Table 3: Results for all the cross-lingual systems. Bold indicates the overall highest scores. As a lower bound, we show a simple deterministic baseline that, for pronominal mentions, selects the closest non-pronominal antecedent, and, for non-pronominal mentions, selects the closest non-pronominal mention that is a superstring of the current mention.

5.2 Baseline #1: Delexicalized Transfer With Cross-Lingual Embeddings

We now turn to the cross-lingual systems. Delexicalized transfer is a popular strategy in NLP (Zeman and Resnik, 2008; McDonald et al., 2011), recently strengthened with cross-lingual word representations (Täckström et al., 2012). The procedure works as follows: a delexicalized model for the source language is trained by eliminating all the language-specific features (such as lexical features); then, this model is used directly in the target language. We report here the performance of this baseline on coreference resolution for Spanish and Portuguese, using the delexicalized models trained on the English data as mentioned in §5.1.

To achieve a unified feature representation, we mapped all language-specific POS tags to universal tags (Petrov et al., 2012). All lexical features were replaced either by **cross-lingual word embeddings** (for words that are not pronouns); or by a universal representation containing the gender, number, and person information of the pronoun. To obtain the cross-lingual word embeddings, we ran the method described by Hermann and Blunsom (2014) for the English-Spanish and English-Portuguese pairs, using the parallel sentences in §2. When used as features, these 128-dimensional continuous representations were scaled by a factor of 0.5 (selected on the dev-set), using the procedure of Turian et al. (2010).

The second and seventh rows in Table 3 show the performance of this baseline, which is rather disappointing. For Spanish, we observe a large drop in performance when going from supervised training to delexicalized transfer (about 11–13% in averaged F_1). For Portuguese, where the supervised system is not so accurate, the difference is less sharp (about 9–11%). These drops are mainly due to the fact that this method does not take into account the intricacies of each language—*e.g.*, possessive forms have different agreement rules in English and in Romance languages;[9] those, on the other hand, have clitic pronouns that are absent in English. Feature weights that promote certain English agreement relations may then harm performance more than they help.

5.3 Baseline #2: Bitext Direct Projection

Another popular strategy for cross-lingual learning is bitext direct projection, which consists in projecting annotations through parallel data in the source and target languages (Yarowsky et al., 2001; Hwa et al., 2005). This is essentially the same as Algorithm 1, except that line 4 is replaced by simple supervised learning, via a minimization

[9] For example, in Figure 1, *their* agrees in number with the possessor (*the alveoli*), but the corresponding *sua* agrees in number and gender with the thing possessed (*função*).

of the loss function in Eq. 4 with ℓ_2-regularization. This procedure has the disadvantage of being very sensitive to annotation errors, as we shall see. For Portuguese, this baseline is a near-reproduction of Souza and Orăsan (2011)'s work, discussed in §6.

The third and eighth rows in Table 3 show that this baseline is stronger than the delexicalized baseline, but still 6–8 points away from the supervised systems. This gap is due to a mix of two factors: prediction errors in the English side of the bitext, and missing alignments. Indeed, when automatic alignments are used, false negatives for coreferent pairs of mentions are common, due to words that have not been aligned with sufficiently high confidence. The direct projection method is not robust to these annotation errors.

5.4 Baseline #3: Vanilla PR

Our last baseline is a vanilla PR approach; this is an adaptation of the procedure carried out by Ganchev and Das (2013) to our coreference resolution problem. The motivation is to increase the robustness of bitext projection to annotation errors, which we do by applying the soft constraints in §4.4. We seek a saddle-point of the PR objective by running 20 epochs of SGD, alternating $\boldsymbol{w}$-updates and $\boldsymbol{u}$-updates. The best results in the dev-set were obtained with $\eta_1 = 1.0$ and $\eta_2 = 0.9$.

By looking at the fourth and ninth rows of Table 3, we observe that vanilla PR manages to reduce the gap to supervised systems, obtaining consistent gains over the bitext projection baseline (with the exception of the Portuguese dev-set). This confirms the ability of PR methods to handle annotation mistakes in a robust manner.

5.5 Our Proposal: Softmax-Margin PR

Finally, the fifth and last rows in Table 3 show the performance of our systems trained with softmax-margin PR, as described in §4.1. We optimized the loss function in Eq. 11 with $\gamma = 1.0$ by running 20 epochs of SGD, setting $u_1 = +\infty$ and $u_2 = 1.0$ (cf. §4.4)—the last value was tuned in the dev-set. As shown in Figure 2, this penalized variant was more effective than the saddle point formulation.

From Table 3, we observe that softmax-margin PR consistently beats all the baselines, narrowing the gap with respect to supervised systems to about 5 points for Spanish, and 2–3 points for Portuguese. Gains over the vanilla PR procedure (the strongest baseline) lie in the range 0.5–3%. These gains come from the ability of softmax-margin PR to handle task-specific cost functions, enabling a better management of precision/recall tradeoffs.

5.6 Error Analysis

We carried out some error analysis, focused on the Spanish development dataset, to better understand where the improvements of softmax-margin PR come from. The main conclusions carry out to the Portuguese case, with a few exceptions, mostly due to different human annotation criteria.

Table 4 shows the precision and recall scores for mention prediction and the different coreference evaluation metrics. Note that all systems predict the same candidate mentions; however a final post-processing discards all mentions that ended up in singleton entities, for compliance with the official scorer. Therefore, the mention prediction score reflects how well a system does in predicting if a mention is anaphoric or not. The first thing to note is that the PR methods, due to their ability to create new links during training (via constraint #2) tend to predict fewer singletons than the direct projection method. Indeed, we observe that soft max-margin PR achieves 47.1% mention prediction recall, which is more than 5% above the direct projection method, and 10% above the delexicalized transfer method. Note also that, while the vanilla PR method achieves higher recall than the two other baselines, it is still almost 5% below the system trained with soft-max margin PR. This is because vanilla PR does not benefit from the cost function in §4.3—such cost is able to penalize false non-anaphoric mentions and encourage larger clusters, allowing softmax-margin PR to achieve a better precision-recall trade-off. From Table 4, we can see that this improvement in mention recall consistently translates into higher recall for the MUC, B^3 and CEAF_e coreference metrics.

Further analysis revealed that a major source of error for the delexicalized baseline is its inability to handle pronominal mentions robustly across languages—as hinted in footnote 9. In practice, we found the delexicalized systems to be quite conservative with possessive pronouns: for the Spanish dataset, where the vast majority of possessive pronouns are anaphoric, the delexicalized model incorrectly predicts 53.3% of these pronouns as non-anaphoric. The direct projection model is slightly less conservative, missing 30.1% of the possessives (arguably due to its inability to recover missing links in the projected data, dur-

	Mention	MUC	B^3	CEAF$_e$
delex.	37.1 / 62.2	25.6 / 46.5	19.6 / 45.7	27.9 / 39.5
dir. proj.	41.7 / 77.5	29.3 / 60.4	19.2 / 69.5	31.8 / 47.9
vanilla PR	42.2 / 78.0	30.9 / 62.3	23.2 / 61.7	31.9 / 48.8
our PR	47.1 / 74.1	33.7 / 57.1	26.0 / 56.1	34.9 / 46.7

Table 4: Recall/precision scores for mention prediction, MUC, B^3 and CEAF$_e$, all computed in the Spanish dev set.

ing training). By comparison, the vanilla and softmax margin PR models only miss 4.9% and 3.4% of the possessives, respectively. In Portuguese, where many possessives are not annotated in the gold data, we observe a similar but much less pronounced trend.

6 Related Work

While multilingual coreference resolution has been the subject of recent SemEval and CoNLL shared tasks, no submitted system attempted cross-lingual training. As shown by Recasens and Hovy (2010), language-specific issues pose a challenge, due to phenomena as pronoun dropping and grammatical gender that are absent in English but exist in other languages. We have discussed some of these issues in the scope of the present work.

Harabagiu and Maiorano (2000) and Postolache et al. (2006) projected English corpora to Romanian to bootstrap human annotation, either manually or via automatic alignments. Rahman and Ng (2012) applied translation-based projection at test time (but require an external translation service). Hardmeier et al. (2013) addressed the related task of cross-lingual pronoun prediction. While all these approaches help alleviate the corpus annotation bottleneck, none resulted in a full coreference resolver, which our work accomplished.

The work most related with ours is Souza and Orăsan (2011), who also used parallel data to transfer an English coreference resolver to Portuguese, but could not beat a simple baseline that clusters together mentions with the same head. Their approach is similar to our bitext direct projection baseline, except that they used Reconcile (Stoyanov et al., 2010) instead of the Berkeley Coreference System, and a smaller version of the FAPESP corpus. We have shown that our softmax-margin PR procedure is superior to this approach.

Discriminative PR has been proposed by Ganchev et al. (2010). The same idea underlies the generalized expectation criterion (Mann and McCallum, 2010; Wang and Manning, 2014). An SGD algorithm for solving the resulting saddle point problem has been proposed by Liang et al. (2009), and used by Ganchev and Das (2013) for cross-lingual learning of sequence models. We extended this framework in two aspects: by incorporating a task-specific cost in the objective function, and by formulating a penalized variant of PR.

7 Conclusions

We presented a framework for cross-lingual transfer of coreference resolvers. Our method uses word-aligned bitext to project information from the source to the target language. Robustness to projection errors was achieved via a PR framework, which we generalized to handle task-specific costs, yielding softmax-margin PR. We also proposed a penalized formulation that is effective for a small number of corpus-based constraints. Empirical gains were shown over three popular cross-lingual methods: delexicalized transfer, bitext direct projection, and vanilla PR.

Acknowledgments

I would like to thank the reviewers for their helpful comments, José Guilherme Camargo de Souza for pointing to existing datasets, and Mariana Almeida for valuable feedback. A Proof of Proposition 1

Let us fix $\boldsymbol{w}$ and see how to evaluate $\mathbf{KL}(\mathcal{Q}\|p'_{\boldsymbol{w}}) = \min_{q\in\mathcal{Q}} \mathbf{KL}(q\|p'_{\boldsymbol{w}})$. We have:

$$\begin{aligned}\mathbf{KL}(q\|p'_{\boldsymbol{w}}) &= -\mathbf{H}(q) - \textstyle\sum_{\mathbf{Y}} q(\mathbf{Y}) \log p'_{\boldsymbol{w}}(\mathbf{Y}|\mathbf{X}) \\ &= -\mathbf{H}(q) + \textstyle\sum_n \log Z'(\boldsymbol{w}, x^{(n)}) - \\ &\quad \textstyle\sum_{\mathbf{Y}} q(\mathbf{Y})(\boldsymbol{w}^\top \boldsymbol{f}(\mathbf{X},\mathbf{Y}) + \ell(\mathbf{Y})),\end{aligned}$$

where $\ell(\mathbf{Y}) := \sum_{n=1}^N \ell(y, \mathcal{Y}(\mathcal{E}^{(n)}))$ and $\boldsymbol{f}(\mathbf{X},\mathbf{Y}) := \sum_{n=1}^N \boldsymbol{f}(x^{(n)}, y^{(n)})$. Introducing Lagrange multipliers $\boldsymbol{u}$ for the posterior constraints, we get the Lagrangian function:

$$\begin{aligned}\mathcal{L}(q,\boldsymbol{u}) &= -\mathbf{H}(q) + \textstyle\sum_n \log Z'(\boldsymbol{w}, x^{(n)}) - \boldsymbol{b}^\top \boldsymbol{u} \\ &\quad - \textstyle\sum_{\mathbf{Y}} q(\mathbf{Y})(\boldsymbol{w}^\top \boldsymbol{f}(\mathbf{X},\mathbf{Y}) + \ell(\mathbf{Y}) - \boldsymbol{u}^\top \boldsymbol{g}(\mathbf{X},\mathbf{Y})).\end{aligned}$$

By standard variational arguments (namely, Fenchel duality between the the log-partition function and the negative entropy; see *e.g.* Martins et al. (2010)), we have that the optimal q^* that minimizes the Lagrangian is

$$q^*(\mathbf{Y}) = \frac{e^{\boldsymbol{w}^\top \boldsymbol{f}(\mathbf{X},\mathbf{Y}) + \ell(\mathbf{Y}) - \boldsymbol{u}^\top \boldsymbol{g}(\mathbf{X},\mathbf{Y})}}{\prod_{n=1}^N Z'_{\boldsymbol{u}}(\boldsymbol{w}, x^{(n)})}.$$

Plugging this in the Lagrangian yields Eq. 8.

Abstract

We introduce the *Hierarchical Ideal Point Topic Model*, which provides a rich picture of policy issues, framing, and voting behavior using a joint model of votes, bill text, and the language that legislators use when debating bills. We use this model to look at the relationship between Tea Party Republicans and "establishment" Republicans in the U.S. House of Representatives during the 112th Congress.

1 Capturing Political Polarization

Ideal-point models are one of the most widely used tools in contemporary political science research (Poole and Rosenthal, 2007). These models estimate political preferences for legislators, known as their *ideal points*, from binary data such as legislative votes. Popular formulations analyze legislators' votes and place them on a one-dimensional scale, most often interpreted as an ideological spectrum from liberal to conservative.

Moving beyond a single dimension is attractive, however, since people may lean differently based on policy issues; for example, the conservative movement in the U.S. includes fiscal conservatives who are relatively liberal on social issues, and vice versa. In *multi-dimensional* ideal point models, therefore, the ideal point of each legislator is no longer characterized by a single number, but by a multi-dimensional vector. With that move comes a new challenge, though: the additional dimensions are often difficult to interpret. To mitigate this problem, recent research has introduced methods that estimate multi-dimensional ideal points using both voting data and the texts of the bills being voted on, e.g., using topic models and associating each dimension of the ideal point space with a topic. The words most strongly associated with the topic can sometimes provide a readable description of its corresponding dimension.

In this paper, we develop this idea further by introducing HIPTM, the *Hierarchical Ideal Point Topic Model*, to estimate multi-dimensional ideal points for legislators in the U.S. Congress. HIPTM differs from previous models in three ways. First, HIPTM uses not only votes and associated bill text, but also the *language* of the legislators themselves; this allows predictions of ideal points from politicians' writing alone. Second, HIPTM improves the interpretability of ideal-point dimensions by incorporating data from the Congressional Bills Project (Adler and Wilkerson, 2015), in which bills are labeled with major topics from the Policy Agendas Project Topic Codebook.[1] And third, HIPTM discovers a *hierarchy* of topics, allowing us to analyze both agenda issues and issue-specific frames that legislators use on the congressional floor, following Nguyen et al. (2013) in modeling framing as second-level agenda setting (McCombs, 2005).

Using this new model, we focus on Republican legislators during the 112th U.S. Congress, from January 2011 until January 2013. This is a particularly interesting session of Congress for political scientists, because of the rise of the Tea Party, a decentralized political movement with populist, libertarian, and conservative elements. Although united with "establishment" Republicans against Democrats in the 2010 midterm elections, leading to massive Democratic defeats, the Tea Party was—and still is—wrestling with establishment Republicans for control of the Republican party.

The Tea Party is a new and complex phenomenon for political scientists; as Carmines and D'Amico (2015) observe: "Conventional views of ideology as a single-dimensional, left-right spectrum experience great difficulty in understanding or explaining the Tea Party." Our model identifies legislators who have low (or high) levels of "Tea Partiness" but are (or are not) members of the Tea Party Caucus, and providing insights into the na-

ture of polarization within the Republican party. HIPTM also makes it possible to investigate a number of questions of interest to political scientists. For example, are there Republicans who identify themselves as members of the Tea Party, but whose votes and language betray a lack of enthusiasm for Tea Party issues? How well can we predict from someone's language alone whether they are likely to associate themselves with the Tea Party? Our computational modeling approach to "Tea Partiness", distinct from self-declared Tea Party Caucus membership, may have particular value in understanding Republican party politics going forward because, despite the continued influence of the Tea Party, the official Tea Party Caucus in the House of Representatives is largely inactive and its future uncertain (Fuller, 2015).

2 Polarization across Dimensions

Ideal point models describe probabilistic relationships between observed responses (votes) on a set of items (bills) by a set of responders (legislators) who are characterized by continuous latent traits (Fox, 2010). A popular formulation posits an *ideal point* u_a for each lawmaker a, a *polarity* x_b, and *popularity* y_b for each bill b, all being values in $(-\infty, +\infty)$ (Martin and Quinn, 2002; Bafumi et al., 2005; Gerrish and Blei, 2011). Lawmaker a votes "Yes" on bill b with probability

$$p(v_{a,b} = \text{Yes} \mid u_a, x_b, y_b) = \Phi(u_a x_b + y_b) \quad (1)$$

where $\Phi(\alpha) = \exp(\alpha)/(1 + \exp(\alpha))$ is the logistic (or inverse-logit) function.[2] Intuitively, most lawmakers vote "Yes" on bills with high popularity y_b and "No" on bills with low y_b. When a bill's popularity is lower, the outcome of the vote $v_{a,b}$ depends more on the interaction between the lawmaker's ideal point u_a and the bill's polarity x_b.

Multi-dimensional ideal point models replace scalars u_a and x_b with K-dimensional vectors $\boldsymbol{u}_a$ and $\boldsymbol{x}_b$ (Heckman and Jr., 1997; Jackman, 2001; Clinton et al., 2004). Unfortunately, as Lauderdale and Clark (2014) observe, the binary data used for these models are "insufficiently informative to support analyses beyond one or two dimensions", and the additional dimensions are difficult to interpret. To address this lack of interpretability, recent work has proposed multi-dimensional ideal point models to jointly capture both binary votes and the associated text (Gerrish and Blei, 2012; Gu et al., 2014; Lauderdale and Clark, 2014; Sim et al., 2015).

3 Hierarchical Ideal Point Topic Model

Bringing topic models (Blei and Lafferty, 2009) into ideal-point modeling provides an interpretable, text-based foundation for political scientists to understand why the models make the predictions they do. However, both the *topic*—what is discussed—and the *framing*—how it is discussed—also reveal political preferences. We therefore introduce *frame-specific* ideal points, using a hierarchy of topics to model issues and their issue-specific frames. Although the definition of "frame" is itself a moving target in political science (Entman, 1993), we adopt the theoretically motivated but pragmatic approach of Nguyen et al. (2013): just as agenda-issues map naturally to topics in probabilistic topic models (e.g., Grimmer (2010)), the frames as second-level agenda-setting (McCombs, 2005) map to second-level topics in a hierarchical topic model.

Our model's inputs are votes $\{v_{a,b}\}$, each the response of legislator $a \in [1, A]$ to bill $b \in [1, B]$. Two types of text supplement the votes: floor speeches (documents) $\{\boldsymbol{w}_d\}$ from legislator a_d, and the text $\boldsymbol{w}'_b$ of bill b. While congressional debates are typically about one piece of legislation, we make no assumptions about the mapping between $\boldsymbol{w}_d$ and $\boldsymbol{w}'_b$. In principle this allows $\boldsymbol{w}_d$ to be *any* text by legislator a_d (e.g., not just floor speeches about this bill, but blogs, social media, press releases) and—unlike Gerrish and Blei (2011)—this permits us to make predictions about individuals even without vote data for them. Figure 1 shows the plate notation diagram of HIPTM, which has the following generative process:

1. For each issue $k \in [1, K]$
   (a) Draw k's associated topic $\phi_k \sim \text{Dir}(\beta, \phi^\star_k)$
   (b) Draw issue-specific distribution over frames $\psi_k \sim \text{GEM}(\lambda_0)$
   (c) For each frame $j \in [1, \infty)$ (specific to issue k)
      i. Draw j's associated topic $\phi_{k,j} \sim \text{Dir}(\beta, \phi_k)$
      ii. Draw j's regression weight $\eta_{k,j} \sim \mathcal{N}(0, \gamma)$
2. For each document $d \in [1, D]$ by legislator a_d
   (a) Draw topic (i.e., issue) distribution $\theta_d \sim \text{Dir}(\alpha)$
   (b) For each issue $k \in [1, K]$, draw frame distribution $\psi_{d,k} \sim \text{DP}(\lambda, \psi_k)$
   (c) For each token $n \in [1, N_d]$
      i. Draw an issue $z_{d,n} \sim \text{Mult}(\theta_d)$
      ii. Draw a frame $t_{d,n} \sim \text{Mult}(\psi_{d,z_{d,n}})$
      iii. Draw word $w_{d,n} \sim \text{Mult}(\phi_{z_{d,n},t_{d,n}})$
3. For each legislator $a \in [1, A]$ on each issue $k \in [1, K]$
   (a) Draw issue-specific ideal point $u_{a,k} \sim \mathcal{N}(\sum_{j=1}^{J_k} \hat{\psi}_{a,k,j} \eta_{k,j}, \rho)$ weighting $\eta_{k,j}$ by how much the legislator talks about that frame

[2] A probit function is also often used where $\Phi(\alpha)$ is instead the cumulative distribution function of a Gaussian distribution (Martin and Quinn, 2002).

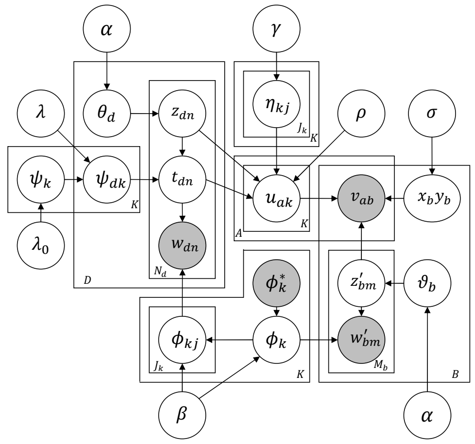

Figure 1: Plate notation diagram of HIPTM.

4. For each bill $b \in [1, B]$
   (a) Draw polarity $x_b \sim \mathcal{N}(0, \sigma)$
   (b) Draw popularity $y_b \sim \mathcal{N}(0, \sigma)$
   (c) Draw topic (i.e., issue) proportions $\vartheta_b \sim \text{Dir}(\alpha)$
   (d) For each token $m \in [1, M_b]$ in the text of bill b
      i. Draw an issue $z'_{b,m} \sim$ Mult(ϑ_b)
      ii. Draw a word type $w'_{b,m} \sim$ Mult($\phi_{z'_{b,m}}$)
5. For each vote $v_{a,b}$ of legislator a on bill b
   (a) $p(v_{a,b} \mid \boldsymbol{u}_a, x_b, y_b, \hat{\vartheta}_b) = \Phi\left(x_b \sum_k \hat{\vartheta}_{b,k} u_{a,k} + y_b\right)$

Topic Hierarchy. With the goal of analyzing agendas and frames in mind, our topic hierarchy has two levels: (1) *issue nodes* and (2) *frame nodes*. (Look ahead to Figure 6 for an illustration.) More specifically, there are K issue nodes, each with a topic ϕ_k drawn from a Dirichlet distribution with concentration parameter β and a prior mean vector $\phi_k^\star$, i.e., $\phi_k \sim \text{Dir}(\beta, \phi_k^\star)$. In this hierarchical structure, first-level nodes map to agenda issues, which we treat as non-polarized, and second-level nodes map to issue-specific frames, which we assume polarize on the issue-specific dimension.[3]

To improve topic interpretability, issue nodes have an informed prior from the Congressional Bills Project $\{\phi_k^\star\}$ (Table 1).[4] The frame topic $\phi_{k,j}$ at each frame node is a Dirichlet draw centered at the corresponding (parent) issue node. While the number of issues is fixed *a priori*, the number of second-level frames is unbounded. We also associate each second-level frame node with an ideal point $\eta_{k,j} \sim \mathcal{N}(0, \gamma)$. This resembles how supervised topic models (Blei and McAuliffe, 2007; Nguyen et al., 2015) discover polarized topics' associated response variables.

Generating Text from Legislators. One of our model's goal is to study how legislators *frame* policy agenda issues. To achieve that, we analyze congressional speeches (documents) $\{\boldsymbol{w}_d\}$, each of which is delivered by a legislator a_d. To generate each token $w_{d,n}$ of a speech d, legislator a_d will (1) first choose an issue $z_{d,n} \in [1, K]$ from a document-specific multinomial θ_d, then (2) choose a frame $t_{d,n}$ from the set of infinitely many possible frames of the given issue $z_{d,n}$ using the frame proportion $\psi_{d,k}$ drawn from a Dirichlet process, and finally (3) choose a word type from the chosen frame's topic $\phi_{z_{d,n}, t_{d,n}}$. In other words, our model generates speeches using a mixture of K HDPs (Teh et al., 2006).[5]

Generating Bill Text. The bill text provides information about the policy agenda issues that each bill addresses. We use LDA to model the bill text $\{\boldsymbol{w}'_b\}$. Each bill b is a mixture ϑ_b over K issues, which is drawn from a symmetric Dirichlet prior, i.e., $\vartheta_b \sim \text{Dir}(\alpha)$. Each token $w'_{b,m}$ in bill b is generated by first choosing a topic $z'_{b,m} \sim$ Mult(ϑ_b), and then choosing a word type $w'_{b,m} \sim$ Mult($\phi_{z'_{b,m}}$), as in LDA.

Generating Roll Call Votes. Following recent work on multi-dimensional ideal points (Lauderdale and Clark, 2014; Sim et al., 2015), we define the probability of legislator a voting "Yes" on bill b as $p(v_{a,b} = \text{Yes} \mid \boldsymbol{u}_a, x_b, y_b, \hat{\vartheta}_b) =$

$$\Phi\left(x_b \sum_{k=1}^{K} \hat{\vartheta}_{b,k} u_{a,k} + y_b\right) \qquad (2)$$

where $\hat{\vartheta}_b$ is the empirical distribution of bill b over the K issues and is defined as $\hat{\vartheta}_{b,k} = \frac{M_{b,k}}{M_{b,\cdot}}$. Here, $M_{b,k}$ is the number of times in which tokens in b

[3] Nguyen et al. (2013) allow first-level nodes to polarize but find first-level nodes are typically neutral.

[4] The Congressional Bills Project provides a large collection of labeled congressional bill text. We compute $\{\phi_k^\star\}$ as the empirical word distribution from all bills labeled with k. $K = 19$, corresponding to 19 major topic headings in the Policy Agendas Project Topic Codebook.

[5] If we abandoned the labeled data from the Congressional Bills Project to obtain the prior means $\phi_k^\star$, it would be relatively straightforward to extend to a fully nonparametric model with unbounded K (Ahmed et al., 2013; Paisley et al., 2014).

are assigned to issue k and $M_{b,\cdot}$ is the marginal count, i.e., the number of tokens in bill b.

The ideal point of legislator a specifically on issue k is $u_{a,k}$ and comes from a normal distribution

$$\mathcal{N}(\hat{\psi}_{a,k}^{T}\boldsymbol{\eta}_k, \rho) \equiv \mathcal{N}\left(\sum_{j=1}^{J_k} \hat{\psi}_{a,k,j}\eta_{k,j}, \rho\right) \qquad (3)$$

where J_k is the number of frames for topic k, which is unbounded. The mean of the Normal distribution is a linear combination of the ideal points $\{\eta_{k,j}\}$ of all issue k's frames, weighted by how much time legislator a spends on each frame when talking about issue k, i.e., $\psi_{a,k,j} = \frac{N_{a,k,j}}{N_{a,k,\cdot}}$. Here, $N_{a,k,j}$ is the number of tokens authored by a that are assigned to frame j of issue k, and $N_{a,k,\cdot}$ is the marginal count. When $N_{a,k,\cdot} = 0$, which means that legislator a does not talk about issue k, we back off to an uninformed zero mean.

Equation 3 resembles how supervised topic models (SLDA) link topics with a response, in that the response—the issue-specific ideal point $u_{a,k}$—is latent. It is similar to how Gerrish and Blei (2011) use the bill text to regress on the bill's latent polarity x_b and popularity y_b. In this paper, we only use text from congressional speeches for regression, as these can capture how legislators frame specific topics. Incorporating the bill text into the regression is an interesting direction for future work.

4 Inference

Given observed data of (1) votes $\{v_{a,b}\}$ by A legislators on B bills, (2) speeches $\{\boldsymbol{w}_d\}$ from legislators, and (3) bill text $\{\boldsymbol{w}'_b\}$, we estimate the latent variables using stochastic EM. In each iteration, we perform the following steps: (1) sampling issue assignments $\{z'_{b,m}\}$ for bill text tokens, (2) sampling the issue assignments $\{z_{d,n}\}$ and frame assignments $\{t_{d,n}\}$ for speech tokens, (3) sampling the topics at first-level issue nodes $\{\phi_k\}$, (4) sampling the distribution over frames $\{\psi_k\}$ for all issues, (5) optimizing frames' regression parameters $\{\eta_{k,j}\}$ using L-BFGS (Liu and Nocedal, 1989), and (6) updating legislators' ideal points $\{u_{a,k}\}$ and bills' polarity $\{x_b\}$ and popularity $\{y_b\}$ using gradient ascent.

Sampling Issue Assignments for Bill Tokens The probability of assigning a token $w'_{b,m}$ in the bill text to an issue k is

$$p(z'_{b,m} = k \mid \text{rest}) \propto \frac{M_{b,k}^{-b,m} + \alpha}{M_{b,\cdot}^{-b,m} + K\alpha} \cdot \hat{\phi}_{k,w'_{b,m}} \qquad (4)$$

where $M_{b,k}$ denotes the number of tokens in bill text b assigned to issue k. The current estimated probability of word type v given issue k is $\hat{\phi}_{k,v}$ (Equation 7). Marginal counts are denoted by $\cdot$ and the superscript $^{-b,m}$ excludes the assignment for token $w'_{b,m}$ from the corresponding count.

Sampling Frame Assignments in Speeches To sample the assignments for tokens in the speeches, we first sample an issue using

$$p(z_{d,n} = k \mid \text{rest}) \propto \frac{N_{d,k}^{-d,n} + \alpha}{N_{d,\cdot}^{-d,n} + K\alpha} \cdot \hat{\phi}_{k,w_{d,n}} \qquad (5)$$

where $N_{d,k}$ similarly denotes the number of times that tokens in d are assigned to issue k. Given the sampled issue k, we sample the frame as

$$p(t_{d,n} = j \mid z_{d,n} = k, a_d = a, \text{rest}) \propto$$
$$\begin{cases} \mathcal{N}(u_{a,k}; \mu_{a,k,j}, \rho) \cdot \left(\frac{N_{d,k,j}^{-d,n}}{N_{d,k,j}^{-d,n} + \lambda} + \frac{\lambda \cdot \hat{\psi}_{k,j}}{N_{d,k,j}^{-d,n} + \lambda} \right), \\ \mathcal{N}(u_{a,k}; \mu_{a,k,j^{\text{new}}}, \rho) \cdot \frac{\lambda}{N_{d,k,j}^{-d,n} + \lambda} \cdot \hat{\psi}_{k,j^{\text{new}}}, \end{cases} \qquad (6)$$

where $\mu_{a,k,j} = (\sum_{j'=1}^{J_k} \eta_{k,j'} N_{d,k,j'}^{-d,n} + \eta_{k,j})/N_{d,k,\cdot}$ for an existing frame j, and for a newly created frame j^{new}, we have $\mu_{a,k,j^{\text{new}}} = (\sum_{j'=1}^{J_k} \eta_{k,j'} N_{d,k,j'}^{-d,n} + \eta_{k,j^{\text{new}}})/N_{d,k,\cdot}$, where $\eta_{k,j^{\text{new}}}$ is drawn from the Gaussian prior $\mathcal{N}(0, \gamma)$. Here, the estimated global probability of choosing a frame j of issue k is $\hat{\psi}_{k,j}$.

Sampling Issue Topics In the generative process of HIPTM, the topic ϕ_k of issue k (1) generates tokens in the bill text and (2) provides the Dirichlet priors of the issue's frames. Rather than collapsing multinomials and factorizing (Hu and Boyd-Graber, 2012), we follow Ahmed et al. (2013) and sample

$$\hat{\phi}_k \sim \text{Dir}(\boldsymbol{m}_k + \tilde{\boldsymbol{n}}_k + \beta\phi_k^{\star}) \qquad (7)$$

where $\boldsymbol{m}_k \equiv (M_{k,1}, M_{k,2}, \cdots, M_{k,V})$ is the token count vector from the bill text assigned to each issue. The vector $\tilde{\boldsymbol{n}}_k \equiv (\tilde{N}_{k,1}, \tilde{N}_{k,2}, \cdots, \tilde{N}_{k,V})$ denotes the token counts propagated from words assigned to topics that are associated with frames of issue k, approximated using minimal or maximal path assumptions (Cowans, 2006; Wallach, 2008).

Sampling Frame Proportions Following the *direct assignment* method described in Teh et al. (2006), we sample the global frame proportion as

$$\hat{\psi}_k \equiv (\hat{\psi}_{k,1}, \hat{\psi}_{k,2}, \cdots, \hat{\psi}_{k,j^{\text{new}}})$$
$$\sim \text{Dir}(\hat{N}_{\cdot,k,1}, \hat{N}_{\cdot,k,2}, \cdots, \hat{N}_{\cdot,k,J_k}, \lambda_0) \qquad (8)$$

where $\hat{N}_{\cdot,k,j} = \sum_{d=1}^{D} \hat{N}_{d,k,j}$ and $\hat{N}_{d,k,j}$ can be sampled effectively using the Antoniak distribution (Antoniak, 1974).

Optimizing Frame Regression Parameters We update the regression parameters $\boldsymbol{\eta}_k$ of frames under issue k using L-BFGS (Liu and Nocedal, 1989) to optimize $\mathcal{L}(\boldsymbol{\eta}_k)$

$$-\frac{1}{2\rho}\sum_{a=1}^{A}(u_{a,k} - \boldsymbol{\eta}_k^T \hat{\boldsymbol{\psi}}_{a,k}) - \frac{1}{2\gamma}\sum_{j=1}^{J_k}\eta_{k,j}^2 \qquad (9)$$

Updating Ideal Points, Polarity and Popularity We update the multi-dimensional ideal point $\boldsymbol{u}_a$ of each legislator a and the polarity x_b and popularity y_b of each bill b by optimizing the log likelihood using gradient ascent.

5 Data Collection

What makes a Tea Partier? To address that question, we use *key votes* identified by Freedom Works as the most important votes on issues of economic freedom. Led by former House Majority Leader Dick Armey (R-TX), Freedom Works is a conservative non-profit organization which promotes "Lower Taxes, Less Government, More Freedom".[6] Karpowitz et al. (2011) report that Freedom Works endorsements are more effective than other Tea Party organizations at getting out votes for Republican candidates in the 2010 midterms.

For the 112th Congress, Freedom Works selected 60 key votes, 40 in 2011 and 20 in 2012. We are interested in ideal points with respect to the Tea Party movement, i.e., on the anti-pro Tea Party dimension: whether a legislator agrees with Freedom Works on a bill. More specifically, we assign $v_{a,b}$ to be 1 if legislator a agrees with Freedom Works on bill b, and 0 otherwise. In addition to the votes, we obtained the bill text with labels from the Congressional Bills Project[7] and the congressional speeches from GovTrack.[8] In total, we have 240 Republicans, 60 who self-identify with the Tea Party Caucus, and 13,856 votes.

6 Predicting Tea Party Membership

To quantitatively evaluate the effectiveness of HIPTM in capturing "Tea Partiness", we predict Tea Party Caucus membership of legislators given their votes and text. This examines (1) how effective the baseline features extracted from the votes and text are in predicting the Caucus membership, and (2) how much prediction improves using features extracted from HIPTM. For baselines, we consider simple feature sets where each legislator is represented by their speeches as either (1) a TF-IDF vector (Salton, 1968), (2) a normalized TF-IDF vector, or (3) a binary vector containing their votes.

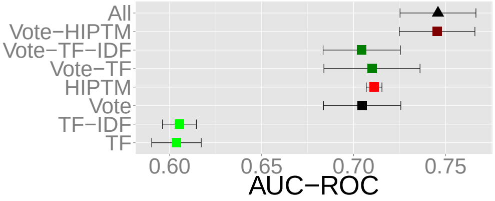

Figure 2: Tea Party Caucus membership prediction results over five folds using AUC-ROC (higher is better, random baseline achieves 0.5). The features extracted from our model are estimated using both the votes and the text.

Our dataset for binary prediction comprises a set of 60 Republican representatives who self-identify as Tea Party Caucus members and 180 who do not. These are divided using 5-fold cross-validation with stratified sampling, which preserves the ratio of the two classes in both the training and test sets. We report performance using AUC-ROC (Lusted, 1971) using SVM^{light} (Joachims, 1999).[9] After preprocessing, our vocabulary contains 5,349 unique word types.

Membership from Votes and Text. First, given the votes and text of all the legislators, we run HIPTM for 1,000 iterations with a burn-in period of 500 iterations. After burning in, we keep the sampled state of the model after every fifty iterations. The feature values are obtained by averaging over the ten stored models as suggested in Nguyen et al. (2014). Each legislator a is represented by a vector concatenating:

- K-dimensional ideal point vector estimated from both votes and text $u_{a,k}$
- K-dimensional vector, estimating the ideal point using only text $\boldsymbol{\eta}_k^T \hat{\boldsymbol{\psi}}_{a,k}$
- B probabilities estimating a's votes on B bills $\Phi(x_b \sum_{k=1}^{K} \hat{\vartheta}_{b,k} u_{a,k} + y_b)$

Figure 2 shows AUC-ROC results for our feature sets. VOTE-based features clearly outperform text-based features like TF and TF-IDF. Combining VOTE with either TF or TF-IDF does not improve the prediction performance much (i.e., VOTE-TF and VOTE-TF-IDF). Features extracted from our

[6] http://congress.freedomworks.org/

[7] http://congressionalbills.org/

[8] https://www.govtrack.us/data/us/112/

[9] We use the default settings of SVM^{light}, except that we set the cost-factor equal to the ratio between the number of negative examples (i.e., number of non-Tea Party Caucus members) and the number of positive examples (i.e., number of Tea Party Caucus members).

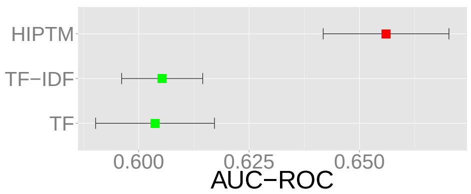

Figure 3: Tea Party Caucus membership prediction results over five folds using AUC-ROC (higher is better, random baseline achieves 0.5). The features extracted from our model for unseen legislators are estimated using their text only.

model, HIPTM, also outperform TF and TF-IDF significantly, but only slightly better than VOTE. However, HIPTM and VOTE together significantly outperform VOTE alone.

Membership Prediction from Text Only. The results in Figure 2 require both votes and legislators' language. This is limiting, since it permits predictions of "Tea Partiness" only for people with an established congressional voting record. A potentially more interesting and practical task is prediction based on language alone.

Thus, we first run our inference algorithm on the training data, which includes both votes and text. After training, using multiple models, we sample the issue and frame assignments for each token of the text authored by test lawmakers. Since the votes are not available, HIPTM's extracted features here only consist of (1) the K-dimensional vector $\boldsymbol{\eta}_k^T \hat{\boldsymbol{\psi}}_{a,k}$ estimating legislators' ideal point using text alone, and (2) the B probabilities $\Phi(x_b \sum_{k=1}^{K} \hat{\vartheta}_{b,k} u_{a,k} + y_b)$ estimating the votes.

Figure 3 compares this approach with the two baselines capable of using text alone, TF and TF-IDF. Since HIPTM can no longer access the votes in the test data, its performance drops significantly compared with VOTE. However, it still quite strongly outperforms the two text-based baselines, showing that jointly modeling the voting behavior improves the text-based elements of the model.

7 How the Tea Party Votes

In this section, we examine legislators' ideal points. We first expose Tea Party-specific ideal points by examining one-dimensional ideal points and then move on to the issue-specific ideal points that HIPTM enables.

7.1 One-dimensional Ideal Points

First, as a baseline, we estimate the one-dimensional ideal points of the legislators in our dataset.[10] Figure 4 shows the box plots of estimated Tea Party ideal points for both members and non-members.[11] The Tea Party ideal points correlate with DW-NOMINATE ($\rho = 0.91$), and the median ideal point of Tea Party Caucus members is higher than non-members. This confirms that Tea Partiers are more conservative than other Republicans (Williamson et al., 2011; Karpowitz et al., 2011; Gervais and Morris, 2012; Gervais and Morris, 2014).

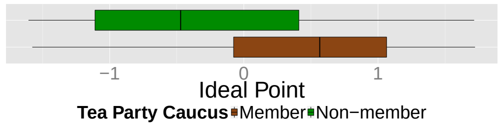

Figure 4: Box plots of the one-dimensional Tea Party ideal points, estimated as a baseline in Section 7.1, for members and non-members of the Tea Party Caucus among Republican Representatives in the 112th U.S. House. The median of members' ideal points is significantly higher than that of non-members'.

Divergences involving these ideal points help demonstrate the face validity of our approach. For example, the model gives Jeff Flake (R-AZ) the second highest ideal point; he only disagrees with Freedom Works position on one of 60 Freedom Works key votes, but he is not a member of the Tea Party Caucus. Another example is Justin Amash (R-MI), who founded and is the Chairman of the Liberty Caucus. Its members are conservative and libertarian Republicans, and Amash has agreed with Freedom Works on every single key vote selected by Freedom Works since 2011.

Conversely, some self-identified Tea Partiers often disagree with Freedom Works and thus have relatively low ideal points. For example, Rodney Alexander (R-LA) only agrees with Freedom Works 48% of the time, and was a Democrat before 2004. Alexander and Ander Crenshaw (R-FL, 50% agreement) are categorized as "Green Tea" by Gervais and Morris (2014), i.e. Republican legislators who are "associated with the Tea Party on their own initiative" but lack support from Tea Party organizations.

[10] We use gradient ascent to optimize the likelihood of votes whose probabilities are defined in Equation 1. We also put a Gaussian prior $\mathcal{N}(0, \sigma)$ on u_a, x_b, and y_b.

[11] Estimated ideal point signs might be flipped, as $u_a x_b = (-u_a)(-x_b)$, which makes no difference in Equation 1. To ensure that higher ideal points are "pro-Tea Party", we first sort the legislators according to the fraction of votes for which they agree with Freedom Works and initialize the ideal points of the top and bottom five legislators with +3σ and -3σ, where σ is the variance of u_a's Gaussian prior.

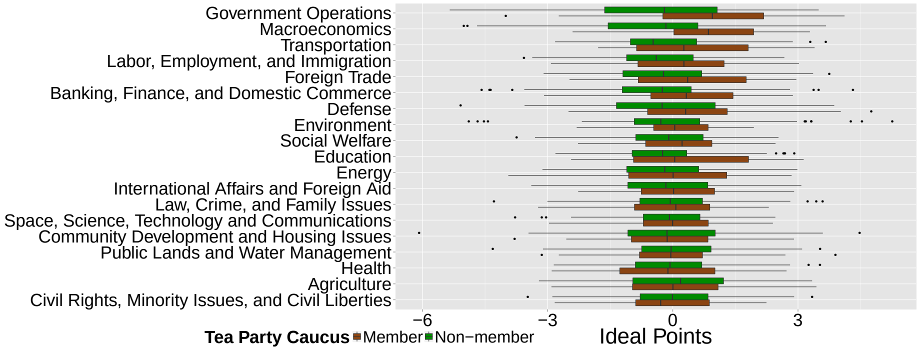

Figure 5: Box plots of ideal points dimensions, each corresponding to a major topic in the Policy Agendas Topics Codebook estimated by our model. On most issues the ideal point distributions over the two Republican groups (member vs. non-member of the Tea Party Caucus) overlap. The most polarized issues are Government Operations and Macroeconomics, which align well with the agenda of the Tea Party movement supporting small government and lower taxes.

7.2 Multi-dimensional Ideal Points

While it is interesting to compare holistic measures of Tea Partiness, it doesn't reveal *how* legislators conform or deviate from what defines a mainstream Tea Partier. In this section, HIPTM reveals how *issue-specific* ideal points of the two groups of Republican representatives differ.

Figure 5 shows estimated ideal points for each policy agenda issue, sorted by the difference between the median of the two groups' ideal points. On most issues, the ideal point distributions of the two Republican groups are nigh identical.

On several issues, though, the ideal point distributions of the two groups of legislators diverge. In the remainder of this section, we consider the Government Operation, Macroeconomics, and Transportation topics, and look at why HIPTM estimates these issues as the most polarized.

Government operations Tea Partiers differ from their Republican colleagues on reducing government spending on the Economic Development Administration, the Energy Efficiency and Renewable Energy Program and Fossil Fuel Research and Development. More specifically, for example, on the key vote *to eliminate the Energy Efficiency and Renewable Energy Program*, nearly 80% (41 out of 53) of Tea Partiers vote "Yea" (with Freedom Works) but only 43% of non-Tea Partiers agree.

Macroeconomics Our model estimates Macroeconomics policies as being the second most polarizing topic for House Republicans, which is consistent with the emphasis that the Tea Party places on issues like a balanced budget and reduced federal spending. Indeed, we see that Tea Party Republicans have distinct preferences on these types of issues as compared to more mainstream Republican legislators. An illustration of this polarization can be seen in the intra-party fight over the budget. Roll call vote 275 in 2011 and roll call vote 149 in 2012 both would have replaced Paul Ryan's budget (the "establishment" Republican budget) with the Republican Study Committee's (RSC) "Back to Basics" budget that would cut spending more aggressively and balance the budget in a decade. In 2011, non-Tea Party Republicans were evenly split in their budget preferences, but three quarters of the Tea Party Caucus supported it, which illustrates the difference between the two factions of the Republican party. Similarly, in 2012, more than 80% of Tea Partiers voted for the the RSC budget, but fewer than half of non-Tea Party Republicans did. Other polarizing votes in the Macroeconomics topic include votes to raise the debt ceiling and to avert the "fiscal cliff". In these cases, support for these votes was 25 percentage points higher among Tea Partiers than non-Tea Party Republicans, which again illustrates their distinct policy preferences.

Transportation Transportation is the third most polarized issue estimated by our model, with two key votes focusing on federal spending on transportation that illustrate some polarization, but also some shared preferences among Republicans. Consistent with the Tea Party's emphasis on reducing government spending, Tea Party Republicans voted differently from their non-Tea Party colleagues on these issues. The first key vote, roll call vote 378 in 2012, caps highway spending at the amount taken in by the gas tax. More than half of Tea Party Caucus members (32 out of 55) voted in favor, while non-members voted against it by a greater than 2:1 margin (122 of 172). Conversely, the second key vote (roll call vote 451 in 2012) authorizes fed-

Figure 6: Framing of Macroeconomics (top) and Health (bottom) among House Republicans, 2011-2012. Higher ideal point values are associated with the Tea Party.

eral highway spending at a level that far exceeds its revenue from the gas tax, which was opposed by Freedom Works. This measure was broadly popular with Republicans regardless of Tea Party affiliation and a majority of both Tea Partiers and non-Tea Partiers opposed it.

8 How the Tea Party Talks

Looking at HIPTM's induced topic hierarchy, using labeled data to create informative priors produces highly interpretable topics at the agenda-issue level; e.g., see the first-level nodes in Figure 6, which capture key issue-level debates. For example, one major event during the 112th Congress was the 2011 debt-ceiling crisis, which dominates discussions in Macroeconomics. Similarly, Defense is dominated by withdrawing U.S. troops from Iraq.

Turning to framing, recall that second-level nodes of the hierarchy capture issue-specific frames of parent issues, each one associated with a frame-specific ideal point. To analyze intra-Republican polarization, we first compute, for each issue k, the *span* of ideal points the frames associated with k, i.e., the difference between the maximum and the minimum ideal points for frames under that issue.[12] We then consider several issues with a large span, i.e. whose frames are highly polarized.

Macroeconomics. The HIPTM subtree for Macroeconomics, in Figure 6 (top), foregrounds Republican polarization related to budget issues. The most Tea Party oriented frame node, M3, focuses on criticizing government overspending, a recurring Tea Party theme.[13] In contrast, Frame M1, least oriented toward the Tea Party, focuses on the downsides of a government shutdown, highlighting establishment Republican concerns about being held responsible for the political and economic consequences.

Health. Healthcare was a central issue during the 112th Congress, particularly the Affordable Care Act (Obamacare). Although all Republicans voted to repeal Obamacare, Figure 6 (bottom) highlights intra-party differences in framing the issue. Frame H1 leans strongest toward the establishment Republican end of the spectrum, and frames opposition in terms of the implementation of health care exchanges and the mandatory costs of the program. In contrast, H3 captures the more strident Tea Party framing of Obamacare as an unconstitutional government takeover. More neutral from an intra-party perspective, Frame H2 emphasizes Medicare, Medicaid, and the role of health care professionals within these systems.[14]

Labor, Employment and Immigration. The discussion of this issue illustrates how HIPTM sometimes captures frames that are distinct from Tea Partiness, *per se*. For example, it discovered a strongly Tea Party oriented frame that focused on "union, south carolina, nlrb, boeing". On inspection, this frame reflects a controversy in which the National Labor Relations Board accused airline manufacturer Boeing of violating Federal labor law by transferring production to a non-union facility in South Carolina "for discriminatory reasons",[15] and surfaces mainly in speeches by four legislators from South Carolina, three of whom are from the Tea Party Caucus. This second-level topic illustrates a limitation of HIPTM; it does not formally distinguish frames from other kinds of subtopics. We observe that modeling polarization on other kinds of sub-issues is nonetheless valuable: here it highlights a geographic locus of conflict involv-

[12] The frame proportions Dirichlet process ψ_k creates many frames with one or two observations (Miller and Harrison, 2013). We ignore those with posterior probability $\psi_{k,j} < 0.1$.

[13] E.g., Scott Garrett (R-NJ): "We will not compromise on our principles; our principles of defending the Constitution and defending Americans and making sure that our posterity does not have this excessive debt on it."

[14] This does not mean that discussions using this frame lacked combative or partisan elements. For example, Glenn Thompson (R-PA) argues that "on the Democratic side, they're just willing to pull the plug and let [Medicare] die".

Ideal Point Distributions		Not	Polarized
Distribution of Issue Frames	Not	Civil Rights, Minority Issues, Civil Liberties	Banking and Finance; Transportation
	Polarized	Health; Public Lands and Water Management	Macroeconomics; Government Operations

Table 2: Examples of agenda issues classified by polarization of ideal points and issue frames within the Republican party.

ing South Carolina, where many representatives are Tea Party Caucus members. This may provide insight into how geography shapes Tea Party membership (Gervais and Morris, 2012).

9 Latent and Visible Disagreement

Our analyses suggest a novel framework for understanding the political and policymaking implications of the Tea Party in the 112th Congress, illustrated in Table 2. Each issue can be characterized by two features: (1) the degree to which ideal points among Republican legislators are polarized, and (2) the degree to which the frames used are polarized. From these two assessments, we can organize all policy issues into four categories that have meaningful implications for congressional politics and policy outcomes. At upper left we will find issues where HIPTM indicates low intra-party polarization between Tea Party and non-Tea Party, and all Republicans tend to frame the issue in similar ways; e.g., Civil Rights, Minority Issues, and Civil Liberties. In such cases, we expect cooperation among Republicans regardless of Tea Party status, therefore a greater likelihood of bill passage in a majority-Republican House. In stark contrast, issues at lower right involve polarized ideal points and polarized framing, e.g., the budget crisis, where many establishment Republicans balked at a government shutdown but hard-line Tea Party legislators did not. These issues pose the greatest challenge to Republican party leaders.

Between these extremes are the issues in which *either* Republicans' ideal points *or* their policy frames are polarized. Our model suggests that on issues at upper right, with similar framing, the Tea Party and establishment Republicans will *appear* to be in sync, and therefore it may seem to voters that legislative progress is likely, but the underlying issue polarization will make it hard to find policy common ground, potentially increasing public frustration. Last, at lower left are issues where Republicans generally share similar ideal points and vote similarly, but frame the issue in distinct ways, e.g., Obamacare. Here legislative success may come despite the appearance that Republican factions are talking past each other, because the distribution of their ideal points on the policy is actually quite similar. Put differently, Republicans share policy goals on issues in this quadrant even if they frame those preferences differently, and this underlying agreement on the ideal point may allow Republicans to reach consensus even when the political rhetoric suggests otherwise.

10 Conclusion

We introduce HIPTM, which integrates hierarchical topic modeling with multi-dimensional ideal points to jointly model voting behavior, the text content of bills, and the language used by legislators. HIPTM is more effective than previous methods on the task of predicting membership in the Tea Party Caucus. This improvement is especially consequential as the formal organization of the Tea Party Caucus is now defunct in the House, yet Tea Party legislators remain both numerous and influential in Congress. In addition, unlike previous ideal-point methods, HIPTM makes it possible to make predictions for members of Congress who have not yet established a voting record. More intriguingly, this also suggests the possibility of assessing the "Tea Partiness" of candidates (or, anyone else, e.g., media outlets) based on language.

It is political conventional wisdom that the influx of Tea Party legislators in the 112th Congress complicated the task of governance and policymaking for Republican leaders. By looking at issue-level ideal points and issue-specific framing using our model, we begin to address the complexity of this relationship, finding the model successful both in establishing face validity and in suggesting novel insights into the dynamics of a Republican Congress. In future work, we plan to pursue the new framework suggested by our analyses, investigating the interaction of issue polarization and framing-based polarization. With the help of these new tools, we aim to both understand and predict substantive policy areas in which the Tea Party is likely to be most successful working with the Republican party, and, conversely, to flag ahead of time policy areas in which we can expect to see legislative gridlock and grandstanding.

KB-LDA: Jointly Learning a Knowledge Base of Hierarchy, Relations, and Facts

Abstract

Many existing knowledge bases (KBs), including Freebase, Yago, and NELL, rely on a fixed ontology, given as an input to the system, which defines the data to be cataloged in the KB, i.e., a hierarchy of categories and relations between them. The system then extracts facts that match the predefined ontology. We propose an unsupervised model that jointly learns a latent ontological structure of an input corpus, and identifies facts from the corpus that match the learned structure. Our approach combines mixed membership stochastic block models and topic models to infer a structure by jointly modeling text, a latent concept hierarchy, and latent semantic relationships among the entities mentioned in the text. As a case study, we apply the model to a corpus of Web documents from the software domain, and evaluate the accuracy of the various components of the learned ontology.

1 Introduction

Knowledge base (KB) construction methods can be broadly categorized along several dimensions. One dimension is ontology-guided construction, where the list of categories and relations that define the schema of the KB are explicit, versus open IE methods, where they are not. Another dimension is the type of relations and types included in the KB: some KBs, like WordNet, are hierarchical, in that they contain mainly concept types, supertypes and instances, while other KBs contain many types of relationships between concepts. Hierarchical knowledge can be learned by methods including distributional clustering (Pereira et al., 1993), as well as Hearst patterns (Hearst, 1992) and similar techniques (Snow et al., 2006). Reverb (Fader et al., 2011) and TextRunner (Yates et al., 2007) are open methods for learning multi-relation KBs. Finally, NELL (Carlson et al., 2010; Mitchell et al., 2015), FreeBase (Google, 2011) and Yago (Suchanek et al., 2007; Hoffart et al., 2013) are ontology-guided methods for extracting KBs containing both hierarchies and relations.

One advantage of ontology-guided methods is that the extracted knowledge is easier to reason with. An advantage of open IE methods is that ontologies may be incomplete, and are expensive to construct for a new domain. Ontology design involves assembling a set of categories, organized in a meaningful hierarchical structure, often providing seeds, i.e., representative examples for each category, and finally, defining inter-category relations. This process is often done manually (Carlson et al., 2010) leading to a rigid set of categories. Redesigning a new ontology for a specialized domain represents an additional challenge as it requires extensive knowledge of the domain.

In this paper, we propose an unsupervised model that learns a latent hierarchical structure of categories from an input corpus, learns latent semantic relations between categories, and also identifies facts from the corpus that match the learned structure. In other words, the model learns both the schema for a KB, and a set of facts that are related to that schema, thus combining the processes of KB population and ontology construction. The intent is to build systems that extract facts which can be interpreted relative to a meaningful ontology without requiring the effort of manual ontology construction.

The input to the learning method is a corpus of documents, plus two sets of resources extracted from the same corpus: a set of hypernym-hyponym pairs (e.g., "animal", "horse") extracted using Hearst patterns, and a set of subject-verb-object triples (e.g., "horse", "eats", "hay") extracted from parsed sentences. These resources are analogous to the output of open IE systems for

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1449–1459,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

hierarchies and relations, and as we demonstrate, our method can be used to highlight domain-specific data from open IE repositories.

Our approach combines mixed membership stochastic block models and topic models to infer a structure by jointly modeling text documents, and links that indicate hierarchy and relation among the entities mentioned in the text. Joint modeling allows information on topics of nouns (referred to as *instances*) and verbs (referred to as *relations*) to be shared between text documents and an ontological structure, resulting in a set of compelling topics. This model offers a complete solution for KB construction based on an input corpus, and we therefore name it *KB-LDA*.

We additionally propose a method for recovering meaningful names for concepts in the learned hierarchy. These are equivalent to category names in other KBs, however, following our method we extract from the data a set of potential alternative concepts describing each category, including probabilities for their strength of association.

To show the effectiveness of our method, we apply the model to a dataset of Web based documents from the software domain, and learn a software KB. This is an example of a specialized domain in which, to our knowledge, no broad-coverage ontology exists. We evaluate the model on the induced categories, relations, and facts, and we compare the proposed categories with an independent set of human-provided labels for documents. Finally, we use KB-LDA to retrieve domain-specific relations from an open IE resource. We provide the learned software KB as supplemental material.

2 KB-LDA

Modeling latent sets of entities from observed interactions among them is a well researched task, often encountered in social network analysis for the purpose of identifying specialized communities in the network. Mixed Membership Stochastic Blockmodels (Airoldi et al., 2009; Parkkinen et al., 2009) model entities as graph nodes with pairwise relations drawn from latent blocks with mixed membership. A related approach is taken by topic models such as LDA (Latent Dirichlet Allocation; (Blei et al., 2003)), which model documents as generated by a mixture of latent topics, and words in the documents as generated by topic-specific word distributions. The KB-LDA model combines the two approaches. It models links between tuples of two or three entities using stochastic block models, and these are additionally influenced by latent topic assignments of the entities in a document corpus.

$\boldsymbol{\pi_O}$ – multinomial over ontology topic pairs, with Dirichlet prior α_O

$\boldsymbol{\pi_R}$ – multinomial over relation topic tuples, with Dirichlet prior α_R

$\boldsymbol{\theta_d}$ – topic multinomial for document d, with Dirichlet prior α_D

$\boldsymbol{\sigma_k}$ – multinomial over instances for topic k, with Dirichlet prior γ_I

$\boldsymbol{\delta_{k'}}$ – multinomial over relations for topic k', with Dirichlet prior γ_R

$\mathrm{CI}_i = \langle C_i, I_i \rangle$ – i-th ontological assignment pair

$\mathrm{SVO}_j = \langle S_j, O_j, V_j \rangle$ – j-th relation assignment tuple

$\boldsymbol{z_i^{CI}} = \langle z_{C_i}, z_{I_i} \rangle$ – topic pair chosen for example $\langle C_i, I_i \rangle$

$\boldsymbol{z_j^{SVO}} = \langle z_{S_j}, z_{O_j}, z_{V_j} \rangle$ – topic tuple chosen for example $\langle S_j, O_j, V_j \rangle$

$\boldsymbol{z_{E_1}^D}, \boldsymbol{z_{E_2}^D}$ – topic chosen for instance entity E_1, or relation entity E_2, respectively, in a document

$\boldsymbol{n_{z,i}^I}$ – number of times instance i is observed under topic z (in either z^D, z^{CI} or z^{SVO})

$\boldsymbol{n_{z,r}^R}$ – number of times relation r is observed under topic z (in either z^D or z^{SVO})

$\boldsymbol{n_{\langle z_c, z_i \rangle}^O}$ – count of ontological pairs assigned the topic pair $\langle z_c, z_i \rangle$ (in z^{CI})

$\boldsymbol{n_{\langle z_s, z_o, z_v \rangle}^R}$ – count of relation tuples assigned the topic tuple $\langle z_s, z_o, z_v \rangle$ (in z^{SVO})

Table 1: KB-LDA notation.

In the KB-LDA model, shown as a plate diagram in Figure 1 with notation in Table 1, information is shared between three components, through common latent topics over noun and verb entities. The *Ontology* component (upper right) models hierarchical links between Concept-Instance (CI) entity pairs. The *Relations* component (left) models links between Subject-Verb-Object (SVO) entity triples, where the subject and object are nouns and the verb represents a relation between them. Finally, the *Documents* component (lower left) is a link-LDA model (Erosheva et al., 2004) of text documents containing a combination of noun and verb entity types. In this formulation, distributions over noun and verb entities that are related according to hierarchical or relational constraints, are linked with a text model via shared parameters.

In more detail, the *Documents* component provides the context in which noun and verb entities are being used in text. It is modeled as an extension of LDA, viewing documents as sets of "bags of words", where in this case, each bag contains either noun or verb entities. Each entity type has a topic-wise multinomial distribution over the set of entities in the vocabulary of that type.

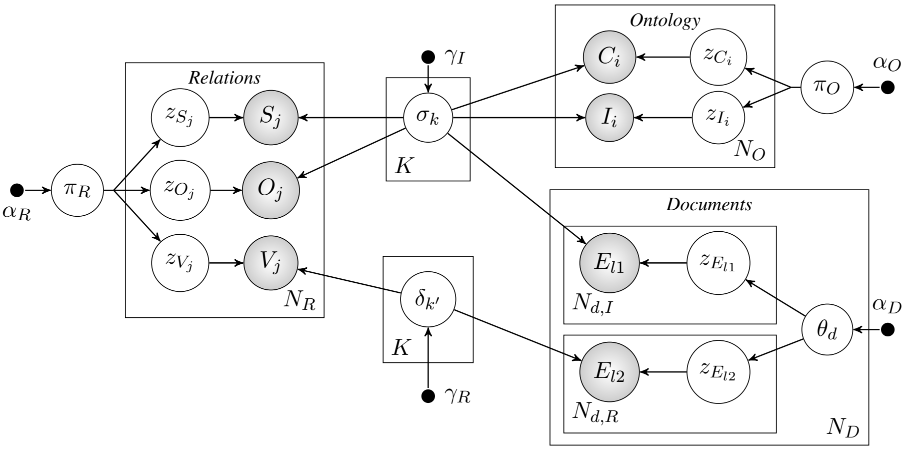

Figure 1: Plate Diagram of KB-LDA.

The *Ontology* component is a generative model representing hierarchal links between pairs of nouns. The examples for this component are extracted using a small collection of Hearst patterns indicating concept-instance or concept-concept links, including, 'X such as Y', and 'X including Y'. For example, the sentence "websites such as StackOverflow" indicates that Stackoverflow is a type of website, leading to the extracted noun pair ⟨websites, StackOverflow⟩. We refer to the examples extracted using these hierarchical patterns as *concept-instance pairs*, and to the individual entities as *instances*.

The pairs have an underlying block structure derived from a sparse block model (Parkkinen et al., 2009). They are generated by topic specific instance distributions conditioned on topic pair edges, which are defined by the multinomial π_O over the Cartesian product of the noun topic set with itself. The individual instances, therefore, have a mixed membership in topics. Note that we allow for a concept and instance to be drawn from different noun topics, defined by σ. For example, we may learn a topic highlighting concept tokens like 'websites', 'platforms', 'applications'. Another topic can highlight instances shared by these concepts, such as, 'stackoverflow', 'google', and 'facebook'. Finally, the observation that the former topic frequently contains concepts of instances from the latter topic, is encoded in the multinomial distribution π_O. From this we infer that the former topic should be placed higher in the induced hierarchy.

Similarly, the *Relations* component represents relational links between a noun subject, a verb and a noun object. The examples for this component are extracted from SVO patterns found in the document corpus, following Talukdar et al. (2012). An extracted example looks like: ⟨websites, execute, javascript⟩. Subject and object topics are drawn from the noun topics (σ), while the verb topics is drawn from the verb topics, defined by δ. The multinomial π_R encodes the interaction of noun and verb topics based on the extracted relational links, and it is defined over the Cartesian product of the noun topic set with itself and with

Let K be the number of target latent topics.

1. **Generate topics:** For topic $k \in 1, \ldots, K$, sample:
   - $\sigma_k \sim$ Dirichlet(γ_I), the per-topic instance distribution
   - $\delta_k \sim$ Dirichlet(γ_R), the per-topic relation distribution
2. **Generate ontology:** Sample $\pi_O \sim$ Dirichlet(α_O), the instance topic pair distribution.
   - For each concept-instance pair CI$_i$, $i \in 1, \ldots, N_O$:
     - Sample topic pair $z_i^{CI} \sim$ Multinomial(π_O)
     - Sample instances $C_i \sim$ Multinomial($\sigma_{z_{C_i}}$), $I_i \sim$ Multinomial($\sigma_{z_{I_i}}$), then CI$_i = \langle C_i, I_i \rangle$
3. **Generate relations:** Sample $\pi_R \sim$ Dirichlet(α_R), the relation topic tuple distribution.
   - For each tuple SVO$_j$, $j \in 1, \ldots, N_R$:
     - Sample topic tuple $z_j^{SVO} \sim$ Multinomial(π_R)
     - Sample instances, $S_j \sim$ Multinomial($\sigma_{z_{S_j}}$), $O_j \sim$ Multinomial($\sigma_{z_{O_j}}$), and sample a relation $V_j \sim$ Multinomial($\delta_{z_{V_j}}$)
4. **Generate documents:** For document $d \in 1, \ldots, D$:
   - Sample $\theta_d \sim$ Dirichlet(α_D), the topic mixing distribution for document d.
   - For every noun entity (E_{l1}) and verb entity (E_{l2}), $l1 \in 1, \ldots, N_{d,I}$, $l2 \in 1, \ldots, N_{d,R}$:
     - Sample topics $z_{E_{l1}}, z_{E_{l2}} \sim$ Multinomial(θ_d)
     - Sample entities $E_{l1} \sim$ Multinomial($\sigma_{z_{E_{l1}}}$) and $E_{l2} \sim$ Multinomial($\delta_{z_{E_{l2}}}$)

Table 2: KB-LDA generative process.

the verb topic set.

The generative process of KB-LDA is described in Table 2. Given the hyperparameters $(\alpha_O, \alpha_R, \alpha_D, \gamma_I, \gamma_R)$, the joint distribution over CI pairs, SVO tuples, documents, topics and topic assignments is given by

$$p(\pi_O, \pi_R, \sigma, \delta, \mathbf{CI}, \boldsymbol{z^{CI}}, \mathbf{SVO}, \boldsymbol{z^{SVO}}, \boldsymbol{\theta}, \mathbf{E}, \boldsymbol{z^{D}} | \\ \alpha_O, \alpha_R, \alpha_D, \gamma_I, \gamma_R) = \\ \prod_{k=1}^{K} \mathrm{Dir}(\sigma_k|\gamma_I) \times \prod_{k'=1}^{K} \mathrm{Dir}(\delta_{k'}|\gamma_R) \times \qquad (1) \\ \mathrm{Dir}(\pi_O|\alpha_O) \prod_{i=1}^{N_O} \pi_O^{\langle z_{C_i}, z_{I_i} \rangle} \sigma_{z_{C_i}}^{C_i} \sigma_{z_{I_i}}^{I_i} \times \\ \mathrm{Dir}(\pi_R|\alpha_R) \prod_{j=1}^{N_R} \pi_R^{\langle z_{S_j}, z_{O_j}, z_{V_j} \rangle} \sigma_{z_{S_j}}^{S_j} \sigma_{z_{O_j}}^{O_j} \delta_{z_{V_j}}^{V_j} \times \\ \prod_{d=1}^{N_D} \mathrm{Dir}(\theta_d|\alpha_D) \prod_{l1=1}^{N_{d,I}} \theta_d^{z^D_{E_{l1}}} \sigma^{E_{l1}}_{z^D_{E_{l1}}} \prod_{l2=1}^{N_{d,R}} \theta_d^{z^D_{E_{l2}}} \delta^{E_{l2}}_{z^D_{E_{l2}}}$$

2.1 Inference in KB-LDA

Exact inference is intractable in the KB-LDA model. We use a collapsed Gibbs sampler (Griffiths and Steyvers, 2004) to perform approximate inference in order to query the topic distributions and assignments. It samples a latent topic pair for a CI pair in the corpus conditioned on the assignments to all other CI pairs, SVO tuples, and document entities, using the following expression, after collapsing π_O:

$$\hat{p}(z_i^{CI}|\mathrm{CI}_i, z_{\neg i}^{CI}, z^{SVO}, z^D, \mathrm{CI}_{\neg i}, \alpha_O, \gamma_I) \qquad (2) \\ \propto \left(n^{O \neg i}_{z_i^{CI}} + \alpha_O \right) \times \\ \frac{(n^{I\neg i}_{z_{C_i}, C_i} + \gamma_I)(n^{I\neg i}_{z_{I_i}, I_i} + \gamma_I)}{(\sum\limits_C n^{I\neg i}_{z_{C_i}, C} + T_I\gamma_I)(\sum\limits_I n^{I\neg i}_{z_{I_i}, I} + T_I\gamma_I)}$$

where counts of observations from the training set are noted by n (see Table 1), and T_I is the number of instance entities (size of noun vocabulary).

We similarly sample topics for each SVO tuple conditioned on the assignments to all other tuples, CI pairs and document entities, using the following expression, after collapsing π_R:

$$\hat{p}(z_j^{SVO}|\mathrm{SVO}_j, z_{\neg j}^{SVO}, z^{CI}, z^D, \mathrm{SVO}_{\neg j}, \alpha_R, \gamma_I, \gamma_R) \qquad (3) \\ \propto \left(n^{R\neg j}_{z_j^{SVO}} + \alpha_R \right) \times \\ \frac{(n^{I\neg j}_{z_{S_j}, S_j} + \gamma_I)(n^{I\neg j}_{z_{O_j}, O_j} + \gamma_I)(n^{R\neg j}_{z_{V_j}, V_j} + \gamma_R)}{(\sum\limits_I n^{I\neg j}_{z_{S_i}, I} + T_I\gamma_I)(\sum\limits_I n^{I\neg j}_{z_{O_i}, I} + T_I\gamma_I)(\sum\limits_V n^{R\neg j}_{z_{V_j}, V} + T_R\gamma_R)}$$

We sample a latent topic for an entity mention in a document from the text corpus conditioned on the assignments to all other entity mentions after collapsing θ_d. The following expression shows topic sampling for a noun entity in a document:

$$\hat{p}(z_{E_{l1}}|E, \mathrm{CI}, \mathrm{SVO}, z^D, z^{CI}, z^{SVO}, \alpha_D, \gamma_I) \quad (4) \\ \propto (n^{\neg l1}_{d,z} + \alpha_D) \frac{n^{I\neg l1}_{z_{E_{l1}}, E_{l1}} + \gamma_I}{\sum_{E'_{l1}} n^{I\neg l1}_{z_{E_{l1}}, E'_{l1}} + T_I\gamma_I}$$

The per-topic multinomial parameters and topic distributions of CI pairs, SVO tuples and documents can be recovered with MLE estimates using their observation counts:

$$\hat{\sigma}_k^I = \frac{n^I_{k,I} + \gamma_I}{\sum_{I'} n^I_{k,I'} + T_I\gamma_I}, \hat{\delta}_k^R = \frac{n^R_{k,R} + \gamma_R}{\sum_{R'} n^R_{k,R'} + T_R\gamma_R}$$

$$\hat{\theta}_d^z = \frac{n_{z,d} + \alpha_D}{\sum_{z'} n_{z',d} + K\alpha_D}$$

$$\hat{\pi}_O^{\langle z_C, z_I \rangle} = \frac{n^O_{\langle z_C, z_I \rangle} + \alpha_O}{\sum\limits_{z'_C, z'_I} n^O_{\langle z'_C, z'_I \rangle} + K^2 \cdot \alpha_O}$$

$$\hat{\pi}_R^{\langle z_S, z_O, z_V \rangle} = \frac{n^R_{\langle z_S, z_O, z_V \rangle} + \alpha_R}{\sum\limits_{z'_S, z'_O, z'_V} n^R_{\langle z'_S, z'_O, z'_V \rangle} + K^3 \cdot \alpha_R}$$

Using the KB-LDA model we can describe the latent topic hierarchy underlying the input corpus. We consider the multinomial of the *Ontology* component, π_O, as an adjacency matrix describing a network where the nodes are instance topics and edges indicate a hypernym-to-hyponym relation. By extracting the maximum spanning tree over this adjacency matrix, we recover a hierarchy over the input data. We recover relations among instance topics by extracting from the Relations multinomial, π_R, the set of most probable tuples of a ⟨subject topic, verb topic, object topic⟩.

Our model is implemented using a fast, parallel approximation of collapsed Gibbs sampling, following Newman et al. (2009). In each sampling iteration, topics are sampled locally on a subset of the training examples. At the end of each iteration, data from worker threads is joined and model parameters are updated with complete information. In the next iteration, thread-local sampling starts with complete topic assignment information from the previous iteration. In each thread, the process can be viewed as a reordering of the input examples, where the examples sampled in that thread are viewed first. It has been shown that parallel approaches considerably speed up iterative inference methods such as collapsed Gibbs sampling, resulting in test data log probabilities indistinguishable from those obtained using serial methods (Porteous et al., 2008; Newman et al., 2009). A parallel approach is especially important when training the KB-LDA model due to the large dimensions of the multinomials of the *Ontology* and *Relations* components (K^2 and K^3, respectively for a model with K topics). We train KB-LDA over 2000 iterations, more than what has traditionally been used for collapsed Gibbs samplers.

2.2 Data-driven discovery of topic concepts

The KB-LDA model described above clusters noun entities into sets of instance topics, and recovers a latent hierarchical structure among these topics. Each instance topic can be described by a multinomial distribution of the underlying nouns. It is often more intuitive, however, to refer to a topic containing a set of high probability nouns by a name, or category, just as traditional ontologies describe hierarchies over categories.

Our model is trained over nouns that originate from concept-instance example pairs (used to train the *Ontology* component). We describe a method for selecting a category name for a topic, based on concepts that best represent high probability nouns of the topic in the concept-instance examples.

We calculate the probability that a concept noun c describes the set of instances I that have been assigned the topic z using

$$\begin{aligned} p(c,z|I) &\propto p(I|c,z) * p(c,z) \\ &= p(I|c,z) * p(z|c) * p(c) \end{aligned} \tag{5}$$

Let $rep(c,z) = \sum_{i:C_i=c} n^I_{z,I_i}$ describe how well concept c represents topic z according to the assignments of instances with concept c to the topic. Then,

$$p(z|c) = \frac{rep(c,z)}{\sum_{z'} rep(c,z')} \tag{6}$$

The concept prior, $p(c)$, is based on the relative weight of instances with concept c in the concept-instance example set, and is an indicator of the generality of a concept:

$$p(c) = \frac{\sum_{i:C_i=c} w_{c,I_i}}{\sum_{c'} \sum_{i:C_i=c'} w_{c',I_i}} \tag{7}$$

where $w_{C,I}$ is the number of occurrences of concept-instance pair $\langle C, I \rangle$ in the corpus.

Finally, $p(I|c,z)$ measures how specific are the topic instances to the concept c,

$$p(I|c,z) = \frac{\sum_{i:I_i \in I, C_i=c} w_{c,I_i}}{\sum_{i:C_i=c} w_{c,I_i}} \Big/ Z \tag{8}$$

where I is the set of training instances assigned with topic z, and Z is a normalizer over all concepts and topics.

Following this method we extract concepts that have a high probability $p(c,z|I)$ with respect to a topic z. These can be thought of as equivalent to the single, fixed, category name provided by traditional KB ontologies; however, here we extract *from the data* a set of potential alternative noun phrases describing each topic, including a probability for the strength of this association.

3 Experimental Evaluation

We evaluate the KB-LDA model on a corpus of 5.5M documents from the software domain; thereby we are using the model to construct a software domain knowledge base. Our evaluation explores the following questions:

- Can KB-LDA learn categories, relations, a hierarchy and topic concepts with high precision?
- How well do KB-LDA topics correspond with human-provided document labels?
- Is KB-LDA useful in extracting facts from existing open IE resources?

3.1 Data

We use data from the Q&A website StackOverflow[1] where users ask and answer technical questions about software development, tools, algorithms, etc'. We extracted 562K concept-instance example pairs from the data, and kept the 17K examples appearing at least twice. Noun phrases in these examples make up our *Instance Dictionary*. Out of 6.8M SVO examples found in the data we keep 37K in which the subject and object are in the Instance Dictionary, and the example appears at least twice in the corpus. The verbs in these SVOs make up our *Relation Dictionary*. Finally, we consider as documents the 5.5M questions from StackOverflow with all their answers.

3.2 Evaluating the learned KB precision

In this section we evaluate the direct output of a model trained with 50 topics: the extracted in-

[1] Data source: https://archive.org/details/stackexchange

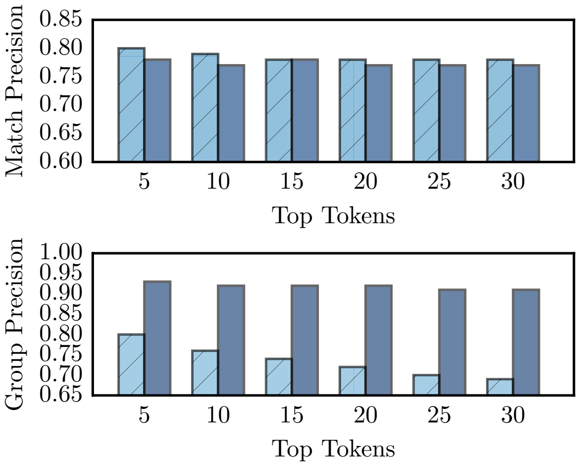

Figure 2: Average *Match* (top) and *Group* (bottom) precision of top tokens of 50 topics learned with KB-LDA, according to expert (dark blue) and non-expert (light blue, stripes) labeling.

stance topics, topic hierarchy, relations among topics and extracted topic concepts. In each of the experiments below, we extract facts based on one of the learned components and evaluate each fact based on annotations from human judges: two experts and three non-expert users, collected using Mechanical Turk, that were pre-tested on a basic familiarity with concepts from the software domain, such as *programming languages, version control systems*, and *databases*.

3.2.1 Precision of Instance Topics

We measure the coherence of instance topics using an approach called *word intrusion* (Chang et al., 2009). We extract the top 30 instance tokens of a topic ranked by the instance topic multinomial σ. We present to workers tokens 1-5,6-10,. . . ,26-30, where each 5 tokens are randomly ordered and augmented with an extra token that is ranked low for the topic, (the intruder). We ask workers to select all tokens that do not belong in the group (and at least one). We define the topic *Match Precision* as the fraction of questions for which the reviewer identified the correct intruder (out of 6 questions per topic), and the topic *Group Precision* as the fraction of correct tokens (those not selected as not belonging in the group). Thus *Match Precision* measures how well labelers understand the topic, and *Group Precision* measures what fraction of words appeared relevant to the topic.

Figure 2 shows the average Match and Group precision over the top tokens of all 50 topics learned with the model, as evaluated by expert and non-expert workers. Both groups find the intruder token in over 75% of questions. In the more subtle task of validating each topic token (Group precision) we see a greater variance among the two labeler groups. This highlights the difficulty of evaluating domain specific facts with non-expert users. Table 3 displays the top 20 instance topics learned with KB-LDA, ranked by expert Group precision.

3.2.2 Precision of Topic Concepts

We assess the precision of the top 5 concept names proposed for instance topics, following the method presented in Section 2.2. Top concepts for a subset of topics are shown in Table 3. For each topic, we present to the user a hypernym-hyponym pattern of the topic based on the top concepts and top instances of the topic. As an example, if the top 5 instances of a topic are *ie, firefox, chrome, buttons, safari* and the top 5 concepts for this topic are *web browsers, web browser, browser, ie, chrome*, the pattern presented to workers is

- [ie, firefox, chrome, buttons, safari] **is a** [web browsers, web browser, browser, ie, chrome]

Workers were asked to match at least 3 instances to a proposed concept name. In addition, the same assessment was applied for each topic using randomly sampled concepts. We present in Table 4 the number and precision of patterns based on extracted concepts (Concepts) and random concepts (Random), that were labeled by 1, 2 or 3 workers, as well as the average results among experts. We achieve nearly 90% precision according to expert labeling, however we do not observe large agreement among non-expert labelers.

3.2.3 Precision of Relations

To assess the precision of the relations learned in the KB-LDA model, we extract the top 100 relations learned according to their probability in the relation multinomial π_R. Relation patterns were presented to workers as sets of the top subject-verb-object tokens of the respective topics in the relation. An example relation is

- Subject words: [user, users, people, customer, client]
- Verb words: [clicks, selects, submits, click, hits]
- Object words: [function, method, class, object, query]

and workers are asked to state whether the pattern indicates a valid relation or not, by checking whether a reasonable number of combinations of subject-verb-object triples extracted from each of the relation groups can produce valid relations.

Top 2 Topic Concepts	Top 10 Topic Tokens
table, key	table, query, database, sql, column, data, tables, mysql, index, columns
properties, css	image, code, images, problem, point, color, data, size, screen, points
credentials, user information	name, images, id, number, text, password, address, strings, files, string
page, content	page, html, code, file, image, javascript, browser, http, jquery, js
orm tools, orm tool	tomcat, hibernate, server, boost, apache, spring, mongodb, framework, nhibernate, png
clients, apps	app, application, http, android, device, phone, code, api, iphone, google
applications, systems	devices, systems, applications, services, platforms, tools, sites, apps, system, service
systems, platforms	google, windows, linux, facebook, git, ant, database, gmail, android, so
limits, limit	memory, time, thread, code, threads, process, file, program, data, object
data, table	query, table, data, list, example, number, results, search, database, rows
type, value	code, function, value, type, pointer, array, memory, compiler, example, string
table, request	data, information, types, properties, details, fields, values, content, resources, attributes
dependencies, jar file	libraries, library, framework, frameworks, formats, format, database, databases, tools, server
type, object	value, focus, place, property, method, reference, interface, effect, pointer, data
kinds, code	languages, language, features, objects, functions, methods, code, operations, structures, types
element, elements	button, form, link, item, *file*, mouse, image, value, option, row
javascript libraries, javascript framework	jquery, mysql, http, json, xml, library, html, sqlite, *asp*, php
process, operating system	server, client, connection, *data*, http, socket, message, request, port, service
folder, files	file, files, directory, folder, path, *code*, name, resources, project, folders
value, array	array, list, value, values, number, string, code, elements, *loop*, object

Table 3: Top 20 instance topics learned with KB-LDA. For each topic we show the top 2 concepts recovered for the topic, and top 10 tokens. In *italics* are words marked as out-of-topic by expert labelers.

