, and leveraging the unique linguistic structure of web-search queries can improve search experience.

1 Introduction

Web-search queries are widely acknowledged to be short (2.8 words (Spink et al., 2002)) and to be frequently reformulated, but little else is understood about their grammatical structure. Since search queries are a fundamental part of the information retrieval task, it is essential that we interpret them correctly. However, the variable forms queries take complicate interpretation significantly. We hypothesize that elucidating the grammatical structure of search queries would be highly beneficial for the associated information retrieval task.

Previous work with queries (Allan and Raghavan, 2002) considered that short queries may be ambiguous in their part of speech and that different documents are relevant depending on how this ambiguity is resolved. For example, the word "boat" in a query may be intended as subject of a verb, object of a verb, or as a verb, with each case reflecting a distinct intent. To distinguish between the possibilities, Allan and Raghavan (Allan and Raghavan, 2002) propose eliciting feedback from the user by showing them possible contexts for the query terms.

In addition to disambiguating query terms for retrieval of suitable documents, part-of-speech tagging can help increase recall by facilitating query reformulation. Zukerman and Raskutti (Zukerman and Raskutti, 2002) part-of-speech tag well-formed questions, and use the part-of-speech tags to substitute synonyms for the content words.

Several authors have leveraged part-of-speech tagging towards improved index construction for information retrieval through part-of-speech-based weighting schemas and stopword detection (Crestani et al., 1998), (Chowdhury and McCabe, 2000), (Dincer and Karaoglan, 2004). Their experiments show degrees of success. Recently, along with term weighting, Lioma has been using part-of-speech n-grams for noise and content detection in indexes (Lioma, 2008). Our study differs from these in that linguistic and part-of-speech focus is almost exclusively placed on queries as opposed to the indexed documents, reflecting our opinion that queries exhibit their own partially predictable and unique linguistic structure different from that of the natural language of indexed documents. Similarly, (Strzalkowski et al., 1998) added a layer of natural language processing using part-of-speech tags and syntactical parsing to the common statistical information-retrieval framework, much like experiments detailed in sections 4 and 5. Our system differs in that our syntactic parsing system was applied to web-search queries and uses rules derived from the observed linguistic structure of queries as opposed to natural-language corpora. By focusing on the part-of-speech distribution and syntactic structure of queries over tagged indexed documents, with a simple bijection mapping our query tags to other tag sets, our system offers a complementary approach that can be used in tandem with the techniques referenced above.

Lima and Pederson (de Lima and Pederson, 1999) conducted related work in which part-of-speech tagging using morphological analysis was used as a preprocessing step for labeling tokens of web-search queries before being parse by a probabilistic context-free grammar tuned to query syntax. We believe this technique and others relying on part-of-speech tagging of queries could benefit from using a query-trained tagger prior to deeper linguistic analysis.

Pasca (Pasca, 2007) showed that queries can be used as a linguistic resource for discovering named entities. In this paper we show that the majority of query terms are proper nouns, and the majority of queries are noun-phrases, which may explain the success of this data source for named-entity discovery.

In this work, we use metrics that assume a unique correct part-of-speech tagging for each query, implicitly addressing the disambiguation issue through inter-annotator-agreement scores and tagger generalization error. To identify these tags, we first analyze the different general forms of queries. In Section 2 we determine a suitable set of part-of-speech labels for use with search queries. We then use manually labeled query data to train a tagger and evaluate its performance relative to one trained on the Brown corpus in Section 3. We make observations about the syntactic structure of web-search queries in Section 4, showing that the majority (70%) of queries are noun-phrases, in contrast with the commonly held belief that queries consist of unstructured collections of terms. Finally, we examine the potential use of tagging in the tasks of search relevance evaluation and query reformulation in Section 5.

2 Data

We sampled queries from the Yahoo! search engine recorded in August 2006. Queries were systematically lower-cased and white-spaced normalized. We removed any query containing a non-ASCII character. Queries were then passed through a high-precision proprietary query spelling corrector, followed by the Penn Treebank tokenizer. No other normalization was carried out. Despite Penn-tokenization, queries were typical in their average length (Jansen et al., 2000). We sampled 3,283 queries from our dataset to label, for a total of 2,508 unique queries comprised of 8,423 individual tokens.

2.1 Inter-rater Agreement

The sparse textual information in search queries presents difficulties beyond standard corpora, not only for part-of-speech tagging software but also for human labelers. To quantify the level of these difficulties we measured inter-rater agreement on a set of 100 queries labeled by each editor. Since one labeler annotated 84.4% of the queries, we used a non-standard metric to determine agreement. One hundred queries were selected at random from each of our secondary labelers. Our primary labeler then re-labeled these queries. Accuracy was then calculated as a weighted average, specifically the mean of the agreement between our primary labeler and secondary labelers, weighted by the number of queries contributed by each secondary labeler. Measuring agreement with respect to the individual part-of-speech tag for each token, our corpus has an inter-rater agreement of 79.3%. If we require agreement between all tokens in a query, agreement falls to 65.4%. Using Cohen's kappa coefficient, we have that token-level agreement is a somewhat low 0.714 and query-level agreement is an even lower 0.641.

We attempted to accurately quantify token-level ambiguity in queries by examining queries where chosen labels differ. An author-labeler examined conflicting labels and made a decision whether the difference was due to error or genuine ambiguity. Error can be a result of accidentally selecting the wrong label, linguistic misunderstanding (e.g., "chatting" labeled as a verb or gerund), or lack of consensus between editors (e.g., model numbers could be nouns, proper nouns, or even numbers). Examples of genuinely ambiguous queries include "download" and "rent," both of which could be a noun or verb. Another major source of genuine token-level ambiguity comes from strings of proper nouns. For example, some editors considered "stillwater chamber of commerce" one entity and hence four proper-noun tokens while others considered only the first token a proper noun. Of the 99 conflicting token labels in our queries used to measure inter-annotator agreement, 69 were judged due to genuine ambiguity. This left us with a metric indicating query ambiguity accounts for 69.7% of labeling error.

2.2 Tags for Part-of-Speech Tagging Queries

In preliminary labeling experiments we found many standard part-of-speech tags to be extremely rare in web-search queries. Adding them to the set of possible tags made labeling more difficult without adding any necessary resolution. In Table 1 we give the set of tags we used for labeling. In general, part-of-speech tags are defined according to the distributional behavior of the corresponding parts of speech.

Our tag set differs dramatically from the Brown or Penn tag sets. Perhaps most noticeably, the sizes of the tag sets are radically different. The Brown tag set contains roughly 90 tags. In addition, several tags can be appended with additional symbols to indicate negation, genitives, etc. Our tag set contains just 19 unique classes.

Tag	Example	Count (%)
proper-noun	texas	3384 (40.2%)
noun	pictures	2601 (30.9%)
adjective	big	599 (7.1%)
URI	ebay.com	495 (5.9%)
preposition	in	310 (3.7%)
unknown	y	208 (2.5%)
verb	get	198 (2.4%)
other	conference06-07	174 (2.1%)
comma	,	72 (0.9%)
gerund	running	69 (0.8%)
number	473	67 (0.8%)
conjunction	and	65 (0.8%)
determiner	the	56 (0.7%)
pronoun	she	53 (0.6%)
adverb	quickly	28 (0.3%)
possessive	's	19 (0.2%)
symbol	(	18 (0.2%)
sentence-ender	?	5 (0.1%)
not	n't	2 (0.0%)

Table 1: Tags used for labeling part-of-speech in web-search queries.

Our contrasting tag sets reflect an extremely different use of the English language and corresponding part-of-speech distribution. For example, the Brown tag set contains unique tags for 35 types of verbs. We use a single label to indicate all cases of verbs. However, the corpora the Brown tag set was designed for consists primarily of complete, natural-language sentences. Essentially, every sentence contains at least one verb. In contrast, a verb of any type accounts for only 2.35% of our tags. Similarly, the Brown corpus contains labels for 15 types of determiners. This class makes up just 0.66% of our data.

Our most common tag is the proper noun, which constitutes 40% of all query terms, and proper nouns and nouns together constitute 71% of query terms. In the Brown corpus, by contrast, the most common tag, noun, constitutes about 13% of terms. Thus the distribution of tag types in queries is quite different from typical edited and published texts, and in particular, proper nouns are more common than regular nouns.

2.3 Capitalization in Query Data

Although we have chosen to work with lowercase data, web search queries sometimes contain capi-

Use of Capitals	Count	%	Example
Proper-nouns capitalized	48	47%	list of Filipino riddles
Query-Initial-Caps	10	10%	Nautical map
Init-Caps + Proper-Nouns	7	7%	Condos in Yonkers
Acronym	4	4%	location by IP address
Total standard capitalization	69	67%	
All-caps	26	25%	FAX NUMBER FOR ALLEN CANNING CO
Each word capitalized	6	6%	Direct Selling
Mixed	2	2%	SONGS OF MEDONA music feature:audio
Total non-standard capitalization	34	33%	

Table 2: Ways capitalization is used in web-search queries.

talization information. Since capitalization is frequently used in other corpora to identify proper nouns, we reviewed its use in web-search queries. We found that the use of capitalization is inconsistent. On a sample of 290,122 queries from August 2006 only 16.8% contained some capitalization, with 3.9% of these all-caps. To review the use of capitalization, we hand-labeled 103 queries containing capital letters (Table 2).

Neither all-lowercase (83.2%) nor all-caps (3.9%) queries can provide us with any part-of-speech clues. But we would like to understand the use of capitalization in queries with varied case. In particular, how frequently does first-letter capitalization indicate a proper noun? We manually part-of-speech tagged 75 mixed-case queries, which contained 289 tokens, 148 of which were proper nouns. The baseline fraction of proper nouns in this sample is thus 51% (higher than the overall background of 40.2%). A total of 176 tokens were capitalized, 125 of them proper nouns. Proper nouns thus made up 73.3% of capitalized tokens, which is larger than the background occurrence of proper nouns. We can conclude from this that capitalization in a mixed-case query is a fair indicator that a word is a proper noun. However, the great majority of queries contain no informative capitalization, so the great majority of proper nouns in search queries must be uncapitalized. We cannot, therefore, rely on capitalization to identify proper nouns.

With this knowledge of the infrequent use of capital letters in search queries in mind, we will examine the effects of ignoring or using a query's capitalization for part-of-speech tagging in Section 3.4.2.

3 Tagger Accuracy on Search Queries

To investigate automation of the tagging process, we trained taggers on our manually labeled query set. We used 10-fold cross-validation, with 90% of the data used for training and the remaining data used for testing. In the sections below, we used two datasets. The first consists of 1602 manually labeled queries. For the experiments in Section 3.5 we labeled additional queries, for a total of 2503 manually labeled queries.

3.1 Part-of-Speech Tagging Software

We experimented with two freely available part-of-speech taggers: The Brill Tagger (Brill, 1995) and The Stanford Tagger (Toutanova and Manning, 2000; Toutanova et al., 2003).

The Brill tagger works in two stages. The initial tagger queries a lexicon and labels each token with its most common part-of-speech tag. If the token is not in the lexicon, it labels the token with a default tag, which was "proper noun" in our case. In the second stage, the tagger applies a set of lexical rules which examine prefixes, suffixes, and infixes. The tagger may then exchange the default tag based on lexical characteristics common to particular parts of speech. After application of lexical rules, a set of contextual rules analyze surrounding tokens and their parts of speech, altering tags accordingly.

We chose to experiment primarily with the Brill tagger because of its popularity, the human-readable rules it generates, and its easily modifiable code base. In addition, the clearly defined stages and incorporation of the lexicon provide an accessible way to supply external lexicons or entity-detection routines, which could compensate for the sparse contextual information of search queries.

We also experimented with the Stanford Log-Linear Part-of-Speech Tagger, which presently holds the best published performance in the field at 96.86% on the Penn Treebank corpus. It achieves this accuracy by expanding information sources for tagging. In particular, it provides "(i) more extensive treatment of capitalization for unknown words; (ii) features for the disambiguation of the tense forms of verbs; (iii) features for disambiguating particles from prepositions and adverbs." It uses a maximum-entropy approach to handle information diversity without assuming predictor independence (Toutanova and Manning, 2000).

3.2 Baseline: Most Common Tag

With proper nouns dominating the distribution, we first considered using the accuracy of labeling all tokens "proper noun" as a baseline. In this case, we labeled 1953 of 4759 (41.0%) tokens correctly. This is a significant improvement over the accuracy of tagging all words as "noun" on the Brown corpus (approximately 13%), reflecting the frequent occurrence of proper nouns in search queries. However, to examine the grammatical structure of search queries we must demonstrate that they are not simply collections of words. With this in mind, we chose instead to use the most common part-of-speech tag for a word as a baseline. We evaluated the baseline performance on our manually labeled dataset, with URLs removed. Each token in the set was assigned its most common part of speech, according to the Brill lexicon. In this case, 4845 of 7406 tokens were tagged correctly (65.42%).

3.3 Effect of Type of Training Data

The Brill tagger software is pre-trained on the standard Wall Street Journal corpus, so the simplest possible approach is to apply it directly to the query data set. We evaluated this "out-of-the-box" performance on our 1602 manually labeled queries, after mapping tags to our reduced tag set. (Our effective training-set size is 1440 queries, since 10% were held out to measure accuracy through cross validation.) The WSJ-trained tagger labeled 2293 of 4759 (48.2%) tags correctly, a number well below the baseline performance, demonstrating that application of the contextual rules that Brill learns from the syntax of natural-language corpora has a negative effect on accuracy in the context of queries. When we re-trained Brill's tagger on a manually labeled set of queries, we saw accuracy increase to 69.7%. The data used to train the tagger therefore has a significant effect on its accuracy (Table 3). The accuracy of the tagger trained on query data is above the baseline, indicating that search queries are somewhat more than collections of words.

3.4 Improving Tagger Accuracy

We conducted several experiments in improving tagger accuracy, summarized in Table 3 and described in detail below.

3.4.1 Adding External Lexicon

With a training-set size of 1500 queries, comprising a lexicon of roughly 4500 words, it is natural to question if expanding the lexicon by incorporating external sources boosts performance. To this end, we lower-cased the lexicon of 93,696 words provided by the Brill tagger, mapped the tags to our own tag set, and merged our lexicon from queries. This experiment resulted in an accuracy of 71.1%, a 1.4% increase.

One explanation for the limited increase is that this lexicon is derived from the Brown corpus and the Penn Treebank tagging of the Wall Street Journal. These corpora are based on works published in 1961 and 1989-1992 respectively. As shown in Table 1, proper nouns dominate the distribution of search-engine queries. Many of these queries will involve recent products, celebrities, and other time-sensitive proper nouns. We speculate that Web-based information resources could be leveraged to expand the lexicon of timely proper nouns, thereby enhancing performance.

3.4.2 Experiments with Perfect Capitalization

The overall performance of the pre-trained Brill tagger on our query set may be due to its poor performance on proper nouns, our most frequent part of speech. In the WSJ newspaper training data, proper-nouns always start with a capital letter. As discussed in Section 2.3, capitalization is rare in web-search queries. To examine the effect of the missing capitalization of proper nouns, we evaluated a pre-trained Brill tagger on our previously mentioned manually labeled corpus of 1602 queries altered such that only the proper nouns were capitalized. In this case, the tagger reached an extraordinary 89.4% accuracy (Table 3). Unfortunately, the vast majority of queries do not contain capitalization information and those that do often contain misleading information. The pre-trained tagger achieved only a 45.6% accuracy on non-lowercased queries, performing even worse than on the set with no capitalization at all.

Experiment	Accuracy
Label-all-proper-noun	41.0%
WSJ-trained	48.2%
most-freq-tag-WSJ	64.4%
re-trained	69.7%
retrained + WSJ lexicon	71.1%
user capitalization	45.6%
oracle capitalization	89.4%
automatic capitalization	70.9%

Table 3: Tagging experiments on small labeled corpus. Experiments were conducted on lower-cased queries except where specifically indicated.

3.4.3 Automatic Capitalization

We saw in Section 2.3 that web searchers rarely use capitalization. We have also seen that a pre-trained Brill tagger run on queries with perfect capitalization ("oracle" capitalization) can achieve 89.4% accuracy. We now look at how performance might be affected if we used an imperfect algorithm for capitalization.

In order to attempt to capitalize the proper nouns in queries, we used a machine-learned system which searches for the query terms and examines how often they are capitalized in the search results, weighting each capitalization occurrence by various features (Bartz et al., 2008). Though the capitalization system provides 79.3% accuracy, using this system we see an only a small increase of accuracy in part-of-speech tagging at 70.9%. This system does not improve significantly over the tagger trained on the lower-cased corpus. One explanation is that capitalization information of this type could only be obtained for 81.9% of our queries. Multiplied by accuracy, this implies that roughly 81.9% * 79.3% = 65.0% of our proper nouns are correctly cased. This suggests that any technique for proper-noun detection in search-engine queries must provide over 65.0% accuracy to see any performance increase.

Finally we looked at the capitalization as input by searchers. We trained on the oracle-capitalized corpus, and tested on raw queries without normalization. We saw an accuracy of just 45.6%. Thus using the capitalization input by web searchers is misleading and actually hurts performance.

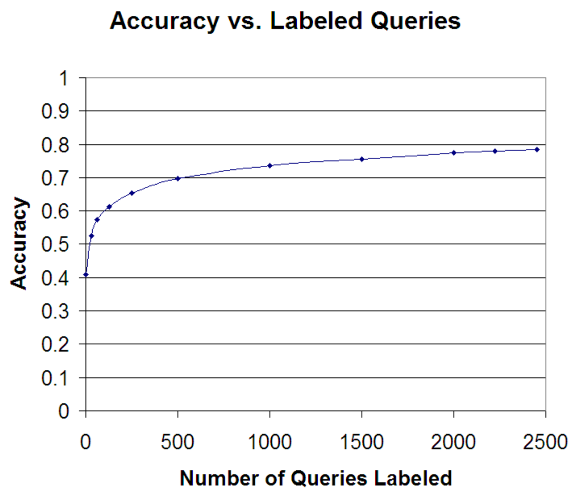

Figure 1: Brill's tagger trained on web-search queries. We see that the most significant gains in performance are with the first few hundred labeled examples, but even after 2500 examples are labeled, more labeled data continues to improve performance.

3.5 Learning Curve

It is important to understand whether tagger accuracy is limited by the small size of our manually labeled dataset. To examine the effect of dataset size, we trained Brill's tagger with increasing numbers of labeled queries and evaluated accuracy with each set size. In the interim between conducting the experiments of sections 3.1 through 3.3 and those of section 3.5, we were able to obtain 1120 new labeled queries, allowing us to extend the learning curve. With our complete corpus of 2722 labeled examples (for a cross-validated training-set size of 2450 labeled examples, URLs omitted), we see an accuracy of 78.6% on a per-token basis. We see the most significant gains in performance with the first few hundred labeled examples, but even after 2500 examples are labeled, more labeled data continues to improve performance.

3.6 Comparing Taggers to Suggest Methods for Boosting Performance

In Table 4 we see a comparison of Brill's tagger to the Stanford tagger trained on 2450 labeled queries. The 0.3% performance increase is not statistically significant. As listed in Section 3, the features the Stanford tagger adds to achieve high accuracy in traditional natural-language corpora are not in-

Tagger	Accuracy
Brill	78.6%
Stanford	78.9%

Table 4: Comparison of Brill's tagger to the Stanford tagger, on our corpus of manually annotated query logs.

formative in the domain of search-engine queries. We believe greater performance on our data will be achieved primarily through examination of common sources of inter-rater disagreement (such as consistent handling of ambiguity) and incorporation of external sources to detect proper nouns not in the lexicon.

To validate our intuition that expanding the lexicon will boost performance, we obtained a proprietary list of 7385 known trademarked terms used in the sponsored-search industry. Treating these phrases as proper nouns and adding them to the lexicon from the Wall Street Journal supplied with the Brill tagger, we see our cross validated accuracy improve to 80.2% (with a standard deviation of 1.85%), the highest score achieved in our experiments. We find it likely that incorporation of more external lexical sources will result in increased performance.

Our experiments also support our hypothesis that addressing inter-annotator agreement will boost performance. We can see this by examining the results of the experiments in section 3.3 verses section 3.5. In section 3.3, we see the accuracy on the query-trained Brill tagger is 69.7%. As mentioned, for the experiment in section 3.5, we were able to obtain 1120 new queries. Each of these newly labeled queries came from the same labeler, who believes their handling of the ambiguities inherent in search queries became more consistent over time. With the same training-set size of 1440 used in section 3.3, Figure 1 shows performance at 1440 queries is roughly 6% higher. We believe this significant improvement is a result of more consistent handling of query ambiguity obtained through labeling experience.

4 Query Grammar

The above-baseline performance of the Brill tagger trained on web-search queries suggests that web-search queries exhibit some degree of syntactical structure. With a corpus of queries labeled with part-of-speech information, we are in a position to analyze this structure and characterize the typical patterns of part-of-speech used by web searchers. To this end, we randomly sampled and manually labeled a set of 222 queries from the part-of-speech dataset used for tagger training mentioned above. Each query was labeled with a single meta-tag indicating query type. Two author-judges simultaneously labeled queries and created the set of meta-tags during much discussion, debate, and linguistic research. A list of our meta-tags and the distribution of each are provided in Table 5. We can see that queries consisting of a noun-phrase dominate the distribution of query types, in contrast with the popularly held belief that queries consist of unstructured collections of terms.

To determine how accurately a meta-tag can be determined based on part-of-speech labels, we created a grammar consisting of a set of rules to rewrite part-of-speech tags into higher-level grammatical structures. These higher-level grammatical structures are then rewritten into one of the seven classes of meta-tags seen in Table 5. Our grammar was constructed by testing the output of our rewrite rules on queries labeled with par-of-speech tags that were not part of the 222 queries sampled for meta-tag labeling. Grammar rules were revised until the failure rate on previously untested part-of-speech-labeled queries stabilized. Failure was evaluated by two means. In the first case, the grammar rules failed to parse the sequence of part-of-speech tags. In the second case, the grammar rules led to an inappropriate classification for a query type. As during the labeling phase, the two author-labelers simultaneously reached a consensus on whether a parse failed or succeeded, rendering an inter-annotator score inapplicable. The resulting grammar was then tested on the 222 queries with query-type meta-tags.

Our rules function much like production rules in context-free grammars. As an example, the two-tag sequence "determiner noun" will be rewritten as "noun phrase." This in turn could be re-written into a larger structure, which will then be rewritten into a meta-tag of query type. The primary difference between a context-free grammar or probabilistic context-free grammar (such as that employed by Lima and Pederson (de Lima and Pederson, 1999))

Query Gramm. Type	Example	Freq (%)
noun-phrase	free mp3s	155 (69.8%)
URI	http:answers.yahoo.com/	24 (10.8%)
word salad	mp3s free	19 (8.1%)
other-query	florida elementary reading conference2006-2007	15 (6.8%)
unknown	nama-nama calon praja ipdn	6 (2.7%)
verb-phrase	download free mp3s	3 (1.4%)
question	where can I download free mp3s	1 (0.45%)

Table 5: Typical grammatical forms of queries used by web searchers, with distribution based on a sample of 222 hand-labeled queries.

and our grammar is that our rules are applied iteratively as opposed to recursively. As such, our grammar yields a single parse for each input.

Some of our rules reflect the telegraphic nature of web queries. For example, it is much more common to see an abbreviated noun-phrase consisting of adjective-noun, than one consisting of determiner-adjective-noun.

Examining the Table 5, we see that just labeling a query "noun-phrase" results in an accuracy of 69.8%. Our grammar boosted this high baseline by 14% to yield an final accuracy result of 83.3% at labeling queries with their correct meta-type. These meta-types could be useful in deciding how to handle a query. Further enhancements to the grammar would likely yield a performance increase. However, we feel accuracy is currently high enough to continue with experiments towards application of leveraging grammar-deduced query types for information retrieval.

We can think of some of these meta-types as elided sentences. For example, the noun-phrase queries could be interpreted as requests of the form "how can I obtain X" or "where can I get information on X", while the verb-phrase queries are requests of the form "I would like to DO-X".

5 Applications of Part-of-Speech Tagging

Since search queries are part of an information retrieval task, we would like to demonstrate that part-of-speech tagging can assist with that task. We conducted two experiments with a large-scale machine-learned web-search ranking system. In addition, we considered the applicability of part-of-speech tags to the question of query reformulation.

5.1 Web Search Ranking

We worked with a proprietary experimental testbed in which features for predicting the relevance of a query to a document can be tested in a machine-learning framework. Features can take a wide variety of forms (boolean, real-valued, relational) and apply to a variety of scopes (the page, the query, or the combination). These features are evaluated against editorial judgements and ranked according to their significance in improving the relevance of results. We evaluated two part-of-speech tag-based features in this testbed.

The first experiment involved a simple query-level feature indicating whether the query contained a noun or a proper noun. This feature was evaluated on thousands of queries for the test. At the conclusion of the test, this feature was found to be in the top 13% of model features, ranked in order of significance. We believe this significance represents the importance of recognizing the presence of a noun in a query and, of course, matching it. Within this experimental testbed a statistically significant improvement of information-retrieval effectiveness is notoriously difficult to attain. We did not see a significant improvement in this metric. However, we feel that our feature's high ranking warrants reporting and hints at a potentially genuine boost in retrieval performance in a system less feature-rich.

The second experiment was more involved and reflected more of our intuition about the likely application of part-of-speech tagging to the improvement of search results. In this experiment, we part-of-speech tagged both queries and documents. Documents were tagged with a conventionally trained Brill tagger with the resulting Penn-style tags mapped to our tag set. Many thousands of query-document pairs were processed in this manner. The feature was based on the percent of times the part-of-speech tag of a word in the query matched the part-of-speech tag of the same word in the document. This feature was ranked in the top 12% by significance, though we again saw no statistically significant increase in overall retrieval performance.

5.2 Query Reformulation

We considered the application of part-of-speech tagging to the problem of query reformulation, in which

Part-of-speech	p(subst)	subst / seen
Number	0.49	148 / 302
Adjective	0.46	2877 / 6299
Noun	0.42	15038 / 35515
Proper noun	0.39	21478 / 55331
Gerund	0.37	112 / 300
Verb	0.31	1769 / 5718
Pronoun	0.23	300 / 1319
Conjunction	0.18	85 / 464
Adverb	0.13	105 / 790
Determiner	0.10	22 / 219
Preposition	0.08	369 / 4574
Possessive	0.08	25 / 330
Not	0.03	1 / 32
Symbol	0.02	16 / 879
Other	0.02	78 / 3294
Sentence-ender	0.01	3 / 234
Comma	0.00	4 / 991

Table 6: Probability of a word being reformulated from one query to the next, by part-of-speech tag. While proper-nouns are the most frequent tag in our corpus, adjectives are more frequently reformulated, reflecting the fact that the proper nouns carry the core meaning of the query.

a single word in the query is altered within the same user session. We used a set of automatically tagged queries to calculate change probabilities of each word by part-of-speech tag and the results are shown in Table 6.

The type of word most likely to be reformulated is "number." Examples included changing a year ("most popular baby names 2007" → "most popular baby names 2008"), while others included model, version and edition numbers ("harry potter 6" → "harry potter 7") most likely indicating that the user is looking at variants on a theme, or correcting their search need. Typically a number is a modifier of the core search meaning. The next most commonly changed type was "adjective," perhaps indicating that adjectives can be used to refine, but not fundamentally alter, the search intent. Nouns and proper nouns are the next most commonly modified types, perhaps reflecting user modification of their search need, refining the types of documents retrieved. Other parts of speech are relatively seldom modified, perhaps indicating that they are not viewed as having a large impact on the documents retrieved.

We can see from the impact of the search engine ranking features and from the table of query reformulation likelihood that making use of the grammatical structure of search queries can have an impact on result relevance. It can also assist with tasks associated with improving recall, such as query reformulation.

6 Conclusion

We have quantified, through a lexicostatistical analysis, fundamental differences between the natural language used in standard English-language corpora and English search-engine queries. These differences include reduced granularity in part-of-speech classes as well as the dominance of the noun classes in queries at the expense of classes such as verbs frequently found in traditional corpora. In addition, we have demonstrated the poor performance of taggers trained on traditional corpora when applied to search-engine queries, and how this poor performance can be overcome through query-based corpora. We have suggested that greater improvement can be achieved by proper-noun detection through incorporation of external lexicons or entity detection. Finally, in preliminary investigations into applications of our findings, we have shown that query part-of-speech tagging can be used to create significant features for improving the relevance of web search results and may assist with query reformulation. Improvements in accuracy can only increase the value of POS information for these applications. We believe that query grammar can be further exploited to increase query understanding and that this understanding can improve the overall search experience.

Mining and Modeling Relations between Formal and Informal Chinese Phrases from Web Corpora

Zhifei Li and **David Yarowsky**

Johns Hopkins University, Baltimore, MD 21218, USA
zhifei.work@gmail.com and yarowsky@cs.jhu.edu

Abstract

We present a novel method for discovering and modeling the relationship between informal Chinese expressions (including colloquialisms and instant-messaging slang) and their formal equivalents. Specifically, we proposed a bootstrapping procedure to identify a list of candidate informal phrases in web corpora. Given an informal phrase, we retrieve contextual instances from the web using a search engine, generate hypotheses of formal equivalents via this data, and rank the hypotheses using a conditional log-linear model. In the log-linear model, we incorporate as feature functions both rule-based intuitions and *data co-occurrence* phenomena (either as an explicit or indirect definition, or through formal/informal usages occurring in free variation in a discourse). We test our system on manually collected test examples, and find that the (*formal-informal*) relationship discovery and extraction process using our method achieves an average 1-best precision of 62%. Given the ubiquity of informal conversational style on the internet, this work has clear applications for text normalization in text-processing systems including machine translation aspiring to broad coverage.

1 Introduction

Informal text (e.g., newsgroups, online chat, blogs, etc.) is the majority of all text appearing on the Internet. Informal text tends to have very different style from formal text (e.g., newswire, magazine, etc.). In particular, they are different in vocabulary, syntactic structure, semantic interpretation, discourse structure, and so on. On the other hand, certain relations exist between the informal and formal text, and informal text often has a viable formal equivalent. Table 1 shows several naturally occurring examples of informal expressions in Chinese, and Table 2 provides a more detailed inventory and characterization of this phenomena[1]. The first example of informal phrase "88" is used very often in Chinese on-line chat when a person wants to say "bye-bye" to the other person. This can be explained as follows. In Chinese, the standard equivalent to "bye-bye" is "拜拜" whose *PinYin* is "BaiBai". Coincidentally, the *PinYin* of "88" is "BaBa". Because "BaBa" and "BaiBai" are near homophones, people often use "88" to represent "拜拜", either for input convenience or just for fun. The other relations in Table 1 are formed due to similar processes as will be described later.