Workers	Concepts		Relations		Subsumptions	
	KB-LDA (p)	Random (p)	KB-LDA (p)	Random (p)	KB-LDA (p)	Random (p)
1	48 (0.96)	6 (0.12)	90 (0.9)	69 (0.69)	31 (0.63)	28 (0.57)
2	42 (0.84)	0 (0.0)	63 (0.63)	22 (0.22)	16 (0.33)	9 (0.18)
3	26 (0.52)	0 (0.0)	15 (0.15)	4 (0.05)	3 (0.06)	4 (0.08)
Experts	44 (0.88)	0 (0.0)	70 (0.7)	13 (0.13)	25 (0.51)	4 (0.08)

Table 4: Precision of topic concepts, relations, and subsumptions. For items extracted from the model (KB-LDA), and randomly (Random), we show the number of items marked as correct, and precision in parentheses (p), as labeled by 1, 2, or 3 non-expert workers, and the average precision by experts.

We present in Table 4 the number and precision of patterns based on the top 100 relations (Relations) and 100 random relations (Random), that were labeled by 1, 2 or 3 workers, and the average results among experts. We achieve 80% precision according to experts, and only 18% on random relations. We observe similar agreement among expert and non-expert workers as in the concept evaluation experiment, however we note that random relations prove more confusing for non-experts and more of them are (falsely) labeled as correct.

3.2.4 Precision of Hierarchy

We assess the precision of subsumption relations making up the ontology hierarchy. These are extracted using the maximum spanning tree over the graph represented by the *Ontology* component, π_O (see Section 2.1 for details), resulting in 49 subsumption relations. We compare their quality to that of 49 randomly sampled subsumption relations. Subsumptions are presented to the worker using *is a* patterns, similar to the ones described above for concept evaluation, however in this case, the concept tokens are the top tokens of the hypernym topic. An example subsumption relation is

- [java, python, javascript, lists, ruby] **is a** [languages, language, features, objects, functions]

The results shown in Table 4 indicate a low precision among the extracted subsumption relations. This might be explained by the fact that at the final training iteration (2K) of the model, the perplexity of the *Ontology* component was still improving, while the perplexity of the other model components seemed closer to convergence. It is possible that the low precision observed here indicates that more training iterations are needed to achieve an accurate ontology using KB-LDA.

Topic	string, character, characters, text, line
Tags	regex, string, python, php, ruby
Topic	element, div, css, elements, http
Tags	css, html, jquery, html5, javascript
Topic	table, query, database, sql, column
Tags	sql, mysql, database, performance, php
Topic	jquery, mysql, http, json, xml
Tags	jquery, json, javascript, ruby, string

Table 5: Top tags associated with sample topics.

3.3 Overlap of KB-LDA topics with human-provided labels

We evaluated how well topics from KB-LDA correspond to document labels provided by humans, over a randomly sampled set of 40K documents from our corpus. In StackOverflow, questions (which we consider as documents) can be labeled with predefined tags. Here, we estimate the overlap with the most frequently used tags. First, for topic k, we aggregate tags from documents where $k = \text{argmax}_{k'}\, \theta_d^{k'}$, where θ_d is the document topic distribution. Table 5 shows examples of the top tags associated with sample topics, indicating a good correlation between top topic words and the underlying concepts.

Next, for each tested document $d \in D$, let W_d be the top 30 words of the most probable topic in θ_d, and T_d the set of human provided document tags. We consider the following metrics:

$$\text{Docs-Overlap} = \frac{\sum_d^D \mathbb{1}_{\{\exists t \in T_d : t \in W_d\}}}{|D|}$$

measures the ratio of documents for which at least one tag overlaps with a top topic word. The average ratio of overlapping tags per document is

$$\text{Tag-Overlap} = \frac{1}{|D|} \sum_d^D \frac{|t : t \in T_d \wedge t \in W_d|}{|T_d|}$$

As a baseline, we measure similar overlap metrics using the 30 most frequent instance tokens in the document corpus. The results in Table 6 indicate an overlap of nearly half of the 20, 50, 100, and 500 most frequent tags with top topic tokens – significantly higher than the overlap with frequent token. Our evaluation is based on the subset of tags found in the instance dictionary of KB-LDA.

Top	Found in	KB-LDA		Frequent Tokens	
Tags	Dictionary	Docs	Tag	Docs	Tag
20	14	0.45	0.42	0.21	0.16
50	36	0.48	0.42	0.20	0.14
100	72	0.45	0.38	0.20	0.13
500	322	0.44	0.33	0.18	0.10

Table 6: Docs and Tag overlap of human-provided tags with KB-LDA topics, and frequent tokens.

Top 10 ranked triples: ⟨server, not found, error⟩, ⟨user, can access, file⟩, ⟨method, not found, error⟩, ⟨user, can change, password⟩, ⟨page, not found, error⟩, ⟨user, can upload, videos⟩, ⟨compiler, will generate, error⟩, ⟨users, can upload, files⟩, ⟨users, can upload, files⟩, ⟨object, not found, error⟩
Bottom 10 ranked triples: ⟨france, will visit, germany⟩, ⟨utilities, may include, heat⟩, ⟨iran, has had, russia⟩, ⟨russia, can stop, germany⟩, ⟨macs, do not support, windows media player⟩, ⟨cell phones, do not make, phone calls⟩, ⟨houses, have made, equipment⟩, ⟨guests, will find, restaurants⟩, ⟨guests, can request, bbq⟩, ⟨inspectors, do not make, appointments⟩

Table 7: Top and bottom ReVerb software triples ranked with KB-LDA.

3.4 Extracting facts from an open IE resource

We use KB-LDA to extract domain specific triples from an existing open IE KB, the 15M relations extracted using ReVerb (Fader et al., 2011) from ClueWeb09. By extracting the relations in which the subject, verb and object noun phrases are included in the KB-LDA dictionary, we are left with under 5K triples, indicating the low coverage of software related triples using open domain extraction, in comparison with the 37K triples extracted from StackOverflow and given as an input to KB-LDA.

Due to word polysemy, many of the 5K extracted triples are themselves not specific to the domain. This suggests a hybrid approach in which KB-LDA is used to rank open IE triples for relevance to a domain. We ranked the 5K open triples by the probability of the triple given a trained KB-LDA model: $p(s, v, o) = \sum_{k_s}^{K} \sum_{k_v}^{K} \sum_{k_o}^{K} \pi_R^{\langle k_s, k_v, k_o \rangle} \sigma_{k_s}^{s} \sigma_{k_o}^{o} \delta_{k_v}^{v}$. Table 7 shows the top and bottom 10 triples according to this ranking, which suggests that the triples ranked higher by KB-LDA are more relevant to the software domain.

We compare the ranking based on KB-LDA to

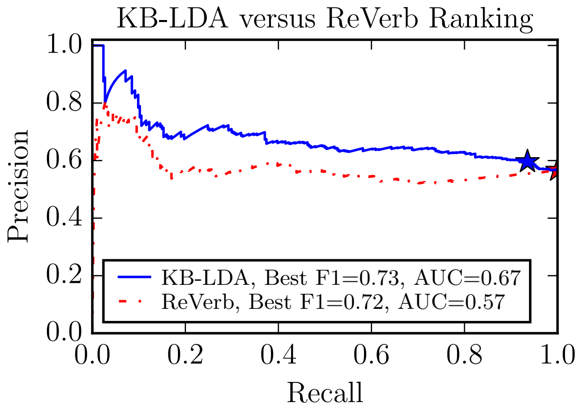

Figure 3: Precision-recall curves of rankers of open IE triples by software relevance, based on KB-LDA probabilities (blue), and ReVerb confidence (red). A star is pointing the highest F1.

a ranking using a confidence score for the triple as assigned by ReVerb. We manually labeled 500 of the triples according to their relevance to the software domain, and measured the precision and recall of the two rankings at any cutoff threshold. Figure 3 shows precision-recall curves for the two rankings, demonstrating that the ranking using probabilities based on KB-LDA leads to a more accurate detection of domain-relevant triples (with AUC of 0.67 for KB-LDA versus 0.57 for ReVerb).

4 Related Work

KB-LDA is an extension to LDA and link-LDA (Blei et al., 2003; Erosheva et al., 2004), modeling documents as a mixed membership over entity types with additional annotated metadata, such as links (Nallapati et al., 2008; Chang and Blei, 2009). It is a generalization of Block-LDA (Balasubramanyan and Cohen, 2011), however, KB-LDA models two link components, and the input links have a meaningful semantic correspondence to a KB structure (hierarchical and relational). In a related approach, Dalvi et al. (2012) cluster web table concepts to non-probabilistically create hierarchies with assigned concept names.

Our work is related to latent tensor representation of KBs, aimed at enhancing the ontological structure of existing KBs with relational data in the form of tensor structures. Nickel et al. (2012) factorized the ontology of Yago 2 for relational learning. A related approach was using Neural Tensor Networks to extract new facts from an existing KB (Chen et al., 2013; Socher et al., 2013). In contrast, in KB-LDA, relational data is learned jointly with the model through the *Relations* component.

Statistical language models have recently been adapted for modeling software code and text documents. Most tasks focused on enhancing the software development workflow with code and comment completion (Hindle et al., 2012; Movshovitz-Attias and Cohen, 2013), learning coding conventions (Allamanis et al., 2014), and extracting actionable tasks from software documentation (Treude et al., 2014). In related work, specific semantic relations, coordinate relations, have been extracted for a restricted class of software entities, ones that refer to Java classes (Movshovitz-Attias and Cohen, 2015). KB-LDA extends previous work by reasoning over a large variety of semantic relations among general software entities, as found in a document corpus.

5 Conclusions

We presented a model that jointly learns a latent ontological structure of a corpus augmented by relations, and identifies facts matching the learned structure. The quality of the produced structure was demonstrated through a series of real-world evaluations employing human judges, which measured the semantic coherence of instance topics, relations, topic concepts, and hierarchy. We further validated the semantic meaning of topic concepts, by their correspondence to an independent source of human-provided document tags. The experimental evaluation validates the usefulness of the proposed model for corpus exploration.

The results highlight the benefits of generalizing pattern-based facts (hypernym-hyponym pairs and subject-verb-object tuples), using text documents in a topic model framework. This modular approach offers opportunities to further improve an induced KB structure by posing additional constraints on corpus entities in the form of additional components to the model.

Abstract

Most existing topic models make the *bag-of-words* assumption that words are generated independently, and so ignore potentially useful information about word order. Previous attempts to use *collocations* (short sequences of adjacent words) in topic models have either relied on a pipeline approach, restricted attention to bigrams, or resulted in models whose inference does not scale to large corpora. This paper studies how to simultaneously learn both collocations and their topic assignments. We present an efficient reformulation of the Adaptor Grammar-based topical collocation model (AG-colloc) (Johnson, 2010), and develop a point-wise sampling algorithm for posterior inference in this new formulation. We further improve the efficiency of the sampling algorithm by exploiting sparsity and parallelising inference. Experimental results derived in text classification, information retrieval and human evaluation tasks across a range of datasets show that this reformulation scales to hundreds of thousands of documents while maintaining the good performance of the AG-colloc model.

1 Introduction

Probabilistic topic models like Latent Dirichlet Allocation (LDA) (Blei et al., 2003) are commonly used to study the meaning of text by identifying a set of latent topics from a collection of documents and assigning each word in these documents to one of the latent topics. A document is modelled as a mixture of latent topics, and each topic is a distribution over a finite vocabulary of words. It is common for topic models to treat documents as bags-of-words, ignoring any internal structure. While this simplifies posterior inference, it also ignores the information encoded in, for example, syntactic relationships (Boyd-Graber and Blei, 2009), word order (Wallach, 2006) and the topic structure of documents (Du et al., 2013). Here we are interested in topic models that capture dependencies between adjacent words in a topic dependent way. For example, the phrase "white house" can be interpreted compositionally in a real-estate context, but not in a political context.

Several extensions of LDA have been proposed that assign topics not only to individual words but also to multi-word phrases, which we call *topical collocations*. However, as we will discuss in section 2, most of those extensions either rely on a pre-processing step to identify potential collocations (e.g., bigrams and trigrams) or limit attention to bigram dependencies. We want a model that can jointly learn collocations of arbitrary length and their corresponding topic assignments from a large collection of documents. The AG-colloc model (Johnson, 2010) does exactly this. However, because the model is formulated within the Adaptor Grammar framework (Johnson et al., 2007), the time complexity of its inference algorithm is cubic in the length of each text fragment, and so it is not feasible to apply the AG-colloc model to large collections of text documents.

In this paper we show how to reformulate the AG-colloc model so it is no longer relies on a general Adaptor Grammar inference procedure. The new formulation facilitates more efficient inference by extending ideas developed for Bayesian word segmentation (Goldwater et al., 2009). We adapt a point-wise sampling algorithm from Bayesian word segmentation, which has also been used in Du et al. (2013), to simultaneously sample collocation boundaries and collocation topic assignments. This algorithm retains the good performance of the AG-colloc model in document classification and information retrieval

tasks. By exploiting the sparse structure of both collocation and topic distributions, using techniques inspired by Yao et al. (2009), our new inference algorithm produces a remarkable speedup in running time and allows our reformulation to scale to a large number of documents. This algorithm can also be easily parallelised to take advantage of multiple cores by combining the ideas of the distributed LDA model (Newman et al., 2009). Thus, the contribution of this paper is three-fold: 1) a novel reformulation of the AG-colloc model, 2) an easily parallelisable and fast point-wise sampling algorithm exploiting sparsity and 3) systematic experiments with both qualitative and quantitative analysis.

The structure of the paper is as follows. In Section 2 we briefly discuss prior work on learning topical collocations. We then present our reformulation of the AG-colloc model in Section 3. Section 4 derives a point-wise Gibbs sampler for the model and shows how this sampler can take advantage of sparsity and be parallelised across multiple cores. Experimental results are reported in Section 5. Section 6 concludes this paper and discusses future work.

2 Related Work

There are two main approaches to incorporating topical collocations in LDA: 1) pipeline approaches that use a pre-processing step prior to LDA, and 2) extensions to LDA, which modify the generative process. In this section we discuss prior work that falls into these two categories and their limitations.

Pipeline Approaches (Lau et al., 2013), denoted here by PA, involve two steps. The first step identifies a set of bigrams that are potentially relevant collocations from documents by using simple heuristics for learning collocations, e.g., the Student's t-test method of Banerjee and Pedersen (2003). For each identified bigram "w_1 w_2", a new pseudo word "$\mathrm{w}_1\_\mathrm{w}_2$" is added to the vocabulary and the documents are re-tokenised to treat every instance of this bigram as a new token. LDA is then applied directly to the modified corpus without any changes to the model. While Lau et al. demonstrated that this two-step approach improves performance on a document classification task, it is limited in two ways. First, it can identify only collocations of a fixed length (i.e., bigrams). Second, the pre-processing step that identifies collocation candidates has no access to contextual cues (e.g. the topic of the context in which a bigram occurs),

A variety of extensions to the LDA model have been proposed to address this second shortcoming. Most extensions add some ability to capture word-to-word dependencies directly into the underlying generative process. For example, Wallach (2006) incorporates a hierarchical Dirichlet language model (MacKay and Peto, 1995), enabling her model to automatically cluster function words together. The model proposed by Griffiths et al. (2004) combines a hidden Markov model with LDA, using the former to model syntax and the latter to model semantics.

The LDA collocation model (LDACOL) (Griffiths et al., 2007) infers both the per-topic word distribution in the standard LDA model and, for each word in the vocabulary, a distribution over the words that follow it. The generative process of the LDACOL model allows words in a document to be generated in two ways. A word is generated either by drawing it directly from a per-topic word distribution corresponding to its topic as in LDA, or by drawing it from the word distribution associated with its preceding word w. The two alternatives are controlled by a set of Bernoulli random variables associated with individual words. Sequences of words generated from their predecessors constitute topical collocations.

Wang et al. (2007) extended the LDACOL model to generate the second word of a collocation from a distribution that conditions on not only the first word but also the first word's topic assignment, proposing the topical N-gram (TNG) model. In other words, whereas LDACOL only adds a distribution for every word-type to LDA, TNG adds a distribution for every possible word-topic pair. Wang et al. found that this modification allowed TNG to outperform LDACOL on a standard information retrieval task. However, both LDACOL and TNG do not require words within a sequence to share the same topic, which can result in semantically incoherent collocations.

Subsquent models have sought to encourage topically coherent collocations, including Phrase-Discovering LDA (Lindsey et al., 2012), the time-based topical n-gram model (Jameel and Lam, 2013a) and the n-gram Hierarchical Dirichlet Process (HDP) model (Jameel and Lam, 2013b). Phrase-Discovering LDA is a non-parametric extension of TNG inspired by Bayesian N-gram models Teh (2006) that incorporate a Pitman-Yor Process prior. The n-gram HDP is a nonparametric extension of LDA-colloc, putting an HDP prior on the per-document topic distribution. Both of these non-parametric extensions use the Chinese Franchise representation for posterior inference.

Our work here is based on the AG-colloc model proposed by Johnson (2010). He showed how Adaptor Grammars can generalise LDA to learn topical collocations of unbounded length while jointly identifying the topics that occur in each document. Unfortunately, because the Adaptor Grammar inference algorithm uses Probabilistic Context-Free Grammar (PCFG) parsing as a subroutine, the time complexity of inference is cubic in the length of individual text fragments. In order to improve the efficiency of the AG-colloc model, we re-express it using ideas from Bayesian word segmentation models. This allows us to develop an efficient inference algorithm for the AG-colloc model that scales to large corpora. Finally, we evaluate our model in terms of classification, information retrieval, and topic intrusion detection tasks; to our knowledge, we are the first to evaluate topical collocation models along all the three dimensions.

3 Topical Collocation Model

In this section we present our reformulation of the AG-colloc model, which we call the Topical Collocation Model (TCM) to emphasise that we are not using a grammar-based formulation. We start with the Unigram word segmentation model and Adaptor Grammar model of topical collocations, and then present our reformulation.

Goldwater et al. (2009) introduced a Bayesian model for word segmentation known as the Unigram model. This model is based on the Dirichet Process (DP) and assumes the following generative process for a sequence of words.

$$G \sim DP(\alpha_0, P_0), \qquad w_i \mid G \sim G$$

Here, P_0 is some distribution over the countably infinite set of all possible word forms (which are in turn sequences of a finite number of characters), and G is a draw from a Dirichlet Process. Inference is usually performed under a collapsed model in which G is integrated out, giving rise to a Chinese Restaurant Process (CRP) representation. The CRP is defined by the following predictive probability of w_i given $w_{1:i-1}$:

$$p(w_i = l | w_{1:i-1}) = \frac{n_l}{i-1+\alpha_0} + \frac{\alpha_0 P_0(l)}{i-1+\alpha_0},$$

where n_l is the number of times word form l appears in the first $n-1$ words.

During inference, the words are not known, and the model observes only a sequence of characters. Goldwater et al. (2009) derived a linear time Gibbs sampler that samples from the posterior distribution over possible segmentations of a given corpus according to the model. Their key insight is that sampling can be performed over a vector of Boolean boundary indicator variables – not included in the original description of the model – that indicates which adjacent characters are separated by a word boundary. We will show how this idea can be generalised to yield an inference algorithm for the AG-colloc model.

Adaptor Grammars (Johnson et al., 2007) are a generalisation of PCFGs. In a PCFG, a non-terminal A is expanded by selecting a rule $A \rightarrow \beta$ with probability $P(\beta|A)$, where β is a sequence of terminal and non-terminal node labels. Because the rules are selected independently, PCFGs introduce strong conditional independence assumptions. In an Adaptor Grammar, some of the non-terminal labels are *adapted*. These nodes can be expanded either by selecting a rule, as in PCFGs, or by retrieving an entire subtree from a Dirichlet Process cache specific to that node's non-terminal label,[1] breaking the conditional independence assumptions and capturing longer-range statistical relationships.

The AG-colloc model can be concisely expressed using context free grammar rule schemata, where adapted non-terminals are underlined:

$$\begin{aligned} \text{Top} &\rightarrow \text{Doc}_m \\ \text{Doc}_m &\rightarrow_{-m} \mid \text{Doc}_m \ \underline{\text{Topic}_i} \\ \underline{\text{Topic}_i} &\rightarrow \text{Word}^+ \end{aligned}$$

Here m ranges over the documents, i ranges over topics, "|" separates possible expansions, and "+" means "one or more". As in LDA, each document is defined as a mixture of K topics with the mixture probabilities corresponding to the probabili-

[1] Strictly speaking, Adaptor Grammars are defined using the Pitman-Yor process. In this paper we restrict ourselves to considering the Dirichlet Process which is a special case of the PYP where the discount parameter is set to 0. For more details, refer to Johnson et al. (2007) and Johnson (2010).

ties of the different expansions of Doc_m. However, the topic distributions are modelled using an adapted non-terminal $\underline{\text{Topic}_i}$. This means that there is an infinite number of rules expanding $\underline{\text{Topic}_i}$, one for every possible sequence over the finite vocabulary of words. $\underline{\text{Topic}_i}$ non-terminals cache sequences of words, just as G caches sequences of characters in the Unigram model.

The base distribution of the AG-colloc model is a geometric distribution over sequences of a finite vocabulary of words: $P_0(c = (w_1, \ldots, w_M)) = p_{\#}(1-p_{\#})^{M-1} \prod_{j=1}^{M} P_w(w_j)$, where $P_w(\cdot)$ is the uniform distribution over the finite set of words. This is the same base distribution used by Goldwater et al. (2009), except characters have been replaced by words. $p_{\#}$ is the probability of seeing the end of a collocation, and so controls the length of collocations. With this, we can re-express the AG-colloc model as a slight modification of the Unigram model:

1. For each topic $k, 1 \leq k \leq K$, $\phi_k \sim \text{DP}(\alpha_0, P_0)$
2. For each document $d, 1 \leq d \leq D$
   (a) Draw a topic distribution $\boldsymbol{\theta}_d | \alpha \sim \text{Dirichlet}_K(\alpha)$
   (b) For each collocation $c_{d,n}$ in document $d, 1 \leq n \leq N_d$
      i. Draw a topic assignment: $z_{d,n} \mid \boldsymbol{\theta}_d \sim \text{Discrete}(\boldsymbol{\theta}_d)$
      ii. Draw a collocation: $c_{d,n} \mid z_{d,n}, \boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_K \sim \boldsymbol{\phi}_{z_{d,n}}$

where the length of a collocation $c_{d,n}$ is greater than or equal to 1, i.e., $|c_{d,n}| \geq 1$. Unlike previous models, the TCM associates each topic with a Unigram model over topical collocations. Therefore, the TCM learns different vocabularies for different topics.[2]

4 Posterior Inference

We develop an efficient point-wise sampling algorithm that can jointly sample collocations and their topics. The observed data consists of a sequence of word tokens which are grouped into D documents. We sample from the posterior distribution over segmentations of documents into collocations, and assignments of topics to collocations. Let each document d be a sequence of N_d words $w_{d,1}, \ldots, w_{d,N_d}$. We introduce a set of auxiliary random variables $b_{d,1}, \ldots, b_{d,N_d}$. The value of $b_{d,j}$ indicates whether there is a collocation boundary between $w_{d,j}$ and $w_{d,j+1}$, and, if there is, the topic of the collocation to the left of the boundary. If there is no boundary then $b_{d,j} = 0$. Otherwise, there is a collocation to the left of the boundary consisting of the words $w_{d,l+1}, \ldots, w_{d,j}$ where $l = \max\{i \mid 1 \leq i \leq j-1 \wedge b_{d,i} \neq 0\}$, and $b_{d,j} = k$ $(1 \leq k \leq K)$ is the topic of the collocation. Note that b_{d,N_d} must not be 0 as the end of a document is always a collocation boundary.

For example, consider the document consisting of the words "the white house." We use the K+1-valued variables b_1, b_2 (after 'the' and 'white') and the K-valued variable b_3 (after 'house') to describe every possible segmentation of this document into topical collocations.[3] If there are K topics and N words, there are $(K+1)^{N-1}K$ possible topical segmentations. To illustrate, see how each of the following triples (b_1, b_2, b_3) encodes a different analysis of "the white house" into bracketed collocations and subscripted topic numbers:

- $(0, 0, 1)$: (the white house)$_1$
- $(1, 0, 2)$: (the)$_1$ (white house)$_2$
- $(2, 1, 1)$: (the)$_2$ (white)$_1$ (house)$_1$

The next section elaborates the Gibbs sampler over these K+1 boundary variables.

4.1 A Point-wise Gibbs Sampler for the TCM

We consider a collapsed version of the TCM in which the document-specific topic mixtures $\boldsymbol{\theta}_{1:D}$ and the K non-parametric topic distributions $\boldsymbol{\phi}_{1:K}$ are integrated out. We introduce the sampling equations using a concrete example, considering again the toy document, "the white house."

Let the sampler start in state $b_1 = b_2 = 0$, $b_3 = z_0, 1 \leq z_0 \leq K$. This corresponds to the analysis

$$\underbrace{(\text{the}_0 \ \text{white}_0 \ \text{house}_{z_0})}_{c_0}.$$

This analysis consists of a single collocation c_0 which spans the entire document and is assigned to topic z_0. For simplicity, we will not show how to model document boundaries.

If we resample b_1, we have to consider two different hypotheses, i.e., putting or not putting a collocation boundary at b_1. The analysis corresponding to not putting a boundary is the one we just

[2] In the TCM, the vocabulary differs from topic to topic. Given a sequence of adjacent words, it is hard to tell if it is a collocation without knowing the topic of its context. Therefore, the Pointwise Mutual Information (PMI) (Newman et al., 2010) and its variant (Lau et al., 2014) are not applicable to our TCM in evaluation.

[3] A similar strategy of using K-valued rather than boolean boundary variables in Gibbs sampling was used in Börschinger et al. (2013) and Du et al. (2014).

saw. Putting a boundary corresponds to a new segmentation,

$$\underbrace{(\text{the}_{z_1})}_{c_1}\underbrace{(\text{white}_0\ \text{house}_{z_2})}_{c_2}\,.$$

We need to consider the K possible topics for c_1, for each of which we calculate the probability as follows. If $b_1 = 0$ (i.e., there is no collocation boundary after "the") we have

$$p(z_0, c_0|\boldsymbol{\mu}) = p(z_0|\alpha)p(c_0|\alpha_0, P_0, z_0)\,, \qquad (1)$$

where $\boldsymbol{\mu} = \{\alpha, \alpha_0, P_0\}$. $p(c_0|\alpha_0, P_0, z_0)$ is the probability of generating collocation c_0 from topic z_0 with a CRP, i.e.,

$$p(c_0|\alpha_0, P_0, z_0) = \frac{n_{z_0}^{-c_0} + \alpha_0 P_0(c_0)}{N_{z_0}^{-c_0} + \alpha_0}\,, \qquad (2)$$

where $n_{z_0}^{-c_0}$ is the number of times that collocation c_0 was assigned to topic z_0 and $N_{z_0}^{-c_0}$ is the total number of collocations assigned to z_0. Both counts exclude the parts of the analysis that are affected by the boundary c_0. As in LDA,

$$p(z_0 = k|\alpha) = \frac{\hat{n}_k^{-c_0} + \alpha}{\sum_{k=1}^{K} \hat{n}_k^{-c_0} + K\alpha}\,, \qquad (3)$$

where $\hat{n}_k^{-c_0}$ is the total number of collocations assigned to topic k in a document, again excluding the count for the parts of the document that are affected by the current boundary. For the hypothesis that $b_1 = z_1$ (with $1 \leq z_1 \leq K$), the full conditional to generate two adjacent collocations is

$$\begin{aligned} &p(z_1, z_2, c_1, c_2|\boldsymbol{\mu}) \propto \qquad (4)\\ &\quad p(z_1|\alpha)p(c_1|\alpha_0, P_0, z_1)\\ &\quad p(z_2|\alpha, z_1)p(c_2|\alpha_0, P_0, c_1, z_1, z_2)\,, \end{aligned}$$

where $p(z_1|\alpha)$ and $p(c_1|\alpha_0, P_0, z_1)$ can be computed with Eqs (3) and (2), respectively. The remaining probabilities are computed as

$$\begin{aligned} &p(z_2 = k|\alpha, z_1) =\\ &\qquad \frac{\hat{n}_k^{-c_1,c_2} + \alpha + \mathbb{I}_{z_2=z_1}}{\sum_{k=1}^{K} \hat{n}_k^{-c_1,c_2} + K\alpha + 1}\,, \qquad (5) \end{aligned}$$

$$\begin{aligned} &p(c_2|\alpha_0, P_0, c_1, z_1, z_2) =\\ &\qquad \frac{n_{z_2}^{-c_1,c_2} + \mathbb{I}_{z_1=z_2}\mathbb{I}_{c_1=c_2} + \alpha_0 P_0(c_2)}{\alpha_0 + N_{z_2}^{-c_1,c_2} + \mathbb{I}_{z_1=z_2}} \qquad (6) \end{aligned}$$

where $\mathbb{I}_{x=y}$ is an indicator function that is equal to 1 if $x = y$ and 0 otherwise, $n_{z_2}^{-c_1,c_2}$ is the number of collocations c_2 assigned to topic z_2, and $N_{z_2}^{-c_1,c_2}$ is the total number of collocations assigned to topic z_2. Both counts exclude the current c_2, and also exclude c_1 if $z_1 = z_2$ and $c_1 = c_2$. Our sampler does random sweeps over all the boundary positions, and calculates the joint probability of the corresponding collocations and their topic assignment using Eqs (1) and (4) at each position.

4.2 Parallelised Sparse Sampling Algorithm

The word distributions and topic distributions in LDA are typically sparse, and Yao et al. (2009) proposed a 'sparseLDA' Gibbs sampler that takes advantage of this sparsity to substantially reduce running time. These two distributions are even sparser for the TCM than LDA, because collocations are less frequent than unigrams. Here we show how to modify our sampler to take advantage of sparsity. Sampling boundaries according the two probabilities shown Eqs (1) and (4) requires the generation of a random number x from a uniform distribution, $\mathcal{U}(0, \mathcal{P})$, where

$$\mathcal{P} = p(z_0, c_0) + \sum_{z_1=1}^{K} p(z_1, c_1)p(z_2, c_2|c_1, z_1)\,. \quad (7)$$

Here the first term corresponds to the case that there is no collocation boundary, and the summation corresponds to the case that there is a collocation boundary. Thus, if x is less than $P(z_0, c_0)$, there will be no boundary. Otherwise, we need to sample z_1 according to Eq (4).

The sampling algorithm requires calculation of Eq (7), even though the probability mass may be concentrated on just a few topics. We have observed in our experiments that the denominators of Eqs (5) and (6) are often quite large and the indicator functions usually turn out to be zero, so we approximate the two equations by removing the indicator functions. This approximation not only facilitates the computation of Eq (7), but also means that $p(z_2, c_2|c_1, z_1)$ no longer depends on z_1 and c_1. Thus, Eq (7) can be approximated as

$$\mathcal{P} \approx p(z_0, c_0) + p(z_2, c_2) \sum_{z_1=1}^{K} p(z_1, c_1)\,. \qquad (8)$$

Now that $p(z_0, c_0)$ and $p(z_2, c_2)$ are both out of the summation; they can be pre-computed and cached.

To reduce the computational complexity of the summation term in Eq (8), we use the "buckets" method (Yao et al., 2009). We divide the summation term in $p(z_1, c_1)$ into three parts as follows, each of which corresponds to a bucket:

$$\begin{aligned} & p(z_1 = k, c_1) \\ = & \frac{\hat{n}_k^{-c_1,c_2} + \alpha}{\sum_{k=1}^{K} \hat{n}_k^{-c_1,c_2} + K\alpha} \frac{n_k^{-c_1,c_2} + \alpha_0 P_0(c_1)}{N_k^{-c_1,c_2} + \alpha_0} \\ \propto & \frac{\alpha_0 P_0(c_1)\alpha}{N_k^{-c_1,c_2} + \alpha_0} + \frac{\hat{n}_k^{-c_1,c_2} \alpha_0 P_0(c_1)}{N_k^{-c_1,c_2} + \alpha_0} \\ & + \frac{(\hat{n}_k^{-c_1,c_2} + \alpha) n_k^{-c_1,c_2}}{N_k^{-c_1,c_2} + \alpha_0} \end{aligned} \quad (9)$$

Then, the summation in Eq (8) is proportional to the sum of the following three equations:

$$s = \sum_{k=1}^{K} \frac{\alpha_0 P_0(c_1)\alpha}{N_k^{-c_1,c_2} + \alpha_0} \quad (10)$$

$$r = \sum_{k=1}^{K} \frac{\hat{n}_k^{-c_1,c_2} \alpha_0 P_0(c_1)}{N_k^{-c_1,c_2} + \alpha_0} \quad (11)$$

$$q = \sum_{k=1}^{K} \frac{(\hat{n}_k^{-c_1,c_2} + \alpha) n_k^{-c_1,c_2}}{N_k^{-c_1,c_2} + \alpha_0} \quad (12)$$

We can now use the sampling techniques used in the sparse-LDA model to sample z_1. Firstly, sample $U \sim \mathcal{U}(0, s + r + q)$. If $U < s$ we have hit bucket s. In this case, we need to compute the probability for each possible topic. If $s < x < (s + r)$ we have hit the second bucket r. In this case, we compute probabilities only for topics such that $\hat{n}_k^{-c_1,c_2} \neq 0$. If $x > (s + r)$ we have hit bucket q, which is the "topic collection" bucket, and we need only consider topics such that $n_k^{-c_1,c_2} \neq 0$. Although we use an approximation in computing the full conditionals, experimental results have shown that our TCM is as accurate as the original AG-colloc model, see Section 5.

Our sparse sampling algorithm can be easily parallelised with the same multi-threading strategy used by Newman et al. (2009) in their distributed LDA (AD-LDA). In AD-LDA, documents are distributed evenly across P processors, each of which also has a copy of the word-topic count matrix. Gibbs updates are performed simultaneously on each of the P processors. At the end of each Gibbs iteration, the P copies of the word-topic count matrices are collected and summed into the global word-topic count matrix.

In the TCM, collocations in each topic are generated from a CRP. Hence, distributing the word-topic count matrix in AD-LDA now corresponds to distributing a set of Chinese restaurants in the parallelised TCM. The challenge is how to merge the Chinese Restaurant copies from the P processors into a single global restaurant for each topic, similar to the merging problem in Du et al. (2013). However, Eqs (2) and (6) show that the statistics that need to be collected are the number of collocations generated for each topic. The number of tables in a restaurant does not matter.[4] Therefore, we can adapt the summation technique used in AD-LDA.

We further observed that if P is large, using a single processor to perform the summation operation could result in a large overhead. The summation step could be even costlier in TCM than in LDA, since the number of distinct collocations is much larger than the number of distinct words. Thus we also parallelise the summation step using all the processors that are free in this step.

5 Experimental Results

In this section we evaluate the effectiveness and efficiency of our Topical Collocation Model (TCM) on different tasks, i.e., a document classification task, an information retrieval task and a topic intrusion detection task. All the empirical results show that our TCM performs as well as the AG-colloc model and outperforms other collocation models (i.e., LDACOL (Griffiths et al., 2007), TNG (Wang et al., 2007), PA (Lau et al., 2013)). The TCM also runs much faster than the other models. We also compared the TCM with the Mallet implementation of AD-LDA (Newman et al., 2009), denoted by Mallet-LDA, for completeness. Following Griffiths et al. (2007), we used punctuation and Mallet's stop words to split the documents into subsequences of word tokens, then removed those punctuation and stop words from the input. All experiments were run on a cluster with 80 Xeon E7-4850 processors (2.0GHz) and 96 GB memory.

5.1 Classification Evaluation

In the classification task, we used three datasets: the movie review dataset (Pang and Lee, 2012) (**MReviews**), the 20 Newsgroups dataset, and the Reuters-21578 dataset. The movie review dataset includes 1,000 positive and 1,000 negative reviews. The 20 Newsgroups dataset is organised

[4] The number of tables is used only when sampling the concentration parameters, α_0, see Blunsom et al. (2009).

Task	Classification	IR
Dataset	MReview	SJMN-2k
Mallet-LDA	71.30	18.85
LDACOL	71.75	19.03
TNG	71.40	19.06
PA	72.74	19.16
AG-colloc	***73.15***	***19.37***
Non-sparse TCM	**73.14**	**19.30**
Sparse TCM	**73.13**	**19.31**

Table 1: Comparison of all models in the classification task (accuracy in %) and the information retrieval task (MAP scores in %) on small corpora. Bold face indicates scores not significantly different from the best score (in italics) according to a Wilcoxon signed rank test ($p < 0.05$).

	Mallet-LDA	PA	TCM
Politics	**89.1**	***89.2***	***89.2***
Comp	86.3	87.4	*87.9*
Sci	92.0	93.2	*93.4*
Sports	91.6	91.7	*92.6*
Reuter-21578	97.3	**97.5**	***97.6***

Table 2: Classification accuracy (%) on larger datasets. Bold face indicates scores not significantly different from the best score (in italics) according to a Wilcoxon signed rank test ($p < 0.05$).

into 20 different categories according to different topics. We further partitioned the 20 newsgroups dataset into four subsets, denoted by **Comp**, **Sci**, **Sport**, and **Politics**. They have $4,891$, $3,952$, $1,993$, and $2,625$ documents respectively. We applied document classification to each subset. The **Reuters-21578** dataset has 21,578 Reuters news articles which are split into 10 categories.

	Mallet-LDA	PA	TCM
SJMN	20.7	20.9	***21.2***
AP	24.0	24.5	***24.8***

Table 3: Mean average Precision (MAP in %) scores in the information retrieval task. Scores in bold and italics are the significantly best MAP scores according to a Wilcoxon signed rank test ($p < 0.05$).

The classification evaluation was carried out as follows. First, we ran each model on each dataset to derive point estimates of documents' topic distributions ($\boldsymbol{\theta}$), which were used as the only features in classification. We then randomly selected from each dataset 80% documents for training and 20% for testing. A Support Vector Machine (SVM) with a linear-kernel was used. We ran all models for 10,000 iterations with 50 topics on the movie review dataset and 100 on the other two. We set $\alpha = 1/K$ and $\beta = 0.02$ for Mallet-LDA, LDACOL, TNG and PA. We used the reported settings in Johnson (2010) for the AG-colloc model. For the TCM, we used $\alpha = 1/K$. The concentration parameter α_0 was initially set to 100 and resampled using approximated table counts (Blunsom et al., 2009).

Since efficient inference is unavailable for LDACOL, TNG and AG-colloc, making it impractical to evaluate them on the large corpora, we compared our TCM with them only on the **MReviews** dataset. The first column of Table 1 shows the classification accuracy of those models. All the collocation models outperform Mallet-LDA. The AG-colloc model yields the highest classification accuracy, and our TCM with/without sparsity performs as well as the AG-colloc model according to the Wilcoxon signed rank test. The Pipeline Approach (PA) is always better than LDACOL and TNG. Therefore, in the following experiments we will focus on the comparison among our TCM, Mallet-LDA and PA.

Table 2 shows the classification accuracy of those three models on the larger datasets, i.e., the 20 Newsgroups dataset, and the Reuters-21578 dataset. The TCM outperforms both Mallet-LDA and PA on 3 out of 5 datasets, and performs equally well as PA on the **Politics** and **Reuter-21578** datasets according to a Wilcoxon signed rank test ($p < 0.05$).

5.2 Information Retrieval Evaluation

For the information retrieval task, we used the method presented by Wei and Croft (2006) and Wang et al. (2007) to calculate the probability of a query given a document. We used the San Jose Mercury News (**SJMN**) dataset and the **AP** News dataset from TREC. The former has 90,257 documents, the latter has 242,918 documents. Queries 51-150 were used. We ran all the models for 10,000 iteration with 100 topics. The other parameter settings were the same as those used in Section 5.1. Queries were tokenised using unigrams for Mallet-LDA and collocations for all collocation models.

Models	$p(w\|t)$	$p(t\|w)$
Mallet-LDA	71.9	73.2
PA	72.8	76.7
TCM	**73.2**	**79.7**

Table 4: The model precision (%) derived from the intrusion detection experiments.

On a small subset of the SJMN data, which contains 2,000 documents (**SJMN-2k**), we find again that TCM and AG-colloc perform equally well and outperform all other models (LDACOL, TNG, PA), as shown in the second column of Table 1. We further compare the TCM, Mallet-LDA and PA on the full **SJMN** dataset and the **AP** news dataset, as these models can run on large scale. Table 3 shows the mean average precision (MAP) scores. The TCM significantly outperforms both Mallet-LDA and the PA approach, and yields the highest MAP score.

5.3 Topic Coherence Evaluation

We ran a set of topic intrusion detection experiments (Chang et al., 2009) that provide a human evaluation of the coherence of the topics learnt by Mallet-LDA, PA and TCM on the **SJMN** dataset. This set of experiments was use to measure how well the inferred topics match human concepts. Each subject recruited from Amazon Mechanical Turk was presented with a randomly ordered list of 10 tokens (either words or collocations). The task of the subject was to identify the token which is semantically different from the others.

To generate the 10-token lists, we experimented with two different methods for selecting tokens (either words or collocations) most strongly associated with a topic t. The standard method chooses the tokens w that maximise $p(w|t)$. This method is biased toward high frequency tokens, since low-frequency tokens are unlikely to have a large $p(w|t)$. We also tried choosing words and collocations w that maximise $p(t|w)$. This method finds w that are unlikely to appear in any other topic except t, and is biased towards low frequency w. We reduce this low-frequency bias by using a smoothed estimate for $p(t|w)$ with a Dirichlet pseudo-count $\alpha = 5$.

Dataset	MReview		SJMN-2k	
#Topic	100	800	100	800
AG-colloc	84.9	1305	37.5	692
Non-sparse TCM	13.8	233	6.6	85.7
Sparse TCM	0.28	0.35	0.14	0.2

Table 5: The average running time (in seconds) per iteration.

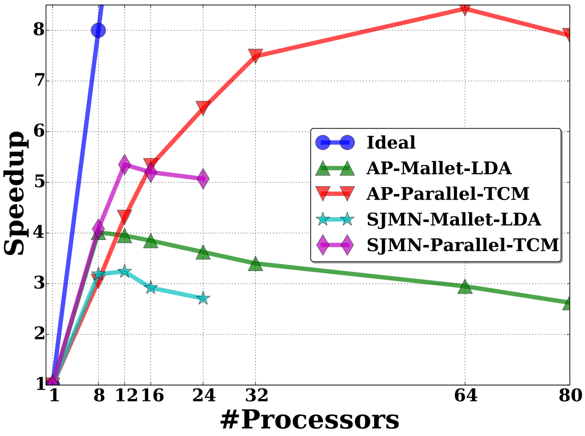

Figure 1: Plot of speedup in running time for the Mallet-LDA and our TCM.

An intruder token was randomly selected from a set of tokens that had low probability in the current topic but high probability in some other topic. We then randomly selected one of the 10 tokens to be replaced by the intruder token. We expect collocations to be more useful in lists that are constructed using $p(t|w)$ than lists constructed using $p(w|t)$. This is because $p(w|t)$ can be dominated by the frequency of w, but individual collocations are rare.

The performance was measured by model precision (Chang et al., 2009), which measures the fraction of subjects that agreed with the model. Table 4 shows that our TCM outperforms both PA and Mallet-LDA under both ways of constructing the intrusion lists. As expected, the collocation models PA and TCM perform better with lists constructed according to $p(t|w)$ than lists constructed according to $p(w|t)$.

5.4 Efficiency of the TCM

In this section we study the efficiency of our TCM model in terms of running time. We first compare the efficiency of our TCM model with and without sparsity with the AG-colloc model on the **MReview** dataset and the **SJMN-2k** dataset. Table 5 shows the average running time per iteration for the two models. We used 100 and 800 topics. The TCM algorithm that does not exploit sparsity in sampling runs about 6 times faster than the AG-colloc model. Our sparse sampler runs even faster, and takes less than a second per iteration. Therefore, Tables 1 and 5 jointly show that our reformulation runs an order of magnitude faster than AG-colloc without losing performance, thereby making the AG-colloc model inference feasible at large scales.

We further studied the scalability of our sampling algorithm after parallelisation on the **SJMN** dataset and the **AP** news dataset. We fixed the number of topics to 100, and varied the number of processors from 1 to 24 for the SJMN dataset and from 1 to 80 for the AP dataset. The plots in Figure 1 show that our parallelised sampler achieved a remarkable speedup. We have also observed that there is a point at which using additional processors actually slows running time. This is common in parallel algorithms when communication and synchronisation take more time than the time saved by parallelisation. This slowdown occurs in the highly-optimized Mallet implementation of LDA with fewer cores than it does in our implementation. The speedup achieved by our TCM also shows the benefit of parallelising the summation step mentioned in Section 4.2.

6 Conclusion

In this paper we showed how to represent the AG-colloc model without using Adaptor Grammars, and how to adapt Gibbs sampling techniques from Bayesian word segmentation to perform posterior inference under the new representation. We further accelerated the sampling algorithm by taking advantage of the sparsity in the collocation count matrix. Experimental results derived in different tasks showed that 1) our new representation performs as well as the AG-colloc model and outperforms the other collocation models, 2) our point-wise sampling algorithm scales well to large corpora. There are several ways in which our model can be extended. For example, our algorithm could be further sped up by using the sampling techniques presented by Smola and Narayanamurthy (2010), Li et al. (2014) and Buntine and Mishra (2014). One can also consider using a hybrid of MCMC and variational inference as in Ke et al. (2014).

Compositional Semantic Parsing on Semi-Structured Tables

Abstract

Two important aspects of semantic parsing for question answering are the breadth of the knowledge source and the depth of logical compositionality. While existing work trades off one aspect for another, this paper simultaneously makes progress on both fronts through a new task: answering complex questions on semi-structured tables using question-answer pairs as supervision. The central challenge arises from two compounding factors: the broader domain results in an open-ended set of relations, and the deeper compositionality results in a combinatorial explosion in the space of logical forms. We propose a logical-form driven parsing algorithm guided by strong typing constraints and show that it obtains significant improvements over natural baselines. For evaluation, we created a new dataset of 22,033 complex questions on Wikipedia tables, which is made publicly available.

1 Introduction

In semantic parsing for question answering, natural language questions are converted into logical forms, which can be executed on a knowledge source to obtain answer denotations. Early semantic parsing systems were trained to answer highly compositional questions, but the knowledge sources were limited to small closed-domain databases (Zelle and Mooney, 1996; Wong and Mooney, 2007; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011). More recent work sacrifices compositionality in favor of using more open-ended knowledge bases such as Freebase (Cai and Yates, 2013; Berant et al., 2013; Fader et al., 2014; Reddy et al., 2014). However, even these broader knowledge sources still define a rigid schema over entities and relation types, thus restricting the scope of answerable questions.

Year	City	Country	Nations
1896	Athens	Greece	14

y_5: {10}

Figure 1: Our task is to answer a highly compositional question from an HTML table. We learn a semantic parser from question-table-answer triples $\{(x_i, t_i, y_i)\}$.

To simultaneously increase both the *breadth* of the knowledge source and the *depth* of logical compositionality, we propose a new task (with an associated dataset): answering a question using an HTML table as the knowledge source. Figure 1 shows several question-answer pairs and an accompanying table, which are typical of those in our dataset. Note that the questions are logically quite complex, involving a variety of operations such as comparison (x_2), superlatives (x_3), aggregation (x_4), and arithmetic (x_5).

The HTML tables are semi-structured and not normalized. For example, a cell might contain multiple parts (e.g., "*Beijing, China*" or "*200 km*"). Additionally, we mandate that the training and test tables are disjoint, so at test time, we will see relations (column headers; e.g., "*Nations*") and entities (table cells; e.g., "*St. Louis*")

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1470–1480,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

that were not observed during training. This is in contrast to knowledge bases like Freebase, which have a global fixed relation schema with normalized entities and relations.

Our task setting produces two main challenges. Firstly, the increased breadth in the knowledge source requires us to generate logical forms from novel tables with previously unseen relations and entities. We therefore cannot follow the typical semantic parsing strategy of constructing or learning a lexicon that maps phrases to relations ahead of time. Secondly, the increased depth in compositionality and additional logical operations exacerbate the exponential growth of the number of possible logical forms.

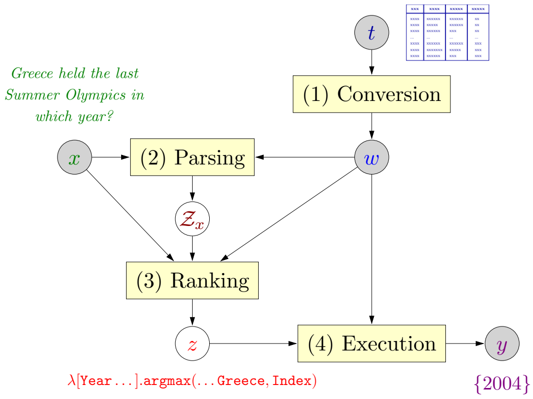
We trained a semantic parser for this task from question-answer pairs based on the framework illustrated in Figure 2. First, relations and entities from the semi-structured HTML table are encoded in a graph. Then, the system parses the question into candidate logical forms with a high-coverage grammar, reranks the candidates with a log-linear model, and then executes the highest-scoring logical form to produce the answer denotation. We use beam search with pruning strategies based on type and denotation constraints to control the combinatorial explosion.

To evaluate the system, we created a new dataset, WIKITABLEQUESTIONS, consisting of 2,108 HTML tables from Wikipedia and 22,033 question-answer pairs. When tested on unseen tables, the system achieves an accuracy of 37.1%, which is significantly higher than the information retrieval baseline of 12.7% and a simple semantic parsing baseline of 24.3%.

2 Task

Our task is as follows: given a table t and a question x about the table, output a list of values y that answers the question according to the table. Example inputs and outputs are shown in Figure 1. The system has access to a training set $\mathcal{D} = \{(x_i, t_i, y_i)\}_{i=1}^{N}$ of questions, tables, and answers, but the tables in test data do not appear during training.

The only restriction on the question x is that a person must be able to answer it using just the table t. Other than that, the question can be of any type, ranging from a simple table lookup question to a more complicated one that involves various logical operations.



Greece held the last Summer Olympics in which year?
t

x
(2) Parsing
w
$\mathcal{Z}_x$
(3) Ranking
z
(4) Execution
y
λ[Year . . .].argmax(. . . Greece, Index)
{2004}

Figure 2: The prediction framework: (1) the table t is deterministically converted into a knowledge graph w as shown in Figure 3; (2) with information from w, the question x is parsed into candidate logical forms in $\mathcal{Z}_x$; (3) the highest-scoring candidate $z \in \mathcal{Z}_x$ is chosen; and (4) z is executed on w, yielding the answer y.

Dataset. We created a new dataset, WIKITABLEQUESTIONS, of question-answer pairs on HTML tables as follows. We randomly selected data tables from Wikipedia with at least 8 rows and 5 columns. We then created two Amazon Mechanical Turk tasks. The first task asks workers to write trivia questions about the table. For each question, we put one of the 36 generic prompts such as *"The question should require calculation"* or *"contains the word* 'first' *or its synonym"* to encourage more complex utterances. Next, we submit the resulting questions to the second task where the workers answer each question based on the given table. We only keep the answers that are agreed upon by at least two workers. After this filtering, approximately 69% of the questions remains.

The final dataset contains 22,033 examples on 2,108 tables. We set aside 20% of the tables and their associated questions as the test set and develop on the remaining examples. Simple preprocessing was done on the tables: We omit all non-textual contents of the tables, and if there is a merged cell spanning many rows or columns, we unmerge it and duplicate its content into each unmerged cell. Section 7.2 analyzes various aspects of the dataset and compares it to other datasets.

3 Approach

We now describe our semantic parsing framework for answering a given question and for training the model with question-answer pairs.

Prediction. Given a table t and a question x, we predict an answer y using the framework illustrated in Figure 2. We first convert the table t into a *knowledge graph* w ("world") which encodes different relations in the table (Section 4). Next, we generate a set of candidate logical forms $\mathcal{Z}_x$ by parsing the question x using the information from w (Section 6.1). Each generated logical form $z \in \mathcal{Z}_x$ is a graph query that can be executed on the knowledge graph w to get a *denotation* $[\![z]\!]_w$. We extract a feature vector $\phi(x, w, z)$ for each $z \in \mathcal{Z}_x$ (Section 6.2) and define a log-linear distribution over the candidates:

$$p_\theta(z \mid x, w) \propto \exp\{\theta^\top \phi(x, w, z)\}, \qquad (1)$$

where θ is the parameter vector. Finally, we choose the logical form z with the highest model probability and execute it on w to get the answer denotation $y = [\![z]\!]_w$.

Training. Given training examples $\mathcal{D} = \{(x_i, t_i, y_i)\}_{i=1}^N$, we seek a parameter vector θ that maximizes the regularized log-likelihood of the correct denotation y_i marginalized over logical forms z. Formally, we maximize the objective function

$$J(\theta) = \frac{1}{N}\sum_{i=1}^{N} \log p_\theta(y_i \mid x_i, w_i) - \lambda \left\|\theta\right\|_1, \qquad (2)$$

where w_i is deterministically generated from t_i, and

$$p_\theta(y \mid x, w) = \sum_{z \in \mathcal{Z}_x;\, y = [\![z]\!]_w} p_\theta(z \mid x, w). \qquad (3)$$

We optimize θ using AdaGrad (Duchi et al., 2010), running 3 passes over the data. We use L_1 regularization with $\lambda = 3 \times 10^{-5}$ obtained from cross-validation.

The following sections explain individual system components in more detail.

4 Knowledge graph

Inspired by the graph representation of knowledge bases, we preprocess the table t by deterministically converting it into a *knowledge graph* w as illustrated in Figure 3. In the most basic form, table rows become row nodes, strings in table cells become entity nodes,[1] and table columns become directed edges from the row nodes to the entity nodes of that column. The column headers are used as edge labels for these row-entity relations.

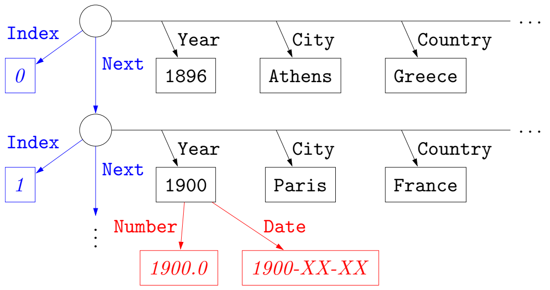

Figure 3: Part of the knowledge graph corresponding to the table in Figure 1. Circular nodes are row nodes. We augment the graph with different entity normalization nodes such as `Number` and `Date` (red) and additional row node relations `Next` and `Index` (blue).

The knowledge graph representation is convenient for three reasons. First, we can encode different forms of entity normalization in the graph. Some entity strings (e.g., *"1900"*) can be interpreted as a number, a date, or a proper name depending on the context, while some other strings (e.g., *"200 km"*) have multiple parts. Instead of committing to one normalization scheme, we introduce edges corresponding to different normalization methods from the entity nodes. For example, the node `1900` will have an edge called `Date` to another node *1900-XX-XX* of type date. Apart from type checking, these normalization nodes also aid learning by providing signals on the appropriate answer type. For instance, we can define a feature that associates the phrase *"how many"* with a logical form that says "traverse a row-entity edge, then a `Number` edge" instead of just "traverse a row-entity edge."

The second benefit of the graph representation is its ability to handle various logical phenomena via graph augmentation. For example, to answer questions of the form *"What is the next . . . ?"* or *"Who came before . . . ?"*, we augment each row node with an edge labeled `Next` pointing to the next row node, after which the questions can be answered by traversing the `Next` edge. In this work, we choose to add two special edges on each row node: the `Next` edge mentioned above and an `Index` edge pointing to the row index number ($0, 1, 2, \ldots$).

Finally, with a graph representation, we can query it directly using a logical formalism for knowledge graphs, which we turn to next.

[1] Two occurrences of the same string constitute one node.

Name	Example
Join	City.Athens (row nodes with a City edge to Athens)
Union	City.(Athens $\sqcup$ Beijing)
Intersection	City.Athens $\sqcap$ Year.Number.<.*1990*
Reverse	$\mathbf{R}$[Year].City.Athens (entities where a row in City.Athens has a Year edge to)
Aggregation	count(City.Athens) (the number of rows with city Athens)
Superlative	argmax(City.Athens, Index) (the last row with city Athens)
Arithmetic	sub(*204*, *201*) $(= 204 - 201)$
Lambda	λx[Year.Date.x] (a binary: composition of two relations)

Table 1: The lambda DCS operations we use.

5 Logical forms

As our language for logical forms, we use lambda dependency-based compositional semantics (Liang, 2013), or lambda DCS, which we briefly describe here. Each lambda DCS logical form is either a *unary* (denoting a list of values) or a *binary* (denoting a list of pairs). The most basic unaries are singletons (e.g., China represents an entity node, and *30* represents a single number), while the most basic binaries are relations (e.g., City maps rows to city entities, Next maps rows to rows, and >= maps numbers to numbers). Logical forms can be combined into larger ones via various operations listed in Table 1. Each operation produces a unary except lambda abstraction: $\lambda x[f(x)]$ is a binary mapping x to $f(x)$.

6 Parsing and ranking

Given the knowledge graph w, we now describe how to parse the utterance x into a set of candidate logical forms $\mathcal{Z}_x$

6.1 Parsing algorithm

We propose a new *floating parser* which is more flexible than a standard chart parser. Both parsers recursively build up derivations and corresponding logical forms by repeatedly applying deduction rules, but the floating parser allows logical form predicates to be generated independently from the utterance.

Chart parser. We briefly review the CKY algorithm for chart parsing to introduce notation. Given an utterance with tokens $x_1, \dots, x_n$, the CKY algorithm applies deduction rules of the following two kinds:

$$(\mathit{TokenSpan}, i, j)[s] \rightarrow (c, i, j)[f(s)], \tag{4}$$

$$(c_1, i, k)[z_1] + (c_2, k+1, j)[z_2] \tag{5}$$
$$\rightarrow (c, i, j)[f(z_1, z_2)].$$

The first rule is a lexical rule that matches an utterance token span $x_i \cdots x_j$ (e.g., $s =$ *"New York"*) and produces a logical form (e.g., $f(s) =$ NewYorkCity) with category c (e.g., Entity). The second rule takes two adjacent spans giving rise to logical forms z_1 and z_2 and builds a new logical form $f(z_1, z_2)$. Algorithmically, CKY stores derivations of category c covering the span $x_i \cdots x_j$ in a *cell* (c, i, j). CKY fills in the cells of increasing span lengths, and the logical forms in the top cell $(\mathit{ROOT}, 1, n)$ are returned.

Rule	Semantics	Example
Anchored to the utterance		
TokenSpan → *Entity*	match(z_1)	Greece
(match(s) = entity with name s)		anchored to *"Greece"*
TokenSpan → *Atomic*	val(z_1)	*2012-07-XX*
(val(s) = interpreted value)		anchored to *"July 2012"*
Unanchored (floating)		
$\emptyset$ → *Relation*	r	Country
(r = row-entity relation)		
$\emptyset$ → *Relation*	$\lambda x[r.p.x]$	λx[Year.Date.x]
(p = normalization relation)		
$\emptyset$ → *Records*	Type.Row	(list of all rows)
$\emptyset$ → *RecordFn*	Index	(row $\leftarrow$ row index)

Table 2: Base deduction rules. Entities and atomic values (e.g., numbers, dates) are anchored to token spans, while other predicates are kept floating. ($a \leftarrow b$ represents a binary mapping b to a.)

Floating parser. Chart parsing uses lexical rules (4) to generate relevant logical predicates, but in our setting of semantic parsing on tables, we do not have the luxury of starting with or inducing a full-fledged lexicon. Moreover, there is a mismatch between words in the utterance and predicates in the logical form. For instance, consider the question *"Greece held its last Summer Olympics in which year?"* on the table in Figure 1 and the correct logical form $\mathbf{R}[\lambda x$[Year.Date.x]].argmax(Country.Greece, Index). While the entity Greece can be anchored to the token *"Greece"*, some logical predicates (e.g., Country) cannot be clearly anchored to a token span. We could potentially learn to anchor the logical form Country.Greece to *"Greece"*, but if the relation Country is not seen during training, such a mapping is impossible to learn from the training data. Similarly, some prominent tokens

Rule	Semantics	Example
	Join + Aggregate	
Entity or *Atomic* → *Values*	z_1	$\texttt{China}$
Atomic → *Values*	$c.z_1$	$\texttt{>=}.\mathit{30}$ (at least 30)
($c \in \{\texttt{<}, \texttt{>}, \texttt{<=}, \texttt{>=}\}$)		
Relation + *Values* → *Records*	$z_1.z_2$	$\texttt{Country.China}$ (events (rows) where the country is China)
Relation + *Records* → *Values*	$\mathbf{R}[z_1].z_2$	$\mathbf{R}[\texttt{Year}].\texttt{Country.China}$ (years of events in China)
Records → *Records*	$\texttt{Next}.z_1$	$\texttt{Next.Country.China}$ (. . . before China)
Records → *Records*	$\mathbf{R}[\texttt{Next}].z_1$	$\mathbf{R}[\texttt{Next}].\texttt{Country.China}$ (. . . after China)
Values → *Atomic*	$a(z_1)$	$\texttt{count}(\texttt{Country.China})$ (How often did China . . .)
($a \in \{\texttt{count}, \texttt{max}, \texttt{min}, \texttt{sum}, \texttt{avg}\}$)		
Values → *ROOT*	z_1	
	Superlative	
Relation → *RecordFn*	z_1	$\lambda x[\texttt{Nations.Number}.x]$ (row ← value in Nations column)
Records + *RecordFn* → *Records*	$s(z_1, z_2)$	$\texttt{argmax}(\texttt{Type.Row}, \lambda x[\texttt{Nations.Number}.x])$
($s \in \{\texttt{argmax}, \texttt{argmin}\}$)		(events with the most participating nations)
		$\texttt{argmin}(\texttt{City.Athens}, \texttt{Index})$ (first event in Athens)
Relation → *ValueFn*	$\mathbf{R}[\lambda x[a(z_1.x)]]$	$\mathbf{R}[\lambda x[\texttt{count}(\texttt{City}.x)]]$ (city ← num. of rows with that city)
Relation + *Relation* → *ValueFn*	$\lambda x[\mathbf{R}[z_1].z_2.x]$	$\lambda x[\mathbf{R}[\texttt{City}].\texttt{Nations.Number}.x]$
		(city ← value in Nations column)
Values + *ValueFn* → *Values*	$s(z_1, z_2)$	$\texttt{argmax}(\ldots, \mathbf{R}[\lambda x[\texttt{count}(\texttt{City}.x)]])$ (most frequent city)
	Other operations	
ValueFn + *Values* + *Values* → *Values*	$o(\mathbf{R}[z_1].z_2, \mathbf{R}[z_1].z_3)$	$\texttt{sub}(\mathbf{R}[\texttt{Number}].\mathbf{R}[\texttt{Nations}].\texttt{City.London}, \ldots)$
($o \in \{\texttt{add}, \texttt{sub}, \texttt{mul}, \texttt{div}\}$)		(How many more participants were in London than . . .)
Entity + *Entity* → *Values*	$z_1 \sqcup z_2$	$\texttt{China} \sqcup \texttt{France}$ (China or France)
Records + *Records* → *Records*	$z_1 \sqcap z_2$	$\texttt{City.Beijing} \sqcap \texttt{Country.China}$ (. . . in Beijing, China)

Table 3: Compositional deduction rules. Each rule $c_1, \ldots, c_k \to c$ takes logical forms $z_1, \ldots, z_k$ constructed over categories $c_1, \ldots, c_k$, respectively, and produces a logical form based on the semantics.

(e.g., *"Olympics"*) are irrelevant and have no predicates anchored to them.

Therefore, instead of anchoring each predicate in the logical form to tokens in the utterance via lexical rules, we propose parsing more freely. We replace the anchored cells (c, i, j) with *floating cells* (c, s) of category c and logical form size s. Then we apply rules of the following three kinds:

$$(\mathit{TokenSpan}, i, j)[s] \to (c, 1)[f(s)], \tag{6}$$

$$\emptyset \to (c, 1)[f()], \tag{7}$$

$$(c_1, s_1)[z_1] + (c_2, s_2)[z_2] \to (c, s_1 + s_2 + 1)[f(z_1, z_2)]. \tag{8}$$

Note that rules (6) are similar to (4) in chart parsing except that the floating cell $(c, 1)$ only keeps track of the category and its size 1, not the span (i, j). Rules (7) allow us to construct predicates out of thin air. For example, we can construct a logical form representing a table relation $\texttt{Country}$ in cell $(\mathit{Relation}, 1)$ using the rule $\emptyset \to \mathit{Relation}\,[\texttt{Country}]$ independent of the utterance. Rules (8) perform composition, where the induction is on the size s of the logical form rather than the span length. The algorithm stops when the specified maximum size is reached, after which the logical forms in cells (ROOT, s) for any s are included in $\mathcal{Z}_x$. Figure 4 shows an example derivation generated by our floating parser.

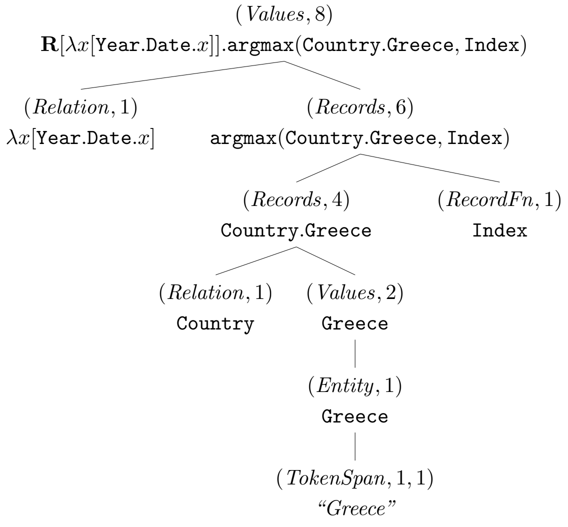

Figure 4: A derivation for the utterance *"Greece held its last Summer Olympics in which year?"* Only $\texttt{Greece}$ is anchored to a phrase *"Greece"*; $\texttt{Year}$ and other predicates are floating.

The floating parser is very flexible: it can skip tokens and combine logical forms in any order. This flexibility might seem too unconstrained, but we can use strong typing constraints to prevent nonsensical derivations from being constructed.

Tables 2 and 3 show the full set of deduction rules we use. We assume that all named entities will explicitly appear in the question x, so we an-

"Greece held its last Summer Olympics in which year?"
$z = \mathbf{R}[\lambda x[\texttt{Year.Number}.x]].\texttt{argmax}(\texttt{Type.Row}, \texttt{Index})$
$y = \{\textit{2012}\}$ (type: NUM, column: YEAR)

Feature Name	**Note**
(*"last"*, predicate = `argmax`)	lex
phrase = predicate	unlex (∵ *"year"* = `Year`)
missing entity	unlex (∵ missing *Greece*)
denotation type = NUM	
denotation column = YEAR	
(*"which year"*, type = NUM)	lex
phrase = column	unlex (∵ *"year"* = YEAR)
(Q = *"which"*, type = NUM)	lex
(H = *"year"*, type = NUM)	lex
H = column	unlex (∵ *"year"* = YEAR)

Table 4: Example features that fire for the (incorrect) logical form z. All features are binary. (lex = lexicalized)

chor all entity predicates (e.g., `Greece`) to token spans (e.g., *"Greece"*). We also anchor all numerical values (numbers, dates, percentages, etc.) detected by an NER system. In contrast, relations (e.g., `Country`) and operations (e.g., `argmax`) are kept floating since we want to learn how they are expressed in language. Connections between phrases in x and the generated relations and operations in z are established in the ranking model through features.

6.2 Features

We define features $\phi(x, w, z)$ for our log-linear model to capture the relationship between the question x and the candidate z. Table 4 shows some example features from each feature type. Most features are of the form $(f(x), g(z))$ or $(f(x), h(y))$ where $y = [\![z]\!]_w$ is the denotation, and f, g, and h extract some information (e.g., identity, POS tags) from x, z, or y, respectively.

phrase-predicate: Conjunctions between n-grams $f(x)$ from x and predicates $g(z)$ from z. We use both lexicalized features, where all possible pairs $(f(x), g(z))$ form distinct features, and binary unlexicalized features indicating whether $f(x)$ and $g(z)$ have a string match.

missing-predicate: Indicators on whether there are entities or relations mentioned in x but not in z. These features are unlexicalized.

denotation: Size and type of the denotation $y = [\![x]\!]_w$. The type can be either a primitive type (e.g., NUM, DATE, ENTITY) or the name of the column containing the entity in y (e.g., CITY).

phrase-denotation: Conjunctions between n-grams from x and the types of y. Similar to the phrase-predicate features, we use both lexicalized and unlexicalized features.

headword-denotation: Conjunctions between the question word Q (e.g., *what*, *who*, *how many*) or the headword H (the first noun after the question word) with the types of y.

6.3 Generation and pruning

Due to their recursive nature, the rules allow us to generate highly compositional logical forms. However, the compositionality comes at the cost of generating exponentially many logical forms, most of which are redundant (e.g., logical forms with an `argmax` operation on a set of size 1). We employ several methods to deal with this combinatorial explosion:

Beam search. We compute the model probability of each partial logical form based on available features (i.e., features that do not depend on the final denotation) and keep only the $K = 200$ highest-scoring logical forms in each cell.

Pruning. We prune partial logical forms that lead to invalid or redundant final logical forms. For example, we eliminate any logical form that does not type check (e.g., $\texttt{Beijing} \sqcup \texttt{Greece}$), executes to an empty list (e.g., $\texttt{Year.Number}.\textit{24}$), includes an aggregate or superlative on a singleton set (e.g., $\texttt{argmax}(\texttt{Year.Number}.\textit{2012}, \texttt{Index})$), or joins two relations that are the reverses of each other (e.g., $\mathbf{R}[\texttt{City}].\texttt{City.Beijing}$).

7 Experiments

7.1 Main evaluation

We evaluate the system on the development sets (three random 80:20 splits of the training data) and the test data. In both settings, the tables we test on do not appear during training.

Evaluation metrics. Our main metric is *accuracy*, which is the number of examples (x, t, y) on which the system outputs the correct answer y. We also report the *oracle* score, which counts the number of examples where at least one generated candidate $z \in \mathcal{Z}_x$ executes to y.

Baselines. We compare the system to two baselines. The first baseline (IR), which simulates information retrieval, selects an answer y among the entities in the table using a log-linear model over entities (table cells) rather than logical forms. The features are conjunctions between phrases in x and properties of the answers y, which cover all features in our main system that do not involve the logical form. As an upper bound of this baseline,

	dev		test	
	acc	ora	acc	ora
IR baseline	13.4	69.1	12.7	70.6
WQ baseline	23.6	34.4	24.3	35.6
Our system	37.0	76.7	37.1	76.6

Table 5: Accuracy (acc) and oracle scores (ora) on the development sets (3 random splits of the training data) and the test data.

	acc	ora
Our system	37.0	76.7
(a) **Rule Ablation**		
join only	10.6	15.7
join + count (= WQ baseline)	23.6	34.4
join + count + superlative	30.7	68.6
all − $\{\sqcap, \sqcup\}$	34.8	75.1
(b) **Feature Ablation**		
all − features involving predicate	11.8	74.5

all − lex phrase-predicate	17.6	75.9
all − unlex phrase-predicate	34.3	76.7
all − missing-predicate	35.9	76.7
all − features involving denotation	33.5	76.8
all − denotation	34.3	76.6
all − phrase-denotation	35.7	76.8
all − headword-denotation	36.0	76.7
(c) **Anchor operations to trigger words**	37.1	59.4

Table 6: Average accuracy and oracle scores on development data in various system settings.

69.1% of the development examples have the answer appearing as an entity in the table.

In the second baseline (WQ), we only allow deduction rules that produce join and count logical forms. This rule subset has the same logical coverage as Berant and Liang (2014), which is designed to handle the WEBQUESTIONS (Berant et al., 2013) and FREE917 (Cai and Yates, 2013) datasets.

Results. Table 5 shows the results compared to the baselines. Our system gets an accuracy of 37.1% on the test data, which is significantly higher than both baselines, while the oracle is 76.6%. The next subsections analyze the system components in more detail.

7.2 Dataset statistics

In this section, we analyze the breadth and depth of the WIKITABLEQUESTIONS dataset, and how the system handles them.

Number of relations. With 3,929 unique column headers (relations) among 13,396 columns, the tables in the WIKITABLEQUESTIONS dataset contain many more relations than closed-domain datasets such as Geoquery (Zelle and Mooney, 1996) and ATIS (Price, 1990). Additionally, the logical forms that execute to the correct denotations refer to a total of 2,056 unique column headers, which is greater than the number of relations in the FREE917 dataset (635 Freebase relations).

Operation	**Amount**
join (table lookup)	13.5%
+ join with `Next`	+ 5.5%
+ aggregate (`count`, `sum`, `max`, . . .)	+ 15.0%
+ superlative (`argmax`, `argmin`)	+ 24.5%
+ arithmetic, ⊓, ⊔	+ 20.5%
+ other phenomena	+ 21.0%

Table 7: The logical operations required to answer the questions in 200 random examples.

Knowledge coverage. We sampled 50 examples from the dataset and tried to answer them manually using Freebase. Even though Freebase contains some information extracted from Wikipedia, we can answer only 20% of the questions, indicating that WIKITABLEQUESTIONS contains a broad set of facts beyond Freebase.

Logical operation coverage. The dataset covers a wide range of question types and logical operations. Table 6(a) shows the drop in oracle scores when different subsets of rules are used to generate candidates logical forms. The *join only* subset corresponds to simple table lookup, while *join* + *count* is the WQ baseline for Freebase question answering on the WEBQUESTIONS dataset. Finally, *join* + *count* + *superlative* roughly corresponds to the coverage of the Geoquery dataset.

To better understand the distribution of logical operations in the WIKITABLEQUESTIONS dataset, we manually classified 200 examples based on the types of operations required to answer the question. The statistics in Table 7 shows that while a few questions only require simple operations such as table lookup, the majority of the questions demands more advanced operations. Additionally, 21% of the examples cannot be answered using any logical form generated from the current deduction rules; these examples are discussed in Section 7.4.

Compositionality. From each example, we compute the logical form size (number of rules applied) of the highest-scoring candidate that executes to the correct denotation. The histogram in Figure 5 shows that a significant number of logical forms are non-trivial.

Beam size and pruning. Figure 6 shows the results with and without pruning on various beam

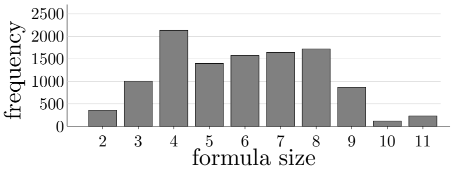

Figure 5: Sizes of the highest-scoring correct candidate logical forms in development examples.

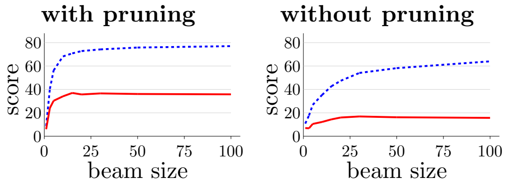

Figure 6: Accuracy (solid red) and oracle (dashed blue) scores with different beam sizes.

sizes. Apart from saving time, pruning also prevents bad logical forms from clogging up the beam which hurts both oracle and accuracy metrics.

7.3 Features

Effect of features. Table 6(b) shows the accuracy when some feature types are ablated. The most influential features are lexicalized phrase-predicate features, which capture the relationship between phrases and logical operations (e.g., relating *"last"* to `argmax`) as well as between phrases and relations (e.g., relating *"before"* to < or `Next`, and relating *"who"* to the relation `Name`).

Anchoring with trigger words. In our parsing algorithm, relations and logical operations are not anchored to the utterance. We consider an alternative approach where logical operations are anchored to "trigger" phrases, which are hand-coded based on co-occurrence statistics (e.g., we trigger a `count` logical form with *how*, *many*, and *total*).

Table 6(c) shows that the trigger words do not significantly impact the accuracy, suggesting that the original system is already able to learn the relationship between phrases and operations even without a manual lexicon. As an aside, the huge drop in oracle is because fewer "semantically incorrect" logical forms are generated; we discuss this phenomenon in the next subsection.

7.4 Semantically correct logical forms

In our setting, we face a new challenge that arises from learning with denotations: with deeper compositionality, a larger number of nonsensical logical forms can execute to the correct denotation. For example, if the target answer is a small number (say, 2), it is possible to count the number of rows with some random properties and arrive at the correct answer. However, as the system encounters more examples, it can potentially learn to disfavor them by recognizing the characteristics of semantically correct logical forms.

Generating semantically correct logical forms. The system can learn the features of semantically correct logical forms only if it can generate them in the first place. To see how well the system can generate correct logical forms, looking at the oracle score is insufficient since bad logical forms can execute to the correct denotations. Instead, we randomly chose 200 examples and manually annotated them with logical forms to see if a trained system can produce the annotated logical form as a candidate.

Out of 200 examples, we find that 79% can be manually annotated. The remaining ones include artifacts such as unhandled question types (e.g., yes-no questions, or questions with phrases *"same"* or *"consecutive"*), table cells that require advanced normalization methods (e.g., cells with comma-separated lists), and incorrect annotations.

The system generates the annotated logical form among the candidates in 53.5% of the examples. The missing examples are mostly caused by anchoring errors due to lexical mismatch (e.g., *"Italian"* → `Italy`, or *"no zip code"* → an empty cell in the zip code column) or the need to generate complex logical forms from a single phrase (e.g., *"May 2010"* → *>=.2010-05-01⊓<=.2010-05-31*).

7.5 Error analysis

The errors on the development data can be divided into four groups. The first two groups are unhandled question types (21%) and the failure to anchor entities (25%) as described in Section 7.4. The third group is normalization and type errors (29%): although we handle some forms of entity normalization, we observe many unhandled string formats such as times (e.g., *3:45.79*) and city-country pairs (e.g., *Beijing, China*), as well as complex calculation such as computing time periods (e.g., *12pm–1am* → 1 hour). Finally, we have ranking errors (25%) which mostly occur when the utterance phrase and the relation are obliquely related (e.g., *"airplane"* and `Model`).

8 Discussion

Our work simultaneously increases the breadth of knowledge source and the depth of compositionality in semantic parsing. This section explores the connections in both aspects to related work.

Logical coverage. Different semantic parsing systems are designed to handle different sets of logical operations and degrees of compositionality. For example, form-filling systems (Wang et al., 2011) usually cover a smaller scope of operations and compositionality, while early statistical semantic parsers for question answering (Wong and Mooney, 2007; Zettlemoyer and Collins, 2007) and high-accuracy natural language interfaces for databases (Androutsopoulos et al., 1995; Popescu et al., 2003) target more compositional utterances with a wide range of logical operations. This work aims to increase the logical coverage even further. For example, compared to the Geoquery dataset, the WIKITABLEQUESTIONS dataset includes a move diverse set of logical operations, and while it does not have extremely compositional questions like in Geoquery (e.g., *"What states border states that border states that border Florida?"*), our dataset contains fairly compositional questions on average.

To parse a compositional utterance, many works rely on a lexicon that translates phrases to entities, relations, and logical operations. A lexicon can be automatically generated (Unger and Cimiano, 2011; Unger et al., 2012), learned from data (Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011), or extracted from external sources (Cai and Yates, 2013; Berant et al., 2013), but requires some techniques to generalize to unseen data. Our work takes a different approach similar to the logical form growing algorithm in Berant and Liang (2014) by not anchoring relations and operations to the utterance.

Knowledge domain. Recent works on semantic parsing for question answering operate on more open and diverse data domains. In particular, large-scale knowledge bases have gained popularity in the semantic parsing community (Cai and Yates, 2013; Berant et al., 2013; Fader et al., 2014). The increasing number of relations and entities motivates new resources and techniques for improving the accuracy, including the use of ontology matching models (Kwiatkowski et al., 2013), paraphrase models (Fader et al., 2013; Berant and Liang, 2014), and unlabeled sentences (Krishnamurthy and Kollar, 2013; Reddy et al., 2014).

Our work leverages open-ended data from the Web through semi-structured tables. There have been several studies on analyzing or inferring the table schemas (Cafarella et al., 2008; Venetis et al., 2011; Syed et al., 2010; Limaye et al., 2010) and answering search queries by joining tables on similar columns (Cafarella et al., 2008; Gonzalez et al., 2010; Pimplikar and Sarawagi, 2012). While the latter is similar to question answering, the queries tend to be keyword lists instead of natural language sentences. In parallel, open information extraction (Wu and Weld, 2010; Masaum et al., 2012) and knowledge base population (Ji and Grishman, 2011) extract information from web pages and compile them into structured data. The resulting knowledge base is systematically organized, but as a trade-off, some knowledge is inevitably lost during extraction and the information is forced to conform to a specific schema. To avoid these issues, we choose to work on HTML tables directly.

In future work, we wish to draw information from other semi-structured formats such as colon-delimited pairs (Wong et al., 2009), bulleted lists (Gupta and Sarawagi, 2009), and top-k lists (Zhang et al., 2013). Pasupat and Liang (2014) used a framework similar to ours to extract entities from web pages, where the "logical forms" were XPath expressions. A natural direction is to combine the logical compositionality of this work with the even broader knowledge source of general web pages.

Graph parsing with s-graph grammars

Jonas Groschwitz and **Alexander Koller** and **Christoph Teichmann**

Abstract

A key problem in semantic parsing with graph-based semantic representations is *graph parsing*, i.e. computing all possible analyses of a given graph according to a grammar. This problem arises in training synchronous string-to-graph grammars, and when generating strings from them. We present two algorithms for graph parsing (bottom-up and top-down) with s-graph grammars. On the related problem of graph parsing with hyperedge replacement grammars, our implementations outperform the best previous system by several orders of magnitude.

1 Introduction

The recent years have seen an increased interest in *semantic parsing*, the problem of deriving a semantic representation for natural-language expressions with data-driven methods. With the recent availability of graph-based meaning banks (Banarescu et al., 2013; Oepen et al., 2014), much work has focused on computing graph-based semantic representations from strings (Jones et al., 2012; Flanigan et al., 2014; Martins and Almeida, 2014).

One major approach to graph-based semantic parsing is to learn an explicit synchronous grammar which relates strings with graphs. One can then apply methods from statistical parsing to parse the string and read off the graph. Chiang et al. (2013) and Quernheim and Knight (2012) represent this mapping of a (latent) syntactic structure to a graph with a grammar formalism called *hyperedge replacement grammar* (HRG; (Drewes et al., 1997)). As an alternative to HRG, Koller (2015) introduced *s-graph grammars* and showed that they support linguistically reasonable grammars for graph-based semantics construction.

One problem that is only partially understood in the context of semantic parsing with explicit grammars is *graph parsing*, i.e. the computation of the possible analyses the grammar assigns to an input *graph* (as opposed to string). This problem arises whenever one tries to generate a string from a graph (e.g., on the generation side of an MT system), but also in the context of extracting and training a synchronous grammar, e.g. in EM training. The state of the art is defined by the bottom-up graph parsing algorithm for HRG by Chiang et al. (2013), implemented in the Bolinas tool (Andreas et al., 2013).