Formal	**Informal**
拜拜 (BaiBai)[bye-bye]	88 (BaBa)
喜欢 (XiHuan)[like]	稀饭 (XiFan)[gruel]
哥哥 (GeGe)[elder brother]	GG
歌迷 (GeMi)[fans]	粉丝 (FenSi)[a food]

Table 1: Example Chinese *Formal-informal* Relations. The *PinYin* pronunciation is in parentheses and an optional literal gloss is in brackets.

Due to the often substantial divergence between

[1]For clarity, we represent Chinese words in the format: Chinese characters (optional *PinYin* equivalent in parentheses and optional English gloss in brackets).

informal and formal text, a text-processing system trained on formal text does not typically work well on informal genres. For example, in a machine translation system (Koehn et al., 2007), if the bilingual training data does not contain the word "稀饭" (the second example in Table 1), it leaves the word untranslated. On the other hand, if the word "稀饭" does appear in the training data but it has only a translation "gruel" as that is the meaning in the formal text, the translation system may wrongly translate "稀饭" into "gruel" for the *informal* text where the word "稀饭" is more likely to mean "like". Therefore, as a text-normalization step, it is desirable to transform the informal text into its standard formal equivalent before feeding it into a general-purpose text-processing system. Unfortunately, there are many processes for generating informal expressions in common use today. Such transformations are highly flexible/diverse, and new phrases are invented on the Internet every day due to major news events, popular movies, TV shows, radio talks, political activities, and so on. Therefore, it is of great interest to have a *data-driven* method that can *automatically* find the relations between informal and formal expressions.

In this paper, we present a novel method for discovering and modeling the relationship between informal Chinese expressions found in web corpora and their formal equivalents. Specifically, we implement a bootstrapping procedure to identify a list of candidate informal phrases. Given an individual informal phrase, we retrieve contextual instances from the web using a search engine (in this case, *www.baidu.com*), generate hypotheses of formal equivalents via this data, and rank the hypotheses using a conditional log-linear model. In the log-linear model, we incorporate as feature functions both rule-based intuitions and *data co-occurrence* phenomena (either as an explicit or indirect definition, or through formal/informal usages occurring in free variation in a discourse). We test our system on manually collected test examples[2], and find that the (*formal-informal*) relationship discovery and extraction process using our method achieves an average precision of more than 60%. This work has applications for text normalization in many general-purpose text-processing tasks, e.g., machine translation.

To the best of our knowledge, our work is the first published machine-learning approach to productively model the broad types of relationships between informal and formal expressions in Chinese using web corpora.

2 Formal to Informal: Phenomena and Examples

In this section, we describe the phenomena and provide examples of the relations between formal and informal expressions in Chinese (we refer to the relation as *formal-informal* phrases hereafter, even in the case of single-word expressions). We manually collected 908 *formal-informal* relations, and classified these relations into four categories. We collected these pairs by investigating multiple webpages where the *formal-informal* relations are manually compiled, and then merged these seed relations and removed duplicates. In this way, the 908 examples should give good coverage on the typical categories in the *formal-informal* relations. Also, the distribution of the categories found in the 908 examples should be representative of the actual distribution of the *formal-informal* relations occurring in the real text. Table 2 presents these categories and examples in each category. In the last column, the table also shows the relative frequency of each category, computed based on the 908 examples. Recall that we represent Chinese words in the format: Chinese characters (optional *PinYin* equivalent in parentheses and optional English gloss in brackets).

2.1 Homophone

In general, a homophone is a word that is pronounced the same as another word but differs in meaning and/or written-form. Here, we use the word "homophone" in a loose way. In particular, we refer an informal phrase as a homophone of a formal phrase if its pronunciation is the same or *similar* to the formal phrase. In the three examples belonging to the homophone category in Table 2, the first example is a true homophone, while the other two are loose homophones. The third example represents a major sub-class where the informal phrase is a *number* (e.g., 88).

[2]The training and test examples are freely available at http://www.cs.jhu.edu/∼zfli.

Category	**Formal**	**Informal**	**%**
Homophone	版主 (BanZhu) [system administrator]	斑竹 (BanZhu) [bamboo]	4.2
	喜欢 (XiHuan)[like]	稀饭 (XiFan)[gruel]	4.4
	拜拜 (BaiBai)[bye-bye]	88 (BaBa)	21
Abbreviation	美国军队 (MeiGuoJunDui)[american army]	美军 (MeiJun)[american army]	3.8
Acronym	哥哥 (GeGe)[elder brother]	GG	12.3
	女朋友 (N*ü*PengYou)[girl friend]	GF	7.2
Transliteration	歌迷 (GeMi)[fans]	粉丝 (FenSi)[a Chinese food]	2.3
	谢谢 (XieXie)[thank you]	3Q (SanQiu)	
Others	希拉里粉丝 (XiLaLiFenSi)[fans of Hilary]	稀饭 (XiFan)[gruel]	44.8
	奥巴马粉丝 (AoBaMaFenSi)[fans of Obama]	藕粉 (OuFen)[a food]	
	超强 (ChaoQiang)[super strong]	走召弓虽 (ZouZhaoGongXu)	

Table 2: Chinese *Formal-informal* Relations: Categories and Examples. Literal glosses in brackets.

For illustrative purposes, we can present the *transformation path* showing how the informal phrase is obtained from the formal phrase. In particular, the *transformation path* for this category is “Formal → PinYin → Informal (similar or same PinYin as the formal phrase)”.

2.2 Abbreviation and Acronym

A Chinese *abbreviation* of a formal phrase is obtained by selecting *one or more* characters from this formal phrase, and the selected characters can be at *any* position in the formal phrase (Li and Yarowsky, 2008; Lee, 2005; Yin, 1999). In comparison, an *acronym* is a special form of abbreviation, where only the first character of each word in the formal phrase is selected to form the informal phrase. Table 2 presents three examples belonging to this category. While the first example is an abbreviation, and the other two examples are acronyms.

The *transformation path* for the second example is “Formal → PinYin → Acronym”, and the *transformation path* for the third example is “Formal → English → Acronym”. Clearly, they differ in whether *PinYin* or English is used as a bridge.

2.3 Transliteration

A transliteration is transcribing a word or text written in one writing system into another writing system. Table 2 presents examples belonging to this category. In the first example, the Chinese informal phrase “粉丝 (FenSi)[a Chinese food]” can be thought as a transliteration of the English phase “fans” as the pronunciation of “fans” is quite similar to the *PinYin* “FenSi”.

The *transformation path* for this category is “Formal → English → Chinese Transliteration”.

2.4 Others

Due to the inherently informal and flexible nature of expressions in informal genre, the formation of an informal phrase can be very complex or ad-hoc. For example, an informal phrase can be generated by applying the above transformation rules *jointly*. More importantly, many relations cannot be described using a simple set of rules. Table 2 presents three such examples, where the first two examples are generated by applying rules *jointly* and the third example is created by decomposing the Chinese characters in the formal form. The statistics collected from the 904 examples tells us that about 45% of the relations belonging to this category. This motivates us to use a *data-driven* method to automatically discover the relations between informal and formal phrases.

3 Data Co-occurrence

In natural language, related words tend to appear together (i.e., co-occurrence). For example, *Bill Gates* tends to appear together with *Microsoft* more often than expected by chance. Such co-occurrence may imply the existence of a relationship, and is exploited in *formal-informal* relation discovery under different conditions.

3.1 Data Co-occurrence in Definitions

In general, for many informal phrases in popular use, there is likely to be an explicit definition somewhere that provides or paraphrases its meaning for an unfamiliar audience. People have created dedicated definition web-pages to explain the relations between formal and informal phrases. For example, the first example in Table 3 is commonly explained in many dedicated definition web-pages on the Internet. On the other hand, in some formal text (e.g., research papers), people tend to define the informal phrase before it is used frequently in the later part of the text. The second example of Table 3 illustrates this phenomena. Clearly, the definition text normally contains salient patterns. For example, the first example follows the "*informal*是*formal*的意思" definition pattern, while the second example follows the pattern "*formal* (*informal*)". This gives us a reliable way to seed and bootstrap a list of informal phrases as will be discussed in Section 4.1.

Relation	**Definition Text**
(女朋友, GF)	GF是女朋友的意思。
(世界卫生组织, 世卫)	香港的食水采用世界卫生组织 (世卫)饮用水水质指引……

Table 3: Data Co-occurrence in Definitions

3.2 Data Co-occurrence in Online Chat

Informal phrases appear in online chat very often for input convenience or just for fun. Since different people may have different ways or traditions to express semantically-equivalent phrases, one may find many nearby *data co-occurrence* examples in chat text. For example, in Table 4, after a series of message exchanges, person A wants to end the conversation and types "拜拜" (meaning "bye-bye"), person B later includes the same semantic content, but in a different (more or less formal) expression (e.g. "88").

	⋮
Person A:	对不起， 我要先下线了
Person A:	拜拜
Person B:	88

Table 4: Data Co-occurrence in Online Chat for Relation (拜拜, 88) meaning "bye-bye"

3.3 Data Co-occurrence in News Articles

For some *formal-informal* relations, since both of the informal and formal phrases have been used in public very often and people are normally aware of these relations, an author may use the informal and formal phrases interchangeably without bothering to explain the relations. This is particularly true in news articles for some well-known relations. Table 5 shows an example, where the abbreviation "冬奥会" (meaning "winter olympics") appears in the title and its full-form "冬季奥运会" appears in the text of the same document. In general, the relative distance between an informal phrase and its formal phrase varies. For example, they may appear in the same sentence, or in neighboring sentences.

Title	都灵**冬奥会**开幕式将激情上演
Text	新华社都灵2月9日电(记者丁莹阎涛)第20届**冬季奥运会**的开幕式将于当地时间10日晚8点在都灵奥林匹克体育场正式揭开神秘的面纱。

Table 5: Data Co-occurrence in News Article for Relation (冬季奥运会, 冬奥会) meaning "winter olympics"

4 Mining Relations between Informal and Formal Phrases from Web

In this section, we describe an approach that automatically discovers the relation between a formal phrase and an informal phrase from web corpora. Specifically, we propose a bootstrapping procedure to identify a list of candidate informal phrases. Given a target informal phrase, we retrieve a large set of of instances in context from the Web, generate candidate hypotheses (i.e, candidate formal phrases) from the data, and rank the hypotheses by using a conditional log-linear model. The log-linear model is very flexible to incorporate both the rule- and data-driven intuitions (described in Sections 2 and 3, respectively) into the model as feature functions.

4.1 Identifying Informal Phrases

Before finding the formal phrase corresponding to an informal phrase, we first need to identify informal phrases of interest. For example, one can collect informal phrases manually. However, this is too expensive as new relations between informal and formal phrases emerge every day on the Internet. Alternatively, one can employ a large amount of formal text (e.g., newswire) and informal text (e.g., Internet blogs) to derive such a list as follows. Specifically, from the informal corpus we can extract those phrases whose frequency in the informal corpus is significantly different from that in the formal corpus. However, such a list may be quite noisy, i.e., many of them are not informal phrases at all.

An alternative approach to extracting the informal phrases is to use a bootstrapping algorithm (e.g., Yarowsky (1995)). Specifically, we first manually collect a small set of example relations. Then, using these relations as a *seed set*, we extract the text *patterns* (e.g., the definition pattern showing how the informal and formal phrases co-occur in the data as discussed in Section 3.1). With these patterns, we identify many more new relations from the data and augment them into the seed set. The procedure iterates. Using such an approach, we should be able to extract a large list of *formal-informal* relations. Clearly, the list extracted in this way may be quite noisy, and thus it is important to exploit both the data- and rule-driven intuitions to rank these relations properly.

4.2 Retrieving Data from Web

Given an informal phrase, we retrieve training data from the web on the fly. Specifically, we first use a search engine to identify a set of hyper-links that point to web pages containing contexts relevant to the informal phrase, and then follow the hyper-links to download the web pages. The input to the search engine is a text query. One can simply use the informal phrase as a query. However, this may lead to a set of pages that have nothing to do with the informal phrase. For example, if we search the informal phrase “88” (the third example in Table 2) using the well-known Chinese search engine *www.baidu.com*, none of the top-10 pages are related to the informal phrase “88”. To avoid this situation, one can use a search engine that is dedicated to informal text search (e.g., *blogsearch.baidu.com*). Alternatively, one can use the general-purpose search engine but expanding the query with domain information. For example, for the informal phrase “88”, we can use a query “88 网络语言”, where “网络语言” means *internet language*.

4.3 Generating Candidate Hypotheses

Given an informal phrase, we generate a set of hypotheses which are candidate formal phrases corresponding to the informal phrase. We considered two general approaches to the generation of hypotheses.

Rule-driven Hypothesis Generation: One can use the rules described in Section 2 to generate a set of hypotheses. However, with this approach, one may generate an exponential number of hypotheses. For example, assuming the number of English words starting with a given letter is O($|V|$), we can generate O($|V|^n$) hypotheses given an *acronym* containing n letters. Another problem with this approach is that a relation between an informal phrase and a formal phrase may not be explained by a specific rule. In fact, as shown in the last row of Table 2, such relations consist of 44.8% of all corpus instances.

Data-driven Hypothesis Generation: With data retrieved from the Web, we can generate hypotheses by enumerating the frequent n-grams co-occurring with the informal phrase within certain distance. This exploits the *data co-occurrence* phenomena described in Section 3, that is, the formal phrase tends to co-occur with the informal phrase nearby in the data, for the multiple reasons described above. This can deal with the cases where the relation between an informal phrase and a formal phrase cannot be explained by a rule. However, it also suffers from the over-generation problem as in the rule-driven approach.

In this paper, we use the data-driven method to generate hypotheses, and rank the hypotheses using a conditional log-linear model that incorporates both the rule and data intuitions as feature functions.

4.4 Ranking Hypotheses: Conditional Log-linear Model

Log-linear models are known for flexible incorporation of features into the model. Each feature function reflects a hint/intuition that can be used to rank the hypotheses. In this subsection, we develop a conditional log-linear model that incorporates both the rule and data intuitions as feature functions.

4.4.1 Conditional Log-linear Model

Given an informal phrase (say x) and a candidate formal phrase (say y), the model assigns the pair a score (say $s(x, y)$), which will be used to rank the hypothesis y. The score $s(x, y)$ is a linear combination of the feature scores (say $\Phi_i(x, y)$) over a set of feature functions indexed by i. Formally,

$$s(x, y) = \sum_{i=1}^{K} \Phi_i(x, y) \times \alpha_i \tag{1}$$

where K is the number of feature functions defined and α_i is the weight assigned to the i-th feature function (i.e., Φ_i). To learn the weight vector $\vec{\alpha}$, we first define a probability measure,

$$P_{\vec{\alpha}}(y|x) = \frac{1}{Z(x, \vec{\alpha})} e^{s(x,y)} \tag{2}$$

where $Z(x, \vec{\alpha})$ is a normalization constant. Now, we define the regularized log-likelihood (LL_R) of the training data (i.e, a set of pairs of (x, y)), as follows,

$$LL_R(\vec{\alpha}) = \sum_{j=1}^{N} \log P_{\vec{\alpha}}(y_j|x_j) - \frac{||\vec{\alpha}||^2}{2\sigma^2} \tag{3}$$

where N is the number of training examples, and the regularization term $\frac{||\vec{\alpha}||^2}{2\sigma^2}$ is a Gaussian prior with a variance σ^2 (Roark et al., 2007). The optimal weight vector $\vec{\alpha}^*$ is obtained by maximizing the regularized log-likelihood (LL_R), that is,

$$\vec{\alpha}^* = \arg\max_{\vec{\alpha}} LL_R(\vec{\alpha}) \tag{4}$$

To maximize the above function, we use a limited-memory variable method (Benson and More, 2002) that is implemented in the TAO package (Benson et al., 2002) and has been shown to be very effective in various natural language processing tasks (Malouf, 2002).

During test time, the following **decision rule** is normally used to predict the optimal formal phrase y^* for a given informal phrase x,

$$y^* = \arg\max_{y} s(x, y). \tag{5}$$

4.4.2 Feature Functions

As mentioned before, we incorporate both the rule- and data-driven intuitions as feature functions in the log-linear model.

Rule-driven feature functions: Clearly, if a pair (x, y) matches the rule patterns described in Table 2, the pair has a high possibility to be a true *formal-informal* relation. To reflect this intuition, we develop several feature functions as follows.

- LD-PinYin(x, y): the *Levenshtein distance* on PinYin of x and y. The distance between two PinYin characters is weighted based on the similarity of pronunciation, for example, the weight $w(l, n)$ is smaller than the weight $w(a, z)$.
- LEN-PinYin(x, y): the difference in the number of PinYin characters between x and y.
- Is-PinYin-Acronym(x, y): is x a PinYin acronym of y? For example,
  Is-PinYin-Acronym(GG, 哥哥)=1,
  Is-PinYin-Acronym(GG, 兄弟)=0.
- Is-CN-Abbreviation(x, y): is x a Chinese abbreviation of y? For example,
  Is-CN-Abbreviation(美军,美国军队)=1,
  Is-CN-Abbreviation(美军,中国军队)=0.

Data-driven feature functions: As described in Section 3, the informal and formal phrases tends to co-occur in the data. Here, we develop several feature functions to reflect this intuition.

- n-gram co-occurrence relative frequency: we collect the n-grams that occur in the data within a window of the occurrence of the informal phrase, and compute their relative frequency as feature values. Since different orders of grams will have quite different statistics, we define 7 features in this category: 1-gram, 2-gram, 3-gram, 4-gram, 5-gram, 6to10-gram, and 11to15-gram. Note that the *order* n of a n-gram is in terms of number of Chinese characters instead of words.

- Features on a definition pattern: we have discussed definition patterns in Section 3.1. For each definition pattern, we can define a feature function saying that if the co-occurrence of x and y satisfies the definition pattern, the feature value is one, otherwise is zero.
- Features on the number of relevant web-pages: another interesting feature function can be defined as follows. For each candidate relation (x, y), we use the pair as a query to search the web, and treat the *number* of pages returned by the search engine as a feature value.[3] However, these features are quite expensive as millions of queries may need to be served.

Category	**Feature**	**Weight**
Rule-driven	LD-PinYin	0.800
	Len-PinYin	0.781
	Is-PinYin-Acronym	7.594
	Is-CN-Abbreviation	7.464
Data-driven	1-gram	14.506
	2-gram	108.193
	3-gram	82.975
	4-gram	66.872
	5-gram	42.258
	6to10-gram	21.229
	11to15-gram	0.985

Table 6: Optimal Weights in the Log-linear Model

5 Experimental Results

Recall that in Section 2 we categorize the *formal-informal* relations based on the manually collected relations. In this section, we use a subset of them for training and testing. In particular, we use 252 examples to train the log-linear model that is described in Section 4, and use 249 examples as test data to compute the precision.[4]

Table 6 shows the weights[5] learned for the various feature functions described in Section 4.4. Clearly, different feature functions get quite different weights. This is intuitive as the feature functions may differ in the scale of the feature values or in their importance in ranking the hypotheses. In fact, this shows the importance of using the log-linear model to learn the optimal weights in a principled and automatic manner, instead of manually tuning the weights in an ad-hoc way.

Tables 7-9 show the precision results for different categories as described in Section 2, using the rule-driven, data-driven, or both rule and data-driven features, respectively. In the tables, the precision corresponding to the "top-N" is computed in the following way: if the true hypothesis is among the top-N hypotheses ranked by the model, we tag the classification as correct, otherwise as wrong. Clearly, the larger the N is, the higher the precision is. Computing the top-N precision (instead of just computing the usual top-1 precision) is meaningful especially when we consider our relation extractor as an intermediate step in an end-to-end text-processing system (e.g., machine translation) since the final decision can be delayed to later stage based on more evidence. In general, our model gets quite respectably high precision for such a task (e.g., more than 60% for top-1 and more than 85% for top-100) when using both data and rule-driven features, as shown in Table 9. Moreover, the data-driven features are more helpful than the rule-driven features (e.g, 25.3% absolute improvement in 1-best precision), while the combination of these features does boost the performance of any individual feature set (e.g., 10.4% absolute improvement in 1-best precision over the case using data-driven features only).

We also carried out experiments (see Table 10) in the bootstrapping procedure described in Section 4.1. In particular, we start from a seed set having 130 relations. We identify the frequent patterns from the data retrieved from the web for these seed examples. Then, we use these patterns to identify many more new possible *formal-informal* relations. After the first iteration, we select the top 3000 pairs of relations matched by the patterns. The recall of a manually collected test set (having 750 pairs) on these 3000 pairs is around 30%, which is quite promising given the highly noisy data.

[3]Note that the number of pages relevant to a query can be easily obtained as most search engines return this number.

[4]Again, the training and test examples are freely available at http://www.cs.jhu.edu/∼zfli.

[5]Note that we do not use the features on definition patterns and on the number of relevant web pages, for efficiency.

6 Related Work

Automatically extracting the relations between full-form Chinese phrases and their abbreviations is an interesting and important task for many NLP applications (e.g., machine translation, information retrieval, etc.). Recently, Chang and Lai (2004), Lee (2005), Chang and Teng (2006), Li and Yarowsky (2008) have investigated this task. Specifically, Chang and Lai (2004) describes a hidden markov model (HMM) to model the relationship between a full-form phrase and its abbreviation, by treating the abbreviation as the *observation* and the full-form words as *states* in the model. Using a set of manually-created *full-abbreviation* relations as training data, they report experimental results on a *recognition* task (i.e., given an abbreviation, the task is to obtain its full-form, or the vice versa). Chang and Teng (2006) extends the work in Chang and Lai (2004) to automatically extract the relations between full-form phrases and their abbreviations, where both the full-form phrase and its abbreviation are not given. Clearly, the method in (Chang and Lai, 2004; Chang and Teng, 2006) is *supervised* because it requires the *full-abbreviation* relations as training data. Li and Yarowsky (2008) propose an *unsupervised* method to extract the relations between full-form phrases and their abbreviations. They exploit the *data co-occurrence* phenomena in the newswire text, as we have done in this paper. Moreover, they augment and improve a statistical machine translation by incorporating the extracted relations into the baseline translation system.

Other interesting work that addresses a similar task as ours includes the work on homophones (e.g., Lee and Chen (1997)), abbreviations with their definitions (e.g., Park and Byrd (2001)), abbreviations and acronyms in the medical domain (Pakhomov, 2002), and transliteration (e.g., (Knight and Graehl, 1998; Virga and Khudanpur, 2003; Li et al., 2004; Wu and Chang, 2007)).

While all the above work deals with the relations occurring within the *formal* text, we consider the *formal-informal* relations that occur across both formal and informal text, and we extract the relations from the web corpora, instead from just formal text. Moreover, our method is *semi-supervised* in the sense that the weights of the feature functions are tuned in a *supervised* log-linear model using a small number of seed relations while the generation and ranking of the hypotheses are *unsupervised* by exploiting the *data co-occurrence* phenomena.

7 Conclusions

In this paper, we have first presented a taxonomy of the *formal-informal* relations occurring in Chinese text. We have then proposed a novel method for discovering and modeling the relationship between informal Chinese expressions (including colloquialisms and instant-messaging slang) and their formal equivalents. Specifically, we have proposed a bootstrapping procedure to identify a list of candidate informal phrases in web corpora. Given an informal phrase, we retrieved contextual instances from the web using a search engine, generated hypotheses of formal equivalents via this data, and ranked the hypotheses using a conditional log-linear model. In the log-linear model, we incorporated as feature functions both rule-based intuitions and *data co-occurrence* phenomena (either as an explicit or indirect definition, or through formal/informal usages occurring in free variation in a discourse). We tested our system on manually collected test examples, and found that the (*formal-informal*) relationship discovery and extraction process using our method achieves an average 1-best precision of 62%. Given the ubiquity of informal conversational style on the internet, this work has clear applications for text normalization in text-processing systems including machine translation aspiring to broad coverage.

Abstract

We demonstrate the effectiveness of multilingual learning for unsupervised part-of-speech tagging. The key hypothesis of multilingual learning is that by combining cues from multiple languages, the structure of each becomes more apparent. We formulate a hierarchical Bayesian model for jointly predicting bilingual streams of part-of-speech tags. The model learns language-specific features while capturing cross-lingual patterns in tag distribution for aligned words. Once the parameters of our model have been learned on bilingual parallel data, we evaluate its performance on a held-out monolingual test set. Our evaluation on six pairs of languages shows consistent and significant performance gains over a state-of-the-art monolingual baseline. For one language pair, we observe a relative reduction in error of 53%.

1 Introduction

In this paper, we explore the application of multilingual learning to part-of-speech tagging when no annotation is available. This core task has been studied in an unsupervised monolingual framework for over a decade and is still an active area of research. In this paper, we demonstrate the effectiveness of multilingual learning when applied to both closely related and distantly related language pairs. We further analyze the language features which lead to robust bilingual performance.

The fundamental idea upon which our work is based is that the patterns of ambiguity inherent in part-of-speech tag assignments differ across languages. At the lexical level, a word with part-of-speech tag ambiguity in one language may correspond to an unambiguous word in the other language. For example, the word "can" in English may function as an auxiliary verb, a noun, or a regular verb. However, each of the corresponding functions in Serbian is expressed with a distinct lexical item. Languages also differ in their patterns of structural ambiguity. For example, the presence of an article in English greatly reduces the ambiguity of the succeeding tag. In Serbian, a language without articles, this constraint is obviously absent. The key idea of multilingual learning is that by combining cues from multiple languages, the structure of each becomes more apparent.

While multilingual learning can address ambiguities in each language, it must be flexible enough to accommodate cross-lingual variations such as tag inventory and syntactic structure. As a result of such variations, two languages often select and order their tags differently even when expressing the same meaning. A key challenge of multilingual learning is to model language-specific structure while allowing information to flow between languages.

We jointly model bilingual part-of-speech tag sequences in a hierarchical Bayesian framework. For each word, we posit a hidden tag state which generates the word as well as the succeeding tag. In addition, the tags of words with common semantic or syntactic function in parallel sentences are combined into bilingual nodes representing the tag pair. These joined nodes serve as anchors that create probabilistic dependencies between the tag se-

Proceedings of the 2008 Conference on Empirical Methods in Natural Language Processing, pages 1041–1050,
Honolulu, October 2008. ©2008 Association for Computational Linguistics

quences in each language. We use standard tools from machine translation to discover aligned word-pairs, and thereafter our model treats the alignments as observed data.

Our model structure allows language-specific tag inventories. Additionally, it assumes only that the tags at joined nodes are *correlated*; they need not be identical. We factor the conditional probabilities of joined nodes into two individual transition probabilities as well as a coupling probability. We define priors over the transition, emission, and coupling parameters and perform Bayesian inference using Gibbs sampling and the Metropolis-Hastings algorithm.

We evaluate our model on a parallel corpus of four languages: English, Bulgarian, Serbian, and Slovene. For each of the six language pairs, we train a bilingual model on this corpus, and evaluate it on held-out monolingual test sets. Our results show consistent improvement over a monolingual baseline for all languages and all pairings. In fact, for one language pair – Serbian and Slovene – the error is reduced by over 53%. Moreover, the multilingual model significantly reduces the gap between unsupervised and supervised performance. For instance, in the case of Slovene this gap is reduced by 71%. We also observe significant variation in the level of improvement across language pairs. We show that a cross-lingual entropy measure corresponds with the observed differentials in performance.

2 Related Work

Multilingual Learning A number of approaches for multilingual learning have focused on inducing cross-lingual structures, with applications to machine translation. Examples of such efforts include work on the induction of synchronous grammars (Wu and Wong, 1998; Chiang, 2005) and learning multilingual lexical resources (Genzel, 2005).

Another thread of work using cross-lingual links has been in word-sense disambiguation, where senses of words can be *defined* based on their translations (Brown et al., 1991; Dagan et al., 1991; Resnik and Yarowsky, 1997; Ng et al., 2003).

When annotations for a task of interest are available in a source language but are missing in the target language, the annotations can be projected across a parallel corpus (Yarowsky et al., 2000; Diab and Resnik, 2002; Padó and Lapata, 2006; Xi and Hwa, 2005). In fact, projection methods have been used to train highly accurate part-of-speech taggers (Yarowsky and Ngai, 2001; Feldman et al., 2006). In contrast, our own work assumes that annotations exist for neither language.

Finally, there has been recent work on applying unsupervised multilingual learning to morphological segmentation (Snyder and Barzilay, 2008). In this paper, we demonstrate that unsupervised multilingual learning can be successfully applied to the sentence-level task of part-of-speech tagging.

Unsupervised Part-of-Speech Tagging Since the work of Merialdo (1994), the HMM has been the model of choice for unsupervised tagging (Banko and Moore, 2004). Recent advances in these approaches include the use of a fully Bayesian HMM (Johnson, 2007; Goldwater and Griffiths, 2007). In very recent work, Toutanova and Johnson (2008) depart from this framework and propose an LDA-based generative model that groups words through a latent layer of ambiguity classes thereby leveraging morphological features. In addition, a number of approaches have focused on developing discriminative approaches for unsupervised and semi-supervised tagging (Smith and Eisner, 2005; Haghighi and Klein, 2006).

Our focus is on developing a simple model that effectively incorporates multilingual evidence. We view this direction as orthogonal to refining monolingual tagging models for any particular language.

3 Model

We propose a bilingual model for unsupervised part-of-speech tagging that jointly tags parallel streams of text in two languages. Once the parameters have been learned using an untagged bilingual parallel text, the model is applied to a held-out monolingual test set.