We present two graph parsing algorithms (top-down and bottom-up) for s-graph grammars. S-graph grammars are equivalent to HRGs, but employ a more fine-grained perspective on graph-combining operations. This simplifies the parsing algorithms, and facilitates reasoning about them. Our bottom-up algorithm is similar to Chiang et al.'s, and derives the same asymptotic number of rule instances. The top-down algorithm is novel, and achieves the same asymptotic runtime as the bottom-up algorithm by reasoning about the biconnected components of the graph. Our evaluation on the "Little Prince" graph-bank shows that our implementations of both algorithms outperform Bolinas by several orders of magnitude. Furthermore, the top-down algorithm can be more memory-efficient in practice.

2 Related work

The AMR-Bank (Banarescu et al., 2013) annotates sentences with *abstract meaning representations (AMRs)*, like the one shown in Fig. 1(a). These are graphs that represent the predicate-argument structure of a sentence; notably, phenomena such as control are represented by reentrancies in the graph. Another major graph-bank is the SemEval-2014 shared task on semantic dependency parsing dataset (Oepen et al., 2014).

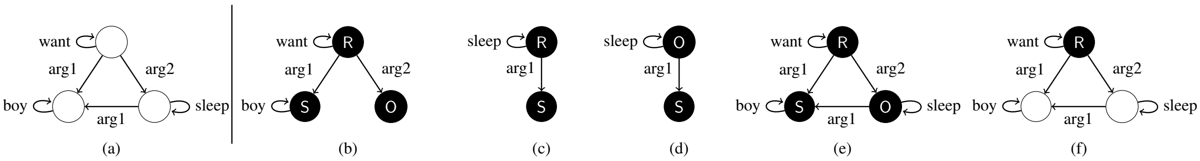

Figure 1: AMR (a) for 'The boy wants to sleep', and s-graphs. We call (b) SG_{want} and (c) SG_{sleep}.

The primary grammar formalism currently in use for synchronous graph grammars is *hyperedge replacement grammar (HRG)* (Drewes et al., 1997), which we sketch in Section 4.3. An alternative is offered by Koller (2015), who introduced *s-graph grammars* and showed that they lend themselves to manually written grammars for semantic construction. In this paper, we show the equivalence of HRG and s-graph grammars and work out graph parsing for s-graph grammars.

The first polynomial graph parsing algorithm for HRGs on graphs with limited connectivity was presented by Lautemann (1988). Lautemann's original algorithm is a top-down parser, which is presented at a rather abstract level that does not directly support implementation or detailed complexity analysis. We extend Lautemann's work by showing how new parse items can be represented and constructed efficiently. Finally, Chiang et al. (2013) presented a bottom-up graph parser for HRGs, in which the representation and construction of items was worked out for the first time. It produces $O((n \cdot 3^d)^{k+1})$ instances of the rules in a parsing schema, where n is the number of nodes of the graph, d is the maximum degree of any node, and k is a quantity called the *tree-width* of the grammar.

3 An algebra of graphs

We start by introducing the exact type of graphs that our grammars and parsers manipulate, and by developing some theory.

Throughout this paper, we define a *graph* $G = (V, E)$ as a directed graph with edge labels from some label alphabet L. The graph consists of a finite set V of nodes and a finite set $E \subseteq V \times V \times L$ of edges $e = (u, v, l)$, where u and v are the nodes connected by e, and $l \in L$ is the *edge label*. We say that e is *incident* to both u and v, and call the number of edges incident to a node its *degree*. We write $u \overset{e}{\leftrightarrow} v$ if either $e = (u, v, l)$ or $e = (v, u, l)$ for some l; we drop the e if the identity of the edge is irrelevant. Edges with $u = v$ are called *loops*; we use them here to encode node labels. Given a graph G, we write $n = |V|$, $m = |E|$, and d for the maximum degree of any node in V.

If $f : A \rightsquigarrow B$ and $g : A \rightsquigarrow B$ are partial functions, we let the partial function $f \cup g$ be defined if for all $a \in A$ with both $f(a)$ and $g(a)$ defined, we have $f(a) = g(a)$. We then let $(f \cup g)(a)$ be $f(a)$ if $f(a)$ is defined; $g(a)$ if $g(a)$ is defined; and undefined otherwise.

3.1 The HR algebra of graphs with sources

Our grammars describe how to build graphs from smaller pieces. They do this by accessing nodes (called *source nodes*) which are assigned "public names". We define an *s-graph* (Courcelle and Engelfriet, 2012) as a pair $SG = (G, \phi)$ of a graph G and a *source assignment*, i.e. a partial, injective function $\phi : S \rightsquigarrow V$ that maps some *source names* from a finite set S to the nodes of G. We call the nodes in $\phi(S)$ the *source nodes* or *sources* of SG; all other nodes are *internal nodes*. If ϕ is defined on the source name σ, we call $\phi(\sigma)$ the *σ-source* of SG. Throughout, we let $s = |S|$.

Examples of s-graphs are given in Fig. 1. We use numbers as node names and lowercase strings for edge names (except in the concrete graphs of Fig. 1, where the edges are marked with edge labels instead). Source nodes are drawn in black, with source names drawn on the inside. Fig. 1(b) shows an s-graph SG_{want} with three nodes and four edges. The three nodes are marked as the R-, S-, and O-source, respectively. Likewise, the s-graph SG_{sleep} in (c) has two nodes (one of which is an R-source and the other an S-source) and two edges.

We can now apply operations to these graphs. First, we can *rename* the R-source of (c) to an O-source. The result, denoted $SG_d = SG_{sleep}[\mathsf{R} \to \mathsf{O}]$, is shown in (d). Next, we can *merge* SG_d with SG_{want}. This copies the edges and nodes of SG_d and SG_{want} into a new s-graph; but crucially, for every source name σ the two s-graphs have in common, the σ-sources of the graphs are fused into a single node (and become a σ-source of the result). We write $||$ for the merge operation;

thus we obtain $SG_e = SG_d \mid\mid SG_{want}$, shown in (e). Finally, we can *forget* source names. The graph $SG_f = \mathsf{f}_{\mathsf{S}}(\mathsf{f}_{\mathsf{O}}(SG_e))$, in which we forgot S and O, is shown in (f). We refer to Courcelle and Engelfriet (2012) for technical details.[1]

We can take the set of all s-graphs, together with these operations, as an *algebra* of s-graphs. In addition to the binary merge operation and the unary operations for forget and rename, we fix some finite set of *atomic* s-graphs and take them as constants of the algebra which evaluate to themselves. Following Courcelle and Engelfriet, we call this algebra the *HR algebra*. We can *evaluate* any term τ consisting of these operation symbols into an s-graph $[\![\tau]\!]$ as usual. For instance, the following term encodes the merge, forget, and rename operations from the example above, and evaluates to the s-graph in Fig. 1(f).

(1) $\mathsf{f}_{\mathsf{S}}(\mathsf{f}_{\mathsf{O}}(SG_{want} \mid\mid SG_{sleep}[\mathsf{R} \to \mathsf{O}]))$

The set of s-graphs that can be represented as the value $[\![\tau]\!]$ of some term τ over the HR algebra depends on the source set S and on the constants. For simplicity, we assume here that we have a constant for each s-graph consisting of a single labeled edge (or loop), and that the values of all other constants can be expressed by combining these using merge, rename, and forget.

3.2 S-components

A central question in graph parsing is how some s-graph that is a subgraph of a larger s-graph SG (a *sub-s-graph*) can be represented as the merge of two smaller sub-s-graphs of SG. In general, $SG_1 \mid\mid SG_2$ is defined for any two s-graphs SG_1 and SG_2. However, if we see SG_1 and SG_2 as subgraphs of SG, $SG_1 \mid\mid SG_2$ may no longer be a subgraph of SG. For instance, we cannot merge the s-graphs (b) and (c) in Fig. 2 as part of the graph (a): The startpoints of the edges a and d are both A-sources and would thus become the same node (unlike in (a)), and furthermore the edge d would have to be duplicated. In graph parsing, we already know the identity of all nodes and edges in sub-s-graphs (as nodes and edges in SG), and must thus pay attention that merge operations do not accidentally fuse or duplicate them. In particular, two sub-s-graphs cannot be merged if they have edges in common.

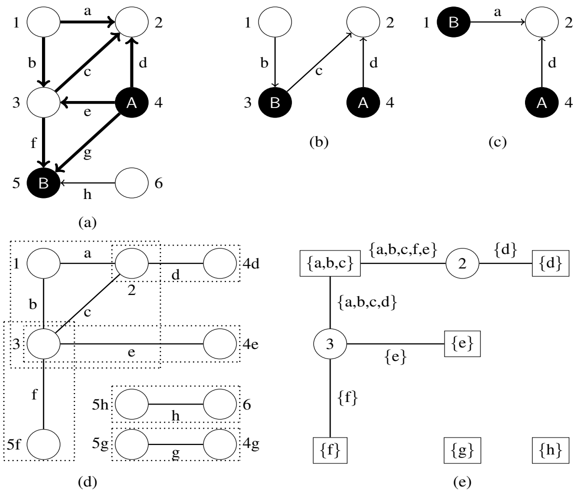

Figure 2: (a) An s-graph with (b,c) some sub-s-graphs, (d) its BCCs, and (e) its block-cutpoint graph.

We call a sub-s-graph SG_1 of SG *extensible* if there is another sub-s-graph SG_2 of SG such that $SG_1 \mid\mid SG_2$ contains the same edges as SG. An example of a sub-s-graph that is not extensible is the sub-s-graph (b) of the s-graph in (a) in Fig. 2. Because sources can only be renamed or forgotten by the algebra operations, but never introduced, we can never attach the missing edge a: this can only happen when 1 and 2 are sources. As a general rule, a sub-s-graph can only be extensible if it contains all edges that are adjacent to all of its internal nodes in SG. Obviously, a graph parser need only concern itself with sub-s-graphs that are extensible.

We can further clarify the structure of extensible sub-s-graphs by looking at the *s-components* of a graph. Let $U \subseteq V$ be some set of nodes. This set splits the edges of G into equivalence classes that are separated by U. We say that two edges $e, f \in E$ are *equivalent* with respect to U, $e \sim_U f$, if there is a sequence $v_1 \overset{e}{\leftrightarrow} v_2 \leftrightarrow \dots v_{k-1} \overset{f}{\leftrightarrow} v_k$ with $v_2, \dots, v_{k-1} \notin U$, i.e. if we can reach f from an endpoint of e without visiting a node in U. We call the equivalence classes of E with respect to $\sim_U$ the *s-components* of G and denote the s-component that contains an edge e with $[e]$. In Fig. 2(a), the edges a and f are equivalent with respect to $U = \{4, 5\}$, but a and h are not. The s-components are $[a] = \{a, b, c, d, e, f\}$, $[g] = \{g\}$, and $[h] = \{h\}$.

It can be shown that for any s-graph $SG =$

[1] Note that the rename operation of Courcelle and Engelfriet (2012) allows for swapping source assignments and making multiple renames in one step. We simplify the presentation here, but all of our techniques extend easily.

(G, ϕ), a sub-s-graph SH with source nodes U is extensible iff its edge set is the union of a set of s-components of G with respect to U. We let an *s-component representation* $\mathcal{C} = (C, \phi)$ in the s-graph $SG = (G, \phi')$ consist of a source assignment $\phi : S \rightsquigarrow V$ and a set C of s-components of G with respect to the set $\mathrm{VS}_{\mathcal{C}} = \phi(S) \subseteq V$ of source nodes of ϕ. Then we can represent every extensible sub-s-graph $SH = (H, \phi)$ of SG by the s-component representation $\mathcal{C} = (C, \phi)$ where C is the set of s-components of which SH consists. Conversely, we write $T(\mathcal{C})$ for the unique extensible sub-s-graph of SG represented by the s-component representation $\mathcal{C}$.

The utility of s-component representations derives from the fact that merge can be evaluated on these representations alone, as follows.

Lemma 1. *Let $\mathcal{C} = (C, \phi), \mathcal{C}_1 = (C_1, \phi_1), \mathcal{C}_2 = (C_2, \phi_2)$ be s-component representations in the s-graph SG. Then $T(\mathcal{C}) = T(\mathcal{C}_1) \mid\mid T(\mathcal{C}_2)$ iff $C = C_1 \uplus C_2$ (i.e., disjoint union) and $\phi_1 \cup \phi_2$ is defined, injective, and equal to ϕ.*

3.3 Boundary representations

If there is no $\mathcal{C}$ such that all conditions of Lemma 1 are satisfied, then $T(\mathcal{C}_1) \mid\mid T(\mathcal{C}_2)$ is not defined. In order to check this efficiently in the bottom-up parser, it will be useful to represent s-components explicitly via their *boundary*.

Consider an s-component representation $\mathcal{C} = (C, \phi)$ in SG and let E be the set of all edges that are adjacent to a source node in $\mathrm{VS}_{\mathcal{C}}$ and contained in an s-component in C. Then we let the *boundary representation (BR)* β of $\mathcal{C}$ in the s-graph SG be the pair $\beta = (E, \phi)$. That is, β represents the s-components through the *in-boundary edges*, i.e. those edges inside the s-components (and thus the sub-s-graph) which are adjacent to a source. The BR β specifies $\mathcal{C}$ uniquely if the base graph SG is connected, so we write $T(\beta)$ for $T(\mathcal{C})$ and VS_β for $\mathrm{VS}_{\mathcal{C}}$.

In Fig. 2(a), the bold sub-s-graph is represented by $\beta = \langle \{d, e, f, g\}, \{\mathsf{A}{:}4, \mathsf{B}{:}5\} \rangle$, indicating that it contains the A-source 4 and the B-source 5; and further, that the edge set of the sub-s-graph is $[d] \cup [e] \cup [f] \cup [g] = \{a, b, c, d, e, f, g\}$. The edge h (which is also incident to 5) is not specified, and therefore not in the sub-s-graph.

The following lemma can be shown about computing merge on boundary representations. Intuitively, the conditions (b) and (c) guarantee that the component sets are disjoint; the lemma then follows from Lemma 1.

Lemma 2. *Let SG be an s-graph, and let $\beta_1 = (E_1, \phi_1), \beta_2 = (E_2, \phi_2)$ be two boundary representations in SG. Then $T(\beta_1) \mid\mid T(\beta_2)$ is defined within SG iff the following conditions hold:*

(a) $\phi_1 \cup \phi_2$ is defined and injective;

(b) the two BRs have no in-boundary edges in common, i.e. $E_1 \cap E_2 = \emptyset$;

(c) for every source node v of β_1, the last edge on the path in SG from v to the closest source node of β_2 is not an in-boundary edge of β_2, and vice versa.

Furthermore, if these conditions hold, we have $T(\beta_1 \mid\mid \beta_2) = T(\beta_1) \mid\mid T(\beta_2)$, where we define $\beta_1 \mid\mid \beta_2 = (E_1 \cup E_2, \phi_1 \cup \phi_2)$.

4 S-graph grammars

We are now ready to define s-graph grammars, which describe languages of s-graphs. We also introduce graph parsing and relate s-graph grammars to HRGs.

4.1 Grammars for languages of s-graphs

We use *interpreted regular tree grammars* (IRTGs; Koller and Kuhlmann (2011)) to describe languages of s-graphs. IRTGs are a very general mechanism for describing languages over and relations between arbitrary algebras. They separate conceptually the generation of a grammatical derivation from its interpretation as a string, tree, graph, or some other object.

Consider, as an example, the tiny grammar in Fig. 3; see Koller (2015) for linguistically meaningful grammars. The left column consists of a regular tree grammar $\mathcal{G}$ (RTG; see e.g. Comon et al. (2008)) with two rules. This RTG describes a regular language $L(\mathcal{G})$ of *derivation trees* (in general, it may be infinite). In the example, we can derive $\mathsf{S} \Rightarrow \mathsf{r}_1(\mathsf{VP}) \Rightarrow \mathsf{r}_1(\mathsf{r}_2)$, therefore we have $t = \mathsf{r}_1(\mathsf{r}_2) \in L(\mathcal{G})$.

We then use a *tree homomorphism* h to rewrite the derivation trees into terms over an algebra; in this case the HR algebra. In the example, the values $h(\mathsf{r}_1)$ and $h(\mathsf{r}_2)$ are specified in the second column of Fig. 3. We compute $h(t)$ by substituting the variable x_1 in $h(\mathsf{r}_1)$ with $h(\mathsf{r}_2)$. The term $h(t)$ is thus the one shown in (1). It evaluates to the s-graph SG_f in Fig. 1(f).

Rule of RTG $\mathcal{G}$	homomorphism h
$\mathsf{S} \to \mathsf{r}_1(\mathsf{VP})$	$\mathsf{f_S}(\mathsf{f_O}(SG_{want} \Vert x_1[\mathsf{R} \to \mathsf{O}]))$
$\mathsf{VP} \to \mathsf{r}_2$	SG_{sleep}

Figure 3: An example s-graph grammar.

In general, the IRTG $\mathbb{G} = (\mathcal{G}, h, \mathcal{A})$ generates the *language* $L(\mathbb{G}) = \{[\![h(t)]\!] \mid t \in L(\mathcal{G})\}$, where $[\![\cdot]\!]$ is evaluation in the algebra $\mathcal{A}$. Thus, in the example, we have $L(\mathbb{G}) = \{SG_f\}$.

In this paper, we focus on IRTGs that describe languages $L(\mathbb{G}) \subseteq \mathcal{A}$ of objects in an algebra; specifically, of s-graphs in the HR algebra. However, IRTGs extend naturally to a synchronous grammar formalism by adding more homomorphisms and algebras. For instance, the grammars in Koller (2015) map each derivation tree simultaneously to a string and an s-graph, and therefore describe a binary relation between strings and s-graphs. We call IRTGs where at least one algebra is the HR algebra, *s-graph grammars*.

4.2 Parsing with s-graph grammars

In this paper, we are concerned with the parsing problem of s-graph grammars. In the context of IRTGs, parsing means that we are looking for those derivation trees t that are (a) grammatically correct, i.e. $t \in L(\mathcal{G})$, and (b) match some given input object a, i.e. $h(t)$ evaluates to a in the algebra. Because the set P of such derivation trees may be large or infinite, we aim to compute an RTG $\mathcal{G}_a$ such that $L(\mathcal{G}_a) = P$. This RTG plays the role of a parse chart, which represents the possible derivation trees compactly.

In order to compute $\mathcal{G}_a$, we need to solve two problems. First, we need to determine all the possible ways in which a can be represented by terms τ over the algebra $\mathcal{A}$. This is familiar from string parsing, where a CKY parse chart spells out all the ways in which larger substrings can be decomposed into smaller parts by concatenation. Second, we need to identify all those derivation trees $t \in L(\mathcal{G})$ that map to such a decomposition τ, i.e. for which $h(t)$ evaluates to a. In string parsing, this corresponds to retaining only such decompositions into substrings that are justified by the grammar rules.

While any parsing algorithm must address both of these issues, they are usually conflated, in that parse items combine information about the decomposition of a (such as a string span) with information about grammaticality (such as nonterminal symbols). In IRTG parsing, we take a different, more generic approach. We assume that the set D of all decompositions τ, i.e. of all terms τ that evaluate to a in the algebra, can be represented as the language $D = L(D_a)$ of a *decomposition grammar* D_a. D_a is an RTG over the signature of the algebra. Crucially, D_a only depends on the algebra and a itself, and not on $\mathcal{G}$ or h, because D contains *all* terms that evaluate to a and not just those that are licensed by the grammar. However, we can compute $\mathcal{G}_a$ from D_a efficiently by exploiting the closure of regular tree languages under intersection and inverse homomorphism; see Koller and Kuhlmann (2011) for details.

In practice, this means that whenever we want to apply IRTGs to a new algebra (as, in this paper, to the HR algebra), we can obtain a parsing algorithm by specifying how to compute decomposition grammars over this algebra. This is the topic of Section 5.

4.3 Relationship to HRG

We close our exposition of s-graph grammars by relating them to HRGs. It is known that the graph languages that can be described with s-graph grammars are the same as the HRG languages (Courcelle and Engelfriet, 2012, Prop. 4.27). Here we establish a more precise equivalence result, so we can compare our asymptotic runtimes directly to those of HRG parsers.

An HRG rule, such as the one shown in Fig. 4, rewrites a nonterminal symbol into a graph. The example rule constructs a graph for the nonterminal S by combining the graph G_r in the middle (with nodes $1, 2, 3$ and edges e, f) with graphs G_X and G_Y that are recursively derived from the nonterminals X and Y. The combination happens by merging the *external* nodes of G_X and G_Y with nodes of G_r: the squiggly lines indicate that the external node I of G_X should be 1, and the external node II should be 2. Similarly the external nodes of G_Y are unified with 1 and 3. Finally, the external nodes I and II of the HRG rule for S itself, shaded gray, are 1 and 3.

The fundamental idea of the HRG-to-IRTG translation is to encode external nodes as sources, and to use rename and merge to unify the nodes of the different graphs. In the example, we might say that the external nodes of G_X and G_Y are represented using the source names I and II, and extend G_r to an s-graph by saying that the nodes 1, 2, and

3 are its I-source, III-source, and II-source respectively. This results in the expression

$$\text{(2)}\ \ \mathsf{f}_{\mathrm{III}}(\langle \mathrm{I}\rangle \xrightarrow{e} \langle \mathrm{III}\rangle \mid\mid x_1[\mathrm{II} \to \mathrm{III}] \\ \mid\mid \langle \mathrm{I}\rangle \xrightarrow{f} \langle \mathrm{II}\rangle \mid\mid x_2)$$

where we write "$\langle \mathrm{I}\rangle \xrightarrow{e} \langle \mathrm{III}\rangle$" for the s-graph consisting of the edge e, with node 1 as I-source and 2 as III-source.

However, this requires the use of three source names (I, II, and III). The following encoding of the rule uses the sources more economically:

$$\text{(3)}\ \ \mathsf{f}_{\mathrm{II}}(\langle \mathrm{I}\rangle \xrightarrow{e} \langle \mathrm{II}\rangle \mid\mid x_1) \mid\mid \langle \mathrm{I}\rangle \xrightarrow{f} \langle \mathrm{II}\rangle \mid\mid x_2$$

This term uses only two source names. It forgets II as soon as we are finished with the node 2, and frees the name up for reuse for 3. The complete encoding of the HRG rule consists of the RTG rule $\mathrm{S} \to \mathsf{r}(\mathrm{X}, \mathrm{Y})$ with $h(\mathsf{r}) = (3)$.

In the general case, one can "read off" possible term encodings of a HRG rule from its *tree decompositions*; see Chiang et al. (2013) or Def. 2.80 of Courcelle and Engelfriet (2012) for details. A tree decomposition is a tree, each of whose nodes π is labeled with a subset V_π of the nodes in the HRG rule. We can construct a term encoding from a tree decomposition bottom-up. Leaves map to variables or constants; binary nodes introduce merge operations; and we use rename and forget operations to ensure that the subterm for the node π evaluates to an s-graph in which exactly the nodes in V_π are source nodes.[2] In the example, we obtain (3) from the tree decomposition in Fig. 4 like this.

The *tree-width* k of an HRG rule is measured by finding the tree decomposition of the rule for which the node sets have the lowest maximum size s and setting $k = s - 1$. It is a crucial measure because Chiang et al.'s parsing algorithm is exponential in k. The translation we just sketched uses s source names. Thus we see that a HRG with rules of tree-width $\leq k$ can be encoded into an s-graph grammar with $k + 1$ source names. (The converse is also true.)

5 Graph parsing with s-graph grammars

Now we show how to compute decomposition grammars for the s-graph algebra. As we explained in Section 4.2, we can then obtain a complete parser for s-graph grammars through generic methods.

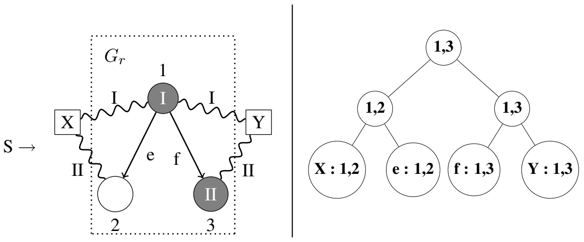

Figure 4: An HRG rule (left) with one of its tree decompositions (right).

Given an s-graph SG, the language of the decomposition grammar D_{SG} is the set of all terms over the HR algebra that evaluate to SG. For example, the decomposition grammar for the graph SG in Fig. 1(a) contains – among many others – the following two rules:

(4) $SG \to \mathsf{f}_{\mathsf{R}}(SG_f)$
(5) $SG_e \to \ \mid\mid (SG_b, SG_d)$,

where SG_f, SG_e, SG_b, and SG_d are the graphs from Fig. 1 (see Section 3.1). In other words, D_{SG} keeps track of sub-s-graphs in the nonterminals, and the rules spell out how "larger" sub-s-graphs can be constructed from "smaller" sub-s-graphs using the operations of the HR algebra. The algorithms below represent sub-s-graphs compactly using s-component and boundary representations.

Because the decomposition grammars in the s-graph algebra can be very large (see Section 6), we will not usually compute the entire decomposition grammar explicitly. Instead, it is sufficient to maintain a lazy representation of D_{SG}, which allows us to answer *queries* to the decomposition grammar efficiently. During parsing, such queries will be generated by the generic part of the parsing algorithm. Specifically, we will show how to answer the following types of query:

- *Top-down:* given an s-component representation $\mathcal{C}$ of some s-graph and an algebra operation o, enumerate all the rules $\mathcal{C} \to o(\mathcal{C}_1, \dots, \mathcal{C}_k)$ in D_{SG}. This asks how a larger sub-s-graph can be derived from other sub-s-graphs using the operation o. In the example above, a query for SG and $\mathsf{f}_{\mathsf{R}}(\cdot)$ should yield, among others, the rule in (4).

- *Bottom-up:* given boundary representations $\beta_1, \dots, \beta_k$ and an algebra operation o, enumerate all the rules $\beta \to o(\beta_1, \dots, \beta_k)$ in D_{SG}. This asks how smaller sub-s-graphs can be combined into a bigger one using the

[2] This uses the swap operations mentioned in Footnote 1.

	forget	rename	merge
bottom-up	$O(d+s)$	$O(s)$	$O(ds)$
top-down	$O(ds)$	$O(s)$	$O(ds)$

Table 1: Amortized per-rule runtimes T for the different rule types.

operation o. In the example above, a merge query for SG_b and SG_d should yield the rule in (5). Unlike in the top-down case, every bottom-up query returns at most one rule.

The runtime of the complete parsing algorithm is bounded by the number I of different queries to D_{SG} that we receive, multiplied by the *per-rule runtime* T that we need to answer each query. The factor I is analogous to the number of rule instances in schema-based parsing (Shieber et al., 1995). The factor T is often ignored in the analysis of parsing algorithms, because in parsing schemata for strings, we typically have $T = O(1)$. This need not be the case for graph parsers. In the HRG parsing schema of Chiang et al. (2013), we have $I = O(n^{k+1}3^{d(k+1)})$, where k is the treewidth of the HRG. In addition, each of their rule instances takes time $T = O(d(k+1))$ to actually calculate the new item.

Below, we show how we can efficiently answer both bottom-up and top-down queries to D_{SG}. Every s-graph grammar has an equivalent normal form where every constant describes an s-graph with a single edge. Assuming that the grammar is in this normal form, queries of the form $\beta \rightarrow g$ (resp. $\mathcal{C} \rightarrow g$), where g is a constant of the HR-algebra, are trivial and we will not consider them further. Table 1 summarizes our results.

5.1 Bottom-up decomposition

Forget and rename. Given a boundary representation $\beta' = (E', \phi')$, answering the bottom-up forget query $\beta \rightarrow \mathsf{f}_\mathsf{A}(\beta')$ amounts to verifying that all edges incident to $\phi'(\mathsf{A})$ are in-boundary in β', since otherwise the result would not be extensible. This takes time $O(d)$. We then let $\beta = (E, \phi)$, where ϕ is like ϕ' but undefined on A, and E is the set of edges in E' that are still incident to a source in ϕ. Computing β thus takes time $O(d+s)$.

The rename operation works similarly, but since the edge set remains unmodified, the per-rule runtime is $O(s)$.

A BR is fully determined by specifying the node and in-boundary edges for each source name, so there are at most $O\left(\left(n2^d\right)^s\right)$ different BRs. Since the result of a forget or rename rule is determined by the child β', this is an upper bound for the number I of rule instances of forget or rename.

Merge. Now consider the bottom-up merge query for the boundary representations β_1 and β_2. As we saw in Section 3.3, $T(\beta_1) \mid\mid T(\beta_2)$ is not always defined. But if it is, we can answer the query with the rule $(\beta_1 \mid\mid \beta_2) \rightarrow \ \mid\mid (\beta_1, \beta_2)$, with $\beta_1 \mid\mid \beta_2$ defined as in Section 3.3. Computing this BR takes time $O(ds)$.

We can check whether $T(\beta_1) \mid\mid T(\beta_2)$ is defined by going through the conditions of Lemma 2. The only nontrivial condition is (c). In order to check it efficiently, we precompute a data structure which contains, for any two nodes $u, v \in V$, the length k of the shortest undirected path $u = v_1 \leftrightarrow \ldots \overset{e}{\leftrightarrow} v_k = v$ and the last edge e on this path. This can be done in time $O(n^3)$ using the Floyd-Warshall algorithm. Checking (c) for every source pair then takes time $O(s^2)$ per rule, but because sources that are common to both β_1 and β_2 automatically satisfy (c) due to (a), one can show that the total runtime of checking (c) for all merge rules of D_SG is $O(n^s 3^{ds} s)$.

Observe finally that there are $I = O(n^s 3^{ds})$ instances of the merge rule, because each of the $O(ds)$ edges that are incident to a source node can be either in β_1, in β_2, or in neither. Therefore the runtime for checking (c) amortizes to $O(s)$ per rule. The Floyd-Warshall step amortizes to $O(1)$ per rule for $s \geq 3$; for $s \leq 2$ the node table can be computed in amortized $O(1)$ using more specialized algorithms. This yields a total amortized per-rule runtime T for bottom-up merge of $O(ds)$.

5.2 Top-down decomposition

For the top-down queries, we specify sub-s-graphs in terms of their s-component representations. The number I of instances of each rule type is the same as in the bottom-up case because of the one-to-one correspondence of s-component and boundary representations. We focus on merge and forget queries; rename is as above.

Merge. Given an s-component representation $\mathcal{C} = (C, \phi)$, a top-down merge query asks us to enumerate the rules $\mathcal{C} \rightarrow \ \mid\mid (\mathcal{C}_1, \mathcal{C}_2)$ such that $T(\mathcal{C}_1) \mid\mid T(\mathcal{C}_2) = T(\mathcal{C})$. By Lemma 1, we can do this by using every distribution of the s-components in C over $\mathcal{C}_1$ and $\mathcal{C}_2$ and restricting ϕ

accordingly. This brings the per-rule time of top-down merge to $O(ds)$, the maximum number of s-components in C.

Block-cutpoint graphs. The challenging query to answer top-down is forget. We will first describe the problem and introduce a data structure that supports efficient top-down forget queries.

Consider top-down forget queries on the sub-s-graph SG_1 drawn in bold in Fig. 2(a); its s-component representation is $\langle\{[a],[g]\},\{\mathsf{A}{:}4,\mathsf{B}{:}5\}\rangle$. A top-down forget might promote the node 3 to a C-source, yielding a sub-s-graph SG_2 (that is, $\mathsf{f}_{\mathsf{C}}(SG_2)$ is the original s-graph SG_1). In SG_2, a, e, and f are no longer equivalent; its s-component representation is $\langle\{[a],[e],[f],[g]\},\{\mathsf{A}{:}4,\mathsf{B}{:}5,\mathsf{C}{:}3\}\rangle$. Thus promoting 3 to a source splits the original s-component into smaller parts.

By contrast, the same top-down forget might also promote the node 1 to a C-source, yielding a sub-s-graph SG_3; $\mathsf{f}_{\mathsf{C}}(SG_3)$ is also SG_1. However, all edges in $[a]$ are still equivalent in SG_3; its s-component representation is $\langle\{[a],[g]\},\{\mathsf{A}{:}4,\mathsf{B}{:}5,\mathsf{C}{:}1\}\rangle$.

An algorithm for top-down forget must be able to determine whether promotion of a node splits an s-component or not. To do this, let G be the input graph. We create an undirected auxiliary graph G^U from G and a set U of (source) nodes. G^U contains all nodes in $V \backslash U$, and for each edge e that is incident to a node $u \in U$, it contains a node (u,e). Furthermore, G^U contains undirected versions of all edges in G; if an edge $e \in E$ is incident to a node $u \in U$, it becomes incident to (u,e) in G^U instead. The auxiliary graph $G^{\{4,5\}}$ for our example graph is shown in Fig. 2(d).

Two edges are connected in G^U if and only if they are equivalent with respect to U in G. Therefore, promotion of u splits s-components iff u is a *cutpoint* in G^U, i.e. a node whose removal disconnects the graph. Cutpoints can be characterized as those nodes that belong to multiple *biconnected components (BCCs)* of G^U, i.e. the maximal subgraphs such that any node can be removed without disconnecting a graph segment. In Fig. 2(d), the BCCs are indicated by the dotted boxes. Observe that 3 is a cutpoint and 1 is not.

For any given U, we can represent the structure of the BCCs of G^U in its *block-cutpoint graph*. This is a bipartite graph whose nodes are the cutpoints and BCCs of G^U, and a BCC is connected to all of its cutpoints; see Fig. 2(e) for the block-cutpoint graph of the example. Block-cutpoint graphs are always forests, with the individual trees representing the s-components of G. Promoting a cutpoint u splits the s-component into smaller parts, each corresponding to an incident edge of u. We annotate each edge with that part.

Forget. We can now answer a top-down forget query $\mathcal{C} \rightarrow \mathsf{f}_{\mathsf{A}}(\mathcal{C}')$ efficiently from the block-cutpoint graph for the sources of $\mathcal{C} = (C,\phi)$. We iterate over all components $c \in C$, and then over all internal nodes u of c. If u is not a cutpoint, we simply let $\mathcal{C}' = (C',\phi')$ by making u an A-source and letting $C' = C$. Otherwise, we also remove c from C and add the new s-components on the edges adjacent to u in the block-cutpoint graph. The query returns rules for all $\mathcal{C}'$ that can be constructed like this.

The per-rule runtime of top-down forget is $O(ds)$, the time needed to compute C' in the cutpoint case. We furthermore precompute the block-cutpoint graphs for the input graph with respect to all sets $U \subseteq V$ of nodes with $|U| \leq s-1$. For each U, we can compute the block-cutpoint graph and annotate its edges in time $O(nd^2s)$. Thus the total time for the precomputation is $O(n^s \cdot d^2s)$, which amortizes to $O(1)$ per rule.

6 Evaluation

We evaluate the performance of our algorithms on the "Little Prince" AMR-Bank version 1.4, available from `amr.isi.edu`. This graph-bank consists of 1562 sentences manually annotated with AMRs. We implemented our algorithms in Java as part of the Alto parser for IRTGs (Alto Developers, 2015), and compared them to the Bolinas HRG parser (Andreas et al., 2013). We measured runtimes using Java 8 (for Alto) and Pypy 2.5.0 (for Bolinas) on an Intel Xeon E7-8857 CPU at 3 GHz, after warming up the JIT compilers.

As there are no freely available grammars for this dataset, we created our own for the evaluation, using Bayesian grammar induction roughly along the lines of Cohn et al. (2010). We provide the grammars as supplementary material. Around 64% of the AMRs in the graph-bank have treewidth 1 and can thus be parsed using $s = 2$ source names. 98% have treewidth 1 or 2, corresponding to $s = 3$ source names. All experiments evaluated parser times on the same AMRs from which the grammar was sampled.

Top-down versus bottom-up. Fig. 5 compares the performance of the top-down and the bottom-up algorithm, on a grammar with three source names sampled from all 1261 graphs with up to 10 nodes. Each point in the figure is the geometric mean of runtimes for all graphs with a given number of nodes; note the log-scale. We aborted the top-down parser after its runtimes grew too large.

We observe that the bottom-up algorithm outperforms the top-down algorithm, and yields practical runtimes even for nontrivial graphs. One possible explanation for the difference is that the top-down algorithm spends more time analyzing ungrammatical s-graphs, particularly subgraphs that are not connected.

Comparison to Bolinas. We also compare our implementations to Bolinas. Because Bolinas is much slower than Alto, we restrict ourselves to two source names (= treewidth 1) and sampled the grammar from 30 randomly chosen AMRs each of size 2 to 8, plus the 21 AMRs of size one.

Fig. 6 shows the runtimes. Our parsers are generally much faster than in Fig. 5, due to the decreased number of sources and grammar size. They are also both much faster than Bolinas. Measuring the total time for parsing all 231 AMRs, our bottom-up algorithm outperforms Bolinas by a factor of 6722. The top-down algorithm is slower, but still outperforms Bolinas by a factor of 340.

Further analysis. In practice, memory use can be a serious issue. For example, the decomposition grammar for s=3 for AMR #194 in the corpus has over 300 million rules. However, many uses of decomposition grammars, such as sampling for grammar induction, can be phrased purely in terms of top-down queries. The top-down algorithm can answer these without computing the entire grammar, alleviating the memory problem.

Finally, we analyzed the asymptotic runtimes in Table 1 in terms of the maximum number $d \cdot s$ of in-boundary edges. However, the top-down parser does not manipulate individual edges, but entire s-components. The maximum number D_s of s-components into which a set of s sources can split a graph is called the *s-separability* of G by Lautemann (1990). We can analyze the runtime of the top-down parser more carefully as $O(n^s 3^{D_s} ds)$; as the dotted line in Fig. 5 shows, this predicts the runtime well. Interestingly, D_s is much lower in practice than its theoretical maximum. In the "Little Prince" AMR-Bank, the mean of D_3 is 6.0, whereas the mean of $3 \cdot d$ is 12.7. Thus exploiting the s-component structure of the graph can improve parsing times.

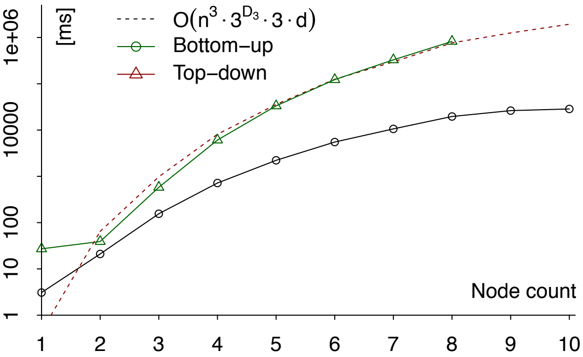

Figure 5: Runtimes of our parsers with $s = 3$.

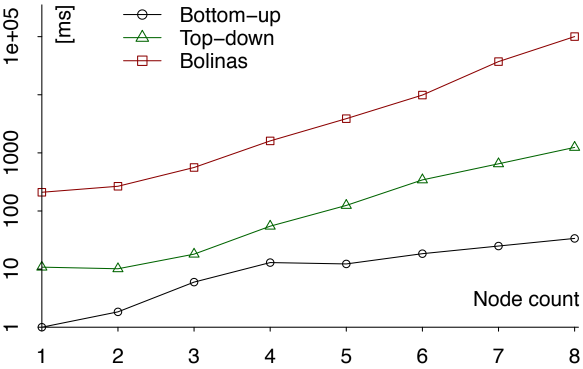

Figure 6: Runtimes of our parsers and Bolinas with $s = 2$.

7 Conclusion

We presented two new graph parsing algorithms for s-graph grammars. These were framed in terms of top-down and bottom-up queries to a decomposition grammar for the HR algebra. Our implementations outperform Bolinas, the previously best system, by several orders of magnitude. We have made them available as part of the Alto parser.

A challenge for grammar-based semantic parsing is grammar induction from data. We will explore this problem in future work. Furthermore, we will investigate methods for speeding up graph parsing further, e.g. with different heuristics.

Acknowledgments. We thank the anonymous reviewers for their comments, and Daniel Bauer for his help with Bolinas. We received valuable feedback at the 2015 Dagstuhl seminar on graph grammars and the 2014 Johns Hopkins workshop in Prague. This work was supported by the DFG grant KO 2916/2-1.

Abstract

Current distributed representations of words show little resemblance to theories of lexical semantics. The former are dense and uninterpretable, the latter largely based on familiar, discrete classes (e.g., supersenses) and relations (e.g., synonymy and hypernymy). We propose methods that transform word vectors into sparse (and optionally binary) vectors. The resulting representations are more similar to the interpretable features typically used in NLP, though they are discovered automatically from raw corpora. Because the vectors are highly sparse, they are computationally easy to work with. Most importantly, we find that they outperform the original vectors on benchmark tasks.

1 Introduction

Distributed representations of words have been shown to benefit NLP tasks like parsing (Lazaridou et al., 2013; Bansal et al., 2014), named entity recognition (Guo et al., 2014), and sentiment analysis (Socher et al., 2013). The attraction of word vectors is that they can be derived directly from raw, unannotated corpora. Intrinsic evaluations on various tasks are guiding methods toward discovery of a representation that captures many facts about lexical semantics (Turney, 2001; Turney and Pantel, 2010).

Yet word vectors do not look anything like the representations described in most lexical semantic theories, which focus on identifying classes of words (Levin, 1993; Baker et al., 1998; Schuler, 2005) and relationships among word meanings (Miller, 1995). Though expensive to construct, conceptualizing word meanings symbolically is important for theoretical understanding and also when we incorporate lexical semantics into computational models where interpretability is desired. On the surface, discrete theories seem incommensurate with the distributed approach, a problem now receiving much attention in computational linguistics (Lewis and Steedman, 2013; Kiela and Clark, 2013; Vecchi et al., 2013; Grefenstette, 2013; Lewis and Steedman, 2014; Paperno et al., 2014).

Our contribution to this discussion is a new, principled sparse coding method that transforms any distributed representation of words into sparse vectors, which can then be transformed into binary vectors (§2). Unlike recent approaches of incorporating semantics in distributional word vectors (Yu and Dredze, 2014; Xu et al., 2014; Faruqui et al., 2015), the method does not rely on any external information source. The transformation results in longer, sparser vectors, sometimes called an "overcomplete" representation (Olshausen and Field, 1997). Sparse, overcomplete representations have been motivated in other domains as a way to increase separability and interpretability, with each instance (here, a word) having a small number of active dimensions (Olshausen and Field, 1997; Lewicki and Sejnowski, 2000), and to increase stability in the presence of noise (Donoho et al., 2006).

Our work builds on recent explorations of sparsity as a useful form of inductive bias in NLP and machine learning more broadly (Kazama and Tsujii, 2003; Goodman, 2004; Friedman et al., 2008; Glorot et al., 2011; Yogatama and Smith, 2014, *inter alia*). Introducing sparsity in word vector dimensions has been shown to improve dimension interpretability (Murphy et al., 2012; Fyshe et al., 2014) and usability of word vectors as features in downstream tasks (Guo et al., 2014). The word vectors we produce are more than 90% sparse; we also consider binarizing transformations that bring them closer to the categories and relations of lex-

ical semantic theories. Using a number of state-of-the-art word vectors as input, we find consistent benefits of our method on a suite of standard benchmark evaluation tasks (§3). We also evaluate our word vectors in a word intrusion experiment with humans (Chang et al., 2009) and find that our sparse vectors are more interpretable than the original vectors (§4).

We anticipate that sparse, binary vectors can play an important role as features in statistical NLP models, which still rely predominantly on discrete, sparse features whose interpretability enables error analysis and continued development. We have made an implementation of our method publicly available.[1]

2 Sparse Overcomplete Word Vectors

We consider methods for transforming dense word vectors to sparse, binary overcomplete word vectors. Fig. 1 shows two approaches. The one on the top, method A, converts dense vectors to sparse overcomplete vectors (§2.1). The one beneath, method B, converts dense vectors to sparse and binary overcomplete vectors (§2.2 and §2.4).

Let V be the vocabulary size. In the following, $\mathbf{X} \in \mathbb{R}^{L \times V}$ is the matrix constructed by stacking V non-sparse "input" word vectors of length L (produced by an arbitrary word vector estimator). We will refer to these as initializing vectors. $\mathbf{A} \in \mathbb{R}^{K \times V}$ contains V sparse overcomplete word vectors of length K. "Overcomplete" representation learning implies that $K > L$.

2.1 Sparse Coding

In sparse coding (Lee et al., 2006), the goal is to represent each input vector $\mathbf{x}_i$ as a sparse linear combination of basis vectors, $\mathbf{a}_i$. Our experiments consider four initializing methods for these vectors, discussed in Appendix A. Given $\mathbf{X}$, we seek to solve

$$\operatorname*{arg\,min}_{\mathbf{D},\mathbf{A}} \|\mathbf{X} - \mathbf{D}\mathbf{A}\|_2^2 + \lambda\Omega(\mathbf{A}) + \tau\|\mathbf{D}\|_2^2, \quad (1)$$

where $\mathbf{D} \in \mathbb{R}^{L \times K}$ is the dictionary of basis vectors. λ is a regularization hyperparameter, and Ω is the regularizer. Here, we use the squared loss for the reconstruction error, but other loss functions could also be used (Lee et al., 2009). To obtain sparse word representations we will impose an ℓ_1 penalty on $\mathbf{A}$. Eq. 1 can be broken down into loss for each word vector which can be optimized separately in parallel (§2.3):

$$\operatorname*{arg\,min}_{\mathbf{D},\mathbf{A}} \sum_{i=1}^{V} \|\mathbf{x}_i - \mathbf{D}\mathbf{a}_i\|_2^2 + \lambda\|\mathbf{a}_i\|_1 + \tau\|\mathbf{D}\|_2^2 \quad (2)$$

where $\mathbf{m}_i$ denotes the ith column vector of matrix $\mathbf{M}$. Note that this problem is not convex. We refer to this approach as **method A**.

2.2 Sparse Nonnegative Vectors

Nonnegativity in the feature space has often been shown to correspond to interpretability (Lee and Seung, 1999; Cichocki et al., 2009; Murphy et al., 2012; Fyshe et al., 2014; Fyshe et al., 2015). To obtain nonnegative sparse word vectors, we use a variation of the nonnegative sparse coding method (Hoyer, 2002). Nonnegative sparse coding further constrains the problem in Eq. 2 so that $\mathbf{D}$ and $\mathbf{a}_i$ are nonnegative. Here, we apply this constraint only to the representation vectors $\{\mathbf{a}_i\}$. Thus, the new objective for nonnegative sparse vectors becomes:

$$\operatorname*{arg\,min}_{\mathbf{D} \in \mathbb{R}_{\geq 0}^{L \times K}, \mathbf{A} \in \mathbb{R}_{\geq 0}^{K \times V}} \sum_{i=1}^{V} \|\mathbf{x}_i - \mathbf{D}\mathbf{a}_i\|_2^2 + \lambda\|\mathbf{a}_i\|_1 + \tau\|\mathbf{D}\|_2^2 \quad (3)$$

This problem will play a role in our second approach, **method B**, to which we will return shortly. This nonnegativity constraint can be easily incorporated during optimization, as explained next.

2.3 Optimization

We use online adaptive gradient descent (AdaGrad; Duchi et al., 2010) for solving the optimization problems in Eqs. 2–3 by updating $\mathbf{A}$ and $\mathbf{D}$. In order to speed up training we use asynchronous updates to the parameters of the model in parallel for every word vector (Duchi et al., 2012; Heigold et al., 2014).

However, directly applying stochastic subgradient descent to an ℓ_1-regularized objective fails to produce sparse solutions in bounded time, which has motivated several specialized algorithms that target such objectives. We use the AdaGrad variant of one such learning algorithm, the regularized dual averaging algorithm (Xiao, 2009), which keeps track of the online average gradient at time t: $\bar{g}_t = \frac{1}{t}\sum_{t'=1}^{t} g_{t'}$ Here, the subgradients do not include terms for the regularizer; they are derivatives of the unregularized objective ($\lambda = 0, \tau = 0$)

Sparse, binary overcomplete vectors

Figure 1: Methods for obtaining sparse overcomplete vectors (top, method A, §2.1) and sparse, binary overcomplete word vectors (bottom, method B, §2.2 and §2.4). Observed dense vectors of length L (left) are converted to sparse non-negative vectors (center) of length K which are then projected into the binary vector space (right), where $L \ll K$. $\mathbf{X}$ is dense, $\mathbf{A}$ is sparse, and $\mathbf{B}$ is the binary word vector matrix. Strength of colors signify the magnitude of values; negative is red, positive is blue, and zero is white.

with respect to $\mathbf{a}_i$. We define

$$\gamma = -\text{sign}(\bar{g}_{t,i,j})\frac{\eta t}{\sqrt{G_{t,i,j}}}(|\bar{g}_{t,i,j}| - \lambda),$$

where $G_{t,i,j} = \sum_{t'=1}^{t} g_{t',i,j}^2$. Now, using the average gradient, the ℓ_1-regularized objective is optimized as follows:

$$a_{t+1,i,j} = \begin{cases} 0, & \text{if } |\bar{g}_{t,i,j}| \leq \lambda \\ \gamma, & \text{otherwise} \end{cases} \tag{4}$$

where, $a_{t+1,i,j}$ is the jth element of sparse vector $\mathbf{a}_i$ at the tth update and $\bar{g}_{t,i,j}$ is the corresponding average gradient. For obtaining nonnegative sparse vectors we take projection of the updated $\mathbf{a}_i$ onto $\mathbb{R}_{\geq 0}^K$ by choosing the closest point in $\mathbb{R}_{\geq 0}^K$ according to Euclidean distance (which corresponds to zeroing out the negative elements):

$$a_{t+1,i,j} = \begin{cases} 0, & \text{if } |\bar{g}_{t,i,j}| \leq \lambda \\ 0, & \text{if } \gamma < 0 \\ \gamma, & \text{otherwise} \end{cases} \tag{5}$$

2.4 Binarizing Transformation

Our aim with **method B** is to obtain word representations that can emulate the binary-feature space designed for various NLP tasks. We could

$\mathbf{X}$	L	λ	τ	K	% Sparse
Glove	300	1.0	10^{-5}	3000	91
SG	300	0.5	10^{-5}	3000	92
GC	50	1.0	10^{-5}	500	98
Multi	48	0.1	10^{-5}	960	93

Table 1: Hyperparameters for learning sparse overcomplete vectors tuned on the WS-353 task. Tasks are explained in §B. The four initial vector representations $\mathbf{X}$ are explained in §A.

hot, fresh, fish, 1/2, wine, salt
series, tv, appearances, episodes
1975, 1976, 1968, 1970, 1977, 1969
dress, shirt, ivory, shirts, pants
upscale, affluent, catering, clientele

Table 2: Highest frequency words in randomly picked word clusters of binary sparse overcomplete Glove vectors.

state this as an optimization problem:

$$\operatorname*{arg\,min}_{\substack{\mathbf{D}\in\mathbb{R}^{L\times K}\\ \mathbf{B}\in\{0,1\}^{K\times V}}} \sum_{i=1}^{V} \|\mathbf{x}_i - \mathbf{D}\mathbf{b}_i\|_2^2 + \lambda\|\mathbf{b}_i\|_1^1 + \tau\|\mathbf{D}\|_2^2 \tag{6}$$

where $\mathbf{B}$ denotes the binary (and also sparse) representation. This is an mixed integer bilinear program, which is NP-hard (Al-Khayyal and Falk, 1983). Unfortunately, the number of variables in the problem is $\approx KV$ which reaches 100 million when $V = 100,000$ and $K = 1,000$, which is intractable to solve using standard techniques.

A more tractable relaxation to this hard problem is to first constrain the continuous representation $\mathbf{A}$ to be nonnegative (i.e, $\mathbf{a}_i \in \mathbb{R}^K_{\geq 0}$; §2.2). Then, in order to avoid an expensive computation, we take the nonnegative word vectors obtained using Eq. 3 and project nonzero values to 1, preserving the 0 values. Table 2 shows a random set of word clusters obtained by (i) applying our method to Glove initial vectors and (ii) applying k-means clustering ($k = 100$). In §3 we will find that these vectors perform well quantitatively.

2.5 Hyperparameter Tuning

Methods A and B have three hyperparameters: the ℓ_1-regularization penalty λ, the ℓ_2-regularization penalty τ, and the length of the overcomplete word vector representation K. We perform a grid search on $\lambda \in \{0.1, 0.5, 1.0\}$ and $K \in \{10L, 20L\}$, selecting values that maximizes performance on one "development" word similarity task (WS-353, discussed in §B) while achieving at least 90% sparsity in overcomplete vectors. τ was tuned on one collection of initializing vectors (Glove, discussed in §A) so that the vectors in $\mathbf{D}$ are near unit norm. The four vector representations and their corresponding hyperparameters selected by this procedure are summarized in Table 1. There hyperparameters were chosen for method A and retained for method B.

3 Experiments

Using methods A and B, we constructed sparse overcomplete vector representations $\mathbf{A}$, starting from four initial vector representations $\mathbf{X}$; these are explained in Appendix A. We used one benchmark evaluation (WS-353) to tune hyperparameters, resulting in the settings shown in Table 1; seven other tasks were used to evaluate the quality of the sparse overcomplete representations. The first of these is a word similarity task, where the score is correlation with human judgments, and the others are classification accuracies of an ℓ_2-regularized logistic regression model trained using the word vectors. These tasks are described in detail in Appendix B.

3.1 Effects of Transforming Vectors

First, we quantify the effects of our transformations by comparing their output to the initial ($\mathbf{X}$) vectors. Table 3 shows consistent improvements of sparsifying vectors (method A). The exceptions are on the SimLex task, where our sparse vectors are worse than the skip-gram initializer and on par with the multilingual initializer. Sparsification is beneficial across all of the text classification tasks, for all initial vector representations. On average across all vector types and all tasks, sparse overcomplete vectors outperform their corresponding initializers by 4.2 points.[2]

Binarized vectors (from method B) are also usually better than the initial vectors (also shown in Table 3), and tend to outperform the sparsified variants, except when initializing with Glove. On average across all vector types and all tasks, binarized overcomplete vectors outperform their corresponding initializers by 4.8 points and the continuous, sparse intermediate vectors by 0.6 points.

From here on, we explore more deeply the sparse overcomplete vectors from method A (denoted by $\mathbf{A}$), leaving binarization and method B aside.

3.2 Effect of Vector Length

How does the length of the overcomplete vector (K) affect performance? We focus here on the Glove vectors, where $L = 300$, and report average performance across all tasks. We consider $K = \alpha L$ where $\alpha \in \{2, 3, 5, 10, 15, 20\}$. Figure 2 plots the average performance across tasks against α. The earlier selection of $K = 3,000$ ($\alpha = 10$) gives the best result; gains are monotonic in α to that point and then begin to diminish.

3.3 Alternative Transformations

We consider two alternative transformations. The first preserves the original vector length but

[2] We report correlation on a 100 point scale, so that the average which includes accuracuies and correlation is equally representatitve of both.

Vectors		SimLex Corr.	Senti. Acc.	TREC Acc.	Sports Acc.	Comp. Acc.	Relig. Acc.	NP Acc.	Average
Glove	**X**	36.9	77.7	76.2	95.9	79.7	86.7	77.9	76.2
	A	38.9	**81.4**	**81.5**	**96.3**	**87.0**	**88.8**	**82.3**	**79.4**
	B	**39.7**	81.0	81.2	95.7	84.6	87.4	81.6	78.7
SG	**X**	**43.6**	81.5	77.8	97.1	80.2	85.9	80.1	78.0
	A	41.7	**82.7**	81.2	**98.2**	84.5	86.5	81.6	79.4
	B	42.8	81.6	**81.6**	95.2	**86.5**	**88.0**	**82.9**	**79.8**
GC	**X**	9.7	68.3	64.6	75.1	60.5	76.0	79.4	61.9
	A	12.0	73.3	77.6	77.0	68.3	**81.0**	**81.2**	67.2
	B	**18.7**	**73.6**	**79.2**	**79.7**	**70.5**	79.6	79.4	**68.6**
Multi	**X**	**28.7**	75.5	63.8	83.6	64.3	81.8	79.2	68.1
	A	28.1	**78.6**	79.2	93.9	78.2	84.5	81.1	74.8
	B	**28.7**	77.6	**82.0**	**94.7**	**81.4**	**85.6**	**81.9**	**75.9**

Table 3: Performance comparison of transformed vectors to initial vectors **X**. We show sparse overcomplete representations **A** and also binarized representations **B**. Initial vectors are discussed in §A and tasks in §B.

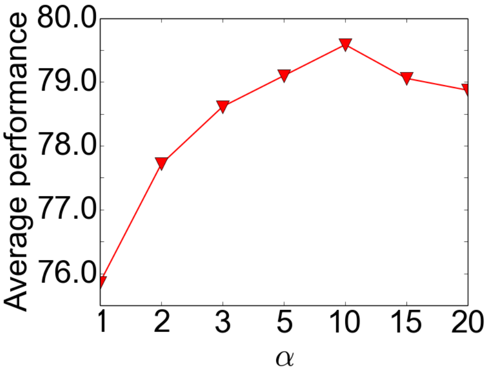

Figure 2: Average performace across all tasks for sparse overcomplete vectors (**A**) produced by Glove initial vectors, as a function of the ratio of K to L.

achieves a binary, sparse vector (**B**) by applying:

$$b_{i,j} = \begin{cases} 1 & \text{if } x_{i,j} > 0 \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

The second transformation was proposed by Guo et al. (2014). Here, the original vector length is also preserved, but sparsity is achieved through:

$$a_{i,j} = \begin{cases} 1 & \text{if } x_{i,j} \geq M^{+} \\ -1 & \text{if } x_{i,j} \leq M^{-} \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

where M^{+} (M^{-}) is the mean of positive-valued (negative-valued) elements of **X**. These vectors are, obviously, not binary.

We find that on average, across initializing vectors and across all tasks that our sparse overcomplete (**A**) vectors lead to better performance than either of the alternative transformations.

4 Interpretability

Our hypothesis is that the dimensions of sparse overcomplete vectors are more interpretable than those of dense word vectors. Following Murphy et al. (2012), we use a word intrusion experiment (Chang et al., 2009) to corroborate this hypothesis. In addition, we conduct qualitative analysis of interpretability, focusing on individual dimensions.

4.1 Word Intrusion

Word intrusion experiments seek to quantify the extent to which dimensions of a learned word representation are coherent to humans. In one instance of the experiment, a human judge is presented with five words in random order and asked to select the "intruder." The words are selected by the experimenter by choosing one dimension j of the learned representation, then ranking the words on that dimension alone. The dimensions are chosen in decreasing order of the variance of their values across the vocabulary. Four of the words are the top-ranked words according to j, and the "true" intruder is a word from the bottom half of the list, chosen to be a word that appears in the top 10% of some other dimension. An example of an instance is:

naval, industrial, technological, marine, identity

$\mathbf{X}$:	Glove	SG	GC	Multi	Average
$\mathbf{X}$	76.2	78.0	61.9	68.1	71.0
Eq. 7	75.7	75.8	60.5	64.1	69.0
Eq. 8 (Guo et al., 2014)	75.8	76.9	60.5	66.2	69.8
$\mathbf{A}$	**79.4**	**79.4**	**67.2**	**74.8**	**75.2**

Table 4: Average performance across all tasks and vector models using different transformations.

Vectors	A1	A2	A3	Avg.	IAA	κ
$\mathbf{X}$	61	53	56	57	70	0.40
$\mathbf{A}$	71	70	72	71	77	0.45

Table 5: Accuracy of three human annotators on the word intrusion task, along with the average inter-annotator agreement (Artstein and Poesio, 2008) and Fleiss' κ (Davies and Fleiss, 1982).

(The last word is the intruder.)

We formed instances from initializing vectors and from our sparse overcomplete vectors ($\mathbf{A}$). Each of these two combines the four different initializers $\mathbf{X}$. We selected the 25 dimensions d in each case. Each of the 100 instances per condition (initial vs. sparse overcomplete) was given to three judges.

Results in Table 5 confirm that the sparse overcomplete vectors are more interpretable than the dense vectors. The inter-annotator agreement on the sparse vectors increases substantially, from 57% to 71%, and the Fleiss' κ increases from "fair" to "moderate" agreement (Landis and Koch, 1977).

4.2 Qualitative Evaluation of Interpretability

If a vector dimension is interpretable, the top-ranking words for that dimension should display semantic or syntactic groupings. To verify this qualitatively, we select five dimensions with the highest variance of values in initial and sparsified GC vectors. We compare top-ranked words in the dimensions extracted from the two representations. The words are listed in Table 6, a dimension per row. Subjectively, we find the semantic groupings better in the sparse vectors than in the initial vectors.

Figure 3 visualizes the sparsified GC vectors for six words. The dimensions are sorted by the average value across the three "animal" vectors. The animal-related words use many of the same dimensions (102 common active dimensions out of 500 total); in constrast, the three city names use mostly distinct vectors.

$\mathbf{X}$	combat, guard, honor, bow, trim, naval 'll, could, faced, lacking, seriously, scored see, n't, recommended, depending, part due, positive, equal, focus, respect, better sergeant, comments, critics, she, videos
$\mathbf{A}$	fracture, breathing, wound, tissue, relief relationships, connections, identity, relations files, bills, titles, collections, poems, songs naval, industrial, technological, marine stadium, belt, championship, toll, ride, coach

Table 6: Top-ranked words per dimension for initial and sparsified GC representations. Each line shows words from a different dimension.

5 Related Work

To the best of our knowledge, there has been no prior work on obtaining overcomplete word vector representations that are sparse and categorical. However, overcomplete features have been widely used in image processing, computer vision (Olshausen and Field, 1997; Lewicki and Sejnowski, 2000) and signal processing (Donoho et al., 2006). Nonnegative matrix factorization is often used for interpretable coding of information (Lee and Seung, 1999; Liu et al., 2003; Cichocki et al., 2009).

Sparsity constraints are in general useful in NLP problems (Kazama and Tsujii, 2003; Friedman et al., 2008; Goodman, 2004), like POS tagging (Ganchev et al., 2009), dependency parsing (Martins et al., 2011), text classification (Yogatama and Smith, 2014), and representation learning (Bengio et al., 2013). Including sparsity constraints in Bayesian models of lexical semantics like LDA in the form of sparse Dirichlet priors has been shown to be useful for downstream tasks like POS-tagging (Toutanova and Johnson, 2007), and improving interpretation (Paul and Dredze, 2012; Zhu and Xing, 2012).

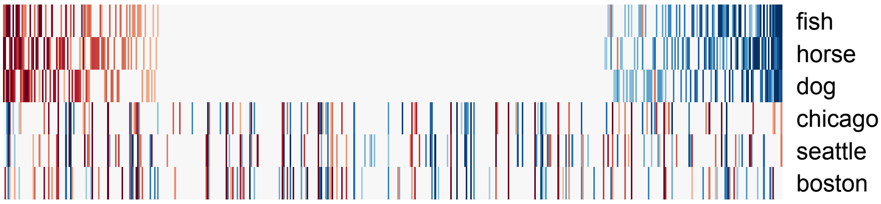

Figure 3: Visualization of sparsified GC vectors. Negative values are red, positive values are blue, zeroes are white.

6 Conclusion

We have presented a method that converts word vectors obtained using any state-of-the-art word vector model into sparse and optionally binary word vectors. These transformed vectors appear to come closer to features used in NLP tasks and outperform the original vectors from which they are derived on a suite of semantics and syntactic evaluation benchmarks. We also find that the sparse vectors are more interpretable than the dense vectors by humans according to a word intrusion detection test.

A Initial Vector Representations (X)

Our experiments consider four publicly available collections of pre-trained word vectors. They vary in the amount of data used and the estimation method.

Glove. Global vectors for word representations (Pennington et al., 2014) are trained on aggregated global word-word co-occurrence statistics from a corpus. These vectors were trained on 6 billion words from Wikipedia and English Gigaword and are of length 300.[3]

Skip-Gram (SG). The word2vec tool (Mikolov et al., 2013) is fast and widely-used. In this model, each word's Huffman code is used as an input to a log-linear classifier with a continuous projection layer and words within a given context window are predicted. These vectors were trained on 100 billion words of Google news data and are of length 300.[4]

Global Context (GC). These vectors are learned using a recursive neural network that incorporates both local and global (document-level) context features (Huang et al., 2012). These vectors were trained on the first 1 billion words of English Wikipedia and are of length 50.[5]

Multilingual (Multi). Faruqui and Dyer (2014) learned vectors by first performing SVD on text in different languages, then applying canonical correlation analysis on pairs of vectors for words that align in parallel corpora. These vectors were trained on WMT-2011 news corpus containing 360 million words and are of length 48.[6]

B Evaluation Benchmarks

Our comparisons of word vector quality consider five benchmark tasks. We now describe the different evaluation benchmarks for word vectors.

Word Similarity. We evaluate our word representations on two word similarity tasks. The first is the WS-353 dataset (Finkelstein et al., 2001), which contains 353 pairs of English words that have been assigned similarity ratings by humans. This dataset is used to tune sparse vector learning hyperparameters (§2.5), while the remaining of the tasks discussed in this section are completely held out.

[5] http://nlp.stanford.edu/~socherr/ACL2012_wordVectorsTextFile.zip

[6] http://cs.cmu.edu/~mfaruqui/soft.html

A more recent dataset, SimLex-999 (Hill et al., 2014), has been constructed to specifically focus on similarity (rather than relatedness). It contains a balanced set of noun, verb, and adjective pairs. We calculate cosine similarity between the vectors of two words forming a test item and report Spearman's rank correlation coefficient (Myers and Well, 1995) between the rankings produced by our model against the human rankings.

Sentiment Analysis (Senti). Socher et al. (2013) created a treebank of sentences annotated with fine-grained sentiment labels on phrases and sentences from movie review excerpts. The coarse-grained treebank of positive and negative classes has been split into training, development, and test datasets containing 6,920, 872, and 1,821 sentences, respectively. We use average of the word vectors of a given sentence as feature for classification. The classifier is tuned on the dev. set and accuracy is reported on the test set.

Question Classification (TREC). As an aid to question answering, a question may be classified as belonging to one of many question types. The TREC questions dataset involves six different question types, e.g., whether the question is about a location, about a person, or about some numeric information (Li and Roth, 2002). The training dataset consists of 5,452 labeled questions, and the test dataset consists of 500 questions. An average of the word vectors of the input question is used as features and accuracy is reported on the test set.

20 Newsgroup Dataset. We consider three binary categorization tasks from the 20 Newsgroups dataset.[7] Each task involves categorizing a document according to two related categories with training/dev./test split in accordance with Yogatama and Smith (2014): (1) Sports: baseball vs. hockey (958/239/796) (2) Comp.: IBM vs. Mac (929/239/777) (3) Religion: atheism vs. christian (870/209/717). We use average of the word vectors of a given sentence as features. The classifier is tuned on the dev. set and accuracy is reported on the test set.

NP bracketing (NP). Lazaridou et al. (2013) constructed a dataset from the Penn Treebank (Marcus et al., 1993) of noun phrases (NP) of length three words, where the first can be an adjective or a noun and the other two are nouns. The task is to predict the correct bracketing in the parse tree for a given noun phrase. For example, *local (phone company)* and *(blood pressure) medicine* exhibit *right* and *left* bracketing, respectively. We append the word vectors of the three words in the NP in order and use them as features for binary classification. The dataset contains 2,227 noun phrases split into 10 folds. The classifier is tuned on the first fold and cross-validation accuracy is reported on the remaining nine folds.

Abstract

In this paper, we propose a general framework to incorporate semantic knowledge into the popular data-driven learning process of word embeddings to improve the quality of them. Under this framework, we represent semantic knowledge as many ordinal ranking inequalities and formulate the learning of semantic word embeddings (SWE) as a constrained optimization problem, where the data-derived objective function is optimized subject to all ordinal knowledge inequality constraints extracted from available knowledge resources such as Thesaurus and WordNet. We have demonstrated that this constrained optimization problem can be efficiently solved by the stochastic gradient descent (SGD) algorithm, even for a large number of inequality constraints. Experimental results on four standard NLP tasks, including word similarity measure, sentence completion, name entity recognition, and the TOEFL synonym selection, have all demonstrated that the quality of learned word vectors can be significantly improved after semantic knowledge is incorporated as inequality constraints during the learning process of word embeddings.

1 Introduction

Distributed word representation (i.e., word embedding) is a technique that represents words as continuous vectors, which is an important research topic in natural language processing (NLP) (Hinton et al., 1986; Turney et al., 2010). In recent years, it has been widely used in various NLP tasks, including neural language model (Bengio et al., 2003; Schwenk, 2007), sequence labelling tasks (Collobert and Weston, 2008; Collobert et al., 2011), machine translation (Devlin et al., 2014; Sutskever et al., 2014), and antonym selection (Chen et al., 2015). Typically, word vectors are learned based on *the distributional hypothesis* (Harris, 1954; Miller and Charles, 1991), which assumes that words with a similar context tend to have a similar meaning. Under this hypothesis, various models, such as the skip-gram model (Mikolov et al., 2013a; Mikolov et al., 2013b; Levy and Goldberg, 2014) and GloVe model (Pennington et al., 2014), have been proposed to leverage the context of each word in large corpora to learn word embeddings. These methods can efficiently estimate the co-occurrence statistics to model contextual distributions from very large text corpora and they have been demonstrated to be quite effective in a number of NLP tasks. However, they still suffer from some major limitations. In particular, these corpus-based methods usually fail to capture the precise meanings for many words. For example, some semantically related but dissimilar words may have similar contexts, such as synonyms and antonyms. As a result, these corpus-based methods may lead to some antonymous word vectors being located much closer in the learned embedding space than many synonymous words. Moreover, as word representations are mainly learned based on the co-occurrence information, the learned word embeddings do not capture the accurate relationship between two semantically similar words if either one appears less frequently in the corpus.

To address these issues, some recent work has been proposed to incorporate prior lexical knowledge (WordNet, PPDB, etc.) or knowledge graph (Freebase, etc.) into word representations. Such knowledge enhanced word embedding methods have achieved considerable improvements on various natural language processing tasks, like (Yu and Dredze, 2014; Bian et al., 2014; Xu et al., 2014). These methods attempt to increase the semantic similarities between words belonging to

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1501–1511,
Beijing, China, July 26-31, 2015.

one semantic category or to explicitly model the semantic relationships between different words. For example, Yu and Dredze (2014) have proposed a new learning objective function to enhance word embeddings by combining neural models and a prior knowledge measure from semantic resources. Bian et. al (2014) have recently proposed to leverage morphological, syntactic, and semantic knowledge to improve the learning of word embeddings. Besides, a novel framework has been proposed in (Xu et al., 2014) to take advantage of both relational and categorical knowledge to learn high-quality word representations, where two regularization functions are used to model the relational and categorical knowledge respectively. More recently, a retrofitting technique has been introduced in (Faruqui et al., 2014) to improve semantic vectors by leveraging lexicon-derived relational information in a post-processing stage.

In this paper, we propose a new and flexible method to incorporate semantic knowledge into the corpus-based learning of word embeddings. In our approach, we propose to represent semantic knowledge as many word ordinal ranking inequalities. Furthermore, these inequalities are cast as semantic constraints in the optimization process to learn semantically sensible word embeddings. The proposed method has several advantages. Firstly, many different types of semantic knowledge can all be represented as a number of such ranking inequalities, such as synonym-antonym, hyponym-hypernym and etc. Secondly, these inequalities can be easily extracted from many existing knowledge resources, such as Thesaurus, WordNet (Miller, 1995) and knowledge graphs. Moreover, the ranking inequalities can also be manually generated by human annotation because ranking orders is much easier for human annotators than assigning specific scores. Next, we present a flexible learning framework to learn distributed word representation based on the *ordinal semantic knowledge*. By solving a constrained optimization problem using the efficient stochastic gradient descent algorithm, we can obtain semantic word embedding enhanced by the ordinal knowledge constraints. Experiments on four popular natural language processing tasks, including word similarity, sentence completion, name entity recognition and synonym selection, have all demonstrated that the proposed method can learn good semantically sensible word embeddings.

2 Representing Knowledge By Ranking

Many types of lexical semantic knowledge can be quantitatively represented by a large number of ranking inequalities such as:

$$\mathrm{similarity}(w_i, w_j) > \mathrm{similarity}(w_i, w_k) \qquad (1)$$

where w_i, w_j and w_k denote any three words in vocabulary. For example, eq.(1) holds if w_j is a synonym of w_i and w_k is an antonym of w_i. In general, the similarity between a word and its synonymous word should be larger than the similarity between the word and its antonymous word. Moreover, a particular word should be more similar to the words belonging to the same semantic category as this word than other words belonging to a different category. Besides, eq.(1) holds if w_i and w_j have shorter distance in a semantic hierarchy than w_i and w_k do in the same hierarchy (Leacock and Chodorow, 1998; Jurafsky and Martin, 2000).

Equivalently, each of the above similarity inequalities may be represented as the following constraint in the embedding space:

$$\mathrm{sim}(\mathbf{w}_i^{(1)}, \mathbf{w}_j^{(1)}) > \mathrm{sim}(\mathbf{w}_i^{(1)}, \mathbf{w}_k^{(1)}) \qquad (2)$$

where $\mathbf{w}_i^{(1)}$, $\mathbf{w}_j^{(1)}$ and $\mathbf{w}_k^{(1)}$ denote the embedding vectors of the words, w_i, w_j and w_k.

In this paper, we use the following three rules to gather the ordinal semantic knowledge from available lexical knowledge resources, such as Thesaurus and WordNet.

- *Synonym Antonym Rule*: Similarities between a word and its synonymous words are always larger than similarities between the word and its antonymous words. For example, the similarity between *foolish* and *stupid* is expected to be bigger than the similarity between *foolish* and *clever*, i.e., $\mathrm{similarity}(\textit{foolish}, \textit{stupid}) > \mathrm{similarity}(\textit{foolish}, \textit{clever})$.

- *Semantic Category Rule*: Similarities of words that belong to the same semantic category would be larger than similarities of words that belong to different categories. This rule refers to the idea of Fisher linear discriminant algorithm in (Fisher, 1936). A semantic category may be defined as a synset in WordNet, a hypernym in a semantic hierarchy, or an entity category in

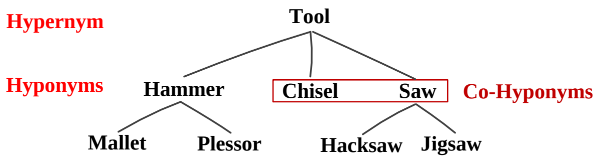

Figure 1: An example of hyponym and hypernym.

knowledge graphs. Figure 1 shows a simple example of the relationship between hyponyms and hypernyms. From there, it is reasonable to assume the following similarity inequality: similarity$(Mallet, Plessor) >$ similarity$(Mallet, Hacksaw)$.

- *Semantic Hierarchy Rule*: Similarities between words that have shorter distances in a semantic hierarchy should be larger than similarities of words that have longer distances. In this work, the semantic hierarchy refers to the hypernym and hyponym structure in WordNet. From Figure 1, this rule may suggest several inequalities like: similarity$(Mallet, Hammer) >$ similarity$(Mallet, Tool)$.

In addition, we may generate many such semantically ranking similarity inequalities by human annotation through crowdsourcing.

3 Semantic Word Embedding

In this section, we first briefly review the conventional skip-gram model (Mikolov et al., 2013b). Next, we study how to incorporate the ordinal similarity inequalities to learn semantic word embeddings.

3.1 The skip-gram model

The skip-gram model is a recently proposed learning framework (Mikolov et al., 2013b; Mikolov et al., 2013a) to learn continuous word vectors from text corpora based on the aforementioned distributional hypothesis, where each word in vocabulary (size of V) is mapped to a continuous embedding space by looking up an embedding matrix $\mathbf{W}^{(1)}$. And $\mathbf{W}^{(1)}$ is learned by maximizing the prediction probability, calculated by another prediction matrix $\mathbf{W}^{(2)}$, of its neighbouring words within a context window.

Given a sequence of training data, denoted as $w_1, w_2, w_3, ..., w_T$ with T words, the skip-gram model aims to maximize the following objective function:

$$\mathcal{Q} = \frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0} \log p(w_{t+j}|w_t) \tag{3}$$

where c is the size of context windows, w_t denotes the input central word and w_{t+j} for its neighbouring word. The skip-gram model computes the above conditional probability $p(w_{t+j}|w_t)$ using the following softmax function:

$$p(w_{t+j}|w_t) = \frac{\exp(\mathbf{w}_{t+j}^{(2)} \cdot \mathbf{w}_t^{(1)})}{\sum_{k=1}^{V} \exp(\mathbf{w}_k^{(2)} \cdot \mathbf{w}_t^{(1)})} \tag{4}$$

where $\mathbf{w}_t^{(1)}$ and $\mathbf{w}_k^{(2)}$ denotes row vectors in matrices $\mathbf{W}^{(1)}$ and $\mathbf{W}^{(2)}$, corresponding to word w_t and w_k respectively.

The training process of the skip-gram model can be formulated as an optimization problem to maximize the above objective function $\mathcal{Q}$. As in (Mikolov et al., 2013b), this optimization problem is solved by the stochastic gradient descent (SGD) method and the learned embedding matrix $\mathbf{W}^{(1)}$ is used as the word embeddings for all words in vocabulary.

3.2 Semantic Word Embedding (SWE) as Constrained Optimization

Here we consider how to combine the ordinal knowledge representation in section 2 and the skip-gram model in 3.1 to learn semantic word embeddings (SWE).

As shown in section 2, each ranking inequality involves a triplet, (i, j, k), of three words, $\{w_i, w_j, w_k\}$. Assume the ordinal knowledge is represented by a large number of such inequalities, denoted as the inequality set S. For $\forall(i, j, k) \in S$, we have:

$$\begin{aligned} &\text{similarity}(w_i, w_j) > \text{similarity}(w_i, w_k) \\ &\Leftrightarrow \text{sim}(\mathbf{w}_i^{(1)}, \mathbf{w}_j^{(1)}) > \text{sim}(\mathbf{w}_i^{(1)}, \mathbf{w}_k^{(1)}). \end{aligned}$$

For notational simplicity, we denote $s_{ij} = \text{sim}(\mathbf{w}_i^{(1)}, \mathbf{w}_j^{(1)})$ hereafter.

Next, we propose to use the following constrained optimization problem to learn semantic word embeddings (SWE):

$$\{\mathbf{W}^{(1)}, \mathbf{W}^{(2)}\} = \arg\max_{\mathbf{W}^{(1)}, \mathbf{W}^{(2)}} \mathcal{Q}(\mathbf{W}^{(1)}, \mathbf{W}^{(2)}) \tag{5}$$

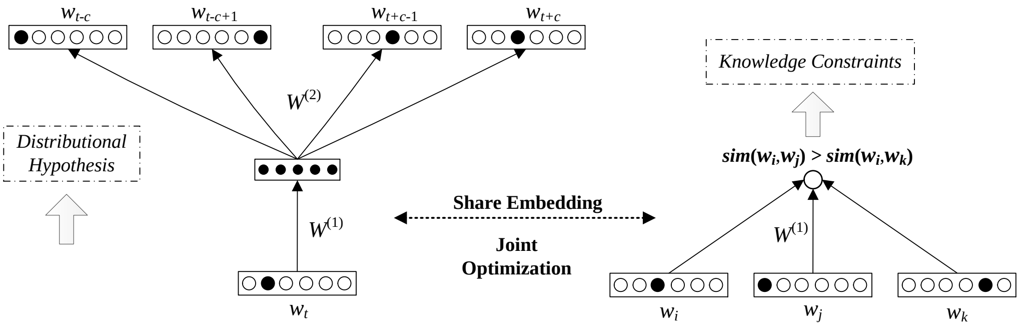

Figure 2: The proposed semantic word embedding (SWE) learning framework (The left part denotes the state-of-the-art skip-gram model; The right part represents the semantic constraints).

subject to

$$s_{ij} > s_{ik} \quad \forall (i, j, k) \in S. \tag{6}$$

In this work, we formulate the above constrained optimization problem into an unconstrained one by casting all the constraints as a penalty term in the objective function. The penalty term can be expressed as follows:

$$\mathcal{D} = \sum_{(i,j,k)\in S} f(i, j, k) \tag{7}$$

where the function $f(\cdot)$ is a normalization function. It can be a sigmoid function like $f(i, j, k) = \sigma(s_{ik} - s_{ij})$ with $\sigma(x) = 1/(1 + \exp(-x))$. Alternatively, it may be a hinge loss function like $f(i, j, k) = h(s_{ik} - s_{ij})$ where $h(x) = \max(\delta_0, x)$ with δ_0 denoting a parameter to control the decision margin. In this work, we adopt to use the hinge function to compute the penalty term in eq.(7) and δ_0 is set to be 0 for all experiments.

Finally, the proposed semantic word embedding (SWE) model aims to maximize the following combined objective function:

$$\mathcal{Q}' = \mathcal{Q} - \beta \cdot \mathcal{D} \tag{8}$$

where β is a control parameter to balance the contribution of the penalty term in the optimization process. It balances between the semantic information estimated from the corpus based on the distributional hypothesis and the semantic knowledge encoded in the ordinal ranking inequalities. In Rocktäschel et al. (2014), a similar approach was proposed to capture knowledge constraint as extra terms in the objective function for optimization.

In Figure 2, we show a diagram for the the overall SWE learning framework to incorporate semantic knowledge into the basic skip-gram word embeddings. Comparing with the previous work in (Xu et al., 2014) and (Faruqui et al., 2014), the proposed SWE framework is more general in terms of encoding the semantic knowledge for learning word embeddings. It is straightforward to show that the work in (Xu et al., 2014; Zweig, 2014; Faruqui et al., 2014) can be viewed as some special cases under our SWE learning framework.

3.3 Optimization algorithm for SWE

In this work, the proposed semantic word embeddings (SWE) are learned using the standard mini-batch stochastic gradient descent (SGD) algorithm. Furthermore, we adopt to use the cosine distance of the embedding vectors to compute the similarity between two words in the penalty term.

In the following, we show how to compute the derivatives of the penalty term for the SWE learning.

$$\begin{aligned}\frac{\partial \mathcal{D}}{\partial \mathbf{w}_t^{(1)}} &= \sum_{(i,j,k)\in S} \frac{\partial f\left(s_{ik} - s_{ij}\right)}{\partial \mathbf{w}_t^{(1)}} \\ = \sum_{(i,j,k)\in S} & f' \cdot \left(\delta_{ik}(t) \frac{\partial s_{ik}}{\partial \mathbf{w}_t^{(1)}} - \delta_{ij}(t) \frac{\partial s_{ij}}{\partial \mathbf{w}_t^{(1)}} \right)\end{aligned} \tag{9}$$

where $\delta_{ik}(t)$ and $\delta_{ij}(t)$ are computed as

$$\delta_{ik}(t) = \begin{cases} 1 & t = i \texttt{ or } t = k \\ 0 & \texttt{otherwise} \end{cases} \tag{10}$$

and for the hinge loss function $f(x)$, we have

$$f' = \begin{cases} 1 & (s_{ik} - s_{ij}) > \delta_0 \\ 0 & (s_{ik} - s_{ij}) \le \delta_0 \end{cases} \tag{11}$$

and the derivatives of the cosine similarity measure, $s_{ij} = \frac{\mathbf{w}_i^{(1)} \cdot \mathbf{w}_j^{(1)}}{|\mathbf{w}_i^{(1)}||\mathbf{w}_j^{(1)}|}$, with respect to a word vector, i.e., $\frac{\partial s_{ik}}{\partial \mathbf{w}_i^{(1)}}$, which can be derived as follows:

$$\frac{\partial s_{ij}}{\partial \mathbf{w}_i^{(1)}} = -\frac{s_{ij}\mathbf{w}_i^{(1)}}{|\mathbf{w}_i^{(1)}|^2} + \frac{\mathbf{w}_j^{(1)}}{|\mathbf{w}_i^{(1)}||\mathbf{w}_j^{(1)}|}. \tag{12}$$

The learning rate used for the SWE learning is the same as that for the skip-gram model. In each mini-batch of SGD, we sample terms in the same way as the skip-gram model. As for the constraints, we do not sample them but use all inequalities relevant to any words in a minibatch to update the model for the minibatch. Finally, by jointly optimizing the two terms in the combined objective function, we may learn a new set of word vectors encoding with ordinal semantic knowledge.

4 Experiments

In this section, we report all experiments conducted to evaluate the effectiveness of the proposed semantic word embeddings (SWE). Here we compare the performance of the proposed SWE model with the conventional skip-gram baseline model on four popular natural language processing tasks, including word similarity measure, sentence completion, name entity recognition, and synonym selection. In the following, we first describe the experimental setup, training corpora, semantic knowledge databases. Next, we report the experimental results on these four NLP tasks. Note that the SWE training codes and scripts are made publicly available at `http://home.ustc.edu.cn/~quanliu/`.

4.1 Experimental setup

4.1.1 Training corpora

In this work, we use the popular Wikipedia corpus as our training data to learn word embeddings for experiments on the word similarity task and the TOEFL synonym selection task. Particularly, we utilize two Wikipedia corpora with different sizes. The first corpus with a smaller size is a data set including the first one billion characters from Wikipedia[1], named as *Wiki-Small* in our experiments. The second corpus with a relatively large size is the latest Wikipedia dump[2], named as *Wiki-Large* in our experiments. Both Wikipedia corpora have been pre-processed by removing all the HTML meta-data and hyper-links and replacing the digit numbers with English words using the perl script from the Matt Mahoney's page[3]. After text normalization, the *Wiki-Small* corpus contains totally 130 million words, for which we create a lexicon of 225,909 distinct words appearing more than 5 times in the corpus. Similarly, the *Wiki-Large* corpus contains about 5 billion words, for which we create a lexicon of 228,069 words appearing more than 200 times.

For the other two tasks, sentence completion and name entity recognition, we use the same training corpora from the previous state-of-the-art work for fair comparisons. The training corpus for the sentence completion is the Holmes text (Zweig and Burges, 2011; Mikolov et al., 2013a). The training corpus for the name entity recognition task is the Reuters English newswire from RCV1 (Turian et al., 2010; Lewis et al., 2004). Refer to section 4.4 and section 4.5 for detailed descriptions respectively.

4.1.2 Semantic constraint collections

In this work, we use WordNet as the resource to collect ordinal semantic knowledge. WordNet is a large semantic lexicon database of English words (Miller, 1995), where nouns, verbs, adjectives and adverbs are grouped into sets of cognitive synonyms (usually called synsets). Each synset usually expresses a distinct semantic concept. All synsets in WordNet are interlinked by means of conceptual-semantic and/or lexical relations such as synonyms and antonyms, hypernyms and hyponyms.

In our experiments, we use the version WordNet-3.1 for creating the corresponding semantic constraints. In detail, we follow the following process to extract semantic similarity inequalities from WordNet and Thesaurus:

1. Based on the *Synonym Antonym Rule* described in section 2, for each word in vocabulary, find its synset and use the synonym and antonym relations to find all related synonymous and antonymous synsets. Note that the antonymous synset is selected as long as there exists an antonymous relation between any word in this synset and any word in an synonymous synset. After finding the synonymous and antonymous synsets

[1] http://mattmahoney.net/dc/enwik9.zip

[2] http://dumps.wikimedia.org/enwiki/latest/enwiki-latest-pages-articles.xml.bz2

[3] http://mattmahoney.net/dc/textdata.html

of the current word, the similarity inequalities could be generated according to the ranking rule. After processing all words, we have collected about 30,000 inequalities related to the synonym and antonym relations. Furthermore, we extract additional 320,000 inequalities from an old English dictionary (Fernald, 1896). In total, we have about 345,000 inequalities related to the synonym and antonym relations. This set of inequalities is denoted as *Synon-Anton* constraints in our experiments.

2. Based on the *Semantic Category Rule* and *Semantic Hierarchy Rule*, we extract another inequality set consisting of 75,000 inequalities from WordNet. We defined this collection as *Hyper-Hypon* constraints in our experiments.

In the following experiments, we just use all of these collected inequality constraints as is without further manually checking or cleaning-up. They may contain a very small percentage of errors or conflicts (due to multiple senses of a word).

4.1.3 Training parameter setting

Here we describe the control parameters used to learn the baseline skip-gram model and the proposed SWE model. In our experiments, we use the open-source *word2vec* toolkit[4] to train the baseline skip-gram model, where the context window size is set to be 5. The initial learning rate is set as 0.025 and the learning rate is decreased linearly during the SGD model training process. We use the popular negative sampling technique to speed up model training and set the negative sample number as 5.

To train the proposed SWE model, we use the same configuration as the skip-gram model to maximize $\mathcal{Q}'$. For the penalty term in eq. (7), we set $\delta_0 = 0$ for the hinge loss function. The semantic similarity between words is computed by the cosine distance. The combination coefficient β in eq. (8) is usually set to be a number between 0.001 and 0.3 in our experiments.

In the following four NLP tasks, the dimensionality of embedding vectors is different since we try to use the same settings from the state-of-the-art work for the comparison purpose. In the Word Similarity task and the TOEFL Synonym Selection task, we followed the state of the art work in (Xu et al., 2014), to set word embeddings to 300-dimension. Similarly, we refer to Bian et al. (2014) to set the dimensionality of word vectors to 600 for the Sentence Completion task. And we set the dimensionality of word vectors to 50 for the NER task according to (Turian et al., 2010; Pennington et al., 2014).

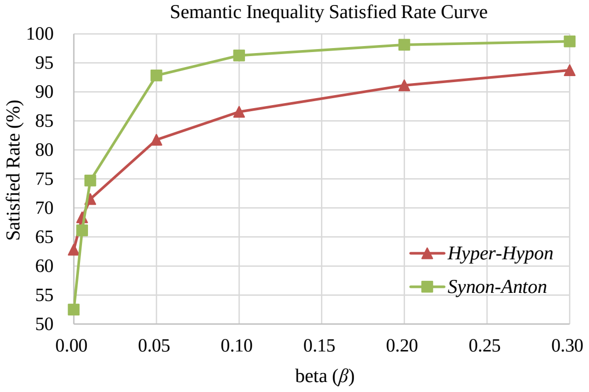

Figure 3: A curve of inequality satisfied rates (All models trained on the *Wiki-Small* corpus. *Hyper-Hypon* and *Synon-Anton* stand for different semantic constraint sets employed for training semantic word embeddings).

4.2 Semantic inequality satisfied rates

Here we first examine the inequality satisfied rates of various word embeddings. The inequality satisfied rate is defined as how many percentage of semantic inequalities are satisfied based on the underlying word embedding vectors. In Figure 3, we show a typical curve of the inequality satisfied rates as a function of β used in model training. This figure is plotted based on the *Wiki-Small* corpus. Two semantic constraint sets *Synon-Anton* and *Hyper-Hypon* created in section 4.1.2 are employed to learn semantic word embeddings.

In the framework of the proposed semantic word embedding method, we just need to tune one more parameter β, comparing with the skip-gram model. It shows that the baseline skip-gram ($\beta = 0$) can only satisfy about 50-60% of inequalities in the training set. As we choose a proper value for β, we may significantly improve the inequality satisfied rate, up to 85-95%. Although we can get higher inequality satisfying rate on the training set by increasing beta continuously, however, we do not suggest to use a big beta value because it would make the model overfitting. The major reason for this is that the constraints only

[4] https://code.google.com/p/word2vec.

cover a subset of words in vocabulary. Increasing the rate too much may screw up the entire word embeddings due to the sparsity of the constraints.

Meanwhile, we have found that the proposed SGD method is very efficient to handle a large number of inequalities in model training. When we use the total 345,000 inequalities, the SWE training is comparable with the baseline skip-gram model in terms of training speed. In the following, we continue to examine the SWE model on four popular natural language processing tasks, including word similarity, sentence completion, name entity recognition and the TOEFL synonym selection.

4.3 Task 1: Word Similarity Task

4.3.1 Task description

Measuring word similarity is a traditional NLP task (Rubenstein and Goodenough, 1965). Here we compare several word embedding models on a popular word similarity task, namely WordSim-353 (Finkelstein et al., 2001), which contains 353 English word pairs along with human-assigned similarity scores, which measure the relatedness of each word pair on a scale from 0 (totally unrelated words) to 10 (very much related or identical words). The final similarity score for each pair is the average across 13 to 16 human judges. When evaluating word embeddings on this task, we measure the performance by calculating the Spearman rank correlation between the human judgments and the similarity scores computed based on the learned word embeddings.

4.3.2 Experimental results

Here we compare the proposed SWE model with the baseline skip-gram model on the WordSim-353 task. Both word embedding models are trained using the Wikipedia corpora. We set the dimension of word embedding vectors to be 300. In Table 1, we have shown all the Spearman rank correlation results. The baseline results on this task include PPMI (Levy and Goldberg, 2014), GloVe (Pennington et al., 2014), and ESA-Wikipedia (Gabrilovich and Markovitch, 2007).

From the results in Table 1, we can see that the proposed SWE model can achieve consistent improvements over the baseline skip-gram model, no matter which training corpus is used. These results have demonstrated that, by incorporating semantic ordinal knowledge into the word vectors, the proposed semantic word embedding framework can capture much better semantics for many words. The SWE model using the *Wiki-Large* corpus has achieved the state-of-the-art performance on this task, significantly outperforming other popular word embedding methods, such as skip-gram and GloVe. Moreover, we also find that the *Synon-Anton* constraint set is more relevant than *Hyper-Hypon* for the word similarity task.

	Word Embeddings	**Result**
Others	SPPMI	0.6870
	GloVe (6 billion)	0.6580
	GloVe (42 billion)	0.7590
	ESA-Wikipedia	0.7500

4.4 Task 2: Sentence Completion Task

4.4.1 Task description

The Microsoft sentence completion challenge has recently been introduced as a standard benchmark task for language modeling and other NLP techniques (Zweig and Burges, 2011). This task consists of 1040 sentences, each of which misses one word. The goal is to select a word that is the most coherent with the rest of the sentence, from a list of five candidates. Many NLP techniques have already been reported on this task, including N-gram model and LSA-based model proposed in (Zweig and Burges, 2011), log-bilinear model (Mnih and Teh, 2012), recurrent neural networks (RNN) (Mikolov, 2012), the skip-gram model (Mikolov et al., 2013a), a combination of the skip-gram and RNN model, and a knowledge enhanced word embedding model proposed by Bian et. al. (2014). The performance of all these techniques is listed in Table 2 for comparison.

In this work, we follow the the same procedure as in (Mikolov et al., 2013a) to examine the performance of our proposed semantic word embeddings (SWE) on this task. We first train 600-

dimension word embeddings based on a training corpus of 50M words provided by (Zweig and Burges, 2011), with and without using the collected ordinal knowledge. Then, for each sentence in the test set, we use the learned word embeddings to compute a sentence score for predicting all surrounding words based on each candidate word in the list. Finally, we use the computed sentence prediction scores to choose the most likely word from the given list to answer the question.

	System	Acc

	SWE + Both	**56.2**

Table 2: Results on Sentence Completion Task.

4.4.2 Experimental results

In Table 2, we have shown the sentence completion accuracy on this task for various word embedding models. We can see that the proposed SWE model has achieved considerable improvements over the baseline skip-gram model. Once again, this suggests that the semantic knowledge represented by the ordinal inequalities can significantly improve the quality of the word embeddings. Besides, the SWE model significantly outperforms the recent work in (Bian et al., 2014), which considers syntactics and semantics of the sentence contexts.

4.5 Task 3: Name Entity Recognition

4.5.1 Task description

To further investigate the performance of semantic word embeddings, we have further conducted some experiments on the standard CoNLL03 name entity recognition (NER) task. The CoNLL03 NER dataset is drawn from the Reuters newswire. The training set contains 204K words (14K sentences, 946 documents), the test set contains 46K words (3.5K sentences, 231 documents), and the development set contains 51K words (3.3K sentences, 216 documents). We have listed the state-of-the-art performance in Table 3 for this task (Turian et al., 2010).

To make a fair comparison, we have used the exactly same experimental configurations as in (Turian et al., 2010), including the used training algorithm, the baseline discrete features and so on. Like the C&W model, we use the same training text resource to learn word vectors, which contains one year of Reuters English newswire from RCV1, from August 1996 to August 1997, having about 810,000 news stories (Lewis et al., 2004). Meanwhile, the dimension of word embeddings is set to 50 for all experiments on this task.

4.5.2 Experimental results

In our experiments, we compare the proposed SWE model with the baseline skip-gram model for name entity recognition, measured by the standard F1 scores. We present the final NER F1 scores on the CoNLL03 NER task in Table 3. The notation "Gaz" stands for gazetteers that are added into the NER system as an auxiliary feature. For the SWE model, we experiment two configurations by adding gazetteers or not (denoted by "IsGaz" and "NoGaz" respectively).

	System	Dev	Test	MUC7
Others	C&W	92.3	87.9	75.7
	C&W + Gaz	93.0	88.9	81.4
NoGaz	Skip-gram	92.6	88.3	76.7
	+ *Synon-Anton*	92.5	88.4	77.2
	+ *Hyper-Hypon*	92.6	**88.6**	**77.7**
	+ Both	92.6	88.4	77.5
IsGaz	Skip-gram	93.3	89.5	80.0
	+ *Synon-Anton*	93.1	89.6	80.7
	+ *Hyper-Hypon*	93.1	89.7	80.7
	+ Both	93.0	89.5	**80.8**

Table 3: F1 scores on the CoNLL03 NER task.

From the results shown in Table 3, we could find the proposed semantic word embedding (SWE) model can consistently achieve 0.8% (or more) absolute improvements on the MUC7 task no matter whether the gazetteers features are used or not. The proposed SWE model can also obtain 0.3% improvement in the CoNLL03 test set when no gazetteers is added into the NER system. However, no significant improvement is observed in this test set for the proposed SWE model after we add the gazetteers feature.

4.6 Task 4: TOEFL Synonym Selection

4.6.1 Task description

The goal of a synonym selection task is to select, from a list of candidate words, the semantically closest word for each given target word. The dataset we use for this task is the standard TOEFL dataset (Landauer and Dumais, 1997), which contains 80 questions. Each question consists of a target word along with 4 candidate lexical substitutes for selection.

The evaluation criterion on this task is the synonym selection accuracy which indicates how many synonyms are correctly selected for all 80 questions. Similar to the configurations on the word similarity task, all the experiments on this task are conducted on the English Wikipedia corpora. In our experiments, we set all the vector dimensions to 300.

4.6.2 Experimental Results

Corpus	Model	Accuracy (%)
Wiki-Small	Skip-gram	61.25
	+ *Synon-Anton*	**70.00**
	+ *Hyper-Hypon*	66.25
	+ Both	**71.25**
Wiki-Large	Skip-gram	83.75
	+ *Synon-Anton*	**87.50**
	+ *Hyper-Hypon*	85.00
	+ Both	**88.75**

Table 4: The TOEFL synonym selection task.

In Table 4, we have shown the experimental results for different word embedding models, learned from different Wikipedia corpora: *Wiki-Small* or *Wiki-Large*. We compare the proposed SWE with the baseline skip-gram model. From the experimental results in Table 4, we can see that the proposed SWE model can achieve consistent improvements over the baseline skip-gram model on the TOEFL synonym selection task, about 5-8% improvements on the selection accuracy. We find the similar performance differences between the SWE model trained with the *Synon-Anton* and *Hyper-Hypon* constraint set. The main reason would be that the synonym selection task is mainly related to lexical level similarity and less relevant to the hypernym-hyponym relations.

5 Conclusions and Future Work

Word embedding models with good semantic representations are quite invaluable to many natural language processing tasks. However, the current data-driven methods that learn word vectors from corpora based on the distributional hypothesis tend to suffer from some major limitations. In this paper, we propose a general and flexible framework to incorporate various types of semantic knowledge into the popular data-driven learning procedure for word embeddings. Our main contributions are to represent semantic knowledge as a number of ordinal similarity inequalities as well as to formulate the entire learning process as a constrained optimization problem. Meanwhile, the optimization problem could be solved by efficient stochastic gradient descend algorithm. Experimental results on four popular NLP tasks have all demonstrated that the propose semantic word embedding framework can significantly improve the quality of word representations.

As for the future work, we would incorporate more types of knowledge, such as knowledge graphs and FrameNet, into the learning process for more powerful word representations. We also expect that some common sense related semantic knowledge may be generated as ordinal inequality constraints by human annotators for learning semantic word embeddings. At the end, we plan to apply the SWE word embedding models for more natural language processing tasks.

Abstract

We add an interpretable semantics to the paraphrase database (PPDB). To date, the relationship between phrase pairs in the database has been weakly defined as approximately equivalent. We show that these pairs represent a variety of relations, including directed entailment (*little girl/girl*) and exclusion (*nobody/someone*). We automatically assign semantic entailment relations to entries in PPDB using features derived from past work on discovering inference rules from text and semantic taxonomy induction. We demonstrate that our model assigns these relations with high accuracy. In a downstream RTE task, our labels rival relations from WordNet and improve the coverage of a proof-based RTE system by 17%.

Riots in Denmark were sparked by 12 editorial cartoons that were offensive to Muhammad.

12	$\equiv$	Twelve
editorial cartoons	$\sqsupset$	illustrations
offensive	$\sqsupset$	insulting
Muhammad	$\equiv$	the prophet
sparked	$\sqsupset$	caused
riots	$\sqsupset$	unrest
in Denmark	$\mid$	in Jordan

Twelve illustrations insulting the prophet caused unrest in Jordan.

Figure 1: An example sentence pair for the RTE task. In order for a system to conclude that the premise (top) does not entail the hypothesis (bottom), it should recognize that *sparked* implies *caused* but that *in Denmark* precludes *in Jordan*. These phrase-level entailment relationships are modeled by natural logic.

1 Motivation

A basic precursor to language understanding is the ability to recognize when two expressions mean the same thing. Different expressions of the same information is the central problem addressed by paraphrasing and the closely related task of recognizing textual entailment (RTE). In RTE, a system is given two pieces of text, often called the *text* (T) and the *hypothesis* (H), and asked to determine whether T entails H, T contradicts H, or T and H are unrelatable (Figure 1). In contrast, data-driving paraphrasing typically sidesteps developing a clear definition of “meaning the same thing” and instead “assume[s] paraphrasing is a coherent notion and concentrate[s] on devices that can produce paraphrases” (Barzilay, 2003). Recent work on paraphrase extraction has resulted in enormous paraphrase collections (Lin and Pantel, 2001; Dolan et al., 2004; Ganitkevitch et al., 2013), but the usefulness of these collections is limited by the fast-and-loose treatment of the meaning of paraphrases. One concrete definition that is sometimes used for paraphrases requires that they be bidirectionally entailing (Androutsopoulos and Malakasiotis, 2010). That is, in terms of RTE, it is assumed that if P is a paraphrase of Q, then P entails Q and Q entails P. In reality, paraphrases are often more nuanced (Bhagat and Hovy, 2013), and the entries in most paraphrase resources certainly do not match this definition. For instance, Lin and Pantel (2001) extracted 12 million “inference rules” from monolingual text by exploiting shared dependency contexts. Their method learns paraphrases that are truly meaning equivalent, but it just as readily learns contradictory pairs such as ⟨*X rises*, *X falls*⟩. Ganitkevitch et al. (2013) extract over 150 million paraphrase rules by pivoting through foreign translations. This bilingual method often learns hypernym/hyponym pairs, e.g. due to variation in the discourse structure of translations (Callison-

Table 1: Examples of different types of entailment relations appearing in PPDB.

Burch, 2007), and unrelated pairs, e.g. due to misalignments or polysemy in the foreign language.

The unclear semantics severely limits the applicability of paraphrase resources to natural language understanding (NLU) tasks. Some efforts have been made to identify directionality of paraphrases (Bhagat et al., 2007; Kotlerman et al., 2010), but tasks like RTE require even richer semantic information. For example, in the T/H pair shown in Figure 1, a system needs information not only about equivalent words (*12/twelve*) and asymmetric entailments (*riots/unrest*), but also semantic exclusion (*Denmark/Jordan*). Such lexical entailment relations are captured by *natural logic*, a formalism which views natural language itself as a meaning representation, eschewing external representations such as First Order Logic (FOL). This is a great fit for automatically extracted paraphrases, since the phrase pairs themselves can be used as the semantic representation with minimal additional annotation. But as is, paraphrase resources lack such annotation.

As a result, NLU systems rely on manually built resources like WordNet, which are limited in coverage and often lead to incorrect inferences (Kaplan and Schubert, 2001). In fact, in the most recent RTE challenge, over half of the submitted systems used WordNet (Pontiki et al., 2014). Even the NatLog system (MacCartney and Manning, 2007), which popularized natural logic for RTE, relied on WordNet and did not solve the problem of assigning natural logic relations at scale.

The main contributions of this paper are:

- We add a concrete, interpretable semantics to the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013), the largest paraphrase resource currently available. We give each entry in the database a label describing the entailment relationship between the phrases.
- We develop a statistical model to predict these relations. The enormous size of PPDB– over 77 million phrase pairs!– makes it impossible to perform this task manually. Our wide range of monolingual and bilingual features results in high intrinsic accuracy.
- We demonstrate improvements to a proof-based RTE system, showing that our automatic labels increase the number of proofs that it is able to find by 17%, while maintaining the same accuracy as when using gold-standard, manual labels.

2 Related Work

Lexical entailment resources Approaches to paraphrase identification have exploited signal from distributional contexts (Lin and Pantel, 2001; Szpektor et al., 2004), comparable corpora (Dolan et al., 2004; Xu et al., 2014), and graph structures (Berant et al., 2011; Brockett et al., 2013). These approaches are scalable, but they often assume that all relations are equivalence relations (Madnani and Dorr, 2010). Several efforts have attempted to build or augment lexical ontologies automatically, to discover other types of lexical relations like hypernyms. Most of these approaches rely on lexico-syntactic patterns. Hearst (1992) searched for hand-written patterns (e.g. “an X is a Y”) in a large corpus in order to learn taxonomic relations between nouns. Snow et al. (2006) used dependency parses to automatically learn such patterns, which they used to augment WordNet with new hypernym relations. Similar monolingual signals have been used to learn fine-grained relationships between verbs, such as *enablement* and *happens-before* (Chklovski and Pantel, 2004; Hashimoto et al., 2009).

Recognizing Textual Entailment The shared RTE tasks (Dagan et al., 2006) have been a springboard for research in natural language inference,

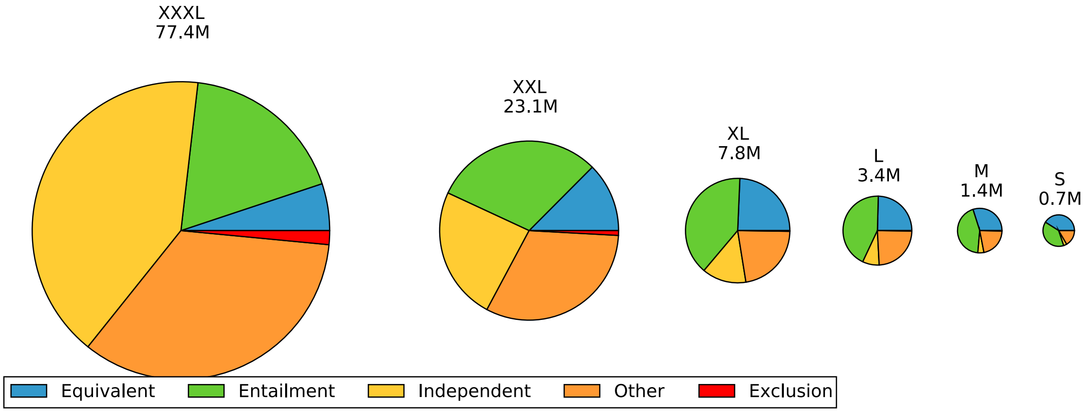

Figure 2: Distribution of entailment relations in different sizes of PPDB. Distributions are estimated from our manual annotations of randomly sampled pairs. PPDB-XXXL contains over 77MM paraphrase pairs (where the majority type is independent), compared to only 700K in PPDB-S (where the majority type is equivalent).

using data motivated by the applications to information retrieval, information extraction, summarization, machine translation evaluation, and more recently, question answering (Giampiccolo et al., 2007) and essay grading (Clark et al., 2013). RTE systems vary considerably in their choice of representation and inference procedure. In the most recent shared task on RTE, some systems used deep logical representations of text, allowing them to invoke theorem provers (Bjerva et al., 2014) or Markov Logic Networks (Beltagy et al., 2014) to perform the inference, while others used shallower representations, relying on machine learning to perform inference (Lai and Hockenmaier, 2014; Zhao et al., 2014). Systems based on natural logic (MacCartney and Manning, 2007) use natural language as a representation, but still perform inference using a structured algebra rather than a statistical model. Regardless of the inference procedure, improvements to external lexical resources can improve RTE systems across the board (Clark et al., 2007).

3 The Paraphrase Database (PPDB)

PPDB is currently the largest available collection of paraphrases. Compared to other paraphrase resources such as the DIRT database (12 million rules) (Lin and Pantel, 2001) and the MSR paraphrase phrase table (13 million) (Dolan et al., 2004), PPDB contains over 150 million paraphrase rules covering three paraphrase types– lexical (single word), phrasal (multiword), and syntactic restructuring rules. We focus on lexical and phrasal paraphrases, of which there are over 77 million rules. Of these, a large fraction are true paraphrases– either equivalent (*distant/remote*) or asymmetric entailment (*girl/little girl*)– but many are not. PPDB contains some pairs which are related by semantic exclusion (*nobody/someone*), some of which are related by something other than entailment (*swim/water*), and some which are simply unrelated (*car/family*). Table 1 gives examples of pairs in PPDB falling into each of these categories.

PPDB is released in six sizes (S, M, L, XL, XXL and XXXL), which fall roughly on a continuum from highest precision and lowest recall to lowest average precision and highest recall. Figure 2 shows how the distribution of entailment relations differs across the sizes of PPDB.[1] Our goal is to make these relations explicit, by providing annotations for each phrase pair. Because of the enormous scale of PPDB, this annotation must be done automatically.

4 Selection of Paraphrases

In this paper we focus on paraphrases pairs from PPDB that occur in RTE data. We use the recent SICK dataset from in the 2014 SemEval RTE challenge (Marelli et al., 2014) for our experiments. The data consists of 10K sentences split roughly evenly into training and testing sets. The sentence pairs are labeled using a 3-way entailment classification: ENTAILMENT, (29%) CONTRADICTION (15%), or NEUTRAL (56%). We consider all phrase pairs from PPDB $\langle p_1, p_2 \rangle$ up to three words in length such that there is some T/H sentence pair in which p_1 appears in T and p_2 appears

[1] These distributions were estimated based on a random sample of pairs drawn from each size of PPDB, annotated on MTurk as described in Section 5

Lexical	We use the lemmas, POS tags, and phrase lengths of p_1 and p_2, the substrings shared by p_1 and p_2, and the Levenstein, Jaccard, and Hamming distances between p_1 and p_2.
Distributional	Given a dependency context vectors for p_1 and p_2, we compute the number of shared contexts, and the Jaccard, Cosine, Lin1998, Weeds2004, Clarke2009, and Szpektor2008 similarities between the vectors.
Paraphrase	We include 33 paraphrase features distributed with PPDB, which include the paraphrase probabilities as computed in Bannard and Callison-Burch (2005). We refer the reader to Ganitkevitch and Callison-Burch (2014) for a complete description of all of the features included with PPDB.
Translation	We include the number of foreign language "pivots" (translations) shared by p_1 and p_2 for each of 24 languages used in the construction of PPDB, as a fraction of the total number of translations observed for each of p_1 and p_2.
Path	We include a sparse vector of all lexico-syntactic patterns (paths through a dependency parse) which are observed between p_1 and p_2 in the Annotated Gigaword corpus (Napoles et al., 2012).
WordNet	We include binary features indicating whether WordNet classifies p_1 and p_2 according to any of the following relations: synonym, hypernym, hyponym, antonym, holonym, meronym, cause, entailment, derivationally-related, similar-to, also-see, or attribute.

Figure 3: Summary of features extracted for each phrase pair $\langle p_1, p_2 \rangle$. Full descriptions of the features used are given in the supplementary material.

in H. Roughly 55% of the word types and 5% of the phrase (bigram and trigram) types in the SICK data appear in PPDB. This gives us a list of 9,600 pairs, half from the training sentences, which we use for development in Section 6, and half from the test sentences, which we use for evaluation in Section 7.

The SICK data has a relatively small vocabulary, with 86% of words types and <1% of the phrase types covered by WordNet. Still, over half of the words in SICK which are covered by PPDB do not appear in WordNet. In general, PPDB covers a much larger vocabulary (1.6MM words) than does WordNet (155K words), and we expect the potential benefit of using PPDB in addition to or in place of WordNet to be larger on datasets with richer vocabularies.

5 Entailment Relations

We use the relations from Bill MacCartney's thesis on natural language inference as the basis for our categorization of relations (MacCartney, 2009). He outlines 7 basic entailment relationships:[2]

Equivalence ($P \equiv Q$): $\forall x[P(x) \leftrightarrow Q(x)]$
Forward Entailment ($P \sqsubset Q$): $\forall x[P(x) \rightarrow Q(x)]$
Reverse Entailment ($P \sqsupset Q$): $\forall x[Q(x) \rightarrow P(x)]$
Negation ($P\,\hat{}\,Q$): $\forall x\ [P(x) \leftrightarrow \neg\ Q(x)]$
Alternation ($P|Q$): $\forall x\ \neg[P(x) \wedge Q(x)]$
Cover ($P \smile Q$): $\forall x[P(x) \vee Q(x)]$
Independence (P#Q): All other cases.

These relations are based on the theory of *natural logic*, meaning they are defined between pairs of natural language expressions rather than requiring an external formal representation. This makes them an ideal fit for the phrase pairs in in PPDB and similar automatically-constructed paraphrase resources.

Nat. Log.	This work	MTurk description
≡	≡	X is the same as Y
⊏	⊏	X is more specific than/is a type of Y
⊐	⊐	X is more general than/encompasses Y
ˆ	¬	X is the opposite of Y
|		X is mutually exclusive with Y
#	∼	X is related in some other way to Y
	#	X is not related to Y

Table 2: Column 1 gives the semantics of each label under MacCartney's Natural Logic. Column 2 gives the notation we use throughout the remainder of this paper. Column 3 gives the description that was shown to Turkers.

Annotation We use Amazon Mechanical Turk (MTurk) to collect labels for our phrase pairs. We asked workers to choose between the options show in Table 2, which represent a modified version of MacCartney's relations. We replace negation (ˆ) with the weaker notion of "opposites," effectively merging it with the alternation (|) relation; we split the independent (#) class into two cases: truly independent phrases and phrases which are related by something other than entailment (which we denote ∼). We omit the cover ($\smile$) relation entirely, as its practicality is not obvious. We show each pair to 5 workers, taking the majority label as truth. Each HIT consisted of two control questions taken from WordNet. Workers achieved good accuracies on our controls (82% overall) and moder-

[2] To further clarify the definitions here: "negation" is XOR (exclusive disjunction), "alternation" is NAND, and "cover" is OR (inclusive disjunction)

Cosine Similarity		Monolingual (symmetric)		Monolingual (asymmetric)		Bilingual	
$\sqsupset$	shades/the shade	$\neg$	large/small	$\sqsupset$	boy/little boy	$\equiv$	dad/father
$\sqsupset$	yard/backyard	$\equiv$	few/several	$\sqsupset$	man/two men	$\sqsupset$	some kid/child
$\#$	each other/man	$\neg$	different/same	$\sqsupset$	child/three children	$\equiv$	a lot of/many
$\sqsupset$	picture/drawing	$\neg$	other/same	$\equiv$	is playing/play	$\equiv$	female/woman
$\sim$	practice/target	$\neg$	put/take	$\sqsupset$	side/both sides	$\equiv$	male/man

Table 3: Top scoring pairs (x/y) according to various similarity measures, along with their manually classified entailment labels. Column 1 is cosine similarity based on dependency contexts. Column 2 is based on Lin (1998), column 3 on Weeds (2004), and column 4 is a novel feature. Precise definitions of each metric are given in the supplementary material.

ate levels of agreement (Fleiss's $\kappa = 0.56$) (Landis and Koch, 1977). For a fuller discussion of the annotation, refer to the supplementary material.

6 Automatic Classification

We aim to build a classifier to automatically assign entailment types to entries in the PPDB, and to demonstrate that it performs well both intrinsically and extrinsically. We fix the direction of the $\sqsubset$ and $\sqsupset$ relations to create a single class and train a logistic regression classifier to distinguish between the 5 classes $\{\#, \equiv, \sqsupset, \neg, \sim\}$. We compute variety of basic lexical features and WordNet features (summarized in Figure 3). We categorize the remaining features into two broad groups: monolingual features, which are based on observed usage in the Annotated Gigaword corpus (Napoles et al., 2012), and bilingual features, which are based on translation probabilities observed in bilingual parallel corpora. Full descriptions of all the features used are provided in the supplementary material.

6.1 Monolingual features

Path features Snow et al. (2004) used lexico-syntactic patterns to mine taxonomic relations (hypernyms and hyponyms) between noun pairs. They were able to verify the earlier work of Hearst (1992) which found that certain patterns, e.g. *X and other Y*, are strong indicators of hypernymy. Using similar path features, we learn new patterns to differentiate between more subtle relations. For example, we learn the pattern *separate X from Y* is highly indicative of the $\neg$ relation. We learn that the pattern *X including Y* suggests $\sqsupset$ more than it suggests $\equiv$ whereas the pattern *X known as Y* suggests $\equiv$ more than $\sqsupset$. Table 4 gives examples of some of the paths most indicative of the $\neg$ relation.

Distributional features Lin and Pantel (2001) attempted to mine inference rules from text by finding paths in a dependency tree which connect the same nouns. The intuition is that good paraphrases should tend to modify and be modified by the same words. Given context vectors, Lin and Pantel (2001) used a symmetric similarity metric (Lin, 1998) to find candidate paraphrases. We build dependency context vectors for each word in our data and compute both symmetric as well as more recently proposed asymmetric similarity measures (Weeds et al., 2004; Szpektor and Dagan, 2008; Clarke, 2009), which are potentially better suited for identifying $\sqsupset$ paraphrases. Table 3 gives a comparison of the pairs which are considered "most similar" according to several of these metrics.

in X and in Y	*in foods and in beverages*
separate X from Y	*separate the old from the young*
to X and/or to Y	*to the left or to the right*
from X to Y	*from 7 a.m. to 10 p.m.*
more/less X than Y	*more harm than good*

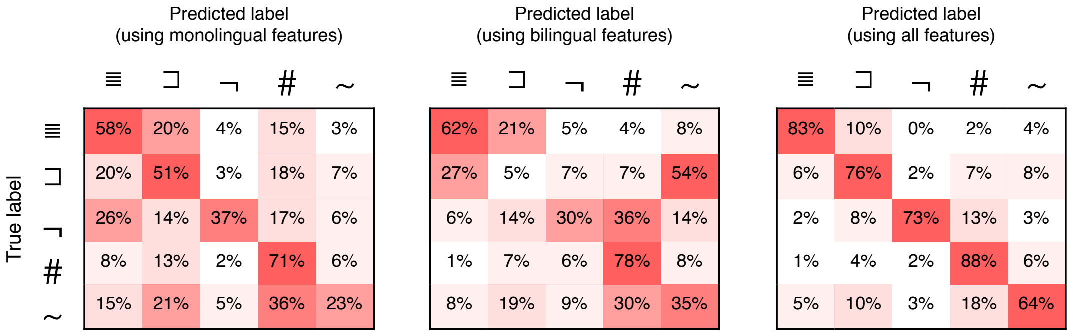
Table 4: Top paths associated with the $\neg$ class.

6.2 Bilingual features

We explore a variety of bilingual features, which we expect to provide complimentary signal to the monolingual features. Each pair in PPDB is associated with several paraphrase probabilities, which are based on the probabilities of aligning each word to the foreign "pivot" phrase (a foreign translation shared by the two phrases), computed as described in Bannard and Callison-Burch (2005). We also compute the total number of shared foreign translations for each phrase pair. Table 3 shows the highest ranked pairs by this bilingual similarity score, in comparison to several of the monolingual scores.

6.3 Analysis

Table 5 shows an ablation analysis. The bilingual features are especially important for distinguishing the $\equiv$ class, and the path and WordNet features are important for the $\neg$ class. The lexical features show strong performance across the board; this is often because they capture negation words (e.g. *no*) and substring features (*little boy* $\sqsubset$ *boy*).



Monolingual	≡	⊐	¬	#	∼
≡	58%	20%	4%	15%	3%
⊐	20%	51%	3%	18%	7%
¬	26%	14%	37%	17%	6%
#	8%	13%	2%	71%	6%
∼	15%	21%	5%	36%	23%

Bilingual	≡	⊐	¬	#	∼
≡	62%	21%	5%	4%	8%
⊐	27%	5%	7%	7%	54%
¬	6%	14%	30%	36%	14%
#	1%	7%	6%	78%	8%
∼	8%	19%	9%	30%	35%

All	≡	⊐	¬	#	∼
≡	83%	10%	0%	2%	4%
⊐	6%	76%	2%	7%	8%
¬	2%	8%	73%	13%	3%
#	1%	4%	2%	88%	6%
∼	5%	10%	3%	18%	64%

Figure 4: Confusion matrices for classifier trained using only monolingual features (distributional and path) versus bilingual features (paraphrase and translation). True labels are shown along rows, predicted along columns. The matrix is normalized along rows, so that the predictions for each (true) class sum to 100%. The confusion matrices reflect classifier's performance on held-out phrase pairs from the SICK test set.

		Δ F1 when excluding					
	All	Lex.	Dist.	Path	Para.	Tran.	WN
#	79	-2.0	-0.2	-1.2	-1.7	-0.2	-0.1
≡	57	-3.5	+0.2	-0.7	-2.4	-3.7	+0.5
⊐	68	-4.6	-0.3	-0.8	-0.8	-0.7	-1.6
¬	49	-4.0	-0.8	-2.9	+0.3	-0.0	-2.2
∼	51	-4.9	-0.5	-0.7	-1.2	-0.9	-0.3

Table 5: F1 measure (×100) achieved by entailment classifier using 10-fold cross validation on the training data.

Table 3 shines some light onto the differences between monolingual and bilingual similarities. While the monolingual asymmetric metrics are good for identifying ⊐ pairs, the symmetric metrics consistently identify ¬ pairs; none of the monolingual scores we explored were effective in making the subtle distinction between ≡ pairs and the other types of paraphrase. In contrast, the bilingual similarity metric is fairly precise for identifying ≡ pairs, but provides less information for distinguishing between types of non-equivalent paraphrase. These differences are further exhibited in the confusion matrices shown in Figure 4; when the classifier is trained using only monolingual features, it misclassifies 26% of ¬ pairs as ≡, whereas the bilingual features make this error only 6% of the time. On the other hand, the bilingual features completely fail to predict the ⊐ class, calling over 80% of such pairs ≡ or ∼.

7 Evaluation

7.1 Intrinsic Evaluation

We test the performance of our classifier intrinsically, through its ability to reproduce the human labels for the phrase pairs from the SICK test sentences. Table 7 shows the precision and recall achieved by the classifier for each of our 5 entailment classes. The classifier is able to achieve an overall 79% accuracy, reaching >70% precision while maintaining good levels of recall on all classes.

True	Pred.	N	Example misclassifications
∼	#	169	boy/little, an empy/the air
#	∼	114	little/toy, color/hair
⊐	∼	108	drink/juice, ocean/surf
⊐	#	97	in front of/the face of, vehicle/horse
⊐	≡	83	cat/kitten, pavement/sidewalk
≡	⊐	46	big/grand, a girl/a young lady
⊐	¬	29	kid/teenager, no small/a large
¬	⊐	29	old man/young man, a car/a window
#	≡	15	a person/one, a crowd/a large
≡	#	9	he is/man is, photo/still
≡	¬	1	girl is/she is

Table 6: Example misclassifications from some of the most frequent and most interesting error categories.

Figure 4 shows the classifier's confusion matrix and Table 6 shows some examples of common and interesting error cases. The majority of errors (26%) come from confusing the ∼ class with the # class. This mistake is not too concerning from an RTE perspective since ∼ can be treated as a special case of # (Section 5). There are very few cases in which the classifier makes extreme errors, e.g. confusing ≡ with ¬ or with #; some interesting examples of such errors arise when the phrases contain pronouns (e.g. *girl* ≡ *she*) or when the relation uses a highly infrequent word sense (e.g. *photo* ≡ *still*).

7.2 The Nutcracker RTE System

To further test our classifier, we evaluate the usefulness of the automatic entailment predictions in a downstream RTE task. We run our experiments using Nutcracker, a state-of-the-art RTE system based on formal semantics (Bjerva et al., 2014).

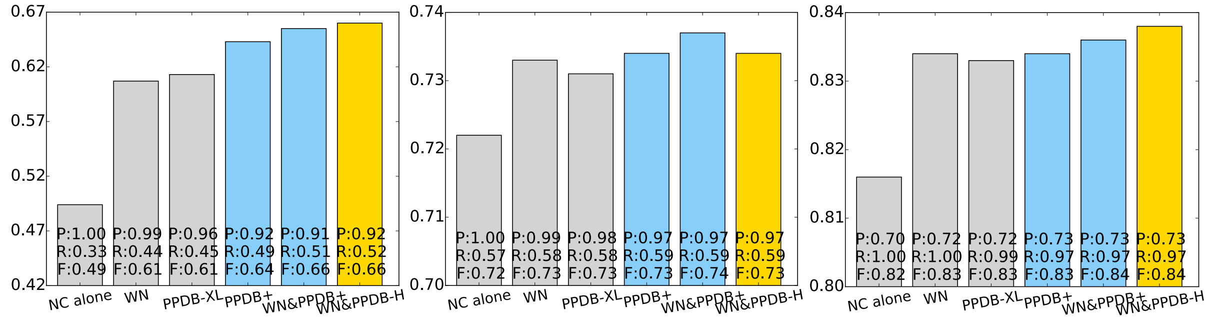


Figure 5: ENTAILMENT

Figure 6: CONTRADICTION

Figure 7: NEUTRAL

Figure 8: F1 measures achieved by Nutcracker on SICK test data when using various KBs. Baselines are in gray, this work in blue, human references in gold. PPDB-XL refers to a run in which every pair which appears in PPDB is assumed to be equivalent. PPDB-H refers to a run in which manual labels were used to generate axioms. PPDB+ refers to runs in which the automatic classifications were used to generate axioms. In some cases, better proof coverage causes NC to find incorrect proofs, illustrated by the decreased performance on CONTRADICTION when using PPDB-H. For example, using PPDB-H, NC finds an inconsistency for the pair *Someone is not playing piano./A person is playing a keyboard.* Using the PPDB+, in which *piano/keyboard* is falsely classified as #, NC fails to find a proof and so correctly guesses NEUTRAL.

	Freq.	Precision	Recall	F score
#	39%	84.22	87.55	85.85
≡	8%	70.36	83.07	76.19
⊐	26%	79.81	76.00	77.85
¬	7%	73.73	73.33	73.53
∼	19%	70.57	63.70	66.96

Table 7: F1 measure (×100) achieved by entailment classifier on the held out phrase pairs from the sentences in SICK test.

	Acc.	# Proofs	Coverage
MFC	56.4	0	0%
NC alone	74.3	878	17.8%
+ WN	77.5	1,051	21.3%
+ PPDB-XL	77.5	1,091	22.1%
+ PPDB+	78.0	1,197	24.3%
+ WN, PPDB+	**78.4**	**1,230**	**25.0%**
+ WN, PPDB-H	*78.6*	*1,232*	*25.0%*

Table 8: Nutcracker's overall system accuracy and proof coverage when using different sources of axioms. Coverage is measured as the percent of sentence pairs for which NC's theorem prover or model builder is able to find a complete logical proof of either entailment or contradiction. When NC fails to find either type of proof, it guesses the most frequent class, NEUTRAL. NC alone uses no axioms. PPDB+ refers to the axioms generated automatically using the classifier described in this paper. PPDB-H refers axioms generated using the human labels on which the classifier was trained.

In the SemEval 2014 RTE challenge, this system performed in the top 5 out of the more than 20 participating systems (Marelli et al., 2014).

Given a text/hypothesis (T/H) pair, Nutcracker (NC) uses the Boxer parser (Bos, 2008) to produce a formal semantic representation of both T and H, which it translates into standard first-order logic. The logical formulae are passed to an off-the-shelf theorem prover, which searches for a logical entailment, and to a model builder, which attempts to find a logical contradiction. By default, when the system fails to find a proof for either entailment or inconsistency, it predicts the most frequent class (in our case, NEUTRAL). Therefore, NC relies heavily on lexical entailment resources in order to improve the recall of the theorem prover and model builder.

Baselines The most frequent class baseline is achieved by labeling every sentence pair as NEUTRAL, and results in an accuracy of 56%. A stronger baseline is obtained by running NC alone, without any external axioms; in this case, words are only equivalent if they are lemma-identical.

As an additional baseline, we generate a "basic" PPDB-XL[3] knowledge base (KB), which consists exclusively of axioms expressing synonym relationships. I.e. for every pair of phrases $\langle p_1, p_2 \rangle$ in PPDB-XL, the PPDB-XL KB contains the equivalence axiom $syn(p_1, p_2)$. We also generate the WordNet (WN) KB, which is the default used by NC. This KB consists of axioms for all synonyms, antonyms, and hypernyms in WN, which generate syn, $isnota$, and isa axioms, respectively.

PPDB+ We convert our classifier's predictions into a set of axioms for NC. When our classifier predicts ≡ we generate an syn axiom, when it predicts ⊐ we generate an isa axiom, and when it predicts ¬ we generate an $isnota$ axiom. # and ∼ do not generate any axioms. To handle the directionality of the ⊐ relation, we run the classifier

[3] We generated basic KBs for all six sizes of PPDB, but XL performed best.

True	PPDB+	WN	Text/Hypothesis pair
ENTAIL.	ENTAIL.	NEUTRAL	A **bride** in a white dress is running/A **girl** in a white dress is running.
ENTAIL.	NEUTRAL	ENTAIL.	A **lemur** is biting a person's finger./An **animal** is biting a person's finger.
CONTRA.	CONTRA.	NEUTRAL	**Someone** is playing a piano./There is **no one** playing a piano.
CONTRA.	NEUTRAL	CONTRA.	There is **no man** pouring oil into a **pan**./**A man** is pouring oil into a **skillet**.

Table 9: Examples of T/H pairs for which the system's prediction differed when using PPDB+ vs. WN.

over every pair in both directions, and we choose whichever direction and relation receives the highest confidence score to be the final prediction. We refer to this set of automatically-predicted axioms as PPDB+.

To calibrate our improvements, we also generate a KB using the human labels collected from MTurk, which we refer to as PPDB-Human or PPDB-H.

Results Table 8 reports NC's overall prediction accuracy and the number of proofs found when using each of the described KBs. Figure 8 shows the performance in terms of the precision and recall achieved for each of the three entailment classes: ENTAILMENT, CONTRADICTION, and NEUTRAL. Table 9 provides some examples of T/H pairs on which predictions differed using the PPDB+ compared to the WN KB, and Figure 9 shows some illustrative misclassifications.

Our automatic labels result in a 4% improvement in accuracy over the baseline of using NC alone (Figure 8), and a 15 point improvement in F1 measure for the entailment class (Table 8). By all performance measures, PPDB+ also outperforms WordNet as a source of axioms for NC. Moreover, adding PPDB+ to WordNet gives a 17% relative increase in the number of proofs found compared to using WordNet alone (Table 8). These additional proofs lead NC to make a greater number of correct predictions for the "right reasons" (i.e. finding a proof/contradiction) rather than by lucky guessing (recall NC guesses the most frequent class when it cannot find a proof).

For comparison, we run the same experiments using a KB of oracle human labels in place of the predicted labels in PPDB+. Using PPDB+, NC comes very close to the performance achieved when using PPDB-Human, demonstrating that the automatically generated PPDB+ provides as much utility to the end-to-end system as does a gold-standard resource.

8 Data Release

Upon publication, we are releasing a new PPDB fully annotated with semantic relations. We are also releasing the set of 14K manually labeled phrase pairs occurring in RTE data, and our software for extracting features and running the classifier, so that researchers can apply our model to their own paraphrase collections. This will constitute the largest lexical entailment resources available, while also offering new fine-grained annotation necessary for challenging NLU tasks. An evaluation of the predicted relations appearing in the entire Paraphrase Database (not just those occurring in RTE data) is given in the supplementary material.

9 Conclusion

We argue that a significant failing of recent work on data-driven paraphrasing is the weak definition of paraphrases as being more-or-less equivalent. In this paper, we show how a clear concept of semantics can be applied to large-scale paraphrase resources. In particular, the entailment relations given by natural logic are a great fit for paraphrase resources, since natural logic operates on pairs of natural language expressions (like the entries in PPDB). By classifying paraphrase entries with entailment relations, we provide them with an interpretable semantics. Our classifier uses extensive feature sets to scale natural logic to the enormous number of phrase pairs in PPDB. We rigorously evaluate our model, demonstrating high accuracy on an intrinsic task. On an extrinsic RTE task, our model's predictions allow an RTE system to find 17% more proofs and achieve a higher overall accuracy than when using WordNet's manual relations. Our new release of PPDB, annotated with semantic entailments, will dramatically improve PPDB's utility for NLU tasks.

Abstract

We reduce phrase-based parsing to dependency parsing. Our reduction is grounded on a new intermediate representation, "head-ordered dependency trees," shown to be isomorphic to constituent trees. By encoding order information in the dependency labels, we show that any off-the-shelf, trainable dependency parser can be used to produce constituents. When this parser is non-projective, we can perform discontinuous parsing in a very natural manner. Despite the simplicity of our approach, experiments show that the resulting parsers are on par with strong baselines, such as the Berkeley parser for English and the best non-reranking system in the SPMRL-2014 shared task. Results are particularly striking for discontinuous parsing of German, where we surpass the current state of the art by a wide margin.

1 Introduction

Constituent parsing is a central problem in NLP—one at which statistical models trained on treebanks have excelled (Charniak, 1996; Klein and Manning, 2003; Petrov and Klein, 2007). However, most existing parsers are slow, since they need to deal with a heavy grammar constant. Dependency parsers are generally faster, but less informative, since they do not produce constituents, which are often required by downstream applications (Johansson and Nugues, 2008; Wu et al., 2009; Berg-Kirkpatrick et al., 2011; Elming et al., 2013). How to get the best of both worlds?

Coarse-to-fine decoding (Charniak and Johnson, 2005) and shift-reduce parsing (Sagae and Lavie, 2005; Zhu et al., 2013) were a step forward to accelerate constituent parsing, but typical runtimes still lag those of dependency parsers. This is only made worse if **discontinuous** constituents are allowed—such discontinuities are convenient to represent wh-movement, scrambling, extraposition, and other linguistic phenomena common in free word order languages. While non-projective dependency parsers, which are able to model such phenomena, have been widely developed in the last decade (Nivre et al., 2007; McDonald et al., 2006; Martins et al., 2013), discontinuous constituent parsing is still taking its first steps (Maier and Søgaard, 2008; Kallmeyer and Maier, 2013).

In this paper, we show that an off-the-shelf, trainable, **dependency parser** is enough to build a highly-competitive constituent parser. This (surprising) result is based on a **reduction**[1] of constituent to dependency parsing, followed by a simple post-processing procedure to recover unaries. Unlike other constituent parsers, ours does not require estimating a grammar, nor binarizing the treebank. Moreover, when the dependency parser is non-projective, our method can perform discontinuous constituent parsing in a very natural way.

Key to our approach is the notion of **head-ordered dependency trees** (shown in Figure 1): by endowing dependency trees with this additional layer of structure, we show that they become isomorphic to constituent trees. We encode this structure as part of the dependency labels, enabling a dependency-to-constituent conversion. A related conversion was attempted by Hall and Nivre (2008) to parse German, but their complex encoding scheme blows up the number of arc labels, affecting the final parser's quality. By contrast, our light encoding achieves a 10-fold decrease in the label alphabet, leading to more accurate parsing.

While simple, our reduction-based parsers are on par with the Berkeley parser for English (Petrov

and Klein, 2007), and with the best single system in the recent SPMRL shared task (Seddah et al., 2014), for eight morphologically rich languages. For discontinuous parsing, we surpass the current state of the art by a wide margin on two German datasets (TIGER and NEGRA), while achieving fast parsing speeds. We provide a free distribution of our parsers along with this paper, as part of the TurboParser toolkit.[2]

2 Background

We start by reviewing constituent and dependency representations, and setting up the notation. Following Kong and Smith (2014), we use c-/d- prefixes for convenience (*e.g.*, we write c-parser for constituent parser and d-tree for dependency tree).

2.1 Constituent Trees

Constituent-based representations are commonly seen as derivations according to a context-free grammar (CFG). Here, we focus on properties of the c-trees, rather than of the grammars used to generate them. We consider a broad scenario that permits c-trees with discontinuities, such as the ones derived with linear context-free rewriting systems (LCFRS; Vijay-Shanker et al. (1987)). We also assume that the c-trees are lexicalized.

Formally, let $w_1 w_2 \ldots w_L$ be a sentence, where w_i denotes the word in the ith position. A **c-tree** is a rooted tree whose leaves are the words $\{w_i\}_{i=1}^{L}$, and whose internal nodes (constituents) are represented as a tuple $\langle Z, h, \mathcal{I} \rangle$, where Z is a non-terminal symbol, $h \in \{1, \ldots, L\}$ indicates the lexical head, and $\mathcal{I} \subseteq \{1, \ldots, L\}$ is the node's yield. Each word's parent is a pre-terminal unary node of the form $\langle p_i, i, \{i\} \rangle$, where p_i denotes the word's part-of-speech (POS) tag. The yields and lexical heads are defined so that for every constituent $\langle Z, h, \mathcal{I} \rangle$ with children $\{\langle X_k, m_k, \mathcal{J}_k \rangle\}_{k=1}^{K}$, (i) we have $\mathcal{I} = \bigcup_{k=1}^{K} \mathcal{J}_k$; and (ii) there is a unique k such that $h = m_k$. This kth node (called the head-child node) is commonly chosen applying a handwritten set of head rules (Collins, 1999; Yamada and Matsumoto, 2003).

A c-tree is **continuous** if all nodes $\langle Z, h, \mathcal{I} \rangle$ have a contiguous yield $\mathcal{I}$, and **discontinuous** otherwise. Trees derived by a CFG are always continuous; those derived by a LCFRS may have discontinuities, the yield of a node being a union of spans, possibly with gaps in the middle. Figure 1 shows an example of a continuous and a discontinuous c-tree. Discontinuous c-trees have crossing branches, if the leaves are drawn in left-to-right surface order. An internal node which is not a preterminal is called a **proper node**. A node is called unary if it has exactly one child. A c-tree without unary proper nodes is called **unaryless**. If all proper nodes have exactly two children then it is called a **binary** c-tree. Continuous binary trees may be regarded as having been generated by a CFG in Chomsky normal form.

Prior work. There has been a long string of work in statistical c-parsing, shifting from simple models (Charniak, 1996) to more sophisticated ones using structural annotation (Johnson, 1998; Klein and Manning, 2003), latent grammars (Matsuzaki et al., 2005; Petrov and Klein, 2007), and lexicalization (Eisner, 1996; Collins, 1999). An orthogonal line of work uses ensemble or reranking strategies to further improve accuracy (Charniak and Johnson, 2005; Huang, 2008; Björkelund et al., 2014). Discontinuous c-parsing is considered a much harder problem, involving mildly context-sensitive formalisms such as LCFRS or range concatenation grammars, with treebank-derived c-parsers exhibiting near-exponential runtime (Kallmeyer and Maier, 2013, Figure 27). To speed up decoding, prior work has considered restrictons, such as bounding the fan-out (Maier et al., 2012) and requiring well-nestedness (Kuhlmann and Nivre, 2006; Gómez-Rodríguez et al., 2010). Other approaches eliminate the discontinuities via tree transformations (Boyd, 2007; Kübler et al., 2008), sometimes as a pruning step in a coarse-to-fine parsing approach (van Cranenburgh and Bod, 2013). However, reported runtimes are still superior to 10 seconds per sentence, which is not practical. Recently, Versley (2014a) proposed an easy-first approach that leads to considerable speed-ups, but is less accurate. In this paper, we design fast discontinuous c-parsers that outperform all the ones above by a wide margin, with similar runtimes as Versley (2014a).

2.2 Dependency Trees

In this paper, we use d-parsers as a black box to parse constituents. Given a sentence $w_1 \ldots w_L$, a **d-tree** is a directed tree spanning all the words in the sentence.[3] Each arc in this tree is a tuple

[2] http://www.ark.cs.cmu.edu/TurboParser

[3] We assume throughout that dependency trees have a single root among $\{w_1, \ldots, w_L\}$. Therefore, there is no need to

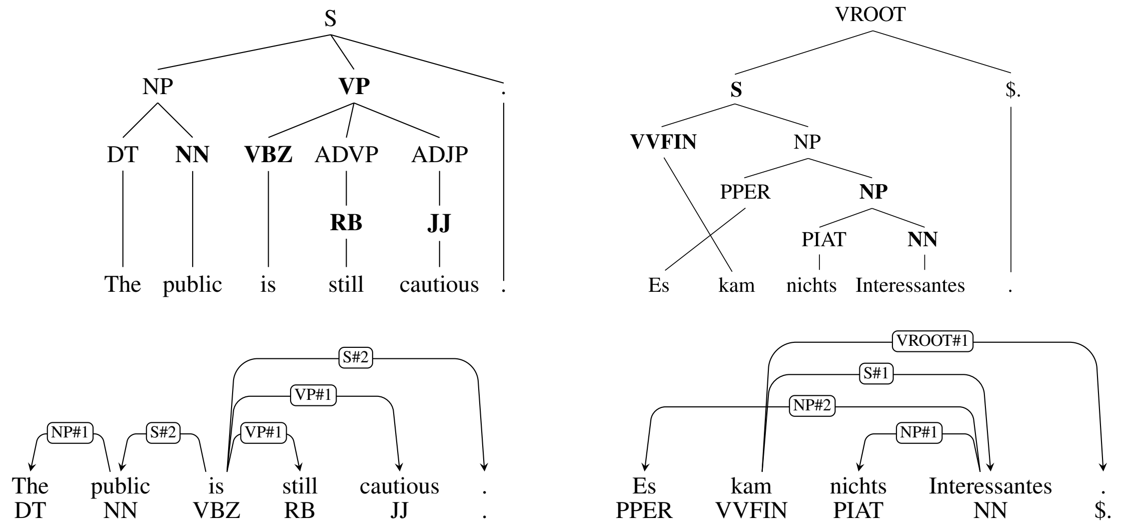

Figure 1: Top: a continuous (left) and a discontinuous (right) c-tree, taken from English PTB §22 and German NEGRA, respectively. Head-child nodes are in bold. Bottom: corresponding head-ordered d-trees. The indices #1, #2, etc. denote the order of attachment events for each head. Note that the English unary nodes ADVP and ADJP are dropped in the conversion.

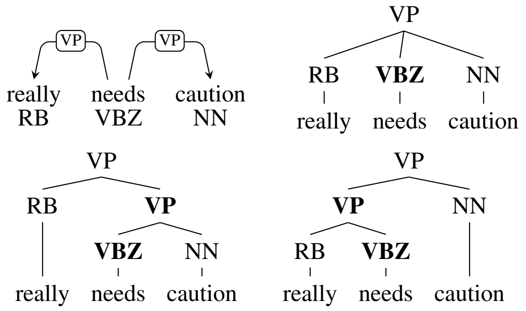

Figure 2: Three different c-structures for the VP "*really needs caution*." All are consistent with the d-structure at the top left.

$\langle h, m, \ell \rangle$, expressing a typed dependency relation ℓ between the head word w_h and the modifier w_m.

A d-tree is **projective** if for every arc $\langle h, m, \ell \rangle$ there is a directed path from h to all words that lie between h and m in the surface string (Kahane et al., 1998). Projective d-trees can be obtained from continuous c-trees by reading off the lexical heads and dropping the internal nodes (Gaifman, 1965). However, this relation is many-to-one: as shown in Figure 2, several c-trees may project onto the same d-tree, differing on their flatness and on left or right-branching decisions. In the next section, we introduce the concept of head-ordered d-trees and express one-to-one mappings between these two representations.

Prior work. There has been a considerable amount of work developing rich-feature d-parsers. While projective d-parsers can use dynamic programming (Eisner and Satta, 1999; Koo and Collins, 2010), non-projective d-parsers typically rely on approximate decoders, since the underlying problem is NP-hard beyond arc-factored models (McDonald and Satta, 2007). An alternative are transition-based d-parsers (Nivre et al., 2006; Zhang and Nivre, 2011), which achieve observed linear time. Since d-parsing algorithms do not have a grammar constant, typical implementations are significantly faster than c-parsers (Rush and Petrov, 2012; Martins et al., 2013). The key contribution of this paper is to reduce c-parsing to d-parsing, allowing to bring these runtimes closer.

3 Head-Ordered Dependency Trees

We next endow d-trees with another layer of structure, namely **order information**. In this framework, not all modifiers of a head are "born equal." Instead, their attachment to the head occurs as a sequence of "events," which reflect the head's preference for attaching some modifiers before others. As we will see, this additional structure will undo the ambiguity expressed in Figure 2.

3.1 Strictly Ordered Dependency Trees

Let us start with the simpler case where the attachment order is strict. For each head word h with modifiers $M_h = \{m_1, \ldots, m_K\}$, we endow M_h with a **strict order relation** $\prec_h$, so we can organize all the modifiers of h as a chain, $m_{i_1} \prec_h m_{i_2} \prec_h \ldots \prec_h m_{i_K}$. We regard this chain as reflecting the order by which words are attached (*i.e.*, if $m_i \prec_h m_j$ this means that "m_i is attached

consider an extra root symbol, as often done in the literature.

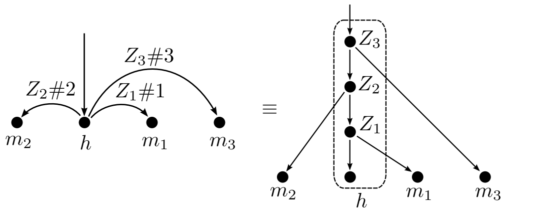

Figure 3: Transformation of a strictly-ordered d-tree into a binary c-tree. Each node is split into a linked list forming a spine, to which modifiers are attached in order.

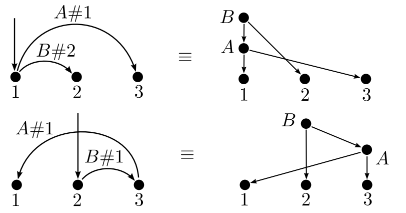

Figure 4: Two discontinuous constructions caused by a non-nested order (top) and a non-projective d-tree (bottom). In both cases node A has a non-contiguous yield.

to h before m_j"). We represent this graphically by decorating d-arcs with indices ($\#1, \#2, \ldots$) to denote the order of events, as we do in Figure 1.

A d-tree endowed with a strict order for each head is called a **strictly ordered d-tree**. We establish below a correspondence between strictly ordered d-trees and binary c-trees. Before doing so, we need a few more definitions about c-trees. For each word position $h \in \{1, \ldots, L\}$, we define $\psi(h)$ as the node higher in the c-tree whose lexical head is h. We call the path from $\psi(h)$ down to the pre-terminal p_h the **spine** of h. We may regard a c-tree as a set of L spines, one per word, which attach to each other to form a tree (Carreras et al., 2008). We then have the following

Proposition 1. *Binary c-trees and strictly-ordered d-trees are isomorphic, i.e., there is a one-to-one correspondence between the two sets, where the number of symbols is preserved.*

Proof. We use the construction in Figure 3. A formal proof is given as supplementary material. □

3.2 Weakly Ordered Dependency Trees

Next, we relax the strict order assumption, restricting the modifier sets $M_h = \{m_1, \ldots, m_K\}$ to be only **weakly ordered**. This means that we can partition the K modifiers into J equivalence classes, $M_h = \bigcup_{j=1}^{J} \bar{M}_h^j$, and define a strict order $\prec_h$ on the quotient set: $\bar{M}_h^1 \prec_h \ldots \prec_h \bar{M}_h^J$. Intuitively, there is still a sequence of events (1 to J), but now at each event j it may happen that multiple modifiers (the ones in the equivalence set $\bar{M}_h^j$) are simultaneously attached to h. A **weakly ordered d-tree** is a d-tree endowed with a weak order for each head and such that any pair m, m' in the same equivalence class (written $m \equiv_h m'$) receive the same dependency label ℓ.

Algorithm 1 Conversion from c-tree to d-tree

```
Input: c-tree $\mathcal{C}$.
Output: head-ordered d-tree $\mathcal{D}$.
Nodes := GetPostOrderTraversal($\mathcal{C}$).
Set $j(h) := 1$ for every $h = 1, \ldots, L$.
for $v := \langle Z, h, \mathcal{I} \rangle \in$ Nodes do
    for every $u := \langle X, m, \mathcal{J} \rangle$ which is a child of $v$ do
        if $m \neq h$ then
            Add to $\mathcal{D}$ an arc $\langle h, m, Z \rangle$, and put it in $\bar{M}_h^{j(h)}$.
        end if
    end for
    Set $j(h) := j(h) + 1$.
end for
```

We now show that Proposition 1 can be generalized to weakly ordered d-trees.

Proposition 2. *Unaryless c-trees and weakly-ordered d-trees are isomorphic.*

Proof. This is a simple extension of Proposition 1. The construction is the same as in Figure 3, but now we can collapse some of the nodes in the linked list, originating multiple modifiers attaching to the same position of the spine—this is only possible for sibling arcs with the same index and arc label. Note, however, that if we start with a c-tree with unary nodes and apply the inverse procedure to obtain a d-tree, the unary nodes will be lost, since they do not involve attachment of modifiers. In a chain of unary nodes, only the last node is recovered in the inverse transformation. □

We emphasize that Propositions 1–2 hold without blowing up the number of symbols. That is, the dependency label alphabet is exactly the same as the set of phrasal symbols in the constituent representations. Algorithms 1–2 convert back and forth between the two formalisms, performing the construction of Figure 3. Both algorithms run in linear time with respect to the size of the sentence.

3.3 Continuous and Projective Trees

What about the more restricted class of projective d-trees? Can we find an equivalence relation with continuous c-trees? In this section, we give a precise answer to this question. It turns out that we need an additional property, illustrated in Figure 4.

We say that $\prec_h$ has the **nesting property** iff closer words in the same direction are always attached first, *i.e.*, iff $h < m_i < m_j$ or $h > m_i >$

Algorithm 2 Conversion from d-tree to c-tree

```
Input: head-ordered d-tree $\mathcal{D}$.
Output: c-tree $\mathcal{C}$.
Nodes := GetPostOrderTraversal($\mathcal{D}$).
for $h \in$ Nodes do
    Create $v := \langle p_h, h, \{h\}\rangle$ and set $\psi(h) := v$.
    Sort $M_h(\mathcal{D})$, yielding $\bar{M}_h^1 \prec_h \bar{M}_h^2 \prec_h \ldots \prec_h \bar{M}_h^J$.
    for $j = 1, \ldots, J$ do
        Let $Z$ be the label in $\{\langle h, m, Z\rangle \mid m \in \bar{M}_h^j\}$.
        Obtain c-nodes $\psi(h) = \langle X, h, \mathcal{I}\rangle$ and $\psi(m) = \langle Y_m, m, \mathcal{J}_m\rangle$ for all $m \in \bar{M}_h^j$.
        Add c-node $v := \langle Z, h, \mathcal{I} \cup \bigcup_{m \in \bar{M}_h^j} \mathcal{J}_m\rangle$ to $\mathcal{C}$.
        Set $\psi(h)$ and $\{\psi(m) \mid m \in \bar{M}_h^j\}$ as children of $v$.
        Set $\psi(h) := v$.
    end for
end for
```

m_j implies that either $m_i \equiv_h m_j$ or $m_i \prec_h m_j$. A weakly-ordered d-tree which is projective and whose orders $\prec_h$ have the nesting property for every h is called a **nested-weakly ordered projective d-tree**. We then have the following result.

Proposition 3. *Continuous unaryless c-trees and nested-weakly ordered projective d-trees are isomorphic.*

Proof. See the supplementary material. □

Together, Propositions 1–3 have as corollary that nested-strictly ordered projective d-trees are in a one-to-one correspondence with binary continuous c-trees. The intuition is simple: if $\prec_h$ has the nesting property, then, at each point in time, all one needs to decide about the next event is whether to attach the closest available modifier on the *left* or on the *right*. This corresponds to choosing between left-branching or right-branching in a c-tree. While this is potentially interesting for most continuous c-parsers, which work with binarized c-trees when running the CKY algorithm, our c-parsers (to be described in §4) do not require any binarization since they work with weakly-ordered d-trees, using Proposition 2.

4 Reduction-Based Constituent Parsers

We now invoke the equivalence results established in §3 to build c-parsers when only a trainable d-parser is available. Given a c-treebank provided as input, our procedure is outlined as follows:

1. Convert the c-treebank to dependencies (Algorithm 1).
2. Train a labeled d-parser on this treebank.
3. For each test sentence, run the labeled d-parser and convert the predicted d-tree into a c-tree without unary nodes (Algorithm 2).
4. Do post-processing to recover unaries.

The next subsections describe each of these steps in detail. Along the way, we illustrate with experiments using the English Penn Treebank (Marcus et al., 1993), which we lexicalized by applying the head rules of Collins (1999).[4]

4.1 Dependency Encoding

The first step is to convert the c-treebank to head-ordered dependencies, which we do using Algorithm 1. If the original treebank has discontinuous c-trees, we end up with non-projective d-trees or with violations of the nested property, as established in Proposition 3. We handle this gracefully by training a non-projective d-parser in the subsequent stage (see §4.2). Note also that this conversion drops the unary nodes (a consequence of Proposition 2). These nodes will be recovered in the last stage, as described in §4.4.

Since in this paper we are assuming that only an off-the-shelf d-parser is available, we need to convert head-ordered d-trees to plain d-trees. We do so by encoding the order information in the dependency labels. We tried two different strategies. The first one, **direct encoding**, just appends suffixes #1, #2, etc., as in Figure 1. A disadvantage is that the number of labels grows unbounded with the treebank size, as we may encounter complex substructures where the event sequences are long. The second strategy is a **delta-encoding** scheme where, rather than writing the absolute indices in the dependency label, we write the *differences* between consecutive ones.[5] We used this strategy for the continuous treebanks only, whose d-trees are guaranteed to satisfy the nested property.

For comparison, we also implemented a replication of the encoding proposed by Hall and Nivre (2008), which we call **H&N-encoding**. This strategy concatenates all the c-nodes' symbols in the modifier's spine with the attachment position in the head's spine (*e.g.*, in Figure 3, if the modifier m_2 has a spine with nodes X_1, X_2, X_3, the generated d-label would be $\mathtt{X_1|X_2|X_3\#2}$; our direct encoding scheme generates $\mathtt{Z_2\#2}$ instead). Since their strategy encodes the entire spines into com-

[4] We train on §02–21, use §22 for validation, and test on §23. We predict automatic POS tags with *TurboTagger* (Martins et al., 2013), with 10-fold jackknifing on the training set.

[5] For example, if $\#1, \#3, \#4$ and $\#2, \#3, \#3, \#5$ are respectively the sequence of indices from the head to the left and to the right, we encode these sequences as $\#1, \#2, \#1$ and $\#2, \#1, \#0, \#2$ (using 3 distinct indices instead of 5).

plex arc labels, many such labels will be generated, leading to slower runtimes and poorer generalization, as we will see.

For the training portion of the English PTB, which has 27 non-terminal symbols, the direct encoding strategy yields 75 labels, while delta encoding yields 69 labels (2.6 indices per symbol). By contrast, the H&N-encoding procedure yields 731 labels, more than 10 times as many. We later show (in Tables 1–2) that delta-encoding leads to a slightly higher c-parsing accuracy than direct encoding, and that both strategies are considerably more accurate than H&N-encoding.

4.2 Training the Labeled Dependency Parser

The next step is to train a labeled d-parser on the converted treebank. If we are doing continuous c-parsing, we train a projective d-parser; otherwise we train a non-projective one.

In our experiments, we found it advantageous to perform labeled d-parsing in two stages, as done by McDonald et al. (2006): first, train an unlabeled d-parser; then, train a dependency labeler.[6] Table 1 compares this approach against a one-shot strategy, experimenting with various off-the-shelf d-parsers: *MaltParser* (Nivre et al., 2007), *MSTParser* (McDonald et al., 2005), *ZPar* (Zhang and Nivre, 2011), and *TurboParser* (Martins et al., 2013), all with the default settings. For *TurboParser*, we used basic, standard and full models.

Our separate d-labeler receives as input a backbone d-structure and predicts a label for each arc. For each head h, we predict the modifiers' labels using a simple sequence model, with features of the form $\phi(h, m, \ell)$ and $\phi(h, m, m', \ell, \ell')$, where m and m' are two consecutive modifiers (possibly on opposite sides of the head) and ℓ and ℓ' are their labels. We use the same arc label features $\phi(h, m, \ell)$ as *TurboParser*. For $\phi(h, m, m', \ell, \ell')$, we use the POS triplet $\langle p_h, p_m, p_{m'} \rangle$, plus unilexical features where each of the three POS is replaced by the word form. Both features are conjoined with the label pair ℓ and ℓ'. Decoding under this model can be done by running the Viterbi algorithm independently for each head. The runtime is almost negligible compared with the time to parse: it took 2.1 seconds to process PTB §22, a fraction of about 5% of the total runtime.

Table 2: Impact of direct and delta encodings on the dev sets of the SPMRL14 shared task. Reported are the number of labels and the F$_1$-scores yielded by each encoding technique.

4.3 Decoding into Unaryless Constituents

After training the labeled d-parser, we can run it on the test data. Then, we need to convert the predicted d-tree into a c-tree without unaries.

To accomplish this step, we first need to recover, for each head h, the weak order of its modifiers M_h. We do this by looking at the predicted dependency labels, extracting the event indices j, and using them to build and sort the equivalent classes $\{\bar{M}_h^j\}_{j=1}^J$. If two modifiers have the same index j, we force them to have consistent labels (by always choosing the label of the modifier which is the closest to the head). For continuous c-parsing, we also decrease the index j of the modifier closer to the head as much as necessary to make sure that the nesting property holds. In PTB §22, these corrections were necessary only for 0.6% of the tokens. Having done this, we use Algorithm 2 to obtain a predicted c-tree without unary nodes.

[6] The reason why a two-stage approach is preferable is that one-shot d-parsers, for efficiency reasons, use label features parsimoniously. However, for our reduction approach, d-labels are crucial and strongly interdependent, since they jointly encode the c-structure.

4.4 Recovery of Unary Nodes

The last stage is to recover the unary nodes. Given a unaryless c-tree as input, we predict unaries by running independent classifiers at each node in the tree (a simple unstructured task). Each class is either `NULL` (in which case no unary node is appended to the current node) or a concatenation of unary node labels (*e.g.*, `S->ADJP` for a node `JJ`). We obtained 64 classes by processing the training sections of the PTB, the fraction of unary nodes being about 11% of the total number of nodes. To reduce complexity, for each node symbol we only consider classes that have been observed with that symbol in the training data. In PTB §22, this yields an average of 9.9 candidates per node occurrence.

The classifiers are trained on the original c-treebank, stripping off unary nodes and trained to recover those nodes. We used the following features (conjoined with the class and with a flag indicating if the node is a pre-terminal):

- The production rules above and beneath the node (*e.g.*, `S->NP VP` and `NP->DT NN`);
- The node's label, alone and conjoined with the parent's label or the left/right sibling's label;
- The leftmost and rightmost word/lemma/POS tag/morpho-syntactic tags in the node's yield;
- If the left/right node is a pre-terminal, the word/lemma/morpho-syntactic tags beneath.

This is a relatively easy task: when gold unaryless c-trees are provided as input, we obtain an EVALB F$_1$-score of 99.43%. This large figure is due to the small amount of unary nodes, making this module have less impact on the final parser than the d-parser. Being a lightweight unstructured task, this step took only 0.7 seconds to run on PTB §22, a tiny fraction (less than 2%) of the total runtime.

Table 1 shows the accuracies obtained with the d-parser followed by the unary predictor. Since two-stage TP-Full with delta-encoding is the best strategy, we use this configuration in the sequel. To further explore the impact of delta encoding, we report in Table 2 the scores obtained by direct and delta encodings on eight other treebanks (see §5.2 for details on these datasets). With the exception of German, in all cases the delta encoding yielded better `EVALB` F$_1$-scores with fewer labels.

5 Experiments

To evaluate the performance of our reduction-based parsers, we conduct experiments in a variety of treebanks, both continuous and discontinuous.

Table 3: Results on the English PTB §23. All systems reporting runtimes were run on the same machine. Marked as * are reranking and semi-supervised c-parsers.

5.1 Results on the English PTB

Table 3 shows the accuracies and speeds achieved by our system on the English PTB §23, in comparison to state-of-the-art c-parsers. We can see that our simple reduction-based c-parser surpasses the three Stanford parsers (Klein and Manning, 2003; Socher et al., 2013, and Stanford Shift-Reduce), and is on par with the Berkeley parser (Petrov and Klein, 2007), while being more than 5 times faster.

The best supervised competitor is the recent shift-reduce parser of Zhu et al. (2013), which achieves similar, but slightly better, accuracy and speed. Our technique has the advantage of being flexible: since the time for d-parsing is the dominating factor (see §4.4), plugging a faster d-parser automatically yields a faster c-parser. While reranking and semi-supervised systems achieve higher accuracies, this aspect is orthogonal, since the same techniques can be applied to our parser.

5.2 Results on the SPMRL Datasets

We experimented with datasets for eight languages, from the SPMRL14 shared task (Seddah et al., 2014). We used the official training, development and test sets with the provided predicted POS tags. For French and German, we used the lexicalization rules detailed in Dybro-Johansen (2004) and Rehbein (2009), respectively. For Basque, Hungarian and Korean, we always took the rightmost modifier as head-child node. For Hebrew and Polish we used the leftmost modifier instead. For Swedish we induced head rules from the provided dependency treebank, as described in Versley (2014b). These choices were based on dev-set experiments.

Table 4 shows the results. For all languages except French, our system outperforms the Berkeley parser (Petrov and Klein, 2007), with or without prescribed POS tags. Our average F_1-scores are superior to the best non-reranking system participating in the shared task (Crabbé and Seddah, 2014) and to the c-parser of Hall et al. (2014), achieving the best results for 4 out of 8 languages.

5.3 Results on the Discontinuous Treebanks

Finally, we experimented on two widely-used discontinuous German treebanks: TIGER (Brants et al., 2002) and NEGRA (Skut et al., 1997). For the former, we used two different splits: TIGER-SPMRL, provided in the SPMRL14 shared task; and TIGER-H&N, used by Hall and Nivre (2008). For NEGRA, we used the standard splits. In these experiments, we skipped the unary recovery stage, since very few unary nodes exist in the data.[7] We ran *TurboTagger* to predict POS tags for TIGER-H&N and NEGRA, while in TIGER-SPMRL we used the predicted POS tags provided in the shared task. All treebanks were lexicalized using the head-rule sets of Rehbein (2009). For comparison to related work, sentence length cut-offs of 30, 40 and 70 were applied during the evaluation.

Table 5 shows the results. We observe that our approach outperforms all the competitors considerably, achieving state-of-the-art accuracies for both datasets. The best competitor, van Cranenburgh and Bod (2013), is more than 3 points behind, both in TIGER-H&N and in NEGRA. Our reduction-based parsers are also much faster: van Cranenburgh and Bod (2013) report 3 hours to parse NEGRA with $L \leq 40$. Our system parses all NEGRA sentences (regardless of length) in 27.1 seconds in a single core, which corresponds to a rate of 618 tokens per second. This approaches the speed of the easy-first system of Versley (2014a), who reports runtimes in the range 670–920 tokens per second, but is much less accurate.

Table 5: F_1 / exact match scores on TIGER and NEGRA test sets, with gold and predicted POS tags. These scores are computed by the DISCO-DOP evaluator ignoring root nodes and, for TIGER-H&N and NEGRA, punctuation tokens. The baselines are published results by Hall and Nivre 2008 (HN08), Maier et al. 2012 (M12), van Cranenburgh 2012 (C12), Kallmeyer and Maier 2013 (KM13), van Cranenburgh and Bod 2013 (CB13), and Versley 2014a, 2014b (V14a, V14b).

6 Related Work

Conversions between constituents and dependencies have been considered by De Marneffe et al. (2006) in one direction, and by Collins et al. (1999) and Xia and Palmer (2001) in the other, toward multi-representational treebanks (Xia et al., 2008). This prior work aimed at linguistically sound conversions, involving grammar-specific transformation rules to handle the kind of ambiguities expressed in Figure 2. Our work differs in that we are not concerned about the linguistic plausibility of our conversions, but only with the formal aspects that underlie the two representations.

The work most related to ours is Hall and Nivre (2008), who also convert dependencies to constituents to prototype a c-parser for German. Their encoding strategy is compared to ours in §4.1: they encode the entire spines into the dependency labels, which become rather complex and numerous. A similar strategy has been used by Versley (2014a) for discontinuous c-parsing. Both are largely outperformed by our system, as shown in §5.3. The crucial difference is that we encode only the top node's label and its position in the spine—besides being a much lighter representation, ours has an interpretation as a weak ordering, leading to the isomorphisms expressed in Propositions 1–3.

Joint constituent and dependency parsing have been tackled by Carreras et al. (2008) and Rush et al. (2010), but the resulting parsers, while accurate, are more expensive than a single c-parser. Very recently, Kong et al. (2015) proposed a much cheaper pipeline in which d-parsing is performed first, followed by a c-parser constrained to be con-

[7] NEGRA has no unaries; for the TIGER-SPMRL and H&N dev-sets, the fraction of unaries is 1.45% and 1.01%.