Our key hypothesis is that the patterns of ambiguity found in each language at the part-of-speech level will differ in systematic ways; by considering multiple language simultaneously, the total inherent ambiguity can be reduced in each language. The model is designed to permit information to flow across the

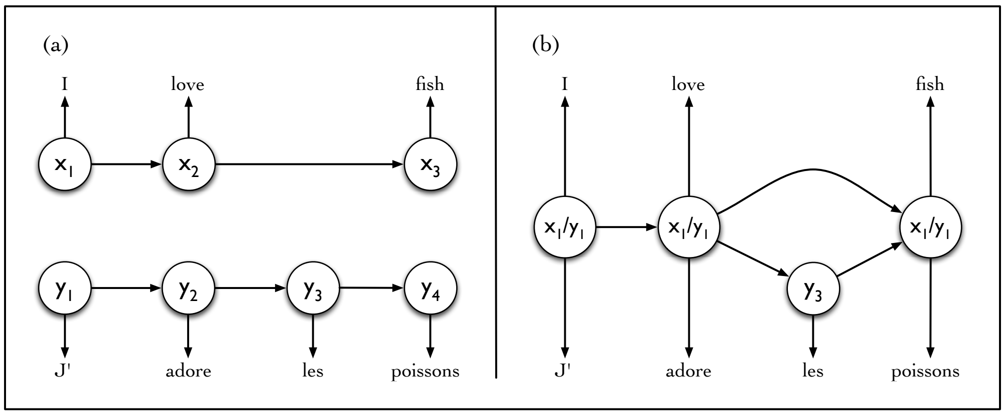

Figure 1: (a) Graphical structure of two standard monolingual HMM's. (b) Graphical structure of our bilingual model based on word alignments.

language barrier, while respecting language-specific idiosyncrasies such as tag inventory, selection, and order. We assume that for pairs of words that share similar semantic or syntactic function, the associated tags will be statistically correlated, though not necessarily identical. We use such word pairs as the bilingual anchors of our model, allowing cross-lingual information to be shared via joint tagging decisions. We use standard tools from machine translation to identify these aligned words, and thereafter our model treats them as fixed and observed data. To avoid cycles, we remove crossing edges from the alignments.

For unaligned parts of the sentence, the tag and word selections are identical to standard monolingual HMM's. Figure 1 shows an example of the bilingual graphical structure we use, in comparison to two independent monolingual HMM's.

We formulate a hierarchical Bayesian model that exploits both language-specific and cross-lingual patterns to explain the observed bilingual sentences. We present a generative story in which the observed words are produced by the hidden tags and model parameters. In Section 4, we describe how to infer the posterior distribution over these hidden variables, given the observations.

3.1 Generative Model

Our generative model assumes the existence of two tagsets, T and T', and two vocabularies W and W', one of each for each language. For ease of exposition, we formulate our model with bigram tag dependencies. However, in our experiments we used a trigram model, which is a trivial extension of the model discussed here and in the next section.

1. For each tag $t \in T$, draw a *transition* distribution ϕ_t over tags T, and an *emission* distribution θ_t over words W, both from symmetric Dirichlet priors.[1]

2. For each tag $t \in T'$, draw a *transition* distribution ϕ'_t over tags T', and an *emission* distribution θ'_t over words W', both from symmetric Dirichlet priors.

3. Draw a bilingual *coupling* distribution ω over tag pairs $T \times T'$ from a symmetric Dirichlet prior.

4. For each bilingual parallel sentence:

   (a) Draw an alignment a from an alignment distribution A (see the following paragraph for formal definitions of a and A),

   (b) Draw a bilingual sequence of part-of-speech tags $(x_1, ..., x_m)$, $(y_1, ..., y_n)$ according to:
   $P(x_1, ..., x_m,\ \ y_1, ..., y_n | a, \phi, \phi', \omega)$. [2]
   This joint distribution is given in equation 1.

[1]The Dirichlet is a probability distribution over the simplex, and is conjugate to the multinomial (Gelman et al., 2004).

[2]Note that we use a special end state rather than explicitly modeling sentence length. Thus the values of m and n depend on the draw.

(c) For each part-of-speech tag x_i in the first language, emit a word from W: $e_i \sim \theta_{x_i}$,

(d) For each part-of-speech tag y_j in the second language, emit a word from W': $f_j \sim \theta'_{y_j}$.

We define an alignment a to be a set of one-to-one integer pairs with no crossing edges. Intuitively, each pair $(i, j) \in a$ indicates that the words e_i and f_j share some common role in the bilingual parallel sentences. In our experiments, we assume that alignments are directly observed and we hold them fixed. From the perspective of our generative model, we treat alignments as drawn from a distribution A, about which we remain largely agnostic. We only require that A assign zero probability to alignments which either: *(*i) align a single index in one language to multiple indices in the other language or *(*ii) contain crossing edges. The resulting alignments are thus one-to-one, contain no crossing edges, and may be sparse or even possibly empty. Our technique for obtaining alignments that display these properties is described in Section 5.

Given an alignment a and sets of transition parameters ϕ and ϕ', we factor the conditional probability of a bilingual tag sequence $(x_1, ...x_m),\ (y_1, ..., y_n)$ into transition probabilities for unaligned tags, and joint probabilities over aligned tag pairs:

$$P(x_1, ..., x_m,\ y_1, ..., y_n | a, \phi, \phi', \omega) = \prod_{\text{unaligned } i} \phi_{x_{i-1}}(x_i) \cdot \prod_{\text{unaligned } j} \phi'_{y_{j-1}}(y_j) \cdot \prod_{(i,j) \in a} P(x_i, y_j | x_{i-1}, y_{j-1}, \phi, \phi', \omega) \quad (1)$$

Because the alignment contains no crossing edges, we can model the tags as generated sequentially by a stochastic process. We define the distribution over aligned tag pairs to be a product of each language's transition probability and the coupling probability:

$$P(x_i, y_j | x_{i-1}, y_{j-1}, \phi, \phi', \omega) = \frac{\phi_{x_{i-1}}(x_i)\ \phi'_{y_{j-1}}(y_j)\ \omega(x_i, y_j)}{Z} \quad (2)$$

The normalization constant here is defined as:

$$Z = \sum_{x,y} \phi_{x_{i-1}}(x)\ \phi'_{y_{j-1}}(y)\ \omega(x, y)$$

This factorization allows the language-specific transition probabilities to be shared across aligned and unaligned tags. In the latter case, the addition of the coupling parameter ω gives the tag pair an additional role: that of multilingual anchor. In essence, the probability of the aligned tag pair is a product of three experts: the two transition parameters and the coupling parameter. Thus, the combination of a high probability transition in one language and a high probability coupling can resolve cases of inherent transition uncertainty in the other language. In addition, any one of the three parameters can "veto" a tag pair to which it assigns low probability.

To perform inference in this model, we predict the bilingual tag sequences with maximal probability given the observed words and alignments, while integrating over the transition, emission, and coupling parameters. To do so, we use a combination of sampling-based techniques.

4 Inference

The core element of our inference procedure is Gibbs sampling (Geman and Geman, 1984). Gibbs sampling begins by randomly initializing all unobserved random variables; at each iteration, each random variable z_i is sampled from the conditional distribution $P(z_i|\mathbf{z}_{-i})$, where $\mathbf{z}_{-i}$ refers to all variables other than z_i. Eventually, the distribution over samples drawn from this process will converge to the unconditional joint distribution $P(\mathbf{z})$ of the unobserved variables. When possible, we avoid explicitly sampling variables which are not of direct interest, but rather integrate over them—this technique is known as "collapsed sampling," and can reduce variance (Liu, 1994).

We sample: *(i)* the bilingual tag sequences $(\mathbf{x}, \mathbf{y})$, *(ii)* the two sets of transition parameters ϕ and ϕ', and *(iii)* the coupling parameter ω. We integrate over the emission parameters θ and θ', whose priors are Dirichlet distributions with hyperparameters θ_0 and θ'_0. The resulting emission distribution over words e_i, given the other words $\mathbf{e}_{-i}$, the tag sequences $\mathbf{x}$

and the emission prior θ_0, can easily be derived as:

$$\begin{aligned} P(e_i|\mathbf{x}, \mathbf{e}_{-i}, \theta_0) &= \int_{\theta_{x_i}} \theta_{x_i}(e_i)\, P(\theta_{x_i}|\theta_0)\; d\theta_{x_i} \\ &= \frac{n(x_i, e_i) + \theta_0}{n(x_i) + W_{x_i}\theta_0} \end{aligned} \tag{3}$$

Here, $n(x_i)$ is the number of occurrences of the tag x_i in $\mathbf{x}_{-i}$, $n(x_i, e_i)$ is the number of occurrences of the tag-word pair (x_i, e_i) in $(\mathbf{x}_{-i}, \mathbf{e}_{-i})$, and W_{x_i} is the number of word types in the vocabulary W that can take tag x_i. The integral is tractable due to Dirichlet-multinomial conjugacy (Gelman et al., 2004).

We will now discuss, in turn, each of the variables that we sample. Note that in all cases we condition on the other sampled variables as well as the observed words and alignments, $\mathbf{e}$, $\mathbf{f}$ and a, which are kept fixed throughout.

4.1 Sampling Part-of-speech Tags

This section presents the conditional distributions that we sample from to obtain the part-of-speech tags. Depending on the alignment, there are several scenarios. In the simplest case, both the tag to be sampled and its succeeding tag are not aligned to any tag in the other language. If so, the sampling distribution is identical to the monolingual case, including only terms for the emission (defined in equation 3), and the preceding and succeeding transitions:

$$\begin{aligned} &P(x_i|\mathbf{x}_{-i}, \mathbf{y}, \mathbf{e}, \mathbf{f}, a, \phi, \phi', \omega, \theta_0, \theta_0') \propto \\ &\qquad P(e_i|\mathbf{x}, \mathbf{e}_{-i}, \theta_0)\; \phi_{x_{i-1}}(x_i)\; \phi_{x_i}(x_{i+1}). \end{aligned}$$

For an aligned tag pair (x_i, y_j), we sample the identity of the tags jointly. By applying the chain rule we obtain terms for the emissions in both languages and a joint term for the transition probabilities:

$$\begin{aligned} &P(x_i, y_j|\mathbf{x}_{-i}, \mathbf{y}_{-j}, \mathbf{e}, \mathbf{f}, a, \phi, \phi', \omega, \theta_0, \theta_0') \propto \\ &\qquad P(e_i|\mathbf{x}, \mathbf{e}_{-i}, \theta_0) P(f_j|\mathbf{y}, \mathbf{f}_{-j}, \theta_0') \\ &\qquad\qquad P(x_i, y_j|\mathbf{x}_{-i}, \mathbf{y}_{-j}, a, \phi, \phi', \omega) \end{aligned}$$

The expansion of the joint term depends on the alignment of the succeeding tags. In the case that the successors are not aligned, we have a product of the bilingual coupling probability and four transition probabilities (preceding and succeeding transitions in each language):

$$\begin{aligned} &P(x_i, y_j|\mathbf{x}_{-i}, \mathbf{y}_{-j}, a, \phi, \phi', \omega) \propto \\ &\quad \omega(x_i, y_j)\phi_{x_{i-1}}(x_i)\; \phi'_{y_{j-1}}(y_j)\; \phi_{x_i}(x_{i+1})\; \phi'_{y_j}(y_{j+1}) \end{aligned}$$

Whenever one or more of the succeeding tags is aligned, the sampling formulas must account for the effect of the sampled tag on the joint probability of the succeeding tags, which is no longer a simple multinomial transition probability. We give the formula for one such case—when we are sampling an aligned tag pair (x_i, y_j), whose succeeding tags (x_{i+1}, y_{j+1}) are also aligned to one another:

$$\begin{aligned} &P(x_i, y_j|\mathbf{x}_{-i}, \mathbf{y}_{-j}, a, \phi, \phi', \omega) \propto \omega(x_i, y_j) \\ &\quad \cdot \phi_{x_{i-1}}(x_i)\, \phi'_{y_{j-1}}(y_j) \left[\frac{\phi_{x_i}(x_{i+1})\, \phi'_{y_j}(y_{j+1})}{\sum_{x,y} \phi_{x_i}(x)\, \phi'_{y_j}(y)\, \omega(x, y)} \right] \end{aligned}$$

Similar equations can be derived for cases where the succeeding tags are not aligned to each other, but to other tags.

4.2 Sampling Transition Parameters and the Coupling Parameter

When computing the joint probability of an aligned tag pair (Equation 2), we employ the transition parameters ϕ, ϕ' and the coupling parameter ω in a normalized product. Because of this, we can no longer regard these parameters as simple multinomials, and thus can no longer sample them using the standard closed formulas.

Instead, to resample these parameters, we resort to the Metropolis-Hastings algorithm as a subroutine within Gibbs sampling (Hastings, 1970). Metropolis-Hastings is a Markov chain sampling technique that can be used when it is impossible to directly sample from the posterior. Instead, samples are drawn from a *proposal* distribution and then stochastically accepted or rejected on the basis of: their likelihood, their probability under the proposal distribution, and the likelihood and proposal probability of the previous sample.

We use a form of Metropolis-Hastings known as an *independent sampler*. In this setup, the proposal distribution does not depend on the value of the previous sample, although the accept/reject decision does depend on the previous model likelihood. More formally, if we denote the proposal distribution as $Q(z)$, the target distribution as $P(z)$, and the previous sample as z, then the probability of accepting a new sample $z^* \sim Q$ is set at:

$$\min\left\{1, \frac{P(z^*)\,Q(z)}{P(z)\,Q(z^*)}\right\}$$

Theoretically any non-degenerate proposal distribution may be used. However, a higher acceptance rate and faster convergence is achieved when the proposal Q is a close approximation of P. For a particular transition parameter ϕ_x, we define our proposal distribution Q to be Dirichlet with parameters set to the bigram counts of the tags following x in the sampled tag data. Thus, the proposal distribution for ϕ_x has a mean proportional to these counts, and is thus likely to be a good approximation to the target distribution.

Likewise for the coupling parameter ω, we define a Dirichlet proposal distribution. This Dirichlet is parameterized by the counts of aligned tag pairs (x, y) in the current set of tag samples. Since this sets the mean of the proposal to be proportional to these counts, this too is likely to be a good approximation to the target distribution.

4.3 Hyperparameter Re-estimation

After every iteration of Gibbs sampling the hyperparameters θ_0 and θ'_0 are re-estimated using a single Metropolis-Hastings move. The proposal distribution is set to a Gaussian with mean at the current value and variance equal to one tenth of the mean.

5 Experimental Set-Up

Our evaluation framework follows the standard procedures established for unsupervised part-of-speech tagging. Given a tag dictionary (i.e., a set of possible tags for each word type), the model has to select the appropriate tag for each token occurring in a text. We also evaluate tagger performance when only incomplete dictionaries are available (Smith and Eisner, 2005; Goldwater and Griffiths, 2007). In both scenarios, the model is trained only using untagged text.

In this section, we first describe the parallel data and part-of-speech annotations used for system evaluation. Next we describe a monolingual baseline and our procedures for initialization and hyperparameter setting.

Data As a source of parallel data, we use Orwell's novel "Nineteen Eighty Four" in the original English as well as translations to three Slavic languages — Bulgarian, Serbian and Slovene. This data is distributed as part of the Multext-East corpus which is publicly available. The corpus provides detailed morphological annotation at the world level, including part-of-speech tags. In addition a lexicon for each language is provided.

We obtain six parallel corpora by considering all pairings of the four languages. We compute word level alignments for each language pair using Giza++. To generate one-to-one alignments at the word level, we intersect the one-to-many alignments going in each direction and automatically remove crossing edges in the order in which they appear left to right. This process results in alignment of about half the tokens in each bilingual parallel corpus. We treat the alignments as fixed and observed variables throughout the training procedure.

The corpus consists of 94,725 English words (see Table 2). For every language, a random three quarters of the data are used for learning the model while the remaining quarter is used for testing. In the test set, only monolingual information is made available to the model, in order to simulate future performance on non-parallel data.

	Tokens	Tags/Token

SR	83.41	85.05	96.72	1.789

Table 1: Monolingual tagging accuracy for English, Bulgarian, Slovene, and Serbian for two unsupervised baselines (random tag selection and a Bayesian HMM (Goldwater and Griffiths, 2007)) as well as a supervised HMM. In addition, the trigram part-of-speech tag entropy is given for each language.

in our experiments.[3]

In the Multext-East corpus, punctuation marks are not annotated. We expand the tag repository by defining a separate tag for all punctuation marks. This allows the model to make use of any transition or coupling patterns involving punctuation marks. We do not consider punctuation tokens when computing model accuracy.

Table 2 shows the tag/token ratio for these languages. For Slavic languages, we use the tag dictionaries provided with the corpus. For English, we use a different process for dictionary construction. Using the original dictionary would result in the tag/token ratio of 1.5, in comparison to the ratio of 2.3 observed in the Wall Street Journal (WSJ) corpus. To make our results on English tagging more comparable to previous benchmarks, we expand the original dictionary of English tags by merging it with the tags from the WSJ dictionary. This process results in a tag/token ratio of 2.58, yielding a slightly more ambiguous dictionary than the one used in previous tagging work. [4]

Monolingual Baseline As our monolingual baseline we use the unsupervised Bayesian HMM model of Goldwater and Griffiths (2007) (BHMM1). This model modifies the standard HMM by adding priors and by performing Bayesian inference. Its is in line with state-of-the-art unsupervised models. This model is a particulary informative baseline, since our model reduces to this baseline model when there are no alignments in the data. This implies that any performance gain over the baseline can only be attributed to the multilingual aspect of our model. We used our own implementation after verifying that its performance on WSJ was identical to that reported in (Goldwater and Griffiths, 2007).

[3]The remaining two tags are Particle and Determiner; The English tagset does not include *Particle* while the other three languages Serbian, Slovene and Bulgarian do not have *Determiner* in their tagset.

[4]We couldn't perform the same dictionary expansion for the Slavic languages due to a lack of additional annotated resources.

Supervised Performance In order to provide a point of comparison, we also provide supervised results when an annotated corpus is provided. We use the standard supervised HMM with Viterbi decoding.

Training and Testing Framework Initially, all words are assigned tags randomly from their tag dictionaries. During each iteration of the sampler, aligned tag pairs and unaligned tags are sampled from their respective distributions given in Section 4.1 above. The hyperparameters θ_0 and θ_0' are initialized with the values learned during monolingual training. They are re-estimated after every iteration of the sampler using the Metropolis Hastings algorithm. The parameters ϕ and ϕ' are initially set to trigram counts and the ω parameter is set to tag pair counts of aligned pairs. After every 40 iterations of the sampler, a Metropolis Hastings subroutine is invoked that re-estimates these parameters based on the current counts. Overall, the algorithm is run for 1000 iterations of tag sampling, by which time the resulting log-likelihood converges to stable values. Each Metropolis Hastings subroutine samples 20 values, with an acceptance ratio of around 1/6, in line with the standard recommended values.

After training, trigram and word emission probabilities are computed based on the counts of tags assigned in the final iteration. For smoothing, the final sampled values of the hyperparameters are used. The highest probability tag sequences for each monolingual test set are then predicted using trigram Viterbi decoding. We report results averaged over five complete runs of all experiments.

6 Results

Complete Tag Dictionary In our first experiment, we assume that a complete dictionary listing the possible tags for every word is provided in each language. Table 1 shows the monolingual results of a random baseline, an unsupervised Bayesian HMM and a supervised HMM. Table 3 show the results of our bilingual models for different language pairings while repeating the monolingual unsupervised results from Table 1 for easy comparison. The final column indicates the absolute gain in performance over this monolingual baseline.

Across all language pairs, the bilingual model consistently outperforms the monolingual baseline. All the improvements are statistically significant by a Fisher sign test at $p < 0.05$. For some language pairs, the gains are quite high. For instance, the pairing of Serbian and Slovene (two closely related languages) yields absolute improvements of 6.7 and 7.7 percentage points, corresponding to relative reductions in error of 51.4% and 53.2%. Pairing Bulgarian and English (two distantly related languages) also yields large gains: 5.6 and 1.3 percentage points, corresponding to relative reductions in error of 50% and 14%, respectively.[5]

When we compare the best bilingual result for each language (Table 3, in bold) to the monolingual supervised results (Table 1), we find that for all languages the gap between supervised and unsupervised learning is reduced significantly. For English, this gap is reduced by 21%. For the Slavic languages, the supervised-unsupervised gap is reduced by even larger amounts: 57%, 69%, and 78% for Serbian, Bulgarian, and Slovene respectively.

While all the languages benefit from the bilingual learning framework, some language combinations are more effective than others. Slovene, for instance, achieves a large improvement when paired with Serbian ($+7.7$), a closely related Slavic language, but only a minor improvement when coupled with English ($+1.3$). On the other hand, for Bulgarian, the best performance is achieved when coupling with English ($+5.6$) rather than with closely related Slavic languages ($+3.1$ and $+2.4$). As these results show, an optimal pairing cannot be predicted based solely on the family connection of paired languages.

To gain a better understanding of this variation in performance, we measured the internal tag entropy of each language as well as the cross-lingual tag entropy of language pairs. For the first measure, we computed the conditional entropy of a tag decision given the previous two tags. Intuitively, this should correspond to the inherent structural uncertainty of part-of-speech decisions in a language. In fact, as Table 1 shows, the trigram entropy is a good indicator of the relative performance of the monolingual baseline. To measure the cross-lingual tag entropies of language pairs, we considered all bilingual aligned tag pairs, and computed the conditional entropy of the tags in one language given the tags in the other language. This measure should indicate the amount of information that one language in a pair can provide the other. The results of this anal-

	Entropy	Mono-lingual	Bilingual	Absolute Gain

Table 3: The tagging accuracy of our bilingual models on different language pairs, when a full tag dictionary is provided. The Monolingual Unsupervised results from Table 1 are repeated for easy comparison. The first column shows the cross-lingual entropy of a tag when the tag of the aligned word in the other language is known. The final column shows the absolute improvement over the monolingual Bayesian HMM. The best result for each language is shown in boldface.

[5]The accuracy of the monolingual English tagger is relatively high compared to the 87% reported by (Goldwater and Griffiths, 2007) on the WSJ corpus. We attribute this discrepancy to the slight differences in tag inventory used in our dataset. For example, when *Particles* and *Prepositions* are merged in the WSJ corpus (as they happen to be in our tag inventory and corpus), the performance of Goldwater's model on WSJ is similar to what we report here.

	Mono-lingual	Bilingual	Absolute Gain
EN	63.57	68.22	+4.66

Table 4: Tagging accuracy for Bilingual models with reduced dictionary: Lexicon entries are available for only the 100 most frequent words, while all other words become fully ambiguous. The improvement over the monolingual Bayesian HMM trained under similar circumstances is shown. The best result for each language is shown in boldface.

ysis are given in the first column of Table 3. We observe that the cross-lingual entropy is lowest for the Serbian and Slovene pair, corresponding with their large gain in performance. Bulgarian, on the other hand, has lowest cross-lingual entropy when paired with English. This corresponds with the fact that English provides Bulgarian with its largest performance gain. In general, we find that the largest performance gain for any language is achieved when minimizing its cross-lingual entropy.

Reduced Tag Dictionary We also conducted experiments to investigate the impact of the dictionary size on the performance of the bilingual model. Here, we provide results for the realistic scenario where only a very small dictionary is present. Table 4 shows the performance when a tag dictionary for the 100 most frequent words is present in each language. The bilingual model's results are consistently and significantly better than the monolingual baseline for all language pairs.

7 Conclusion

We have demonstrated the effectiveness of multilingual learning for unsupervised part-of-speech tagging. The key hypothesis of multilingual learning is that by combining cues from multiple languages, the structure of each becomes more apparent. We formulated a hierarchical Bayesian model for jointly predicting bilingual streams of tags. The model learns language-specific features while capturing cross-lingual patterns in tag distribution. Our evaluation shows significant performance gains over a state-of-the-art monolingual baseline.

Abstract

Code-switching is an interesting linguistic phenomenon commonly observed in highly bilingual communities. It consists of mixing languages in the same conversational event. This paper presents results on Part-of-Speech tagging Spanish-English code-switched discourse. We explore different approaches to exploit existing resources for both languages that range from simple heuristics, to language identification, to machine learning. The best results are achieved by training a machine learning algorithm with features that combine the output of an English and a Spanish Part-of-Speech tagger.

1 Introduction

Worldwide the percentage of bilingual speakers is fairly large, and it keeps increasing at a high rate. In the U.S., 18% of the total population speaks a language other than English at home, the majority of which speaks Spanish (U.S. Census Bureau, 2003). A significant percentage of this Spanish-English bilingual population code-switch between the two languages in what is often referred as Spanglish, the mix of Spanish and English. Spanish and English are not the only occurrence of language mixtures. Examples of other popular combinations include Arabic dialects, French and German, Spanish and Catalan, Maltese and English, and English and French. Typically when there are linguistic borders, or when the country has more than one official language, we can find instances of code-switching.

Despite the wide use of code-switched discourse among bilinguals, this linguistic phenomenon has received little attention in the fields of Natural Language Processing and Computational Linguistics. Part-of-Speech (POS) tagging is a well studied problem in these fields. For languages such as English, German, Spanish, and Chinese there are several different POS taggers that reach high accuracies, especially in news text corpora. However, to our knowledge, there is no previous work on developing a POS tagger for text with mixes of languages.

In this paper we present results on the problem of POS tagging English-Spanish code-switched discourse by taking advantage of existing taggers for both languages. This rationale follows the evidence from studies of code-switching on different language pairs, which have shown code-switching to be grammatical according to both languages being switched. We use different heuristics to combine POS tag information from existing monolingual taggers. We also explore the use of different language identification methods to select POS tags from the appropriate monolingual tagger. However, the best results are achieved by a machine learning approach using features generated by the monolingual POS taggers.

The next section presents the facts about code-switching, including some previous work done mainly in linguistics. Then in Section 3 we discuss previous work related to the automated processing of code-switched discourse. In Section 4 we describe the English-Spanish code-switched data set gathered for the experimental evaluation. Section 5 presents the heuristics-based approaches for POS tagging that we explored. In Section 6 we describe our machine learning approach and show

Proceedings of the 2008 Conference on Empirical Methods in Natural Language Processing, pages 1051–1060,
Honolulu, October 2008. ©2008 Association for Computational Linguistics

results on POS tagging code-switched text. An in depth analysis of results is presented in Section 7, and we conclude this paper with a summary of the findings and directions for future work in Section 8.

2 Rules of Code-switching

In the linguistic, sociolinguistic, psychology, and psycholinguistic literature, bilingualism and the inherent phenomena it exhibits have been studied for nearly a century (Espinosa, 1917; Ervin and Osgood, 1954; Gumperz, 1964; Gumperz and Hernandez-Chavez, 1971; Gumperz, 1971; Sankoff, 1968; Lipski, 1978). Despite the numerous previous studies of linguistic characteristics of bilingualism, there is no clear consensus on the terminology related to language alternation patterns in bilingual speakers. The alternation of languages within a sentence is known as code-mixing, but it has also been referred as intrasentential code-switching, and intrasentential alternation (Poplack, 1980; Grosjean, 1982; Ardila, 2005). Alternation across sentence boundaries is known as intersentential code-switching, or just code-switching. In the rest of this paper we will refer to the mixing of languages as code-switching. When necessary, we will differentiate the type of code-switching by referring to alternations within sentences as intrasentential code-switching and alternations across sentence boundaries as intersentential code-switching.

Linguistic phenomena in bilingual speakers have been analyzed on different language pairs, including English-French, English-Dutch, Finish-English, Arabic-French, and Spanish-English, to name a few. There is a general agreement that code-switched patterns are not generated randomly; according to these studies, they follow specific grammatical rules. Furthermore, some studies suggest that, if these rules are violated, the resulting discourse will sound unnatural (Toribio, 2001b; Toribio, 2001a). The following shows the rules governing code-switching discourse described in several studies (Poplack, 1980; Poplack, 1981; Sankoff, 1981; Sankoff, 1998a).

- Switches can take place only between full word boundaries. This is also known as the free morpheme constraint.
- Monolingual constructs within the sentence will follow the grammatical rules of the monolingual fragment.
- Permissible switch points are those that do not violate the order of adjacent constituents on both sides of the switch point of either of the languages. This is called the equivalence constraint.

Although these rules are somewhat controversial, and most of the studies on this area have been conducted on small samples, we cannot ignore the fact that patterns bearing the above rules have emerged in different bilingual communities with different backgrounds.

3 Automated Processing of Code-Switched Discourse

A previous work related to the processing of code-switched text deals with language identification on English-Maltese code-switched SMS messages (Rosner and Farrugia, 2007). In addition to dealing with intrasentential code-switching, they have to deal with text where misspellings and ad hoc word contractions abound. What Rosner and Farrigua have found to work best for language identification in this noisy domain is a combination of a bigram Hidden Markov Model, trained on language transitions, and a trigram character Markov Model for handling unknown words. In another related work, Franco and Solorio present preliminary results on training a language model for Spanish-English code-switched text (Franco and Solorio, 2007). To evaluate their language model, they asked a human subject to judge sentences generated by a PCFG induced from training data and the language model. However, they only used one human judge.

Regarding the automated POS tagging and parsing of code-mixed utterances there is little prior work. To the best of our knowledge, there is no parser, nor POS tagger, currently available for the syntactic analysis of this type of discourse. There are theoretical approaches that propose formalisms to represent the structure of code-switched utterances and describe a framework for parsing and generating mixed sentences, for example for Marathi and English (Joshi, 1982), or Hindi and English (Goyal *et al.*, 2003). Sankoff proposed a production model of bilingual discourse that accounts for the equivalence constraint and the unpredictability of code-switching (Sankoff, 1998a; Sankoff, 1998b). His real-time production model draws on the alternation of fragments from two virtual monolingual sentences. It also accounts for other types of code-switching such as repetition-translation and insertional code-switching. But no statistical assessment has been conducted on real corpora.

Our goal is to develop a POS tagger for code-switched utterances, which is the first step of the syntactic analysis of any language. Among the challenges we face is the lack of a representative sample of code-mixed discourse. Most POS taggers are built using large collections, usually at least a million words, such as the Brown corpus (Kucera and Francis, 1967), the Wall Street Journal corpus (Paul and Baker, 1992), or the Switchboard corpus (Godfrey *et al.*, 1992). Currently, there is no annotation of code-switched text of comparable size. But in contrast to the lack of linguistic resources available for Spanish-English code-mixed discourse, English and Spanish have sufficient resources, especially English. Thus, rather than starting from scratch, we will draw on existing taggers for both languages, which will reduce the amount of code-switched data needed. Some examples of POS taggers that perform reasonably well on monolingual text of each language can be found in (Brants, 2000; Brill, 1992; Carreras and Padró, 2002; Charniak, 1993; Ratnaparkhi, 1996; Schmid, 1994). However, these tools are designed to work on monolingual text, therefore if applied as they are to code-switched text, their accuracy will decrease by a large margin. In the following sections we will explore different methods for combining monolingual taggers.

4 Data Set

Data collections that have instances of Spanish-English code-switching, Spanglish for short, are not easily found since code-switching is primarily used in spoken form. To gather data we recorded a conversation among three staff members of a southwest university in the U.S. The three speakers come from a highly bilingual background and code-switch regularly when speaking among themselves, or other bilingual speakers.

This recording session has around 39 minutes of continuous speech (922 sentences, about 8k words) and was transcribed and annotated with POS tags by a human annotator. The annotations were later revised by a different annotator but no inter-annotator agreement was measured. The POS tag set used in the annotation is the combination of the tag sets from the English and the Spanish Tree Taggers (see Section 5). The vocabulary of the transcription has a total of 1,516 different word forms[1]. In the conversation a total of 239 switches were identified manually, out of which 129 are intrasentential code-switches, and the rest are intersentential. English is the predominant language used, with a total of 6,020 tokens and 576 monolingual sentences. In contrast, the transcription has close to 2k tokens in Spanish. Table 1 shows examples of code-switching taken from the recorded conversation; (a) and (b) are instances of intrasentential code-switching, and (c) shows intersentential code-switching.

Table 1: Excerpts taken from the Spanglish data set.

Spanglish	**English Translation**
(a)*Entonces le dió el virus y no se lo atendió and the virus spread through his body.*	(a)Then he got the virus and he didn't receive treatment and the virus spread through his body.
(b)*Cuando yo lo vi he looked pretty bad.*	(b)When I saw him he looked pretty bad.
(c)*I think she was taller than he was.*	(c)I think she was taller than he was.
Y un carácter muy bonito también ella.	And a very nice character she as well.
Very easy going.	Very easy going.

5 Rule-based Methods for Exploiting Existing Resources

In this section we present several heuristics-based methods for POS tagging code-switched text. First, we describe the monolingual taggers used in this work. Then we present the different approaches explored and contrast their performance.

[1]This transcription and the audio file are freely available for research purposes by contacting the first author.

5.1 Monolingual Taggers

We used the Tree Tagger (Schmid, 1994) for this work because of the following considerations:

1. It has both English and Spanish versions. The English tagger uses a slightly modified version of the Penn Treebank tag set and was trained and evaluated on different portions of the Penn Treebank, reaching a POS tagging accuracy of 96.36%. The Spanish one uses a different tagset with 75 different POS tags[2] and was trained on the Spanish CRATER corpus.
2. The transition probabilities are estimated using a modified version of the ID3 decision tree algorithm (Quinlan, 1986), which provides more freedom to learn contextual cues than n-grams.
3. Both taggers include a special tag for foreign words, PE for Spanish and FW for English. We do not expect this tag to identify correctly all foreign words, but when available this information will be exploited.
4. The Tree tagger generates probability estimates on the tags that can be used as features.
5. Finally, when the tagger fails to lemmatize a word it outputs the special token $\langle$*unknown*$\rangle$. This information can be used as a hint of words that do not belong to that particular language.

5.2 Heuristic-based Systems

For all heuristics the complete Spanglish data set was given to both taggers as a single text, then the final tag for each word was selected from the output of the taggers according to the different heuristics. Table 2 shows the tagging accuracies of the different heuristics we explored, which are explained below.

1. Using the monolingual tagger. Here we simply give the Spanglish text to the Spanish and the English tree tagger. We expect from both taggers a performance degradation due to the inclusion of foreign words in code-switching, as compared against their accuracy on monolingual texts. Another complicating factor to keep in mind is that we are dealing with spoken language. Hesitations, fillers, disfluencies, and interruption points, such as *Umm*, *Mmmhmm*, and *Uh-huh*, are frequently observed in speech and it is well known that they complicate the POS tagging task. The tagging accuracy from using the individual taggers is rather low, 26% for the Spanish tagger and 54% for the English one. The large difference between the two taggers can be attributed to the fact that the majority of the words in the corpus are in English.

[2]The authors were unable to identify the source of the Spanish tagset.

Table 2: Accuracy on POS tagging Spanglish text using simple heuristics for combining the output of the English and Spanish tagger.

	Heuristic	**Accuracy (%)**
1	Spanish Tree Tagger	25.99
	English Tree Tagger	54.59
2	Highest prob tag or English	51.51
	Highest prob tag or Spanish	49.16
3	Prob + special tags + lemmas	64.27
4	Dictionary-based Language Id	**86.03**
	Character 5-grams Language Id	81.46
	Human Language Id	89.72

2. Using confidence thresholds. The Tree Tagger can output probabilities for each tag, showing the confidence of the tagger on each particular tag. To use this information we choose for each word the tag from the tagger with the highest confidence. When there is a tie we use either the English or the Spanish tag. Table 2 shows the results for the two cases. The "Highest prob tag or English" heuristic gives an accuracy of 51%, which is almost as accurate as using only the English tagger. The "Highest prob tag or Spanish" achieves an accuracy of 49%, which is an improvement over using only the monolingual Spanish tagger, but it is still below the accuracy of the English monolingual tagger. This is also possibly due to the task being easier for the English tagger.

3. Combining confidence thresholds with knowledge from special tags and lemmas. This heuristic uses confidence thresholds combined with decisions based on the special tags, described in Section 5.1, and the unknown lemmas found. Let $POS_E(w_i)$ and $POS_S(w_i)$ be the POS tags assigned to word w_i by the English and Spanish tagger respectively; and let $Prob_E(w_i)$ and $Prob_S(w_i)$ be the confidence scores of POS tags for word w_i computed by the English and Spanish tree taggers, respectively. For each word w_i in the text, the final POS tag,

$POS_F(w_i)$, will be assigned as follows:

1. **If** $POS_E(w_i) = FW$, **then** $POS_F(w_i) \leftarrow POS_S(w_i)$
2. **Else if** $POS_S(w_i) = PE$, **then** $POS_F(w_i) \leftarrow POS_E(w_i)$
3. **Else if** $POS_E(w_i) = \langle unknown \rangle$, **then** $POS_F(w_i) \leftarrow POS_S(w_i)$
4. **Else if** $POS_S(w_i) = \langle unknown \rangle$, **then** $POS_F(w_i) \leftarrow POS_E(w_i)$
5. **Else if** $Prob_E(w_i) > Prob_S(w_i)$, **then** $POS_F(w_i) \leftarrow POS_E(w_i)$
6. **Else** $POS_F(w_i) \leftarrow POS_S(w_i)$

This heuristic performs better than the other methods explored so far, yielding an accuracy of 64.27%. It seems that knowledge of the taggers can be used to improve results. However, POS tagging accuracy is still poor.
4. Selecting POS tags based on automated language identification. We used two different strategies for automatically identifying the language at the word level. One is based on dictionary look-up and the other is character-based language models. For the first approach, every word in the text is searched in the English and Spanish dictionaries. If a word is found in the English dictionary, then we identify that word as belonging to English and the POS tags from the English tagger are used for that word and the following ones, until a word is found in the Spanish dictionary. Similarly, for a word not found in the English dictionary, but found in the Spanish dictionary, we use the Spanish tags until an English word is found. Note that this simple heuristic will always label words that belong to both languages as English, which is also the case for words not found in either dictionary. This dictionary-based method has a language identification accuracy of 94% on the Spanglish corpus.

The character language models were trained on the Agence France Presse (AFP) portions of the Gigaword for English and Spanish, respectively. For each of the words in the Spanglish corpus, we first decide its language by choosing the one with the lowest perplexity, calculated using character n-gram language models, then we use the corresponding POS tag. We experimented with different language model orders, with n ranging from 2 to 6, and found that we achieve the highest accuracy, 81.46%, on POS tagging using a 5-gram language model. This 5-gram method reached a language identification accuracy of 85% for the Spanglish corpus. However, the language identification method using dictionary look-up achieved the best POS tagging result so far: 86.03%. The Spanglish conversation is dominated by every-day language that is easily found in dictionaries, while the text used to train the character based n-gram language models includes vocabulary that is not commonly used in conversations. This can explain why the simple dictionary look-up approach yielded better results for our corpus. Performing manual identification of the language and sending to the appropriate tagger just the corresponding fragments yields a very high POS tagging accuracy, 89.72%. This shows that it is important to deal with the language switches for boosting accuracy. However relying on human annotated language tags would be expensive and for some tasks unfeasible.

6 Machine Learning for POS Tagging Code-Switched Discourse

From Table 2 we can see that, with the exception of the language identification heuristic, accuracies are low for the previous experiments. However, we believe that we can improve results further by using Machine Learning (ML) algorithms trained specifically for this task. In this section we describe the ML setting and present a comparison of the different algorithms we tested.

6.1 Approach

The key point is that the features selected for describing the learning instances are the output from the English and the Spanish taggers. This scheme is similar to a stacked classifier approach (Wolpert, 1992), where the final classifier takes as input the predictions made by the different learners on the first pass and is trained to select the right tag from them, or a different one if the right answer is not available.

The gold-standard POS tags are used as the class label, and instances in this learning task are described by the following attributes:

1. The word (word)
2. English POS tag (E_t)
3. English POS tagger lemma (E_l)
4. English POS tagger confidence (E_p)
5. Spanish POS tag (S_t)
6. Spanish POS tagger lemma (S_l)
7. Spanish POS tagger confidence (S_p)

Feature 1 is just the lexical word form as it appears in the transcript. Features 2 to 4 are generated by the English Tree tagger, while features 5 to 7 are generated by the Spanish Tree tagger. Thus all features are automatically extracted.

6.2 Results

We evaluated experimentally the idea of using ML with different learning algorithms in WEKA (Witten and Frank, 1999). We selected some of the most widely known algorithms, including Support Vector Machines (SVM) with a polynomial kernel of exponent one (Schölkopf and Smola, 2002), Weka's modified version of Quinlan's C4.5 (J48) (Quinlan, 1986), Additive Logistic Regression with Decision Stumps (Logit Boost) (Friedman *et al.*, 1998) and Naive Bayes. The only parameter we modified was for J48 –we enabled the option for reducing error pruning.

Table 3: POS tagging accuracy of Spanglish text with different Machine Learning algorithms. Oracle shows the accuracy achieved when always selecting the right POS tag from the output of both Tree Taggers. Language Id shows accuracy of identifying the language and then choosing the output of the corresponding tagger.

ML Algorithms	Mean Accuracy (%)	Variance
Naive Bayes	88.50	1.9280
SVM	**93.48**	1.2784
Logit Boost	**93.19**	1.4437
J48	91.11	2.1527
Oracle	90.31	-
Language Id	85.80	-

Table 3 shows the average accuracy of 10-fold cross-validation for each classifier together with the variance. SVM and Logit Boost performed the best and the difference between the two algorithms is not significant according to the paired t-test (P-value = 0.1). For comparison, we show the accuracy of the language identification approach together with the oracle accuracy. The oracle is the accuracy achieved when always selecting the right POS tag, when it is available, from the output of both Tree Taggers. We did not expect the oracle's accuracy to be an upper bound on the accuracy for the ML learning algorithm. Our intuition is that the ML algorithm can be trained to identify when the taggers have made a mistake and what the right answer should be. As the results show, the ML approach can indeed outperform the oracle, and the language identification method.

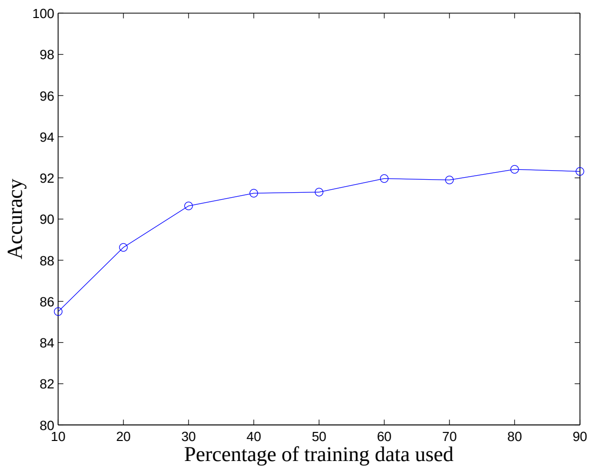

Figure 1: Effect of different amounts of training data on accuracy

In Figure 1 we show the effect of the amount of training data on the accuracy using Logit Boost. We selected Logit Boost for this and the following experiments since its accuracy is comparable to SVMs but it is computationally less expensive. We randomly partitioned the transcription into 10 subgroups. Then we used one subgroup as the test set and the rest for training. Starting with one subgroup in the training set, we incrementally added one subgroup to the training set and evaluate the tagging performance of the test set. We repeated this process several times, choosing randomly a new test set each time. The percentages shown are the average over all the experiments. With only 10% of the sentences for training we are reaching very good accuracy already, as high as that from the strategy based on language identification. The curve flattens after

Table 4: Accuracy of Logit Boost with different subsets of attributes. 'X' marks attributes included. E_t, E_l, E_p, and S_t, S_l, and S_p are the POS tag, lemma and confidence output by the English and the Spanish POS tagger, respectively.

word	E_t	E_l	E_p	S_t	S_l	S_p	**Accuracy**
X	X	X	X	–	–	–	88.80
–	X	X	X	–	–	–	86.22
X	–	–	–	X	X	X	78.59
–	–	–	–	X	X	X	65.28
X	X	X	–	X	X	–	**92.95**
X	X	–	X	X	–	X	92.53
X	X	–	–	X	–	–	91.22
X	X	X	–	–	X	–	89.76
X	–	X	X	–	X	X	77.08
–	–	X	–	–	X	–	74.18
X	X	–	–	–	–	–	85.76
X	–	–	–	–	–	–	71.17
–	–	–	X	–	–	X	24.96
X	X	X	X	X	–	–	92.55
X	X	X	X	–	–	X	88.89
X	–	X	–	X	–	–	78.74
X	X	X	X	–	X	–	89.62
–	X	–	–	X	X	–	90.76
–	–	X	X	–	X	X	75.94
X	–	X	–	X	X	X	80.24
X	–	–	X	X	X	X	79.13

60% of the training data is used. We do not gain much by adding more training data after this.

Results shown in Table 3 demonstrate that POS tagging can be learned effectively based on the attributes described in Subsection 6.1, even if we are not explicitly adding contextual information. To determine the extent to which each attribute is contributing to the learning task, we performed another set of experiments where we selected different subsets of the attributes. Table 4 shows the results with Logit Boost. Overall, the attributes taken from the English POS tagger are more valuable for this learning task. If we only take the word form and the features from the English Tree tagger (first row in Table 4) we are reaching an accuracy that outperforms all heuristics. Still, there is some valuable information provided by the Spanish POS tagger output since the highest accuracy is achieved by including the Spanish-based attributes in combination with the English-based ones. Surprisingly, we can manage to outperform the oracle by using only three attributes: the lexical word form and the POS tags from the English and Spanish tagger (see row 7 in table), or the POS tags from the monolingual taggers together with the lemma from the Spanish tagger (see row 4 from bottom to top). We also experimented adding as an attribute the output of the language identification method, but found no significant changes in the accuracy.

7 Discussion

We analyzed the different results gathered through the experiments and we present here the most relevant insights.

The first discovery, is that a lot of the errors made by the oracle, and the other methods as well, are due to the difficulties inherent in dealing with spontaneous speech where fillers, interruption points, hesitations, and the like abound. About as much as 20% of the errors made by the oracle are due to these features. Another roughly 20% is due to unknown tokens in the transcription, such as mumbling, slang words such as "gonna" and "wanna", or other sounds unintelligible for the human transcriber. For the rest of the analysis we decided to ignore these types of mistakes for all methods and focus only on the remaining mistakes. In the case of the oracle we are left with 445 erroneously POS tagged words. From those, about 50%, or 233 to be exact, are errors in sentences with code-switches. We consider this to be a strong indication of the complexity that intrasentential switches add to the task of POS tagging. For the taggers, these sentences are incomplete, or ill-formed, since they have fragments with foreign words and thus, they fail to identify them. The rest of the oracle mistakes can not be attributable to a single cause. Some are fragmented sentences, and some are due to errors inherent of the tagger, but nothing is particulary salient about them.

The language identification methods share, of course, the same mistakes made by the oracle, plus 342 more, for a total of 787 (in the case of the dictionary-based language identification). The challenge of POS tagging code-switched text is more evident for this method. Out of the mistakes made by the language identification method, 540 lie in sentences with code-switching, that is, nearly 70% of the mistakes. For 307 of these mistakes the right

POS tag was available from one of the taggers. Some typical examples of these errors are words that belong to both languages, such as "a", "no", "me" and "con".

The ML approach outperformed both the language identification method and the oracle. Analyzing the predictions made by SVM we verified that out of the 445 errors made by the oracle, SVM correctly tagged 223, the majority of which are words in sentences with code-switching (142 words). When compared against the errors from the method based on language identification, SVM correctly tagged 481 words out of the 787, 374 of which are words in sentences with code-switches. In summary, the ML approach is more robust to code-switched sentences. Note that we did find some errors made by the ML approach that are not shared by the oracle or the language identification method, a total of 105. Some of these mistakes are due to inconsistencies on the human-annotated tags. For instance, in most cases slang words such as "gonna" and "wanna" are labeled as unknown words, but we found that these words were labeled as verbs in a few cases. Not surprisingly this caused the ML algorithm to fail, since these class labels were misleading. The majority of the mistakes, however, seem to be due to systematic mistakes by the POS taggers.

One last remark is regarding our decision to find a method for successfully exploiting the existing taggers for POS tagging Spanglish text. Our original motivation came from the lack of linguistic resources to process Spanglish text. However, we did train from scratch a sequential model for POS tagging Spanglish, namely Conditional Random Fields (CRFs) (Lafferty *et al.*, 2001). We used MALLET (McCallum, 2002) for this experiment and the same training/testing partitions used in the experiment reported in Table 3. The CRF POS tagger was trained using capitalization information and the previous token as context. The average accuracy of this CRF was 81%, which is lower than the language identification heuristic. We believe that this low accuracy is due to the lack of a representative sample of annotated Spanglish. It will be interesting to see if when more data becomes available the ML algorithms still yield the best results.

8 Conclusions

Code-switching is a fresh and exciting research area that has received little attention in the language processing community. Research on this topic has many interesting applications, including automatic speech recognition, machine translation, and computer assisted language learning. In this paper we present preliminary work towards developing a POS tagger for English-Spanish code-switched text that, to the best of our knowledge, is the first effort towards this end.

We explored different heuristics for taking advantage of existing linguistic resources for English and Spanish with unimpressive results. A simple word-level language identification strategy outperformed all heuristics tested. But the best results, even better than the oracle, were achieved by using machine learning using the output of monolingual POS taggers as input features.

In the error analysis we showed that most of the mistakes made by the language identification method, and the oracle itself, occur in sentences with intrasentential code-switching, showing the difficulty of the task. In contrast, our machine learning approach was less sensitive to the complexity of this alternation pattern.

There is still a lot of work to do in this area. Our ongoing efforts include gathering a larger corpus, with different speakers and conversational styles, as well as written forms of code-switching from blogs and Internet forums. In addition, we are exploring the use of context information. The features we are currently using to represent each word do not take into account the context surrounding the word. We want to test if by using contextual features we can further improve our results.

In this study we focused on code-switching, but borrowing is another complex language alternation pattern that we want the POS tagger to handle. We are working on developing a special method for identification and morphological analysis of borrowings. This method will help increase the accuracy of the POS tagger.

Spanish-English is not the only popular combination of languages. An interesting line of future work would be to explore if the method presented here can be adapted to different language combinations. Moreover, multilingual communities will code-switch among more than two codes and this poses fascinating research challenges as well.

Abstract

This paper presents a novel, ranking-style word segmentation approach, called *RSVM-Seg*, which is well tailored to Chinese information retrieval(CIR). This strategy makes segmentation decision based on the ranking of the internal associative strength between each pair of adjacent characters of the sentence. On the training corpus composed of query items, a ranking model is learned by a widely-used tool Ranking SVM, with some useful statistical features, such as mutual information, difference of t-test, frequency and dictionary information. Experimental results show that, this method is able to eliminate overlapping ambiguity much more effectively, compared to the current word segmentation methods. Furthermore, as this strategy naturally generates segmentation results with different granularity, the performance of CIR systems is improved and achieves the state of the art.

1 Introduction

To improve information retrieval systems' performance, it is important to comprehend both queries and corpus precisely. Unlike English and other western languages, Chinese does not delimit words by white-space. Word segmentation is therefore a key preprocessor for Chinese information retrieval to comprehend sentences.

Due to the characteristics of Chinese, two main problems remain unresolved in word segmentation: segmentation ambiguity and unknown words, which are also demonstrated to affect the performance of Chinese information retrieval (Foo and Li, 2004). Overlapping ambiguity and combinatory ambiguity are two forms of segmentation ambiguity. The first one refers to that ABC can be segmented into AB C or A BC. The second one refers to that string AB can be a word, or A can be a word and B can be a word. In CIR, the combinatory ambiguity is also called segmentation granularity problem (Fan et al., 2007). There are many researches on the relationship between word segmentation and Chinese information retrieval (Foo and Li, 2004; Peng et al., 2002a; Peng et al., 2002b; Jin and Wong, 2002). Their studies show that the segmentation accuracy does not monotonically influence subsequent retrieval performance. Especially the overlapping ambiguity, as shown in experiments of (Wang, 2006), will cause more performance decrement of CIR. Thus a CIR system with a word segmenter better solving the overlapping ambiguity, may achieve better performance. Besides, it also showed that the precision of new word identification was more important than the recall.

There are some researches show that when compound words are split into smaller constituents, better retrieval results can be achieved (Peng et al., 2002a). On the other hand, it is reasonable that the longer the word which co-exists in query and corpus, the more similarity they may have. A hypothesis, therefore, comes to our mind, that different segmentation granularity can be incorporated to obtain better CIR performance.

In this paper we present a novel word segmentation approach for CIR, which can not only obviously reduce the overlapping ambiguity, but also introduce different segmentation granularity for the first time.

In our method, we first predict the ranking result of all internal association strength (IAS) between each pair of adjacent characters in a sentence using Ranking SVM model, and then, we segment the sentence into sub-sentences with smaller and smaller granularity by cutting adjacent character pairs according to this rank. Other machine-learning based segmentation algorithms (Zhang et al., 2003; Lafferty et al., 2001; Ng and Low, 2004) treat segmentation problem as a character sequence tagging problem based on classification. However, these methods cannot directly obtain different segmentation granularity. Experiments show that our method can actually improve information retrieval performance.

This paper is structured as follows. It starts with a brief introduction of the related work on the word segmentation approaches. Then in Section 3, we introduce our segmentation method. Section 4 evaluates the method based on experimental results. Finally, Section 5 makes summary of this whole paper and proposes the future research orientation.

2 Related Work

Various methods have been proposed to address the word segmentation problem in previous studies. They fall into two main categories, rule-based approaches that make use of linguistic knowledge and statistical approaches that train on corpus with machine learning methods. In rule-based approaches, algorithms of string matching based on dictionary are the most commonly used, such as maximum matching. They firstly segment sentences according to a dictionary and then resort to some rules to resolve ambiguities (Liu, 2002; Luo and Song, 2001). These rule-based methods are fast, however, their performances depend on the dictionary which cannot include all words, and also on the rules which cost a lot of time to make and must be updated frequently. Recent years statistical approaches became more popular. These methods take advantage of various probability information gained from large corpus to segment sentences. Among them, Wang's work (Wang, 2006) is the most similar to our method, since both of us apply statistics information of each gap in the sentence to eliminate overlapping ambiguity in methods. However, when combining different statistics, Wang decided the weight by a heuristic way which was too simply to be suitable for all sentences. In our method, we employ a machine-learning method to train features' weights.

Many machine-learning methods, such as HMM (Zhang et al., 2003), CRF (Lafferty et al., 2001), Maximum Entropy (Ng and Low, 2004), have been exploited in segmentation task. To our knowledge, machine-learning methods used in segmentation treated word segmentation as a character tagging problem. According to the model trained from training corpus and features extracted from the context in the sentence, these methods assign each character a positional tag, indicating its relative position in the word. These methods are difficult to get different granularity segmentation results directly. Our method has two main differences with them. Firstly, we tag the gap between characters rather than characters themselves. Secondly, our method is based on ranking rather than classification.

Then, we will present our ranking-based segmentation method, *RSVM-Seg*.

3 Ranking based Segmentation

Traditional segmentation methods always take the segmentation problem as classification problem and give a definite segmentation result. In our approach, we try to solve word segmentation problem from the view of ranking. For easy understanding, let's represent a Chinese sentence S as a character sequence:

$$C_{1:n} = C_1C_2\dots C_n$$

We also explicitly show the gap $G_i(i = 1\dots n-1)$ between every two adjacent characters C_i and C_{i+1}:

$$C_{1:n}|G_{1:n-1} = C_1G_1C_2G_2\dots G_{n-1}C_n$$

$IAS_i(i = 1\dots n)$ is corresponding to $G_i(i = 1\dots n)$, reflecting the internal association strength between C_i and C_{i+1}. The higher the IAS value is, the stronger the associative between the two characters is. If the association between two characters is weak, then they can be segmented. Otherwise, they should be unsegmented. That is to say we could make segmentation based on the ranking of IAS value. In our ranking-style segmentation method, Ranking SVM is exploited to predict IAS ranking.

In next subsections, we will introduce how to take advantage of Ranking SVM model to solve our problem. Then, we will describe features used for training the Ranking SVM model. Finally, we will give a scheme how to get segmentation result from predicted ranking result of Ranking SVM.

3.1 Segmentation based on Ranking SVM

Ranking SVM is a classical algorithm for ranking, which formalizes learning to rank as learning for classification on pairs of instances and tackles the classification issue by using SVM (Joachims, 2002). Suppose that $X \epsilon R^d$ is the feature space, where d is the number of features, and $Y = r_1, r_2, \ldots, r_K$ is the set of labels representing ranks. And there exists a total order between ranks $r_1 > r_2 > \ldots > r_K$, where $>$ denotes the order relationship. The actual task of learning is formalized as a Quadratic Programming problem as shown below:

$$\begin{aligned} & min_{\omega,\xi_{ij}} \frac{1}{2}\|\omega\|^2 + C\Sigma\xi_{ij} \\ & s.t.\langle \omega, x_i - x_j \rangle > 1 - \xi_{ij}, \forall x_i \succ x_j, \xi_{ij} \geq 0 \end{aligned} \quad (1)$$

where $\|\omega\|$ denotes l_2 norm measuring the margin of the hyperplane and ξ_{ij} denotes a slack variable. $x_i \succ x_j$ means the rank class of x_i has an order prior to that of x_j, i.e. $Y(x_i) > Y(x_j)$. Suppose that the solution to (1) is ω_*, then we can make the ranking function as $f(x) = \langle \omega_*, x \rangle$.

When applying Ranking SVM model to our problems, an instance (feature vector x) is created from all bigrams (namely $C_iC_{i+1}, i = 1 \ldots n-1$) of a sentence in the training corpus. Each feature is defined as a function of bigrams (we will describe features in detail in next subsection). The instances from all sentences are then combined for training. And Y refers to the class label of the IAS degree. As we mentioned above, segmentation decision is based on IAS value. Therefore, the number of IAS degree's class label is also correspondent to the number of segmentation class label. In traditional segmentation algorithms, they always label segmentation as two classes, segmented and unsegmented. However, for some phrases, it is a dilemma to make a segmentation decision based on this two-class scheme. For example, Chinese phrase "笔记本电脑(Notepad)" can be segmented as "笔记本(Note)" and "电脑(computer)" or can be viewed as one word. We cannot easily classify the gap between "本" and "脑" as segmented or unsegmented. Therefore, beside these two class labels, we define another class label, semisegmented, which means that the gap between two characters could be segmented or unsegmented, either will be right. Correspondingly, IAS degree is also divided into three classes, definitely inseparable (marked as 3), partially inseparable (marked as 2), and separable (marked as 1). "Separable" corresponds to be segmented"; "partially inseparable" corresponds to semisegmented; "definitely inseparable" corresponds to be unsegmented. Obviously, there exists orders between these labels' IAS values, namely $IAS(1) < IAS(2) < IAS(3), IAS(*)$ represents the IAS value of different labels. Next, we will describe the features used to train Ranking SVM model.

3.2 Features for IAS computation

Mutual Information: Mutual information, measuring the relationship between two variables, has been extensively used in computational language research. Given a Chinese character string 'xy' (as mentioned above, in our method, 'xy' refers to bigram in a sentence), mutual information between characters x and y is defined as follows:

$$mi(x,y) = log_2 \frac{p(x,y)}{p(x)p(y)} \quad (2)$$

where $p(x,y)$ is the co-occurrence probability of x and y, namely the probability that bigram 'xy' occurs in the training corpus, and $p(x), p(y)$ are the independent probabilities of x and y respectively. From (2), we conclude that $mi(x,y) \gg 0$ means that IAS is strong; $mi(x,y) \approx 0$ means that it is indefinite for IAS between characters x and y; $mi(x,y) \ll 0$ means that there is no association been characters x and y. However, mutual information has no consideration of context, so it cannot solve the overlapping ambiguity effectively (Sili Wang 2006). To remedy this defect, we introduce another statistics measure, difference of t-test.