Table 4: F_1-scores on eight treebanks of the SPMRL14 shared task, computed with the provided `EVALB_SPMRL` tool, which takes into account all tokens except root nodes. Berkeley Tagged is a version of Petrov and Klein (2007) using the predicted POS tags provided by the organizers. Crabbé and Seddah (2014) is the best non-reranking system in the shared task, and Björkelund et al. (2014) the ensemble and reranking-based system which won the official task. We report their published scores.

sistent with the predicted d-structure. Our work differs in which we do not need to run a c-parser in the second stage—instead, the d-parser already stores constituent information in the arc labels, and the only necessary post-processing is to recover unary nodes. Another advantage of our method is that it can be readily used for discontinuous parsing, while their constrained CKY algorithm can only produce continuous parses.

7 Conclusion

We proposed a reduction technique that allows to implement a c-parser when only a d-parser is given. The technique is applicable to any d-parser, regardless of its nature or kind. This reduction was accomplished by endowing d-trees with a weak order relation, and showing that the resulting class of head-ordered d-trees is isomorphic to constituent trees. We showed empirically that the our reduction leads to highly-competitive c-parsers for English and for eight morphologically rich languages; and that it outperforms the current state of the art in discontinuous parsing of German.

Acknowledgments

Abstract

We present a constituent shift-reduce parser with a structured perceptron that finds the optimal parse in a practical runtime. The key ideas are new feature templates that facilitate state merging of dynamic programming and A* search. Our system achieves 91.1 F1 on a standard English experiment, a level which cannot be reached by other beam-based systems even with large beam sizes.[1]

1 Introduction

A parsing system comprises two components: a scoring model for a tree and a search algorithm. In shift-reduce parsing, the focus of most previous studies has been the former, typically by enriching feature templates, while the search quality has often been taken less seriously. For example, the current state-of-the-art parsers for constituency (Zhu et al., 2013; Wang and Xue, 2014) and dependency (Bohnet et al., 2013) both employ beam search with a constant beam size, which may suffer from severe search errors. This is contrary to ordinary PCFG parsing which, while it often uses some approximations, has nearly optimal quality (Petrov and Klein, 2007).

In this paper, we instead investigate the question of whether we can obtain a practical shift-reduce parser with state-of-the-art accuracy by focusing on optimal search quality like PCFG parsing. We base our system on best-first search for shift-reduce parsing formulated in Zhao et al. (2013), but it differs from their approach in two points. First, we focus on constituent parsing while they use dependency grammar. Second, and more crucially, they use a locally trained MaxEnt model, which is simple but not strong, while we explore a structured perceptron, the current state-of-the-art in shift-reduce parsing (Zhu et al., 2013).

As we will see, this model change makes search quite hard, which motivates us to invent new feature templates as well as to improve the search algorithm. In existing parsers, features are commonly exploited from the parsing history, such as the top k elements on the stack. However, such features are expensive in terms of search efficiency. Instead of relying on features primarily from the stack, our features mostly come from the span of the top few nodes, an idea inspired by the recent empirical success in CRF parsing (Hall et al., 2014). We show that these span features also fit quite well in the shift-reduce system and lead to state-of-the-art accuracy. We further improve search with new A* heuristics that make optimal search for shift-reduce parsers with a structured perceptron tractable for the first time.

The primary contribution of this paper is to demonstrate the effectiveness and the practicality of optimal search for shift-reduce parsing, especially when combined with appropriate features and efficient search. In English Penn Treebank experiments, our parser achieves an F1 score of 91.1 on test set at a speed of 13.6 sentences per second. This score is in excess of that of a beam-based system with larger beam size and same speed.

2 Background and Related Work

2.1 Shift-Reduce Constituent Parsing

We first introduce the shift-reduce algorithm for constituent structures. For space reasons, our exposition is rather informal; See Zhang and Clark (2009) for details. A shift-reduce parser parses a sentence through transitions between *states*, each of which consists of two data structures of a stack and a queue. The stack preserves intermediate parse results, while the queue saves unprocessed tokens. At each step, a parser selects an action,

[1] The open source software of our system is available at https://github.com/mynlp/optsr.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1534–1544,
Beijing, China, July 26-31, 2015.

which changes the current state into the new one. For example, SHIFT pops the front word from the queue and pushes it onto the stack, while REDUCE(X) combines the top two elements on the stack into their parent.[2] For example, if the top two elements on the stack are DT and NN, REDUCE(NP) combines these by applying the CFG rule NP → DT NN.

Unary Action The actions above are essentially the same as those in shift-reduce dependency parsing (Nivre, 2008), but a special action for constituent parsing UNARY(X) complicates the system and search. For example, if the top element on the stack is NN, UNARY(NP) changes it to NP by applying the rule NP → NN. In particular, this causes inconsistency in the numbers of actions between derivations (Zhu et al., 2013), which makes it hard to apply the existing best first search for dependency grammar to our system. We revisit this problem in Section 3.1.

Model The model of a shift-reduce parser gives a score to each derivation, i.e., an action sequence $\mathbf{a} = (a_1, \cdots, a_{|\mathbf{a}|})$, in which each a_i is a shift or reduce action. Let $\mathbf{p} = (p_1, \cdots, p_{|\mathbf{a}|})$ be the sequence of states, where p_i is the state after applying a_i to p_{i-1}. p_0 is the initial state for input sentence $\mathbf{w}$. Then, the score for a derivation $\Phi(\mathbf{a})$ is calculated as the total score of every action:

$$\Phi(\mathbf{a}) = \sum_{1 \le i \le |\mathbf{a}|} \phi(a_i, p_{i-1}). \qquad (1)$$

There are two well-known models, in which the crucial difference is in training criteria. The MaxEnt model is trained *locally* to select the correct action at each step. It assigns a probability for each action a_i as

$$P(a_i|p_{i-1}) \propto \exp(\theta^\intercal f(a_i, p_{i-1})), \qquad (2)$$

where θ and $f(a, p)$ are weight and feature vectors, respectively. Note that the probability of an action sequence $\mathbf{a}$ under this model is the product of local probabilities, though we can cast the total score in summation form (1) by using the log of (2) as a local score $\phi(a_i, p_{i-1})$.

The structured perceptron is instead trained *globally* to select the correct action sequence given an input sentence. It does not use probability and the local score is just $\phi(a_i, p_{i-1}) = \theta^\intercal f(a_i, p_{i-1})$. In practice, this global model is much stronger than the local MaxEnt model. However, training this model without any approximation is hard, and the common practice is to rely on well-known heuristics such as an early update with beam search (Collins and Roark, 2004). We are not aware of any previous study that succeeded in training a structured perceptron for parsing without approximation. We will show how this becomes possible in Section 3.

2.2 Previous Best-First Shift-Reduce Parsing

The basic idea behind best-first search (BFS) for shift-reduce parsing is assuming each parser state as a node on a graph and then searching for the *minimal cost* path from a start state (node) to the final state. This is the idea of Sagae and Lavie (2006), and it was later refined by Zhao et al. (2013). BFS gives a *priority* to each state, and a state with the highest priority (lowest cost) is always processed first. BFS guarantees that the first found goal is the best (*optimality*) if the *superiority* condition is satisfied: a state never has a lower cost than the costs of its previous states.

Though the found parse is guaranteed to be optimal, in practice, current BFS-based systems are not stronger than other systems with approximate search (Zhu et al., 2013; Wang and Xue, 2014) since all existing systems are based on the MaxEnt model. With this model, the speriority can easily be accomplished by using the negative log of (2), which is always positive and becomes smaller with higher probability. We focus instead on the structured perceptron, but achieving superiority with this model is not trivial. We resolve this problem in Section 3.1.

In addition to the mathematical convenience, the MaxEnt model itself helps search. Sagae and Lavie ascribe the empirical success of their BFS to the sparseness of the distribution over subsequent actions in the MaxEnt model. In other words, BFS is very efficient when only a few actions have dominant probabilities in each step, and the MaxEnt model facilitates this with its exponential operation (2). Unfortunately, this is not the case in our global structured perceptron because the score of each action is just the sum of the feature weights. Resolving this search difficulty is the central problem of this paper; we illustrate this problem in Section 4 and resolve it in Section 5.

[2] Many existing constituent parsers use two kinds of reduce actions for selecting the direction of its head child while we do not distinguish these two. In our English experiments, we found no ambiguity for head selection in our binarized grammar (See Section 4).

2.3 Hypergraph Search of Zhao et al. (2013)

The worst time complexity of BFS in Sagae and Lavie (2006) is exponential. For dependency parsing, Zhao et al. (2013) reduce it to polynomial by converting the search graph into a hypergraph by using the state merging technique of Huang and Sagae (2010). This hypergraph search is the basis of our parser, so we will briefly review it here.

The algorithm is closely related to agenda-based best-first parsing algorithms for PCFGs (Klein and Manning, 2001; Pauls and Klein, 2009). As in those algorithms, it maintains two data structures: a chart C that preserves *processed* states as well as a priority queue (agenda) Q. The difference is in the basic items processed in C and Q. In PCFG parsing, they are *spans*. Each span abstracts many *derivations* on that span and the chart maps a span to the best (lowest cost) derivation found so far. In shift-reduce parsing, the basic items are not spans but *states*, i.e., partial representations of the stack.[3] We denote $p = \langle i, j, s_d ... s_0 \rangle$ where s_i is the i-th top subtree on the stack and s_0 spans i to j. We extract features from $s_d ... s_0$. Note that d is constant and a state usually does not contain full information about a derivation. In fact, it only keeps *atomic features*, the minimal information on the stack necessary to recover the full features and packs many derivations. The chart maps a state to the current best derivation. For example, if we extract features only from the root symbol of s_0, each state looks the same as a span of PCFGs.

Differently from the original shift-reduce algorithm, during this search, reduce actions are defined between two states p and q. The basic operation of the algorithm is to pop the best (top) state p from the queue, push it into the chart, and then enqueue every state that can be obtained by a reduce action between p and other states in the chart or a *shift* action from p. The left states $\mathcal{L}(p)$ and right states $\mathcal{R}(p)$ are important concepts. $\mathcal{L}(p)$ is a set of states in the chart, with which p can reduce from the right side. Formally,

$$\mathcal{L}(\langle i, j, s_d ... s_0 \rangle) = \\ \{\langle h, i, s'_d ... s'_0 \rangle | \forall k \in [1, d], f_k(s'_{k-1}) = f_k(s_k)\},$$

where $f_k(\cdot)$ returns atomic features on the k-th top node. See Figure 4 for how they look like in constituent parsing. $\mathcal{R}(p)$ is defined similarly; p can reduce $q \in \mathcal{R}(p)$ from the left side. When p is popped, it searches for every $\mathcal{L}(p)$ and $\mathcal{R}(p)$ in the chart and tries to expand the current derivation.

The priority for each state is a pair (c, v). c is the prefix cost that is the total cost to reach that state, while v is the inside cost, a cost to build the top node s_0. The top state in the queue has the lowest prefix cost, or the lowest inside cost if the two prefix costs are the same.

3 Best-First Shift-Reduce Constituent Parsing with Structured Perceptron

This section describes our basic parsing system, i.e., shift-reduce constituent parsing with BFS and the structured perceptron. We have to solve two problems. The first is how to achieve BFS with the structured perceptron, and the second is how to apply that BFS to constituent parsing. Interestingly, the solution to the first problem makes the second problem relatively trivial.

3.1 Superiority of Structured Perceptron

We must design each priority of a state to satisfy the superiority condition. $\phi(a_i, p_{i-1}) = \theta^\intercal f(a_i, p_{i-1})$ is the usual local *score* employed in structured perceptrons (Huang and Sagae, 2010) but we cannot use it as a local *cost* for two reasons. First, in our system, the best parse should have the lowest cost; it is opposite in the ordinary setting (Collins, 2002). We can resolve this conflict by changing the direction of structured perceptron training so that the best parse has the lowest score.[4] Second, each $\phi(a_i, p_{i-1})$ can take a negative value but the cost should always be positive. This is in contrast to the MaxEnt model in which the negative log probability is always positive. Our strategy is to add a constant offset δ to every local cost. If δ is large enough so that every score is positive, the superiority condition is satisfied.[5]

Unary Merging Though this technique solves the problem with the structured perceptron for a simpler shift-reduce system, say for dependency grammar, the existence of unary actions, as mentioned in Section 2.1, requires additional effort in order to apply it to constituent parsing. In particular, constituent parsing takes different numbers of

[3] Although Zhao et al. (2013) explained that the items in Q are derivations (not states), we can implement Q as a set of states by keeping backpointers in a starndard way.

[4] This is easily accomplished by inverting all signs of the update equations.

[5] To find this value, we train our system using beam search with several beam sizes, choosing the maximum value of the action score during training.

$$\textsc{Sh} \qquad \frac{\overset{\text{state } p:}{\langle \_, j, s_d ... s_0\rangle : (c, \_)}}{\langle j, j+1, s_{d-1} ... s_0 | t_j(w_j)\rangle : (c + c_{\mathsf{sh}}(p), c_{\mathsf{sh}}(p))} \; j < n$$

$$\textsc{Shu}(\mathrm{X}) \qquad \frac{\overset{\text{state } p:}{\langle \_, j, s_d ... s_0\rangle : (c, \_)}}{\langle j, j+1, s_{d-1} ... s_0 | \mathrm{X}(t_j(w_j))\rangle : (c + c_{\mathsf{shu(X)}}(p), c_{\mathsf{shu(X)}}(p))} \; j < n$$

$$\textsc{Re}(\mathrm{X}) \qquad \frac{\overset{\text{state } q:}{\langle k, i, s'_d ... s'_0\rangle : (c', v')} \quad \overset{\text{state } p:}{\langle i, j, s_d ... s_0\rangle : (c, v)}}{\langle k, j, s'_d ... s'_1 | \mathrm{X}(s'_0, s_0)\rangle : (c' + v + c_{\mathsf{re(X)}}(p), v' + v + c_{\mathsf{re(X)}}(p))} \; q \in \mathcal{L}(p)$$

$$\textsc{Reu}(\mathrm{Y}, \mathrm{X}) \qquad \frac{\overset{\text{state } q:}{\langle k, i, s'_d ... s'_0\rangle : (c', v')} \quad \overset{\text{state } p:}{\langle i, j, s_d ... s_0\rangle : (c, v)}}{\langle k, j, s'_d ... s'_1 | \mathrm{Y}(\mathrm{X}(s'_0, s_0))\rangle : (c' + v + c_{\mathsf{reu(Y, X)}}(p), v' + v + c_{\mathsf{reu(Y, X)}}(p))} \; q \in \mathcal{L}(p)$$

Figure 1: The deductive system of our best-first shift-reduce constituent parsing explaining how the prefix cost and inside cost are calculated. FIN is omitted. $|$ on the stack means an append operation and $a(b)$ means a subtree $a \rightarrow b$. t_j is the POS tag of j-th token while w_j is the surface form. $c_a(p)$ is the cost for an action a of which features are extracted from p. Each $c_a(p)$ implicitly includes an offset δ.

actions for each derivation, which means that the scores of two final states may contain different offset values. The existing modification to alleviate this inconsistency (Zhu et al., 2013) cannot be applied here because it is designed for beam search.

We instead develop a new transition system, in which the number of actions to reach the final state is always $2n$ (n is the length of sentence). The basic idea is merging a unary action into each shift or reduce action. Our system uses five actions:

- SH: original shift action;
- SHU(X): shift a node, then immediately apply a unary rule to that node;
- RE(X): original reduce action;
- REU(Y, X): do reduce to X first, then immediately apply an unary rule Y → X to it;
- FIN: finish the process.

Though the system cannot perform consecutive unary actions, in practice it can generate any unary chains as long as those in the training corpus by collapsing a chain into one rule. We preprocess the corpus in this way along with binarization (See Section 4).

Note that this system is quite similar to the transition system for dependency parsing. The only changes are that we have several varieties of shift and reduce actions. This modification also makes it easy to apply an algorithm developed for dependency parsing to constituent parsing, such as dynamic programming with beam search (Huang and Sagae, 2010), which has not been applied into constituent parsing until quite recently (Mi and Huang, 2015) (See Section 7).

Algorithm 1 BFS for Constituent Parsing; Only differences from Zhao et al. (2013)

```
procedure SHIFT($x, Q$)
    TRYADD($\mathsf{sh}(x), Q$)
    for $y \in \mathsf{shu}(x)$ do
        TRYADD($y, Q$)
procedure REDUCE($A, B, Q$)
    for $(x, y) \in A \times B$ do
        for $z \in \mathsf{re}(x, y) \cup \mathsf{reu}(x, y)$ do
            TRYADD($z, Q$)
```

3.2 BFS with Dynamic Programming

Now applying BFS of Zhao et al. (2013) for dependency parsing into constituent parsing is not hard. Figure 1 shows the deductive system of dynamic programming, which is much similar to that in dependency parsing. One important change is that we include a cost for a shift (SH or SHU) action in the prefix cost in a shift step, not a reduce step as in Zhao et al. (2013), since it is unknown whether the top node s_0 of a state p is instantiated with SH or SHU. This modification keeps the correctness of the algorithm and has been employed in another system (Kuhlmann et al., 2011).

The algorithm is also slightly changed. We show only the difference from Zhao et al. (2013) (Algorithm 1) in Algorithm 1. $\mathsf{shu}(x)$ is a function which returns the set of states that can be arrived at by possible SHU rules applied to the state x. $\mathsf{re}(x, y)$ and $\mathsf{reu}(x, y)$ are similar, and they return the set of states arrived at through one of RE or REU actions. As a speed up, we can apply a lazy expansion technique (we do so in our experiment).

Model		F1	Speed (Sent./s.)
SP	(reduced features)	88.9	0.8
ME	(reduced features)	85.1	4.8
ME	(full features)	86.3	2.5

Table 1: Results of BFS systems with dynamic programming for the Penn Treebank development set with different models and features. SP = the structured perceptron; ME = the MaxEnt.

Another difference is in training. The previous best-first shift-reduce parsers are all trained in the same way as a parser with greedy search since the model is local MaxEnt. In our case, we can use structured perceptron training with exact search (Collins, 2002); that is, at each iteration for each sentence, we find the current argmin derivation with BFS, then update the parameters if it differs from the gold derivation. Note that at the beginning of training, BFS is inefficient due to the initial flat parameters. We use a heuristic to speed up this process: For a few iterations (five, in our case), we train the model with beam search and an early update (Collins and Roark, 2004). We find that this approximation does not affect the performance, while it greatly reduces the training time.

4 Evaluation of Best-First Shift-Reduce Constituent Parsing

This section evaluates the empirical performance of our best-first constituent parser that we built in the previous section. As mentioned in Section 2.2, the previous empirical success of best-first shift-reduce parsers might be due to the sparsity property of the MaxEnt model, which may not hold true in the structured perceptron. We investigate the validity of this assumption by comparing two systems, a locally trained MaxEnt model and a globally trained structured perceptron.

Setting We follow the standard practice and train each model on section 2-21 of the WSJ Penn Treebank (Marcus et al., 1993), which is binarized using the algorithm in Zhang and Clark (2009) with the head rule of Collins (1999). We report the F1 scores for the development set of section 22. The Stanford POS tagger is used for part-of-speech tagging.[6] We used the EVALB program to evaluate parsing performance.[7] Every experiment reported here was performed on hardware equipped with an Intel Corei5 2.5GHz processor and 16GB of RAM.

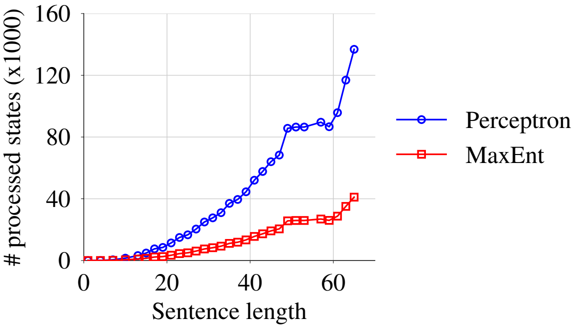

Figure 2: Comparison of the average number of the processed states of the structured perceptron with those of the MaxEnt model.

Feature We borrow the feature templates from Sagae and Lavie (2006). However, we found the full feature templates make training and decoding of the structured perceptron much slower, and instead developed simplified templates by removing some, e.g., that access to the child information on the second top node on the stack.[8]

Result Table 1 summarizes the results that indicate our assumption is true. The structured perceptron has the best score even though we restrict the features. However, its parsing speed is much slower than that of the local MaxEnt model. To see the difference in search behaviors between the two models, Figure 2 plots the number of processed (popped) states during search.

Discussion This result may seem somewhat depressing. We have devised a new method that enables optimal search for the structured perceptron, but it cannot handle even modestly large feature templates. As we will see below, the time complexity of the system depends on the used features. We have tried features from Sagae and Lavie (2006), but their features are no longer state-of-the-art. For example, Zhu et al. (2013) report higher scores by using beam search with much richer feature templates, though, as we have examined, it seems implausible to apply such features to our system. In the following, we find a practical solution for improving both parse accuracy and search efficiency in our system. We will see that our new features not only make BFS tractable, but also lead to comparable or even superior accuracy relative to the current mainstream features. When

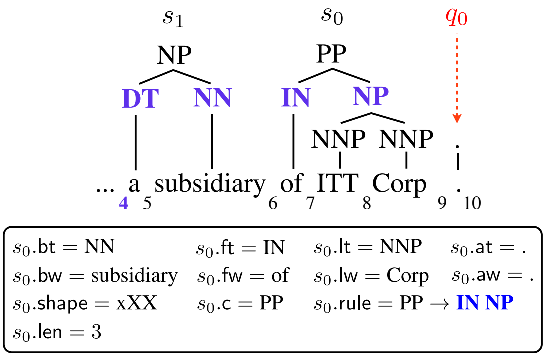

Figure 4: Atomic features of our system largely come from the span of a constituency. For each span (s_0 and s_1), we extract the surface form and POS tag of the preceding word (bw, bt), the first word (fw, ft), the last word (lw, lt), and the subsequent word (aw, at). shape is the same as that in Hall et al. (2014). Bold symbols are additional information from the system of Figure 3. The time complexity is $O(n^4 \cdot |G|^3 \cdot |N|)$.

it is combined with A* search, the speed reaches a practical level.

5 Improving Optimal Search Efficiency

5.1 Span Features

The worst time complexity of hypergraph search for shift-reduce parsing can be analyzed with the deduction rule of the reduce step. Figure 3 shows an example. In this case, the time complexity is $O(n^3 \cdot |G| \cdot |N|)$ since there are three indices (i, j, k) and four nonterminals (A, B, C, D), on which three comprise a rule. The extra factor $|N|$ compared with ordinary CKY parsing comes from the restriction that we extract features only from one state (Huang and Sagae, 2010).

Complexity increases when we add new atomic features to each state. For example, if we lexicalize this model by adding features that depend on the head indices of s_0 and/or s_1, it increases to $O(n^6 \cdot |G| \cdot |N|)$ since we have to maintain three head indices of A, B, and C. This is why Sagae and Lavie's features are too expensive for our system; they rely on head indices of s_0, s_1, s_2, s_3, the left and right children of s_0 and s_1, and so on, leading prohibitively huge complexity. Historically speaking, the success of shift-reduce approach in constituent parsing has been led by its success in dependency parsing (Nivre, 2008), in which the head is the primary element, and we suspect this is the reason why the current constituent shift-reduce parsers mainly rely on deeper stack elements and their heads.

The features we propose here are extracted from fundamentally different parts from these recent trends. Figure 4 explains how we extract atomic features from a state and Table 2 shows the full list of feature templates. Our system is unlexicalized; i.e., it does not use any head indices. This feature design is largely inspired by the recent empirical success of *span features* in CRF parsing (Hall et al., 2014). Their main finding is that the surface information on a subtree, such as the first or the last word of a span, has essentially the same amount of information as its head. For our system, such span features are much cheaper, so we expect they would facilitate our dynamic programming without sacrificing accuracy.

We customize their features for fitting in the shift-reduce framework. Unlike the usual setting of PCFG parsing, shift-reduce parsers receive a POS-tagged sentence as input, so we use both the POS tag and surface form for each word on the span. One difficult part is using features with an applied rule. We include this feature by memorizing the previously applied rule for each span (subtree). This is a bit costly, because it means we have to preserve labels of the left and right children for each node, which lead to an additional $|G|^2$ factor of complexity. However, we will see that this problem can be alleviated by our heuristic cost functions in A* search described below.

5.2 A* Search

We now explain our A* search, another key technique for speeding up our search. To our knowledge, this is the first work to successfully apply A* search to shift-reduce parsing.

A* parsing (Klein and Manning, 2003a) modifies the calculation of priority $\sigma(p_i)$ for state p_i. In BFS, it is basically the prefix cost, the sum of every local cost (Section 3.1), which we denote as β_{p_i}:

$$\beta_{p_i} = \sum_{1 \leq j \leq i} (\phi(a_j, p_{j-1}) + \delta).$$

In A* parsing, $\sigma(p_i) = \beta_{p_i} + h(p_i)$ where $h(p_i)$ is a heuristic cost. β_{p_i} corresponds to the Viterbi inside cost of PCFG parsing (Klein and Manning, 2003a) while $h(p_i)$ is the Viterbi outside cost, an approximation of the cost for the future best path (action sequence) from p_i.

$h(p_i)$ must be a lower bound of the *true* Viterbi outside cost. In PCFG parsing, this is often achieved with a technique called *projection*. Let G^* be a projected, or relaxed, grammar of the original G; then, a rule weight in the relaxed grammar w_{r^*} will become $w_{r^*} = \min_{r \in G: \pi(r) = r^*} w_r$, where $\pi(r)$ is a projection function which returns the set of rules that correspond to r in G^*.

In feature-based shift-reduce parsing, a rule weight corresponds to the sum of feature weights for an action a, that is, $\phi(a, p_i) = \theta^\mathsf{T} f(a, p_i)$. We calculate $h(p_i)$ with a relaxed feature function $\phi^*(a, p_i)$, which always returns a lower bound:

$$\phi^*(a, p_i) = \theta^{*\mathsf{T}} f(a, c_i) \leq \theta^\mathsf{T} f(a, p_i) = \phi(a, p_i).$$

Note that we only have to modify the weight vector. If a relaxed weight satisfies $\theta^*(k) \leq \theta(k)$ for all k, that projection is correct.

Our A* parsing is essentially hierarchical A* parsing (Pauls and Klein, 2009), and we calculate a heuristic cost $h(p)$ on the fly using another chart for the relaxed space when a new state p is pushed into the priority queue. Below we introduce two different projection methods, which are orthogonal and later combined hierarchically.

a	$\circ$	s_1.c	$\circ$	s_1.ft	θ	θ_{GP}	θ_{LF}
Sh	$\circ$	VP	$\circ$	NN	10.53	-5.82	-5.82

		...					
Sh	$\circ$	VP	$\circ$	DT	3.25	1.12	-5.82
Sh	$\circ$	SBAR	$\circ$	DT	**1.12**	1.12	-5.82
Sh	$\circ$	NP	$\circ$	DT	1.98	1.12	-5.82
		...					

Table 3: Example of our feature projection. θ_{GP} is a weight vector with the GP, which collapses every c. θ_{LF} is with the LF, which collapses all elements in Table 4.

s_1.c	s_1.ft	s_1.fw	s_1.bt	s_1.bw
s_1.len	s_1.shape	s_1.rule	s_0.rule	

Table 4: List of feature elements ignored in the LF.

Grammar Projection (GP) Our first projection borrows the idea from the filter projection of Klein and Manning (2003a), in which the grammar symbols (nonterminals) are collapsed into a single label X. Our projection, however, does not collapse all the labels into X; instead, we utilize constituent labels in level 2 from Charniak et al. (2006), in which labels that tend to be head, such as S or VP are collapsed into HP and others are collapsed into MP. θ_{G} in Table 3 is an example of how feature weights are relaxed with this projection. Here we show each feature as a tuple including action name (a). Let π_{GP} be a feature projection function: e.g.,

$$\begin{aligned}&((a \circ s_1.\mathsf{c} \circ s_1.\mathsf{ft}) = (\textsc{Sh} \circ \text{VP} \circ \text{NN}))\\ &\quad \mapsto_{\pi_{\text{GP}}} ((a \circ s_1.\mathsf{c} \circ s_1.\mathsf{ft}) = (\textsc{Sh} \circ \text{HP} \circ \text{NN})).\end{aligned}$$

Formally, for k-th feature, the weight $\theta_{\text{GP}}(k)$ is determined by minimizing over the features collapsed by π_{GP}:

$$\theta_{\text{GP}}(k) = \min_{1 \leq k' \leq K : \pi_{\text{GP}}(g_{k'}) = g_k} \theta(k'),$$

where g_k is the value of the k-th feature.

Less-Feature Projection (LF) The basic idea of our second projection is to *ignore* some of the atomic features in a feature template so that we can reduce the time complexity for computing the heuristics. We apply this technique to the feature elements in Table 4. We can do so by not filling in the actual value in each feature template: e.g.,

$$\begin{aligned}&((a \circ s_1.\mathsf{c} \circ s_1.\mathsf{ft}) = (\textsc{Sh} \circ \text{VP} \circ \text{NN}))\\ &\quad \mapsto_{\pi_{\text{LF}}} ((a \circ s_1.\mathsf{c} \circ s_1.\mathsf{ft}) = (\textsc{Sh} \circ s_1.\mathsf{c} \circ s_1.\mathsf{ft})).\end{aligned}$$

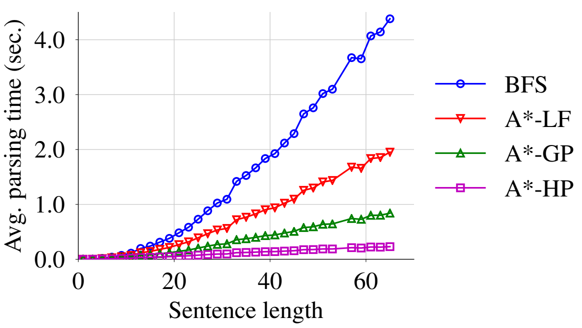

Figure 5: Comparison of parsing times between different A* heuristics.

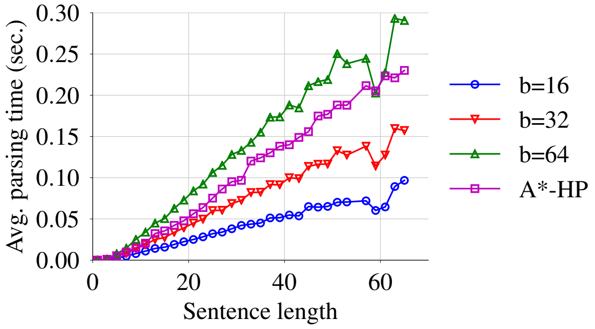

Figure 6: Comparison of parsing times between A* and beam search (with DP).

The elements in Table 4 are selected so that all bold elements in Figure 4 would be eliminated; the complexity is $O(n^3 \cdot |G| \cdot |N|)$. In practice, this is still expensive. However, we note that the effects of these two heuristics are complementary: The LF reduces complexity to a cubic time bound, while the GP greatly reduces the size of grammar $|G|$; We combine these two ideas below.

Hierarchical Projection (HP) The basic idea of this combined projection is to use the heuristics given by the GP to lead search of the LF. This is similar to the hierarchical A* for PCFGs with multilevel symbol refinements (Pauls and Klein, 2009). The difference is that their hierarchy is on the grammar symbols while our projection targets are features. When a state p is created, its heuristic score $h(p)$ is calculated with the LF, which requires search for the outside cost in the space of the LF, but its worst time complexity is cubic. The GP is used to guide this search. For each state p_{LF} in the space of the LF, the GP calculates the heuristic score. We will see that this combination works quite well in practice in the next section.

6 Experiment

We build our final system by combining the ideas in Section 5 and the system in Section 3. We also build beam-based systems with or without dynamic programming (DP) and with the ordinary or the new span features. All systems are trained with the structured perceptron. We use the early update for training beam-based systems.

Effect of A* heuristics Figure 5 shows the effects of A* heuristics. In terms of search quality, the LF is better; it prunes 92.5% of states compared to naive BFS, while the GP prunes 75%. However, the LF takes more time to calculate heuristics than the GP. The HP combines the advantages of both, achieving the best result.

Feaure	Z&C feature set			Span (this work)		
DP		✓			✓	
	F1	F1	Sent./s.	F1	F1	Sent./s.
b=16	89.1	90.1	34.6	88.6	89.9	31.9
b=32	89.6	89.9	20.0	89.3	90.2	17.0
b=64	89.7	90.2	10.6	89.6	90.2	9.1
A*	-	-	-	-	**90.7**	13.6
BFS	-	-	-	-	**90.7**	1.1

Table 5: Results for the Penn Treebank development set. Z&C = feature set of Zhang and Clark (2009). The speeds of non-DP and DP are the same, so we omit them from the comparison.

Accuracy and Speed The F1 scores for the development set are summarized in Table 5. We can see that the systems with our new feature (span) perform surprisingly well, at a competitive level with the more expensive features of Zhang and Clark (2009) (Z&C). This is particularly true with DP; it sometimes outperforms Z&C, probably because our simple features facilitate state merging of DP, which expands search space. However, our main result that the system with optimal search gets a much higher score (90.7 F1) than beam-based systems with a larger beam size (90.2 F1) indicates that ordinary beam-based systems suffer from severe search errors even with the help of DP. Though our naive BFS is slow (1.12 sent./s.), A* search considerably improves parsing speed (13.6 sent./s.), and is faster than the beam-based system with a beam size of 64 (Figure 6).

Unary Merging We have not mentioned the effect of our unary merging (Section 3), but the result indicates it has almost the same effect as the previously proposed padding method (Zhu et al.,

Table 6: The final results for section 23 of the Penn Treebank. The systems with † are reported by authors running on different hardware. We divide baseline state-of-the-art systems into three categories: shift-reduce systems (Sagae and Lavie, 2005; Sagae and Lavie, 2006; Zhu et al., 2013), other chart-based systems (Petrov and Klein, 2007; Socher et al., 2013), and the systems with external semi supervised features or reranking (Charniak and Johnson, 2005; McClosky et al., 2006; Zhu et al., 2013).

2013). The score with the non-DP beam size = 16 and Z&C (89.1 F1) is the same as that reported in their paper (the features are the same).

Final Experiment Table 6 compares our parsing system with those of previous studies. When we look at closed settings, where no external resource other than the training Penn Treebank is used, our system outperforms all other systems including the Berkeley parser (Petrov and Klein, 2007) and the Stanford parser (Socher et al., 2013) in terms of F1. The parsing systems with external features or reranking outperform our system. However, it should be noted that our system could also be improved by external features. For example, the feature of type-level distributional similarity, such as Brown clustering (Brown et al., 1992), can be incorporated with our system without changing the theoretical runtime.

7 Related Work and Discussion

Though the framework is shift-reduce, we can notice that our system is strikingly similar to the CKY-based discriminative parser (Hall et al., 2014) because our features basically come from two nodes on the stack and their spans. From this viewpoint, it is interesting to see that our system outperforms theirs by a large margin (Figure 6). Identifying the source of this performance change is beyond the scope of this paper, but we believe this is an important question for future parsing research. For example, it is interesting to see whether there is any structural advantage for shift-reduce over CKY by comparing two systems with exactly the same feature set.

As shown in Section 4, the previous optimal parser on shift-reduce (Sagae and Lavie, 2006) was not so strong because of the locality of the model. Other optimal parsing systems are often based on relatively simple PCFGs, such as unlexicalized grammar (Klein and Manning, 2003b) or factored lexicalized grammar (Klein and Manning, 2003c) in which A* heuristics from the unlexicalized grammar guide search. However, those systems are not state-of-the-art probably due to the limited context captured with a simple PCFG. A recent trend has thus been extending the context of each rule (Petrov and Klein, 2007; Socher et al., 2013), but the resulting complex grammars make exact search intractable. In our system, the main source of information comes from spans as in CRF parsing. This is cheap yet strong, and leads to a fast and accurate parsing system with optimality.

Concurrently with this work, Mi and Huang (2015) have developed another dynamic programming for constituent shift-reduce parsing by keeping the step size for a sentence to $4n - 2$, instead of $2n$, with an un-unary (stay) action. Their final score is 90.8 F1 on WSJ. Though they only experiment with beam-search, it is possible to build BFS with their transition system as well.

8 Conclusions

To date, all practical shift-reduce parsers have relied on approximate search, which suffers from search errors but also allows to utilize *unlimited* features. The main result of this paper is to show another possibility of shift-reduce by proceeding in an opposite direction: By selecting features and improving search efficiency, a shift-reduce parser with provable search optimality is able to find very high quality parses in a practical runtime.

{ws,duyantao,wanxiaojun}@pku.edu.cn

Abstract

This paper is concerned with building CCG-grounded, semantics-oriented deep dependency structures with a data-driven, factorization model. Three types of factorization together with different higher-order features are designed to capture different syntacto-semantic properties of functor-argument dependencies. Integrating heterogeneous factorizations results in intractability in decoding. We propose a principled method to obtain optimal graphs based on dual decomposition. Our parser obtains an unlabeled f-score of 93.23 on the CCGBank data, resulting in an error reduction of 6.5% over the best published result. which yields a significant improvement over the best published result in the literature. Our implementation is available at http://www.icst.pku.edu.cn/lcwm/grass.

1 Introduction

Combinatory Categorial Grammar (CCG; Steedman, 2000) is a linguistically expressive grammar formalism which has a transparent yet elegant interface between syntax and semantics. By assigning each lexical category a dependency *interpretation*, we can derive typed dependency structures from CCG derivations (Clark et al., 2002), providing a useful approximation to the underlying meaning representations. To date, CCG parsers are among the most competitive systems for generating such deep bi-lexical dependencies that appropriately encode a wide range of local and non-local syntacto-semantic information (Clark and Curran, 2007a; Bender et al., 2011). Such semantic-oriented dependency structures have been shown very helpful for NLP applications e.g. Question Answering (Reddy et al., 2014).

Traditionally, CCG graphs are generated as a by-product by grammar-guided parsers (Clark and Curran, 2007b; Fowler and Penn, 2010). The main challenge is that a *deep-grammar-guided* model usually can only produce limited coverage and corresponding parsing algorithms is of relatively high complexity. Robustness and efficiency, thus, are two major problems for handling practical tasks. To increase the applicability of such parsers, lexical or syntactic pruning has been shown necessary (Clark and Curran, 2004; Matsuzaki et al., 2007; Sagae et al., 2007; Zhang and Clark, 2011).

In the past decade, the techniques for data-driven dependency parsing has made a great progress (McDonald et al., 2005a,b; Nivre et al., 2004; Torres Martins et al., 2009; Koo et al., 2010). The major advantage of the data-driven architecture is complementary to the grammar-driven one. On one hand, data-driven approaches make essential uses of machine learning from linguistic annotations and are flexible to produce analysis for arbitrary sentences. On the other hand, without hard constraints, parsing algorithms for spanning specific types of graphs, e.g. projective (Eisner, 1996) and 1-endpoint-crossing trees (Pitler et al., 2013), can be of low complexity.

This paper proposes a new data-driven dependency parser that efficiently produces globally optimal CCG dependency graphs according to a discriminative, factorization model. The design of the factorization is motivated by three essential properties of the CCG dependencies. First, all arguments associated with the same predicate are highly correlated due to the nature that they approximates type-logical semantics. Second, all predicates govern the same argument exhibit the hybrid syntactic/semantic, i.e. head-complement-adjunct, relationships. Finally, the CCG dependency graphs are not but look very much like

[*] Email correspondence.

trees, which have many good computational properties. Simultaneously modeling the three properties yields intrinsically heterogeneous factorizations over the same graph, and hence results in intractability in decoding. Inspired by (Koo et al., 2010; Rush et al., 2010), we employ dual decomposition to perform principled decoding. Though not always, we can obtain the optimal solution most of time. The time complexity of our parser is $O(n^3)$ when various 1st- and 2nd-order features are incorporated.

We conduct experiments on English CCGBank (Hockenmaier and Steedman, 2007). Though our parser does not use any grammar information, including both lexical categories and syntactic derivations, it produces very accurate CCG dependency graphs with respect to both token and complete matching. Our parser obtains an unlabeled f-score of 93.23, resulting in, perhaps surprisingly, an error reduction of up to 6.5% over the best published performance reported in (Auli and Lopez, 2011). Our work indicates that high-quality data-driven parsers can be built for producing more general dependency graphs, rather than trees. Nevertheless, empirical evaluation indicates that explicitly or implicitly using tree-structured information plays an essential role. The result also suggests that a wider range of complicated linguistic phenomena beyond surface syntax can be well modeled even without explicitly using grammars. Our algorithm is also applicable to other graph-structured representations, e.g. HPSG predicate-argument analysis (Miyao et al., 2004).

2 Related Work

Hockenmaier and Steedman (2007) developed linguistic resources, namely CCGBank, from the Penn Treebank (PTB; Marcus et al., 1993). In CCGBank, PTB phrase-structure trees have been transformed into normal-form CCG derivations, and deep bi-lexical dependency graphs that encode functor-argument strcutures have been extracted from these derivations using coindexation information. The typed dependency analysis provides a useful approximation to the underlying meaning representations, and has been shown very helpful for NLP applications e.g. Question Answering (Reddy et al., 2014).

Traditionally, CCG graphs are generated as a by-product by deep parsers with a core grammar (Clark et al., 2002; Clark and Curran, 2007b; Fowler and Penn, 2010). On the other hand, modeling these dependencies within a CCG parser has been shown very effective to improve the parsing accuracy (Clark and Curran, 2007b; Xu et al., 2014). Besides CCG, similar deep dependency structures can be also extracted from parsers under other deep grammar formalisms, e.g. LFG (King et al., 2003) and HPSG (Miyao et al., 2004).

In recent years, data-driven dependency parsing has been well studied and widely applied to many NLP tasks. Research on data-driven approach to producing dependency graphs that are not limited to tree or forest structures has also been initialized. Sagae and Tsujii (2008) introduced a transition-based parser that is able to handle projective directed dependency graphs for HPSG-style predicate-argument analysis. McDonald and Pereira (2006) presented a graph-based parser that can generate graphs in which a word may depend on multiple heads, and evaluated it on the Danish Treebank. Encouraged by their work, we study factorization models as well as principled decoding for CCG-grounded, graph-structured representations.

Dual decomposition, and more generally Lagrangian relaxation, is a classical method for solving combinatorial optimization problems. It has been successfully applied to several NLP tasks, including parsing (Koo et al., 2010; Rush et al., 2010) and machine translation (Rush and Collins, 2011). To provide principled decoding for our factorization parser, we employ the dual decomposition technique. Our work directly follows (Koo et al., 2010). The two basic factorizations are similar to the model introduced in (Martins and Almeida, 2014). Lluís et al. (2013) introduced a dual decomposition based joint model for joint syntactic and semantic parsing. They are concerned with shallow semantic representation, i.e. Semantic Role Labeling, whose graphs are sparse. Different from their concern on integrating syntactic parsing and semantic role labeling under 1st-order factorization, we are interested in designing higher-order factorization models for more dense and general linguistic graphs.

3 Graph Factorization

3.1 Background Notations

Consider a sentence $s = \langle \mathbf{w}, \mathbf{p} \rangle$ with words $\mathbf{w} = w_1 w_2 \cdots w_n$ and POS-tags $\mathbf{p} = p_1 p_2 \cdots p_n$. First we add one more virtual word $w_0 = \#W_{root}\#$

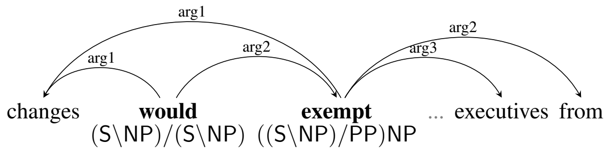

Figure 1: Examples to illustrate the predicate-centric view.

with POS-tag $p_0 = \#P_{root}\#$ which is conventionally considered as the root node of trees or graphs on the sentence. Then we denote the *index set* of all possible dependencies as $\mathcal{I} = \{(i,j)|i \in \{0,\cdots,n\}, j \in \{1,\cdots,n\}, i \neq j\}$. A dependency parse then can be represented as a vector

$$\boldsymbol{y} = \{y(i,j) : (i,j) \in \mathcal{I}\},$$

where $y(i,j) = 1$ if a dependency with predicate i and argument j is in the graph, 0 otherwise. Note that $\boldsymbol{y}$ is not a matrix but a long vector though we use two indexes to index it. In this paper, we only consider the unlabeled parsing task. Nevertheless, it is quite straightforward to extend our models to labeled parsing. Let $\mathcal{Y}$ denote the set of all possible $\boldsymbol{y}$. Given a function $f : \mathcal{Y} \rightarrow \mathbb{R}$ that assigns scores to parse graphs, the optimal parse is

$$\boldsymbol{y}^* = \arg\max_{\boldsymbol{y} \in \mathcal{Y}} f(\boldsymbol{y}).$$

Following recent advances in discriminative dependency parsing, we build disambiguation models based on global linear models, as in (McDonald et al., 2005a). In this framework, we score a dependency graph using a linear model:

$$f_\theta(\boldsymbol{y}) = \theta^\top \Phi(s, \boldsymbol{y}),$$

where $\Phi(s, \boldsymbol{y})$ produces a d-dimensional vector representation of the event that a CCG graph $\boldsymbol{y}$ is assigned to sentence s. In order to perform the decoding efficiently, we assume that the dependency graphs can be *factored* into smaller pieces. The main goal of this paper is to design appropriate factorization models, namely different types of f_θ's, to reflect essential properties of the semantics-oriented CCG dependency graphs.

3.2 Predicate-Centric Factorization

The very fundamental view of the CCG dependency graphs is based on their lexicalized, predicate-centric nature. Every word is assigned a lexical category, which directly encodes its subcategorization information. Due to the type-transparency nature of the formalism, this lexical category provides sufficient information for not only syntactic derivation but also semantic composition. It is important to capture functor-argument relations by putting all arguments of one particular predicate together. Figure 1 gives an example. The predicate "exempt" is of type "((S\NP)/PP)/NP," indicating that it takes three semantic dependents. This part of information is very similar to Semantic Role Labeling (SRL), whose goal is to find semantic roles for verbal predicates as well as their normalization. However, functor-argument analysis grounded in CCG is approximation of underlying logic forms and thus provides bi-lexical relations for almost all words. For instance, the second word in focus—"would"—captures structural information to organize other predicates yet entities.

In order to perform maximization efficiently in this view, we treat each predicate separately. Given a vector $\boldsymbol{y}^p$, we define

$$\boldsymbol{y}^p_{i\frown} = \{y(i,j) : j \in \{1,\cdots,n\}, j \neq i\}$$

and assume that $f(\boldsymbol{y}^p)$ takes the form

$$f^p(\boldsymbol{y}^p) = \sum_{i=0}^{n} f^p_i(\boldsymbol{y}^p_{i\frown})$$

To capture the relationships of all arguments to one particular predicate as a whole, we employ a Markov model. Let $a_1, \cdots, a_m$ be the sequence of the arguments of the word w_i under $\boldsymbol{y}^p_{i\frown}$. To keep the arguments in order, we constrain $1 \leq a_{j_1} < a_{j_2} \leq n$ if $j_1 < j_2$. In a *k-th order predicate-centric model*, we define

$$f^p_i(\boldsymbol{y}^p_{i\frown}) = \sum_{j=1}^{m+k-1} \theta_p^\top \Phi_p(a_{j-(k-1)}, ..., a_j, i, \mathbf{w}, \mathbf{p})$$

where a_j ($j \leq 0$ or $j \geq m+1$) are treated as specific initial or end state.

Higher-order rather than arc-factored features can be conveniently extracted from adjacent arguments. This is similar to the sibling factorization defined by a number of syntactic tree parsers, e.g. (McDonald and Pereira, 2006), (Koo and Collins, 2010) and (Ma and Zhao, 2012).

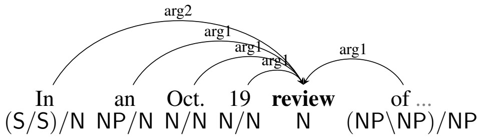

Figure 2: An example to illustrate the argument-centric view.

3.3 Argument-Centric Factorization

The syntactic principle for tree annotation treats the dependency relations between two words as syntactic projection. In another word, the head determines the syntactic category of the whole structure. The (type-logical) semantic principle determines a dependency according the types of the two words. The two kinds of dependency are coherent but not necessarily the same. In particular, an adjunct is a syntactic dependent but usually a semantic predicate of its syntactic head. Figure 2 gives an example to illustrate the idea. The argument in focus is "review" that is the complement of the preposition "in." The direction of this semantic dependency is the same to its corresponding syntactic dependency. Other predicates that semantically govern "review" are actually its modifiers, so the direction of these semantic dependencies are the opposite of their syntactic counterparts. It is important to capture head-complement-adjunct relations by putting all predicates of one particular argument together.

Similar to the predicate-centric model, we treat the graph fragment involved by each argument as independent, and capture the relationships among all predicates that governs the same argument using a Markov model. In the definition of predicate-centric model, if we exchange predicates and arguments, then we get our *argument-centric model.* Formally, we define

$$\boldsymbol{y}^a_{\curvearrowright j} = \{y(i,j) : i \in \{0, \cdots, n\}, j \neq i\}.$$

Let $p_1, \cdots, p_m$ be the sequence of the predicates (in linear word order) that semantically governs the word j under $\boldsymbol{y}^a_{\curvearrowright j}$. A *k-th order argument-centric model* scores the dependency graph as

$$\begin{aligned} f^a(y) &= \sum_{j=1}^{n} f^a_j(\boldsymbol{y}^a_{\curvearrowright j}) \\ &= \sum_{j=1}^{n} \sum_{i=1}^{m+k-1} \theta_a^\top \Phi_a(p_{i-(k-1)}, ..., p_i, j, \mathbf{w}, \mathbf{p}) \end{aligned}$$

Similarly, we define the initial and end states for p_i ($i < 0$ or $i \geq m+1$).

3.4 Tree Approximation Model

Tree structures exhibit many computationally-good properties, and have been widely applied to model linguistic, especially syntactic, structures. Tree-structured representation is an essential prerequisite for both the parsing algorithms and the machine learning methods in state-of-the-art syntactic dependency parsers. The CCG dependency graphs are not but look very much like trees. We thus argue that a tree-centric model can on one hand capture some topologically essential characteristics and on the other hand benefit from mature tree parsing techniques.

To this end, we propose tree approximation to obtain CCG sub-graphs under the factorization using tree parsing algorithms. In particular, we introduce an algorithm to associate every graph with a projective dependency tree, which we call *weighted conversion*. The tree reflects partial information about the corresponding graph. In this algorithm, we assign heuristic weights to all possible edges, and then find the tree with maximum weights. The key idea behind is to find a tree frame of a given graph. Given an arbitrary CCG graph, the conversion is perhaps imperfect in the sense that information about a small portion of edges is "lost." As a result, our tree approximation model can only generate partial graphs. Nevertheless, we will show (in Section 3.5 and 4.2) that such a model can be combined with predicate- and argument-centric factorization models in an elegant way.

3.4.1 Weighted Conversion

We assign weights to all the possible edges, i.e. all pairs of words, and then determine which edges to be kept by finding the maximum spanning tree. More formally, given a graph $\boldsymbol{y} = \{y(i,j)\}$, each possible edge (i,j) is assigned a heuristic weight $\omega(i,j)$. The maximum spanning tree $\boldsymbol{t} = \{t(i,j)\}$ contains the maximum sum of values of edges:

$$\boldsymbol{t}^{\max} = \arg\max_{\boldsymbol{t}} \sum_{(i,j)} t(i,j)\omega(i,j)$$

We separate the $\omega(i,j)$ into three parts ($\omega(i,j) = A(i,j) + B(i,j) + C(i,j)$) that are defined as below.

- $A(i,j) = a \cdot \max\{y(i,j), y(j,i)\}$: a is the weight for the existing edges on graph ignoring direction.
- $B(i,j) = b \cdot y(i,j)$: b is the weight for the forward edges on the graph.
- $C(i,j) = n - |i-j|$: This term estimates the importance of an edge where n is the length of the given sentence. For dependency parsing, we consider edges with short distance to be more important because those edges can be predicted more accurately in future parsing process.
- $a \gg b \gg n$ or $a > bn > n^2$: The converted tree should contain arcs in original graph as many as possible, and the direction of the arcs should not be changed if possible. The relationship of a, b, and c guarantees this.

After all edges are weighted, we can use maximum spanning tree (MST) algorithms to get the converted tree. To get the projective tree, we choose Eisner's algorithm. However, the obtained tree must be labeled in order to encode the original graph. Here we introduce a label vector $\mathbf{l} = \{l(i,j)\}$. For each $(i,j) \in \mathcal{I}$, we assign a label $l(i,j)$ to edge (i,j) as follows.

Case $y(i,j) = 1$**:** label "X";

Case $y(i,j) = 0 \wedge y(j,i) = 1$**:** label "X∼R";

Case $y(i,j) = 0 \wedge y(j,i) = 0$**:** label "None".

We can convert the *labeled* tree back to graph and obtain $\boldsymbol{y}^t$. Tough some edges are lost during the conversion, a lot more are kept. In fact, according to our evaluation, 92.74% of edges in the training set are retained after conversion.

3.4.2 Factorizing Trees

We use the tree parsing model proposed in (Bohnet, 2010) to score the converted trees. The model factorizes a tree into 1st-order and 2nd-order factors. When decoding, the model searches for a tree with the best score. The score defined for graphs as well as trees is

$$\begin{aligned} f^t(\boldsymbol{y}^t) &= g^t(\boldsymbol{t}, \mathbf{l}) = \theta_t^\top \Phi_t(s, \boldsymbol{t}, \mathbf{l}) \\ &= \theta_t^{1\top} \Phi_t^1(s, \boldsymbol{t}, \mathbf{l}) + \theta_t^{2\top} \Phi_t^2(s, \boldsymbol{t}, \mathbf{l}) \\ &= \Big(\sum_{(i,j)\in\mathcal{I}} t(i,j) \theta_t^{1\top} \Phi_t^1(l(i,j), \mathbf{w}, \mathbf{p})\Big) \\ &\quad + \theta_t^{2\top} \Phi_t^2(s, \boldsymbol{t}, \mathbf{l}), \end{aligned}$$

where Φ_t^1 is the 1st-order features and Φ_t^2 is the 2nd-order features.

3.5 Parsing as Optimization

Motivated by linguistic properties of the semantics-oriented CCG dependencies, we have designed three single factorization models from heterogeneous views. Our single models exhibit different predictive strengths considering that they are designed to capture different properties separately. Integrating them can generate better graphs, but is provably hard. To this end, we formulate the parsing problem as the following constrained optimization problem.

$$\begin{array}{ll} \text{maximize} & f^p(\boldsymbol{y}^p) + f^a(\boldsymbol{y}^a) + f^t(\boldsymbol{y}^t) \\ \text{subject to} & y^p(i,j) = y^a(i,j), \\ & y^p(i,j) \geq y^t(i,j), \\ & y^a(i,j) \geq y^t(i,j) \text{ for all } (i,j) \end{array}$$

The equality constraint says that the graph given by the predicate- and the argument-centric model must be identical, while the inequality constraints say that the frame of graph given by the tree approximation model must be a subgraph of what is given by the first two models.

4 Decoding

4.1 Easiness and Hardness of Decoding

The three factorization models are all solvable in polynomial time. The predicate-centric model and the argument-centric model can be decoded using dynamic programming. We provide the detailed description of such an algorithm in our supplementary note. The decoding method for k-th ($k \geq 2$) order model costs time of $O(n^{k+1})$ where n is the length of the sentence. The tree approximation model can re-use existing dependency tree parsing algorithms.

Unfortunately, the exact joint decoding of 2nd-order predicate- and argument-centric models is already NP-hard, not to mention other model combinations. The following gives a brief proof for the problem of combining the 2nd-order predicate- and argument-centric models.

Proof. Formally, we want to find a graph $\boldsymbol{y}$ which maximizes $F(\boldsymbol{y}) = f^p(\boldsymbol{y}) + f^a(\boldsymbol{y})$. We can design the feature function Φ_a and the parameter θ_a, such that for all $1 \leq i_1 \leq i_2 \leq n$,

$$\begin{cases} \theta_a^\top \Phi_a(0, i_1, j, \mathbf{w}, \mathbf{p}) = 0 \\ \theta_a^\top \Phi_a(i_1, n+1, j, \mathbf{w}, \mathbf{p}) = 0 \\ \theta_a^\top \Phi_a(i_1, i_2, j, \mathbf{w}, \mathbf{p}) = -\infty \\ \theta_a^\top \Phi_a(0, n+1, j, \mathbf{w}, \mathbf{p}) = -\infty \end{cases}$$

where n is the length of the sentence. Note that those 4 equations make the nodes except the root node in the optimal graph each have exactly one incoming edge. So the problem of finding a tree $\boldsymbol{t}$ maximizing $f^p(\boldsymbol{t})$ is reduced to this problem. Moreover, the NP-hard problem 3DM can be reduced to the problem of finding a tree $\boldsymbol{t}$ maximizing $f^p(\boldsymbol{t})$ (see McDonald and Pereira (2006)), leading to the NP-hardness of both of the problems. □

4.2 Decoding via Dual Decomposition

To solve the joint decoding problem, optimization techniques based on decomposition with coupling variables are applicable. In this paper, we propose to solve it via dual decomposition. The experiment results show that though not always, we can obtain the optimal solution most of time. To simplify the description, we only consider the 2nd-order case for all three models.

4.2.1 Lagrangian Relaxation

Notice that $y^p(i,j) \geq y^t(i,j)$ can be written as

$$y^p(i,j) = \begin{cases} 1, \text{ if } y^t(i,j) = 1; \\ \text{arbitrary}, \text{ if } y^t(i,j) = 0. \end{cases}$$

So the constraint can be written as $A^p \boldsymbol{y}^p + A^a \boldsymbol{y}^a + A^t \boldsymbol{y}^t = 0$, where

$$A^p = \begin{bmatrix} I \\ D_{\boldsymbol{y}^t} \\ \mathbf{0} \end{bmatrix} A^a = \begin{bmatrix} -I \\ \mathbf{0} \\ D_{\boldsymbol{y}^t} \end{bmatrix} A^t = \begin{bmatrix} \mathbf{0} \\ -D_{\boldsymbol{y}^t} \\ -D_{\boldsymbol{y}^t} \end{bmatrix}$$

I is the identity matrix and $D_{\boldsymbol{y}^t}$ is a diagonal matrix whose main diagonal is the vector $\boldsymbol{y}^t$.

The Lagrangian of the optimization problem is

$$\begin{aligned} \mathcal{L}(\boldsymbol{y}^p, \boldsymbol{y}^a, \boldsymbol{y}^t; u) &= f^p(\boldsymbol{y}^p) + f^a(\boldsymbol{y}^a) + f^t(\boldsymbol{y}^t) \\ &\quad + u^\top (A^p \boldsymbol{y}^p + A^a \boldsymbol{y}^a + A^t \boldsymbol{y}^t), \end{aligned}$$

where u is the Lagrangian multiplier.

Omitting the constraints, the dual objective is

$$\begin{aligned} \mathcal{L}(u) &= \max_{\boldsymbol{y}^p, \boldsymbol{y}^a, \boldsymbol{y}^t} \mathcal{L}(\boldsymbol{y}^p, \boldsymbol{y}^a, \boldsymbol{y}^t; u) \\ &= \max_{\boldsymbol{y}^p} (f^p(\boldsymbol{y}^p) + u^\top A^p \boldsymbol{y}^p) \\ &\quad + \max_{\boldsymbol{y}^a} (f^a(\boldsymbol{y}^a) + u^\top A^a \boldsymbol{y}^a) \\ &\quad + \max_{\boldsymbol{y}^t} (f^t(\boldsymbol{y}^t) + u^\top A^t \boldsymbol{y}^t) \end{aligned}$$

Let $\mathcal{L}^*$ be the maximized value of $\mathcal{L}(\boldsymbol{y}^p, \boldsymbol{y}^a, \boldsymbol{y}^t; u)$ subjected to the constraints, then $\mathcal{L}^* = \min_u \mathcal{L}(u)$, according to the duality principle.

4.2.2 Decoding Algorithm

There are two challenges in solving the dual problem. One challenge is to find the minimum value of the dual objective. For this, we can use subgradient method, as is demonstrated in Algorithm 1. The other is the evaluation of $\mathcal{L}(u)$. For this, we decompose the dual objective into three optimization problems. Let $B^p = u^\top A^p$, $B^a = u^\top A^a$, $B^t = u^\top A^t$, and

$$C^t_{\mathbf{l}}(i,j) = \begin{cases} B^t(i,j), \text{ if } l(i,j) = \text{X}; \\ B^t(j,i), \text{ if } l(i,j) = \text{X} \sim \text{R}; \end{cases}$$

we can just redefine

$$\begin{aligned} f^p_i(\boldsymbol{y}_{i\curvearrowright}) &= \sum_{j=1}^{m+1} \big(\theta_p^\top \Phi_p(a_{j-1}, a_j, i, \mathbf{w}, \mathbf{p}) \\ &\quad + B^p(i,j)\big) \\ f^a_j(\boldsymbol{y}_{\curvearrowright j}) &= \sum_{i=1}^{m+1} \big(\theta_a^\top \Phi_a(p_{i-1}, p_i, j, \mathbf{w}, \mathbf{p}) \\ &\quad + B^a(i,j)\big) \\ f^t(\boldsymbol{y}) &= \Big(\sum_{(i,j) \in \mathcal{I}} t(i,j) \big(\theta_t^{1\top} \Phi_t^1(l(i,j), \mathbf{w}, \mathbf{p}) \\ &\quad + C^t_{\mathbf{l}}(i,j)\big)\Big) + \theta_t^{2\top} \Phi_t^2(s, \boldsymbol{t}, \mathbf{l}), \end{aligned}$$

and decode according to the new scores. In fact, this equals to attach some new weights to 1st-order factors, without changing the decoding algorithms for the subproblems. This nice property also allows using higher-order models for subproblems.

Algorithm 1: Joint decoding algorithm

```
**Initialization**: set $u^{(0)}$ to 0
**for** $k = 1$ **to** $K$ **do**
    $\boldsymbol{y}^p_{(k)} \leftarrow \arg\max_{\boldsymbol{y}} f^p(\boldsymbol{y}) + u_{(k)} A^p \boldsymbol{y}$
    $\boldsymbol{y}^a_{(k)} \leftarrow \arg\max_{\boldsymbol{y}} f^a(\boldsymbol{y}) + u_{(k)} A^a \boldsymbol{y}$
    $\boldsymbol{y}^t_{(k)} \leftarrow \arg\max_{\boldsymbol{y}} f^t(\boldsymbol{y}) + u_{(k)} A^t \boldsymbol{y}$
    **if** $A^p \boldsymbol{y}^p_{(k)} + A^a \boldsymbol{y}^a_{(k)} + A^t \boldsymbol{y}^t_{(k)} = 0$ **then**
        **return** $\boldsymbol{y}_a$
    $u_{(k)} \leftarrow u_{(k-1)}$
        $-\alpha^k (A^p \boldsymbol{y}^p_{(k)} + A^a \boldsymbol{y}^a_{(k)} + A^t \boldsymbol{y}^t_{(k)})$
```

Algorithm 1 is our decoding algorithm. In every iteration, we first compute the optimal $\boldsymbol{y}$'s of the three subproblems. If the $\boldsymbol{y}$'s satisfies the constraints, then we've find the optimal solution for the original problem. If not, we update the Lagrangian multiplier u, towards the negative subgradient. We initialized u to be a zero vector, and use α^k to be the step length of each iteration. When we decode the subproblems, the $D_{\boldsymbol{y}^c}$ in A^p and A^a is derived from the $\boldsymbol{y}^c$ obtained in the current iteration.

We can also assign weights to different factorization models. If we choose to do so, the Lagrangian becomes

$$\begin{aligned}\mathcal{L}(\boldsymbol{y}^p, \boldsymbol{y}^a, \boldsymbol{y}^c; u) &= w^p f^p(\boldsymbol{y}^p) + w^a f^a(\boldsymbol{y}^a) \\ &+ w^c f^t(\boldsymbol{y}^t) + u^\top(A^p\boldsymbol{y}^p + A^a\boldsymbol{y}^a + A^t\boldsymbol{y}^t).\end{aligned}$$

And the decoding of subproblems in our algorithm becomes

$$\begin{aligned}\boldsymbol{y}^p_{(k)} &\leftarrow \arg\max_{\boldsymbol{y}} f^p(\boldsymbol{y}) + \frac{1}{w^p} u_{(k)} A^p \boldsymbol{y}; \\ \boldsymbol{y}^a_{(k)} &\leftarrow \arg\max_{\boldsymbol{y}} f^a(\boldsymbol{y}) + \frac{1}{w^a} u_{(k)} A^a \boldsymbol{y}; \\ \boldsymbol{y}^t_{(k)} &\leftarrow \arg\max_{\boldsymbol{y}} f^t(\boldsymbol{y}) + \frac{1}{w^c} u_{(k)} A^t \boldsymbol{y}.\end{aligned}$$

The algorithm we give here is the joint decoding for all the three models. We can also decode using any two of them, and it is trivial to adapt the algorithm to the decoding.

4.3 Pruning

In order to improve the efficiency of the algorithm, we also do some pruning. One idea is that, in predicate-centric model, different type of predicates has different number of arguments. For example, the predicates POS-tagged "DT" each has only one argument in most cases. Therefore, we assign each POS-tag a max number of arguments. When decoding, we search at most those number of arguments instead of all the words in the sentence. This pruning method can also be applied to the argument-centric model. The other idea is that, some pairs of types never form a predicate-argument relation. So we can skip extracting feature of those POS-tag pairs, just take $-\infty$ to be their scores.

5 Evaluation and Analysis

5.1 Experimental Setup

CCGbank is a translation of the Penn Treebank into a corpus of CCG derivations (Hockenmaier and Steedman, 2007). CCGbank pairs syntactic derivations with sets of word-word dependencies which approximate the underlying functor-argument structure. Our experiments were performed using CCGBank which was split into three subsets for training (Sections 02-21), development testing (Section 00) and the final test (Section 23). We also use the syntactic dependency trees provided by the CCGBank to obtain necessary information for graph parsing. However, different from experiments in the CCG parsing literature, we use no grammar information. Neither lexical categories nor CCG derivations are utilized.

	Devel.	Test
HMM Tagger	96.74%	97.23%
Transition-based Parser	93.48%	93.09%
Graph-based Parser	93.47%	93.19%

Table 1: The accuracy of the POS tagger and the UAS of the syntax tree parsers.

All experiments were performed using automatically assigned POS-tags that are generated by a symbol-refined generative HMM tagger[1] (Huang et al., 2010), and automatically parsed dependency trees that are generated by our in-house implementation of the transition-based model presented in (Zhang and Nivre, 2011) as well as a 2nd-order graph-based parser[2] (Bohnet, 2010). The accuracy of these preprocessors is shown in Table 1. We ran 5-fold jack-knifing on the gold-standard training data to obtain imperfect dependency trees, splitting off 4 of 5 sentences for training and the other 1/5 for testing, 5 times. For each split, we re-trained the tree parsers on the training portion and applied the resulting model to the test portion.

Previous research on dependency parsing shows that structured perceptron (Collins, 2002) is one of the strongest discriminative learning algorithms. To estimate θ's of different models, we utilize the averaged perceptron algorithm. We implement our own the predicate- and argument-centric models. To perform tree parsing, we re-use the open-source implementation provided by the mate-tool. See the source code attached for details. We set iteration 5 to train predicate- and argument-centric models and 10 for the tree approximation model. To perform dual decomposition, we set the maximum iteration 200.

Table 2: Parsing performance on the development data. The column "Tree" denotes the parsers that give dependency tree of development set: no tree (No), transition-based (Tr) or graph-based (Gr). "PC," "AC" and "TA" in the second column denotes the predicate-centric, the argument-centric and the tree approximation models, respectively.

5.2 Effectiveness of Data-driven Models

Table 2 summarizes parsing performance on development set with different configurations. We report unlabeled precision (UP), recall (UR), f-score (UF) as well as complete match (UEM). It can be clearly seen that the data-driven models obtains high-quality graphs with respect to token match. Even without any syntactic information (see the top block associated with "No Tree"), our parser with all three factorization models obtains an f-score of 92.5. when assisted by a syntactic parser, this figure goes up to over 93.1. If the predicate- or argument-centric model is applied by itself, either one can achieve a competitive accuracy, especially when syntactic features are utilized.

5.3 Effectiveness of Multiple Factorization

We use dual decomposition to perform joint decoding. First we combine the predicate-centric model and the argument-centric model. Compared to each single model, an error reduction of about 7% on f-score (UF) on average is achieved. Furthermore, we ensemble all the three models. If no syntactic features are extracted, the "TA" model brings in a remarkable further absolute gain of 1.02 with respect to token match. If syntactic features are used, the "PC" and "AC" models already achieves relatively good performance, and the "TA" model does not contribute much considering token match. The join of the tree approximation model lowers the precision, it increases the recall further, resulting in a modest improvement of the f-score. Nonetheless, the "TA" model still significantly improve the complete match metric. It is noticeable that in all setting, the "TA" model result in very significant boost in complete match.

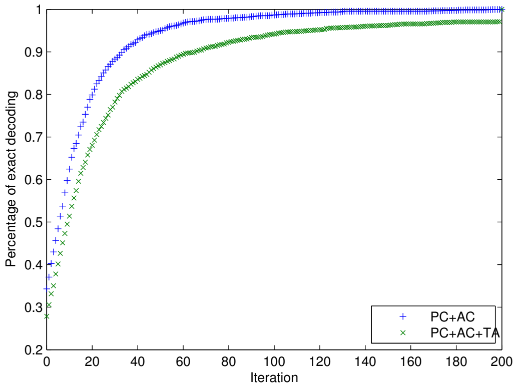

Figure 3: The exact decoding rate.

The dual decomposition does not guarantee to find an exact solution (in a limited number of iterations) in theory but usually works very well in practice. We calculate the percentage of finding exact decoding below k iterations, and the result is show in Figure 3. The transition-based tree parser is utilized here. We can see that for most sentences, dual decomposition practically gives the exact solutions.

5.4 Importance of Tree Structures

Our factorization parser (with best experimental setting) does not utilize a grammar but do use syntactic information in the dependency formalism. In particular, the parser extracts the so-called path features from dependency trees. The syntactic trees is very importance to our parser, which provide a critical set of features for the predicate-centric and the argument-centric models. Without the syntactic trees, their performances decrease significantly. We try two different parsers to obtain the syntax tree parses. One is of the transition-based architecture, and the other graph-

Table 3: Comparing the state-of-art with our models on test set.

based. The architecture of the syntactic tree parser does not affect the results much. The two tree parsers give identical attachment scores, and lead to similar graph parsing accuracy. This result is somehow non-obvious given that the combination of a graph-based and transition-based parser usually gives significantly better parsing performance (Nivre and McDonald, 2008; Torres Martins et al., 2008).

Although the target representation of our parser is general graphs rather trees, implicitly or explicitly using tree-structured information plays an essential role. Syntactic features are able to improve the f-score achieved by the "PC+AC" model from 90.9 to 92.8, while the "TA" model can bring in an absolute gain of 1.6. Note that the "TA" model does not utilize any syntactic tree information. The converted trees are automatically induced from the CCG graphs. Even when syntactic trees are available, the automatically induced trees can still significantly improve the complete match with respect to the whole sentence.

5.5 Comparison to the State-of-the-art

We compare our results with the best published CCG parsing performance obtained by the models presented in (Auli and Lopez, 2011) and (Xu et al., 2014)[3]. Auli and Lopez (2011) reported best numeric performance. The performance is evaluated on sentences that can be parsed by their model. Xu et al. (2014) reported the best published results for sentences with full coverage. All results on the test set is shown in Table 3. Even without any syntactic features, our parser achieves accuracies that are superior to Xu et al.'s parser and comparable to Auli and Lopez's system. When unlabeled syntactic trees are provided, our parser outperform the state-of-the-art.

6 Conclusion

In this paper, we have presented a factorization parser for building CCG-grounded dependency graphs. It achieves substantial improvement over the state-of-the-art. Perhaps surprisingly, our data-driven, grammar-free parser yields a superior accuracy to all CCG parsers in the literature. Our work indicates that high-quality data-driven parsers can be built for producing more general dependency graphs, rather than trees. Our method is also applicable to other deep dependency structures, e.g. HPSG predicate-argument analysis (Miyao et al., 2004), as well as other graph-structured semantic representations, e.g. Abstract Meaning Representations (Banarescu et al., 2013).

Improved Semantic Representations From Tree-Structured Long Short-Term Memory Networks

Kai Sheng Tai, Richard Socher*, Christopher D. Manning
Computer Science Department, Stanford University, *MetaMind Inc.
kst@cs.stanford.edu, richard@metamind.io, manning@stanford.edu

Abstract

Because of their superior ability to preserve sequence information over time, Long Short-Term Memory (LSTM) networks, a type of recurrent neural network with a more complex computational unit, have obtained strong results on a variety of sequence modeling tasks. The only underlying LSTM structure that has been explored so far is a linear chain. However, natural language exhibits syntactic properties that would naturally combine words to phrases. We introduce the Tree-LSTM, a generalization of LSTMs to tree-structured network topologies. Tree-LSTMs outperform all existing systems and strong LSTM baselines on two tasks: predicting the semantic relatedness of two sentences (SemEval 2014, Task 1) and sentiment classification (Stanford Sentiment Treebank).

1 Introduction

Most models for distributed representations of phrases and sentences—that is, models where real-valued vectors are used to represent meaning—fall into one of three classes: bag-of-words models, sequence models, and tree-structured models. In bag-of-words models, phrase and sentence representations are independent of word order; for example, they can be generated by averaging constituent word representations (Landauer and Dumais, 1997; Foltz et al., 1998). In contrast, sequence models construct sentence representations as an order-sensitive function of the sequence of tokens (Elman, 1990; Mikolov, 2012). Lastly, tree-structured models compose each phrase and sentence representation from its constituent subphrases according to a given syntactic structure over the sentence (Goller and Kuchler, 1996; Socher et al., 2011).

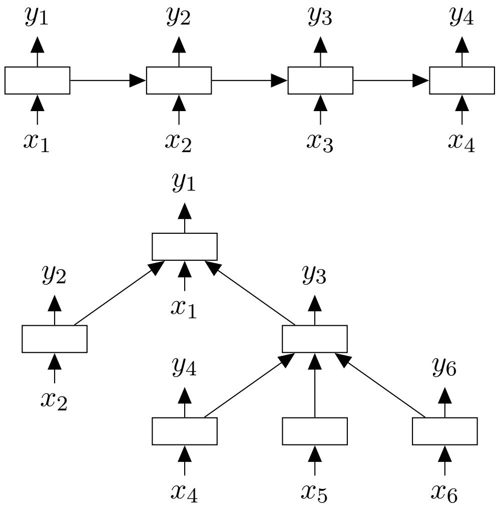

Figure 1: **Top:** A chain-structured LSTM network. **Bottom:** A tree-structured LSTM network with arbitrary branching factor.

Order-insensitive models are insufficient to fully capture the semantics of natural language due to their inability to account for differences in meaning as a result of differences in word order or syntactic structure (*e.g.,* "cats climb trees" *vs.* "trees climb cats"). We therefore turn to order-sensitive sequential or tree-structured models. In particular, tree-structured models are a linguistically attractive option due to their relation to syntactic interpretations of sentence structure. A natural question, then, is the following: to what extent (if at all) can we do better with tree-structured models as opposed to sequential models for sentence representation? In this paper, we work towards addressing this question by directly comparing a type of sequential model that has recently been used to achieve state-of-the-art results in several NLP tasks against its tree-structured generalization.

Due to their capability for processing arbitrary-length sequences, recurrent neural networks

Beijing, China, July 26-31, 2015.

(RNNs) are a natural choice for sequence modeling tasks. Recently, RNNs with Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997) have re-emerged as a popular architecture due to their representational power and effectiveness at capturing long-term dependencies. LSTM networks, which we review in Sec. 2, have been successfully applied to a variety of sequence modeling and prediction tasks, notably machine translation (Bahdanau et al., 2015; Sutskever et al., 2014), speech recognition (Graves et al., 2013), image caption generation (Vinyals et al., 2014), and program execution (Zaremba and Sutskever, 2014).

In this paper, we introduce a generalization of the standard LSTM architecture to tree-structured network topologies and show its superiority for representing sentence meaning over a sequential LSTM. While the standard LSTM composes its hidden state from the input at the current time step and the hidden state of the LSTM unit in the previous time step, the tree-structured LSTM, or Tree-LSTM, composes its state from an input vector and the hidden states of arbitrarily many child units. The standard LSTM can then be considered a special case of the Tree-LSTM where each internal node has exactly one child.

In our evaluations, we demonstrate the empirical strength of Tree-LSTMs as models for representing sentences. We evaluate the Tree-LSTM architecture on two tasks: semantic relatedness prediction on sentence pairs and sentiment classification of sentences drawn from movie reviews. Our experiments show that Tree-LSTMs outperform existing systems and sequential LSTM baselines on both tasks. Implementations of our models and experiments are available at `https://github.com/stanfordnlp/treelstm`.

2 Long Short-Term Memory Networks

2.1 Overview

Recurrent neural networks (RNNs) are able to process input sequences of arbitrary length via the recursive application of a transition function on a *hidden state vector* h_t. At each time step t, the hidden state h_t is a function of the input vector x_t that the network receives at time t and its previous hidden state h_{t-1}. For example, the input vector x_t could be a vector representation of the t-th word in body of text (Elman, 1990; Mikolov, 2012). The hidden state $h_t \in \mathbb{R}^d$ can be interpreted as a d-dimensional distributed representation of the sequence of tokens observed up to time t.

Commonly, the RNN transition function is an affine transformation followed by a pointwise nonlinearity such as the hyperbolic tangent function:

$$h_t = \tanh\left(W x_t + U h_{t-1} + b\right).$$

Unfortunately, a problem with RNNs with transition functions of this form is that during training, components of the gradient vector can grow or decay exponentially over long sequences (Hochreiter, 1998; Bengio et al., 1994). This problem with *exploding* or *vanishing gradients* makes it difficult for the RNN model to learn long-distance correlations in a sequence.

The LSTM architecture (Hochreiter and Schmidhuber, 1997) addresses this problem of learning long-term dependencies by introducing a *memory cell* that is able to preserve state over long periods of time. While numerous LSTM variants have been described, here we describe the version used by Zaremba and Sutskever (2014).

We define the LSTM *unit* at each time step t to be a collection of vectors in $\mathbb{R}^d$: an *input gate* i_t, a *forget gate* f_t, an *output gate* o_t, a *memory cell* c_t and a hidden state h_t. The entries of the gating vectors i_t, f_t and o_t are in $[0,1]$. We refer to d as the *memory dimension* of the LSTM.

The LSTM transition equations are the following:

$$\begin{aligned}
i_t &= \sigma\left(W^{(i)} x_t + U^{(i)} h_{t-1} + b^{(i)}\right), \qquad (1)\\
f_t &= \sigma\left(W^{(f)} x_t + U^{(f)} h_{t-1} + b^{(f)}\right),\\
o_t &= \sigma\left(W^{(o)} x_t + U^{(o)} h_{t-1} + b^{(o)}\right),\\
u_t &= \tanh\left(W^{(u)} x_t + U^{(u)} h_{t-1} + b^{(u)}\right),\\
c_t &= i_t \odot u_t + f_t \odot c_{t-1},\\
h_t &= o_t \odot \tanh(c_t),
\end{aligned}$$

where x_t is the input at the current time step, σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication. Intuitively, the forget gate controls the extent to which the previous memory cell is forgotten, the input gate controls how much each unit is updated, and the output gate controls the exposure of the internal memory state. The hidden state vector in an LSTM unit is therefore a gated, partial view of the state of the unit's internal memory cell. Since the value of the gating variables vary for each vector element, the model can learn to represent information over multiple time scales.

2.2 Variants

Two commonly-used variants of the basic LSTM architecture are the Bidirectional LSTM and the Multilayer LSTM (also known as the *stacked* or *deep* LSTM).

Bidirectional LSTM. A Bidirectional LSTM (Graves et al., 2013) consists of two LSTMs that are run in parallel: one on the input sequence and the other on the reverse of the input sequence. At each time step, the hidden state of the Bidirectional LSTM is the concatenation of the forward and backward hidden states. This setup allows the hidden state to capture both past and future information.

Multilayer LSTM. In Multilayer LSTM architectures, the hidden state of an LSTM unit in layer ℓ is used as input to the LSTM unit in layer $\ell+1$ in the same time step (Graves et al., 2013; Sutskever et al., 2014; Zaremba and Sutskever, 2014). Here, the idea is to let the higher layers capture longer-term dependencies of the input sequence.

These two variants can be combined as a Multilayer Bidirectional LSTM (Graves et al., 2013).

3 Tree-Structured LSTMs

A limitation of the LSTM architectures described in the previous section is that they only allow for strictly sequential information propagation. Here, we propose two natural extensions to the basic LSTM architecture: the *Child-Sum Tree-LSTM* and the *N-ary Tree-LSTM*. Both variants allow for richer network topologies where each LSTM unit is able to incorporate information from multiple child units.

As in standard LSTM units, each Tree-LSTM unit (indexed by j) contains input and output gates i_j and o_j, a memory cell c_j and hidden state h_j. The difference between the standard LSTM unit and Tree-LSTM units is that gating vectors and memory cell updates are dependent on the states of possibly many child units. Additionally, instead of a single forget gate, the Tree-LSTM unit contains one forget gate f_{jk} for each child k. This allows the Tree-LSTM unit to selectively incorporate information from each child. For example, a Tree-LSTM model can learn to emphasize semantic heads in a semantic relatedness task, or it can learn to preserve the representation of sentiment-rich children for sentiment classification.

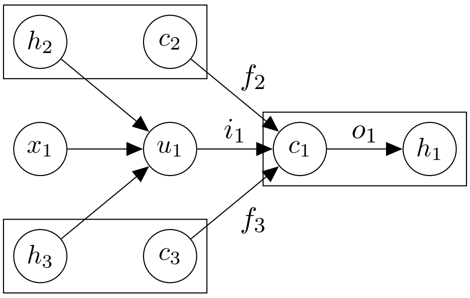

Figure 2: Composing the memory cell c_1 and hidden state h_1 of a Tree-LSTM unit with two children (subscripts 2 and 3). Labeled edges correspond to gating by the indicated gating vector, with dependencies omitted for compactness.

As with the standard LSTM, each Tree-LSTM unit takes an input vector x_j. In our applications, each x_j is a vector representation of a word in a sentence. The input word at each node depends on the tree structure used for the network. For instance, in a Tree-LSTM over a dependency tree, each node in the tree takes the vector corresponding to the head word as input, whereas in a Tree-LSTM over a constituency tree, the leaf nodes take the corresponding word vectors as input.