Difference of t-score (DTS)**:** Difference of t-score is proposed on the basis of t-score. Given a Chinese character string 'xyz', the t-score of the character y relevant to character x and z is defined as:

$$t_{x,z}(y) = \frac{p(z|y) - p(y|x)}{\sqrt{\sigma_2(p(z|y)) + \sigma_2(p(y|x))}} \quad (3)$$

where $p(y|x)$ is the conditional probability of y given x, and $p(z|y)$, of z given y, and $\sigma_2(p(y|x))$, $\sigma_2(p(z|y))$ are variances of $p(y|x)$ and of $p(z|y)$ respectively. Sun et al. gave the derivation formula of $\sigma_2(p(y|x)), \sigma_2(p(z|y))$ (Sun et al., 1997) as

$$\sigma_2(p(z|y)) \approx \frac{r(y,z)}{r^2(y)} \quad \sigma_2(p(y|x)) \approx \frac{r(x,y)}{r^2(x)} \quad (4)$$

where $r(x,y)$, $r(y,z)$, $r(y)$, $r(z)$ are the frequency of string xy, yz, y, and z respectively. Thus formula (3) is deducted as

$$t_{x,z}(y) = \frac{\frac{r(y,z)}{r(y)} - \frac{r(x,y)}{r(x)}}{\sqrt{\frac{r(y,z)}{r^2(y)} + \frac{r(x,y)}{r^2(x)}}} \quad (5)$$

$t_{x,z}(y)$ indicates the binding tendency of y in the context of x and z: if $t_{x,z}(y) > 0$ then y tends to be bound with z rather than with x; if $t_{x,z}(y) < 0$, they y tends to be bound with x rather than with z.

To measure the binding tendency between two adjacent characters 'xy' (also, it refers to bigram in a sentence in our method), we use difference of t-score (DTS) (Sun et al., 1998) which is defined as

$$dts(x,y) = t_{v,y}(x) - t_{x,w}(y) \quad (6)$$

Higher $dts(x,y)$ indicates stronger IAS between adjacent characters x and y.

Dictionary Information: Both statistics measures mentioned above cannot avoid sparse data problem. Then Dictionary Information is used to compensate for the shortage of statistics information. The dictionary we used includes 75784 terms. We use binary value to denote the dictionary feature. If a bigram is in the dictionary or a part of dictionary term, we label it as "1", otherwise, we label is as "0".

Frequency: An important characteristic of new word is its repeatability. Thus, we also use frequency as another feature to train Ranking SVM model. Here, the frequency is referred to the number of times that a bigram occurs in the training corpus.

We give a training sentence for a better understanding of features mentioned above. The sentence is "中国建设银行网(China Construction Bank network)" We extract all bigrams in this sentence, compute the four above features and give the IAS a label for each bigram. The feature vectors of all these bigrams for training are shown in Table 1.

Algorithm 1 : Generate various granularity terms

```
1:  Input: A Chinese sentence $S = C_1 : C_n$
    $IAS = IAS_{1:n-1}$ $LB = 1; RB = n$
2:  $Iterative(S, IAS)$:
3:  while $length(S) \geq 3$ do
4:      $MB = FindMinIAS(IAS)$
5:      $SL = C_{LB:MB}$
6:      $SR = C_{MB+1:RB}$
7:      $IAS_L = IAS_{LB:MB}$
8:      $IAS_R = IAS_{MB+1:RB}$
9:      $Iterative(SL, IAS_L)$
10:     $Iterative(SR, IAS_R)$
11: end while
```

3.3 Segmentation scheme

In order to compare with other segmentation methods, which give a segmentation result based on two class labels, segmented and unsegmented, it is necessary to convert real numbers result given by Ranking SVM to these two labels. Here, we make a heuristic scheme to segment the sentence based on IAS ranking result predicted by Ranking SVM. The scheme is described in Algorithm 1. In each iteration we cut the sentence at the gap with minimum IAS value. Nie et.al. pointed out that the average length of words in usage is 1.59 (Nie et al., 2000). Therefore, we stop the segmentation iterative when the length of sub_sentence is 2 or less than 2. By this method, we could represent the segmentation result as a binary tree. Figure 1 shows an example of this tree. With this tree, we can obtain various granularity segmentations easily, which could be used in CIR. This segmentation scheme may cause some combinatory ambiguity. However, Nie et.al. (Nie et al., 2000) also pointed out that there is no accurate word definition, thus whether combinatory ambiguity occurs is uncertain. What's more, compared to overlapping ambiguity, combinatory ambiguity is not the fatal factor for information retrieval performance as mentioned in introduction. Therefore, this scheme is reasonable for Chinese information re-

4 Experiments and analysis

4.1 Data

Since the label scheme and evaluation measure (described in next subsection) of our segmentation method are both different from the traditional segmentation methods, we did not carry out experiments on SIGHAN. Instead, we used two query logs (QueryLog1 and QueryLog2) as our experiment corpus, which are from two Chinese search engine companies. 900 queries randomly from QueryLog1 were chosen as training corpus. 110 Chinese queries from PKU Tianwang[1] , randomly selected 150 queries from QueryLog1 and 100 queries from QueryLog2 were used as test corpus. The train and test corpus have been tagged by three people. They were given written information need statements, and were asked to judge the IAS of every two adjacent characters in a sentence on a three level scale as mentioned above, separable, partially inseparable, and definitely inseparable. The assessors agreed in 84% of the sentences, the other sentences were checked by all assessors, and a more plausible alternative was selected. We exploited SVM^{light2} as the toolkit to implement Ranking SVM model.

4.2 Evaluation Measure

Since our approach is based on the ranking of IAS values, it is inappropriate to evaluate our method by the traditional method used in other segmentation algorithms. Here, we proposed an evaluation measure RankPrecision based on Kendall's τ (Joachims, 2002), which compared the similarity between the predicted ranking of IAS values and the rankings of these tags as descending order. RankPrecision formula is as follows:

$$RankPrecision = 1 - \frac{\Sigma_{i=1}^{n} InverseCount(s_i)}{\Sigma_{i=1}^{n} CompInverseCount(s_i)} \quad (7)$$

where s_i represents the ith sentence (unsegmented string), $InverseCount(s_i)$ represents the number of discordant pairs inversions in the ranking of the predicted IAS value compared to the correct labeled ranking. $CompInverseCount(s_i)$ represents the number of discordant pairs inversions when the labels totally inverse.

4.3 Experiments Results

Contributions of the Features: We investigated the contribution of each feature by generating many versions of Ranking SVM model. RankPrecision as described above was used for evaluations in these and following experiments. We used Mutual Information(MI); Difference of T-Score(DTS); Frequency(F); mutual information and difference of t-score(MI+DTS); mu-

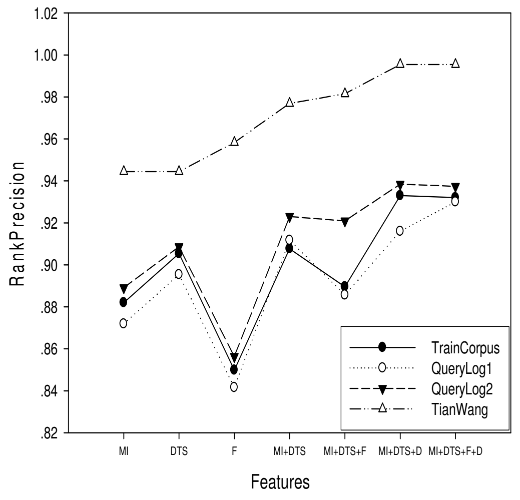

Figure 2: Effects of features

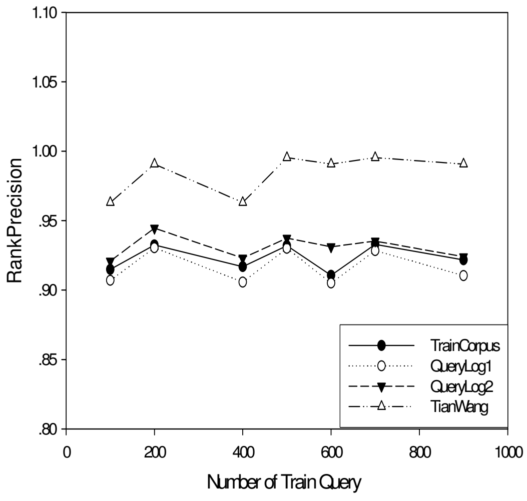

Figure 3: Effects of Corpus Size

tual information, difference of t-score and Frequency(MI+DTS+F); mutual information, difference of t-score and dictionary(MI+DTS+D); mutual information, difference of t-score, frequency and Dictionary(MI+DTS+F+D) as features respectively. The results are shown in Table 2 and Figure 2. From the results, we can see that:

- Using all described features together, the Ranking SVM achieved a good performance. And when we added MI, DTS, frequency, dictionary as features one by one, the RankPrecision improved step by step. It demonstrates that the features we selected are useful for segmentation.
- The lowest RankPrecision is above 85%, which suggests that the predicted rank result by our approach is very close to the right rank. It is shown that our method is effective.
- When we used each feature alone, difference of t-score achieved highest RankPrecise, frequency was worst on most of test corpus (except TianWang). It is induced that difference of t-test is the most effective feature for segmentation. It is explained that because dts is combined with the context information, which eliminates overlapping ambiguity errors.
- It is surprising that when mutual information and difference of t-score was combined with

frequency, the RankPrecision was hurt on three test corpus, even worse than dts feature. The reason is supposed that some non-meaning but common strings, such as ”的人” would be took for a word with high IAS values. To correct this error, we could build a stop word list, and when we meet a character in this list, we treat them as a white-space.

Effects of corpus size: We trained different Ranking SVM models with different corpus size to investigate the effects of training corpus size to our method performance. The results are shown in Table 3 and Figure 3. From the results, we can see that the effect of corpus size to the performance of our approach is minors. Our segmentation approach can achieve good performance even with small training corpus, which indicates that Ranking SVM has generalization ability. Therefore we can use a relative small corpus to train Ranking SVM, saving labeling effort.

Effects on Finding Boundary: In algorithm 1, we could get different granularity segmentation words when we chose different length as stop condition. Figure 4 shows the ”boundary precision” at each stop condition. Here, ”boundary precision” is defined as

$$\frac{No.of\ right\ cut\ boundaries}{No.of\ all\ cut\ boundaries} \tag{8}$$

From the result shown in figure 4, we can see that as the segmentation granularity gets smaller, the boundary precision gets lower. The reason is obvious, that we may segment a whole word into smaller parts. However, as we analyzed in introduction, in CIR, we should judge words boundaries correctly to avoid overlapping ambiguity. As for combinatory ambiguity, through setting different stop length condition, we can obtain different granularity segmentation result.

Effects on Overlapping Ambiguity: Due to the inconsistency of train and test corpus, it is difficult to keep fair for Chinese word segmentation evaluation. Since ICTCLAS is considered as the best Chinese word segmentation systems. We chose ICTCLAS as the comparison object. Moreover, we chose Maximum Match segmentation algorithm, which is rule-based segmentation method, as the baseline.

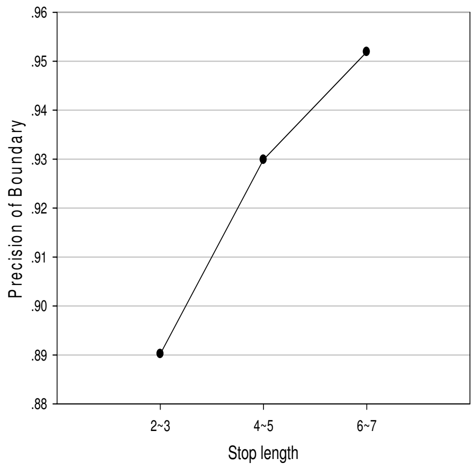

Figure 4: Precision of boundary with different stop word length conditions

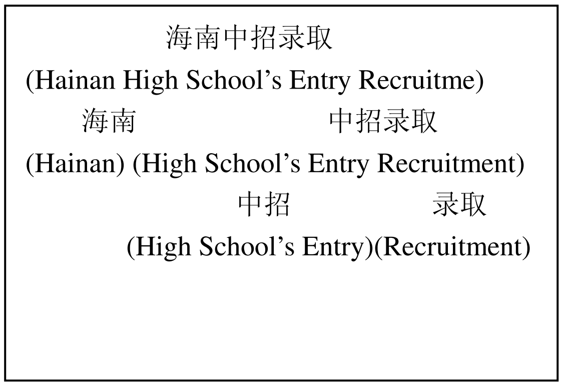
Corpus	**NOA** (RSVM_Seg)	**NOA** (ICTCLAS)	**NOA** (MM)
Query Log1	7	10	21
Query Log2	2	6	16
Tian Wang	0	0	1

Table 4: Number of Overlapping Ambiguity

We compared the number of overlapping ambiguity(NOA) among these three approaches on test corpus QueryLog1, QueryLog2 and TianWang. The result is shown in Table 4. On these three test corpus, the NOA of our approach is smallest, which indicates our method resolve overlapping ambiguity more effectively. For example, the sentence ”基础课件(basic notes)”, the segmentation result of ICTCLAS is ”基础课(basic class)/件(article)”, the word ”课件(notes)” is segmented, overlapping ambiguity occurring. However, with our method, the predicted IAS value rank of positions between every two adjacent characters in this sentence is ”基3础1课2件”, which indicates that the character ”课” has stronger internal associative strength with the character ”件” than with the character ”础”, eliminating overlapping ambiguity according to this ISA rank results.

Effects on Recognition Boundaries of new word: According to the rank result of all IAS values



海南中招录取
(Hainan High School's Entry Recruitme)
海南
中招录取
(Hainan) (High School's Entry Recruitment)
中招
录取
(High School's Entry)(Recruitment)

Figure 5: Example of New Word boundary

in a sentence, our method can recognize the boundaries of new words precisely, avoiding the overlapping ambiguity caused by new words. For example, the phrase "海南中招录取(Hainan High School's Entry Recruitment)", the ICTCLAS segmentation result is "海南/中/招录/取", because the new word "中招" cannot be recognized accurately, thus the character "招" is combined with its latter character "录", causing overlapping ambiguity. By our method, the segmentation result is shown as figure 5, in which no overlapping ambiguity occurs.

Performance of Chinese Information Retrieval: To evaluate the effectiveness of *RSVM-Seg* method on CIR, we compared it with the FMM segmentation. Our retrieval system combines different query representations obtained by our segmentation method, *RSVM-Seg*. In previous TREC Terebyte Track, Markov Random Field(MRF) (Metzler and Croft, 2005) model has displayed better performance than other information retrieval models, and it can much more easily include dependence features. There are three variants of MRF model, full independence(FI), sequential dependence(SD), and full dependence(FD). We chose SD as our retrieval model, since Chinese words are composed by characters and the adjacent characters have strong dependence relationship. We evaluated the CIR performance on the Chinese Web Corpora CWT200g provided by Tianwang [3], which, as we know, is the largest publicly available Chinese web corpus till now. It consists of $37,482,913$ web pages with total size of 197GB. We used the topic set for SEWM2007 and SEWM2006 Topic Distillation (TD) task which contains 121 topics. MAP, R-Precision and GMAP (Robertson, 2006) were as main evaluation metrics. GMAP is the geometric mean of AP(Average Precision) through different queries, which was introduced to concentrate on difficult queries. The result is shown in 5. From the table, we can see that our segmentation method improve the CIR performance compared to FMM.

[3]http://www.cwirf.org/

Segmentation Method	MAP	R-P	GMAP
FMM	0.0548	0.0656	0.0095
RSVM-Seg	0.0623	0.0681	0.0196

Table 5: Evaluation of CIR performance

5 Conclusion and Future work

From what we have discussed above, we can safely draw the conclusion that our work includes several main contributions. Firstly, to our best known, this is the first time to take the Chinese word segmentation problem as ranking problem, which provides a new view for Chinese word segmentation. This approach has been proved to be able to eliminate overlapping ambiguity and also be able to obtain various segmentation granularities. Furthermore, our segmentation method can improve Chinese information retrieval performance to some extent.

As future work, we would search another more encouraging method to make a segmentation decision from the ranking result. Moreover, we will try to relabel SIGHAN corpus on our three labels, and do experiments on them, which will be more convenient to compare with other segmentation methods. Besides, we will carry out more experiments to search the effectiveness of our segmentation method to CIR.

Abstract

Active learning is well-suited to many problems in natural language processing, where unlabeled data may be abundant but annotation is slow and expensive. This paper aims to shed light on the best active learning approaches for sequence labeling tasks such as information extraction and document segmentation. We survey previously used query selection strategies for sequence models, and propose several novel algorithms to address their shortcomings. We also conduct a large-scale empirical comparison using multiple corpora, which demonstrates that our proposed methods advance the state of the art.

1 Introduction

Traditional supervised learning algorithms use whatever labeled data is provided to induce a model. By contrast, *active learning* gives the learner a degree of control by allowing it to select which instances are labeled and added to the training set. A typical active learner begins with a small labeled set $\mathcal{L}$, selects one or more informative *query* instances from a large unlabeled pool $\mathcal{U}$, learns from these labeled queries (which are then added to $\mathcal{L}$), and repeats. In this way, the learner aims to achieve high accuracy with as little labeling effort as possible. Thus, active learning can be valuable in domains where unlabeled data are readily available, but obtaining training labels is expensive.

Such is the case with many *sequence labeling* tasks in natural language domains. For example, part-of-speech tagging (Seung et al., 1992; Lafferty et al., 2001), information extraction (Scheffer et al., 2001; Sang and DeMeulder, 2003; Kim et al., 2004), and document segmentation (Carvalho and Cohen, 2004) are all typically treated as sequence labeling problems. The source data for these tasks (i.e., text documents in electronic form) are often easily obtained. However, due to the nature of sequence labeling tasks, annotating these texts can be rather tedious and time-consuming, making active learning an attractive technique.

While there has been much work on active learning for classification (Cohn et al., 1994; McCallum and Nigam, 1998; Zhang and Oles, 2000; Zhu et al., 2003), active learning for sequence labeling has received considerably less attention. A few methods have been proposed, based mostly on the conventions of *uncertainty sampling*, where the learner queries the instance about which it has the least certainty (Scheffer et al., 2001; Culotta and McCallum, 2005; Kim et al., 2006), or *query-by-committee*, where a "committee" of models selects the instance about which its members most disagree (Dagan and Engelson, 1995). We provide more detail on these and the new strategies we propose in Section 3.

The comparative effectiveness of these approaches, however, has not been studied. Furthermore, it has been suggested that uncertainty sampling and query-by-committee fail on occasion (Roy and McCallum, 2001; Zhu et al., 2003) by querying outliers, e.g., instances considered informative in isolation by the learner, but containing little information about the *rest* of the distribution of instances. Proposed methods for dealing with these shortcomings have so far only considered classification tasks.

This paper presents two major contributions for active learning and sequence labeling tasks. First, we motivate and introduce several new query strategies for probabilistic sequence models. Second, we conduct a thorough empirical analysis of previously proposed methods with our algorithms on a variety of benchmark corpora. The remainder of this paper is organized as follows. Section 2 provides a brief introduction to sequence labeling and conditional random fields (the sequence model used in our experiments). Section 3 describes in detail all the query selection strategies we consider. Section 4 presents the results of our empirical study. Section 5 concludes with a summary of our findings.

2 Sequence Labeling and CRFs

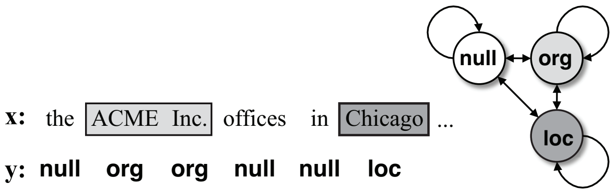
In this paper, we are concerned with active learning for sequence labeling. Figure 1 illustrates how, for example, an information extraction problem can be viewed as a sequence labeling task. Let $\mathbf{x} = \langle x_1, \ldots, x_T \rangle$ be an observation sequence of length T with a corresponding label sequence $\mathbf{y} = \langle y_1, \ldots, y_T \rangle$. Words in a sentence correspond to tokens in the input sequence $\mathbf{x}$, which are mapped to labels in $\mathbf{y}$. These labels indicate whether the word belongs to a particular entity class of interest (in this case, org and loc) or not (null). These labels can be assigned by a sequence model based on a finite state machine, such as the one shown to the right in Figure 1.

We focus our discussion of active learning for sequence labeling on *conditional random fields*, or CRFs (Lafferty et al., 2001). The rest of this section serves as a brief introduction. CRFs are statistical graphical models which have demonstrated state-of-the-art accuracy on virtually all of the sequence labeling tasks mentioned in Section 1. We use linear-chain CRFs, which correspond to conditionally trained probabilistic finite state machines.

A linear-chain CRF model with parameters θ defines the posterior probability of $\mathbf{y}$ given $\mathbf{x}$ to be[1]:

$$P(\mathbf{y}|\mathbf{x};\theta) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_{t=1}^{T}\sum_{k=1}^{K} \theta_k f_k(y_{t-1}, y_t, \mathbf{x}_t)\right). \tag{1}$$

[1]Our discussion assumes, without loss of generality, that each label is uniquely represented by one state, thus each label sequence $\mathbf{y}$ corresponds to exactly one path through the model.



x: the ACME Inc. offices in Chicago ...
y: null org org null null loc
null
org
loc

Figure 1: An information extraction example treated as a sequence labeling task. Also shown is a corresponding sequence model represented as a finite state machine.

Here $Z(\mathbf{x})$ is a normalization factor over all possible labelings of $\mathbf{x}$, and θ_k is one of K model parameter weights corresponding to some feature $f_k(y_{t-1}, y_t, \mathbf{x}_t)$. Each feature f_k describes the sequence $\mathbf{x}$ at position t with label y_t, observed along a transition from label states y_{t-1} to y_t in the finite state machine. Consider the example text from Figure 1. Here, f_k might be the feature WORD=*ACME* and have the value $f_k = 1$ along a transition from the null state to the org state (and 0 elsewhere). Other features set to 1 here might be ALLCAPS and NEXTWORD=*Inc.* The weights in θ are set to maximize the conditional log likelihood ℓ of training sequences in the labeled data set $\mathcal{L}$:

$$\ell(\mathcal{L};\theta) = \sum_{l=1}^{L} \log P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)};\theta) - \sum_{k=1}^{K} \frac{\theta_k^2}{2\sigma^2},$$

where L is the size of the labeled set $\mathcal{L}$, and the second term is a Gaussian regularization penalty on $\|\theta\|$ to prevent over-fitting. After training, labels can be predicted for new sequences using the Viterbi algorithm. For more details on CRFs and their training procedures, see Sutton and McCallum (2006).

Note that, while we describe the active learning algorithms in the next section in terms of linear-chain CRFs, they have analogs for other kinds of sequence models, such as hidden Markov models, or HMMs (Rabiner, 1989), probabilistic context-free grammars (Lari and Young, 1990), and general CRFs (Sutton and McCallum, 2006).

3 Active Learning with Sequence Models

In order to select queries, an active learner must have a way of assessing how *informative* each instance is. Let $\mathbf{x}^*$ be the most informative instance according to some query strategy $\phi(\mathbf{x})$, which is a function used to evaluate each instance $\mathbf{x}$ in the unlabeled pool $\mathcal{U}$.

```
Given: Labeled set $\mathcal{L}$, unlabeled pool $\mathcal{U}$, query
       strategy $\phi(\cdot)$, query batch size $B$
repeat
    // learn a model using the current $\mathcal{L}$
    $\theta = \text{train}(\mathcal{L})$ ;
    for $b = 1$ to $B$ do
        // query the most informative instance
        $\mathbf{x}_b^* = \arg\max_{\mathbf{x}\in\mathcal{U}} \phi(\mathbf{x})$ ;
        // move the labeled query from $\mathcal{U}$ to $\mathcal{L}$
        $\mathcal{L} = \mathcal{L} \cup \langle \mathbf{x}_b^*, \text{label}(\mathbf{x}_b^*)\rangle$ ;
        $\mathcal{U} = \mathcal{U} - \mathbf{x}_b^*$ ;
    end
until some stopping criterion ;
```

Algorithm 1: Pool-based active learning.

Algorithm 1 provides a sketch of the generic pool-based active learning scenario.

In the remainder of this section, we describe various query strategy formulations of $\phi(\cdot)$ that have been used for active learning with sequence models. We also point out where we think these approaches may be flawed, and propose several novel query strategies to address these issues.

3.1 Uncertainty Sampling

One of the most common general frameworks for measuring informativeness is *uncertainty sampling* (Lewis and Catlett, 1994), where a learner queries the instance that it is most uncertain how to label. Culotta and McCallum (2005) employ a simple uncertainty-based strategy for sequence models called **least confidence (LC)**:

$$\phi^{LC}(\mathbf{x}) = 1 - P(\mathbf{y}^*|\mathbf{x};\theta).$$

Here, $\mathbf{y}^*$ is the most likely label sequence, i.e., the Viterbi parse. This approach queries the instance for which the current model has the least confidence in its most likely labeling. For CRFs, this confidence can be calculated using the posterior probability given by Equation (1).

Scheffer et al. (2001) propose another uncertainty strategy, which queries the instance with the smallest margin between the posteriors for its two most likely labelings. We call this approach **margin (M)**:

$$\phi^{M}(\mathbf{x}) = -\big(P(\mathbf{y}_1^*|\mathbf{x};\theta) - P(\mathbf{y}_2^*|\mathbf{x};\theta)\big).$$

Here, $\mathbf{y}_1^*$ and $\mathbf{y}_2^*$ are the first and second best label sequences, respectively. These can be efficiently computed using the N-best algorithm (Schwartz and Chow, 1990), a beam-search generalization of Viterbi, with $N = 2$. The minus sign in front is simply to ensure that ϕ^M acts as a maximizer for use with Algorithm 1.

Another uncertainty-based measure of informativeness is *entropy* (Shannon, 1948). For a discrete random variable Y, the entropy is given by $H(Y) = -\sum_i P(y_i)\log P(y_i)$, and represents the information needed to "encode" the distribution of outcomes for Y. As such, is it often thought of as a measure of uncertainty in machine learning. In active learning, we wish to use the entropy of our model's posteriors over its labelings. One way this has been done with probabilistic sequence models is by computing what we call **token entropy (TE)**:

$$\phi^{TE}(\mathbf{x}) = -\frac{1}{T}\sum_{t=1}^{T}\sum_{m=1}^{M} P_\theta(y_t = m)\log P_\theta(y_t = m), \quad (2)$$

where T is the length of $\mathbf{x}$, m ranges over all possible token labels, and $P_\theta(y_t = m)$ is shorthand for the marginal probability that m is the label at position t in the sequence, according to the model. For CRFs and HMMs, these marginals can be efficiently computed using the *forward* and *backward* algorithms (Rabiner, 1989). The summed token entropies have typically been normalized by sequence length T, to avoid simply querying longer sequences (Baldridge and Osborne, 2004; Hwa, 2004). However, we argue that querying long sequences should not be explicitly discouraged, if in fact they contain more information. Thus, we also propose the **total token entropy (TTE)** measure:

$$\phi^{TTE}(\mathbf{x}) = T \times \phi^{TE}(\mathbf{x}).$$

For most sequence labeling tasks, however, it is more appropriate to consider the entropy of the label sequence $\mathbf{y}$ as a whole, rather than some aggregate of individual token entropies. Thus an alternate query strategy is **sequence entropy (SE)**:

$$\phi^{SE}(\mathbf{x}) = -\sum_{\hat{\mathbf{y}}} P(\hat{\mathbf{y}}|\mathbf{x};\theta)\log P(\hat{\mathbf{y}}|\mathbf{x};\theta), \quad (3)$$

where $\hat{\mathbf{y}}$ ranges over all possible label sequences for input sequence $\mathbf{x}$. Note, however, that the number of possible labelings grows exponentially with the length of $\mathbf{x}$. To make this feasible, previous work (Kim et al., 2006) has employed an approximation we call ***N*-best sequence entropy (NSE)**:

$$\phi^{NSE}(\mathbf{x}) = -\sum_{\hat{\mathbf{y}} \in \mathcal{N}} P(\hat{\mathbf{y}}|\mathbf{x};\theta) \log P(\hat{\mathbf{y}}|\mathbf{x};\theta),$$

where $\mathcal{N} = \{\mathbf{y}_1^*, \ldots, \mathbf{y}_N^*\}$, the set of the N most likely parses, and the posteriors are re-normalized (i.e., $Z(\mathbf{x})$ in Equation (1) only ranges over $\mathcal{N}$). For $N = 2$, this approximation is equivalent to ϕ^M, thus N-best sequence entropy can be thought of as a generalization of the margin approach.

Recently, an efficient entropy calculation via dynamic programming was proposed for CRFs in the context of semi-supervised learning (Mann and McCallum, 2007). We use this algorithm to compute the true sequence entropy (3) for active learning in a constant-time factor of Viterbi's complexity. Hwa (2004) employed a similar approach for active learning with probabilistic context-free grammars.

3.2 Query-By-Committee

Another general active learning framework is the *query-by-committee* (QBC) approach (Seung et al., 1992). In this setting, we use a committee of models $\mathcal{C} = \{\theta^{(1)}, \ldots, \theta^{(C)}\}$ to represent C different hypotheses that are consistent with the labeled set $\mathcal{L}$. The most informative query, then, is the instance over which the committee is in most disagreement about how to label.

In particular, we use the *query-by-bagging* approach (Abe and Mamitsuka, 1998) to learn a committee of CRFs. In each round of active learning, $\mathcal{L}$ is sampled (with replacement) L times to create a unique, modified labeled set $\mathcal{L}^{(c)}$. Each model $\theta^{(c)} \in \mathcal{C}$ is then trained using its own corresponding labeled set $\mathcal{L}^{(c)}$. To measure disagreement among committee members, we consider two alternatives.

Dagan and Engelson (1995) introduced QBC with HMMs for part-of-speech tagging using a measure called **vote entropy (VE)**:

$$\phi^{VE}(\mathbf{x}) = -\frac{1}{T}\sum_{t=1}^{T}\sum_{m=1}^{M} \frac{V(y_t,m)}{C} \log \frac{V(y_t,m)}{C},$$

where $V(y_t, m)$ is the number of "votes" label m receives from all the committee member's Viterbi labelings at sequence position t.

McCallum and Nigam (1998) propose a QBC strategy for classification based on *Kullback-Leibler (KL) divergence*, an information-theoretic measure of the difference between two probability distributions. The most informative query is considered to be the one with the largest average KL divergence between a committee member's posterior label distribution and the consensus. We modify this approach for sequence models by summing the average KL scores using the marginals at each token position and, as with vote entropy, normalizing for length. We call this approach **Kullback-Leibler (KL)**:

$$\phi^{KL}(\mathbf{x}) = \frac{1}{T}\sum_{t=1}^{T} \frac{1}{C}\sum_{c=1}^{C} D(\theta^{(c)} \| \mathcal{C}),$$

where (using shorthand again):

$$D(\theta^{(c)} \| \mathcal{C}) = \sum_{m=1}^{M} P_{\theta^{(c)}}(y_t = m) \log \frac{P_{\theta^{(c)}}(y_t = m)}{P_{\mathcal{C}}(y_t = m)}.$$

Here $P_{\mathcal{C}}(y_t = m) = \frac{1}{C}\sum_{c=1}^{C} P_{\theta^{(c)}}(y_t = m)$, or the "consensus" marginal probability that m is the label at position t in the sequence.

Both of these disagreement measures are normalized for sequence length T. As with token entropy (2), this may bias the learner toward querying shorter sequences. To study the effects of normalization, we also conduct experiments with **non-normalized variants** ϕ^{TVE} and ϕ^{TKL}.

Additionally, we argue that these token-level disagreement measures may be less appropriate for most tasks than measuring the committee's disagreement about the label sequence $\mathbf{y}$ as a whole. Therefore, we propose **sequence vote entropy (SVE)**:

$$\phi^{SVE}(\mathbf{x}) = -\sum_{\hat{\mathbf{y}} \in \mathcal{N}^{\mathcal{C}}} P(\hat{\mathbf{y}}|\mathbf{x};\mathcal{C}) \log P(\hat{\mathbf{y}}|\mathbf{x};\mathcal{C}),$$

where $\mathcal{N}^{\mathcal{C}}$ is the union of the N-best parses from all models in the committee $\mathcal{C}$, and $P(\hat{\mathbf{y}}|\mathbf{x};\mathcal{C}) = \frac{1}{C}\sum_{c=1}^{C} P(\hat{\mathbf{y}}|\mathbf{x};\theta^{(c)})$, or the "consensus" posterior probability for some label sequence $\hat{\mathbf{y}}$. This can be thought of as a QBC generalization of N-best entropy, where each committee member casts a vote for the posterior label distribution. We also explore a **sequence Kullback-Leibler (SKL)** variant:

$$\phi^{SKL}(\mathbf{x}) = \frac{1}{C}\sum_{c=1}^{C}\sum_{\hat{\mathbf{y}} \in \mathcal{N}^{\mathcal{C}}} P(\hat{\mathbf{y}}|\mathbf{x};\theta^{(c)}) \log \frac{P(\hat{\mathbf{y}}|\mathbf{x};\theta^{(c)})}{P(\hat{\mathbf{y}}|\mathbf{x};\mathcal{C})}.$$

3.3 Expected Gradient Length

A third general active learning framework we consider is to query the instance that would impart the greatest change to the current model *if we knew its label*. Since we train discriminative models like CRFs using gradient-based optimization, this involves querying the instance which, if labeled and added to the training set, would create the greatest change in the gradient of the objective function (i.e., the largest gradient vector used to re-estimate parameter values).

Let $\nabla\ell(\mathcal{L};\theta)$ be the gradient of the log-likelihood ℓ with respect to the model parameters θ, as given by Sutton and McCallum (2006). Now let $\nabla\ell(\mathcal{L}^{+\langle\mathbf{x},\mathbf{y}\rangle};\theta)$ be the new gradient that would be obtained by adding the training tuple $\langle\mathbf{x},\mathbf{y}\rangle$ to $\mathcal{L}$. Since the query algorithm does not know the true label sequence $\mathbf{y}$ in advance, we instead calculate the **expected gradient length (EGL)**:

$$\phi^{EGL}(\mathbf{x}) = \sum_{\hat{\mathbf{y}}\in\mathcal{N}} P(\hat{\mathbf{y}}|\mathbf{x};\theta)\left\|\nabla\ell(\mathcal{L}^{+\langle\mathbf{x},\hat{\mathbf{y}}\rangle};\theta)\right\|,$$

approximated as an expectation over the N-best labelings, where $\|\cdot\|$ is the Euclidean norm of each resulting gradient vector. We first introduced this approach in previous work on multiple-instance active learning (Settles et al., 2008), and adapt it to query selection with sequences here. Note that, at query time, $\nabla\ell(\mathcal{L};\theta)$ should be nearly zero since ℓ converged at the previous round of training. Thus, we can approximate $\nabla\ell(\mathcal{L}^{+\langle\mathbf{x},\hat{\mathbf{y}}\rangle};\theta) \approx \nabla\ell(\langle\mathbf{x},\hat{\mathbf{y}}\rangle;\theta)$ for computational efficiency, because the training instances are assumed to be independent.

3.4 Information Density

It has been suggested that uncertainty sampling and QBC are prone to querying outliers (Roy and McCallum, 2001; Zhu et al., 2003). Figure 2 illustrates this problem for a binary linear classifier using uncertainty sampling. The least certain instance lies on the classification boundary, but is not "representative" of other instances in the distribution, so knowing its label is unlikely to improve accuracy on the data as a whole. QBC and EGL exhibit similar behavior, by spending time querying possible outliers simply because they are controversial, or are expected to impart significant change in the model.

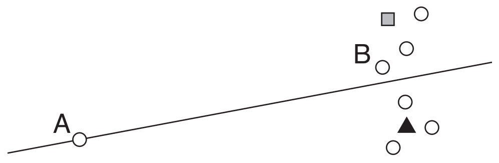


Figure 2: An illustration of when uncertainty sampling can be a poor strategy for classification. Shaded polygons represent labeled instances ($\mathcal{L}$), and circles represent unlabeled instances ($\mathcal{U}$). Since A is on the decision boundary, it will be queried as the most uncertain. However, querying B is likely to result in more information about the data as a whole.

We argue that this phenomenon can occur with sequence labeling tasks as well as with classification. To address this, we propose a new active learning approach called **information density (ID)**:

$$\phi^{ID}(\mathbf{x}) = \phi^{SE}(\mathbf{x}) \times \left(\frac{1}{U}\sum_{u=1}^{U}\text{sim}(\mathbf{x},\mathbf{x}^{(u)})\right)^{\beta}.$$

That is, the informativeness of $\mathbf{x}$ is weighted by its average similarity to all other sequences in $\mathcal{U}$, subject to a parameter β that controls the relative importance of the density term. In the formulation presented above, sequence entropy ϕ^{SE} measures the "base" informativeness, but we could just as easily use any of the instance-level strategies presented in the previous sections.

This density measure requires us to compute the similarity of two sequences. To do this, we first transform each $\mathbf{x}$, which is a sequence of feature vectors (tokens), into a single kernel vector $\vec{\mathbf{x}}$:

$$\vec{\mathbf{x}} = \left[\sum_{t=1}^{T} f_1(x_t), \ldots, \sum_{t=1}^{T} f_J(x_t)\right],$$

where $f_j(x_t)$ is the value of feature f_j for token x_t, and J is the number of features in the input representation[2]. In other words, sequence $\mathbf{x}$ is compressed into a fixed-length feature vector $\vec{\mathbf{x}}$, for which each element is the sum of the corresponding feature's values across all tokens. We can then use cosine

[2]Note that $J \neq K$, and $f_j(x_t)$ here differs slightly from the feature definition given in Section 2. Since the labels y_{t-1} and y_t are unknown before querying, the K features used for model training are reduced down to the J input features here, which factor out any label dependencies.

similarity on this simplified representation:

$$\text{sim}_{cos}(\mathbf{x}, \mathbf{x}^{(u)}) = \frac{\vec{\mathbf{x}} \cdot \vec{\mathbf{x}}^{(u)}}{\|\vec{\mathbf{x}}\| \times \|\vec{\mathbf{x}}^{(u)}\|}.$$

We have also investigated similarity functions based on exponentiated Euclidean distance and KL-divergence, the latter of which was also employed by McCallum and Nigam (1998) for density-weighting QBC in text classification. However, these measures show no improvement over cosine similarity, and require setting additional hyper-parameters.

One potential drawback of information density is that the number of required similarity calculations grows quadratically with the number of instances in $\mathcal{U}$. For pool-based active learning, we often assume that the size of $\mathcal{U}$ is very large. However, these densities only need to be computed once, and are independent of the base information measure. Thus, when employing information density in a real-world interactive learning setting, the density scores can simply be pre-computed and cached for efficient lookup during the actual active learning process.

3.5 Fisher Information

We also introduce a query selection strategy for sequence models based on *Fisher information*, building on the theoretical framework of Zhang and Oles (2000). Fisher information $\mathcal{I}(\theta)$ represents the overall uncertainty about the estimated model parameters θ, as given by:

$$\mathcal{I}(\theta) = -\int_{\mathbf{x}} P(\mathbf{x}) \int_{\mathbf{y}} P(\mathbf{y}|\mathbf{x};\theta) \frac{\partial^2}{\partial\theta^2} \log P(\mathbf{y}|\mathbf{x};\theta).$$

For a model with K parameters, the Fisher information takes the form of a $K \times K$ covariance matrix. Our goal in active learning is to select the query that most efficiently minimizes the model variance reflected in $\mathcal{I}(\theta)$. This can be accomplished by optimizing the **Fisher information ratio (FIR)**:

$$\phi^{FIR}(\mathbf{x}) = -\text{tr}\left(\mathcal{I}_{\mathbf{x}}(\theta)^{-1}\mathcal{I}_{\mathcal{U}}(\theta)\right), \qquad (4)$$

where $\mathcal{I}_{\mathbf{x}}(\theta)$ and $\mathcal{I}_{\mathcal{U}}(\theta)$ are Fisher information matrices for sequence $\mathbf{x}$ and the unlabeled pool $\mathcal{U}$, respectively. The leading minus sign again ensures that ϕ^{FIR} is a maximizer for use with Algorithm 1.

Previously, Fisher information for active learning has only been investigated in the context of simple binary classification. When employing FIR with sequence models like CRFs, there are two additional computational challenges. First, we must integrate over all possible labelings $\mathbf{y}$, which can, as we have seen, be approximated as an expectation over the N-best labelings. Second, the inner product in the ratio calculation (4) requires inverting a $K \times K$ matrix for each $\mathbf{x}$. In most interesting natural language applications, K is very large, making this algorithm intractable. However, it is common in similar situations to approximate the Fisher information matrix with its diagonal (Nyffenegger et al., 2006). Thus we estimate $\mathcal{I}_{\mathbf{x}}(\theta)$ using:

$$\mathcal{I}_{\mathbf{x}}(\theta) = \sum_{\hat{\mathbf{y}} \in \mathcal{N}} P(\hat{\mathbf{y}}|\mathbf{x};\theta) \Bigg[\left(\frac{\partial \log P(\hat{\mathbf{y}}|\mathbf{x};\theta)}{\partial \theta_1} \right)^2 + \delta, \ldots, \left(\frac{\partial \log P(\hat{\mathbf{y}}|\mathbf{x};\theta)}{\partial \theta_K} \right)^2 + \delta \Bigg],$$

and $\mathcal{I}_{\mathcal{U}}(\theta)$ using:

$$\mathcal{I}_{\mathcal{U}}(\theta) = \frac{1}{U} \sum_{u=1}^{U} \mathcal{I}_{\mathbf{x}^{(u)}}(\theta).$$

For CRFs, the partial derivative at the root of each element in the diagonal vector is given by:

$$\frac{\partial \log P(\hat{\mathbf{y}}|\mathbf{x};\theta)}{\partial \theta_k} = \sum_{t=1}^{T} f_k(\hat{y}_{t-1}, \hat{y}_t, \mathbf{x}_t) - \sum_{t=1}^{T} \sum_{y,y'} P(y, y'|\mathbf{x}) f_k(y, y', \mathbf{x}_t),$$

which is similar to the equation used to compute the training gradient, but without a regularization term. A smoothing parameter $\delta \ll 1$ is added to prevent division by zero when computing the ratio.

Notice that this method implicitly selects representative instances by favoring queries with Fisher information $\mathcal{I}_{\mathbf{x}}(\theta)$ that is not only high, but similar to that of the overall data distribution $\mathcal{I}_{\mathcal{U}}(\theta)$. This is in contrast to information density, which tries to query representative instances by explicitly modeling the distribution with a density weight.

4 Empirical Evaluation

In this section we present a large-scale empirical analysis of the query strategies described in Section 3 on eight benchmark information extraction and document segmentation corpora. The data sets are summarized in Table 1.

4.1 Data and Methodology

CoNLL-03 (Sang and DeMeulder, 2003) is a collection of newswire articles annotated with four entities: person, organization, location, and misc. NLPBA (Kim et al., 2004) is a large collection of biomedical abstracts annotated with five entities of interest, such as protein, RNA, and cell-type. BioCreative (Yeh et al., 2005) and FlySlip (Vlachos, 2007) also comprise texts in the biomedical domain, annotated for gene entity mentions in articles from the human and fruit fly literature, respectively. CORA (Peng and McCallum, 2004) consists of two collections: a set of research paper headers annotated for entities such as title, author, and institution; and a collection of references annotated with BibTeX fields such as journal, year, and publisher. The Sig+Reply corpus (Carvalho and Cohen, 2004) is a set of email messages annotated for signature and quoted reply line segments. SigIE is a subset of the signature blocks from Sig+Reply which we have enhanced with several address book fields such as name, email, and phone. All corpora are formatted in the "IOB" sequence representation (Ramshaw and Marcus, 1995).

We implement all fifteen query selection strategies described in Section 3 for use with CRFs, and evaluate them on all eight data sets. We also compare against two baseline strategies: random instance selection (i.e., passive learning), and naïvely querying the longest sequence in terms of tokens. We use a typical feature set for each corpus based on the cited literature (including words, orthographic patterns, part-of-speech, lexicons, etc.). Where the N-best approximation is used $N = 15$, and for all QBC methods $C = 3$; these figures exhibited a good balance of accuracy and training speed in preliminary work. For information density, we arbitrarily set $\beta = 1$ (i.e., the information and density terms have equal weight). In each experiment, $\mathcal{L}$ is initialized with five random labeled instances, and up to 150 queries are subsequently selected from $\mathcal{U}$ in batches of size $B = 5$. All results are averaged across five folds using cross-validation.

We evaluate each query strategy by constructing learning curves that plot the overall F_1 measure (for all entities or segments) as a function of the number of instances queried. Due to lack of space, we cannot show learning curves for every experiment. Instead, Table 2 summarizes our results by reporting the area under the learning curve for all strategies on all data. Figure 3 presents a few representative learning curves for six of the corpora.

4.2 Discussion of Learning Curves

The first conclusion we can draw from these results is that there is no single clear winner. However, information density (ID), which we introduce in this paper, stands out. It usually improves upon the base sequence entropy measure, never performs poorly, and has the highest average area under the learning curve across all tasks. It seems particularly effective on large corpora, which is a typical assumption for the active learning setting. Sequence vote entropy (SVE), a QBC method we propose here, is also noteworthy in that it is fairly consistently among the top three strategies, although never the best.

Second, the top uncertainty sampling strategies are least confidence (LC) and sequence entropy (SE), the latter being the dominant entropy-based method. Among the QBC strategies, sequence vote entropy (SVE) is the clear winner. We conclude that these three methods are the best base information measures for use with information density.

Third, query strategies that evaluate the entire sequence (SE, SVE, SKL) are generally superior to those which aggregate token-level information. Furthermore, the *total* token-level strategies (TTE, TVE, TKL) outperform their *length-*

Table 2: Detailed results for all query strategies on all evaluation corpora. Reported is the area under the F_1 learning curve for each strategy after 150 queries (maximum possible score is 150). For each row, the $\boxed{\textbf{best method}}$ is shown boxed in bold, the $\underline{\textbf{second best}}$ is shown underlined in bold, and the **third best** is shown in bold. The last row summarizes the results across all eight tasks by reporting the average area for each strategy. Query strategy formulations for sequence models introduced in this paper are indicated with italics along the top.

normalized counterparts (TE, VE, KL) in nearly all cases. In fact, the normalized variants are often inferior even to the baselines. While an argument can be made that these shorter sequences might be easier to label from a human annotator's perspective, our ongoing work indicates that the relationship between instance length and actual labeling costs (e.g., elapsed annotation time) is not a simple one. Analysis of our experiment logs also shows that length-normalized methods are occasionally biased toward short sequences with little intuitive value (e.g., sentences with few or no entities to label). In addition, vote entropy appears to be a better disagreement measure for QBC strategies than KL divergence.

Finally, Fisher information (FIR), while theoretically sound, exhibits behavior that is difficult to interpret. It is sometimes the winning strategy, but occasionally only on par with the baselines. When it does show significant gains over the other strategies, these gains appear to be only for the first several queries (e.g., NLPBA and BioCreative in Figure 3). This inconsistent performance may be a result of the approximations made for computational efficiency. Expected gradient length (EGL) also appears to exhibit mediocre performance, and is likely not worth its additional computational expense.

4.3 Discussion of Run Times

Here we discuss the execution times for each query strategy using current hardware. The uncertainty sampling methods are roughly comparable in run time (token-based methods run slightly faster), each routinely evaluating tens of thousands of sequences in under a minute. The QBC methods, on the other hand, must re-train multiple models with each query, resulting in a lag of three to four minutes per query batch (and up to 20 minutes for corpora with more entity labels).

The expected gradient length and Fisher information methods are the most computationally expensive, because they must first perform inference over the possible labelings and then calculate gradients for each candidate label sequence. As a result, they take eight to ten minutes (upwards of a half hour on the larger corpora) for each query. Unlike the other strategies, their time complexities also scale linearly with the number of model parameters K which, in turn, increases as new sequences are added to $\mathcal{L}$.

As noted in Section 3.4, information density incurs a large computational cost to estimate the density weights, but these can be pre-computed and cached for efficient lookup. In our experiments, this pre-processing step takes less than a minute for the smaller corpora, about a half hour for CoNLL-03 and BioCreative, and under two hours for NLPBA. The density lookup causes no significant change in the run time of the base information measure. Given these results, we advocate information density with an uncertainty sampling base measure in practice, particularly for active learning with large corpora.

5 Conclusion

In this paper, we have presented a detailed analysis of active learning for sequence labeling tasks. In particular, we have described and criticized the query selection strategies used with probabilistic se-

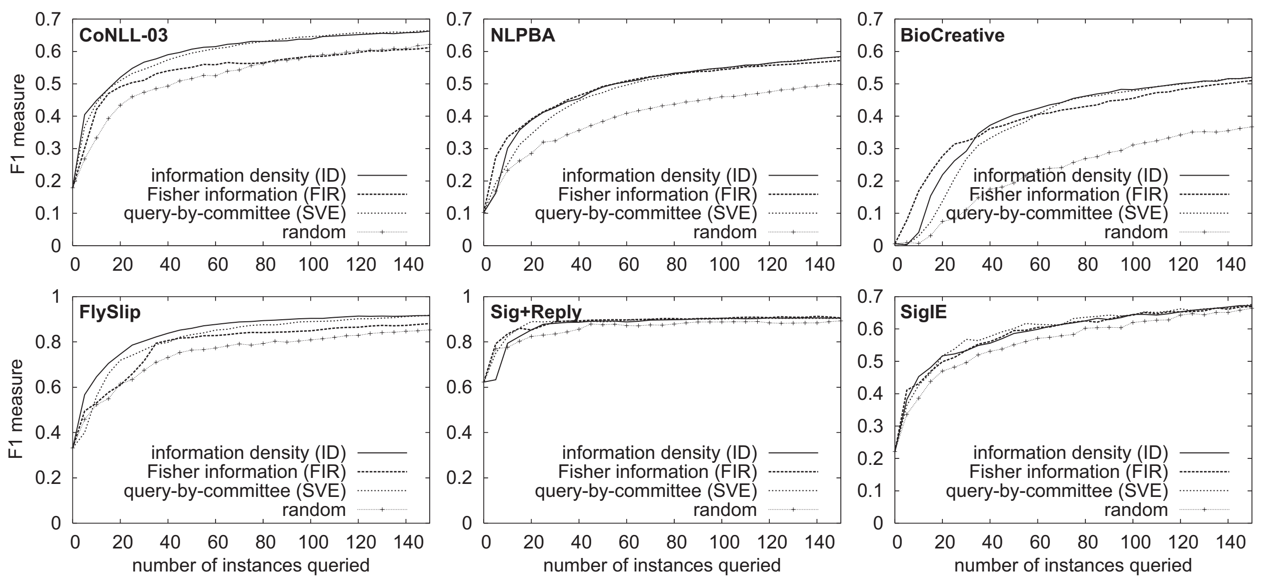

Figure 3: Learning curves for selected query strategies on six of the evaluation corpora.

quence models to date, and proposed several novel strategies to address some of their shortcomings. Our large-scale empirical evaluation demonstrates that some of these newly proposed methods advance the state of the art in active learning with sequence models. These methods include information density (which we recommend in practice), sequence vote entropy, and sometimes Fisher information.

Abstract

String-to-string transduction is a central problem in computational linguistics and natural language processing. It occurs in tasks as diverse as name transliteration, spelling correction, pronunciation modeling and inflectional morphology. We present a conditional log-linear model for string-to-string transduction, which employs overlapping features over latent alignment sequences, and which learns latent classes and latent string pair regions from incomplete training data. We evaluate our approach on morphological tasks and demonstrate that latent variables can dramatically improve results, even when trained on small data sets. On the task of generating morphological forms, we outperform a baseline method reducing the error rate by up to 48%. On a lemmatization task, we reduce the error rates in Wicentowski (2002) by 38–92%.

1 Introduction

A recurring problem in computational linguistics and language processing is transduction of character strings, e.g., words. That is, one wishes to model some systematic mapping from an input string x to an output string y. Applications include:

- *phonology*: underlying representation $\leftrightarrow$ surface representation
- *orthography*: pronunciation $\leftrightarrow$ spelling
- *morphology*: inflected form $\leftrightarrow$ lemma, or differently inflected form
- *fuzzy name matching* (duplicate detection) and *spelling correction*: spelling $\leftrightarrow$ variant spelling
- *lexical translation* (cognates, loanwords, transliterated names): English word $\leftrightarrow$ foreign word

We present a configurable and robust framework for solving such word transduction problems. Our results in morphology generation show that the presented approach improves upon the state of the art.

2 Model Structure

A weighted edit distance model (Ristad and Yianilos, 1998) would consider each character in isolation. To consider more context, we pursue a very natural generalization. Given an input x, we evaluate a candidate output y by moving a sliding window over the aligned (x, y) pair. More precisely, since many alignments are possible, we sum over all these possibilities, evaluating each alignment *separately*.[1]

At each window position, we accumulate log-probability based on the material that appears within the current window. The window is a few characters wide, and successive window positions *overlap*. This stands in contrast to a competing approach (Sherif and Kondrak, 2007; Zhao et al., 2007) that is inspired by phrase-based machine translation (Koehn et al., 2007), which *segments* the input string into substrings that are transduced *independently*, ignoring context.[2]

[*]This work was supported by the Human Language Technology Center of Excellence and by National Science Foundation grant No. 0347822 to the final author. We would also like to thank Richard Wicentowski for providing us with datasets for lemmatization, and the anonymous reviewers for their valuable feedback.

[1]At the other extreme, Freitag and Khadivi (2007) use no alignment; each feature takes its own view of how (x, y) relate.

[2]We feel that this independence is inappropriate. By analogy, it would be a poor idea for a language model to score a string highly if it could be *segmented* into independently frequent n-grams. Rather, language models use overlapping n-grams (indeed, it is the language model that rescues phrase-based MT from producing disjointed translations). We believe phrase-based MT avoids overlapping phrases in the *channel* model only because these would complicate the modeling of reordering (though see, e.g., Schwenk et al. (2007) and Casacuberta (2000)). But in the problems of section 1, letter reordering is rare and we may assume it is local to a window.

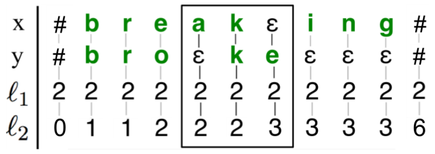

Figure 1: One of many possible alignment strings A for the observed pair *breaking/broke*, enriched with latent strings ℓ_1 and ℓ_2. Observed letters are shown in bold. The box marks a trigram to be scored. See Fig. 2 for features that fire on this trigram.

Joint n-gram models over the input and output dimensions have been used before, but not for morphology, where we will apply them.[3] Most notable is the local log-linear grapheme-to-phoneme model of Chen (2003), as well as generative models for that task (Deligne et al. (1995), Galescu and Allen (2001), Bisani and Ney (2002)).

We advance that approach by adding new *latent* dimensions to the (input, output) tuples (see Fig. 1).[4] This enables us to use certain linguistically inspired features and discover unannotated information. Our features consider *less* or *more* than a literal n-gram. On the one hand, we generalize with features that abstract away from the n-gram window contents; on the other, we specialize the n-gram with features that make use of the added latent linguistic structure.

In section 5, we briefly sketch our framework for concisely expressing and efficiently implementing models of this form. Our framework uses familiar log-linear techniques for stochastic modeling, and weighted finite-state methods both for implementation and for specifying features. It appears general enough to cover most prior work on word transduction. We imagine that it will be useful for future work as well: one might easily add new, linguistically interesting classes of features, each class defined by a regular expression.

2.1 Basic notation

We use an **input alphabet** Σ_x and **output alphabet** Σ_y. We conventionally use $x \in \Sigma_\text{x}^*$ to denote the input string and $y \in \Sigma_\text{y}^*$ to denote the output string.

[3]Clark (2001) does use pair HMMs for morphology.

[4]Demberg et al. (2007) similarly added extra dimensions. However, their added dimensions were supervised, not latent, and their model was a standard generative n-gram model whose generalization was limited to standard n-gram smoothing.

There are many possible alignments between x and y. We represent each as an **alignment string** $A \in \Sigma_\text{xy}^*$, over an **alignment alphabet** of ordered pairs, $\Sigma_\text{xy} \overset{\text{def}}{=} ((\Sigma_\text{x} \cup \{\epsilon\}) \times (\Sigma_\text{y} \cup \{\epsilon\})) - \{(\epsilon, \epsilon)\}$.

For example, one alignment of $x = \texttt{breaking}$ with $y = \texttt{broke}$ is the 9-character string $A = (\texttt{b},\texttt{b})(\texttt{r},\texttt{r})(\texttt{e},\texttt{o})(\texttt{a},\epsilon)(\texttt{k},\texttt{k})(\epsilon,\texttt{e})(\texttt{i},\epsilon)(\texttt{n},\epsilon)(\texttt{g},\epsilon)$. It is pictured in the first two lines of Fig. 1.

The remainder of Fig. 1 shows how we introduce latent variables, by enriching the alignment characters to be tuples rather than pairs. Let $\Sigma \overset{\text{def}}{=} (\Sigma_\text{xy} \times \Sigma_{\ell_1} \times \Sigma_{\ell_2} \times \cdots \times \Sigma_{\ell_K})$, where Σ_{ℓ_i} are alphabets used for the latent variables ℓ_i.

FSA and **FST** stand for "finite-state acceptor" and "finite-state transducer," while **WFSA** and **WFST** are their weighted variants. The $\circ$ symbol denotes composition.

Let T be a relation and w a string. We write $T[w]$ to denote the image of w under T (i.e., range($w \circ T$)), a set of 0 or more strings. Similarly, if W is a weighted language (typically encoded by a WFSA), we write $W[w]$ to denote the weight of w in W.

Let $\pi_\text{x} \subseteq \Sigma^* \times \Sigma_\text{x}^*$ denote the deterministic regular relation that projects an alignment string to its corresponding input string, so that $\pi_\text{x}[A] = x$. Similarly, define $\pi_\text{y} \subseteq \Sigma^* \times \Sigma_\text{y}^*$ so that $\pi_\text{y}[A] = y$. Let $\boldsymbol{A_{xy}}$ be the set of alignment strings A compatible with x and y; formally, $\boldsymbol{A_{xy}} \overset{\text{def}}{=} \{A \in \Sigma^* : \pi_\text{x}[A] = x \wedge \pi_\text{y}[A] = y\}$. This set will range over all possible alignments between x and y, and *also* all possible configurations of the latent variables.

2.2 Log-linear modeling

We use a standard log-linear model whose features are defined on alignment strings $A \in \boldsymbol{A_{xy}}$, allowing them to be sensitive to the alignment of x and y. Given a collection of features $f_i : \Sigma^* \to \mathbb{R}$ with associated weights $\theta_i \in \mathbb{R}$, the conditional likelihood of the training data is

$$p_{\boldsymbol{\theta}}(y \mid x) = \frac{\sum_{A \in \boldsymbol{A_{xy}}} \exp \sum_i \theta_i f_i(A)}{\sum_{y'} \sum_{A \in \boldsymbol{A_{xy'}}} \exp \sum_i \theta_i f_i(A)} \quad (1)$$

Given a parameter vector $\boldsymbol{\theta}$, we compute equation (1) using a finite-state machine. We define a WFSA, $U_{\boldsymbol{\theta}}$, such that $U_{\boldsymbol{\theta}}[A]$ yields the unnormalized probability $u_{\boldsymbol{\theta}}(A) \overset{\text{def}}{=} \exp \sum_i \theta_i f_i(A)$ for any $A \in \Sigma^*$. (See section 5 for the construction.) To obtain the numerator of equation (1), with its $\sum_{A \in \boldsymbol{A}_{\boldsymbol{xy}}}$, we sum over all paths in $U_{\boldsymbol{\theta}}$ that are compatible with x and y. That is, we build $x \circ \pi_{\mathrm{x}}^{-1} \circ U_{\boldsymbol{\theta}} \circ \pi_{\mathrm{y}} \circ y$ and sum over all paths. For the denominator we build the larger machine $x \circ \pi_{\mathrm{x}}^{-1} \circ U_{\boldsymbol{\theta}}$ and again compute the pathsum. We use standard algorithms (Eisner, 2002) to compute the pathsums as well as their gradients with respect to $\boldsymbol{\theta}$ for optimization (section 4.1).

Below, we will restrict our notion of *valid* alignment strings in Σ^*. $U_{\boldsymbol{\theta}}$ is constructed not to accept *invalid* ones, thus assigning them probability 0.

Note that the possible output strings y' in the denominator in equation (1) may have arbitrary length, leading to an infinite summation over alignment strings. Thus, for some values of $\boldsymbol{\theta}$, the sum in the denominator diverges and the probability distribution is undefined. There exist principled ways to avoid such $\boldsymbol{\theta}$ during training. However, in our current work, we simply restrict to finitely many alignment strings (given x), by prohibiting as invalid those with $> k$ *consecutive* insertions (i.e., characters like $(\epsilon, \mathtt{a})$).[5] Finkel et al. (2008) and others have similarly bounded unary rule cycles in PCFGs.