3.1 Child-Sum Tree-LSTMs

Given a tree, let $C(j)$ denote the set of children of node j. The Child-Sum Tree-LSTM transition equations are the following:

$$\tilde{h}_j = \sum_{k \in C(j)} h_k, \tag{2}$$

$$i_j = \sigma\left(W^{(i)} x_j + U^{(i)} \tilde{h}_j + b^{(i)}\right), \tag{3}$$

$$f_{jk} = \sigma\left(W^{(f)} x_j + U^{(f)} h_k + b^{(f)}\right), \tag{4}$$

$$o_j = \sigma\left(W^{(o)} x_j + U^{(o)} \tilde{h}_j + b^{(o)}\right), \tag{5}$$

$$u_j = \tanh\left(W^{(u)} x_j + U^{(u)} \tilde{h}_j + b^{(u)}\right), \tag{6}$$

$$c_j = i_j \odot u_j + \sum_{k \in C(j)} f_{jk} \odot c_k, \tag{7}$$

$$h_j = o_j \odot \tanh(c_j), \tag{8}$$

where in Eq. 4, $k \in C(j)$.

Intuitively, we can interpret each parameter matrix in these equations as encoding correlations between the component vectors of the Tree-LSTM unit, the input x_j, and the hidden states h_k of the unit's children. For example, in a dependency tree application, the model can learn parameters $W^{(i)}$ such that the components of the input gate i_j have values close to 1 (*i.e.*, "open") when a semantically important content word (such as a verb) is given as input, and values close to 0 (*i.e.*, "closed") when the input is a relatively unimportant word (such as a determiner).

Dependency Tree-LSTMs. Since the Child-Sum Tree-LSTM unit conditions its components on the sum of child hidden states h_k, it is well-suited for trees with high branching factor or whose children are unordered. For example, it is a good choice for dependency trees, where the number of dependents of a head can be highly variable. We refer to a Child-Sum Tree-LSTM applied to a dependency tree as a *Dependency Tree-LSTM*.

3.2 N-ary Tree-LSTMs

The N-ary Tree-LSTM can be used on tree structures where the branching factor is at most N and where children are ordered, *i.e.*, they can be indexed from 1 to N. For any node j, write the hidden state and memory cell of its kth child as h_{jk} and c_{jk} respectively. The N-ary Tree-LSTM transition equations are the following:

$$i_j = \sigma\left(W^{(i)} x_j + \sum_{\ell=1}^{N} U_\ell^{(i)} h_{j\ell} + b^{(i)}\right), \quad (9)$$

$$f_{jk} = \sigma\left(W^{(f)} x_j + \sum_{\ell=1}^{N} U_{k\ell}^{(f)} h_{j\ell} + b^{(f)}\right), \quad (10)$$

$$o_j = \sigma\left(W^{(o)} x_j + \sum_{\ell=1}^{N} U_\ell^{(o)} h_{j\ell} + b^{(o)}\right), \quad (11)$$

$$u_j = \tanh\left(W^{(u)} x_j + \sum_{\ell=1}^{N} U_\ell^{(u)} h_{j\ell} + b^{(u)}\right), \quad (12)$$

$$c_j = i_j \odot u_j + \sum_{\ell=1}^{N} f_{j\ell} \odot c_{j\ell}, \quad (13)$$

$$h_j = o_j \odot \tanh(c_j), \quad (14)$$

where in Eq. 10, $k = 1, 2, \ldots, N$. Note that when the tree is simply a chain, both Eqs. 2–8 and Eqs. 9–14 reduce to the standard LSTM transitions, Eqs. 1.

The introduction of separate parameter matrices for each child k allows the N-ary Tree-LSTM model to learn more fine-grained conditioning on the states of a unit's children than the Child-Sum Tree-LSTM. Consider, for example, a constituency tree application where the left child of a node corresponds to a noun phrase, and the right child to a verb phrase. Suppose that in this case it is advantageous to emphasize the verb phrase in the representation. Then the $U_{k\ell}^{(f)}$ parameters can be trained such that the components of f_{j1} are close to 0 (*i.e.*, "forget"), while the components of f_{j2} are close to 1 (*i.e.*, "preserve").

Forget gate parameterization. In Eq. 10, we define a parameterization of the kth child's forget gate f_{jk} that contains "off-diagonal" parameter matrices $U_{k\ell}^{(f)}$, $k \neq \ell$. This parameterization allows for more flexible control of information propagation from child to parent. For example, this allows the left hidden state in a binary tree to have either an *excitatory* or *inhibitory* effect on the forget gate of the right child. However, for large values of N, these additional parameters are impractical and may be tied or fixed to zero.

Constituency Tree-LSTMs. We can naturally apply *Binary* Tree-LSTM units to binarized constituency trees since left and right child nodes are distinguished. We refer to this application of Binary Tree-LSTMs as a *Constituency Tree-LSTM*. Note that in Constituency Tree-LSTMs, a node j receives an input vector x_j only if it is a leaf node.

In the remainder of this paper, we focus on the special cases of Dependency Tree-LSTMs and Constituency Tree-LSTMs. These architectures are in fact closely related; since we consider only binarized constituency trees, the parameterizations of the two models are very similar. The key difference is in the application of the compositional parameters: dependent *vs.* head for Dependency Tree-LSTMs, and left child *vs.* right child for Constituency Tree-LSTMs.

4 Models

We now describe two specific models that apply the Tree-LSTM architectures described in the previous section.

4.1 Tree-LSTM Classification

In this setting, we wish to predict labels $\hat{y}$ from a discrete set of classes $\mathcal{Y}$ for some subset of nodes in a tree. For example, the label for a node in a parse tree could correspond to some property of the phrase spanned by that node.

At each node j, we use a softmax classifier to predict the label $\hat{y}_j$ given the inputs $\{x\}_j$ observed at nodes in the subtree rooted at j. The classifier takes the hidden state h_j at the node as input:

$$\hat{p}_\theta(y \mid \{x\}_j) = \mathrm{softmax}\left(W^{(s)}h_j + b^{(s)}\right), \\ \hat{y_j} = \arg\max_y \hat{p}_\theta\left(y \mid \{x\}_j\right).$$

The cost function is the negative log-likelihood of the true class labels $y^{(k)}$ at each labeled node:

$$J(\theta) = -\frac{1}{m}\sum_{k=1}^{m}\log\hat{p}_\theta\left(y^{(k)} \,\middle|\, \{x\}^{(k)}\right) + \frac{\lambda}{2}\|\theta\|_2^2,$$

where m is the number of labeled nodes in the training set, the superscript k indicates the kth labeled node, and λ is an L2 regularization hyperparameter.

4.2 Semantic Relatedness of Sentence Pairs

Given a sentence pair, we wish to predict a real-valued similarity score in some range $[1, K]$, where $K > 1$ is an integer. The sequence $\{1, 2, \ldots, K\}$ is some ordinal scale of similarity, where higher scores indicate greater degrees of similarity, and we allow real-valued scores to account for ground-truth ratings that are an average over the evaluations of several human annotators.

We first produce sentence representations h_L and h_R for each sentence in the pair using a Tree-LSTM model over each sentence's parse tree. Given these sentence representations, we predict the similarity score $\hat{y}$ using a neural network that considers both the distance and angle between the pair (h_L, h_R):

$$\begin{aligned} h_\times &= h_L \odot h_R, &(15)\\ h_+ &= |h_L - h_R|, \\ h_s &= \sigma\left(W^{(\times)}h_\times + W^{(+)}h_+ + b^{(h)}\right), \\ \hat{p}_\theta &= \mathrm{softmax}\left(W^{(p)}h_s + b^{(p)}\right), \\ \hat{y} &= r^T\hat{p}_\theta, \end{aligned}$$

where $r^T = [1\ 2\ \ldots\ K]$ and the absolute value function is applied elementwise. The use of both distance measures $h_\times$ and h_+ is empirically motivated: we find that the combination outperforms the use of either measure alone. The multiplicative measure $h_\times$ can be interpreted as an elementwise comparison of the signs of the input representations.

We want the expected rating under the predicted distribution $\hat{p}_\theta$ given model parameters θ to be close to the gold rating $y \in [1, K]$: $\hat{y} = r^T\hat{p}_\theta \approx y$. We therefore define a sparse target distribution[1] p that satisfies $y = r^Tp$:

$$p_i = \begin{cases} y - \lfloor y \rfloor, & i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & i = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases}$$

for $1 \leq i \leq K$. The cost function is the regularized KL-divergence between p and $\hat{p}_\theta$:

$$J(\theta) = \frac{1}{m}\sum_{k=1}^{m}\mathrm{KL}\left(p^{(k)} \,\middle\|\, \hat{p}_\theta^{(k)}\right) + \frac{\lambda}{2}\|\theta\|_2^2,$$

where m is the number of training pairs and the superscript k indicates the kth sentence pair.

5 Experiments

We evaluate our Tree-LSTM architectures on two tasks: (1) sentiment classification of sentences sampled from movie reviews and (2) predicting the semantic relatedness of sentence pairs.

In comparing our Tree-LSTMs against sequential LSTMs, we control for the number of LSTM parameters by varying the dimensionality of the hidden states[2]. Details for each model variant are summarized in Table 1.

5.1 Sentiment Classification

In this task, we predict the sentiment of sentences sampled from movie reviews. We use the Stanford Sentiment Treebank (Socher et al., 2013). There are two subtasks: binary classification of sentences, and fine-grained classification over five classes: very negative, negative, neutral, positive, and very positive. We use the standard train/dev/test splits of 6920/872/1821 for the binary classification subtask and 8544/1101/2210 for the fine-grained classification subtask (there are fewer examples for the binary subtask since

[1] In the subsequent experiments, we found that optimizing this objective yielded better performance than a mean squared error objective.

[2] For our Bidirectional LSTMs, the parameters of the forward and backward transition functions are shared. In our experiments, this achieved superior performance to Bidirectional LSTMs with untied weights and the same number of parameters (and therefore smaller hidden vector dimensionality).

	Relatedness		Sentiment	
LSTM Variant	d	$\lvert\theta\rvert$	d	$\lvert\theta\rvert$
Standard	150	203,400	168	315,840
Bidirectional	150	203,400	168	315,840
2-layer	108	203,472	120	318,720
Bidirectional 2-layer	108	203,472	120	318,720
Constituency Tree	142	205,190	150	316,800
Dependency Tree	150	203,400	168	315,840

Table 1: Memory dimensions d and composition function parameter counts $|\theta|$ for each LSTM variant that we evaluate.

neutral sentences are excluded). Standard binarized constituency parse trees are provided for each sentence in the dataset, and each node in these trees is annotated with a sentiment label.

For the sequential LSTM baselines, we predict the sentiment of a phrase using the representation given by the final LSTM hidden state. The sequential LSTM models are trained on the spans corresponding to labeled nodes in the training set.

We use the classification model described in Sec. 4.1 with both Dependency Tree-LSTMs (Sec. 3.1) and Constituency Tree-LSTMs (Sec. 3.2). The Constituency Tree-LSTMs are structured according to the provided parse trees. For the Dependency Tree-LSTMs, we produce dependency parses[3] of each sentence; each node in a tree is given a sentiment label if its span matches a labeled span in the training set.

5.2 Semantic Relatedness

For a given pair of sentences, the semantic relatedness task is to predict a human-generated rating of the similarity of the two sentences in meaning.

We use the Sentences Involving Compositional Knowledge (SICK) dataset (Marelli et al., 2014), consisting of 9927 sentence pairs in a 4500/500/4927 train/dev/test split. The sentences are derived from existing image and video description datasets. Each sentence pair is annotated with a relatedness score $y \in [1, 5]$, with 1 indicating that the two sentences are completely unrelated, and 5 indicating that the two sentences are very related. Each label is the average of 10 ratings assigned by different human annotators.

Here, we use the similarity model described in Sec. 4.2. For the similarity prediction network (Eqs. 15) we use a hidden layer of size 50. We produce binarized constituency parses[4] and dependency parses of the sentences in the dataset for our Constituency Tree-LSTM and Dependency Tree-LSTM models.

Method	Fine-grained	Binary
RAE (Socher et al., 2013)	43.2	82.4

5.3 Hyperparameters and Training Details

The hyperparameters for our models were tuned on the development set for each task.

We initialized our word representations using publicly available 300-dimensional Glove vectors[5] (Pennington et al., 2014). For the sentiment classification task, word representations were updated during training with a learning rate of 0.1. For the semantic relatedness task, word representations were held fixed as we did not observe any significant improvement when the representations were tuned.

Our models were trained using AdaGrad (Duchi et al., 2011) with a learning rate of 0.05 and a minibatch size of 25. The model parameters were regularized with a per-minibatch L2 regularization strength of 10^{-4}. The sentiment classifier was additionally regularized using dropout (Srivastava et al., 2014) with a dropout rate of 0.5. We did not observe performance gains using dropout on the semantic relatedness task.

Table 3: Test set results on the SICK semantic relatedness subtask. For our experiments, we report mean scores over 5 runs (standard deviations in parentheses). Results are grouped as follows: **(1)** SemEval 2014 submissions; **(2)** Our own baselines; **(3)** Sequential LSTMs; **(4)** Tree-structured LSTMs.

6 Results

6.1 Sentiment Classification

Our results are summarized in Table 2. The Constituency Tree-LSTM outperforms existing systems on the fine-grained classification subtask and achieves accuracy comparable to the state-of-the-art on the binary subtask. In particular, we find that it outperforms the Dependency Tree-LSTM. This performance gap is at least partially attributable to the fact that the Dependency Tree-LSTM is trained on less data: about 150K labeled nodes *vs.* 319K for the Constituency Tree-LSTM. This difference is due to (1) the dependency representations containing fewer nodes than the corresponding constituency representations, and (2) the inability to match about 9% of the dependency nodes to a corresponding span in the training data.

We found that updating the word representations during training ("fine-tuning" the word embedding) yields a significant boost in performance on the fine-grained classification subtask and gives a minor gain on the binary classification subtask (this finding is consistent with previous work on this task by Kim (2014)). These gains are to be expected since the Glove vectors used to initialize our word representations were not originally trained to capture sentiment.

6.2 Semantic Relatedness

Our results are summarized in Table 3. Following Marelli et al. (2014), we use Pearson's r, Spearman's ρ and mean squared error (MSE) as evaluation metrics. The first two metrics are measures of correlation against human evaluations of semantic relatedness.

We compare our models against a number of non-LSTM baselines. The mean vector baseline computes sentence representations as a mean of the representations of the constituent words. The DT-RNN and SDT-RNN models (Socher et al., 2014) both compose vector representations for the nodes in a dependency tree as a sum over affine-transformed child vectors, followed by a nonlinearity. The SDT-RNN is an extension of the DT-RNN that uses a separate transformation for each dependency relation. For each of our baselines, including the LSTM models, we use the similarity model described in Sec. 4.2.

We also compare against four of the top-performing systems[6] submitted to the SemEval 2014 semantic relatedness shared task: ECNU (Zhao et al., 2014), The Meaning Factory (Bjerva et al., 2014), UNAL-NLP (Jimenez et al., 2014), and Illinois-LH (Lai and Hockenmaier, 2014). These systems are heavily feature engineered, generally using a combination of surface form overlap features and lexical distance features derived from WordNet or the Paraphrase Database (Ganitkevitch et al., 2013).

Our LSTM models outperform all these sys-

[6] We list the strongest results we were able to find for this task; in some cases, these results are stronger than the official performance by the team on the shared task. For example, the listed result by Zhao et al. (2014) is stronger than their submitted system's Pearson correlation score of 0.8280.

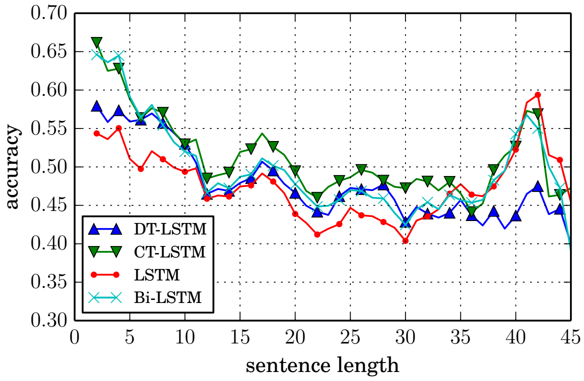

Figure 3: Fine-grained sentiment classification accuracy *vs.* sentence length. For each ℓ, we plot accuracy for the test set sentences with length in the window $[\ell - 2, \ell + 2]$. Examples in the tail of the length distribution are batched in the final window ($\ell = 45$).

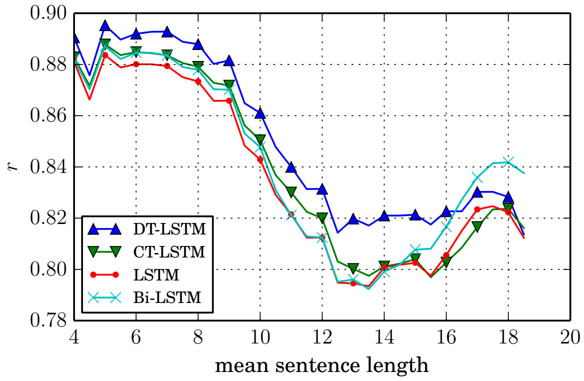

Figure 4: Pearson correlations r between predicted similarities and gold ratings *vs.* sentence length. For each ℓ, we plot r for the pairs with mean length in the window $[\ell-2, \ell+2]$. Examples in the tail of the length distribution are batched in the final window ($\ell = 18.5$).

tems without any additional feature engineering, with the best results achieved by the Dependency Tree-LSTM. Recall that in this task, both Tree-LSTM models only receive supervision at the root of the tree, in contrast to the sentiment classification task where supervision was also provided at the intermediate nodes. We conjecture that in this setting, the Dependency Tree-LSTM benefits from its more compact structure relative to the Constituency Tree-LSTM, in the sense that paths from input word vectors to the root of the tree are shorter on aggregate for the Dependency Tree-LSTM.

7 Discussion and Qualitative Analysis

7.1 Modeling Semantic Relatedness

In Table 4, we list nearest-neighbor sentences retrieved from a 1000-sentence sample of the SICK test set. We compare the neighbors ranked by the Dependency Tree-LSTM model against a baseline ranking by cosine similarity of the mean word vectors for each sentence.

The Dependency Tree-LSTM model exhibits several desirable properties. Note that in the dependency parse of the second query sentence, the word “ocean” is the second-furthest word from the root (“waving”), with a depth of 4. Regardless, the retrieved sentences are all semantically related to the word “ocean”, which indicates that the Tree-LSTM is able to both preserve and emphasize information from relatively distant nodes. Additionally, the Tree-LSTM model shows greater robustness to differences in sentence length. Given the query “two men are playing guitar”, the Tree-LSTM associates the phrase “playing guitar” with the longer, related phrase “dancing and singing in front of a crowd” (note as well that there is zero token overlap between the two phrases).

7.2 Effect of Sentence Length

One hypothesis to explain the empirical strength of Tree-LSTMs is that tree structures help mitigate the problem of preserving state over long sequences of words. If this were true, we would expect to see the greatest improvement over sequential LSTMs on longer sentences. In Figs. 3 and 4, we show the relationship between sentence length and performance as measured by the relevant task-specific metric. Each data point is a mean score over 5 runs, and error bars have been omitted for clarity.

We observe that while the Dependency Tree-LSTM does significantly outperform its sequential counterparts on the relatedness task for longer sentences of length 13 to 15 (Fig. 4), it also achieves consistently strong performance on shorter sentences. This suggests that unlike sequential LSTMs, Tree-LSTMs are able to encode semantically-useful structural information in the sentence representations that they compose.

Table 4: Most similar sentences from a 1000-sentence sample drawn from the SICK test set. The Tree-LSTM model is able to pick up on more subtle relationships, such as that between "beach" and "ocean" in the second example.

Pennington et al., 2014) have found wide applicability in a variety of NLP tasks. Following this success, there has been substantial interest in the area of learning distributed phrase and sentence representations (Mitchell and Lapata, 2010; Yessenalina and Cardie, 2011; Grefenstette et al., 2013; Mikolov et al., 2013), as well as distributed representations of longer bodies of text such as paragraphs and documents (Srivastava et al., 2013; Le and Mikolov, 2014).

Our approach builds on recursive neural networks (Goller and Kuchler, 1996; Socher et al., 2011), which we abbreviate as Tree-RNNs in order to avoid confusion with recurrent neural networks. Under the Tree-RNN framework, the vector representation associated with each node of a tree is composed as a function of the vectors corresponding to the children of the node. The choice of composition function gives rise to numerous variants of this basic framework. Tree-RNNs have been used to parse images of natural scenes (Socher et al., 2011), compose phrase representations from word vectors (Socher et al., 2012), and classify the sentiment polarity of sentences (Socher et al., 2013).

9 Conclusion

In this paper, we introduced a generalization of LSTMs to tree-structured network topologies. The Tree-LSTM architecture can be applied to trees with arbitrary branching factor. We demonstrated the effectiveness of the Tree-LSTM by applying the architecture in two tasks: semantic relatedness and sentiment classification, outperforming existing systems on both. Controlling for model dimensionality, we demonstrated that Tree-LSTM models are able to outperform their sequential counterparts. Our results suggest further lines of work in characterizing the role of structure in producing distributed representations of sentences.

Abstract

We propose a convolutional neural network, named genCNN, for word sequence prediction. Different from previous work on neural network-based language modeling and generation (e.g., RNN or LSTM), we choose not to greedily summarize the history of words as a fixed length vector. Instead, we use a convolutional neural network to predict the next word with the history of words of variable length. Also different from the existing feedforward networks for language modeling, our model can effectively fuse the local correlation and global correlation in the word sequence, with a convolution-gating strategy specifically designed for the task. We argue that our model can give adequate representation of the history, and therefore can naturally exploit both the short and long range dependencies. Our model is fast, easy to train, and readily parallelized. Our extensive experiments on text generation and n-best re-ranking in machine translation show that genCNN outperforms the state-of-the-arts with big margins.

1 Introduction

Both language modeling (Wu and Khudanpur, 2003; Mikolov et al., 2010; Bengio et al., 2003) and text generation (Axelrod et al., 2011) boil down to modeling the conditional probability of a word given the proceeding words. Previously, it is mostly done through purely memory-based approaches, such as n-grams, which cannot deal with long sequences and has to use some heuristics (called smoothing) for rare ones. Another family of methods are based on distributed representations of words, which is usually tied with a neural-network (NN) architecture for estimating the conditional probabilities of words.

Two categories of neural networks have been used for language modeling: 1) recurrent neural networks (RNN), and 2) feedfoward network (FFN):

- The RNN-based models, including its variants like LSTM, enjoy more popularity, mainly due to their flexible structures for processing word sequences of arbitrary lengths, and their recent empirical success(Sutskever et al., 2014; Graves, 2013). We however argue that RNNs, with their power built on the recursive use of a relatively simple computation units, are forced to make greedy summarization of the history and consequently not efficient on modeling word sequences, which clearly have a bottom-up structures.
- The FFN-based models, on the other hand, avoid this difficulty by feeding directly on the history. However, the FFNs are built on fully-connected networks, rendering them inefficient on capturing local structures of languages. Moreover their “rigid” architectures make it futile to handle the great variety of patterns in long range correlations of words.

We propose a novel convolutional architecture, named genCNN, as a model that can efficiently combine local and long range structures of language for the purpose of modeling conditional probabilities. genCNN can be directly used in generating a word sequence (i.e.,

history: / / I was starving after this long meeting, so I rushed to wal-mart to buy a

Figure 1: The overall diagram of a genCNN. Here "/" stands for a zero padding. In this example, each CNN component covers 6 words, while in practice the coverage is 30-40 words.

text generation) or evaluating the likelihood of word sequences (i.e., language modeling). We also show the empirical superiority of genCNN on both tasks over traditional n-grams and its RNN or FFN counterparts.

Notations: We will use $\mathcal{V}$ to denote the vocabulary, $\mathbf{e}_t$ ($\in \{1, \cdots, |\mathcal{V}|\}$) to denote the t^{th} word in a sequence $\mathbf{e}_{1:t} \overset{\text{def}}{=} [\mathbf{e}_1, \cdots, \mathbf{e}_t]$, and $\mathbf{e}_t^{(n)}$ if the sequence is further indexed by n.

2 Overview

As shown in Figure 1, genCNN is overall recursive, consisting of CNN-based processing units of two types:

- αCNN as the "front-end", dealing with the history that is closest to the prediction;
- βCNNs (which can repeat), in charge of more "ancient" history.

Together, genCNN takes history $\mathbf{e}_{1:t}$ of arbitrary length to predict the next word $\mathbf{e}_{t+1}$ with probability

$$p(\mathbf{e}_{t+1} \, |\mathbf{e}_{1:t}; \bar{\Theta}), \tag{1}$$

based on a representation $\phi(\mathbf{e}_{1:t}; \bar{\Theta})$ produced by the CNN, and a $|\mathcal{V}|$-class soft-max:

$$p(\mathbf{e}_{t+1}|\mathbf{e}_{1:t}; \bar{\Theta}) \propto e^{\mu_{\mathbf{e}_{t+1}}^{\top} \phi(\mathbf{e}_{1:t}) + b_{\mathbf{e}_{t+1}}}. \tag{2}$$

genCNN is devised (tailored) fully for modeling the sequential structure in natural language, notably different from conventional CNN (Lawrence et al., 1997; Hu et al., 2014) in 1) its specifically designed weights-sharing strategy (in αCNN), 2) its gating design, and 3) certainly its recursive architectures. Also distinct from RNN, genCNN gains most of its processing power from the heavy-duty processing units (i.e.,αCNN and βCNNs), which follow a bottom-up information flow and yet can adequately capture the temporal structure in word sequence with its convolutional-gating architecture.

3 genCNN: Architecture

We start with discussing the convolutional architecture of αCNN as a stand-alone sentence model, and then proceed to the recursive structure. After that we give a comparative analysis on the mechanism of genCNN.

αCNN, just like a normal CNN, has fixed architecture with predefined maximum words (denoted as L_α). History shorter than L_α will filled with zero paddings, and history longer than that will be folded to feed to βCNN after it, as will be elaborated in Section 3.3. Similar to most other CNNs, αCNN alternates between convolution layers and pooling layers, and finally a fully connected layer to reach the representation before soft-max, as illustrated by Figure 2. Unlike the toyish example in Figure 2, in practice we use a larger and deeper αCNN with L_α = 30 or 40, and two or three convolution layers (see Section 4.1). Different from conventional CNN, genCNN has 1) weight sharing strategy for convolution, and 2)"external" gating networks to replace the normal pooling mechanism, both of which are specifically designed for word sequence prediction.

3.1 αCNN: Convolution

Different from conventional CNN, the weights of convolution units in αCNN is only partially shared. More specifically, in the convolution units there are two types feature-maps: TIME-FLOW and the TIME-ARROW, illustrated re-

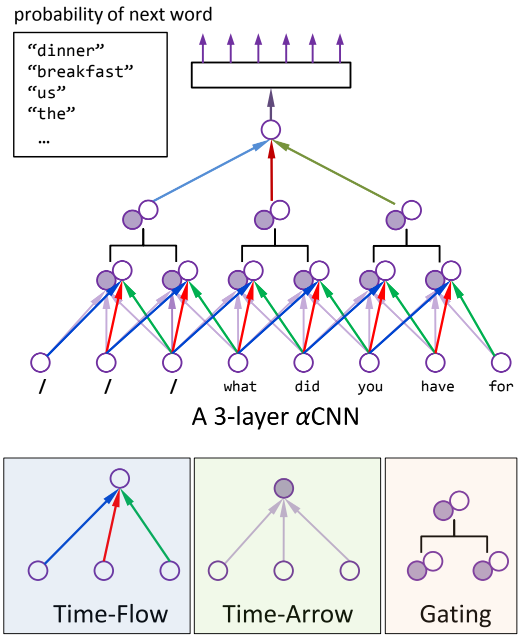

Figure 2: Illustration of a 3-layer αCNN. Here the shadowed nodes stand for the TIME-ARROW feature-maps and the unfilled nodes for the TIME-FLOW.

spectively with the unfilled nodes and filled nodes in Figure 2. The parameters for TIME-FLOW are shared among different convolution units, while for TIME-ARROW the parameters are location-dependent. Intuitively, TIME-FLOW acts more like a conventional CNN (e.g., that in (Hu et al., 2014)), aiming to understand the overall temporal structure in the word sequences; TIME-ARROW, on the other hand, works more like a traditional NN-based language model (Vaswani et al., 2013; Bengio et al., 2003): with its location-dependent parameters, it focuses on capturing the direction of time and prediction task.

For sentence input $\mathbf{x} = \{\mathbf{x}_1, \cdots, \mathbf{x}_T\}$, the feature-map of type-f on Layer-ℓ is

if $f \in$ TIME-FLOW:

$$z_i^{(\ell,f)}(\mathbf{x}) = \sigma(\mathbf{w}_{\text{TF}}^{(\ell,f)} \hat{\mathbf{z}}_i^{(\ell-1)} + b_{\text{TF}}^{(\ell,f)}), \quad (3)$$

if $f \in$ TIME-ARROW:

$$z_i^{(\ell,f)}(\mathbf{x}) = \sigma(\mathbf{w}_{\text{TA}}^{(\ell,f,i)} \hat{\mathbf{z}}_i^{(\ell-1)} + b_{\text{TA}}^{(\ell,f,i)}), \quad (4)$$

where

- $z_i^{(\ell,f)}(\mathbf{x})$ gives the output of feature-map of type-f for location i in Layer-ℓ;
- $\sigma(\cdot)$ is the activation function, e.g., Sigmoid or Relu (Dahl et al., 2013)
- $\mathbf{w}_{\text{TF}}^{(\ell,f)}$ denotes the location-independent parameters for $f \in$TIME-FLOW on Layer-ℓ, while $\mathbf{w}_{\text{TA}}^{(\ell,f,i)}$ stands for that for $f \in$ TIME-ARROW and location i on Layer-ℓ;
- $\hat{\mathbf{z}}_i^{(\ell-1)}$ denotes the segment of Layer-$\ell-1$ for the convolution at location i , while

$$\hat{\mathbf{z}}_i^{(0)} \stackrel{\text{def}}{=} [\mathbf{x}_i^\top, \ \mathbf{x}_{i+1}^\top, \ \cdots, \ \mathbf{x}_{i+k_1-1}^\top]^\top$$

concatenates the vectors for k_1 words from sentence input $\mathbf{x}$.

3.2 Gating Network

Previous CNNs, including those for NLP tasks (Hu et al., 2014; Kalchbrenner et al., 2014), take a straightforward convolution-pooling strategy, in which the "fusion" decisions (e.g., selecting the largest one in max-pooling) are based on the values of feature-maps. This is essentially a soft template matching, which works for tasks like classification, but undesired for maintaining the composition functionality of convolution. In this paper, we propose to use separate gating networks to release the scoring duty from the convolution, and let it focus on composition. Similar idea has been proposed by (Socher et al., 2011) for recursive neural networks on parsing, but never been combined with a convolutional structure.

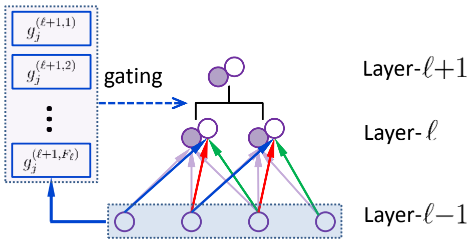

Figure 3: Illustration for gating network.

Suppose we have convolution feature-maps on Layer-ℓ and gating (with window size = 2) on Layer-$\ell+1$. For the j^{th} gating window $(2j-1, 2j)$, we merge $\hat{\mathbf{z}}_{2j-1}^{(\ell-1)}$ and $\hat{\mathbf{z}}_{2j}^{(\ell-1)}$ as the input (denoted as $\bar{\mathbf{z}}_j^{(\ell)}$) for gating network, as illustrated in Figure 3. We use a separate gate for each feature-map, but follow a different parametrization strategy for Time-Flow and Time-Arrow. With window size = 2, the gating is binary, we use a logistic regressor to determine the weights of two candidates. For $f \in$ Time-Arrow, with location-dependent $\mathbf{w}_{\text{gate}}^{(\ell,f,j)}$, the normalized weight for *left* side is

$$g_j^{(\ell+1,f)} = 1/(1+e^{-\mathbf{w}_{\text{gate}}^{(\ell,f,j)}\bar{\mathbf{z}}_j^{(\ell)}}),$$

while for For $f \in$Time-Flow, the parameters for the corresponding gating network, denoted as $\mathbf{w}_{\text{gate}}^{(\ell,f)}$, are shared. The gated feature map is then a weighted sum to feature-maps from the two windows:

$$z_j^{(\ell+1,f)} = g_j^{(\ell+1,f)} z_{2j-1}^{(\ell,f)} + (1-g_j^{(\ell+1,f)}) z_{2j}^{(\ell,f)}. \quad (5)$$

We find that this gating strategy works significantly better than pooling directly over feature-maps, and slightly better than a hard gate version of Equation 5

3.3 Recursive Architecture

As suggested early on in Section 2 and Figure 1, we use extra CNNs with conventional weight-sharing, named βCNN, to summarize the history out of scope of αCNN. More specifically, the output of βCNN (with the same dimension of word-embedding) is put before the first word as the input to the αCNN, as illustrated in Figure 4. Different from αCNN, βCNN is designed just to summarize the history, with weight shared across its convolution units. In a sense, βCNN has only Time-Flow feature-maps. All βCNN are identical and recursively aligned, enabling *gen*CNN to handle sentences with arbitrary length. We put a special switch after each βCNN to turn it off (replacing a pading vector shown as "/" in Figure 4) when there is no history assigned to it. As the result, when the history is shorter than L_α, the recursive structure reduces to αCNN.

In practice, 90+% sentences can be modeled by αCNN with $L_\alpha = 40$ and 99+% sentences can be contained with one extra βCNN. Our experiment shows that this recursive strategy yields better estimate of conditional density than neglecting the out-of-scope history (Section 6.1.2). In practice, we found that a larger (greater L_α) and deeper αCNN works better than small αCNN and more recursion, which is consistent with our intuition that the convolutional architecture is better suited for modeling the sequence.

3.4 Analysis

3.4.1 Time-Flow vs. Time-Arrow

Both conceptually and systemically, *gen*CNN gives two interweaved treatments of word history. With the globally-shared parameters in the convolution units, Time-Flow summarizes *what has been said.* The hierarchical convolution+gating architecture in Time-Flow enables it to model the composition in language, yielding representation of segments at different intermediate layers. Time-Flow is aware of the sequential direction, inherited from the space-awareness of CNN, but it is not sensitive enough about the prediction task, due to the uniform weights in the convolution.

On the other hand, Time-Arrow, living in location-dependent parameters of convolution units, acts like an arrow pin-pointing the prediction task. Time-Arrow has predictive power all by itself, but it concentrates on capturing the direction of time and consequently short on modelling the long-range dependency.

Time-Flow and Time-Arrow have to work together for optimal performance in predicting *what is going to be said.* This intuition has been empirically verified, as our experiments have demonstrated that TIME-FLOW or TIME-ARROW alone perform inferiorly. One can imagine, through the layer-by-layer convolution and gating, the TIME-ARROW gradually picks the most relevant part from the representation of TIME-FLOW for the prediction task, even if that part is long distance ahead.

3.4.2 *gen*CNN vs. RNN-LM

Different from RNNs, which recursively applies a relatively simple processing units, *gen*CNN gains its ability on sequence modeling mostly from its flexible and powerful bottom-up and convolution architecture. *gen*CNN takes the "uncompressed" history, therefore avoids

- the difficulty in finding the representation for history, e.g., those end in the middle of a chunk (e.g.,"`the cat sat on the`"),
- the damping effort in RNN when the history-summarizing hidden state is updated at each time stamp, which renders the long-range memory rather difficult,

both of which can only be partially ameliorated with complicated design of gates (Hochreiter and Schmidhuber, 1997) and or more heavy processing units (essentially a fully connected DNN) (Sutskever et al., 2014).

4 *gen*CNN: Training

The parameters of a *gen*CNN $\bar{\Theta}$ consists of the parameters for CNN Θ_{nn}, word-embedding Θ_{embed}, and the parameters for soft-max $\Theta_{softmax}$. All the parameters are jointly learned by maximizing the likelihood of observed sentences. Formally the log-likelihood of sentence $\mathcal{S}_n$ ($\stackrel{\text{def}}{=} [\mathbf{e}_1^{(n)}, \mathbf{e}_2^{(n)}, \cdots, \mathbf{e}_{T_n}^{(n)}]$) is

$$\log p(\mathcal{S}_n; \bar{\Theta}) = \sum_{t=1}^{T_n} \log p(\mathbf{e}_t^{(n)} | \mathbf{e}_{1:t-1}^{(n)}; \bar{\Theta}),$$

which can be trivially split into T_n training instances during the optimization, in contrast to the training of RNN that requires unfolding through time due to the temporal-dependency of the hidden states.

4.1 Implementation Details

Architectures: In all of our experiments (Section 5 and 6) we set the maximum words for αCNN to be 30 and that for βCNN to be 20. αCNN have two convolution layers (both containing TIME-FLOW and TIME-ARROW convolution) and two gating layers, followed by a fully connected layer (400 dimension) and then a soft-max layer. The numbers of feature-maps for TIME-FLOW are respectively 150 (1st convolution layer) and 100 (2nd convolution layer), while TIME-ARROW has the same feature-maps. βCNN is relatively simple, with two convolution layer containing only TIME-FLOW with 150 feature-maps, two gating layers and a fully connected layer. We use ReLU as the activation function for convolution layers and switch to Sigmoid for fully connected layers. We use word embedding with dimension 100.

Soft-max: Calculating a full soft-max is expensive since it has to enumerate all the words in vocabulary (in our case 40K words) in the denominator. Here we take a simple hierarchical approximation of it, following (Bahdanau et al., 2014). Basically we group the words into 200 clusters (indexed by c_m), and factorize (in an approximate sense) the conditional probability of a word $p(\mathbf{e}_t|\mathbf{e}_{1:t-1}; \bar{\Theta})$ into the probability of its cluster and the probability of $\mathbf{e}_t$ given its cluster

$$p(c_m|\mathbf{e}_{1:t-1}; \bar{\Theta})\, p(\mathbf{e}_t|c_m; \Theta_{softmax}).$$

We found that this simple heuristic can speed-up the optimization by 5 times with only slight loss of accuracy.

Optimization: We use stochastic gradient descent with mini-batch (size 500) for optimization, aided further by AdaGrad (Duchi et al., 2011). For initialization, we use Word2Vec (Mikolov et al., 2013) for the starting state of the word-embeddings (trained on the same dataset as the main task), and set all the other parameters by randomly sampling from uniform distribution in $[-0.1, 0.1]$. The optimization is done mainly on a Tesla K40 GPU, which takes about 2 days for the training on a dataset containing 1M sentences.

5 Experiments: Sentence Generation

In this experiment, we randomly generate sentences by recurrently sampling

$$\mathbf{e}^{\star}_{t+1} \sim p(\mathbf{e}_{t+1}|\mathbf{e}_{1:t};\bar{\Theta}),$$

and put the newly generated word into history, until EOS (end-of-sentence) is generated. We consider generating two types of sentences: 1) the plain sentences, and 2) sentences with dependency parsing, which will be covered respectively in Section 5.1 and 5.2.

5.1 Natural Sentences

We train genCNN on Wiki data with 112M words for one week, with some representative examples randomly generated given in Table 1 (upper and middle blocks). We try two settings, by letting genCNN generate a sentence 1)from the very beginning (middle block), or 2) starting with a few words given by human (upper block). It is fairly clear that most of the time genCNN can generate sentences that are syntactically grammatical and semantically meaningful. More specifically, most of the sentences can be aligned to a parse tree with reasonable structure. It is also worth noting that quotation marks (`` and '') are always generated in pairs and in the correct order, even across a relatively long distance, as exemplified by the first generated sentence in the upper block.

5.2 Sentences with Dependency Tags

For training, we first parse(Klein and Manning, 2002) the English sentences and feed sequences with dependency tags as follows

(I ⋆ like (red ⋆ apple))

to genCNN in training, where 1) each paired parentheses contain a subtree, and 2) the symbol "⋆" indicates that the word next to it is the dependency head in the corresponding subtree. Some representative examples generated by genCNN are given in Table 1 (bottom block). As it suggests, genCNN is fairly accurate on respecting the rules of parentheses, and probably more remarkably, it can get the dependency tree head right most of the time.

6 Experiments: Language Modeling

We evaluate our model as a language model in terms of both perplexity (Brown et al., 1992) and its efficacy in re-ranking the n-best candidates from state-of-the-art models in statistical machine translation, with comparison to the following competitor language models.

Competitor Models we compare genCNN to the following competitor models

- 5-gram: We use SRI Language Modeling Toolkit (Stolcke and others, 2002) to train a 5-gram language model with modified Kneser-Ney smoothing;
- FFN-LM: The neural language model based on feedfoward network (Vaswani et al., 2013). We vary the input window-size from 5 to 20, while the performance stops increasing after window size 20;
- RNN: we use the implementation[1] of RNN-based language model with hidden size 600;
- LSTM: we adopt the code in Groundhog[2], but vary the hyper-parameters, including the depth and word-embedding dimension, for best performance. LSTM (Hochreiter and Schmidhuber, 1997) is widely considered to be the state-of-the-art for sequence modeling.

6.1 Perplexity

We test the performance of genCNN on PENN TREEBANK and FBIS, two public datasets with different sizes.

6.1.1 On PENN TREEBANK

Although a relatively small dataset [3], PENN TREEBANK is widely used as a language modelling benchmark (Graves, 2013; Mikolov et al., 2010). It has $930,000$ words in training set, $74,000$ words in validation set, and $82,000$ words in test set. We use exactly the same settings as in (Mikolov et al., 2010), with a $10,000$-words vocabulary (all out-of-vocabulary words are replaced with `unknown`)

Table 1: Examples of sentences generated by *gen*CNN. In the upper block (row 1-4) the underline words are given by the human; In the middle block (row 5-8), all the sentences are generated without any hint. The bottom block (row 9-12) shows the sentences with dependency tag generated by *gen*CNN trained with parsed examples.

and end-of-sentence token (EOS) at the end of each sentence. In addition to the conventional testing strategy where the models are kept unchanged during testing, Mikolov et al. (2010) proposes to also update the parameters in an online fashion when seeing test sentences. This new way of testing, named “dynamic evaluation”, is also adopted by Graves (2013).

From Table 2 *gen*CNN manages to give perplexity superior in both metrics, with about 25 point reduction over the widely used 5-gram, and over 10 point reduction from LSTM, the state-of-the-art and the second-best performer.

Model	**Perplexity**	**Dynamic**
5-gram, KN5	141.2	–
FFNN-LM	140.2	–
RNN	124.7	123.2
LSTM	126	117
*gen*CNN	**116.4**	**106.3**

Table 2: PENN TREEBANK results, where the 3rd column are the perplexity in dynamic evaluation, while the numbers for RNN and LSTM are taken as reported in the paper cited above. The numbers in boldface indicate that the result is significantly better than *all competitors* in the same setting.

6.1.2 On FBIS

The FBIS corpus (LDC2003E14) is relatively large, with 22.5K sentences and 8.6M English words. The validation set is NIST MT06 and test set is NIST MT08. For training the neural network, we limit the vocabulary to the most frequent 40,000 words, covering $\sim 99.4\%$ of the corpus. Similar to the first experiment, all out-of-vocabulary words are replaced with unknown and the EOS token is counted in the sequence loss.

From Table 3 (upper block), *gen*CNN clearly wins again in the comparison to competitors, with over 25 point margin over LSTM (in its optimal setting), the second best performer. Interestingly *gen*CNN outperforms its variants also quite significantly (bottom block): 1) with only TIME-ARROW (same number of feature-maps), the performance deteriorates considerably for losing the ability of capturing long range correlation reliably; 2) with only TIME-TIME the performance gets even worse,

Model	Perplexity
5-gram, KN5	278.6
FFN-LM(5-gram)	248.3
FFN-LM(20-gram)	228.2
RNN	223.4
LSTM	206.9
genCNN	**181.2**
TIME-ARROW only	192
TIME-FLOW only	203
αCNN only	184.4

Table 3: FBIS results. The upper block (row 1-6) compares genCNN and the competitor models, and the bottom block (row 7-9) compares different variants of genCNN.

for partially losing the sensitivity to the prediction task. It is quite remarkable that, although αCNN (with $L_\alpha = 30$) can achieve good results, the recursive structure in full genCNN can further decrease the perplexity by over 3 points, indicating that genCNN can benefit from modeling the dependency over range as long as 30 words.

6.2 Re-ranking for Machine Translation

In this experiment, we re-rank the 1000-best English translation candidates for Chinese sentences generated by statistical machine translation (SMT) system, and compare it with other language models in the same setting.

SMT setup The baseline hierarchical phrase-based SMT system (Chines→ English) was built using Moses, a widely accepted state-of-the-art, with default settings. The bilingual training data is from NIST MT2012 constrained track, with reduced size of 1.1M sentence pairs using selection strategy in (Axelrod et al., 2011). The baseline use conventional 5-gram language model (LM), estimated with modified Kneser-Ney smoothing (Chen and Goodman, 1996) on the English side of the 329M-word Xinhua portion of English Gigaword(LDC2011T07). We also try FFN-LM, as a much stronger language model in decoding. The weights of all the features are tuned via MERT (Och and Ney, 2002) on NIST MT05, and tested on NIST MT06 and MT08. Case-insensitive NIST BLEU[4] is used in evaluation.

Models	MT06	MT08	Ave.
Baseline	38.63	31.11	34.87
RNN rerank	39.03	31.50	35.26
LSTM rerank	39.20	31.90	35.55
FFN-LM rerank	38.93	31.41	35.14
genCNN rerank	**39.90**	**32.50**	**36.20**
Base+FFN-LM	39.08	31.60	35.34
genCNN rerank	**40.4**	**32.85**	**36.63**

Table 4: The results for re-ranking the 1000-best of Moses. Note that the two bottom rows are on a baseline with enhanced LM.

Re-ranking with genCNN significantly improves the quality of the final translation. Indeed, it can increase the BLEU score by over 1.33 point over Moses baseline on average. This boosting force barely slacks up on translation with a enhanced language model in decoding: genCNN re-ranker still achieves 1.29 point improvement on top of Moses with FFN-LM, which is 1.76 point over the Moses (default setting). To see the significance of this improvement, the state-of-the-art Neural Network Joint Model (Devlin et al., 2014) usually brings less than one point increase on this task.

7 Related Work

In addition to the long thread of work on neural network based language model (Auli et al., 2013; Mikolov et al., 2010; Graves, 2013; Bengio et al., 2003; Vaswani et al., 2013), our work is also related to the effort on modeling long range dependency in word sequence prediction(Wu and Khudanpur, 2003). Different from those work on hand-crafting features for incorporating long range dependency, our model can elegantly assimilate relevant information in an unified way, in both long and short range, with the bottom-up information flow and convolutional architecture.

CNN has been widely used in computer vision and speech (Lawrence et al., 1997; Krizhevsky et al., 2012; LeCun and Bengio, 1995; Abdel-Hamid et al., 2012), and lately in sentence representation(Kalchbrenner and

[4] ftp://jaguar.ncsl.nist.gov/mt/resources/mteval-v11b.pl

Blunsom, 2013), matching(Hu et al., 2014) and classification(Kalchbrenner et al., 2014). To our best knowledge, it is the first time this is used in word sequence prediction. Model-wise the previous work that is closest to genCNN is the convolution model for predicting moves in the Go game (Maddison et al., 2014), which, when applied recurrently, essentially generates a sequence. Different from the conventional CNN taken in (Maddison et al., 2014), genCNN has architectures designed for modeling the composition in natural language and the temporal structure of word sequence.

8 Conclusion

We propose a convolutional architecture for natural language generation and modeling. Our extensive experiments on sentence generation, perplexity, and n-best re-ranking for machine translation show that our model can significantly improve upon state-of-the-arts.

Neural Responding Machine for Short-Text Conversation

Lifeng Shang, Zhengdong Lu, Hang Li

{shang.lifeng,lu.zhengdong,hangli.hl}@huawei.com

Abstract

We propose Neural Responding Machine (NRM), a neural network-based response generator for Short-Text Conversation. NRM takes the general encoder-decoder framework: it formalizes the generation of response as a decoding process based on the latent representation of the input text, while both encoding and decoding are realized with recurrent neural networks (RNN). The NRM is trained with a large amount of one-round conversation data collected from a microblogging service. Empirical study shows that NRM can generate grammatically correct and content-wise appropriate responses to over 75% of the input text, outperforming state-of-the-arts in the same setting, including retrieval-based and SMT-based models.

1 Introduction

Natural language conversation is one of the most challenging artificial intelligence problems, which involves language understanding, reasoning, and the utilization of common sense knowledge. Previous works in this direction mainly focus on either rule-based or learning-based methods (Williams and Young, 2007; Schatzmann et al., 2006; Misu et al., 2012; Litman et al., 2000). These types of methods often rely on manual effort in designing rules or automatic training of model with a particular learning algorithm and a small amount of data, which makes it difficult to develop an extensible open domain conversation system.

Recently due to the explosive growth of microblogging services such as Twitter[1] and Weibo[2], the amount of conversation data available on the web has tremendously increased. This makes a data-driven approach to attack the conversation problem (Ji et al., 2014; Ritter et al., 2011) possible. Instead of multiple rounds of conversation, the task at hand, referred to as Short-Text Conversation (STC), only considers one round of conversation, in which each round is formed by two short texts, with the former being an input (referred to as post) from a user and the latter a response given by the computer. The research on STC may shed light on understanding the complicated mechanism of natural language conversation.

Previous methods for STC fall into two categories, 1) the retrieval-based method (Ji et al., 2014), and 2) the statistical machine translation (SMT) based method (Sordoni et al., 2015; Ritter et al., 2011). The basic idea of retrieval-based method is to pick a suitable response by ranking the candidate responses with a linear or non-linear combination of various matching features (e.g. number of shared words). The main drawbacks of the retrieval-based method are the following

- the responses are pre-existing and hard to customize for the particular text or requirement from the task, e.g., style or attitude.
- the use of matching features alone is usually not sufficient for distinguishing positive responses from negative ones, even after time consuming feature engineering. (e.g., a penalty due to mismatched named entities is difficult to incorporate into the model)

The SMT-based method, on the other hand, is generative. Basically it treats the response generation as a translation problem, in which the model is trained on a parallel corpus of post-response pairs. Despite its generative nature, the method is intrinsically unsuitable for response generation, because the responses are not semantically equivalent to the posts as in translation. Actually one post can receive responses with completely different content, as manifested through the example in the fol-

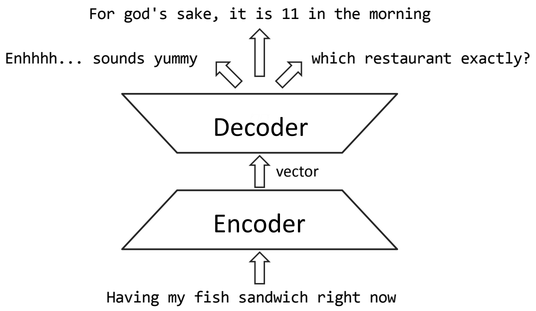
lowing figure:

Post	Having my fish sandwich right now
UserA	For god's sake, it is 11 in the morning
UserB	Enhhhh... sounds yummy
UserC	which restaurant exactly?

Empirical studies also showed that SMT-based methods often yield responses with grammatical errors and in rigid forms, due to the unnecessary alignment between the "source" post and the "target" response (Ritter et al., 2011). This rigidity is still a serious problem in the recent work of (Sordoni et al., 2015), despite its use of neural network-based generative model as features in decoding.

1.1 Overview

In this paper, we take a probabilistic model to address the response generation problem, and propose employing a neural encoder-decoder for this task, named *Neural Responding Machine* (NRM). The neural encoder-decoder model, as illustrated in Figure 1, first summarizes the post as a vector representation, then feeds this representation to a decoder to generate responses. We further generalize this scheme to allow the post representation to dynamically change during the generation process, following the idea in (Bahdanau et al., 2014) originally proposed for neural-network-based machine translation with automatic alignment.



For god's sake, it is 11 in the morning
Enhhhh... sounds yummy
which restaurant exactly?
Decoder
vector
Encoder
Having my fish sandwich right now

Figure 1: The diagram of encoder-decoder framework for automatic response generation.

NRM essentially estimates the likelihood of a response given a post. Clearly the estimated probability should be complex enough to represent all the suitable responses. Similar framework has been used for machine translation with a remarkable success (Kalchbrenner and Blunsom, 2013; Auli et al., 2013; Sutskever et al., 2014; Bahdanau et al., 2014). Note that in machine translation, the task is to estimate the probability of a target language sentence conditioned on the source language sentence with the same meaning, which is much easier than the task of STC which we are considering here. In this paper, we demonstrate that NRM, when equipped with a reasonable amount of data, can yield a satisfying estimator of responses (hence response generator) for STC, despite the difficulty of the task.

Our main contributions are two-folds: 1) we propose to use an encoder-decoder-based neural network to generate a response in STC; 2) we have empirically verified that the proposed method, when trained with a reasonable amount of data, can yield performance better than traditional retrieval-based and translation-based methods.

1.2 RoadMap

In the remainder of this paper, we start with introducing the dataset for STC in Section 2. Then we elaborate on the model of NRM in Section 3, followed by the details on training in Section 4. After that, we report the experimental results in Section 5. In Section 6 we conclude the paper.

2 The Dataset for STC

Our models are trained on a corpus of roughly 4.4 million pairs of conversations from Weibo [3].

2.1 Conversations on Sina Weibo

Weibo is a popular Twitter-like microblogging service in China, on which a user can post short messages (referred to as *post* in the reminder of this paper) visible to the public or a group of users following her/him. Other users make comment on a published post, which will be referred to as a *response*. Just like Twitter, Weibo also has the length limit of 140 Chinese characters on both posts and responses, making the post-response pair an ideal surrogate for short-text conversation.

2.2 Dataset Description

To construct this million scale dataset, we first crawl hundreds of millions of post-response pairs, and then clean the raw data in a similar way as suggested in (Wang et al., 2013), including 1) removing trivial responses like "wow", 2) filtering out potential advertisements, and 3) removing the responses after first 30 ones for topic consistency. Table 1 shows some statistics of the dataset used

[3] http://www.noahlab.com.hk/topics/ShortTextConversation

Training	#posts	219,905
	#responses	4,308,211
	#pairs	4,435,959
Test Data	#test posts	110
Labeled Dataset (retrieval-based)	#posts	225
	#responses	6,017
	#labeled pairs	6,017
Fine Tuning (SMT-based)	#posts	2,925
	#responses	3,000
	#pairs	3,000

Table 1: Some statistics of the dataset. **Labeled Dataset** and **Fine Tuning** are used by retrieval-based method for learning to rank and SMT-based method for fine tuning, respectively.

in this work. It can be seen that each post have 20 different responses on average. In addition to the semantic gap between post and its responses, this is another key difference to a general parallel data set used for traditional translation.

3 Neural Responding Machines for STC

The basic idea of NRM is to build a hidden representation of a post, and then generate the response based on it, as shown in Figure 2. In the particular illustration, the encoder converts the input sequence $\mathbf{x} = (x_1, \cdots, x_T)$ into a set of high-dimensional hidden representations $\mathbf{h} = (h_1, \cdots, h_T)$, which, along with the attention signal at time t (denoted as α_t), are fed to the context-generator to build the context input to decoder at time t (denoted as c_t). Then c_t is linearly transformed by a matrix $\mathbf{L}$ (as part of the decoder) into a stimulus of generating RNN to produce the t-th word of response (denoted as y_t).

In neural translation system, $\mathbf{L}$ converts the representation in source language to that of target language. In NRM, $\mathbf{L}$ plays a more difficult role: it needs to transform the representation of post (or some part of it) to the rich representation of many plausible responses. It is a bit surprising that this can be achieved to a reasonable level with a linear transformation in the "space of representation", as validated in Section 5.3, where we show that one post can actually invoke many different responses from NRM.

The role of attention signal is to determine which part of the hidden representation $\mathbf{h}$ should be emphasized during the generation process. It should be noted that α_t could be fixed over time or changes dynamically during the generation of response sequence $\mathbf{y}$. In the dynamic settings, α_t can be function of historically generated subsequence $(y_1, \cdots, y_{t-1})$, input sequence $\mathbf{x}$ or their latent representations, more details will be shown later in Section 3.2.

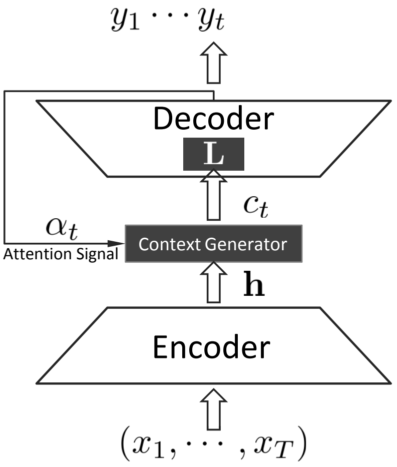


Figure 2: The general framework and dataflow of the encoder-decoder-based NRM.

We use Recurrent Neural Network (RNN) for both encoder and decoder, for its natural ability to summarize and generate word sequence of arbitrary lengths (Mikolov et al., 2010; Sutskever et al., 2014; Cho et al., 2014).

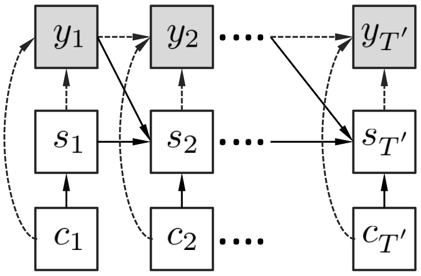

Figure 3: The graphical model of RNN decoder. The dashed lines denote the variables related to the function $g(\cdot)$, and the solid lines denote the variables related to the function $f(\cdot)$.

3.1 The Computation in Decoder

Figure 3 gives the graphical model of the decoder, which is essentially a standard RNN language model except conditioned on the context input $\mathbf{c}$. The generation probability of the t-th word is calculated by

$$p(y_t | y_{t-1}, \cdots, y_1, \mathbf{x}) = g(y_{t-1}, s_t, c_t),$$

where y_t is a one-hot word representation, $g(\cdot)$ is a softmax activation function, and s_t is the hidden state of decoder at time t calculated by

$$s_t = f(y_{t-1}, s_{t-1}, c_t),$$

and $f(\cdot)$ is a non-linear activation function and the transformation $\mathbf{L}$ is often assigned as parameters of $f(\cdot)$. Here $f(\cdot)$ can be a logistic function, the sophisticated long short-term memory (LSTM) unit (Hochreiter and Schmidhuber, 1997), or the recently proposed gated recurrent unit (GRU) (Chung et al., 2014; Cho et al., 2014). Compared to "ungated" logistic function, LSTM and GRU are specially designed for its long term memory: it can store information over extended time steps without too much decay. We use GRU in this work, since it performs comparably to LSTM on squence modeling (Chung et al., 2014; Greff et al., 2015), but has less parameters and easier to train.

We adopt the notation of GRU from (Bahdanau et al., 2014), the hidden state s_t at time t is a linear combination of its previous hidden state s_{t-1} and a new candidate state $\hat{s}_t$:

$$s_t = (1 - z_t) \circ s_{t-1} + z_t \circ \hat{s}_t,$$

where $\circ$ is point-wise multiplication, z_t is the update gate calculated by

$$z_t = \sigma\left(W_z e(y_{t-1}) + U_z s_{t-1} + L_z c_t\right), \quad (1)$$

and $\hat{s}_t$ is calculated by

$$\hat{s}_t = \tanh\left(W e(y_{t-1}) + U(r_t \circ s_{t-1}) + L c_t\right), \quad (2)$$

where the reset gate r_t is calculated by

$$r_t = \sigma\left(W_r e(y_{t-1}) + U_r s_{t-1} + L_r c_t\right). \quad (3)$$

In Equation (1)-(2), and (3), $e(y_{t-1})$ is word embedding of the word y_{t-1}, $\mathbf{L} = \{L, L_z, L_r\}$ specifies the transformations to convert a hidden representation from encoder to that of decoder. In the STC task, $\mathbf{L}$ should have the ability to transform one post (or its segments) to multiple different words of appropriate responses.

3.2 The Computation in Encoder

We consider three types of encoding schemes, namely 1) the global scheme, 2) the local scheme, and the hybrid scheme which combines 1) and 2).

Global Scheme: Figure 4 shows the graphical model of the RNN-encoder and related context generator for a global encoding scheme. The hidden state at time t is calculated by $h_t = f(x_t, h_{t-1})$ (i.e. still GRU unit), and with a trivial context generation operation, we essentially use the final hidden state h_T as the global representation of the sentence. The same strategy has been taken in (Cho et al., 2014) and (Sutskever et al., 2014) for building the intermediate representation for machine translation. This scheme however has its drawbacks: a vectorial summarization of the entire post is often hard to obtain and may lose important details for response generation, especially when the dimension of the hidden state is not big enough[4]. In the reminder of this paper, a NRM with this global encoding scheme is referred to as NRM-glo.

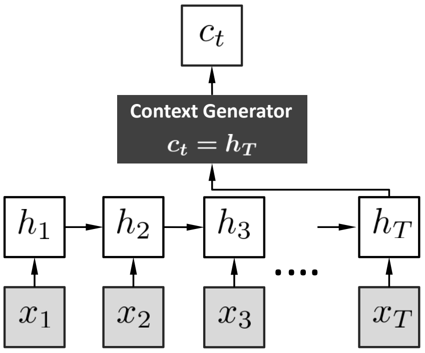

Figure 4: The graphical model of the encoder in NRM-glo, where the last hidden state is used as the context vector $c_t = h_T$.

Local Scheme: Recently, Bahdanau et al. (2014) and Graves (2013) introduced an attention mechanism that allows the decoder to dynamically select and linearly combine different parts of the input sequence $c_t = \sum_{j=1}^{T} \alpha_{tj} h_j$, where weighting factors α_{tj} determine which part should be selected to generate the new word y_t, which in turn is a function of hidden states $\alpha_{tj} = q(h_j, s_{t-1})$, as pictorially shown in Figure 5. Basically, the attention mechanism α_{tj} models the alignment between the inputs around position j and the output at position t, so it can be viewed as a local matching model. This local scheme is devised in (Bahdanau et al., 2014) for automatic alignment be-

[4] Sutskever et al. (2014) has to use $4,000$ dimension for satisfying performance on machine translation, while (Cho et al., 2014) with a smaller dimension perform poorly on translating an entire sentence.

tween the source sentence and the partial target sentence in machine translation. This scheme enjoys the advantage of adaptively focusing on some important words of the input text according to the generated words of response. A NRM with this local encoding scheme is referred to as NRM-loc.

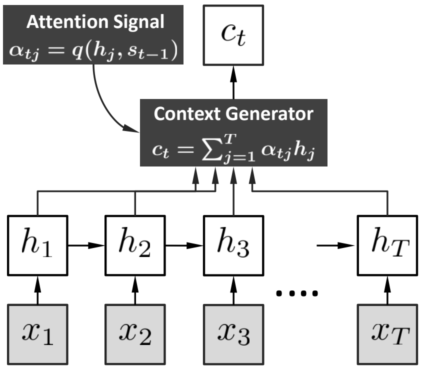

Figure 5: The graphical model of the encoder in NRM-loc, where the weighted sum of hidden sates is used as the context vector $c_t = \sum_{j=1}^{T} \alpha_{tj} h_j$.

3.3 Extensions: Local and Global Model

In the task of STC, NRM-glo has the summarization of the entire post, while NRM-loc can adaptively select the important words in post for various suitable responses. Since post-response pairs in STC are not strictly parallel and a word in different context can have different meanings, we conjecture that the global representation in NRM-glo may provide useful context for extracting the local context, therefore complementary to the scheme in NRM-loc. It is therefore a natural extension to combine the two models by concatenating their encoded hidden states to form an extended hidden representation for each time stamp, as illustrated in Figure 6. We can see the summarization h_T^g is incorporated into c_t and α_{tj} to provide a global context for local matching. With this hybrid method, we hope both the local and global information can be introduced into the generation of response. The model with this context generation mechanism is denoted as NRM-hyb.

It should be noticed that the context generator in NRM-hyb will evoke different encoding mechanisms in the global encoder and the local encoder, although they will be combined later in forming a unified representation. More specifically, the last hidden state of NRM-glo plays a role different from that of the last state of NRM-loc, since it has the responsibility to encode the entire input sentence. This role of NRM-glo, however, tends to be not adequately emphasized in training the hybrid encoder when the parameters of the two encoding RNNs are learned jointly from scratch. For this we use the following trick: we first initialize NRM-hyb with the parameters of NRM-loc and NRM-glo trained separately, then fine tune the parameters in encoder along with training the parameters of decoder.

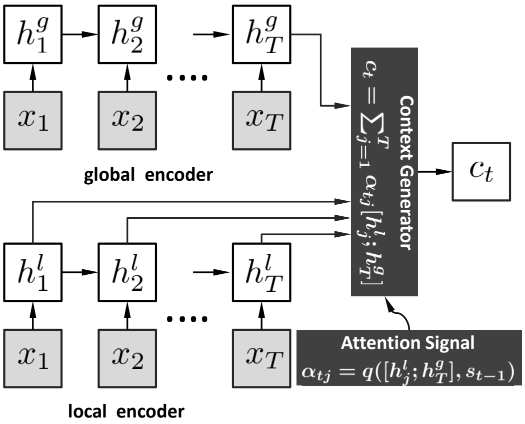

Figure 6: The graphical model for the encoder in NRM-hyb, while context generator function is $c_t = \sum_{j=1}^{T} \alpha_{tj}[h_j^l; h_T^g]$, here $[h_j^l; h_T^g]$ denotes the concatenation of vectors h_j^l and h_T^g

To learn the parameters of the model, we maximize the likelihood of observing the original response conditioned on the post in the training set. For a new post, NRMs generate their responses by using a left-to-right beam search with beam size = 10.

4 Experiments

We evaluate three different settings of NRM described in Section 3, namely NRM-glo, NRM-loc, and NRM-hyb, and compare them to retrieval-based and SMT-based methods.

4.1 Implementation Details

We use Stanford Chinese word segmenter [5] to split the posts and responses into sequences of words. Although both posts and responses are written in the same language, the distributions on words for the two are different: the number of unique words in post text is 125,237, and that of response text is 679,958. We therefore construct two separate vocabularies for posts and responses by using 40,000 most frequent words on each side, covering 97.8%

[5] http://nlp.stanford.edu/software/segmenter.shtml

usage of words for post and 96.2% for response respectively. All the remaining words are replaced by a special token "UNK". The dimensions of the hidden states of encoder and decoder are both 1,000. Model parameters are initialized by randomly sampling from a uniform distribution between -0.1 and 0.1. All our models were trained on a NVIDIA Tesla K40 GPU using stochastic gradient descent (SGD) algorithm with mini-batch. The training stage of each model took about two weeks.

4.2 Competitor Models

Retrieval-based: with retrieval-based models, for any given post p^*, the response r^* is retrieved from a big post-response pairs (p, r) repository. Such models rely on three key components: a big repository, sets of feature functions $\Phi_i(p^*, (p, r))$, and a machine learning model to combine these features. In this work, the whole 4.4 million Weibo pairs are used as the repository, 14 features, ranging from simple cosine similarity to some deep matching models (Ji et al., 2014) are used to determine the suitability of a post to a given post p^* through the following linear model

$$score(p^*, (p, r)) = \sum_i \omega_i \Phi_i(p^*, (p, r)). \quad (4)$$

Following the ranking strategy in (Ji et al., 2014), we pick 225 posts and about 30 retrieved responses for each of them given by a baseline retriever[6] from the 4.4M repository, and manually label them to obtain *labeled* 6,017 post-response pairs. We use ranking SVM model (Joachims, 2006) for the parameters ω_i based on the labeled dataset. In comparison to NRM, only the top one response is considered in the evaluation process.

SMT-based: In SMT-based models, the post-response pairs are directly used as parallel data for training a translation model. We use the most widely used open-source phrase-based translation model-Moses (Koehn et al., 2007). Another parallel data consisting of 3000 post-response pairs is used to tune the system. In (Ritter et al., 2011), the authors used a modified SMT model to obtain the "Response" of Twitter "Stimulus". The main modification is in replacing the standard GIZA++ word alignment model (Och and Ney, 2003) with a new phrase-pair selection method, in which all the possible phrase-pairs in the training data are considered and their associated probabilities are estimated by the Fisher's Exact Test, which yields performance slightly better than default setting[8]. Compared to retrieval-based methods, the generated responses by SMT-based methods often have fluency or even grammatical problems. In this work, we choose the Moses with default settings as our SMT model.

5 Results and Analysis

Automatic evaluation of response generation is still an open problem. The widely accepted evaluation methods in translation (e.g. BLEU score (Papineni et al., 2002)) do not apply, since the range of the suitable responses is so large that it is practically impossible to give reference with adequate coverage. It is also not reasonable to evaluate with Perplexity, a generally used measurement in statistical language modeling, because the naturalness of response and the relatedness to the post can not be well evaluated. We therefore resort to human judgement, similar to that taken in (Ritter et al., 2011) but with an important difference.

5.1 Evaluation Methods

We adopt human annotation to compare the performance of different models. Five labelers with at least three-year experience of Sina Weibo are invited to do human evaluation. Responses obtained from the five evaluated models are pooled and randomly permuted for each labeler. The labelers are instructed to imagine that they were the authors of the original posts and judge whether a response (generated or retrieved) is appropriate and natural to a input post. Three levels are assigned to a response with scores from 0 to 2:

- **Suitable (+2):** the response is evidently an appropriate and natural response to the post;
- **Neutral (+1):** the response can be a suitable response in a *specific* scenario;
- **Unsuitable (0):** it is hard or impossible to find a scenario where response is suitable.

To make the annotation task operable, the suitability of generated responses is judged from the following five criteria:

(a) **Grammar and Fluency**: Responses should be natural language and free of any fluency or grammatical errors;

[6] we use the default similarity function of Lucene [7]

[8] Reported results showed that the new model outperformed the baseline SMT model 57.7% of the time.

Post	意大利禁区里老是八个人... 太夸张了 There are always 8 players at the Italian restricted area. Unbelievable!	**Related Criterion**	**Labels**
Response1	我是意大利队的球迷，等待比赛开始。 I am a big fan of the Italy team, waiting for the football game to start	Logic Consistency	Unsuitable
Response2	意大利的食物太美味了 Italian food is absolutely delicious.	Semantic Relevance	Unsuitable
Response3	太夸张了吧！ Unbelievable!	Generality	Neutral
Response4	哈哈哈仍然是0：0 。还没看到进球。 Ha!Ha!Ha! it is still 0:0, no goal so far.	Scenario Dependence	Neutral
Response5	这正是意大利式防守足球。 This is exactly the Italian defending style football game.	——	Suitable

Figure 7: An example post and its five candidate responses with human annotation. The content of the post implies that the football match is already started, while the author of Response1 is still waiting for the match to start. Response2 talks about the food of Italy. Response3 is a widely used response, but it is suitable to this post. Response4 states that the current score is still 0:0, it is a suitable response only in this specific scenario.

Models	**Mean Score**	**Suitable (+2)**	**Neutral (+1)**	**Unsuitable (0)**	**Agreement**
NRM-glo	0.969	34.0%	28.9%	37.1%	0.397
NRM-loc	1.065	36.0%	34.5%	29.5%	0.247
NRM-hyb	1.156	39.3%	37.1%	23.6%	0.309
Rtr.-based	0.984	29.8%	38.7%	31.5%	0.346
SMT-based	0.313	5.6 %	20.0%	74.4%	0.448

Table 2: The results of evaluated methods. Mean score is the average value of annotated scores over all annotations. (Rtr.-based means the retrieval-based method)

ID	**Post**	**NRM-glo**	**NRM-loc**	**NRM-hyb**	**Rtr.-based**
1	每年元旦都来高烧。 High fever attacks me every New Year’s Day	多休息，增强免疫力！ Rest more to boost your immune system.	每年元旦都去医院看病 Go to see a doctor every New Year’s Day	祝早日康复，身体健康！ Get well soon and stay healthy!	高烧… High fever…
2	又老了一岁，感谢我们组，我很高兴 I gain one more year. Grateful to my group, so happy	生日快乐！永远支持你！ Happy birthday! Will stand by you forever!	生日快乐！永远年轻漂亮！ Happy birthday! Wish you always stay young and pretty!	老了老了，岁月不饶人啊！ Getting old now. Time has no mercy.	我只是老了一岁 I just gain only one more year.
3	吃素第一天，坚持住，崔朵拉。 First day of being a vegetarian. Hold on, **CuiDuoLa**	必须来支持！加油！ I come to offer my support. Keep it up!	坚持住，坚持下去。 Hold on, keep it up.	每天都是素食主义者 I have been being a vegetarian everyday	坚持住！ Hold on!
4	这种天气真应该带个帅锅出去踏青赏花 We should go out with some cute guys to enjoy a great outing in such a nice weather.	这是哪儿啊？真美！ Where is it? It is so beautiful!	阳光明媚，心情舒畅。 Such a nice sunny day! I am in a great mood.	这种天气真不是盖的。 It is indeed a very nice weather.	文山啊 出去踏青寻找灵感 哈哈 **WenShan**, let’s go out to get some inspiration. Ha! Ha!

Figure 8: Some responses generated by different models (originally in Chinese with their literal English translation), where the words in boldfaces are entity names.

(b) **Logic Consistency**: Responses should be logically consistent with the test post;

(c) **Semantic Relevance**: Responses should be semantically relevant to the test post;

(d) **Scenario Dependence**: Responses can depend on a specific scenario but should not contradict the first three criteria;

(e) **Generality**: Responses can be general but should not contradict the first three criteria;

If any of the first three criteria (a), (b), and (c) is contradicted, the generated response should be labeled as "Unsuitable". The responses that are general or suitable to post in a specific scenario should be labeled as "Neutral". Figure 7 shows an example of the labeling results of a post and its responses. The first two responses are labeled as "Unsuitable" because of the logic consistency and semantic relevance errors. Response4 depends on the scenario (i.e., the current score is 0:0), and is therefore annotated as "Neutral".

Model A	**Model B**	**Average rankings**	p **value**
NRM-loc	NRM-glo	(1.463, 1.537)	2.01%

5.2 Results

Our test set consists of 110 posts that do not appear in the training set, with length between 6 to 22 Chinese words and 12.5 words on average. The experimental results based on human annotation are summarized in Table 2, consisting of the ratio of three categories and the agreement among the five labelers for each model. The agreement is evaluated by Fleiss' kappa (Fleiss, 1971), as a statistical measure of inter-rater consistency. Except the SMT-based model, the value of agreement is in a range from 0.2 to 0.4 for all the other models, which should be interpreted as "Fair agreement". The SMT-based model has a relatively higher kappa value 0.448, which is larger than 0.4 and considered as "Moderate agreement", since the responses generated by the SMT often have the fluency and grammatical errors, making it easy to reach an agreement on such unsuitable cases.

From Table 2, we can see the SMT method performs significantly worse than the retrieval-based and NRM models and 74.4% of the generated responses were labeled as unsuitable mainly due to fluency and relevance errors. This observation confirms with our intuition that the STC dataset, with one post potentially corresponding to many responses, can not be simply taken as parallel corpus in a SMT model. Surprisingly, more than 60% of responses generated by all the three NRM are labeled as "Suitable" or "Neutral", which means that most generated responses are fluent and semantically relevant to post. Among all the NRM variants

- NRM-loc outperforms NRM-glo, suggesting that a dynamically generated context might be more effective than a "static" fixed-length vector for the entire post, which is consistent with the observation made in (Bahdanau et al., 2014) for machine translation;
- NRM-hyp outperforms NRM-loc and NRM-glo, suggesting that a global representation of post is complementary to dynamically generated local context.

The retrieval-based model has the similar mean score as NRM-glo, and its ratio on neutral cases outperforms all the other methods. This is because 1) the responses retrieved by retrieval-based method are actually written by human, so they do not suffer from grammatical and fluency problems, and 2) the combination of various feature functions potentially makes sure the picked responses are semantically relevant to test posts. However the picked responses are not customized for new test posts, so the ratio of suitable cases is lower than the three neural generation models.

To test statistical significance, we use the Friedman test (Howell, 2010), which is a non-parametric test on the differences of several related samples, based on ranking. Table 3 shows the average rankings over all annotations and the corresponding p-values for comparisons between different pairs of methods. The comparison between retrieval-based and NRM-glo is not significant and their difference in ranking is tiny. This indicates that the retrieval-based method is comparable to the NRM-glo method. The NRM-hyb outperforms all the other methods, and the difference is statistically significant ($p < 0.05$). The difference between NRM-loc and retrieval-based method is marginal ($p = 0.062$). SMT is significantly worse than retrieval-based and NRM-hyb methods.

5.3 Case Study

Figure 8 shows some example responses generated by our NRMs (only the one with biggest likelihood is given) and the comparable retrieval-based model. It is intriguing to notice that three NRM variants give suitable but quite distinct responses, with different perspectives and choices of words. This, as we conjecture, is caused by both the architecture variations among models as well as the variations from random effects like the initialization of parameters. Another interesting observation is on the fourth example, where the retrieval-based method returns a response with the mismatched entity name "WenShan", which is actually a quite common problem for retrieval-based model, where the inconsistency details (e.g., dates, named entities), which often render the response unsuitable, cannot be adequately considered in the matching function employed in retrieving the responses. In contrast, we observe that NRMs tend to make general response and barely generate those details.

Post	吃素第一天，坚持住，崔朵拉。 First day of being a vegetarian. Hold on, **CuiDuoLa**
R1	坚持住，坚持素食！ Hold on, Keep up your vegetarian diet.
R2	想要健康吗？想要长寿吗？那就关注我的微博吧。 Would you like to be healthy? Would you like to live long? If so, follow me on Weibo.
R3	这就是传说中的吃素吗？ This is the so-called vegetarian diet ?
R4	吃饱了才有力气减肥 Eat up so that you will have enough energy to go for a diet!
R5	身体是革命的本钱，不要着急！ Health is the essence for winning your future battles. No rush!

Figure 9: Multiple responses generated by the NRM-hyb.

We also use the NRM-hyb as an example to investigate the ability of NRM to generate multiple responses. Figure 9 lists 5 responses to the same post, which are gotten with beam search with beam size = 500, among which we keep only the best one (biggest likelihood) for each first word. It can be seen that the responses are fluent, relevant to the post, and still vastly different from each other, validating our initial conjecture that NRM, when fueled with large and rich training corpus, could work as a generator that can cover a lot of modes in its density estimation.

It is worth mentioning that automatic evaluation metrics, such as BLEU (Papineni et al., 2002) as adopted by machine translation and recently SMT-based responding models (Sordoni et al., 2015), do not work very well on this task, especially when the reference responses are few. Our results show that the average BLEU values are less than 2 for all models discussed in this paper, including SMT-based ones, on instances with single reference. Probably more importantly, the ranking given by the BLEU value diverges greatly from the human judgment of response quality.

6 Conclusions and Future Work

In this paper, we explored using encoder-decoder-based neural network system, with coined name Neural Responding Machine, to generate responses to a post. Empirical studies confirm that the newly proposed NRMs, especially the hybrid encoding scheme, can outperform state-of-the-art retrieval-based and SMT-based methods. Our preliminary study also shows that NRM can generate multiple responses with great variety to a given post. In future work, we would consider adding the intention (or sentiment) of users as an external signal of decoder to generate responses with specific goals.

Abstract

We propose an abstraction-based multi-document summarization framework that can construct new sentences by exploring more fine-grained syntactic units than sentences, namely, noun/verb phrases. Different from existing abstraction-based approaches, our method first constructs a pool of concepts and facts represented by phrases from the input documents. Then new sentences are generated by selecting and merging informative phrases to maximize the salience of phrases and meanwhile satisfy the sentence construction constraints. We employ integer linear optimization for conducting phrase selection and merging simultaneously in order to achieve the global optimal solution for a summary. Experimental results on the benchmark data set TAC 2011 show that our framework outperforms the state-of-the-art models under automated pyramid evaluation metric, and achieves reasonably well results on manual linguistic quality evaluation.

1 Introduction

Existing multi-document summarization (MDS) methods fall in three categories: extraction-based, compression-based and abstraction-based. Most summarization systems adopt the **extraction-based** approach which selects some original sentences from the source documents to create a short summary (Erkan and Radev, 2004; Wan et al., 2007). However, the restriction that the whole sentence should be selected potentially yields some overlapping information in the summary. To this end, some researchers apply compression on the selected sentences by deleting words or phrases (Knight and Marcu, 2000; Lin, 2003; Zajic et al., 2006; Harabagiu and Lacatusu, 2010; Li et al., 2015), which is the **compression-based** method. Yet, these compressive summarization models cannot merge facts from different source sentences, because all the words in a summary sentence are solely from one source sentence.

In fact, previous investigations show that human-written summaries are more abstractive, which can be regarded as a result of sentence aggregation and fusion (Cheung and Penn, 2013; Jing and McKeown, 2000). Some works, albeit less popular, have studied **abstraction-based** approach that can construct a sentence whose fragments come from different source sentences. One important work developed by Barzilay and McKeown (2005) employed sentence fusion, followed by (Filippova and Strube, 2008; Filippova, 2010). These works first conduct clustering on sentences to compute the salience of topical themes. Then, sentence fusion is applied within each cluster of related sentences to generate a new sentence containing common information units of the sentences. The abstractive-based approaches gather information across sentence boundary, and hence have the potential to cover more content in a more concise manner.

In this paper, we propose an abstractive MDS framework that can construct new sentences by

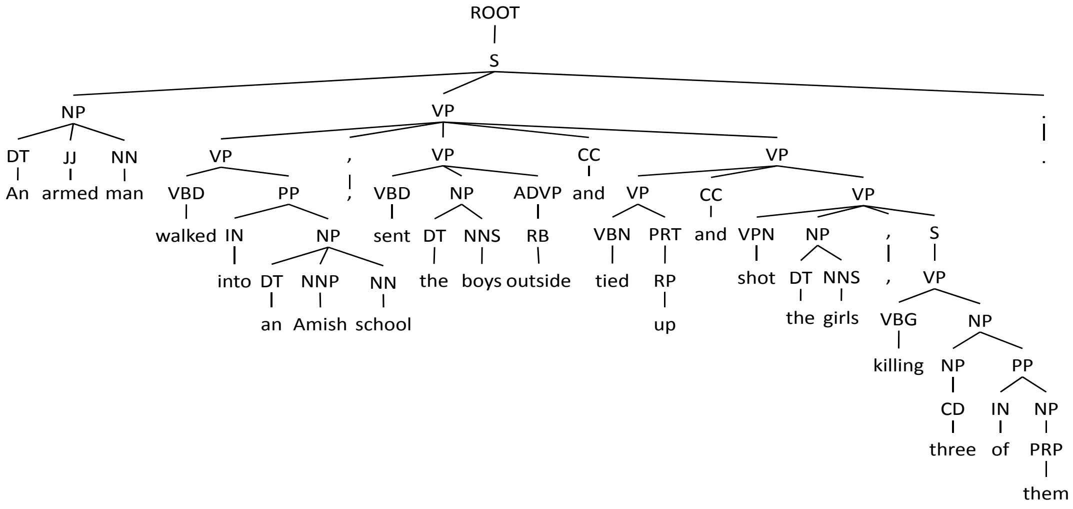

Figure 1: The constituency tree of a sentence from a news document.

exploring more fine-grained syntactic units than sentences, namely, noun/verb phrases (NPs/VPs). This idea is based on two observations. First, the major constituent phrases loosely correspond to the concepts and facts. After reading a set of documents describing the same topic or event, a person digests these documents as key concepts and facts in his/her mind, such as "*an armed man*" and "*walked into an Amish school*" from Figure 1. Second, a summary writer re-organizes the key concepts and facts to form new sentences for the summary. Accordingly, our proposed framework has two major components corresponding to the above observations. The first component creates a pool of concepts and facts represented by NPs and VPs from the input documents. A salience score is computed for each phrase by exploiting redundancy of the document content in a global manner. The second component constructs new sentences by selecting and merging phrases based on their salience scores, and ensures the validity of new sentences using a integer linear optimization model.

The contribution of this paper is two folds. (1) We extract NPs/VPs from constituency trees to represent key concepts/facts, and merge them to construct new sentences, which allows more summary content units (SCUs) (Nenkova and Passonneau, 2004) to be included in a sentence by breaking the original sentence boundaries. (2) The designed optimization framework for addressing the problem is unique and effective. Our optimization algorithm **simultaneously** selects and merges a set of phrases that maximize the number of covered SCUs in a summary. Meanwhile, since the basic unit is phrases, we design compatibility relations among NPs and VPs, as well as other optimization constraints, to ensure that the generated sentences contain correct facts. Compared with the sentence fusion approaches that compute salience scores of sentence clusters, our proposed framework explores a more fine-grained textual unit (i.e., phrases), and maximizes the salience of selected phrases in a global manner.

2 Description of Our Framework

We first introduce how to extract NPs and VPs from constituency trees, and subsequently calculate salience scores for them. Then we formulate the sentence generation task as an optimization problem, and design constraints. In the end, we perform several post-processing steps to improve the order and the readability of the generated sentences.

2.1 Phrase Salience Calculation

The first component decomposes the sentences in documents into a set of noun phrases (NPs) derived from the subject parts of a constituency tree and a set of verb-object phrases (VPs), representing potential key concepts and key facts, respectively. These phrases will serve as the basic elements for sentence generation.

We employ Stanford parser (Klein and Manning, 2003) to obtain a constituency tree for each input sentence. After that, we extract NPs and VPs from the tree as follows: (1) The NPs and VPs that are the direct children of the sentence node (represented by the **S** node) are extracted. (2) VPs (NPs) in a path on which all the nodes are VPs (NPs) are also recursively extracted and regarded as having the same parent node **S**. Recursive operation in the second step will only be carried out in two levels since the phrases in the lower levels may not be able to convey a complete fact. Take the tree in Figure 1 as an example, the corresponding sentence is decomposed into phrases "*An armed man*", "*walked into an Amish school, sent the boys outside and tied up and shot the girls, killing three of them*", "*walked into an Amish school*", "*sent the boys outside*", and "*tied up and shot the girls, killing three of them*". [1] Because of the recursive operation, the extracted phrases may have overlaps. Later, we will show how to avoid such overlapping in phrase selection.

A salience score is calculated for each phrase to indicate its importance. Different types of salience can be incorporated in our framework, such as position-based method (Yih et al., 2007), statistical feature based method (Woodsend and Lapata, 2012), concept-based method (Li et al., 2011), etc. One key characteristic of our approach is that the considered basic units are phrases instead of sentences. Such finer granularity leaves more room for better global salience score by potentially covering more distinct facts. In our implementation, we adopt a concept-based weight incorporating the position information. The concept set is designated to be the union set of unigrams, bigrams, and named entities in the documents. We remove stopwords and perform lemmatization before extracting unigrams and bigrams. The position-based term frequency is used in the concept weighting scheme. When counting the frequency, each occurrence of a concept in an input document is weighted with the paragraph position. The weight larger than 1 is given to the concept occurrences in the first few paragraphs. Specifically, the weight of the first paragraph is B and the weight decreases as the position of the paragraph increases from the beginning of the document. The weighting function is:

$$H(p) = \begin{cases} \rho^p * B & \text{if } p < -(\log B / \log \rho) \\ 1 & \text{otherwise} \end{cases}, \tag{1}$$

where p is the position of the paragraph starting from 0, from beginning of the document, and ρ is a positive constant and smaller than 1. Then, the salience of a phrase is calculated as the summed weights of its concepts.

2.2 New Sentence Construction Model

The construction of new sentences is formulated as an optimization problem which is able to simultaneously generate a group of sentences. Each new sentence is composed of one NP and at least one VP, where the NP and VPs may come from different source sentences. In the process of new sentence generation, the compatibility relation between NP and VP and a variety of summarization requirements are jointly considered.

2.2.1 Compatibility Relation

Compatibility relation is designed to indicate whether an NP and a VP can be used to form a new sentence. For example, the NP "*Police*" from another sentence should not be the subject of the VP "*sent the boys outside*" extracted from Figure 1. We use some heuristics to find compatibility, and then expand the compatibility relation to more phrases by extracting coreference.

To find coreference NPs (different mentions for the same entity), we first conduct coreference resolution for each document with Stanford coreference resolution package (Lee et al., 2013). We adopt those resolution rules that are able to achieve high quality and address our need for summarization. In particular, Sieve 1, 2, 3, 4, 5, 9, and 10 in the package are used. A set of clusters are obtained and each cluster contains the mentions that refer to the same entity in a document. The clusters from different documents in the same topic are merged by matching the named entities. After merging, the mentions that are not NPs extracted in the phrase extraction step are removed in each cluster. Two NPs in the same cluster are determined as alternative of each other.

To find alternative VPs, Jaccard Index is employed as the similarity measure. Specifically, each VP is represented as a set of its concepts and the index value is calculated for each pair of VPs. If the value is larger than a threshold, the two VPs are determined as alternative of each other.

[1] We only consider the recursive operation for a VP with more than one parallel sub-VPs, such as the highest VP in Figure 1. The sub-VPs following modal, link or auxiliary verbs are not extracted as individual VPs. In addition, we also extract the clauses functioning as subjects of sentences as NPs, such as "that clause". Note that we also mention such clauses as "noun phrase" although their syntactic labels could be "SBAR" or "S".

We then define an indicator matrix $\Gamma_{|\mathbf{N}||\mathbf{V}|}$, in which $\Gamma[i,j]=1$ if an NP N_i and a VP V_j come from the same node **S** in the constituency tree, otherwise, $\Gamma[i,j]=0$. Let $\tilde{\mathbf{N}}_i$ and $\tilde{\mathbf{V}}_i$ represent the alternative phrases of N_i and V_i as described above. The compatibility matrix $\tilde{\Gamma}_{|\mathbf{N}||\mathbf{V}|}$ is defined as follows:

$$\tilde{\Gamma}[p,q]=\begin{cases}1 & \text{if } N_p \in \tilde{\mathbf{N}}_i \wedge \Gamma[i,q]=1\\ 1 & \text{if } V_q \in \tilde{\mathbf{V}}_j \wedge \Gamma[p,j]=1\\ 1 & \text{if } \Gamma[p,q]=1\\ 0 & \text{otherwise}\end{cases} \tag{2}$$

where $\tilde{\Gamma}[p,q]=1$ means N_p and V_q are compatible/permitted for constructing a new sentence. $\tilde{\Gamma}$ is the final compatibility matrix that we use in the optimization. The first case of Equation 2 implies that if N_p and N_i are coreferent, N_p can replace N_i and serve as the subject of N_i's VP (i.e., V_q). The second case implies that if V_q is very similar to V_j, V_q can be concatenated to V_j's NP (i.e., N_p).

2.2.2 Phrase-based Content Optimization

The overall objective function of our optimization formulation to select NPs and VPs is defined as:

$$\max\{\sum_i \alpha_i S_i^N - \sum_{i<j}\alpha_{ij}(S_i^N+S_j^N)R_{ij}^N + \sum_i \beta_i S_i^V - \sum_{i<j}\beta_{ij}(S_i^V+S_j^V)R_{ij}^V\}, \tag{3}$$

where α_i and β_i are selection indicators for the NP N_i and the VP V_i, respectively. S_i^N and S_i^V are the salience scores of N_i and V_i. α_{ij} and β_{ij} are co-occurrence indicators of pairs (N_i, N_j) and (V_i, V_j). R_{ij}^N and R_{ij}^V are the similarity of pairs (N_i, N_j) and (V_i, V_j). If N_i and N_j are coreferent, $R_{ij}^N=1$. Otherwise, the similarity is calculated with the above Jaccard Index based method. The notations are summarized in Table 1.

Specifically, we maximize the salience score of the selected NPs and VPs as indicated by the first and the third terms in Equation 3, and penalize the selection of similar NP pairs and similar VP pairs as indicated by the second and the fourth terms. Meanwhile, the phrase selection is governed by a set of constraints so that the selected phrases can generate valid sentences. The constraints will be explained in details in Section 2.2.3.

One characteristic of our objective function is that NPs and VPs are treated differently, i.e., there are different selection/penalty terms for NP and VP. Such design enables us to avoid the false penalty between an NP and a VP. For example, the algorithm produces two sentences: the first sentence is "*the gunman shot ...*" with an NP "*the gunman*", and the other sentence has a VP "*confirmed the gunman died*". Obviously, we should not penalize the redundancy between them, because mentioning the gunman is necessary in both sentences.

Notation	Description
N_i, V_i	Noun phrase i and verb phrase i
α_i, β_i	Selection indicators of N_i and V_i
α_{ij}, β_{ij}	Co-occurrence indicators of pairs (N_i, N_j) and (V_i, V_j)
S_i^N, S_i^V	Salience scores of N_i and V_i
R_{ij}^N, R_{ij}^V	Similarity of pair (N_i, N_j) and pair (V_i, V_j)
$\Gamma_{\|\mathbf{N}\|\|\mathbf{V}\|}$	$\Gamma[i,j]=1$ if N_i and V_j are from the same sentence
$\tilde{\mathbf{N}}_i$, $\tilde{\mathbf{V}}_i$	The alternative phrases of N_i and V_i
$\tilde{\Gamma}_{\|\mathbf{N}\|\|\mathbf{V}\|}$	$\tilde{\Gamma}[i,j]=1$ means N_i and V_j are compatible for being used to construct a new sentence
$\tilde{\gamma}_{ij}$	Sentence generation indicator for N_i and V_j if $\tilde{\Gamma}[i,j]=1$

Table 1: Notations.

2.2.3 Sentence Generation Constraints

To summarize the related sentences in the documents, human writers usually merge the important facts in different VPs about the same entity into a single sentence, and omit the trivial facts. Also, the same entity is likely to be described by coreferent NPs. Therefore, in our approach, only one NP is selected and employed as the subject of the newly generated sentence, which is then concatenated with the merged facts (i.e., VPs). If the compatibility entry $\tilde{\Gamma}[i,j]$ for N_i and V_j is 1, we define a sentence generation indicator $\tilde{\gamma}_{ij}$ to indicate whether both N_i and V_j are selected to construct a new sentence in the summary.

We design the following groups of constraints to realize our aim of phrase selection and new sentence construction. The objective function and constraints are linear, therefore the problem can be solved by existing Integer Linear Programming (ILP) solvers such as simplex algorithm (Dantzig and Thapa, 1997).

`NP validity`. To maintain the consistency between the selection indicator α and the compatibility entry $\tilde{\Gamma}$ for NP N_i, we introduce two constraints as follows:

$$\forall i,j, \alpha_i \geq \tilde{\gamma}_{ij};\ \ \forall i, \sum_j \tilde{\gamma}_{ij} \geq \alpha_i. \tag{4}$$

These two constraints work together to ensure the valid assignment of α according to the compatibility entry $\tilde{\Gamma}$.

VP legality. Similarly, the following requirement guarantees the consistency between the selection indicator β and the compatibility entry $\tilde{\Gamma}$ for selected VP V_i:

$$\forall j, \sum_i \tilde{\gamma}_{ij} = \beta_j. \tag{5}$$

The above two constraints jointly ensure that the selected NPs and VPs are able to form new summary sentences according to the values of sentence generation indicators.

Not i-within-i. Two phrases in the same path of a constituency tree cannot be chosen at the same time:

$$\begin{aligned} &\text{if } \exists V_k \rightsquigarrow V_j, \text{then } \beta_k + \beta_j \leq 1, \\ &\text{if } \exists N_k \rightsquigarrow N_j, \text{then } \alpha_k + \alpha_j \leq 1. \end{aligned} \tag{6}$$

For example, "*walked into an Amish school, sent the boys outside and tied up and shot the girls, killing three of them*" and "*walked into an Amish school*" cannot be both incorporated in the summary, because of the obvious redundancy.

Phrase co-occurrence. These constraints control the co-occurrence relation of NPs or VPs. For NPs, we introduce three constraints:

$$\alpha_{ij} - \alpha_i \leq 0, \tag{7}$$

$$\alpha_{ij} - \alpha_j \leq 0, \tag{8}$$

$$\alpha_i + \alpha_j - \alpha_{ij} \leq 1. \tag{9}$$

Constraints 7 to 9 ensure a valid solution of NP selection. The first two constraints state that if the units N_i and N_j co-occur in the summary (i.e., $\alpha_{ij} = 1$), then we have to include them individually (i.e., $\alpha_i = 1$ and $\alpha_j = 1$). The third constraint is the inverse of the first two. Similarly, the constraints for VPs are as follows:

$$\beta_{ij} - \beta_i \leq 0, \tag{10}$$

$$\beta_{ij} - \beta_j \leq 0, \tag{11}$$

$$\beta_i + \beta_j - \beta_{ij} \leq 1. \tag{12}$$

Sentence number. In abstractive summarization, we do not prefer to generate many short sentences. This is controlled by:

$$\sum_i \alpha_i \leq K, \tag{13}$$

where K is the maximum number of sentences.

Short sentence avoidance. We do not select the VPs from very short sentences because a short sentence normally cannot convey a complete key fact (Woodsend and Lapata, 2012).

$$\text{if } l(\mathbf{S}) < M, V_i \in \mathbf{S}, \text{then } \beta_i = 0, \tag{14}$$

where M is the threshold of the sentence length.

Pronoun avoidance. We exclude the NPs that are pronouns from being selected as the subject of the new sentences. As previously observed (Woodsend and Lapata, 2012), pronouns are normally not used by human summary writers. It is because the summary is short and the narration relation of sentences is relatively simple so that pronouns are not needed. Moreover, in automatic summary, pronouns will cause ambiguity in the summary, especially when the sentence order is automatically determined. Therefore, we model the constraint as:

$$\text{if } N_i \; is \; pronoun, \text{then } \alpha_i = 0. \tag{15}$$

Length constraint. The overall length of the selected NPs and VPs is no larger than a limit L:

$$\sum_i \{l(N_i) * \alpha_i\} + \sum_j \{l(V_j) * \beta_j\} \leq L, \tag{16}$$

where $l()$ is the word-based length of a phrase.

2.3 Postprocessing

Recall that we require that one NP and at least one VP compose a sentence. Thus, we form a raw sentence with a selected NP as the subject followed by the corresponding selected VPs that are indicated by sentence generation indicator $\tilde{\gamma}_{ij}$ having the value 1. The VPs in a summary sentence are ordered according to their natural order if they come from the same document. Otherwise, they are ordered according to the timestamps of the corresponding documents. After that, if the total length is smaller than L, we add conjunctions such as "and" and "then" to concatenate the VPs for improving the readability of the newly generated sentences. The pseudo-timestamp of a sentence is defined as the earliest timestamp of its VPs and the sentences are ordered based on their pseudo-timestamps.

2.4 Relation to Existing MDS Approaches

Many existing extraction-based and compression-based MDS approaches could be regarded as special cases under our framework: (1) To simulate extraction-based summarization, we just need to constrain that the highest NP and the highest VP from the same sentence are selected simultaneously. In addition, no NPs and VPs in lower levels can be selected. Thus, the output only contains the original sentences of the source documents. (2) To simulate compression-based summarization, we can adapt our framework to conduct sentence selection and sentence compression in a joint manner. Specifically, we only need to restrict that the NP and VPs of a summary sentence must come from the same original sentence.

3 Experiments

3.1 Experimental Setup

The data set of traditional summarization task in Text Analysis Conference (TAC) 2011 is used to evaluate the performance of our approach. This data set is the latest one and it contains 44 topics. Each topic falls into one of 5 predefined event categories and contains 10 related news documents. There are four writers to write model summaries for each topic.

The data set of traditional summarization task in TAC 2010 is employed as the development/tuning data set. This data set contains 46 topics from the same predefined categories. Each topic also has 10 documents and 4 model summaries.

Based on the tuning set, the key parameters of our model are set as follows. The constants B and ρ in the weighting function are set to 6 and 0.5 repectively. The similarity threshold in obtaining the alternative VPs is 0.75. We did not observe significant difference between cosine similarity and Jaccard Index.

We mainly evaluate the system by pyramid evaluation. To gain a comprehensive understanding, we also evaluate by ROUGE evaluation and manual linguistic quality evaluation.

3.2 Results with Pyramid Evaluation

The pyramid evaluation metric (Nenkova and Passonneau, 2004) involves semantic matching of summary content units (SCUs) so as to recognize alternate realizations of the same meaning. Different weights are assigned to SCUs based on their frequency in model summaries. A weighted inventory of SCUs named a pyramid is created, which constitutes a resource for investigating alternate realizations of the same meaning. Such property makes pyramid method more suitable to evaluate summaries. Another widely used evaluation metric is ROUGE (Lin and Hovy, 2003) and it evaluates summaries from word overlapping perspective. Because of the strict string matching, it ignores the semantic content units and performs better when larger sets of model summaries are available. In contrast to ROUGE, pyramid scoring is robust with as few as four model summaries (Nenkova and Passonneau, 2004). Therefore, in recent summarization evaluation workshops such as TAC, the pyramid is used as the major metric.

System	Auto-pyr (Th: .6)	Auto-pyr (Th: .65)	Rank in TAC 2011
Our	0.905	0.793	NA
22	0.878	0.775	1
43	0.875	0.756	2
17	0.860	0.741	3

Table 2: Comparison with the top 3 systems in TAC 2011.

Since manual pyramid evaluation is time-consuming, and the exact evaluation scores are not reproducible especially when the assessors for our results are different from those of TAC, we employ the automated version of pyramid proposed in (Passonneau et al., 2013). The automated pyramid scoring procedure relies on distributional semantics to assign SCUs to a target summary. Specifically, all n-grams within sentence bounds are extracted, and converted into 100 dimension latent topical vectors via a weighted matrix factorization model (Guo and Diab, 2012). Similarly, the contributors and the label of an SCU are transformed into 100 dimensional vector representations. An SCU is assigned to a summary if there exists an n-gram such that the similarity score between the SCU low dimensional vector and the n-gram low dimensional vector exceeds a threshold. Passonneau et al. (2013) showed that the distributional similarity based method produces automated scores that correlate well with manual pyramid scores, yielding more accurate pyramid scores than string matching based automated methods (Harnly et al., 2005). In this paper, we adopt the same setting as in (Passonneau et al., 2013): a 100 dimension matrix factorization model is learned on a domain independent corpus, which is drawn from sense definitions of WordNet and Wiktionary[2], and Brown corpus. We exper-

[2] http://en.wiktionary.org/

	ROUGE-2			ROUGE-SU4		
System	P	R	F1	P	R	F1
Our	0.117	0.117	0.117	0.148	0.147	0.148
22	0.112	0.114	0.113	0.147	0.150	0.148
43	0.132	0.135	0.134	0.162	0.166	0.164
17	0.128	0.131	0.129	0.157	0.160	0.159

Table 3: Performance under ROUGE metric.

iment with 2 threshold values, i.e., 0.6 and 0.65, similar to those used in (Passonneau et al., 2013).

The top three systems in TAC 2011 evaluated with manual pyramid score were System 22 (Li et al., 2011), 43, and 17 (Ng et al., 2011). Table 2 shows the comparison with them under the automated pyramid evaluation. Our method achieves the best results in both thresholds, which means that our method is able to find more semantic content units (SCUs) than the state-of-the-art system in TAC 2011. In addition, paired t-test (with $p < 0.01$) comparing our model with the best system in TAC 2011, i.e., System 22, shows that the performance of our model is significantly better. It is worth noting that the three systems used additional external linguistic resources: System 22 used a Wikipedia corpus for providing domain knowledge, System 17 and 43 defined some category-specific features. Without any domain adaption, our framework can still achieve encouraging performance.

We calculate Pearson's correlation to measure how well the automatic pyramid approximates the manual pyramid scores for 50 system submissions in TAC 2011. The values are 0.91 and 0.93 for thresholds 0.6 and 0.65 respectively. It demonstrates that the automated pyramid is reliable to differentiate the performance of different methods.

3.3 Results with ROUGE Evaluation

As mentioned above, we favor the pyramid evaluation over the ROUGE score because it can measure the summary quality beyond simply string matching. Here, we also provide ROUGE score for our reference. ROUGE-1.5.5 package[3] is employed with the same parameters as in TAC. The results are summarized in Table 3. Our performance is slightly better than System 22, and it is not as good as System 43 and 17. The reason is that System 43 and 17 used category-specific features and trained the feature weights with the category information in TAC 2010 data. These features help them select better category-specific content for the summary. However, the usability of such features depends on the availability of predefined categories in the summarization task, as well as the availability of training data with the same predefined categories for estimating feature weights. Therefore, the adaptability of these methods is limited to some extent. In contrast, our framework does not define any category-specific feature and only uses TAC 2010 data to tune the parameters for general summarization purpose.

3.4 Linguistic Quality Evaluation

The linguistic quality of summaries is evaluated using the five linguistic quality questions on grammaticality (Q1), non-redundancy (Q2), referential clarity (Q3), focus (Q4), and coherence (Q5) in Document Understanding Conferences (DUC). A Likert scale with five levels is employed with 5 being very good with 1 being very poor. A summary was blindly evaluated by three assessors on each question. System 22 performed better than System 43 and 17 in TAC 2011 on the evaluation of readability, which is an aggregation of the above questions. Considering the intensive labor force of manual assessment, we only conduct comparison with System 22.

The results are given in Table 4. On average, the two systems perform very closely. System 22 is an extraction-based method that picks the original sentences, hence it achieves higher score in Q1 grammaticality, while our approach has some new sentences with grammar mistakes, which is a common problem for abstractive methods and deserves more future research effort. For Q4 focus, our score is higher than System 22, which reveals that our summary sentences are relatively more cohesive. The score of Q3 referential clarity shows that the referential relation is basically clear in our summaries, even when new sentences are automatically generated. In general, ignoring the grammaticality scores, our system still performs better than System 22. Specifically, the average scores of our system and System 22 on the last four questions are 3.37 and 3.33 respectively.

4 Qualitative Results

4.1 Analysis of Summary Sentence Type

There are three types of sentences in the summaries generated by our framework, namely, new

[3] http://www.berouge.com/Pages/default.aspx

System	Q1	Q2	Q3	Q4	Q5	AVG
Our	3.67	3.50	3.90	3.23	2.83	3.43
22	4.13	3.50	3.97	2.97	2.87	3.49

Table 4: Evaluation of linguistic quality.

sentences, compressed sentences, and original sentences. A new sentence is constructed by merging the phrases from different original sentences. A compressed sentence is generated by deleting phrases from an original sentence. An original sentence in the summary is directly extracted from the input documents.

The percentage of different types of sentences in our summaries is calculated. About 33% of the summary sentences are newly constructed. This demonstrates that our framework has good capability of merging phrases from the original sentences so as to convey more information in compacted summaries. In addition, about 44% of the summary sentences are generated by compression. It shows a unique characteristic of our framework: sentence construction and sentence compression are conducted in a unified model.

4.2 Case Study

Table 5 shows the summary of the first topic, i.e., "*Amish Shooting*", by our framework. The summary sentence ID and the sentence type are given in the form of "[summary sentence ID: sentence type]". Each selected phrase and the original sentence ID where the phrase originated are given in the form of "{selected phrase (original sentence ID)}". There are three compressed sentences with IDs 1, 2, and 4, one new sentence with ID 3, and two original sentences with IDs 5 and 6.

The new sentence is constructed from the following original sentences in which the extracted NPs and VPs are indicated with colored parentheses:

(84): On Monday morning, (NP Charles Carl Roberts IV) (VP (VP entered the West Nickel Mines Amish School in Lancaster County) and (VP shot 10 girls), (VP killing five)).
(85): (NP Roberts) (VP killed himself as police stormed the building).
(150): (NP Roberts) (VP left what they described as rambling notes for his family).

[1:C] {An armed man (25)} {walked into an Amish school (25)} {tied up and shot the girls, killing three of them. (25)} [2:C] {A man who laid siege to a one-room Amish schoolhouse (64)} {told his wife shortly before opening fire that he had molested two young girls who were his relatives decades ago (64)} {was tormented by dreams of molesting again. (64)} [3:N] {Charles Carl Roberts IV (84)} {killed himself as police stormed the building (85)} {left what they described as rambling notes for his family. (150)} [4:C] {The gunman (145)} {was not Amish (145)} {had not attended the school. (145)} [5:O] {The shootings (148)} {occurred about 10:45 a.m. (148)} [6:O] {Police (149)} {could offer no explanation for the killings. (149)}

Table 5: The summary of "*Amish Shooting*" topic.

The NPs of these sentences are coreferent so that some of their VPs are merged and concatenated with one NP, i.e., "*Charles Carl Roberts IV*".

The summary sentences with IDs 1, 2, and 4 are compressions from the following original sentences respectively:

(25): (NP An armed man) (VP (VP walked into an Amish school), (VP sent the boys outside) and (VP tied up and shot the girls, killing three of them)), (NP authorities) (VP said).
(64): (NP (NP A man) who laid siege to a one-room Amish schoolhouse), (VP killing five girls), (VP (VP told his wife shortly before opening fire that he had molested two young girls who were his relatives decades ago) and (VP was tormented by "dreams of molesting again")), (NP authorities) (VP said Tue).
(145): According to media reports, (NP the gunman) (VP (VP was not Amish) and (VP had not attended the school)).

Some uncritical information is excluded from the summary sentences, such as "*sent the boys outside*", "*authorities said*", etc. In addition, the VP "*killing five girls*" of the original sentence with ID 64 is also excluded since it has significant redundancy with the summary sentence with ID 1.

5 Related Work

Existing multi-document summarization (MDS) works can be classified into three categories:

extraction-based approaches, compression-based approaches, and abstraction-based approaches.

Extraction-based approaches are the most studied of the three. Early studies mainly followed a greedy strategy in sentence selection (Çelikyilmaz and Hakkani-Tür, 2011; Goldstein et al., 2000; Wan et al., 2007). Each sentence in the documents is firstly assigned a salience score. Then, sentence selection is performed by greedily selecting the sentence with the largest salience score among the remaining ones. The redundancy is controlled during the selection by penalizing the remaining ones according to their similarity with the selected sentences. An obvious drawback of such greedy strategy is that it is easily trapped in local optima. Later, unified models are proposed to conduct sentence selection and redundancy control simultaneously (McDonald, 2007; Filatova and Hatzivassiloglou, 2004; Yih et al., 2007; Gillick et al., 2007; Lin and Bilmes, 2010; Lin and Bilmes, 2012; Sipos et al., 2012). However, extraction-based approaches are unable to evaluate the salience and control the redundancy on the granularity finer than sentences. Thus, the selected sentences may still contain unimportant or redundant phrases.

Compression-based approaches have been investigated to alleviate the above limitation. As a natural extension of the extractive method, the early works adopted a two-step approach (Lin, 2003; Zajic et al., 2006; Gillick and Favre, 2009). The first step selects the sentences, and the second step removes the unimportant or redundant units from the sentences. Recently, integrated models have been proposed that jointly conduct sentence extraction and compression (Martins and Smith, 2009; Woodsend and Lapata, 2010; Almeida and Martins, 2013; Berg-Kirkpatrick et al., 2011; Li et al., 2015). Note that our model also jointly conducts phrase selection and phrase merging (new sentence generation). Nonetheless, compressive methods are unable to merge the related facts from different sentences.

On the other hand, abstraction-based approaches can generate new sentences based on the facts from different source sentences. In addition to the previously mentioned sentence fusion work, new directions have been explored. Researchers developed an information extraction based approach that extracts *information items* (Genest and Lapalme, 2011) or *abstraction schemes* (Genest and Lapalme, 2012) as components for generating sentences. Summary revision was also investigated to improve the quality of automatic summary by rewriting the noun phrases or people references in the summaries (Nenkova, 2008; Siddharthan et al., 2011). Sentence generation with word graph was applied for summarizing customer opinions and chat conversations (Ganesan et al., 2010; Mehdad et al., 2014).

Recently, the factors of information certainty and timeline in MDS task were explored (Ng et al., 2014; Wan and Zhang, 2014; Yan et al., 2011). Researchers also explored some variants of the typical MDS setting, such as query-chain focused summarization that combines aspects of update summarization and query-focused summarization (Baumel et al., 2014), and hierarchical summarization that scales up MDS to summarize a large set of documents (Christensen et al., 2014). A data-driven method for mining sentence structures on large news archive was proposed and utilized to summarize unseen news events (Pighin et al., 2014). Moreover, some works (Liu et al., 2012; Kågebäck et al., 2014; Denil et al., 2014; Cao et al., 2015) utilized deep learning techniques to tackle some summarization tasks.

6 Conclusions and Future Work

We propose an abstractive MDS framework that constructs new sentences by exploring more fine-grained syntactic units, namely, noun phrases and verb phrases. The designed optimization framework operates on the summary level so that more complementary semantic content units can be incorporated. The phrase selection and merging is done simultaneously to achieve global optimal. Meanwhile, the constructed sentences should satisfy the constraints related to summarization requirements such as NP/VP compatibility. Experimental results on TAC 2011 summarization data set show that our framework outperforms the top systems in TAC 2011 under the pyramid metric. For future work, one aspect is to enhance the grammar quality of the generated new sentences and compressed sentences. Another aspect is to improve time efficiency of our framework, and its major bottleneck is the time consuming ILP optimzation.

Abstract

Automatic timeline summarization (TLS) generates precise, dated overviews over (often prolonged) events, such as wars or economic crises. One subtask of TLS selects the most important dates for an event within a certain time frame. Date selection has up to now been handled via supervised machine learning approaches that estimate the importance of each date separately, using features such as the frequency of date mentions in news corpora. This approach neglects interactions between different dates that occur due to connections between subevents. We therefore suggest a joint graphical model for date selection. Even unsupervised versions of this model perform as well as supervised state-of-the-art approaches. With parameter tuning on training data, it outperforms prior supervised models by a considerable margin.

1 Introduction

Major events (such as the Egypt revolution starting in 2011) often last over a long period of time and have impact for a considerable time afterwards. In order to find out what happened when during such an event, time-related queries to search engines are often insufficient as traditional IR does not handle time-related queries well (Foley and Allan, 2015). To provide readers with comprehensive overviews of long events, many news outlets employ *timeline summaries*: a timeline summary is a list of selected dates with a few sentences describing the most important events on each date. An example can be seen in Table 1. Timelines allow the reader to gain a quick overview over a complex event and to answer questions such as: *How and when did the event start? What were the main consequences of the initial events? What happened to the main protagonists in the event?* In addition, timelines are frequent means in education (such as history teaching) so that their generation is relevant for education as well as journalism.

(a1) 2011-01-25 Egyptians hold nationwide demonstrations against the authoritarian rule of Hosni Mubarak, who has led the country for nearly three decades.
(a2) 2011-01-26 A large security force moves into Cairo's Tahrir Square
(a3) 2011-01-28 Protesters burn down the ruling party's headquarters, and the military is deployed.
(a4) 2011-02-11 Mubarak steps down and turns power over to the military.
(a5) 2011-03-19 In the first post Mubarak vote, Egyptians cast ballots on constitutional amendments ..., including scheduling the first parliamentary and presidential elections
(a8) 2012-04-20 The presidential campaign officially begins.
(a10) 2012-06-24 Election officials declare Morsi the winner
(a26) 2013-07-03 Egypt's military chief says Morsi has been replaced by Adly Mansour, the chief justice of constitutional court.

Table 1: A timeline about the Egypt revolution published by the Associated Press (AP). We leave out intermediate dates due to space constraints. The whole timeline includes 30 dates between 2011-01-25 and 2013-07-07.

Though convenient for the reader, the manual creation of a timeline can take a long time even for experts. For example, the creator of the start-up Timeline says that it initially took a multi-person team a full work day to create a single timeline.[1] Therefore, automatic timeline summarization (TLS) has emerged as an NLP task in the past few years (Tran et al., 2013a; Kessler et al., 2012; Nguyen et al., 2014; Yan et al., 2011b; Yan et al., 2011a; Wang et al., 2012; Tran et al., 2013b; Tran et al., 2015). TLS has been divided into two subtasks: (i) ranking the dates between beginning

[1] http://www.niemanlab.org/2015/02/timeline-is-providing-historical-context-to-the-news-but-is-there-a-business-model-to-support-it/.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1598–1607,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

and end of the timeline in order of importance, to achieve date selection and (ii) generating a good daily summary for each of the selected dates. In this paper, we tackle the first task. Date selection is challenging, as normally only a small set of the available dates is chosen for inclusion in the timeline (see Table 1). Date selection may be partially subjective: different journalists might include different dates.[2]

Existing approaches to date selection (Kessler et al., 2012; Tran et al., 2013a) use supervised machine learning, where each date receives a score for ranking the dates. Features used (such as frequency of date mention) are extracted from a corpus of event-related newspaper articles. Though the features are well-explored, the models score each date independently of other dates.

In contrast, we argue that interaction between dates should be taken into account. Timeline summaries tend to include "substories" in which the majority of selected dates are part of a chain of events that share major actors or demonstrate cause-effect. Table 1 shows at least two such chains: the (a1-4-5) chain of protests leading to Mubarak's resignation and the necessity of new elections, as well as the similar (a8-10-26) chain on Mursi. These chains can also be observed in the corresponding news articles. For example, some background articles on Mubarak's step-down will likely explain the reasons behind it. However, extracting such causal information can be difficult, as demonstrated by the still low results for discourse relation extraction (Lin et al., 2014; Braud and Denis, 2014). Instead, we use *date reference graphs*, which model which date refers to which other date. In our example, articles published on Mubarak's resignation date might refer to the date when the protest started. Although weaker than direct causal links, these links are easy to extract and we will show that they are very useful. In addition, references from important dates (such as Mubarak's resignation date) should be weighted higher than other references. This is akin to IR models such as PageRank, which weigh links from popular pages higher than links from less popular pages.

The main contributions of this work are: (i) we leverage interaction between dates via date reference graphs as a basis for date selection in TLS (ii) we provide a novel random walk model on this graph that incorporates both topical importance of referring sentences as well as frequency and temporal distance of references. We propose both unsupervised as well as supervised versions of this model.

We show that the proposed date selection approach outperforms previous approaches with evaluations on four real-life, long-term news events. We also discuss variations in timeline construction over different events, as well as by different journalists.

2 Related Work

Timeline summarization is a special case of *multi-document summarization* (MDS). As TLS organizes events by date, timelines can be generated by MDS systems (such as (Radev et al., 2004b; Radev et al., 2004a; McKeown et al., 2003; Erkan and Radev, 2004; Metzler and Kanungo, 2008; Hong and Nenkova, 2014) by applying their summarization techniques on news articles for every individual date to create corresponding daily summaries. However, manually written timelines normally only include a small number of dates; in addition, the temporal component imposes constraints on sentence selection for timeline summarization, such as the preference for little overlap between sentences selected for different dates (Yan et al., 2011b).

Many studies specific to timeline summarization, such as (Swan and Allan, 2000; Allan et al., 2001; Chieu and Lee, 2004; Yan et al., 2011b; Tran et al., 2015), focus on the extraction of salient sentences or headlines for generating the textual content of timelines. They assume either that the dates are given in advance or they use simple measures such as *burstiness* (Chieu and Lee, 2004; Yan et al., 2011b) for date selection, where burstiness relies on the number of date mentions.

Prior approaches dedicated specifically to date selection are Tran et al. (2013a) and Kessler et al. (2012).[3] They use supervised machine learning methods that score dates *independently of each other*. Features are extracted from a corpus of event-related newspaper articles, including frequency-based features (such as how often the date is referred to in the corpus), temporal distance features (such as how long into the future a date

[2] Note that the date selection task uses dates as proxies for important events on that date.

[3] Kessler et al. (2012) is also used in Nguyen et al. (2014)'s system.

keeps being referred to) and topical features (such as whether the date mention is associated with the most significant keywords of the event). We, however, score dates *jointly*, making use of interactions between dates in a graphical model. This improves substantially over prior approaches. We also propose unsupervised variations that perform competitively to prior supervised models.

3 Problem Definition and Approach

Similar to Kessler et al. (2012) and Tran et al. (2013a), we use the day as the timeline time unit (so, for example, we exclude hourly timelines).

3.1 Problem Definition

Given a main event and a time window $[t_1, t_2]$ within the event duration, our task is to select the top k dates $(d_1, d_2, ..., d_k) \in [t_1, t_2]$, when the most important (sub)events occurred. Therefore, timelines of variable length can be constructed. Like (Kessler et al., 2012; Tran et al., 2013a), we also assume that we have a corpus $\mathcal{C}$, consisting of news articles about the main event. This corpus gives evidence about the dates in $[t_1, t_2]$.

3.2 Proposed Approach

We build a *date reference graph*, which is a *fully directed graph* $\mathbf{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is the set of dates mentioned in any text in corpus $\mathcal{C}$, including publication dates. The edges $\mathcal{E} = \{e(d_i, d_j)\}$ indicate that at least one text published on d_i refers to the date d_j.

We represent each such link as a multi-value tuple $e(d_i, d_j) = (M_{ij}, freq(d_i, d_j), I_{temporal}(d_i, d_j), I_{topical}(d_i, d_j))$ to integrate different measures of date importance. The first value, $M_{ij} = \frac{1}{N}$ expresses the prior stochastic transitional probability between 2 dates where $N = |\mathcal{V}|$. The others express the strength of the connection between d_i and d_j modelled by the following aspects: frequency ($freq$), temporal influence ($I_{temporal}$) and topical influence ($I_{topical}$). We also suggest different combinations of these parameters.

Then we introduce a random walk model that uses these perspectives to rank the collection of dates.

Frequency of References. When a date d_j is referred to from either a past or future news article (published on d_i), it is likely involved in the events that are reported in that article. An example published on Mubarak's resignation date and referring back to the protest start can be seen below:

(1) On January 25, an uprising of Egyptians erupted calling for Mubaraks resignation as president. Protests continued to grow . . . (CBS Detroit, 2011-02-11)

We hypothesize that the more frequent such references are, the stronger this involvement is. Hence, we compute $freq(d_i, d_j)$ as the number of references to d_j from news articles published on d_i. While prior work (Kessler et al., 2012) uses aggregate frequency of references to d_j over the whole corpus as a feature, they do not handle the interaction between dates and can therefore not score dates jointly.

Topical Influence. In Example 1 above, the reference sentence mentions only major actors in the Egypt crisis (Mubarak, Egyptians) as well as only major subevents (uprising, protests). This makes for a link between 2011-02-11 (publication date) and 2011-01-25 (referred date) that is relevant to the main event and emphasises the importance of the referred date. In contrast, Example 2 also talks about less salient entities in context of the Egypt revolution and makes for a less topical link between 2011-02-02 (publication date) and 2011-01-25 (referred date).

(2) Mr Ghonim is Google's head of marketing for Middle East and North Africa and was in Egypt when the protests started on Jan 25 (DailyMail, 2011-02-02).

We quantify the topical influence between dates as follows: Let $\mathcal{S}_{i \to j} = \{s_{ij}\}$ be the set of sentences that are published in d_i and refer to d_j. We are interested in how relevant this connection is to the overall news event, looking at the content in $\mathcal{S}_{i \to j}$. To do so, we represent the overall content of the news collection by a set of keywords $Q = \{q_1, q_2, ..., q_n\}$, which are computed via TextRank (Mihalcea and Tarau, 2004).[4] We compute a relevance score for each sentence s_{ij} in $\mathcal{S}_{i \to j}$ by the famous Okapi BM25 function (Robertson et al., 1994), which ranks a sentence more topical if it contains more as well as more of the most salient collection keywords Q.[5] We compute topical influence ($I_{topical}$) as either the maximum value or the sum value of the relevance scores of all s_{ij}.

$$I_{\max topical}(d_i, d_j) = \max_{s_{ij} \in \mathcal{S}_{i \to j}} BM25(s_{ij}, Q) \quad (3)$$

$$I_{freq*topical}(d_i, d_j) = \sum_{s_{ij} \in \mathcal{S}_{i \to j}} BM25(s_{ij}, Q) \quad (4)$$

[4] We set n=20 in practice.

[5] We use the standard BM25 parameter settings $k_1 = 1.2$ and $b = 0.75$

Intuitively, $I_{freq*topical}(d_i, d_j)$ is proportional to the size of $\mathcal{S}_{i\rightarrow j}$ as well as to the relevance scores of its sentences whereas $I_{\max topical}(d_i, d_j)$ does not consider reference frequency at all.

When d_j is not mentioned by any articles published on d_i, the value of the topical influence is equal to zero.

Temporal Influence. The longer ago an event happened the more likely it is to have been forgotten. Only very important events are referred to over long time frames. We therefore hypothesise that a date d_j is more influential (for another date d_i) if d_i mentions d_j and the temporal distance between the two dates is high. Overall, d_j gathers importance with several long-term references. Ex. 5 showcases an example:

(5) Military generals took over power from Mubarak when he stepped down on *February 11 last year.* (Daily Mail, 2012-01-25).

We define the temporal influence of an existing edge $I_{temporal}(d_i, d_j)$ as either the absolute value of temporal distance between the two dates or by the product of the temporal distance with the number of references $freq(d_i, d_j)$. In the second computation, the temporal influence between two dates increases when d_i references d_j more than once.

$$I_{|temporal|}(d_i, d_j) = \Delta t = |d_i - d_j| \tag{6}$$

$$I_{freq*temporal}(d_i, d_j) = freq(d_i, d_j) \cdot |d_i - d_j| \tag{7}$$

When d_j is not mentioned by any articles published on d_i, the temporal influence is set as zero.

Random Walk Model for Date Ranking. A random walk on a given graph is a Markov process, where each node represents a state and a walk transiting from one state to another state is based on a transition probability matrix. One well-known random walk algorithm is PageRank (Page et al., 1999), which models web surfer behavior to determine the importance of web pages with the following formula:

$$x_t(j) = \alpha \sum_{i \in L_j^-} M_{ij} x_{t-1}(i) + (1-\alpha)v_j, \tag{8}$$

where M_{ij} is the stochastic transition probability from page p_i to p_j, $x_t(j)$ is the importance score of page p_j at step t, α is a damping factor that controls how often the walker jumps to an arbitrary node, v_j is the initial probabilistic importance score (generally set to $1/N$, where N is the number of nodes in the graph), and L_i^- is the set of incoming links of page p_i. When t is iterated enough, the importance score vector reaches a stationary distribution that can be used for ranking pages.

The traditional PageRank process in Eq. 8 captures only the observed linking characteristics of nodes but ignores other sources of information which can be indicators for their importance.

We extend the model by introducing an influence-based random walk model (**IRW**) that allows the random walker to take into account multiple sources of information and perform voting more effectively. The random walk process we propose can be defined by the following formula:

$$x_t(j) = \alpha \sum_{i \in L_j^-} \mathcal{I}(i,j) \cdot M_{ij} \cdot x_{t-1}(i) + (1-\alpha)v_j \tag{9}$$

where $\mathcal{I}(i,j)$ is the normalized influence factor that indicates how influential the edge $d_i \rightarrow d_j$ is in the global context of the event. The normalization is done by scaling the range of value from [0, 1]. M is the stochastic transitional matrix. In our case, $\mathcal{I}(i,j)$ can be just the value of $freq(d_i, d_j)$, $I_{topical}(d_i, d_j)$, $I_{temporal}(d_i, d_j)$ alone or a linear combination of them. Note that, $(\mathcal{I} \cdot M)$ in most case is not stochastic and *must not* be transformed into a stochastic transitional matrix, as the transformation will collapse the global context of $\mathcal{I}$. IRW is different to PageRank on weighted graph, weighted or personalized PageRank and their variations e.g, (Xing and Ghorbani, 2004; Haveliwala, 2002), among others. In particular, weighted PageRank integrates influence scores into the stochastic transitional matrix. Thus, the random walker contributes the voting impact of a node X to its neighbor with an influence score normalized by the sum of scores on all outgoing connections. That process leverages how good this connection is in the sub-graph (G*) which consists of X and its outgoing neighbors. In contrast, our proposed model uses the non-normalized value of the influence score to leverage how good this connection is on the entire graph instead of G*. To give an example, if date X1 mentions only X2 with a raw temporal distance score of 20 and X3 mentions only X4 with a score of 100, then in weighted Page Rank both would be normalized to a weight one, losing the information that X4 is mentioned after a much longer time period than X2. The process for combination in our model is defined as the following:

$$\begin{aligned} x_t(j) = \alpha\omega & \sum_{i \in L_j^-} W_1(i,j) \cdot M_{ij} \cdot x_{t-1}(i) \\ & + \alpha(1-\omega) \sum_{i \in L_j^-} W_2(i,j) \cdot M_{ij} \cdot x_{t-1}(i) \\ & + (1-\alpha)v_j \end{aligned} \tag{10}$$

where $W_1(i,j) = \frac{I_{topical}(d_i,d_j)}{\max_{uv} I_{topical}(d_u,d_v)}$ is the normalized value for topical influence, and $W_2(i,j) = \frac{I_{temporal}(d_i,d_j)}{\max_{uv} I_{temporal}(d_u,d_v)}$ is the normalized value for temporal influence.[6]

Here, the hyper-parameter $0 \leq \omega \leq 1$ controls the proportion of the topical influence from d_i to d_j. When $\omega = 0$, no topical influence is taken into account. No temporal influence is considered when $\omega = 1$. Intuitively, at every step, the random walker can follow the outgoing nodes and either carry topical influence (the first part) or temporal influence (the second part) to contribute to the rank of the outgoing nodes. Otherwise, it teleports to an arbitrary node with probability $(1 - \alpha)$.

Convergence Property. Starting from Eq. 10, we now show that the IRW model converges to a stationary distribution.

Let Λ and Λ' be the matrix with elements $W_1(i,j)$ and $W_2(ij)$ respectively, with any edge (d_i, d_j), $\mathbf{I}$ be the $n \times n$ identity matrix, and $\mathbf{v}$ be the transpose of $1 \times n$ uniform stochastic vector. $\mathbf{M}$ denotes the transitional matrix for G.

Proposition 1. $(\mathbf{I} - \alpha(w\mathbf{M}^T\Lambda + (1-\omega)\mathbf{M}^T\Lambda'))$ *is invertible for all* $\mathbf{M}, \Lambda, \Lambda', \alpha, \omega$.

Proof. Let $\mathbf{P} = w\mathbf{M}^T\Lambda + (1-\omega)\mathbf{M}^T\Lambda'$, we need to prove that $\mathbf{I} - \alpha\mathbf{P}$ is invertible. Equivalently, we prove its transpose $\mathbf{I} - \alpha\mathbf{P}^T$ is invertible, which can be proved by showing that $(\mathbf{I} - \alpha\mathbf{P}^T)\mathbf{y} = 0$ only has the trivial solution $\mathbf{y} = 0$.

$$\begin{aligned} (\mathbf{I} - \alpha\mathbf{P}^T)\mathbf{y} &= 0 \\ \mathbf{y} &= \alpha\mathbf{P}^T\mathbf{y} \\ y_i &= \alpha \sum_j P_{ji} y_j \\ &= \alpha \sum_j ((\omega W_1(i,j) + (1-\omega)W_2(i,j))M_{ij} y_j). \end{aligned} \tag{11}$$

Let $u = \arg\max_j y_j$. When $i == u$, Eq. 11 infers,

$$\begin{aligned} y_u &\leq \alpha \sum_j ((\omega W_1(u,j) + (1-\omega)W_2(u,j))M_{uj} y_u). \\ y_u &\leq \alpha y_u \sum_j ((\omega W_1(u,j) + (1-\omega)W_2(u,j))M_{uj} \\ y_u(1 - \alpha\mathcal{F}_u) &\leq 0. \end{aligned} \tag{12}$$

where $\mathcal{F}_u = \sum_j((\omega W_1(u,j) + (1-\omega)W_2(u,j))M_{uj}$. Clearly, $\mathcal{F}_u \leq 1$ because $W_1(u,j) \leq 1$ and $W_2(u,j) \leq 1$ and $\sum_j M_{uj} = 1$. Since $\alpha < 1$ and $\mathcal{F}_u \leq 1$, $(1 - \alpha\mathcal{F}_u) > 0$. Therefore $y_u \leq 0$. Similarly, let $v = \arg\min_j y_j$ we have that $y_v \geq 0$. As $y_v \leq y_u$, this implies $y_u = y_v = 0$ to satisfy all inequalities. Consequently, $y_i = 0$ for all i, or $\mathbf{y} = 0$. Thus, $\mathbf{I} - \alpha\mathbf{P}^T$ invertible. Equivalently,$(\mathbf{I} - \alpha(\omega\mathbf{M}^T\Lambda + (1-\omega)\mathbf{M}^T\Lambda'))$ is invertible. □

Proposition 2. *The iteration in Eq. 9 converges to* $(1-\alpha)(\mathbf{I} - \alpha(\omega\mathbf{M}^T\Lambda + (1-\omega)\mathbf{M}^T\Lambda'))^{-1}\mathbf{v}$.

Proof. We can re-write Eq. 9 in matrix form:

$$\begin{aligned} \mathbf{x}_t &= \alpha\mathbf{P}\mathbf{x}_{t-1} + (1-\alpha)\mathbf{v} \\ &= (\alpha\mathbf{P})^t\mathbf{x}_0 + (1-\alpha)(\sum_{i=1}^{t}(\alpha\mathbf{P})^{i-1})\mathbf{v} \end{aligned} \tag{13}$$

We will show that $\lim_{t\to\infty} \mathbf{x}_t = (1-\alpha)(I - \alpha\mathbf{P})^{-1}\mathbf{v}$.

$$\begin{aligned} \sum_i (\alpha P)_{ij}^t &= \sum_i \sum_k (\alpha P)_{ik} (\alpha P)_{kj}^{t-1} \\ &= \sum_k (\alpha P)_{kj}^{t-1} \sum_i (\alpha P)_{ik} \\ &= \sum_k (\alpha P)_{kj}^{t-1} \alpha(\mathcal{F}_k) \\ &\leq \sum_k (\alpha P)_{kj}^{t-1} \alpha \\ &\leq (\alpha)^t \end{aligned} \tag{14}$$

Here, $\mathcal{F}_k = \sum_i((\omega W_1(k,i) + (1-\omega)W_2(k,i))M_{ki} \leq 1$ (proof similarly to Proposition 1

Because $\alpha < 1$, this column sum converges to zero when $t \to \infty$. We then derive $\lim_{t\to\infty} (\alpha\mathbf{P})^t\mathbf{x}_0 = 0$. When $t \to \infty$, given Proposition 1 and Neumann series, Eq. 13 becomes:

$$\mathbf{x}_t = (\alpha\mathbf{P})^t\mathbf{x}_0 + (1-\alpha)(I - \alpha\mathbf{P})^{-1}\mathbf{v}$$

hence, $\lim_{t\to\infty} \mathbf{x}_t = (1-\alpha)(I-\alpha\mathbf{P})^{-1}\mathbf{v}$. Convergence proved. □

4 Experiments

4.1 Ground Truth and Data Preprocessing

Kessler et al. (2012) use 91 timelines from AFP as ground truth along with the AFP news corpus for feature extraction. However, their dataset is not publically available. In addition, although they consider a wide spread of events, each event is only represented by a single timeline from a single source, making that method somewhat vulnerable to journalism bias (as discussed by themselves in their paper). The data collected by us previously (Tran et al., 2013a) is publically available at `http://l3s.de/~gtran/timeline/` and has since been extended by us (Tran et al., 2015). Similar to Kessler et al. (2012), it contains ground truth timelines as well as a corpus of news articles covering each event. The dataset is suitable for our purpose because of the following reasons: (1) it is a heterogeneous dataset which contains news articles and expert timeline summaries from different news agencies. Thus, it is more likely to avoid the issue of bias. Also, each event is represented

[6] In the case of linear combinations we incorporate frequency into topical or temporal influence as described above.

by more than one timeline; (2) it covers long-term stories that have been happening since 2011, making the date selection problem non trivial for any system.

Timelines. The groundtruth contains 21 timelines for 4 main events (Egypt Revolution, Libya War, Syria War, Yemen Crisis), created by professional journalists. Table 2 shows statistics about the timelines. Only a small number of all possible dates in a time range is included in at least one timeline (for example, only 122 dates among a possible 918 dates for the Egypt Revolution).

News Corpus. The news articles have been collected from 24 well-known news outlets by querying Google with the event name together with the outlets' sitename and time range specification. The crawl time range starts from the first of the month of the earliest event in any timeline (for example, 2011-01-01 for the Egypt revolution) and ends at crawl date. The top-ranked 300 news articles from each news site were collected, if still available. The article creation date is parsed from the answers returned by Google. The corpus contains 15,534 news articles. Its statistics are summarised in Table 3. The overlap between timeline date ranges and news corpus date ranges is only partial: on the one hand, the corpora have many articles published after the timelines end; on the other hand, sometimes the corpus has no articles published near the beginning of the timeline (Syria War). The distribution of document frequency leans towards the end date of the news collection. The reason could be that most search engines rank recent documents higher than those published longer ago.

Story	Time Range	#News
Egypt	2011/01/11 - 2013/11/10	3869
Libya	2011/02/16 - 2013/07/18	3994
Syria	2011/11/17 - 2013/07/26	4071
Yemen	2011/01/15 - 2013/07/25	3600

Table 3: Overview of the news corpus

Preprocessing. Accurate date extraction including both implicit (like *last Friday*) and explicit (like *11 Feb*) temporal expressions is vital to our approach as well as for competitor systems. We use the Heideltime state-of-the art toolkit (Strötgen and Gertz, 2010) for this task.

4.2 Experimental settings

As can be seen from Table 2, different timelines for the same event can contain varying dates, due to different ranges timelines might cover but also due to selection preferences by individual writers. Therefore, we consider the union of all timelines for an event. The set of input dates for ranking are all dates from the start t_1 and end t_2 of the union of timelines.[7] We call that input time range $\mathcal{TR}_e$, depending on main event e.

We consider two evaluation settings:

relaxed setting: A date from $\mathcal{TR}_e$ selected by an algorithm is counted as correct if it is included in the union of timelines, therefore in at least one individual timeline.

strict setting: A date from $\mathcal{TR}_e$ selected by an algorithm is counted as correct if it is included in at least two individual timelines.

The first setting is the one used in previous work such as (Kessler et al., 2012; Tran et al., 2013a). It is also the only one that can be used if only one timeline per event is considered as in Kessler et al. (2012). We therefore include it for comparison purposes. However, we think it is better to consider several timelines as it allows us to consider agreement between timeline writers. If more than one writer agrees on a date being important we have more evidence that a system should find that date. Finding dates that only a single writer includes is less important and could even be due to bias or system overfitting. Therefore, our second setting is preferable as it emphasizes highly important dates selected by multiple journalists.

Each system selects the top k dates during the input time range. We evaluate the systems by Mean Average Precision at k (MAP@k) for k = 5, 10, 15, 20 over all four events.

4.3 Systems.

Baseline. We use three unsupervised baselines. The baseline *Document Frequency* ranks dates according to the number of news articles published on that date. Our assumption is that on a date where one or more important events happened, there would be a spread of information over different news agencies in the world. Therefore, this date has more news articles published. This baseline is related to the burstiness date selection used by Yan et al. (2011b).

The baseline *MaxLength* ranks dates by the maximum article length of all articles published on that date. Our hypothesis is that important events

[7] Prior work also uses start and end date of timelines for delimiting input (Kessler et al., 2012; Tran et al., 2013a).

Story	#TL	#atLeastOnce	#atLeastTwice	avgL	maxL	minL	Time Range	#dates
Egypt	4	122	18	36	57	24	2011/01/01 - 2013/07/07	918
Libya	7	118	56	34	62	22	2011/02/14 - 2011/11/22	281
Syria	5	106	17	60	26	13	2011/03/15 - 2013/07/06	844
Yemen	5	81	26	24	42	10	2011/01/22 - 2012/02/27	401

Number of timelines (#TL), number of dates occurring in at least one timeline (#atLeastOnce), number of dates that appear in at least 2 timelines, average (avgL), max (maxL) and min (minL) length of timelines; the Time Range of the union of timelines and all potential dates (#dates) within the time range.

Table 2: Overview of groundtruth timelines

often receive more attention from writers, leading to longer articles.

Date Frequency ranks a date d by the total number of sentences referring to d that are not published on d. This is a simple measure of d's influence without joint scoring of dates or integration of temporal distance or topic.

Competitors. We reimplement *Kessler et al. (2012)*'s model. It first detects all sentences with date references and filters out certain types of sentences according to linguistic features (such as presence of modality as this can put the factuality of the event into question). Then, the importance score of a date is determined by the product of the Lucene score of referring sentences and an ML-predicted score that takes into account date reference frequencies, temporal distance of date references and topical importance of referring sentences. To use the same setting as for our systems, we use the list of keywords extracted by TextRank (Mihalcea and Tarau, 2004) to formulate a topic query for the Lucene index.

We reimplement *Tran et al. (2013a)* who use a supervised ML approach based on a more detailed consideration of date reference frequencies.

Both *Kessler et al. (2012)* and *Tran et al. (2013a)* are retrained and tested via 4-fold cross-validation on events. In addition, we noted that the two supervised systems could profit from the fact that for certain dates in $\mathcal{TR}_e$ no published news articles exist in the news collection and that they are therefore a priori unlikely to be relevant. We therefore also run those systems with a stricter input time range, which intersects $\mathcal{TR}_e$ with the dates that are the publication date of at least one article in the news collection. We indicate these systems as *Kessler et al. (2012) (Pub)* and *Tran et al. (2013a) (Pub)*.

Our Approach. Our system builds graphs with all dates referenced in the news corpus for an event as nodes. We select the top k highest ranked nodes that also fall within $\mathcal{TR}_e$. We measure the performance with different strategies for the *Influence* factor $\mathcal{I}$. We use the following five unsupervised strategies, where we just set the damping factor α to 0.85 as suggested by Page et al. (1999).[8]

IRW_{freq} only uses the frequency aspect. This corresponds to a joint modelling version of the *Date Frequency* baseline.

$IRW_{\max topical}$ uses topical influence, disregarding frequency aspect in its computation.

$IRW_{freq*topical}$ uses topical influence, incorporating the frequency aspect in its computation.

$IRW_{|temporal|}$ uses temporal influence, disregarding the frequency aspect.

$IRW_{freq*temporal}$ uses temporal influence incorporating the frequency aspect.

Furthermore, we are interested in combining topical and temporal influence (with or without frequency aspects). Here, our model is parameterized by ω which controls the impact of *topical influence* vs. *temporal influence*. This parameter is tuned on the training set via 4-fold cross-validation and, therefore, the next two models have a small element of supervision.

$IRW_{\max topical+freq*temporal}$ combines topical and temporal influence, integrating the frequency aspect into temporal influence.

$IRW_{freq*topical+|temporal|}$ combines topical and temporal influence, integrating the frequency aspect into topical influence.

4.4 Analysis of date reference graphs

Table 4 shows an analysis of the four date reference graphs. In this Table, #sent provides the total number of sentences from all news articles while #hasRef shows the number of sentences that refer to a date (around 15%), suggesting a sustainable part of data can be helpful for the interaction-based approach. The number of nodes shows the unique dates that are involved in a date reference link. The number of edges is equivalent to the number of date reference links (d_i, d_j) that indicate that there exist sentences published on d_i but referring to d_j. *toStrict* and *toRelaxed* is the

[8] We could make these models supervised by tuning the damping factor via cross-validation. However, we found it encouraging that we were able to achieve competitive results without tuning — similar to links between web pages in the traditional PageRank algorithm, links between dates seem to embody strong relations, making the same damping factor suitable.

	#sent	#hasRef(%)	#nodes	#Edges	toStrict	reachStrict	toRelaxed	reachRelaxed
Egypt	143,096	26,428 (18.5)	939	2784	15.55%	100.00%	35.99%	89.34%
Libya	140,753	22,166 (15.7)	971	1797	33.78%	98.21%	56.98%	99.15%
Syria	162,305	26,992 (16.6)	812	1555	7.14%	88.24%	31.00%	73.58%
Yemen	140,156	21,606 (15.4)	1106	1608	18.28%	100.00%	37.00%	100.00%

Table 4: Interaction-based analysis on experimental news collections

proportion of the edges that link to groundtruth dates in the *strict setting* and *relaxed setting*. Those edges cover almost all the groundtruth dates (i.e, *reachStrict* and *reachRelaxed*), i.e almost all groundtruth dates are indeed referenced at least once in our corpus.

4.5 Results

Table 5 shows the average performance of different systems over our four events. Several general observations stand out. First, we notice that the scores wrt. *relaxed setting* of all systems are higher than those wrt. *strict setting*. That is expected, as in *relaxed setting*, a selected date has a higher likelihood to be one of the milestones in the timeline of at least one expert. Second, simple baselines such as *Document Frequency* and *MaxLength* perform reasonably well in the relaxed-setting. That confirms our assumptions that important dates often possess more published news articles and are likely to have at least one article of substantial length. However, these baselines are not enough to distinguish highly important dates (which are selected by more than one journalist) as shown by their performance in the *strict setting* (around 0.3 MAP@k only).

Using *Date Frequency* leads to a substantial performance improvement in the strict setting comapred to the publication-based baselines. Therefore, highly important dates are more likely to be kept mentioning in the future and that supports our research direction to better leverage date interaction for ranking date importance. This is further confirmed by the performance of the IRW_{freq} system which is the joint modelling version of the *DateFrequency* baseline and outperfoms the baseline without inclusion of any further information such as topical salience. It can even compete with prior supervised competitors when their input time range is not modified.

Our supervised competitors (Kessler et al., 2012; Tran et al., 2013a) perform overall well and both profit from modifying their input time range as suggested in the *Pub* versions. However, the unsupervised versions of our system $IRW_{\max topical}$ and $IRW_{freq*topical}$ perform very comparably to the supervised competitors in the strict and relaxed setting, respectively.

The last two lines of Table 5 show the results of our proposed method when using a linear combination of the different influence factors, and the hyperparameter ω having been tuned on the training set. $IRW_{\max topical+freq*temporal}$ shows the result of our system with $\omega = 0.2$ and $IRW_{freq*topical+|temporal|}$ with $\omega = 0.1$ These systems outperform the state-of-the-art systems clearly in the strict setting and for most measures in the relaxed setting.

Stability. We also investigated the stability of the performance of different systems by looking into their results on each event. Table 6 presents the performance of our best system $IRW_{\max topical+freq*temporal}$ and its best supervised competitors Tran et al. (2013a) (Pub) and Kessler et al. (2012) (Pub). All systems perform worse on the Syria story although our dropoff is less than the one of prior systems.

We speculate that the competitor systems are more sensitive to the amount of available published content on a target date than ours. In particular, Tran et al. (2013a) use the frequency of published dates and sentences as one of their features, and Kessler et al. (2012) rely on the returned results from Lucene index which tends towards substories from the publication periods. Different to others, the time range for the *Syria* news collection does not include the time range for the Syria timelines fully or almost fully (see Tables 2 and 3). We therefore are not as dependent on an exact match between timeline dates and news collection dates and can use news articles from later dates more effectively.

5 Conclusion and Future Work

This paper addresses the problem of date selection for timeline summarization. Our approach leverages the interactions between dates via a joint model based on a date reference graph, improving on individual scoring of dates.

We capture the interactions between dates from the number of cross-references between dates, and

System	strict setting				relaxed-setting

their temporal and topical influences. We present a novel random walk model that incorporates these perspectives into connectivity-based computation. Experimental results on four news events that span a long time period show that the proposed models outperform state-of-the art approaches. Even unsupervised versions of the model perform on a par with previous supervised methods. We also draw attention to the necessity to take personal bias into account, which leads to differences between manually created timelines for the same event — we encourage future work to always consider several timelines per event in the way that other NLP work uses several annotators to create ground truth.

In future work, we will consider a wider range of events and event types. This will also lead to considering timelines where the day as unit of granularity might not be appropriate or where the unit of granularity might be varying across the timeline. We will also explore in depth the effect of size and type of news corpus on resulting timelines, research further into the issue of human disagreement in timeline creation and explore human evaluation of timeline summarization.

Predicting Salient Updates for Disaster Summarization

Abstract

During crises such as natural disasters or other human tragedies, information needs of both civilians and responders often require urgent, specialized treatment. Monitoring and summarizing a text stream during such an event remains a difficult problem. We present a system for update summarization which predicts the salience of sentences with respect to an event and then uses these predictions to directly bias a clustering algorithm for sentence selection, increasing the quality of the updates. We use novel, disaster-specific features for salience prediction, including geo-locations and language models representing the language of disaster. Our evaluation on a standard set of retrospective events using ROUGE shows that salience prediction provides a significant improvement over other approaches.

1 Introduction

During crises, information is critical for first responders, crisis management organizations, and those caught in the event. When the event is significant, as in the case of Hurricane Sandy, the amount of content produced by traditional news outlets, government agencies, relief organizations, and social media can vastly overwhelm those trying to monitor the situation. Crisis informatics (Palen et al., 2010) is dedicated to finding methods for sharing the right information in a timely fashion during such an event. Research in this field has focused on human-in-the-loop approaches ranging from on the ground information gathering to crowdsourced reporting and disaster management (Starbird and Palen, 2013).

Multi-document summarization has the potential to assist the crisis informatics community. Automatic summarization could deliver relevant and salient information at regular intervals, even when human volunteers are unable to. Perhaps more importantly it could help filter out unnecessary and irrelevant detail when the volume of incoming information is large. While methods for identifying, tracking, and summarizing events from text based input have been explored extensively (Allan et al., 1998; Filatova and Hatzivassiloglou, 2004; Wang et al., 2011), these experiments were not developed to handle streaming data from a heterogeneous environment at web scale. These methods also rely heavily on redundancy which is suboptimal for time sensitive domains where there is a high cost in delaying information.

In this paper, we present an update summarization system to track events across time. Our system predicts sentence salience in the context of a large-scale event, such as a disaster, and integrates these predictions into a clustering based multi-document summarization system. We demonstrate that combining salience with clustering produces more relevant summaries compared to baselines using clustering or relevance alone. Our experiments suggest that this is because our system is better able to adapt to dynamic changes in input volume that adversely affect methods that use redundancy as a proxy for salience.

In addition to the tight integration between clustering and salience prediction, our approach also exploits knowledge about the event to determine salience. Thus, salience represents both how typical a sentence is of the event type (e.g., industrial accident, hurricane, riot) and whether it specifies information about this particular event. Our feature representation includes a set of language models, one for each event type, to measure the typicality of the sentence with regard to the current event, the distance of mentioned locations from the center of the event, and the change in word frequencies over the time of the event. While we evaluate these features in the domain of disasters,

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1608–1617,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

this approach is generally applicable to many update summarization tasks.

Our approach achieves a statistically significant improvement in ROUGE scores compared to multiple baselines. Additionally, we introduce novel methods for estimating the average information gain each update provides and how completely the update summary covers the event it is tracking; our system's updates contain more relevant information on average than the competing baselines.

The remainder of the paper is organized as follows. We begin with a review of related work in the information retrieval and multi-document summarization literature. Section 3 outlines the details of our salience and summarization models. Next we describe our data (Section 4) and experiments (Section 5). Finally, we discuss our results (Section 6) and conclude the paper.

2 Related Work

A principal concern in extractive multi-document summarization is the selection of salient sentences for inclusion in summary output (Nenkova and McKeown, 2012). Existing approaches generally fall into one of three categories, each with specific trade-offs with respect to update summarization.

First, centrality-focused approaches (including graph (Erkan and Radev, 2004), cluster (Hatzivassiloglou et al., 2001), and centroid (Radev et al., 2004) methods) are very natural for retrospective analysis in the sense that they let the data "speak for itself." These methods equate salience with centrality, either to the input or some other aggregate object (i.e. a cluster center or input centroid). However, they rely chiefly on redundancy. When applied to an unfolding event, there may not exist enough redundant content at the event onset for these methods to exploit. Once the event onset has passed, however, the redundancy reduction of these methods is quite beneficial.

The second category, predictive approaches, includes ranking and classification based methods. Sentences have been ranked by the average word probability, average TF*IDF score, and the number of topically related words (topic-signatures in the summarization literature) (Nenkova and Vanderwende, 2005; Hovy and Lin, 1998; Lin and Hovy, 2000). The first two statistics are easily computable from the input sentences, while the third only requires an additional, generic background corpus. In classification based methods, model features are usually derived from human generated summaries, and are non-lexical in nature (e.g., sentence starting position, number of topic-signatures, number of unique words). Seminal work in this area has employed naïve Bayes and logistic regression classifiers to identify sentences for summary inclusion (Kupiec et al., 1995; Conroy et al., 2001). While these methods are less dependent on redundancy, the expressiveness of their features is limited. Our model expands on these basic features to account for geographic, temporal, and language model features.

The last category includes probabilistic (Haghighi and Vanderwende, 2009), information theoretic, and set cover (Lin and Bilmes, 2011) approaches. While these methods are focused on producing diverse summaries, they are difficult to adapt to the streaming setting, where we do not necessarily have a fixed summary length and the corpus to be summarized contains many irrelevant sentences, i.e. there are large portions of the corpora that we specifically want to avoid.

Several researchers have recognized the importance of summarization during natural disasters. (Guo et al., 2013) developed a system for detecting novel, relevant, and comprehensive sentences immediately after a natural disaster. (Wang and Li, 2010) present a clustering-based approach to efficiently detect important updates during natural disasters. The algorithm works by hierarchically clustering sentences online, allowing the system to output a more expressive narrative structure than (Guo et al., 2013). Our system attempts to unify these system's approaches (predictive ranking and clustering respectively).

3 Method

Our update summarization system takes as input *a*) a short query defining the event to be tracked (e.g. 'Hurricane Sandy'), *b*) an event category defining the type of event to be tracked (e.g. 'hurricane'), *c*) a stream of time-stamped documents presented in temporal order, and *d*) an evaluation time period of interest. While processing documents throughout the time period of interest, the system outputs sentences from these documents likely to be useful to the query issuer. We refer to these selected sentences as *updates*.

In order to measure the usefulness of a system's updates, we consider the degree to which the system output reflects the different aspects of

– hurricane force wind warnings are in effect from Rhode Island Sound to Chincoteague Bay
– over 5000 commercial airline flights scheduled for October 28 and October 29 were cancelled

Figure 1: Example nuggets from Hurricane Sandy.

an event. Events are often composed of a variety of sub-events. For example, the Hurricane Sandy event includes sub-events related to the storm making landfall, the ensuing flooding, the many transportation issues, among many others. An ideal system would update the user about each of these sub-events as they occur. We refer to these sub-events as the *nuggets* associated with an event. A nugget is defined as a fine-grained atomic sub-event associated with an event. We present 2 example nuggets associated with the Hurricane Sandy event in Figure 1. Each event has anywhere from 50 to several hundred nuggets in total in our gold dataset. We describe how these nuggets are found in Section 4.

Throughout our treatment of our algorithm, the *salience* of an update captures the degree to which it reflects an event's unobserved nuggets. Assuming that we have a text representation for each of our nuggets, the salience of an update u with respect to a set of nuggets N is defined as,

$$\mathrm{salience}(u) = \max_{n \in N} \mathrm{sim}(u, n) \qquad (1)$$

where $\mathrm{sim}(\cdot)$ is the semantic similarity such as the cosine similarity of latent vectors associated with the update and nugget text (Guo and Diab, 2012).

3.1 Update Summarization

Our system architecture follows a simple pipeline design where each stage provides an additional level of processing or filtering of the input sentences. We begin with an empty update summary U. At each hour we receive a new batch of sentences b_t from the stream of event relevant documents and perform the following actions:

1. predict the salience of sentences in b_t (Section 3.2),
2. select a set of exemplar sentences in b_t by combining clustering with salience predictions (Section 3.3),
3. add the most novel and salient exemplars to U (Section 3.4).

The resultant list of updates U is our summary of the event.

3.2 Salience Prediction

3.2.1 Features

We want our model to be predictive of sentence salience across different event instances so we avoid event-specific lexical features. Instead, we extract features such as language model scores, geographic relevance, and temporal relevance from each sentence.

Basic Features We employ several basic features that have been used previously in supervised models to rank sentence salience (Kupiec et al., 1995; Conroy et al., 2001). These include sentence length, the number of capitalized words normalized by sentence length, document position, and number of named entities. The data stream comprises text extracted from raw html documents; these features help to downweight sentences that are not content (e.g. web page titles, links to other content) or more heavily weight important sentences (e.g., that appear in prominent positions such as paragraph initial or article initial).

Query Features Query features measure the relationship between the sentence and the event query and type. These include the number of query words present in the sentence in addition to the number of event type synonyms, hypernyms, and hyponyms using WordNet (Miller, 1995). For example, for event type *earthquake*, we match sentence terms “quake”, “temblor”, “seism”, and “aftershock”.

Language Model Features Language models allow us to measure the likelihood of producing a sentence from a particular source. We consider two types of language model features. The first model is estimated from a corpus of generic news articles (we used the 1995-2010 Associated Press section of the Gigaword corpus (Graff and Cieri, 2003)). This model is intended to assess the general writing quality (grammaticality, word usage) of an input sentence and helps our model to select sentences written in the newswire style.

The second model is estimated from text specific to our event types. For each event type we create a corpus of related documents using pages and subcategories listed under a related

Storm	Earthquake	Meteor Impact
Accident	Riot	Protest
Hostages	Shooting	Bombing

Figure 2: TREC TS event types.

Wikipedia category. For example, the language model for event type 'earthquake' is estimated from Wikipedia pages under the category *Category:Earthquakes*. Fig. 2 lists the event types found in our dataset. These models are intended to detect sentences similar to those appearing in summaries of other events in the same category (e.g. most earthquake summaries are likely to include higher probability for ngrams including the token 'magnitude'). While we focus our system on the language of news and disaster, we emphasize that the use of language modeling can be an effective feature for multi-document summarization for other domains that have related text corpora.

We use the SRILM toolkit (Stolcke and others, 2002) to implement a 5-gram Kneser-Ney model for both the background language model and the event specific language models. For each sentence we use the average token log probability under each model as a feature.

Geographic Relevance Features The disasters in our corpus are all phenomena that affect some part of the world. Where possible, we would like to capture a sentence's proximity to the event, i.e. when a sentence references a location, it should be close to the area of the disaster.

There are two challenges to using geographic features. First, we do not know where the event is, and second, most sentences do not contain references to a location. We address the first issue by extracting all locations from documents relevant to the event at the current hour and looking up their latitude and longitude using a publicly available geo-location service. Since the documents that are at least somewhat relevant to the event, we assume in aggregate the locations should give us a rough area of interest. The locations are clustered and we treat the resulting cluster centers as the event locations for the current time.

The second issue arises from the fact that the majority of sentences in our data do not contain explicit references to locations, i.e. a sequence of tokens tagged as location named entities. Our intuition is that geographic relevance is important in the disaster domain, and we would like to take advantage of the sentences that do have location information present. To make up for this imbalance, we instead compute an overall location for the document and derive geographic features based on the document's proximity to the event in question. These features are assigned to all sentences in the document.

Our method of computing document-level geographic relevance features is as follows. Using the locations in each document, we compute the median distance to the nearest event location. Because document position is a good indicator of importance we also compute the distance of the first mentioned location to the nearest event location. All sentences in the document take as features these two distance calculations. Because some events can move, we also compute these distances to event locations from the previous hour.

Temporal Relevance Features As we track events over time, it is likely that the coverage of the event may die down, only to spike back up when there is a breaking development. Identifying terms that are "bursty," i.e. suddenly peaking in usage, can help to locate novel sentences that are part of the most recent reportage and have yet to fall into the background.

We compute the IDF for each hour in our data stream. For each sentence, the average TF*IDF for the current hour t is taken as a feature. Additionally, we use the difference in average TF*IDF from time t to $t - i$ for $i = \{1, \ldots, 24\}$ to measure how the TF*IDF scores for the sentence have changed over the last 24 hours, i.e. we keep the sentence term frequencies fixed and compute the difference in IDF. Large changes in IDF value indicate the sentence contains bursty terms. We also use the time (in hours) since the event started as a feature.

3.2.2 Model

Given our feature representation of the input sentences, we need only target salience values for model learning. For each event in our training data, we sample a set of sentences and each sentence's salience is computed according to Equation 1. This results in a training set of sentences, their feature representations, and their target salience values to predict.

We opt to use a Gaussian process (GP) regression model (Rasmussen and Williams, 2006) with a Radial Basis Function (RBF) kernel for the salience prediction task. Our features fall naturally into five groups and we use a separate RBF kernel for each, using the sum of each feature group RBF kernel as the final input to the GP model.

3.3 Exemplar Selection

Once we have predicted the salience for a batch of sentences, we must now select a set of update candidates, i.e. sentences that are both salient and representative of the current batch. To accomplish this, we combine the output of our salience prediction model with the affinity propagation algorithm. Affinity propagation (AP) is a clustering algorithm that identifies a subset of data points as exemplars and forms clusters by assigning the remaining points to one of the exemplars (Frey and Dueck, 2007). AP attempts to maximize the net similarity objective

$$\mathcal{S} = \sum_{i:i \neq e_i}^{n} \mathrm{sim}(i, e_i) + \sum_{i:i = e_i}^{n} \mathrm{salience}(e_i)$$

where e_i is the exemplar of the i-th data point, and functions sim and $\mathrm{salience}$ express the pairwise similarity of data points and our predicted *apriori* preference of a data point to be an exemplar respectively. AP differs from other k-centers algorithms in that it simultaneously considers all data points as exemplars, making it less prone to finding local optima as a result of poor initialization. Furthermore, the second term in $\mathcal{S}$ incorporates the individual importance of data points as candidate exemplars; most other clustering algorithms only make use of the first term, i.e. the pairwise similarities between data points.

AP has several useful properties and interpretations. Chiefly, the number of clusters k is not a model hyper-parameter. Given that our task requires clustering many batches of streaming data, searching for an optimal k would be computationally prohibitive. With AP, k is determined by the similarities and preferences of the data. Generally lower preferences will result in fewer clusters.

Recall that $\mathrm{salience}(s)$ is a prediction of the semantic similarity of s to information about the event be summarized, i.e. the set of event nuggets. Intuitively, when maximizing objective function $\mathcal{S}$, AP must balance between best representing the input data and representing the most salient input. Additionally, when the level of input is high but the salience predictions are low, the preference term will guide AP toward a solution with fewer clusters; *vice-versa* when input is very salient on average but the volume of input is low. The adaptive nature of our model differentiates our method from most other update summarization systems.

3.4 Update Selection

The exemplar sentences from the exemplar selection stage are the most salient and representative of the input for the current hour. However, we need to reconcile these sentences with updates from the previous hour to ensure that the most salient and least redundant updates are selected. To ensure that only the most salient updates are selected we apply a minimum salience threshold; after exemplar sentences have been identified, any exemplars whose salience is less than λ_{sal} are removed from consideration.

Next, to prevent adding updates that are redundant with previous output updates, we filter out exemplars that are too similar to previous updates. The exemplars are examined sequentially in order of decreasing salience and a similarity threshold is applied, where the exemplar is ignored if its maximum semantic similarity to any previous updates in the summary is greater than λ_{sim}.

Exemplars that pass these thresholds are selected as updates and added to the summary.

4 Data

For the document stream, we use the news portion of the 2014 TREC KBA Stream Corpus (Frank et al., 2012). The documents from this corpus come from hourly crawls of the web covering October 2011 through February 2013.

Our experiments also make use of the TREC Temporal Summarization (TS) Track data from 2013 and 2014 (Aslam et al., 2013). This data includes 25 events and event metadata (e.g., a user search query for the event, the event type, and event evaluation time frame). All events occurred during the time span of the TREC KBA Stream Corpus. For each event we create a stream of relevant documents by selecting only documents that contain the complete set of query words.

Along with the metadata, NIST assessors constructed a set of ground truth nuggets for each event. Nuggets are brief and important text snippets that represent sub-events that should be conveyed by an ideal update summary. In order to accomplish this, for each event, assessors were provided with the revision history of the Wikipedia page associated with the event. For example, the revision history for the Wikipedia page for 'Hurricane Sandy' will contain text additions including those related to individual nuggets. The assessment task involves reviewing the Wikipedia revisions in the evaluation time frame and marking the text additions capturing a new, unique nugget. More detail on this process can be found in the track description (Aslam et al., 2013).

5 Experiments

We evaluate our system on two metrics: ROUGE (Lin, 2004), an automatic summarization method and an evaluation of system expected gain and comprehensiveness—metrics adapted from the TREC TS track (Aslam et al., 2013).

5.1 Training and Testing

Of the 25 events in the TREC TS data, 24 are covered by the news portion of the TREC KBA Stream Corpus. From these 24, we set aside three events to use as a development set. All system salience and similarity threshold parameters are tuned on the development set to maximize ROUGE-2 F1 scores.

We train a salience model for each event using 1000 sentences randomly sampled from the event's document stream.

We perform a leave-one-out evaluation of each event. At test time, we predict a sentence's salience using the average predictions of the 23 other models.

5.2 ROUGE Evaluation

ROUGE measures the ngram overlap between a model summary and an automatically generated system summary. Model summaries for each event were constructed by concatenating the event's nuggets. Generally, ROUGE evaluation assumes both model and system summaries are of a bounded length. Since our systems are summarizing events over a span of two weeks time, the total length of our system output is much longer than the model. To address this, for each system/event pair, we sample with replacement 1000 random summaries of length less than or equal to the model summary (truncating the last sentence when neccessary). The final ROUGE scores for the system are the average scores from these 1000 samples.

Because we are interested in system performance over time, we also evaluate systems at 12 hour intervals using the same regime as above. The model summaries in this case are retrospective, and this evaluation reveals how quickly systems can cover information in the model.