2.3 Latent variables

The alignment between x and y is a latent explanatory variable that helps model the distribution $p(y \mid x)$ but is not observed in training. Other latent variables can also be useful. Morphophonological changes are often sensitive to *phonemes* (whereas x and y may consist of graphemes); *syllable boundaries*; a *conjugation class*; *morpheme boundaries*; and the *position* of the change within the form.

Thus, as mentioned in section 2.1, we enrich the alignment string A so that it specifies additional latent variables to which features may wish to refer. In Fig. 1, two latent strings are added, enabling the features in Fig. 2(a)–(h). The first character is not just an input/output pair, but the 4-tuple $(\mathtt{b}, \mathtt{b}, \mathtt{2}, \mathtt{1})$.

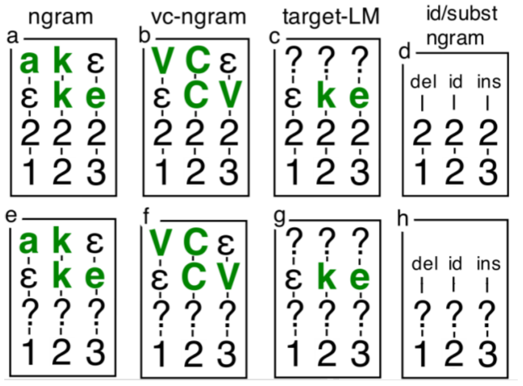

Figure 2: The boxes (a)-(h) represent some of the features that fire on the trigram shown in Fig. 1. These features are explained in detail in section 3.

Here, ℓ_1 indicates that this form pair (*breaking / broke*) as a whole is in a particular cluster, or *word class*, labeled with the arbitrary number $\mathtt{2}$. Notice in Fig. 1 that the class $\mathtt{2}$ is visible in all local windows throughout the string. It allows us to model how certain phenomena, e.g. the vowel change from $\mathtt{ea}$ to $\mathtt{o}$, are more likely in one class than in another. Form pairs in the same class as the *breaking / broke* example might include the following Germanic verbs: *speak*, *break*, *steal*, *tear*, and *bear*.

Of course, word classes are latent (not labeled in our training data). Given x and y, $\boldsymbol{A}_{\boldsymbol{xy}}$ will include alignment strings that specify class $\mathtt{1}$, and others that are identical except that they specify class $\mathtt{2}$; equation (1) sums over both possibilities.[6] In a valid alignment string A, ℓ_1 must be a constant string such as $\mathtt{111}\ldots$ or $\mathtt{222}\ldots$, as in Fig. 1, so that it specifies a single class for the entire form pair. See sections 4.2 and 4.3 for examples of what classes were learned in our experiments.

The latent string ℓ_2 splits the string pair into numbered *regions*. In a valid alignment string, the region numbers must increase throughout ℓ_2, although numbers may be skipped to permit omitted regions. To guide the model to make a useful division into regions, we also require that identity characters such as $(\mathtt{b}, \mathtt{b})$ fall in even regions while change characters such as $(\mathtt{e}, \mathtt{o})$ (substitutions, deletions, or inser-

[5]We set k to a value between 1 and 3, depending on the tasks, always ensuring that no input/output pairs observed in training are excluded. The insertion restriction does slightly enlarge the FSA U_θ: a state must keep track of the number of consecutive ϵ symbols in the immediately preceding x input, and for a few states, this cannot be determined just from the immediately preceding $(n-1)$-gram. Despite this, we found empirically that our approximation is at least as fast as the exact method of Eisner (2002), who sums around cyclic subnetworks to numerical convergence. Furthermore, our approximation does not require us to detect divergence during training.

[6]The latent class is comparable to the latent variable on the tree root symbol *S* in Matsuzaki et al. (2005).

tions) fall in odd regions.[7] Region numbers must not increase within a sequence of consecutive changes or consecutive identities.[8] In Fig. 1, the start of region 1 is triggered by `e:o`, the start of region 2 by the identity `k:k`, region 3 by ϵ`:e`.

Allowing region numbers to be skipped makes it possible to consistently assign similar labels to similar regions across different training examples. Table 2, for example, shows pairs that contain a vowel change in the middle, some of which contain an additional insertion of `ge` in the begining (*verbinden / verbunden*, *reibt / gerieben*). We expect the model to learn to label the `ge` insertion with a 1 and vowel change with a 3, skipping region 1 in the examples where the `ge` insertion is not present (see section 4.2, Analysis).

In the next section we describe features over these enriched alignment strings.

3 Features

One of the simplest ways of scoring a string is an n-gram model. In our log-linear model (1), we include ngram features $f_i(A)$, each of which counts the occurrences in A of a particular n-gram of alignment characters. The log-linear framework lets us include ngram features of different lengths, a form of backoff smoothing (Wu and Khudanpur, 2000).

We use additional backoff features on alignment strings to capture phonological, morphological, and orthographic generalizations. Examples are found in features (b)-(h) in Fig. 2. Feature (b) matches *vowel and consonant* character classes in the input and output dimensions. In the id/subst ngram feature, we have a similar abstraction, where the character classes ins, del, id, and subst are defined over input/output pairs, to match insertions, deletions, identities (matches), and substitutions.

In string transduction tasks, it is helpful to include a language model of the target. While this can be done by mixing the transduction model with a separate language model, it is desirable to include a target language model within the transduction model. We accomplish this by creating target language model features, such as (c) and (g) from Fig. 2, which ignore the input dimension. We also have features which mirror features (a)-(d) but ignore the latent classes and/or regions (e.g. features (e)-(h)).

Notice that our choice of Σ only permits monotonic, 1-to-1 alignments, following Chen (2003). We may nonetheless favor the 2-to-1 alignment (`ea`,`o`) with bigram features such as (`e`,`o`)(`a`,ϵ). A "collapsed" version of a feature will back off from the specific alignment of the characters within a window: thus, (`ea`,`o`) is itself a feature. Currently, we only include collapsed target language model features. These ignore epsilons introduced by deletions in the alignment, so that collapsed `ok` fires in a window that contains `o`ϵ`k`.

4 Experiments

We evaluate our model on two tasks of morphology generation. Predicting morphological forms has been shown to be useful for machine translation and other tasks.[9] Here we describe two sets of experiments: an inflectional morphology task in which models are trained to transduce verbs from one form into another (section 4.2), and a lemmatization task (section 4.3), in which *any* inflected verb is to be reduced to its root form.

4.1 Training and decoding

We train $\boldsymbol{\theta}$ to maximize the regularized[10] conditional log-likelihood[11]

$$\sum_{(x,y^*)\in\mathcal{C}} \log p_{\boldsymbol{\theta}}(y^* \mid x) + ||\boldsymbol{\theta}||^2/2\sigma^2, \qquad (2)$$

where $\mathcal{C}$ is a supervised training corpus. To maximize (2) during training, we apply the gradient-based optimization method L-BFGS (Liu and Nocedal, 1989).[12]

[7]This strict requirement means, perhaps unfortunately, that a single region cannot accommodate the change `ayc:xyz` unless the two `y`'s are not aligned to each other. It could be relaxed, however, to a prior or an initialization or learning bias.

[8]The two boundary characters `#`, numbered 0 and max (max=6 in our experiments), are neither changes nor identities.

[9]E.g., Toutanova et al. (2008) improve MT performance by *selecting* correct morphological forms from a knowledge source. We instead focus on generalizing from observed forms and *generating* new forms (but see *with rootlist* in Table 3).

[10]The variance σ^2 of the L_2 prior is chosen by optimizing on development data. We are also interested in trying an L_1 prior.

[11]Alternatives would include faster error-driven methods (perceptron, MIRA) and slower max-margin Markov networks.

[12]This worked a bit better than stochastic gradient descent.

To decode a test example x, we wish to find $\hat{y} = \operatorname{argmax}_{y \in \Sigma_y^*} p_{\boldsymbol{\theta}}(y \mid x)$. Constructively, $\hat{y}$ is the highest-probability string in the WFSA $T[x]$, where $T = \pi_x^{-1} \circ U_{\boldsymbol{\theta}} \circ \pi_y$ is the trained transducer that maps x nondeterministically to y. Alas, it is NP-hard to find the highest-probability string in a WFSA, even an acyclic one (Casacuberta and Higuera, 2000). The problem is that the probability of each string y is a sum over many paths in $T[x]$ that reflect different alignments of y to x. Although it is straightforward to use a determinization construction (Mohri, 1997)[13] to collapse these down to a single path per y (so that $\hat{y}$ is easily read off the single best path), determinization can increase the WFSA's size exponentially. We approximate by pruning $T[x]$ back to its 1000-best paths before we determinize.[14]

Since the alignments, classes and regions are not observed in $\mathcal{C}$, we do not enjoy the convex objective function of fully-supervised log-linear models. Training equation (2) therefore converges only to some *local* maximum that depends on the starting point in parameter space. To find a good starting point we employ *staged training*, a technique in which several models of ascending complexity are trained consecutively. The parameters of each more complex model are initialized with the trained parameters of the previous simpler model.

Our training is done in four stages. All weights are initialized to zero. ① We first train only features that fire on unigrams of alignment characters, ignoring features that examine the latent strings or backed-off versions of the alignment characters (such as vowel/consonant or target language model features). The resulting model is equivalent to weighted edit distance (Ristad and Yianilos, 1998). ② Next,[15] we train all n-grams of alignment characters, including higher-order n-grams, but no backed-off features or features that refer to latent strings.

Table 2: CELEX forms used in our experiments. Changes from one form to the other are in bold (information not given in training). The changes from rP to pA are very complex. Note also the differing positions of `zu` in z.

③ Next, we add backed-off features as well as all collapsed features. ④ Finally, we train all features. In our experiments, we permitted latent classes `1`–`2` and, where regions are used, regions `0`–`6`. For speed, stages ②–④ used a pruned Σ that included only "plausible" alignment characters: a may not align to b unless it did so in the trained stage-(1) model's optimal alignment of *at least one* training pair (x, y^*).

4.2 Inflectional morphology

We conducted several experiments on the CELEX morphological database. We arbitrarily considered mapping the following German verb forms:[16] 13SIA $\rightarrow$ 13SKE, 2PIE $\rightarrow$ 13PKE, 2PKE $\rightarrow$ z, and rP $\rightarrow$ pA.[17] We refer to these tasks as 13SIA, 2PIE, 2PKE and rP. Table 2 shows some examples of regular and irregular forms. Common phenomena include stem changes (`ei:ie`), prefixes inserted after other morphemes (*ab**zu**brechen*) and circumfixes (***ge**rieb**en***).

We compile lists of form pairs from CELEX. For each task, we sample 2500 data pairs without replacement, of which 500 are used for training, 1000 as development and the remaining 1000 as test data. We train and evaluate models on this data and repeat

[13]Weighted determinization is not always possible, but it is in our case because our limit to k consecutive insertions guarantees that $T[x]$ is acyclic.

[14]This value is high enough; we see no degradations in performance if we use only 100 or even 10 best paths. Below that, performance starts to drop slightly. In both of our tasks, our conditional distributions are usually peaked: the 5 best output candidates amass $> 99\%$ of the probability mass on average. Entropy is reduced by latent classes and/or regions.

[15]When unclamping a feature at the start of stages ②–④, we initialize it to a random value from $[-0.01, 0.01]$.

[16]From the available languages in CELEX (German, Dutch, and English), we selected German as the language with the most interesting morphological phenomena, leaving the multilingual comparison for the lemmatization task (section 4.3), where there were previous results to compare with. The 4 German datasets were picked arbitrarily.

Table 1: Exact-match accuracy and average edit distance (the latter in parentheses) versus the correct answer on the German inflection task, using different combinations of feature classes. The label *ngrams* corresponds to the second stage of training, *ngrams+x* to the third where backoff features may fire (vc = vowel/consonant, tlm = target LM, tlm-coll = collapsed tlm, id = identity/substitution/deletion features), and *ngrams+x+latent* to the fourth where features sensitive to latent classes and latent regions are allowed to fire. The highest n-gram order used is 3, except for *Moses9* and *Moses15* which examine windows of up to 9 and 15 characters, respectively. We mark in **bold** the best result for each dataset, along with all results that are statistically indistinguishable (paired permutation test, $p < 0.05$).

the process 5 times. All results are averaged over these 5 runs.

Table 1 and Fig. 3 report separate results after stages ②, ③, and ④ of training, which include successively larger feature sets. These are respectively labeled *ngrams*, *ngrams+x*, and *ngrams+x+latent*. In Table 1, the last row in each section shows the full feature set at that stage (cf. Fig. 3), while earlier rows test feature subsets.[18]

Our baseline is the SMT toolkit Moses (Koehn et al., 2007) run over letter strings rather than word strings. It is trained (on the same data splits) to find substring-to-substring phrase pairs and translate from one form into another (with phrase reordering turned off). Results reported as *moses3* are obtained from Moses runs that are constrained to the same context windows that our models use, so the maximum phrase length and the order of the target language model were set to 3. We also report results using much larger windows, *moses9* and *moses15*.

[18]The number k of consecutive insertions was set to 3.

Results. The results in Table 1 show that including *latent classes and/or regions* improves the results dramatically. Compare the last line in *ngrams+x* to the last line in *ngrams+x+latent*. The accuracy numbers improve from 82.8 to 87.5 (13SIA), from 88.7 to 93.4 (2PIE), from 74.7 to 87.4 (2PKE), and from 69.9 to 84.9 (rP).[19] This shows that error reductions between 27% and 50% were reached. On 3 of 4 tasks, even our simplest *ngrams* method beats the *moses3* method that looks at the same amount of context.[20] With our full model, in particular using latent features, we always outperform *moses3*—and even outperform *moses15* on 3 of the 4 datasets, reducing the error rate by up to 48.3% (rP). On the fourth task (2PIE), our method and *moses15* are statistically tied. *Moses15* has access to context windows of five times the size than we allowed our methods in our experiments.

[19]All claims in the text are statistically significant under a paired permutation test ($p < .05$).

[20]This bears out our contention in footnote 2 that a "segmenting" channel model is damaging. Moses cannot fully recover by using overlapping windows in the *language* model.

While the gains from *backoff features* in Table 1 were modest (significant gains only on 13SIA), the learning curve in Fig. 3 suggests that they were helpful for smaller training sets on 2PKE (see *ngrams* vs *ngrams+x* on 50 and 100) and helped consistently over different amounts of training data for 13SIA.

Analysis. The types of errors that our system (and the moses baseline) make differ from task to task. Due to lack of space, we mainly focus on the complex rP task. Here, most errors come from wrongly copying the input to the output, without making a change (40-50% of the errors in all models, except for our model with latent classes and no regions, where it accounts for only 30% of the errors). This is so common because about half of the training examples contain identical inputs and outputs (as in the imperative *berechnet* and the participle *(ihr habt) berechnet*). Another common error is to wrongly assume a regular conjugation (just insert the prefix *ge-* at the beginning). Interestingly, this error by simplification is more common in the Moses models (44% of moses3 errors, down to 40% for moses15) than in our models, where it accounts for 37% of the errors of our *ngrams* model and only 19% if latent classes *or* latent regions are used; however, it goes up to 27% if both latent classes and regions are used.[21] All models for rP contain errors where wrong analogies to observed words are made (*verschweisst/verschwissen* in analogy to the observed *durchweicht/durchwichen*, or *bebt/geboben* in analogy to *hebt/gehoben*). In the 2PKE task, most errors result from inserting the *zu* morpheme at a wrong place or inserting two of them, which is always wrong. This error type was greatly reduced by latent regions, which can discover different parameters for different positions, making it easier to identify where to insert the *zu*.

Analysis of the 2 latent classes (when used) shows that a *split into regular and irregular conjugations* has been learned. For the rP task we compute, for each data pair in development data, the posterior probabilities of membership in one or the other class. 98% of the regular forms, in which the past participle is built with *ge-* ... *-t*, fall into one class,

[21]We suspect that training of the models that use classes and regions together was hurt by the increased non-convexity; annealing or better initialization might help.

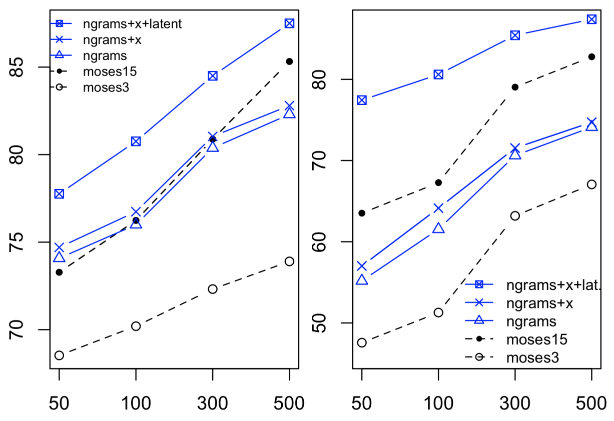

Figure 3: Learning curves for German inflection tasks, 13SIA (left) and 2PKE (right), as a function of the number of training pairs. *ngrams+x* means all backoff features were used, *ngrams+x+latent* means all latent features were used in addition. *Moses15* examines windows of up to 15 characters.

which in turn consists nearly exclusively (96%) of these forms. Different irregular forms are lumped into the other class.

The learned regions are consistent across different pairs. On development data for the rP task, 94.3% of all regions that are labeled 1 are the insertion sequence (ϵ,ge), region 3 consists of vowel changes 93.7% of the time; region 5 represents the typical suffixes (t, en), (et, en), (t, n) (92.7%). In the *2PKE* task, region 0 contains different prefixes (e.g. *entgegen* in *entgegenzutreten*), regions 1 and 2 are empty, region 3 contains the *zu* affix, region 4 the stem, and region 5 contains the suffix.

The pruned alignment alphabet excluded a few gold standard outputs so that the model contains paths for 98.9%–99.9% of the test examples. We verified that the insertion limit did not hurt oracle accuracy.

4.3 Lemmatization

We apply our models to the task of lemmatization, where the goal is to generate the lemma given an inflected word form. We compare our model to Wicentowski (2002, chapter 3), an alternative supervised approach. Wicentowski's *Base* model simply learns how to replace an arbitrarily long suffix string of an input word, choosing some previously observed suffix $\rightarrow$ suffix replacement based on the input word's

	Without rootlist (generation)						With rootlist (selection)

Table 3: Exact-match accuracy and average edit distance (the latter in parentheses) on the 8 lemmatization tasks (2 tasks $\times$ 4 languages). The numbers from Wicentowski (2002) are for his Base, Affix and WFAffix models. The numbers for our models are for the feature sets *ngrams*, *ngrams+x*, *ngrams+x+latent*. The best result per task is in **bold** (as are statistically indistinguishable results when we can do the comparison, i.e., for our own models). Corpus sizes: Basque 5,842, English 4,915, Irish 1,376, Tagalog 9,479.

final n characters (interpolating across different values of n). His *Affix* model essentially applies the Base model after stripping canonical prefixes and suffixes (given by a user-supplied list) from the input and output. Finally, his *WFAffix* uses similar methods to also learn substring replacements for a stem vowel cluster and other linguistically significant regions in the form (identified by a *deterministic* alignment and segmentation of training pairs). This approach is a bit like our change regions combined with Moses's region-independent phrase pairs.

We compare against all three models. Note that *Affix* and *WFAffix* have an advantage that our models do not, namely, user-supplied lists of canonical affixes for each language. It is interesting to see how our models with their more non-committal trigram structure compare to this. Table 3 reports results on the data sets used in Wicentowski (2002), for Basque, English, Irish, and Tagalog. Following Wicentowski, 10-fold cross-validation was used. The columns *n+x* and *n+x+l* mean *ngram+x* and *ngram+x+latent*, respectively. As latent variables, we include 2 word classes but no change regions.[22]

For completeness, Table 3 also compares with Wicentowski (2002) on a *selection* (rather than generation) task. Here, at test time, the lemma is selected from a candidate list of known lemmas, namely, all the output forms that appeared in training data.[23] These additional results are labeled *with rootlist* in the right half of Table 3.

On the supervised generation task *without rootlist*, our models outperform Wicentowski (2002) by a large margin. Comparing our results that use latent classes (*n+x+l*) with Wicentowski's best models we observe error reductions ranging from about 38% (Tagalog) to 92% (Irish). On the selection task *with rootlist*, we outperform Wicentowski (2002) in English, Irish, and Tagalog.

Analysis. We examined the classes learned on English lemmatization by our *ngrams+x+latent* model. For each of the input/output pairs in development data, we found the most probable latent class. For the most part, the 2 classes are separated based on whether or not the correct output ends in e. This use of latent classes helped address many errors like *wronging / wronge* or *owed / ow*). Such missing or surplus final e's account for 72.5% of the errors for *ngrams* and 70.6% of the errors for *ngrams+x*, but only 34.0% of the errors for *ngrams+x+latent*.

The test oracles are between 99.8% – 99.9%, due to the pruned alignment alphabet. As on the inflection task, the insertion limit does not exclude any gold standard paths.

5 Finite-State Feature Implementation

We used the OpenFST library (Allauzen et al., 2007) to implement all finite-state computations, using the expectation semiring (Eisner, 2002) for training.

Our model is defined by the WFSA $U_{\boldsymbol{\theta}}$, which is used to score alignment strings in Σ^* (section 2.2). We now sketch how to construct $U_{\boldsymbol{\theta}}$ from features.

n-gram construction The construction that we currently use is quite simple. All of our current features fire on windows of width $\leq$ 3. We build a WFSA with the structure of a 3-gram language

[22]The insertion limit k was set to 2 for Basque and 1 for the other languages.

[23]Though test data contained no (input, output) pairs from training data, it reused many of the output forms, since many inflected inputs are to be mapped to the same output lemma.

model over Σ^*. Each of the $|\Sigma|^2$ states remembers two previous alignment characters ab of history; for each $c \in \Sigma$, it has an outgoing arc that accepts c (and leads to state bc). The weight of this arc is the total weight (from θ) of the small set of features that fire when the trigram window includes abc. By convention, these also include features on bc and c (which may be regarded as backoff features $?bc$ and $??c$). Since each character in Σ is actually a 4-tuple, this trigram machine is fairly large. We build it lazily ("on the fly"), constructing arcs only as needed to deal with training or test data.

Feature templates Our experiments use over 50,000 features. How do we *specify* these features to the above construction? Rather than writing ordinary code to extract features from a window, we find it convenient to harness FSTs as a "little language" (Bentley, 1986) for specifying entire sets of features.

A **feature template** T is an nondeterministic FST that maps the contents of the sliding window, such as `abc`, to one or more **features**, which are also described as strings.[24] The n-gram machine described above can compute $T[((\mathtt{a}^?\mathtt{b})^?\mathtt{c})^?]$ to find out what features fire on `abc` and its suffixes. One simple feature template performs "vowel/consonant backoff"; e.g., it maps `abc` to the feature named `VCC`. Fig. 2 showed the result of applying several actual feature templates to the window shown in Fig. 1. The extended regular expression calculus provides a flexible and concise notation for writing down these FSTs. As a trivial example, the trigram "vowel/consonant backoff" transducer can be described as $T = VVV$, where V is a transducer that performs backoff on a *single* alignment character. Feature templates should make it easy to experiment with adding various kinds of linguistic knowledge. We have additional algorithms for compiling $U_{\boldsymbol{\theta}}$ from a set of *arbitrary* feature templates,[25] including templates whose features consider windows of variable or even unbounded width. The details are beyond the scope of this paper, but it is worth pointing out that they exploit the fact that feature templates are FSTs and not arbitrary code.

[24]Formally, if i is a string naming a feature, then $f_i(A)$ counts the number of positions in A that are immediately preceded by some string in $T^{-1}[i]$.

[25]Provided that the total number of features is finite.

6 Conclusions

The modeling framework we have presented here is, we believe, an attractive solution to most string transduction problems in NLP. Rather than learn the topology of an arbitrary WFST, one specifies the topology using a small set of feature templates, and simply trains the weights.

We evaluated on two morphology generation tasks. When inflecting German verbs we, even with the simplest features, outperform the *moses3* baseline on 3 out of 4 tasks, which uses the same amount of context as our models. Introducing more sophisticated features that have access to latent classes and regions improves our results dramatically, even on small training data sizes. Using these we outperform *moses9* and *moses15*, which use long context windows, reducing error rates by up to 48%. On the lemmatization task we were able to improve the results reported in Wicentowski (2002) on three out of four tested languages and reduce the error rates by 38% to 92%. The model's errors are often reasonable misgeneralizations (e.g., assume regular conjugation where irregular would have been correct), and it is able to use even a small number of latent variables (including the latent alignment) to capture useful linguistic properties.

In future work, we would like to identify a set of features, latent variables, and training methods that port well across languages and string-transduction tasks. We would like to use features that look at wide context on the *input* side, which is inexpensive (Jiampojamarn et al., 2007). Latent variables we wish to consider are an increased number of word classes; more flexible regions—see Petrov et al. (2007) on learning a state transition diagram for *acoustic* regions in phone recognition—and phonological features and syllable boundaries. Indeed, our local log-linear features over several aligned latent strings closely resemble the soft constraints used by phonologists (Eisner, 1997). Finally, rather than define a fixed set of feature templates as in Fig. 2, we would like to refine empirically useful features during training, resulting in language-specific backoff patterns and adaptively sized n-gram windows. Many of these enhancements will increase the computational burden, and we are interested in strategies to mitigate this, including approximation methods.

Abstract

We propose a new graph-based semi-supervised learning (SSL) algorithm and demonstrate its application to document categorization. Each document is represented by a vertex within a weighted undirected graph and our proposed framework minimizes the weighted Kullback-Leibler divergence between distributions that encode the class membership probabilities of each vertex. The proposed objective is convex with guaranteed convergence using an alternating minimization procedure. Further, it generalizes in a straightforward manner to multi-class problems. We present results on two standard tasks, namely Reuters-21578 and WebKB, showing that the proposed algorithm significantly outperforms the state-of-the-art.

1 Introduction

Semi-supervised learning (SSL) employs small amounts of labeled data with relatively large amounts of unlabeled data to train classifiers. In many problems, such as speech recognition, document classification, and sentiment recognition, annotating training data is both time-consuming and tedious, while unlabeled data are easily obtained thus making these problems useful applications of SSL. Classic examples of SSL algorithms include self-training (Yarowsky, 1995) and co-training (Blum and Mitchell, 1998). Graph-based SSL algorithms are an important class of SSL techniques that have attracted much of attention of late (Blum and Chawla, 2001; Zhu et al., 2003). Here one assumes that the data (both labeled and unlabeled) is embedded within a low-dimensional manifold expressed by a graph. In other words, each data sample is represented by a vertex within a weighted graph with the weights providing a measure of similarity between vertices.

Most graph-based SSL algorithms fall under one of two categories – those that use the graph structure to spread labels from labeled to unlabeled samples (Szummer and Jaakkola, 2001; Zhu and Ghahramani, 2002) and those that optimize a loss function based on smoothness constraints derived from the graph (Blum and Chawla, 2001; Zhu et al., 2003; Joachims, 2003; Belkin et al., 2005). Sometimes the two categories are similar in that they can be shown to optimize the same underlying objective (Zhu and Ghahramani, 2002; Zhu et al., 2003). In general graph-based SSL algorithms are non-parametric and transductive.[1] A learning algorithm is said to be transductive if it is expected to work only on a closed data set, where a test set is revealed at the time of training. In practice, however, transductive learners can be modified to handle unseen data (Zhu, 2005a; Sindhwani et al., 2005). A common drawback of many graph-based SSL algorithms (e.g. (Blum and Chawla, 2001; Joachims, 2003; Belkin et al., 2005)) is that they assume binary classification tasks and thus require the use of sub-optimal (and often computationally expensive) approaches such as one vs. rest to solve multi-class problems, let alone structured domains such as strings and trees. There are also issues related to degenerate solutions (all unlabeled samples classified as belonging to a single

[1]Excluding Manifold Regularization (Belkin et al., 2005).

class) (Blum and Chawla, 2001; Joachims, 2003; Zhu and Ghahramani, 2002). For more background on graph-based and general SSL and their applications, see (Zhu, 2005a; Chapelle et al., 2007; Blitzer and Zhu, 2008).

In this paper we propose a new algorithm for graph-based SSL and use the task of text classification to demonstrate its benefits over the current state-of-the-art. Text classification involves automatically assigning a given document to a fixed number of semantic categories. Each document may belong to one, many, or none of the categories. In general, text classification is a *multi-class* problem (more than 2 categories). Training fully-supervised text classifiers requires large amounts of labeled data whose annotation can be expensive (Dumais et al., 1998). As a result there has been interest is using SSL techniques for text classification (Joachims, 1999; Joachims, 2003). However past work in semi-supervised text classification has relied primarily on one vs. rest approaches to overcome the inherent multi-class nature of this problem. We believe such an approach may be sub-optimal because, disregarding data overlap, the different classifiers have training procedures that are independent of one other. In order to address the above drawback we propose a new framework based on optimizing a loss function composed of Kullback-Leibler divergence (KL-divergence) (Cover and Thomas, 1991) terms between probability distributions defined for each graph vertex. The use of probability distributions, rather than fixed integer labels, not only leads to a straightforward multi-class generalization, but also allows us to exploit other well-defined functions of distributions, such as entropy, to improve system performance and to allow for the measure of uncertainty. For example, with a single integer, at most all we know is its assignment. With a distribution, we can continuously move from knowing an assignment with certainty (i.e., an entropy of zero) to expressions of doubt or multiple valid possibilities (i.e., an entropy greater than zero). This is particularly useful for document classification as we will see. We also show how one can use the alternating minimization (Csiszar and Tusnady, 1984) algorithm to optimize our objective leading to a relatively simple, fast, easy-to-implement, guaranteed to converge, iterative, and closed form update for each iteration.

2 Proposed Graph-Based Learning Framework

We consider the transductive learning problem, i.e., given a training set $\mathcal{D} = \{\mathcal{D}_l, \mathcal{D}_u\}$, where $\mathcal{D}_l$ and $\mathcal{D}_u$ are the sets of labeled and unlabeled samples respectively, the task is to infer the labels for the samples in $\mathcal{D}_u$. In other words, $\mathcal{D}_u$ is the "test-set." Here $\mathcal{D}_l = \{(\mathbf{x}_i, y_i)\}_{i=1}^{l}$, $\mathcal{D}_u = \{\mathbf{x}_i\}_{i=l+1}^{l+u}$, $\mathbf{x}_i \in \mathrm{X}$ (the input space of the classifier, and corresponds to vectors of features) and $y_i \in \mathrm{Y}$ (the space of classifier outputs, and for our case is the space of non-negative integers). Thus $|\mathrm{Y}| = 2$ yields binary classification while $|\mathrm{Y}| > 2$ yields multi-class. We define $n = l + u$, the total number of samples in the training set. Given $\mathcal{D}$, most graph-based SSL algorithms utilize an undirected weighted graph $\mathcal{G} = (V, E)$ where $V = \{1, \ldots, n\}$ are the data points in $\mathcal{D}$ and $E = V \times V$ are the set of undirected edges between vertices. We use $w_{ij} \in \mathbf{W}$ to denote the weight of the edge between vertices i and j. $\mathbf{W}$ is referred to as the weight (or affinity) matrix of $\mathcal{G}$. As will be seen shortly, the input features $\mathbf{x}_i$ effect the final classification results via $\mathbf{W}$, i.e., the graph. Thus graph construction is crucial to the success of any graph-based SSL algorithm. Graph construction "is more of an art, than science" (Zhu, 2005b) and is an active research area (Alexandrescu and Kirchhoff, 2007). In general the weights are formed as $w_{ij} = \mathrm{sim}(\mathbf{x}_i, \mathbf{x}_j)\delta(j \in \mathcal{K}(i))$. Here $\mathcal{K}(i)$ is the set of i's k-nearest-neighbors ($\mathcal{K}$NN), $\mathrm{sim}(\mathbf{x}_i, \mathbf{x}_j)$ is a given measure of similarity between $\mathbf{x}_i$ and $\mathbf{x}_j$, and $\delta(c)$ returns a 1 if c is true and 0 otherwise. Getting the similarity measure right is crucial for the success of any SSL algorithm as that is what determines the graph. Note that setting $\mathcal{K}(i) = |V| = n$ results in a fully-connected graph. Some popular similarity measures include

$$\mathrm{sim}(\mathbf{x}_i, \mathbf{x}_j) = e^{-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|_2^2}{\sigma^2}} \text{ or}$$

$$\mathrm{sim}(\mathbf{x}_i, \mathbf{x}_j) = \cos(\mathbf{x}_i, \mathbf{x}_j) = \frac{\langle \mathbf{x}_i, \mathbf{x}_j \rangle}{\| \mathbf{x}_i \|_2^2 \| \mathbf{x}_j \|_2^2}$$

where $\| \mathbf{x}_i \|_2$ is the $\mathcal{L}_2$ norm, and $\langle \mathbf{x}_i, \mathbf{x}_j \rangle$ is the inner product of $\mathbf{x}_i$ and $\mathbf{x}_j$. The first similarity measure is an RBF kernel applied on the squared Euclidean distance while the second is cosine similarity. In this paper *all* graphs are constructed using cosine similarity.

We next introduce our proposed approach. For every $i \in V$, we define a probability distribution p_i over the elements of Y. In addition let $r_j, j = 1 \ldots l$ be another set of probability distributions again over the elements of Y (recall, Y is the space of classifier outputs). Here $\{r_j\}_j$ represents the labels of the supervised portion of the training data. If the label for a given labeled data point consists only of a single integer, then the entropy of the corresponding r_j is zero (the probability of that integer will be unity, with the remaining probabilities being zero). If, on the other hand, the "label" for a given labeled data point consists of a set of integers (e.g., if the object is a member of multiple classes), then r_j is able to represent this property accordingly (see below). We emphasize again that both p_i and r_j are probability distributions, with r_j fixed throughout training. The goal of learning in this paper is to find the best set of distributions $p_i, \forall i$ that attempt to: 1) agree with the labeled data r_j wherever it is available; 2) agree with each other (when they are close according to a graph); and 3) be smooth in some way. These criteria are captured in the following *new* multi-class SSL optimization procedure:

$$\min_{\mathrm{p}} C_1(\mathrm{p}), \text{ where } C_1(\mathrm{p}) = \left[\sum_{i=1}^{l} D_{KL}\big(r_i || p_i\big) + \mu \sum_{i}^{n} \sum_{j} w_{ij} D_{KL}\big(p_i || p_j\big) - \nu \sum_{i=1}^{n} H(p_i) \right], \tag{1}$$

and where $\mathrm{p} \triangleq (p_1, \ldots, p_n)$ denotes the entire set of distributions to be learned, $H(p_i) = -\sum_{\mathrm{y}} p_i(\mathrm{y}) \log p_i(\mathrm{y})$ is the standard Shannon entropy function of p_i, $D_{KL}(p_i || q_j)$ is the KL-divergence between p_i and q_j, and μ and ν are hyperparameters whose selection we discuss in section 5. The distributions r_i are derived from $\mathcal{D}_l$ (as mentioned above) and this can be done in one of the following ways: (a) if $\hat{y}_i$ is the single supervised label for input $\mathbf{x}_i$ then $r_i(y) = \delta(y = \hat{y}_i)$, which means that r_i gives unity probability for y equaling the label $\hat{y}_i$; (b) if $\hat{y}_i = \{\hat{y}_i^{(1)}, \ldots, \hat{y}_i^{(k)}\}$, $k \leq |\mathrm{Y}|$ is a *set* of possible outputs for input $\mathbf{x}_i$, meaning an object validly falls into all of the corresponding categories, we set $r_i(y) = (1/k)\delta(y \in \hat{y}_i)$ meaning that r_i is uniform over only the possible categories and zero otherwise; (c) if the labels are somehow provided in the form of a set of non-negative scores, or even a probability distribution itself, we just set r_i to be equal to those scores (possibly) normalized to become a valid probability distribution. Among these three cases, case (b) is particularly relevant to text classification as a given document many belong to (and in practice may be labeled as) many classes. The final classification results, i.e., the final labels for $\mathcal{D}_u$, are then given by $\hat{y} = \operatorname*{argmax}_{\mathrm{y} \in \mathrm{Y}} p_i(\mathrm{y})$.

We next provide further intuition on our objective function. SSL on a graph consists of finding a labeling $\mathcal{D}_u$ that is consistent with both the labels provided in $\mathcal{D}_l$ and the geometry of the data induced by the graph. The first term of C_1 will penalize the solution p_i $i \in \{1, \ldots, l\}$, when it is far away from the labeled training data $\mathcal{D}_l$, but it does not insist that $p_i = r_i$, as allowing for deviations from r_i can help especially with noisy labels (Bengio et al., 2007) or when the graph is extremely dense in certain regions. As explained above, our framework allows for the case where supervised training is uncertain or ambiguous. We consider it reasonable to call our approach *soft-supervised* learning, generalizing the notion of semi-supervised learning, since there is even more of a continuum here between fully supervised and fully unsupervised learning than what typically exists with SSL. Soft-supervised learning allows uncertainty to be expressed (via a probability distribution) about any of the labels individually.

The second term of C_1 penalizes a lack of consistency with the geometry of the data and can be seen as a graph regularizer. If w_{ij} is large, we prefer a solution in which p_i and p_j are close in the KL-divergence sense. While KL-divergence is asymmetric, given that $\mathcal{G}$ is undirected implies $\mathbf{W}$ is symmetric ($w_{ij} = w_{ji}$) and as a result the second term is inherently symmetric.

The last term encourages each p_i to be close to the uniform distribution if not preferred to the contrary by the first two terms. This acts as a guard against degenerate solutions commonly encountered in SSL (Blum and Chawla, 2001; Joachims, 2003). For example, consider the case where part of the graph is almost completely disconnected from any labeled vertex (which is possible in the k-nearest neighbor case). In such situations the third term ensures that the nodes in this disconnected region are encouraged to yield a uniform distribution, validly expressing the fact that we do not know the labels of these nodes based on the nature of the graph. More generally, we conjecture that by maximizing the entropy of each p_i, the classifier has a better chance of producing high entropy results in graph regions of low confidence (e.g. close to the decision boundary and/or low density regions). This overcomes a common drawback of a large number of state-of-the-art classifiers that tend to be confident even in regions close to the decision boundary.

We conclude this section by summarizing some of the features of our proposed framework. It should be clear that C_1 uses the “manifold assumption” for SSL (see chapter 2 in (Chapelle et al., 2007)) — it assumes that the input data can be embedded within a low-dimensional manifold (the graph). As the objective is defined in terms of probability distributions over integers rather than just integers (or to real-valued relaxations of integers (Joachims, 2003; Zhu et al., 2003)), the framework generalizes in a straightforward manner to multi-class problems. Further, all the parameters are estimated jointly (compare to one vs. rest approaches which involve solving $|\mathrm{Y}|$ independent problems). Furthermore, the objective is capable of handling label training data uncertainty (Pearl, 1990). Of course, this objective would be useless if it wasn't possible to efficiently and easily optimize it on large data sets. We next describe a method that can do this.

3 Learning with Alternating Minimization

As long as $\mu, \nu \geq 0$, the objective $C_1(\mathrm{p})$ is convex. This follows since $D_{KL}(p_i||p_j)$ is convex in the pair (p_i, p_j) (Cover and Thomas, 1991), negative entropy is convex, and a positive-weighted linear combination of a set of convex functions is convex. Thus, the problem of minimizing C_1 over the space of collections of probability distributions (a convex set) constitutes a convex programming problem (Bertsekas, 2004). This property is *extremely* beneficial since there is a unique global optimum and there are a variety of methods that can be used to yield that global optimum. One possible method might take the derivative of the objective along with Lagrange multipliers to ensure that we stay within the space of probability distributions. This method can sometimes yield a closed form single-step analytical expression for the globally optimum solution. Unfortunately, however, our problem does not admit such a closed form solution because the gradient of $C_1(\mathrm{p})$ with respect to $p_i(\mathrm{y})$ is of the form, $k_1 p_i(\mathrm{y}) \log p_i(\mathrm{y}) + k_2 p_i(\mathrm{y}) + k_3$ (where $k_1,\ k_2,\ k_3$ are fixed constants). Sometimes, optimizing the dual of the objective can also produce a solution, but unfortunately again the dual of our objective also does not yield a closed form solution. The typical next step, then, is to resort to iterative techniques such as gradient descent along with modifications to ensure that the solution stays within the set of probability distributions (the gradient of C_1 alone will not necessarily point in the direction where p is still a valid distribution) - one such modification is called the method of multipliers (MOM). Another solution would be to use computationally complex (and complicated) algorithms like interior point methods (IPM). While all of the above methods (described in detail in (Bertsekas, 2004)) are feasible ways to solve our problem, they each have their own drawbacks. Using MOM, for example, requires the careful tuning of a number of additional parameters such as learning rates, growth factors, and so on. IPM involves inverting a matrix of the order of the number of variables and constraints during each iteration.

We instead adopt a different strategy based on alternating minimization (Csiszar and Tusnady, 1984). This approach has a single additional optimization parameter (contrasted with MOM), admits a closed form solution for each iteration not involving any matrix inversion (contrasted with IPM), and yields guaranteed convergence to the global optimum. In order to render our approach amenable to AM, however, we relax our objective C_1 by defining a new (third) set of distributions for all training samples q_i, $i = 1, \ldots, n$ denoted collectively like the above using the notation $\mathrm{q} \triangleq (q_1, \ldots, q_n)$. We define a new objective to be optimized as follows:

$$\min_{\mathrm{p},\mathrm{q}} C_2(\mathrm{p},\mathrm{q}), \text{ where } C_2(\mathrm{p},\mathrm{q}) = \Bigg[\sum_{i=1}^{l} D_{KL}\big(r_i || q_i\big) + \mu \sum_{i=1}^{n} \sum_{j \in \mathcal{N}(i)} w'_{ij} D_{KL}\big(p_i || q_j\big) - \nu \sum_{i=1}^{n} H(p_i) \Bigg].$$

Before going further, the reader may be wondering at this juncture how might it be desirable for us to have apparently complicated the objective function in an attempt to yield a more computationally and methodologically superior machine learning procedure. This is indeed the case as will be spelled out below. First, in C_2 we have defined a new weight matrix $[W']_{ij} = w'_{ij}$ of the same size as the original where $W' = W + \alpha \mathbf{I}_n$, where $\mathbf{I}_n$ is the $n \times n$ identity matrix, and where $\alpha \geq 0$ is a non-negative constant (this is the optimization related parameter mentioned above). This has the effect that $w'_{ii} \geq w_{ii}$. In the original objective C_1, w_{ii} is irrelevant since $D_{KL}(p||p) = 0$ for all p, but since there are now two distributions for each training point, there should be encouragement for the two to approach each other. Like C_1, the first term of C_2 ensures that the labeled training data is respected and the last term is a smoothness regularizer, but these are done via different sets of distributions, q and p respectively — this choice is what makes possible the relatively simple analytical update equations given below. Next, we see that the two objective functions in fact have identical solutions when the optimization enforces the constraint that p and q are equal:

$$\min_{(\mathrm{p},\mathrm{q}):\mathrm{p}=\mathrm{q}} C_2(\mathrm{p},\mathrm{q}) = \min_{\mathrm{p}} C_1(\mathrm{p}).$$

Indeed, as α gets large, the solutions considered viable are those only where $\mathrm{p} = \mathrm{q}$. We thus have that:

$$\lim_{\alpha\to\infty} \min_{\mathrm{p},\mathrm{q}} C_2(\mathrm{p},\mathrm{q}) = \min_{\mathrm{p}} C_1(\mathrm{p}).$$

Therefore, the two objectives should yield the same solution as long as $\alpha \geq w_{ij}$ for all i, j. A key advantage of this relaxed objective is that it is amenable to alternating minimization, a method to produce a sequence of sets of distributions $(\mathrm{p}^n, \mathrm{q}^n)$ as follows:

$$\mathrm{p}^n = \underset{\mathrm{p}}{\mathrm{argmin}} C_2(\mathrm{p}, \mathrm{q}^{n-1}), \;\; \mathrm{q}^n = \underset{\mathrm{q}}{\mathrm{argmin}} C_2(\mathrm{p}^n, \mathrm{q}).$$

It can be shown (we omit the rather lengthy proof due to space constraints) that the sequence generated using the above minimizations converges to the minimum of $C_2(\mathrm{p},\mathrm{q})$, i.e.,

$$\lim_{n\to\infty} C_2(\mathrm{p}^{(n)}, \mathrm{q}^{(n)}) = \inf_{\mathrm{p},\mathrm{q}} C_2(\mathrm{p},\mathrm{q}),$$

provided we start with a distribution that is initialized properly $q^{(0)}(y) > 0 \;\forall\; y \in \mathrm{Y}$. The update equations for $\mathrm{p}^{(n)}$ and $\mathrm{q}^{(n)}$ are given by

$$p_i^{(n)}(y) = \frac{1}{\mathcal{Z}_i} \exp^{\frac{\beta_i^{(n-1)}(y)}{\gamma_i}},$$

$$q_i^{(n)}(y) = \frac{r_i(y)\delta(i \leq l) + \mu \sum_j w'_{ji} p_j^{(n)}(y)}{\delta(i \leq l) + \mu \sum_j w'_{ji}},$$

where

$$\gamma_i = \nu + \mu \sum_j w'_{ij},$$

$$\beta_i^{(n-1)}(y) = -\nu + \mu \sum_j w'_{ij}(\log q_j^{(n-1)}(y) - 1)$$

and where $\mathcal{Z}_i$ is a normalizing constant to ensure p_i is a valid probability distribution. Note that each iteration of the proposed framework has a closed form solution and is relatively simple to implement, even for very large graphs. Henceforth we refer to the proposed objective optimized using alternating minimization as *AM*.

4 Connections to Other Approaches

Label propagation (LP) (Zhu and Ghahramani, 2002) is a graph-based SSL algorithms that performs Markov random walks on the graph and has a straightforward extension to multi-class problems. The update equations for LP (which also we use for our LP implementations) may be written as

$$p_i^{(n)}(y) = \frac{r_i(y)\delta(i \leq l) + \delta(i > l) \sum_j w_{ij} p_j^{(n-1)}(y)}{\delta(i \leq l) + \delta(i > l) \sum_j w_{ij}}$$

Note the similarity to the update equation for $q_i^{(n)}$ in our AM case. It has been shown that the squared-loss based SSL algorithm (Zhu et al., 2003) and LP have similar updates (Bengio et al., 2007).

The proposed objective C_1 is similar in spirit to the squared-loss based objective in (Zhu et al., 2003; Bengio et al., 2007). Our method, however, differs in that we are optimizing the KL-divergence over probability distributions. We show in section 5 that KL-divergence based loss significantly outperforms the squared-loss. We believe that this could be due to the following: 1) squared loss is appropriate under a Gaussian loss model which may not be optimal under many circumstances (e.g. classification); 2) KL-divergence $D_{KL}(p||q)$ is based on a relative (relative to p) rather than an absolute error; and 3) under certain natural assumptions, KL-divergence is asymptotically consistent with respect to the underlying probability distributions.

AM is also similar to the spectral graph transducer (Joachims, 2003) in that they both attempt to find labellings over the unlabeled data that respect the smoothness constraints of the graph. While spectral graph transduction is an *approximate* solution to a discrete optimization problem (which is NP hard), AM is an *exact* solution obtained by optimizing a convex function over a continuous space. Further, while spectral graph transduction assumes binary classification problems, AM naturally extends to multi-class situations without loss of convexity.

Entropy Minimization (EnM) (Grandvalet and Bengio, 2004) uses the entropy of the unlabeled data as a regularizer while optimizing a parametric loss function defined over the labeled data. While the objectives in the case of both AM and EnM make use of the entropy of the unlabeled data, there are several important differences: (a) EnM is *not* graph-based, (b) EnM is parametric whereas our proposed approach is non-parametric, and most importantly, (c) EnM attempts to *minimize* entropy while the proposed approach aims to *maximize* entropy. While this may seem a triviality, it has catastrophic consequences in terms of both the mathematics and meaning. The objective in case of EnM is not convex, whereas in our case we have a convex formulation with simple update equations and convergence guarantees.

(Wang et al., 2008) is a graph-based SSL algorithm that also employs alternating minimization style optimization. However, it is inherently squared-loss based which our proposed approach out-performs (see section 5). Further, they do not provide or state convergence guarantees and one side of their update approximates an NP-complete optimization procedure.

The information regularization (IR) (Corduneanu and Jaakkola, 2003) algorithm also makes use of a KL-divergence based loss for SSL. Here the input space is divided into regions $\{R_i\}$ which might or might not overlap. For a given point $x_i \in R_i$, IR attempts to minimize the KL-divergence between $p_i(y_i|x_i)$ and $\hat{p}_{R_i}(y)$, the agglomerative distribution for region R_i. Given a graph, one can define a region to be a vertex and its neighbor thus making IR amenable to graph-based SSL. In (Corduneanu and Jaakkola, 2003), the agglomeration is performed by a simple averaging (arithmetic mean). While IR suggests (without proof of convergence) the use of alternating minimization for optimization, one of the steps of the optimization does *not* admit a closed-form solution. This is a serious practical drawback especially in the case of large data sets. (Tsuda, 2005) (hereafter referred to as PD) is an extension of the IR algorithm to hypergraphs where the agglomeration is performed using the geometric mean. This leads to closed form solutions in both steps of the alternating minimization. There are several important differences between IR and PD on one side and our proposed approach: (a) neither IR nor PD use an entropy regularizer, and (b) the update equation for one of the steps of the optimization in the case of PD (equation 13 in (Tsuda, 2005)) is actually a special case of our update equation for $p_i(y)$ and may be obtained by setting $w_{ij} = 1/2$. Further, our work here may be easily extended to hypergraphs.

5 Results

We compare our algorithm (AM) with other state-of-the-art SSL-based text categorization algorithms, namely, (a) SVM (Joachims, 1999), (b) Transductive-SVM (TSVM) (Joachims, 1999), (c) Spectral Graph Transduction (SGT) (Joachims, 2003), and (d) Label Propagation (LP) (Zhu and Ghahramani, 2002). Note that only SGT and LP are graph-based algorithms, while SVM is fully-supervised (i.e., it does not make use of any of the unlabeled data). We implemented SVM and TSVM using *SVM Light* (Joachims, b) and SGT using *SGT Light* (Joachims, a). In the case of SVM, TSVM and SGT we trained |Y| classifiers (one for each class) in a one vs. rest manner precisely following (Joachims, 2003).

5.1 Reuters-21578

We used the "ModApte" split of the Reuters-21578 dataset collected from the Reuters newswire in

1987 (Lewis et al., 1987). The corpus has 9,603 training (not to be confused with $\mathcal{D}$) and 3,299 test documents (which represents $\mathcal{D}_u$). Of the 135 potential topic categories only the 10 most frequent categories are used (Joachims, 1999). Categories outside the 10 most frequent were collapsed into one class and assigned a label "other". For each document i in the training and test sets, we extract features $\mathbf{x}_i$ in the following manner: stop-words are removed followed by the removal of case and information about inflection (i.e., stemming) (Porter, 1980). We then compute TFIDF features for each document (Salton and Buckley, 1987). All graphs were constructed using cosine similarity with TFIDF features.

For this task $\mathrm{Y} = \{$ *earn*, *acq*, *money*, *grain*, *crude*, *trade*, *interest*, *ship*, *wheat*, *corn*, *average*$\}$. For LP and AM, we use the output space $\mathrm{Y}' = \mathrm{Y} \cup \{$ *other* $\}$. For documents in $\mathcal{D}_l$ that are labeled with multiple categories, we initialize r_i to have equal non-zero probability for each such category. For example, if document i is annotated as belonging to classes $\{$ *acq*, *grain*, *wheat*$\}$, then $r_i(\mathit{acq}) = r_i(\mathit{grain}) = r_i(\mathit{wheat}) = 1/3$.

We created 21 transduction sets by randomly sampling l documents from the training set with the constraint that each of 11 categories (top 10 categories and the class *other*) are represented at least once in each set. These samples constitute $\mathcal{D}_l$. All algorithms used the same transduction sets. In the case of SGT, LP and AM, the first transduction set was used to tune the hyperparameters which we then held fixed for all the remaining 20 transduction sets. For all the graph-based approaches, we ran a search over $\mathcal{K} \in \{2, 10, 50, 100, 250, 500, 1000, 2000, n\}$ (note $\mathcal{K} = n$ represents a fully connected graph). In addition, in the case of AM, we set $\alpha = 2$ for all experiments, and we ran a search over $\mu \in \{$1e–8, 1e–4, 0.01, 0.1, 1, 10, 100$\}$ and $\nu \in \{$1e–8, 1e–6, 1e–4, 0.01, 0.1$\}$, for SGT the search was over $c \in \{$3000, 3200, 3400, 3800, 5000, 100000$\}$ (see (Joachims, 2003)).

We report precision-recall break even point (PRBEP) results on the 3,299 test documents in Table 1. PRBEP has been a popular measure in information retrieval (see e.g. (Raghavan et al., 1989)). It is defined as that value for which precision and recall are equal. Results for each category in Table 1 were obtained by averaging the PRBEP over the 20 transduction sets. The final row "average" was obtained by macro-averaging (average of averages). The optimal value of the hyperparameters in case of LP was $\mathcal{K} = 100$; in case of AM, $\mathcal{K} = 2000$, $\mu =$ 1e–4, $\nu =$ 1e–2; and in the case of SGT, $\mathcal{K} = 100$, $c = 3400$. The results show that AM outperforms the state-of-the-art on 6 out of 10 categories and is competitive in 3 of the remaining 4 categories. Further it significantly outperforms all other approaches in case of the macro-averages. AM is significant over its best competitor SGT at the 0.0001 level according to the difference of proportions significance test.

Category	SVM	TSVM	SGT	LP	AM
earn	91.3	95.4	90.4	96.3	**97.9**
acq	67.8	76.6	91.9	90.8	**97.2**
money	41.3	60.0	65.6	57.1	**73.9**
grain	56.2	**68.5**	43.1	33.6	41.3
crude	40.9	**83.6**	65.9	74.8	55.5
trade	29.5	34.0	36.0	**56.0**	47.0
interest	35.6	50.8	50.7	47.9	**78.0**
ship	32.5	46.3	**49.0**	26.4	39.6
wheat	47.9	44.4	59.1	58.2	**64.3**
corn	41.3	33.7	51.2	55.9	**68.3**
average	48.9	59.3	60.3	59.7	**66.3**

Table 1: P/R Break Even Points (PRBEP) for the top 10 categories in the Reuters data set with $l = 20$ and $u = 3299$. All results are averages over 20 randomly generated transduction sets. The last row is the macro-average over all the categories. Note AM is the proposed approach.

Figure 1 shows the variation of "average" PRBEP against the number of labeled documents (l). For each value of l, we tuned the hyperparameters over the first transduction set and used these values for all the other 20 sets. Figure 1 also shows error-bars ($\pm$ standard deviation) all the experiments. As expected, the performance of all the approaches improves with increasing number of labeled documents. Once again in this case, AM, outperforms the other approaches for all values of l.

5.2 WebKB Collection

World Wide Knowledge Base (WebKB) is a collection of 8282 web pages obtained from four academic

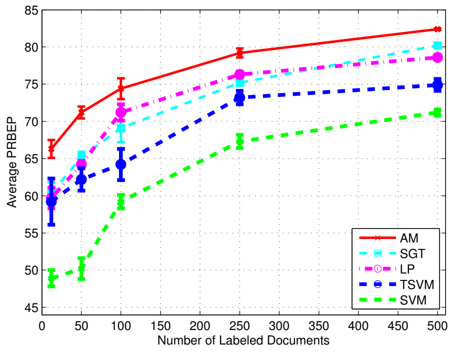

Figure 1: Average PRBEP over all classes vs. number of labeled documents (l) for Reuters data set

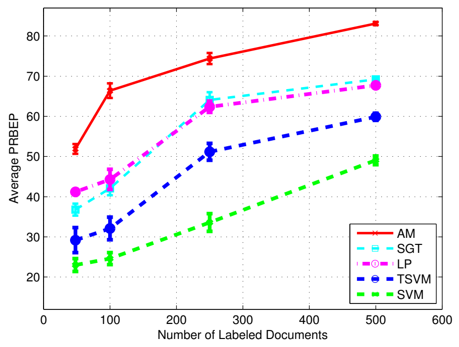

Figure 2: Average PRBEP over all classes vs. number of labeled documents (l) for WebKB collection.

domains. The web pages in the WebKB set are labeled using two different polychotomies. The first is according to topic and the second is according to web domain. In our experiments we only considered the first polychotomy, which consists of 7 categories: *course*, *department*, *faculty*, *project*, *staff*, *student*, and *other*. Following (Nigam et al., 1998) we only use documents from categories *course*, *department*, *faculty*, *project* which gives 4199 documents for the four categories. Each of the documents is in HTML format containing text as well as other information such as HTML tags, links, etc. We used both textual and non-textual information to construct the feature vectors. In this case we did not use either stop-word removal or stemming as this has been found to hurt performance on this task (Nigam et al., 1998). As in the the case of the Reuters data set we extracted TFIDF features for each document and constructed the graph using cosine similarity.

As in (Bekkerman et al., 2003), we created four roughly-equal random partitions of the data set. In order to obtain $\mathcal{D}_l$, we first randomly choose a split and then sample l documents from that split. The other three splits constitute $\mathcal{D}_u$. We believe this is more realistic than sampling the labeled web-pages from a single university and testing web-pages from the other universities (Joachims, 1999). This method of creating transduction sets allows us to better evaluate the generalization performance of the various algorithms. Once again we create 21 transduction sets and the first set was used to tune the hyperparameters. Further, we ran a search over the same grid as used in the case of Reuters. We report precision-recall break even point (PRBEP) results on the 3,148 test documents in Table 2. For this task, we found that the optimal value of the hyperparameter were: in the case of LP, $\mathcal{K} = 1000$; in case of AM, $\mathcal{K} = 1000$, $\mu = 1\text{e–}2$, $\nu = 1\text{e–}4$; and in case of SGT, $\mathcal{K} = 100$, $c = 3200$. Once again, AM is significant at the 0.0001 level over its closest competitor LP. Figure 2 shows the variation of PRBEP with number of labeled documents (l) and was generated in a similar fashion as in the case of the Reuters data set.

Class	SVM	TSVM	SGT	LP	AM
course	46.5	43.9	29.9	45.0	**67.6**
faculty	14.5	31.2	**42.9**	40.3	42.5
project	15.8	17.2	17.5	27.8	**42.3**
student	15.0	24.5	56.6	51.8	**55.0**
average	23.0	29.2	36.8	41.2	**51.9**

Table 2: P/R Break Even Points (PRBEP) for the WebKB data set with $l = 48$ and $u = 3148$. All results are averages over 20 randomly generated transduction sets. The last row is the macro-average over all the classes. AM is the proposed approach.

6 Discussion

We note that LP may be cast into an AM-like framework by using the following sequence of updates,

$$p_i^{(n)}(y) = \delta(i \le l)r_i(y) + \delta(i > l)q_i^{(n-1)},$$
$$q_i^{(n)}(y) = \frac{\sum_j w_{ij} p_i^{(n)}(y)}{\sum_j w_{ij}}$$

To compare the behavior of AM and LP, we applied this form of LP along with AM on a simple 5-node binary-classification SSL graph where two nodes are labeled (node 1 and 2) and the remaining nodes are unlabeled (see Figure 3, top). Since this is binary classification ($|Y| = 2$), each distribution p_i or q_i can be depicted using only a single real number between 0 and 1 corresponding to the probability that each vertex is class 2 (yes two). We show how both LP and AM evolve starting from exactly the same random starting point q^0 (Figure 3, bottom). For each algorithm, the figure shows that both algorithms clearly converge. Each alternate iteration of LP is such that the labeled vertices oscillate due to its clamping back to the labeled distribution, but that is not the case for AM. We see, moreover, qualitative differences in the solutions as well – e.g., AM's solution for the pendant node 5 is less confident than is LP's solution. More empirical comparative analysis between the two algorithms of this sort will appear in future work.

We have proposed a new algorithm for semi-supervised text categorization. Empirical results show that the proposed approach significantly outperforms the state-of-the-art. In addition the proposed approach is relatively simple to implement and has guaranteed convergence properties. While in this work, we use relatively simple features to construct the graph, use of more sophisticated features and/or similarity measures could lead to further improved results.