5.3 Expected Gain and Comprehensiveness

NIST developed metrics for evaluating update summarization systems as part of the TREC TS track. We present results on two of these metrics, the expected gain and comprehensiveness.

Expected Gain We treat the event's nuggets as unique units of information. When a system adds an update to its summary, it is potentially adding some of this nugget information. It would be instructive to know how much unique and novel information each update is adding on average to the summary. To that end, we define

$$\mathbb{E}[\text{Gain}] = \frac{|S_n|}{|S|}$$

where S is the set of system updates, S_n is the set of nuggets contained in S, and $|\cdot|$ is the number of elements in the set. To compute the set S_n we match each system update to 0 or more nuggets, where an update matches a nugget if their semantic similarity is above a threshold. S_n results from the unique set of nuggets matched. Because an update can map to more than one nugget, it is possible to receive an expected gain greater than 1. An expected gain of 1 would indicate that every sentence was both relevant and contained a unique piece of information.

Comprehensiveness Additionally, we can use the nuggets to measure the completeness of an update summary. We define

$$\text{Comprehensiveness} = \frac{|S_n|}{|N|}$$

where N is the set of event nuggets. A comprehensiveness of 1 indicates that the summary has covered all nugget information for the event; the maximum attainable comprehensiveness is 1.

Update-nugget matches are computed automatically; a match exists if the semantic similarity of the update/nugget pair is above a threshold. Determining an optimal threshold to count matches is difficult so we evaluate at threshold values ranging from .5 to 1, where values closer to 1 are more conservative estimates of performance. A manual inspection of matches suggests that semantic similarity values around .7 produce reasonable matches. The average semantic similarity of manual matches performed by NIST assessors was much lower at approximately .25, increasing our confidence in the automatic matches in the .5–1 range.

5.4 Model Comparisons

We refer to our complete model as AP+SALIENCE. We compare this model against several variants and baselines intended to measure the contribution of different components. All thresholds for all runs are tuned on the development set.

Affinity Propagation only (AP) The purpose of this model is to directly measure the effect of integrating salience and clustering by providing a baseline that uses the identical clustering component, but without the salience information. In this model, input sentences are *apriori* equally likely to be exemplars; the salience values are uniformly set as the median value of the input similarity scores, as is commonly used in the AP literature (Frey and Dueck, 2007). After clustering a sentence batch, the exemplars are examined in order of increasing time since event start and selected as updates if their maximum similarity to the previous updates is less than λ_{sim}, as in the novelty filtering stage of AP+SALIENCE.

Hierarchichal Agglomerative Clustering (HAC) We provide another clustering baseline, single-linkage hierarchichal agglomerative clustering. We include this baseline to show that AP+SALIENCE is not just an improvement over AP but centrality driven methods in general. HAC was chosen over other clustering approaches because the number of clusters is not an explicit hyper-parameter. To produce flat clusters from the hierarchical clustering, we flatten the HAC dendrogram using the cophenetic distance criteria, i.e. observations in each flat cluster have no greater a cophenetic distance than a threshold. Cluster centers are determined to be the sentence with highest cosine similariy to the flat cluster mean. Cluster centers are examined in time order and are added to the summary if their similarity to previous updates is below a similarity threshold λ_{sim} as is done in the AP model.

Rank by Salience (RS) We also isolate the impact of our salience model in order to demonstrate that the fusion of clustering and salience prediction improves over predicting salience alone. In this model we predict the salience of sentences as in step 1 for AP+SALIENCE. We omit the clustering phase (step 2). Updates are selected identically to step 3 of AP+SALIENCE, proceeding in order of decreasing salience, selecting updates that are above a salience threshold λ_{sal} and below a similarity threshold λ_{sim} with respect to the previously selected updates.

6 Results

6.1 ROUGE

ROUGE-1

System	Recall	Prec.	F_1
AP+SALIENCE	**0.282**	**0.344**	**0.306**
AP	0.245	0.285	0.263
RS	0.230	0.271	0.247
HAC	0.169	0.230	0.186

ROUGE-2

System	Recall	Prec.	F_1
AP+SALIENCE	**0.045**	**0.056**	**0.049**
AP	0.033	0.038	0.035
RS	0.031	0.037	0.034
HAC	0.017	0.024	0.019

Table 1: System ROUGE performance.

Table 1 shows our results for system output samples against the full summary of nuggets using ROUGE. This improvement is statistically significant for all ngram precision, recall, and F-measures at the $\alpha = .01$ level using the Wilcoxon signed-rank test.

AP+SALIENCE maintains its performance above the baselines over time as well. Figure 3 shows the ROUGE-1 scores over time. We show the difference in unigram precision (bigram precision is not shown but it follows similar curve). Within the initial days of the event, AP+SALIENCE is able to take the lead over the over systems in ngram precision. The AP+SALIENCE model is better able to find salient updates earlier on; for the disaster domain, this is an especially important quality of the model.

Moreover, the AP+SALIENCE's recall is not diminished by the high precision and remains competitive with AP. Over time AP+SALIENCE's recall also begins to pull away, while the other models start to suffer from topic drift.

6.2 Expected Gain and Comprehensiveness

Figure 4 shows the expected gain across a range of similarity thresholds, where thresholds closer

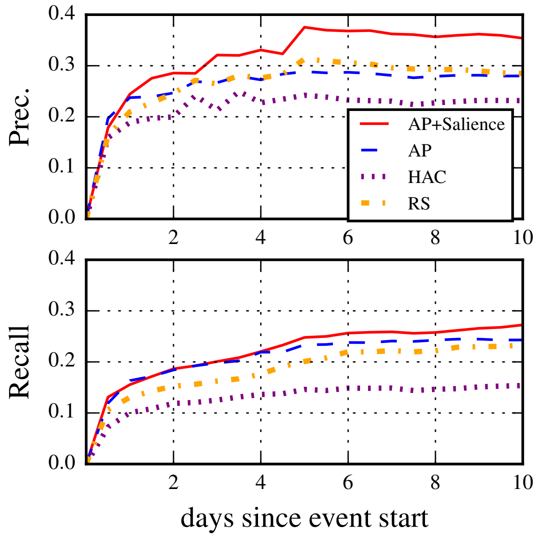

Figure 3: System ROUGE-1 performance over time.

to 1 are more conservative estimates. The ranking of the systems remains constant across the sweep with AP+SALIENCE beating all baseline systems. Predicting salience in general is helpful for keeping a summary on topic as the RS approach out performs the clustering only approaches on expected gain.

When looking at the comprehensiveness of the summaries AP outperforms AP+SALIENCE. The compromise encoded in the AP+SALIENCE objective function, between being representative and being salient, is seen clearly here where the performance of the AP+SALIENCE methods is lower bounded by the salience focused RS system and upper bounded by the clustering only AP system. Overall, AP+SALIENCE achieves the best balance of these two metrics.

6.3 Feature Ablation

Table 2 shows the results of our feature ablation tests. Removing the language models yields a statistically significant drop in both ngram recall and F-measure. Interestingly, removing the basic features leads to an increase in both unigram and bigram precision; in the bigram case this is enough to cause a statistically significant increase in F-measure over the full model. In other words, the generic features actually lead to an inferior model when we can incorporate more appropriate domain specific features. The result mirrors Sparck Jones' claim that generic approaches to summarization cannot produce a useful summary (Sparck-Jones, 1998).

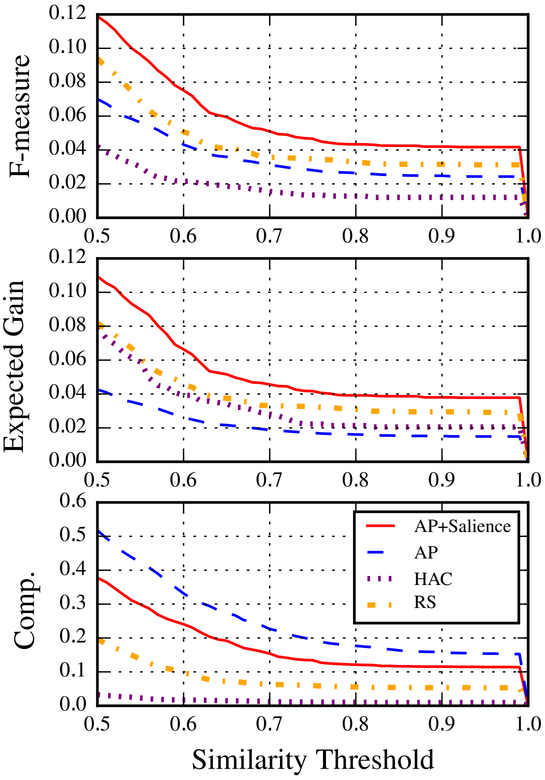

Figure 4: Expected Gain and Comprehensiveness performance.

Removing the language model and geographic relevance features leads to a statistically significant drop in ROUGE-1 F1 scores. Unfortunately, this is not the case for the temporal relevance features. We surmise that these features are too strongly correlated with each other, i.e. the differences in TF*IDF between hours are definitely not i.i.d. variables.

7 Conclusion

In this paper, we have presented an update summarization system for the disaster domain, and demonstrated improved system performance by integrating sentence salience with clustering.

We also have shown that features specifically targeted to the domain of disaster yield better summaries. We developed novel features that capture the language typical of different event types and that identify sentences specific to the particular disaster based on location.

In the future we would like to explore the appli-

2012 Pakistan Garment Factory Fires

- The fire broke out when people in the building were trying to start their generator after the electricity went out.
- Pakistani television showed pictures of what appeared to be a three-story building with flames leaping from the top-floor windows and smoke billowing into the night sky.
- The people went to the back side of the building but there was no access, so we had to made forceful entries and rescue the people, said Numan Noor, a firefighter on the scene.
- “We have recovered 63 bodies, including three found when we reached the basement of the building,” Karachi fire chief Ehtesham Salim told AFP on Wednesday.

2012 Romanian Protests

- Clashes between riot police and demonstrators have also erupted in the Romanian capital Bucharest for a third day in a row.
- BOC urged Romanians to understand that tough austerity measures are needed to avoid a default.
- More than 1,000 protesters rallied in Bucharest’s main university square, blocking traffic.
- Bucharest : a Romanian medical official says 59 people suffered injuries as days of protests against the government and austerity measures turned violent.

Unsupervised Prediction of Acceptability Judgements

Jey Han Lau, Alexander Clark, and Shalom Lappin
jeyhan.lau@gmail.com, alexsclark@gmail.com, shalom.lappin@kcl.ac.uk
King's College London

Abstract

In this paper we present the task of unsupervised prediction of speakers' acceptability judgements. We use a test set generated from the British National Corpus (BNC) containing both grammatical sentences and sentences containing a variety of syntactic infelicities introduced by round trip machine translation. This set was annotated for acceptability judgements through crowd sourcing. We trained a variety of unsupervised language models on the original BNC, and tested them to see the extent to which they could predict mean speakers' judgements on the test set. To map probability to acceptability, we experimented with several normalisation functions to neutralise the effects of sentence length and word frequencies. We found encouraging results with the unsupervised models predicting acceptability across two different datasets. Our methodology is highly portable to other domains and languages, and the approach has potential implications for the representation and the acquisition of linguistic knowledge.

1 Introduction

Language modelling involves predicting the probability of a sentence. Given a trained model, we can infer the quantitative likelihood that a sentence occurs. Acceptability, on the other hand, indicates the extent to which a sentence is permissible or acceptable to native speakers of the language. While acceptability is affected by frequency and exhibits gradience (Keller, 2001; Sprouse, 2007; Lau et al., 2014), there is limited research on the relationship between acceptability and probability. In this paper, we consider the the task of unsupervised prediction of acceptability.

Speakers have robust intuitions about acceptability, and acceptability has been consistently rated on various scales (Sprouse and Almeida, 2012). The acceptability of a sentence appears to be relatively unaffected by its length (within certain bounds), or the frequency of its words, properties that we have confirmed experimentally. By contrast sentence probability does depend on these factors. To filter the effects of sentence length and word frequency, we devise normalising functions to map the probability of a sentence (inferred by our unsupervised language models) to an acceptability score.

Keller (2001) and Lau et al. (2014) present evidence that acceptability exhibits gradience. Accordingly, we treat acceptability as a continuous variable here. We train a variety of unsupervised models for the acceptability prediction task, and we assess the performance of these models by measuring the correlation between their normalised acceptability scores and the mean crowd-sourced acceptability judgements on a set of test sentences.

There are a number of NLP tasks to which our work can be fruitfully applied. It can be used to evaluate the fluency of the output for machine translation and other language generation systems. It could also contribute to automatic essay scoring, and to second language tutorial systems.

There are several reasons to favour unsupervised models. From an engineering perspective, unsupervised models offer greater portability to other domains and languages. Our methodology takes only unannotated text as input. Extending

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1618–1628,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

our methodology to other domains/languages is therefore straightforward, as it requires only a raw training corpus in that domain/language.

Our work may also have significant implications for the cognitive foundations of the representation and acquisition of linguistic knowledge. The unannotated training corpora of our language models are impoverished input in comparison to the data available to humans language learners, who learn from a variety of data sources (visual and auditory cues, interaction with adults and peers in a non-linguistic environment, etc). If an unsupervised language model can reliably predict human acceptability judgements, then it provides a benchmark of what humans could, in principle, achieve with the same learning algorithm.

Success in this task raises interesting questions about the nature of grammatical knowledge. If acceptability judgments can be accurately modeled through these techniques, then it seems unnecessary to posit an underlying binary model of syntax which enumerates all and only the set of well-formed sentences. Instead it is reasonable to suggest that humans represent linguistic knowledge as a probabilistic, rather than as a binary system. Probability distributions provide a natural explanation of the gradience that characterises acceptability judgements. Gradience is intrinsic to probability distributions, and to the acceptability scores that we derive from these distributions.

While our results raise important questions concerning the nature of syntactic representation and of language acquisition, we leave them open for further research. We refrain from making strong claims on cognitive issues here. Clearly additional psychological evidence is required to motivate substantive conclusions on these issues, even if our results suggest them.

Our focus in this paper is on the task of predicting speakers' acceptability judgements through unsupervised language models. We take this to be a problem in natural language processing, whose solution has useful applications in language technology. All models described in this paper are implemented in an open source toolkit.[1]

We describe our dataset in Section 2, which consists of crowd sourced acceptability judgments applied to sentences with errors introduced through round trip machine translation. We describe the models and their results in Section 3. In Section 4 we present results with a different corpus based on English Wikipedia. The new dataset shows that our observations generalise to another domain. We compare our methodology to a supervised system in the acceptability prediction task in Section 5. We look more closely at the influence of sentence length and lexical frequency in Section 6, and we show that the normalising functions succeed in neutralising these effects. Finally, we discuss the implications of our results, and draw conclusions from them in Section 7 and Section 8.

2 Dataset and Methodology

For our experiments, we require a collection of sentences that exhibit varying degrees of grammatical well-formedness. We use the dataset that we discuss in Lau et al. (2014). We translated British National Corpus (BNC Consortium, 2007) English sentences to four other languages – Norwegian, Spanish, Japanese and Chinese – and then back to English using Google Translate. To collect human judgements of acceptability for the sentences, we used Amazon Mechanical Turk. A total of 2,500 sentences were annotated.

Three modes of presentation were used for rating a sentence: (1) binary with two options (unnatural vs. natural); (2) four options (extremely unnatural, somewhat unnatural, somewhat natural and extremely natural); and (3) a sliding scale with two extremes (extremely unnatural and extremely natural). To aggregate the ratings over multiple speakers for each sentence, we computed the arithmetic mean. As there is a high correlation of mean ratings among different modes of presentation, we take the judgements for the four-option mode of presentation as the gold-standard for our experiments.

To predict the ratings of the 2,500 test sentences, we trained several probabilistic models on the BNC, and then used the trained models to infer the probabilities of the test sentences. Models are trained on the written portion of the BNC, which has approximately 100 million words (henceforth referred to as BNC-100M).[2] We used only the words, and no forms of annotation information in the BNC, as input to training.

We first experiment with simple lexical N-gram models, and then move to Bayesian and neural

[1] This toolkit can be accessed at `https://github.com/jhlau/acceptability_prediction`.

[2] We removed sentences with less than 8 words, as well as the 2,500 test sentences, from the training data.

network models, increasing the complexity of the models to better capture word dependencies.

To translate probability into acceptability scores, we compute several *acceptability measures* extracted from the model parameters. The acceptability measures are variants of the sentence's log probability, devised to normalise sentence length and low frequency words. These measures are summarised in Table 1. For each measure (including *LogProb* as a baseline) we compute its Pearson correlation coefficient with the gold standard sentence mean rating to evaluate its effectiveness in predicting acceptability.

We tokenised the training data (BNC-100M) and the test sentences using OpenNLP, and we converted all words to lower case. To address out of vocabulary (OOV) words that are seen in the test sentences but not in the training data, we adopt the Berkeley Parser approach, where we replace low frequency or OOV words using the *UNK* signature. We capture additional surface characteristics of the original word by attaching features at the end of the signature (e.g. the OOV word *1949* would be replaced by the signature *UNK-NUM*).[3]

Acc. Measure	Equation
LogProb	$\log P_m(\xi)$
Mean LP	$\frac{\log P_m(\xi)}{\lvert\xi\rvert}$
Norm LP (Div)	$-\frac{\log P_m(\xi)}{\log P_u(\xi)}$
Norm LP (Sub)	$\log P_m(\xi) - \log P_u(\xi)$
SLOR	$\frac{\log P_m(\xi) - \log P_u(\xi)}{\lvert\xi\rvert}$

Table 1: Acceptability measures for predicting the acceptability of a sentence. Notations: *SLOR* is the syntactic log-odds ratio, introduced by Pauls and Klein (2012); ξ is the sentence ($|\xi|$ is the sentence length); $P_m(\xi)$ is the probability of the sentence given by the model; $P_u(\xi)$ is the unigram probability of the sentence. Note that the negative sign in *Norm LP (Div)* is given to reverse the sign change introduced by the division of log unigram probabilities.

3 Unsupervised Models

3.1 Lexical N-gram Model

Lexical N-gram models were variously explored in tasks related to acceptability estimation (Heilman et al., 2014; Clark et al., 2013; Pauls and Klein, 2012). We use an N-gram model with Kneser-Ney interpolation (Goodman, 2001), and we train bigram, trigram, and 4-gram models on BNC-100M. The trained models are then used to compute the acceptability measures of the test sentences.

The results are detailed in Table 2 (columns: "2-gram", "3-gram" and "4-gram").[4] In general across all models, the *Norm LP (Div)* and *SLOR* measures consistently produce the best correlations.

We see a significant improvement when the context window is increased from 2-gram to 3-gram, but not so from 3-gram to 4-gram (2-gram best: 0.34; 3-gram best: 0.42; 4-gram best: 0.42). This result implies that increasing the context window of the lexical N-gram model does not correspond to a better representation of grammatical structure (insofar as the size of the dataset is fixed), and a more sophisticated model is necessary.

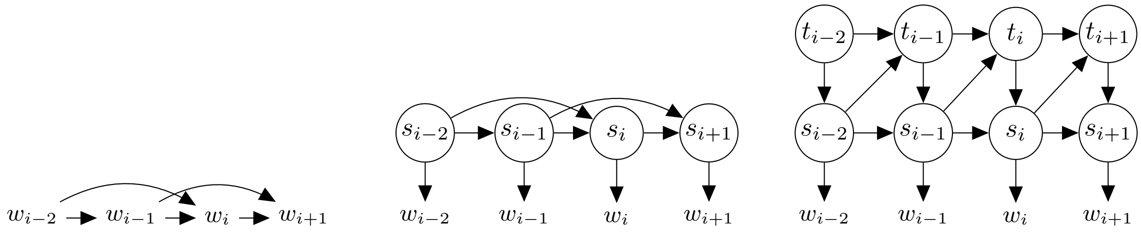
3.2 Bayesian HMM

Seeing that local context is insufficient for predicting acceptability, we explore various Bayesian models that incorporate richer latent structures. We chose a Bayesian implementation because its "rich gets richer" dynamics tends to work well for languages (Goldwater and Griffiths, 2007; Goldwater et al., 2009; Newman et al., 2012; Lau et al., 2012).

Lexical N-grams model the generation of a word based on its preceding words. We introduce a layer of latent variables on top of the words, which can be interpreted as the word classes, and we model the transitions between the latent variables and observed words using Markov processes. In this model we first generate a (latent) word class based on its preceding word classes, and we then generate the word based on its word class. Figure 1(b) illustrates the structure of a second order Hidden Markov model (HMM).

[3] Low frequency words are defined as words occurring less than 4 times in the BNC training data. A total of 15 features are used for the *UNK* signature.

[4] We do not present model perplexity values in the results, as we did not find any correlation between perplexity and task performance.



(a) Lexical 3-gram

(b) Bayesian HMM (2nd Order)

(c) Two-Tier BHMM

Figure 1: A comparison of word structures for 3-gram, BHMM and Two-Tier BHMM. w = observed words; s = tier-1 latent states ("word classes"); t = tier-2 latent states ("phrase classes").

For comparison, the structure of a lexical 3-gram model is given in Figure 1(a).

Goldwater and Griffiths (2007) propose a Bayesian approach for learning the HMM structure. The authors found that their Bayesian HMM (BHMM) significantly outperforms a HMM trained with Maximum Likelihood Estimation in unsupervised part-of-speech tagging. We adopt the methodology of Goldwater and Griffiths (2007), and train a 2nd order BHMM for our task, using collapsed Gibbs sampling for inference. BHMM has two sets of multinomials: the state transition multinomials and the word emission multinomials. To generalise the state transition probabilities for start probabilities, we use dummy words/states for empty preceding words/states.

BHMM has 3 parameters: (1) S, the number of latent states; (2) γ, the Dirichlet hyper-parameter for the state transition multinomials; and (3) δ, the Dirichlet hyper-parameter for the word emission multinomials. We assume symmetric Dirichlet priors for the hyper-parameters, and optimise the 3 parameters based on test perplexity using a greedy search approach, i.e. we optimise locally for one parameter at each stage, while keeping the default or previously optimised values for other parameters.[5] For the optimisation step models are trained using 10% of the full BNC (BNC-10M) for 2,000 iterations.[6]

Using the optimised parameters, we train BHMM on BNC-100M for 10,000 iterations. For test inference, we run the Gibbs sampler using the trained model for 5,000 iterations, and take 50 samples from the final 500 iterations (with a lag of 10 iterations). In each of the samples, we compute the test probabilities and acceptability measures using the MAP estimated states.[7] The final probabilities are computed as a harmonic mean of probabilities over the 50 samples.

We summarise the correlation results in Table 2 (column: "BHMM"). Compared to the N-gram models, we see an improvement in the correlation, indicating that the introduction of a layer of (latent) word classes produces a better structure for modelling acceptability.

3.3 LDAHMM and LDA

To better understand the role of semantics in acceptability, we experimented with LDAHMM (Griffiths et al., 2004), a model that combines syntactic and semantic dependencies between words.

The generative method of LDAHMM to generate a word in a document is to first decide whether to generate a syntactic state or a semantic state for the word. For the former, follow the HMM process to generate a state, and generate the word based on the chosen state. For the latter, follow the LDA (Blei et al., 2003) process to generate a topic based on the document's topic mixture, and generate the word based on the chosen topic.

We use a second order HMM for the HMM part and Collapsed Gibbs sampling for performing inference. LDAHMM has 4 sets of multinomials: the HMM multinomials (state transition and word emission) and the LDA multinomials (document-topic and topic-word).

LDAHMM has 6 parameters to optimise: (1) K the number of topics; (2) S the number of syntactic states (semantic state has only 1 state, designated as state 0); (3) α, the Dirichlet hyper-parameter for document-topic multinomials; (4) β, the Dirichlet hyper-parameter for topic-word multinomials; (5) γ, the Dirichlet hyper-

[5] When optimising for a parameter, we experimented with 4–6 values of various orders of magnitudes.

[6] The optimised parameters are: $S = 100$, $\gamma = 1.0$ and $\delta = 0.01$.

[7] As computing full probabilities gave little difference in the final outcome, we adopted the computationally more efficient MAP approach.

Measure	2-gram	3-gram	4-gram	BHMM	LDA	LDAHMM	2T	Chunker	RNNLM	PCFG*

parameter for state transition multinomials; and (6) δ, the Dirichlet hyper-parameter for word emission multinomials. We follow the same approach as with BHMM for optimising, training, and testing the model.[8] Note that as LDAHMM operates with documents, the training data is partitioned into documents, and each test sentence is treated as a document.

The results are summarised in Table 2 (column: "LDAHMM"). The result shows that LDAHMM underperforms in comparison to BHMM, indicating that the incorporation of LDA did not improve the model. To understand the impact of LDA alone, we repeat the experiments using LDA and find that it performs very poorly. Results are summarised in Table 2 (column: LDA). We suspect that the low performance of LDA and LDAHMM is due to the small context window of the test documents. The LDA part is unable to generate any meaningful topic mixtures, as there is insufficient context.

3.4 Two-Tier BHMM

BHMM uses (latent) word classes to drive word generation. Exploring a richer structure, we introduce another layer of latent variables on top of the word classes. This second layer can be interpreted as phrase classes. The idea behind this model is to use these phrase classes to drive word class and word generation. An illustration of its word structure is given in Figure 1(c).

We use collapsed Gibbs sampling for performing inference. We sample the tier-1 state s and tier-2 state t separately, and the sampling equations are given as follows:

$$P(t_i|\mathbf{t_{-i}}, \mathbf{s}, \mathbf{w}, \alpha, \gamma, \delta) \propto \frac{\#(t_{i-1}, s_{i-1}, t_i) + \alpha}{\#(t_{i-1}, s_{i-1}) + T\alpha} \times \frac{\#(t_i, s_{i-1}, s_i) + \gamma}{\#(t_i, s_{i-1}) + S\gamma} \times \frac{\#(t_i, s_i, t_{i+1}) + \alpha}{\#(t_i, s_i) + T\alpha};$$

$$P(s_i|\mathbf{s_{-i}}, \mathbf{t}, \mathbf{w}, \alpha, \gamma, \delta) \propto \frac{\#(t_i, s_{i-1}, s_i) + \gamma}{\#(t_i, s_{i-1}) + S\gamma} \times \frac{\#(t_i, s_i, t_{i+1}) + \alpha}{\#(t_i, s_i) + T\alpha} \times \frac{\#(t_{i+1}, s_i, s_{i+1}) + \gamma}{\#(t_{i+1}, s_i) + S\gamma} \times \frac{\#(s_i, w_i) + \delta}{\#(s_i) + W\delta}$$

where s_i, t_i are the tier-1 and tier-2 state indices; $\mathbf{s}$, $\mathbf{t}$, $\mathbf{w}$ are the assignments for all tier-1 states, tier-2 states and words, respectively (subscript $_{-i}$ means the current assignment is excluded); α, γ and δ are the Dirichlet hyper-parameters; S = number of tier-1 states; T = number of tier-2 states; W = vocabulary size; and $\#(x, [y], [z])$ are the multinomial counts.

We follow the same process for optimising, training, and testing the model, and we summarise the results in Table 2 (column: "2T").[9] We see an improved correlation relative to BHMM (BHMM best: 0.45, Two-Tier BHMM best: 0.50). In fact it has the best performance of all models thus far. This is encouraging, as it implies that the introduction of the phrase layer produces a more optimal structure for representing acceptability.

3.5 Bayesian Chunker

Goldwater et al. (2009) propose a Bayesian approach to segment words in speech streams. Newman et al. (2012) extend the approach to segment phrases – i.e. multiword units – in sentences, and they apply it to the task of index term identification and keyphrase extraction.

The core machinery of the methodology is driven by the Dirichlet Process, where segments (words in Goldwater et al. (2009) or phrases in Newman et al. (2012)) are retrieved from a cache,

[8] The final optimised parameters are: $K = 100$, $S = 80$, $\alpha = 0.1$, $\beta = 0.0001$, $\gamma = 0.1$, and $\delta = 0.01$.

[9] The optimised parameters: $S = 100$, $T = 60$, $\alpha = 1.0$, $\gamma = 1.0$, $\delta = 0.01$.

or newly generated. Using Gibbs sampling for inference, the sampler considers one boundary point at a time, and computes the probability of two hypotheses: H_0, for *not* generating a boundary; and H_1, for generating a boundary.

Borrowing the notation of Newman et al. (2012), given $p_{\#}$ is the probability of generating a segment boundary, at the boundary point between words w_x and w_y, the probability of the hypotheses is computed as follows:

$$P(H_0|H^-) = \frac{n(w_{xy}) + \alpha P_0(w_{xy})}{n + \alpha};$$
$$P(H_1|H^-) = \frac{n(w_x) + \alpha P_0(w_x)}{n + \alpha} \times \frac{n(w_y) + \alpha P_0(w_y)}{n + 1 + \alpha}$$

where H^- is all of the structure shared by both hypotheses; w_{xy} is a multiword unit consisting of w_x and w_y; n is the number of multiword tokens; α is the concentration parameter of the Dirichlet process; $n(w)$ is the count of multiword w; and $P_0(w)$ is the probability of generating a novel w. i.e. $P_0(w_{xy}) = p_{\#}(1 - p_{\#})P(w_x)P(w_y)$.

We extend their methodology to segment *word classes* to do unsupervised chunking, motivated by the idea that a well-formed sentence contains predictable patterns of word class chunks. We extend the sampling process to incorporate transitions between chunks. Given the word classes "$c_w c_x c_y c_z$", at the boundary point between word class c_x and c_y, the hypothesis H_0 to not generate a boundary (therefore producing a single chunk c_{xy}), and the hypothesis H_1 to generate a boundary (therefore producing two chunks c_x and c_y), are computed as follows:

$$P(H_0|H^-) = \frac{\#(c_w, c_{xy}) + \beta\left(\frac{n(c_{xy}) + \alpha P_0(c_{xy})}{n+\alpha}\right)}{\#(c_w) + m\beta} \times \frac{\#(c_{xy}, c_z) + \beta\left(\frac{n(c_z) + \alpha P_0(c_z)}{n+\alpha}\right)}{\#(c_{xy}) + m\beta};$$
$$P(H_1|H^-) = \frac{\#(c_w, c_x) + \beta\left(\frac{n(c_x) + \alpha P_0(c_x)}{n+\alpha}\right)}{\#(c_w) + m\beta} \times \frac{\#(c_x, c_y) + \beta\left(\frac{n(c_y) + \alpha P_0(c_y)}{n+\alpha}\right)}{\#(c_x) + m\beta} \times \frac{\#(c_y, c_z) + \beta\left(\frac{n(c_z) + \alpha P_0(c_z)}{n+\alpha}\right)}{\#(c_y) + m\beta}$$

where m = number of chunk types; n = number of chunk tokens; β is the Dirichlet hyperparameter for the chunk transition multinomials; and $\#(x, [y])$ is the count for the chunk transition multinomials.

As the model takes word classes as input, we use the word classes induced by two-tier BHMM. We follow the same process for optimising, training and testing the model.[10] The results are summarised in Table 2 (column: "Chunker"). The model produces a moderate correlation, performing on par with the lexical 4-gram model.

3.6 Recurrent Neural Network Language Model

In recent years, we have seen a resurgence in the use of neural networks for deep machine learning and NLP. Rather than designing structures or handcrafting features that seem intuitive for a task, deep learning introduces an entirely general architecture for machine learning. It has yielded some impressive results for NLP tasks: automatic speech recognition, parsing, part of speech tagging, and named entity recognition, to name a few (Seide et al., 2011; Mikolov et al., 2011a; Collobert et al., 2011; Chen and Manning, 2014).

We experiment with a recurrent neural network language model (RNNLM: (Elman, 1998; Mikolov, 2012)) for our task. We choose this model because it has an internal state that keeps track of previously observed sequences, which is well suited for natural language problems. To train the model, we use stochastic gradient descent combined with back propagation through time. RNNLM is optimised to reduce the error in predicting the following word, based on the current word and its history (represented in a compressed dimension in the size of the hidden layer). Full details of RNNLM can be found in the original papers (Mikolov et al., 2011b; Mikolov, 2012).[11]

We experimented with some of the parameters of RNNLM using BNC-10M and found that most parameters have an intuitive setting. Its performance largely depends on the number of neurons in the hidden layer. Mikolov (2012) introduced a variant of RNNLM that does joint learning with a Maximum Entropy model which learns direct connections of N-gram features. We found that although there are advantages to using the ME model, the benefits disappear as we increase the number of neurons in the hidden layer. We saw optimal performance at 600 neurons, without using the ME model. All our results are based

[10] The optimised parameters are: $\alpha = 0.1$, $\beta = 0.001$, $p_{\#} = 0.5$.

[11] We use Mikolov's implementation of RNNLM for our experiment: `http://rnnlm.org/`.

Measure	2-gram	3-gram	4-gram	BHMM	LDAHMM	2T	Chunker	RNNLM
LogProb	0.31	0.36	0.38	0.32	0.33	0.35	0.42	0.44
Mean LP	0.28	0.36	0.37	0.28	0.28	0.35	0.45	0.46
Norm LP (Div)	0.34	**0.41**	**0.41**	0.44	0.42	0.49	**0.43**	0.55
Norm LP (Sub)	0.11	0.20	0.22	0.32	0.32	0.44	0.14	0.33
SLOR	**0.35**	**0.41**	**0.41**	**0.46**	**0.44**	**0.50**	0.41	**0.57**

Table 3: Pearson's r of acceptability measure and mean sentence rating for all experimented models in ENWIKI. Boldface indicates the best performing measure.

on the original RNNLM with 600 neurons in the hidden layer, trained on BNC-100M (Table 2 column: "RNNLM").[12] We see that RNNLM performs very well. It outperforms the other models, achieving a correlation of 0.53.

3.7 PCFG Parser (Supervised)

Although we are interested in unsupervised models, for purposes of comparison we experimented with a constituent PCFG parser for our task. We use the Stanford Parser (Klein and Manning, 2003a; Klein and Manning, 2003b), and tested both the unlexicalised and lexicalised PCFG parser with the supplied model. To compute the log probability of test sentences, we experimented with both top-1 and top-1K best parses.

We found that the unlexicalised variant gives better performance, but we saw little difference between using the top-1 and the top-1K best parses for computing log probability. In Table 2 (column: "PCFG"), we report results for the unlexicalised variant based on the top-1 best parse. The supervised PCFG parser performs poorly. This is not surprising, given that the parser is trained on a different domain.[13] Moreover, the log probability scores are not true probabilities, but arbitrary values used for ranking the parse trees.

4 English Wikipedia

For the BNC domain we saw that *SLOR* and *Norm LP (Div)* give the best acceptability measures, and that BHMM, two-tier BHMM and RNNLM are the best performing models. These findings are limited to a particular dataset. To better understand if these observations generalise to another domain, we developed an English Wikipedia dataset (ENWIKI), following the same process described in Lau et al. (2014) to generate test sentences through round-trip machine translation ,and to collect annotations via Mechanical Turk.[14] As before, we follow the same procedures described in Section 3 to optimise, train, and test all models (excluding LDA and PCFG). The Pearson correlations with mean AMT annotations are presented in Table 3.

We identify similar trends in ENWIKI: *Norm LP (Div)* and *SLOR* are the best acceptability measures, and we see improvements when we use a richer structure in the language model (two-tier BHMM>BHMM>N-grams). Interestingly, LDAHMM performs much better in this domain (possibly due to increased coherence in the document structure of ENWIKI). RNNLM has the best performance of all models, surpassing two-tier BHMM by a substantial margin. Overall, the correlation values are very similar across the two domains, indicating that the models and the acceptability measures are robust.

5 Comparison with a Supervised System

Although not a focus of this paper, supervised learning can further improve the correlation performance of our models. The acceptability measures can be combined in a supervised context. We experimented with this approach in a support vector regression model (with an RBF kernel). We achieved a correlation performance of 0.64 in BNC and of 0.69 in ENWIKI.[15]

Heilman et al. (2014) propose a system for predicting acceptability. They built a dataset consisting of sentences from essays written by non-native speakers for an ESL test. Acceptability ratings were judged by the authors, and through crowdsourcing (henceforth we refer to this annotated data set as the GUG data set). They applied

[12] Other parameter values of RNNLM: number of classes = 550; bptt = 4; bptt-block = 100.

[13] The Stanford English model is trained on the parse tree hand annotated WSJ (section 1–21), Genia, and a few other datasets.

[14] Both the BNC and the English Wikipedia datasets are available at `http://www.dcs.kcl.ac.uk/staff/lappin/smog/?page=research`.

[15] We use only the unsupervised models, excluding the supervised PCFG parser. The models are trained and tested using 10-fold cross validation.

a 4-category ordinal scale for rating the sentences. To predict sentence acceptability, they employ a linear regression model that draws features from spelling errors, an N-gram model, precision grammar parsers, and the Stanford PCFG parser.

To better understand the performance of our system compared to other acceptability prediction systems, we evaluated our methodology against that of Heilman et al. (2014) on the GUG dataset. We preprocessed the GUG dataset minimally. We removed 15 short sentences that have less than 5 words, lowercased all words, and tokenised the sentences using OpenNLP. This yields 2255 sentences for the training and development subset, and 749 sentences for the test set. Using the output – i.e. the acceptability measures – of our unsupervised models (trained on BNC) as features, we trained an SVR model using GUG training and development subsets to predict acceptability ratings on GUG test sentences. We applied the default SVR parameters, and so it was not necessary to use the development subset separately to optimise the parameters. For evaluation we computed the correlation of the predicted ratings and mean human ratings.

We present a comparison of results in Table 4. We first tested the unsupervised models, with the best correlation of 0.472 produced by the lexical 4-gram model using the *Norm LP (Div)* measure. Combining the models in SVR, we achieve a correlation of 0.603.

Heilman et al. (2014) note that spelling is one of the important features in their regression model, as the dataset often contains spelling mistakes. We borrowed this feature, computed as the proportion of misspelled words, and incorporated into our model. It produced a significant improvement in the correlation (0.636), a performance almost on par with that of Heilman et al. (2014).[16]

Our results demonstrate the robustness and portability of our system in a new domain. Our SVR model requires significantly less supervision than that of Heilman et al. (2014), which relies on precision and constituent parsers. Moreover, our methodology provides a completely unsupervised alternative that requires only raw text for training.

System	**Pearson's r**
Heilman et al. (2014)	0.644
Unsupervised Best	0.472
SVR: All Models	0.603
SVR: All Models+Spell	0.636

Table 4: A comparison of results of our system and Heilman et al. (2014) on GUG.

6 Influence of Sentence Length and Lexical Frequency

Our primary motivation in doing this research has been to use acceptability predictions to explore whether acceptability can be represented through probability information. Unlike probability, acceptability is generally not influenced by sentence length or low frequency words.

The acceptability measures we apply normalise sentence length and word frequency. To evaluate their effectiveness, we computed two correlations in the BNC domain: (1) acceptability measure vs. sentence length (Table 5); and (2) acceptability measure vs. sentence minimum word frequency (Table 6).[17]

For comparison we additionally computed the correlation of these factors with human ratings. The correlations are: +0.13 with sentence length; and +0.07 with minimum word frequency. These observations confirm the view that acceptability is not affected by these two factors.

Table 5 shows that although *LogProb* yields a strong negative correlation with sentence length, *Mean LP*, *Norm LP (Div)* and *SLOR* all produce low correlations. The only exception is *Norm LP (Sub)*, which still has a significant correlation with sentence length.

In Table 6 we see some degree of correlation in *LogProb* with the minimum word frequency, but it is relatively small. In general, *SLOR* is the scoring function that most effectively normalises word frequency, producing low correlation for most models. *Norm LP (Div)* also does very well, for all models except N-grams.

7 Discussion

In principle, the upper bound of the correlation between our models' predicted acceptability values and mean human ratings is 1.0. But no individual human annotator will match mean judgements perfectly. It is more plausible to measure our models'

[16] We use PyEnchant for spellcheck: `http://pythonhosted.org/pyenchant/`. Note that we also tried adding the spelling feature to our original BNC derived dataset, but it yielded no improvement in the correlation. This is not surprising, given that it contains few spelling errors.

[17] We use BNC-100M for computing word frequency.

Measure	2-gram	3-gram	4-gram	BHMM	LDAHMM	2T	Chunker	RNNLM

SLOR	+0.16	+0.14	+0.12	+0.06	±0.00	+0.10	+0.04	+0.03

Table 6: Pearson's r of acceptability measure and sentence minimum word frequency for all models in BNC. The correlation with the human ratings is $+0.07$.

rate of success against an estimated level of individual human performance. We do this by mimicking an arbitrary speaker, and testing the correlation of this construct's judgements with the mean scores of the annotators.

We simulate such an individual human judge by randomly selecting a single annotator rating for each sentence, and computing the Pearson correlation between these judgements and the mean ratings for the rest of the annotators (one vs the rest) in our test sets. We ran this experiment 50 times for each test set to reduce sample variation, producing a mean correlation of 0.67 for BNC and 0.74 for ENWIKI. For comparison, the best unsupervised model (RNNLM) achieves a correlation of 0.53 in BNC and 0.57 in ENWIKI (Section 3). The supervised model (SVR) produces a correlation of 0.64 in BNC and 0.69 in ENWIKI (Section 5). Although there is still room for improvement for the unsupervised methodology, it is encouraging to note that the supervised variant predicts acceptability at a level that approaches estimated human performance.

To test the robustness of our methodology across languages, we are currently developing datasets in other languages, based on Wikipedia. Our preliminary results show similar performance to that which we report here for ENWIKI, suggesting that these results hold across languages.

8 Conclusion

We developed a methodology for using unsupervised language models to predict human acceptability judgements. We experimented with a variety of unsupervised models. To map probability to acceptability we proposed a set of acceptability measures to normalise sentence length and lexical frequency. We achieved encouraging results across two datasets constructed through round trip machine translation, and the methodology is highly portable to other domains and languages. This research has potential implications for our understanding of human language acquisition and the way in which linguistic knowledge is represented.

Abstract

Framing is a sophisticated form of discourse in which the speaker tries to induce a cognitive bias through consistent linkage between a topic and a specific context (frame). We build on political science and communication theory and use probabilistic topic models combined with time series regression analysis (autoregressive distributed-lag models) to gain insights about the language dynamics in the political processes. Processing four years of public statements issued by members of the U.S. Congress, our results provide a glimpse into the complex dynamic processes of framing, attention shifts and agenda setting, commonly known as 'spin'. We further provide new evidence for the divergence in party discipline in U.S. politics.

1 Introduction

Language is one of the main tools used by politicians to promote their agenda, gain popularity, win elections and drive societal change (Luntz, 2007). The growing availability of online archives of political data such as public statements, bill proposals, floor speeches, interviews or social media streams allows computational analysis of many aspects of the political process. The analysis performed can increase transparency, facilitate a better educated constituency and improve understanding of the political process.

In this paper we propose a framework for automatic analysis of a large collection of political texts. Specifically, we demonstrate how the use of Bayesian methods and time series analysis captures the different ways in which political parties control the political discourse. We show that topic ownership and framing strategies can be inferred using topic models. Moreover, we demonstrate how the models learned are used to construct time series of expressed agendas. These time series are fitted using autoregressive distributive-lag models in order to learn the partisan temporal relations between topics and expressed agendas.

This framework could also be applied in other domains such as ideology divergence in online forums of radical groups or for measuring the changes in public sentiment toward commercial brands.

Contribution (i) To the best of our knowledge this is the first work to analyze framing strategies on large scale in an unsupervised manner[1]. (ii) we combine topic models with regression analysis in recovering longitudinal trends. (iii) We further provide evidence for the dynamics of framing campaigns, commonly known as 'political spin[2]'. Finally, (iv) we show how this framework can shed new light on the broad scholarship on the divergence of party discipline.

2 Related Work

2.1 Political Communication Theory

Some of the theoretical constructs employed by Political Science scholars to describe features of the political communication mechanism include: *topic ownership*, *framing*, and *agenda setting*. Understanding these theoretical concepts is necessary in laying the ground for our computational approach. This subsection provides the key definitions and a brief survey of the relevant literature.

Topic/Issue Ownership We say that a candidate, a representative or a party *owns* a topic if this topic, set of ideas or the competence in handling specific issues are strongly associated with her/the

[1] We do use some meta data such as the speaker's party and its timestamp for the time series analysis.

[2] 'Political spin' may also refer to fact twisting and factual distractions promoted using various media outlets. We do not refer to these types of spin in this work.

party (Petrocik, 1991; Petrocik, 1996; Damore, 2004). For example, environmental issues are traditionally associated with specific parties and not others (e.g. in U.S. politics, environmental issues are mostly associated with the Democratic party (Dunlap et al., 2001)).

Framing Framing is the psychological schema we use in order to organize and process our experiences. Politicians can use different contextual *frames* when referring to a specific topic, giving the public very different views on the topic at hand (Goffman, 1974; Gamson, 1989; Entman, 1993; Chong and Druckman, 2007). A notable example is the divisive partisan rhetoric used by U.S. politicians when referring to the legality of abortion. Democratic and Republican positions, framed as 'pro choice' and 'pro life', respectively, spin the abortion discourse as an issue of values of individual freedom (pro-choice) or validating the sanctity of life (pro-life). Similarly, Republicans refer to the inheritance tax by the overwhelmingly negative coinage 'death tax', while Democrats use 'estate tax'.

Framing strategies, however, go beyond the use of fixed phrases such as 'death tax' and 'pro-choice'. The Affordable Care Act (ACA) and the debate over raising the minimum wage can be framed as an issue of social justice or in the context of the economic burden it incurs on tax payers and by potential job loss.

Agenda Setting and shifting Agenda setting is achieved by framing and by increased or decreased *attention* (attention shifts) in order to set or change the political, media or public agenda (McCombs and Shaw, 1972; Scheufele and Tewksbury, 2007). Some examples of agenda setting campaigns are the repeated comments about the importance of child vaccination, highlighting the need for equal pay in the 2015 State of the Union Presidential Address, or, more broadly, repeatedly addressing the need for affordable healthcare.

2.2 Computational Analysis of Political Data

The availability of archives and streams of political data is driving a growing number of computational works that address a wide array of Political Science questions. Methods vary from simple word matching to more sophisticated Bayesian models and deep learning techniques.

Slant in news articles has been modeled by (Gentzkow and Shapiro, 2010) and (Lee, 2013), comparing word tokens and n-grams to predefined lists extracted from labeled data. Hidden Markov Models are used by (Sim et al., 2013) in order to measure ideological proportions in political speech, and (Iyyer et al., 2014) use recursive neural networks for a similar task.

Topic models have been used to detect connections between contributions and political agendas as expressed in microblogging platforms (Yano et al., 2013) and for reconstructing voting patterns based on the language in congressional bills (Gerrish and Blei, 2012). The flow of policy ideas has been modeled via measuring text reuse in different versions of bill proposals (Wilkerson et al., 2013).

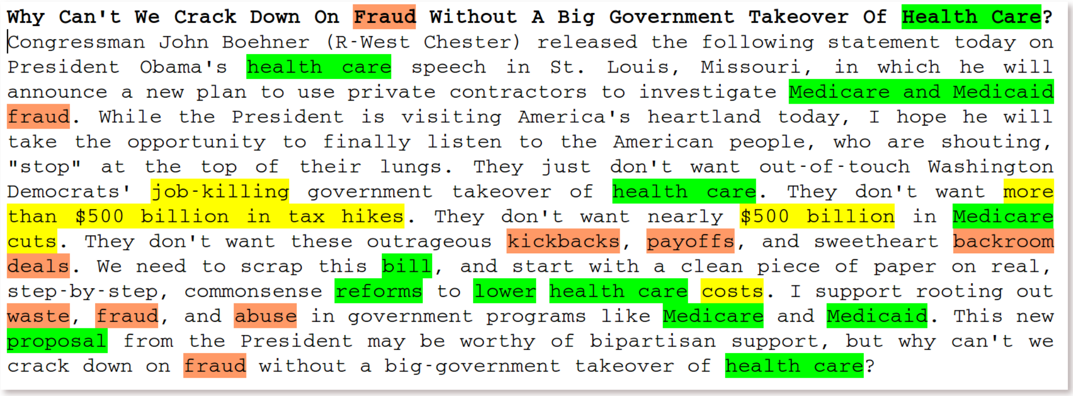
Nguyen et al. (2013) use supervised hierarchical topic regression to improve prediction of political affiliation and sentiment.

Expressed agendas in press releases issued by U.S. Senators have been modeled by Grimmer using author topic models (Grimmer, 2010). It is important to point to some key differences between our work and Grimmer's work. While the model used by Grimmer allows attribution of a single topic per document, we are interested in a mixed membership model as we hypothesize possible correspondence between topics and frames. Moreover, while we are interested in partisan dynamics, Grimmer is interested in the expressed agendas of individuals thus focusing on an authorship model. Finally, unlike Grimmer, we also introduce autoregressive distributed-lag models in order to capture temporal dynamics between topics and parties as reflected in the data.

Another line of work can be found in the more traditional Political Science scholarship. The success of framing strategies is studied by the analysis of real time reactions to political debates (Boydstun et al., 2014). Autoregressive models are used for analyzing adjustment of issue positions with respect to news items during the Dutch national election campaign of 2006 (Kleinnijenhuis and de Nooy, 2013). This approach is based on manual annotation of data.

Logistic regression on manually coded campaign advertisements is used in order to learn the dynamics of issue ownership by individual candidates (Damore, 2004).

While some of the works above address related research questions (agenda setting, topic ownership) or use similar computational approaches (topic models, regression models), our work is the



Why Can't We Crack Down On Fraud Without A Big Government Takeover Of Health Care?

Congressman John Boehner (R-West Chester) released the following statement today on President Obama's health care speech in St. Louis, Missouri, in which he will announce a new plan to use private contractors to investigate Medicare and Medicaid fraud. While the President is visiting America's heartland today, I hope he will take the opportunity to finally listen to the American people, who are shouting, "stop" at the top of their lungs. They just don't want out-of-touch Washington Democrats' job-killing government takeover of health care. They don't want more than $500 billion in tax hikes. They don't want nearly $500 billion in Medicare cuts. They don't want these outrageous kickbacks, payoffs, and sweetheart backroom deals. We need to scrap this bill, and start with a clean piece of paper on real, step-by-step, commonsense reforms to lower health care costs. I support rooting out waste, fraud, and abuse in government programs like Medicare and Medicaid. This new proposal from the President may be worthy of bipartisan support, but why can't we crack down on fraud without a big-government takeover of health care?

Figure 1: Examples of a public statement released on March 10, 2010 by Republican minority leader – Congressman John Boehner (now speaker of the U.S. House of Representatives). The highlighted sequences illustrate the different topics/frames used - health care (green), economy/budget (yellow) and corruption (orange).

first to offer a complete framework for automatic detection of topic ownership and attention shifting on a large scale. Additionally, our partisan analysis provides a model for longitudinal partisan communication strategies without the need for encoding of external events and specific campaigns.

3 Data

A brief overview of the U.S. Congress The American political system is a bicameral legislature composed of the Senate (100 senators, two from each state) and the House of Representatives (435 voting members plus 6 non-voting representatives, number depends on the population of each state). Election is held every two years, in which one third of the Senators and all members of the House face reelection. Members are typically affiliated with either the Democratic Party or the Republican Party. Congressional election and Presidential election coincide every four years.

The Corpus We use a corpus of public statements released by members of Congress in both the Senate and The House of Representatives, collected by Project Vote Smart[3]. An example of a public statement is presented in Figure 1.

In this work we use all individual statements and press releases in a span of four years (2010-2013), a total of 134000 statements made by 641 representatives. This time span encompasses two Congressional elections (November 2010 and 2012). Table 1 gives the number of Democratic and Republican representatives in the three Congress terms (111-113) covered in our data.

Chamber	Party	Congress Term		
		111th	112th	113th
Senate	DEM	57	51	53
	REP	41	47	45
House	DEM	257	193	199
	REP	178	242	234

Table 1: Majority shifts in the House in the 111-113 Congress terms. Independent representatives are omitted.

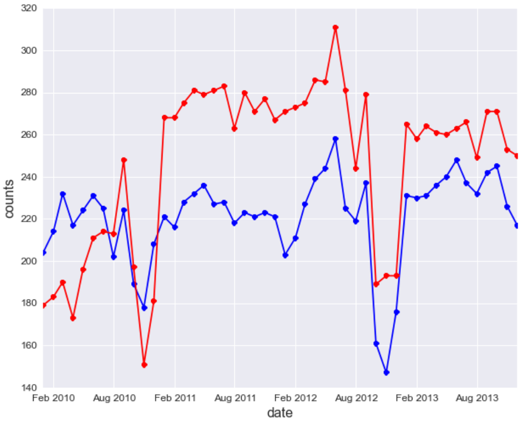


Figure 2: Monthly average number of statements by party.

While the administration was Democratic during all four years of our data, notice the Democratic loss of majority in the 112th Congress. We focus on the years 2010-2013 since Project Vote Smart has better coverage of the political discourse after 2009.

It is interesting to note that while the total number of statements per month reflects the change of majority in the November 2010 and 2012 elections (Table 1 and Figure 2), accounting for the number of seats per party it appears that the average Democrat is consistently more 'productive' with $\mu = 6.24$, $\sigma^2 = 2.1$ (Dem) and $\mu = 5.5$,

[3] http://votesmart.org/

$\sigma^2 = 1.5$ (Rep) statements per month. We hence report all results after normalization by the number of seats each party posses at each timestamp.

4 Computational Framework

In order to automatically discover the correlated dynamics of attention shifts, we take a layered approach, consisting of the stages described below.

4.1 Topic Inference

In the first stage, we use topic models in order to learn topic distribution over words and identify the set of topics addressed in the corpus. Topic Modeling describes a general algorithmic framework for unsupervised discovery of a set of topics expressed in a collection of documents. The framework is based on the assumption that documents are generated by mixtures of k topics. It is therefore assumed that documents are generated by the following process: for each word in a document, we choose a topic from a given topic distribution, then choose a word from the distribution over words that the chosen topic specifies. Latent Dirichlet Allocation (LDA), the framework employed here, assumes that the distribution over topics has a Dirichlet prior. In practice, we assume a Dirichlet prior on topics and use variational Bayes (VB) optimization to infer topic distributions over words (Blei et al., 2003). In order to considerably improve efficiency, we use an online variational Bayes inference algorithm, shown to perform similarly to batch LDA (Hoffman et al., 2010). It is important to note that our goals and assumptions about the data do not lend themselvse to the use of dynamic or correlated topic models (Blei and Lafferty, 2006a; Blei and Lafferty, 2006b)[4].

4.2 Topic Assignment and Unification

The distribution of ranked topics over documents presents a “long tailed” distribution in which a few topics achieve a significant coverage of a document. This is a result of the mixed membership “generative” approach and the bag-of-words assumption. In a more realistic setting the number of topics per document is restricted. We wish to restrict the number of topics per document while still conforming to the mixture model assumption. We therefore reassign topics to each document (statement) d in the following manner:

1. Assign a topic to each word based on distribution of topics over words infferred in the previous stage.
2. Find a set T' of k' topics ($k' < k$) that cover $q\%$ of the document in a greedy way. The topic assignment for document d will then be $d \rightarrow T'$.

4.3 Data Slicing

We slice the data according to four parameters: topic (or topical cluster), time, party and document (statement). These slicing parameters allow us the flexibility required to thoroughly analyze the data. In the time parameter, we have four settings: no slicing (all data is treated as if it were produced simultaneously), monthly slicing, weekly slicing and daily slicing, each gives different granularity of ownership patterns.

4.4 Autoregressive-Distributed-Lag Models

A linear function $b + w^T X = b + \sum_j w_j^T X^j$ is a simple yet robust method for testing dependency between X and Y. Ordinary least square regression finds the coefficients that minimize the mean square error of $Y = b + \sum_j w_j^T X^j$ given (X, Y). In our case (X, Y) are time series. We argue that a lagged dependency between two time series suggests a framing or attention shifting campaign.

Regression analysis of time series assumes independence between error terms. This key statistical property is often violated in real world data as y_t often depends on y_{t-1} thus the time series residuals tend to correlate. The consequences of violating the independence of errors are threefold: i) Statistical tests of significance are uninformative and cannot be used to prove dependency between the model parameters, ii) The coefficients learned lose accuracy, and iii) error terms are correlated, and hence contain information that is lost in analysis instead of used to leverage the prediction power of the model. The importance of controlling for autoregressive properties and for seasonality effects was recently demonstrated in the error analysis of the Google Flu Trends algorithm (Lazer et al., 2014).

In order to control for error dependency we add the auto regressing component $\gamma^T Y^n$ to the ordinary regression, as shown in Equation 1:

$$y_t = \alpha + \beta^T X^m + \gamma^T Y^n + \epsilon_t \qquad (1)$$

[4] We are interested in the change of the proportions of topics over time and not in the change of the word distribution within topics and we don’t assume inherent correlation of topics.

Cluster	Topic ID	Top Words

Table 2: Top twenty words in selected topics in four topical clusters.

where, $\beta^T X^m$ indicates the distributed-lag terms:

$$\beta^T X^m = \sum_{i=0}^{m} \beta_i x_{t-i} \tag{2}$$

and $\gamma^T Y^n$ indicates the autoregressive component described by:

$$\gamma^T Y^n = \sum_{j=1}^{n} \gamma_j y_{t-j} \tag{3}$$

for some $n \leqslant t$ (notice that i ranges from 0 while j ranges from 1).

In order to control for seasonality (such as holidays and recess') we add a set of categorical variables indicating the weekday and the week-in-year of a statement, so the autoregressive model is:

$$y_t = \alpha + \beta^T X^m + \gamma^T Y^n + \sum_l W_l^T I^l(t) + \epsilon_t \tag{4}$$

Where $l \in \{day, week\}$ thus $I^l(t)$ is the identity matrix with the dimension of the seasonal granularity, in our case $I^{day} = I_{7\times 7}$ for each day of the week and $I^{week} = I_{52\times 52}$ for the week of the year. $I^l_{i,i} = 1$ iff t timestamp falls in the i-th day-of-week/week-in-year.

Finally, in practice it is usually sufficient restrict the autoregressive term to one parameter with $j = 1$ (accounting to the y value at the previous time stamp), this is consistent with the 24 hours news cycle reported by (Leskovec et al., 2009) among others. Since our goal is to find correlated attention shifts we can substitute the summation distributed-lag term by a single lagged term. Thus, we aim to minimize the MSE in the following model:

$$y_t = \alpha + \beta x_{t'} + \gamma y^n_{t-1} + \sum_l W_l^T I^l(t) + \epsilon_t \tag{5}$$

Where $t' = t-i$ and $i \in \{0, 1, 2, ..., 28\}$ indicating no lag, one day lag, 2 days lag, a week's lag, etc.

5 Results

5.1 Topical Ownership and Framing

5.1.1 Inferred Topics

As an input for the topic modeling module (stage 1 of the system) we use a lexicon of the 10000 most frequent words in the corpus. We use $k = 100$ as the number of topics. Experiments with $k \in \{30, 50, 500, 1000\}$ produced topics that were either too general or too incoherent. Once the topic-word distributions were inferred, topics were validated by two annotators examining the top 50 words for each topic. Annotators used hierarchical labels – an energy related topic t_i could be annotated *energy / clean-tech*, while another topic t_j could be annotated *energy / economy / keystone-xl*. Annotations were consolidated to unify the coding[5]. After consolidation annotators agreed on all topic annotations. Some examples of topics labels are 'health', 'energy', 'economy', 'boilerplate', 'political process', 'local' and a few 'random' topics.

After topic assignment as described in Section 4.2 each document is associated with only 2–6 topics. In this work we focus on the 14 most salient (concise, general and frequent) topics in the corpus. These 14 topics fall under four topical clusters - Health, Energy, Army/Security and Economy/Budget. Table 2 contains examples of top words and labels for some of the topics from four topical clusters.

[5] For example, if topic t_i was labeled *energy, cleantech* by one annotator and *energy, green* by the other, the annotators would agree to use either *cleantech* or *green* consistently.

	52	190	12	123	0

Table 4: Number of *weeks* each party "owned" a topic by issuing more statements (DEM, REP) and number of weeks the party owned the topic with statistical significance $p < 0.05$ (DEM*, REP*).

5.1.2 Partisan Topic Ownership

Table 3 shows the partisan ownership by providing the number of statements issued by each party on each topic and for topical clusters. It also illustrates that different topical granularities portray different ownership patterns. For example, while it seems like the health cluster is owned by the Republican party (Table 3, cluster level), a closer look at specific topics in the cluster reveals a more complex picture – the Republicans actually own only topic 30, which turns to be the most dominant topic in the cluster. Similarly, while the statement counts in the Economy cluster are quite balanced (31604 vs. 31706), the counts of the individual topics in the cluster are polarized. Remember that these topical classes were all inferred by the LDA in an unsupervised way. These partisan ownership patterns were also confirmed by domain experts.

Longevity is a crucial factor in topic ownership. A weekly ownership of a topic is achieved by a party Q if it issued more statements on the topic than party R in that particular week. We compute the significance of the ownership assuming a null hypothesis that statements are issued by the parties by two Bernoulli processes with the same parameters. Table 4 provides the number of weeks each party owned each topic and the number of weeks it had a significant ownership ($p < 0.05$)[6].

Topic 30 illustrates the different perspectives. The total statement count (see Table 3) reveals a clear ownership by the Republican party, issuing 73% of the statements. While turning to weekly ownership (Table 4) we get similar number (Republicans control 77% of the weeks); assuming only significance ownership, Republicans significantly own the discourse for 79 weeks while Democrats have significant ownership in only 2 weeks which means the Republicans own 97% of the significantly owned weeks.

5.1.3 Topic Cooccurrence

Topic cooccurrence could approximate the way topics are framed. A heatmap of *within* statement topic cooccurrence based on Pointwise Mutual Information (PMI) (Church and Hanks, 1990) is presented in Figure 4. The topical clusters are characterized by blocks along the diagonal. The blocks structure is to be expected due to the inherent topical similarity within clusters. It is interesting to see the inter-cluster differences in PMI between the two parties. At the cluster level, Republicans tend to use the Budget & Economy topics with topics in all other topical clusters, evident by the stronger colors in the five bottom (left) rows (columns) in 4b comparing to 4c.

A notable example is the way Republicans frame the controversial Keystone XL project (Energy, topic 38) with the impact on the job market and small businesses (Budget & Economy, topic 88), a topic traditionally owned by Democrats (see top topical words in Table 2 and topic ownership at Table 4).

5.2 Partisan Discipline

Party discipline is of great interest for political scientists (Crook and Hibbing, 1985; Bowler et al., 1999; Krehbiel, 2000; McCarty, 2001) . Typically, party discipline is examined by analysis of roll call votes on bills. Discipline, however can be also measured by adherence to party lines in talking points and agenda setting campaigns. Discipline, therefore, can be captured by conformity of language in public statements. While it is "common knowledge" among political scientists that Republicans are more adherent to "talking points" – to the best of our knowledge there are no large scale studies that support (or refute) that.

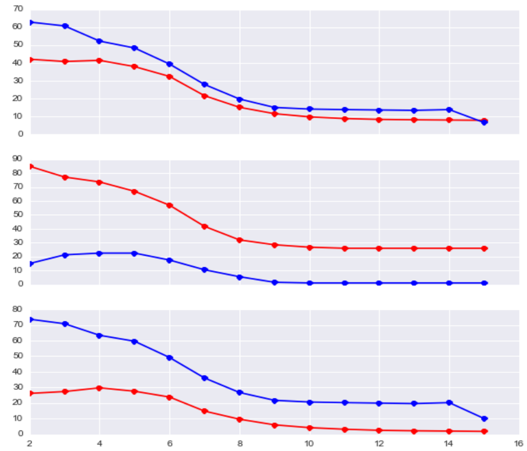

Figure 5: Average number of n-grams owned by each party on all topics (top), in Republican owned topics (middle) and in Democrat owned topics (bottom).

In the absence of official lists of "talking points", repeated use of similar phrases (n-grams) can provide an indication for the level of party discipline. In each topic, we looked at all n-grams ($n \in \{2, ..., 14\}$) that were used by more than five members of the Congress. For example, the trigram "the American people" (topic 38) appears in 81 statements made by 54 members of congress, only two of them were Democrats. Similarly, the tri-gram "social security benefits" (topic 51) appears in 123 statements, issued by 89 members, 71 of which were Democrats. Examining "ownership" of n-grams (per n-gram, per topic) reveals that that Republicans do tend to stick to talking points more than Democrats do.

Figure 5 provides the average number of n-grams owned by each party over all topics (top), over Republican owned topics (middle) and over Democratic owned topics (bottom). While on average Democrats own more n-grams than Republicans (Figure 5, top), the difference is marginal and is attributed to the fact that Democrats own more topics than the Republicans (10 vs. 4, see Table 3). Comparison between n-gram ownership in Democratic owned topics and Republican owned topics (Figure 5, middle and bottom) shows that while each party owns more n-grams in the *topics it owns*, Republicans present stronger ownership over the n-grams in their owned topics than Democrats in their respective owned topics. Moreover, Republicans present relative discipline even

[6] The numbers do not necessarily add up to 208 (the number of weeks in four years) due to weeks with no significant ownership , e.g. the parties issued a similar number of statements (usually zero) on that topic.

in Democratic owned topics.

Manually looking at some sampled n-grams it appears that mid-length n-grams are shared "talking points" and longer n-grams are full citations from bill proposals and committee reports. These findings are in line with textual sharing semantics (Lin et al., 2015).

5.3 Time Series Analysis

To this end we create two time series for each topic $c \in T$: $S_c^{C_D}$ – daily normalized counts for Democrats and $S_c^{C_R}$ – daily normalized counts for Republicans. Normalization of counts is needed in order to account for the bias introduced by the difference in the number of seats each party holds and the changes in that number in the different terms as apparent from Table 1.

Our data exhibit two strong seasonality effects: a weekly cycle with the lowest point on the weekend and peaking on Thursday (Figure 3a), and a yearly cycle with low points at the weeks of 4th of July, Thanksgiving, August recess and Christmas (Figure 3b). These seasonality effects are captured by the added terms in Equation 4.

After time series are constructed we apply first-difference detrending (Enders, 2008) in order to transform the time series to stationary series and avoid trend-incurred correlations.

We fit autoregressive-distributed-lag models for all pairs in $\{X = S_{c,l}, Y = S_{c'}\}$, where $c, c' \in T$ (topics), $l \in \{0, 1, 2, 3, ..., 7, 14, ..., 28\}$.

In this setting we fit 5153 pairs of time series of which 718 pairs had a significant coefficient for X ($p < 0.05$). Artificial significance due to abundance of fitted models was accounted to by applying the strict Bonferroni correction (Dunn, 1961) on the significance level. The correction resulted in 103 significant correlations, most of them with lag of up to 3 days. Table 5 gives the number of intra/inter significant correlation for lags $l \in 0, 1, 2$.

One example for such correlation is the Republicans "responding" to Democratic topic 88 with with topic 8 (intra-cluster) in one and two days lag. We interpret this as a different spin on the budget issue. Another example is the Democratic party corresponds to Republican topic 30 with topic 88 (inter-cluster) on the same day (no lag). We interpret this as a way to place the Acordable Care Act in a specific economic frame. We note that while the lagged correlated time series do not imply a responsive pattern, a significance of lagged correlation may suggest such a pattern. We provide some evidence in the qualitative analysis in the next section.

Cluster	Dependent	Significant Correlations		
		$l = 0$	$l = 1$	$l = 2$
Intra-cluster	DEM	28	1	1
	REP	26	4	5
Inter-cluster	DEM	15	2	0
	REP	17	0	0

Table 5: Number of statistically significant ($p < .05$, Bonferroni corrected) daily lagged correlations between cross-party time series.

5.4 Discussion and Qualitative Analysis

Inter and intra-cluster correlations can be interpreted as manifestations of different types of framing strategies and campaigns for attention shifts. A detailed analysis of the interplay between the different frames is beyond the scope of this paper and is left for political scientists.

The majority of the significant correlations were found with no lag. It is important to note that these correlations are found significant even after accounting to autoregressive patterns. Zero-lag correlations could be interpreted in a number of ways. Two probable interpretations are (i) daily time series are too crude to model lag patterns, and (ii) the parties respond to some external event at the same time. While we cannot address (i) due to sparseness and noise[7], we can sample statements and examine them manually. Manual examination reveals a strong responsive pattern in peaking trends. One typical example is the Republican spike in topic 30 on March 10. The statement at Figure 1 is very illustrative as it *explicitly* refers to a statement by President Obama. Explicit references to statements made by the other side are found more frequently in Republican statements and reveal a clear responsive pattern that also suggest a strong party discipline, in line with the results in Section 5.2. This small scale qualitative analysis complements the quantitative results reported in Section 5.3 and provide evidence for a responsive pattern even in zero lag series.

6 Conclusion

We presented a statistical framework for the analysis of framing strategies and agenda setting campaigns in the political sphere. Combining topic models and time series analysis, we modeled topic

[7] The exact timestamp is sometimes missing, set to midnight or affected by external factors.

ownership and party discipline and analyzed responsive patterns in an unsupervised way and with no prior knowledge of the political system. Our work draws from political science theory, validating some theoretical constructs and shedding new light on others. The proposed framework and the results could be further used and interpreted by political scientists and communication scholars.

Abstract

We propose a language production model that uses dynamic discourse information to account for speakers' choices of referring expressions. Our model extends previous rational speech act models (Frank and Goodman, 2012) to more naturally distributed linguistic data, instead of assuming a controlled experimental setting. Simulations show a close match between speakers' utterances and model predictions, indicating that speakers' behavior can be modeled in a principled way by considering the probabilities of referents in the discourse and the information conveyed by each word.

1 Introduction

Discourse information plays an important role in various aspects of linguistic processing, such as predictions about upcoming words (Nieuwland and Van Berkum, 2006) and scalar implicature processing (Breheny et al., 2006). The relationship between discourse information and speakers' choices of referring expression is one of the most studied problems. Speakers' choices of referring expressions have long been thought to depend on the salience of entities in the discourse (Givón, 1983). For example, speakers normally do not choose a pronoun to refer to a new entity in the discourse, but are more likely to use pronouns for referents that have been referred to earlier in the discourse. A number of grammatical, semantic, and distributional factors related to salience have been found to influence choices of referring expressions (Arnold, 2008). While the relationship between discourse salience and speakers' choices of referring expressions is well known, there is not yet a formal account of why this relationship exists.

In recent years, a number of formal models have been proposed to capture inferences between speakers and listeners in the context of Gricean pragmatics (Grice, 1975; Frank and Goodman, 2012). These models take a game theoretic approach in which speakers optimize productions to convey information for listeners, and listeners infer meaning based on speakers' likely productions. These models have been argued to account for human communication (Jager, 2007; Frank and Goodman, 2012; Bergen et al., 2012a; Smith et al., 2013), and studies report that they robustly predict various linguistic phenomena in experimental settings (Goodman and Stuhlmüller, 2013; Degen et al., 2013; Kao et al., 2014; Nordmeyer and Frank, 2014). However, these models have not yet been applied to language produced outside of the laboratory, nor have they incorporated measures of discourse salience that can be computed over corpora.

In this paper, we propose a probabilistic model to explain speakers' choices of referring expressions based on discourse salience. Our model extends the rational speech act model from Frank and Goodman (2012) to incorporate updates to listeners' beliefs as discourse proceeds. The model predicts that a speaker's choice of referring expressions should depend directly on the amount of information that each word carries in the discourse. Simulations probe the contribution of each model component and show that the model can predict

speakers' pronominalization in a corpus. These results suggest that this model formalizes underlying principles that account for speakers' choices of referring expressions.

The paper is organized as follows. Section 2 reviews relevant studies on choices of referring expressions. Section 3 describes the details of our model. Section 4 describes the data, preprocessing and annotation procedure. Section 5 presents simulation results. Section 6 summarizes this study and discusses implications and future directions.

2 Relevant Work

2.1 Discourse salience

Speakers' choices of referring expressions have long been an object of study. Pronominalization has been examined particularly often in both theoretical and experimental studies. Discourse theories predict that speakers use pronouns when they think that a referent is salient in the discourse (Givón, 1983; Ariel, 1990; Gundel et al., 1993; Grosz et al., 1995), where salience of the referent is influenced by various factors such as grammatical position (Brennan, 1995), recency (Chafe, 1994), topicality (Arnold, 1998), competitors (Fukumura et al., 2011), visual salience (Vogels et al., 2013b), and so on.

Discourse theories have characterized the link between referring expressions and discourse salience by stipulating constructs such as a scale of topicality (Givón, 1983), accessibility hierarchy (Ariel, 1990), or implicational hierarchy (Gundel et al., 1993). All of these assume fixed form-salience correspondences in that a certain referring expression encodes a certain degree of salience. However, it is not clear how this form-salience mapping holds nor why it should be.

There is also a rich body of research that points to the importance of production cost (Rohde et al., 2012; Bergen et al., 2012b; Degen et al., 2013) and listener models (Bard et al., 2004; Van der Wege, 2009; Galati and Brennan, 2010; Fukumura and van Gompel, 2012) in language production. These studies suggest that only considering discourse salience of the referent may not precisely capture speakers' choices of referring expressions, and it is necessary to examine discourse salience in relation to these other factors.

2.2 Formal models

Computational models relevant to speakers' choices of referring expressions have been proposed, but there is a gap between questions that previous models have addressed and the questions that we have raised above.

Grüning and Kibrik (2005) and Khudyakova et al. (2011) examine the significance of various factors that might influence choices of referring expressions by using machine learning models such as neural networks, logistic regression and decision trees. Although these models qualitatively show some significant factors, they are data-driven rather than being explanatory, and have not focused on why and how these factors result in the observed referring choices.

Formal models that go beyond identifying superficial factors focus on only pronouns rather than accounting for speakers' word choices per se. For example, Kehler et al. (2008) formalize a relationship between pronoun comprehension and production using Bayes' rule to account for comprehender's semantic bias in experimental data. Rij et al. (2013) use ACT-R (Anderson, 2007) to examine the effects of working memory load in pronoun interpretation. These models show how certain factors influence pronoun production/interpretation, but it is not clear how these models would predict speakers' choices of referring expressions.

Relevant formal models in computational linguistics include Centering theory (Grosz et al., 1995; Poesio et al., 2004) and Referring Expression Generation (Krahmer and Van Deemter, 2012). These models propose deterministic constraints governing when pronouns are preferred in local discourse, but it is not clear how these would account for speakers' choices of referring expressions, nor it is clear why there should be such deterministic constraints.

2.3 Uniform Information Density

One potential formal explanation for the relation between discourse salience and speakers' choices of referring expressions is the Uniform Information Density hypothesis (UID) (Levy and Jaeger, 2007; Tily and Piantadosi, 2009; Jaeger, 2010). UID states that speakers prefer to smooth the information density distribution of their utterances over time to achieve optimal communication. This theory predicts that speakers should use pronouns instead of longer forms (e.g., *the president*) when a referent is predictable in the context, whereas they should use longer forms for unpredictable referents that carry more information (Jaeger, 2010).

Tily and Piantadosi (2009) empirically examined the relationship between predictability of a referent and choice of referring expressions. They found that predictability is a significant predictor of writers' choices of referring expressions, in that pronouns are used when a referent is predictable.

While these results appear to support UID, there are several inconsistencies with previous UID accounts. Information content of words has been estimated using an n-gram language model (Levy and Jaeger, 2007), a verb's subcategorization frequency (Jaeger, 2010), and so on, whereas here the information content is that of referents with respect to discourse salience. In addition, selecting between a pronoun and a more specified referring expression involves deciding how much information to convey, whereas previous applications of UID (Levy and Jaeger, 2007) have been concerned with deciding between different ways of expressing the same information content. We show in the next section that we can derive predictions about referring expressions directly from a model of language production.

2.4 Summary

Previous linguistic studies have focused on identifying factors that might influence choices of referring expressions. However, it is not clear from this previous work how and why these factors result in the observed patterns of referring expressions. Where formal models relevant to this topic do exist, they have not been built to explain why there is a relation between discourse salience and speakers' choices of referring expressions. Even UID, which relates predictability to word length, is not set up to account for the choice between words that vary in their information content.

In the next section, we propose a speaker model that formalizes the relation between discourse salience and speakers' choices of referring expressions, considering production cost and speakers' inference about listeners in a principled and explanatory way.

3 Speaker model

3.1 Rational speaker-listener model

We adopt the rational speaker-listener model from Frank and Goodman (2012) and extend this model to predict speakers' choices of referring expressions using discourse information.

The main idea of Frank and Goodman's model is that a rational pragmatic listener uses Bayesian inference to infer the speaker's intended referent r_s given the word w, their vocabulary (e.g., 'blue', 'circle'), and shared context that consists of a set of objects O (e.g., visual access to object referents) as in (1), assuming that a speaker has chosen the word informatively.

$$P(r_s|w, O) = \frac{P_S(w|r_s, O)P(r_s)}{\Sigma_{r' \in O} P(w|r', O)P(r')} \qquad (1)$$

While our work does not make use of this pragmatic listener, it does build on the speaker model assumed by the pragmatic listener. This speaker model (the likelihood term in the listener model) is defined using an exponentiated utility function as in (2).

$$P_S(w|r_s, O) \propto e^{\alpha U(w;r_s,O)} \qquad (2)$$

The utility $U(w; r_s, O)$ is defined as $I(w; r_s, O) - D(w)$, where $I(w; r_s, O)$ represents informativeness of word w (quantified as surprisal) and $D(w)$ represents its speech cost. If a listener interprets word w literally and cost $D(w)$ is constant, the exponentiated utility function can be reduced to (3) where $|w|$ denotes the number of referents that the word w can be used to refer to.

$$P_S(w|r_s, O) \propto \frac{1}{|w|} \qquad (3)$$

Thus, the speaker model chooses a word based on its specificity. We show in the next section that this corresponds to a speaker who is optimizing informativeness for a listener with uniform beliefs about what will be referred to in the discourse. The assumption of uniform discourse salience works well in a simple language game where there are a limited number of referents that have roughly equal salience, but we show that a model that lacks a sophisticated notion of discourse falls short in more realistic settings.

3.2 Incorporating discourse salience

To extend Frank and Goodman's model to a natural linguistic situation, we assume that the speaker estimates the listener's interpretation of a word (or referring expression) w based on discourse information. We extend the speaker model from (3) by assuming that a speaker S chooses w to optimize a listener's belief in speaker's intended referent r relative to the speaker's own speech cost C_w. This cost is another factor in the speaker model, roughly corresponding to utterance complexity such as word length.[1]

$$P_S(w|r) \propto P_L(r|w) \cdot \frac{1}{C_w} \tag{4}$$

The term $P_L(r|w)$ in (4) represents informativeness of word w: the speaker chooses w that most helps a listener L to infer referent r. The term C_w in (4) is a cost function: the speaker chooses w that is least costly to speak.

The speaker's listener model, $P_L(r|w)$, infers referent r that is referred to by word w according to Bayes' rule as in (5).

$$P_L(r|w) = \frac{P(w|r)P(r)}{\Sigma_{r'}P(w|r')P(r')} \tag{5}$$

The first term in the numerator, $P(w|r)$, is a word probability: the listener in the speaker's mind guesses how likely the speaker would be to use w to refer to r. The second term in the numerator, $P(r)$, is the discourse salience (or predictability) of referent r. The denominator $\Sigma_{r'}P(w|r')P(r')$ is a sum of potential referents r' that could be referred to by word w. The terms in this sum are non-zero only for referents that are compatible with the meaning of the word. If there are many potential referents that could be referred to by word w, that word would be more ambiguous thus less informative. The whole of the right side in Equation (5) represents the speaker's assumption about the listener: given word w the listener would infer referent r that is salient in a discourse and less ambiguously referred to by word w.

If $P(r)$ is uniform over referents and $P(w|r)$ is constant across words and referents, this listener model reduces to $\frac{1}{|w|}$. Thus, Frank and Goodman (2012)'s speaker model in (3) is a special case of our speaker model in (4) that assumes uniform discourse salience and constant cost.

Our model predicts that the speaker's probability of choosing a word for a given referent should depend on its cost relative to its information content. To see this, we combine (4) and (5), yielding

$$P_S(w|r) \propto \frac{P(w|r)P(r)}{\sum_{r'} P(w|r')P(r')} \cdot \frac{1}{C_w} \tag{6}$$

Because the speaker is deciding what word to use for an intended referent, and the term $P(r)$ denotes the probability of this referent, $P(r)$ is constant in the speaker model and does not affect the relative probability of a speaker producing different words. We further assume for simplicity that $P(w|r)$ is constant across words and referents. This means that all referents have about the same number of words that can be used to refer to them, and that all words for a given referent are equally probable for a naive listener. In this scenario, the speaker's probability of choosing a word is

$$P_S(w|r) \propto \frac{1}{\sum_{r'} P(r')} \cdot \frac{1}{C_w} \tag{7}$$

where the sum denotes the total discourse probability of the referents referred to by that word.

The information content of an event is defined as the negative log probability of that event. In this scenario, the information conveyed by a word is the logarithm of the first term in (7), $-\log \sum_{r'} P(r')$. This means that in deciding which word to use, the highest cost a speaker should be willing to pay for a word should depend directly on that word's information content.

This relationship between cost and information content allows us to derive the prediction tested by Tily and Piantadosi (2009) that the use of referring expressions should depend on the predictability of a referent. For referents that are highly predictable from the discourse, different referring expressions (e.g., pronouns and proper names) will have roughly equal information content, and speakers should choose the referring expression that has the lowest cost. In contrast, for less predictable referents, proper names will carry substantially more information than pronouns, leading speakers to pay a higher cost for the proper names. These are the same predictions that have been discussed in the context of UID, but here the predictions are derived from a principled model of speakers who are trying to provide information to listeners. The extent to which our model can also capture other cases that have been put forward as evidence for the UID hypothesis remains a question for future research.

3.3 Predicting behavior from corpora

The model described in Section 3.2 is fully general, applying to arbitrary word choices, discourse probabilities, and cost fuctions. As an initial step, our simulations focus on the choice between pronouns and proper names. Our work tests the speaker model from (4) directly, asking whether it can predict the referring expressions from corpora of writ-

[1] Our speaker model corresponds to Frank and Goodman's exponentiated utility function (2), with α equal to one and with their cost $D(w)$ being the log of our cost C_w.

ten and spoken language. Implementing the model requires computing word probabilities $P(w|r)$, discourse salience $P(r)$, and word costs C_w.

We simplify the word probability $P(w|r)$ in the speaker's listener model as in (8):

$$P(w|r) = \frac{1}{V} \tag{8}$$

where the count V is the number of words that can refer to referent r. We assume that V is constant across all referents. Our reasoning is as follows. There could be many ways to refer to a single entity. For example, to refer to entity *Barack Obama*, we could say 'he', 'The U.S. president', 'Barack', and so on. We assume that there are the same number of referring expressions for each entity and that each referring expression is equally probable under the listener's likelihood model.

In our simulations, we assume that a speaker is choosing between a proper name and a pronoun. For example, we assume that an entity *Barack Obama* has one and only one proper name 'Barack Obama', and this entity is unambiguously associated with male and singular. Although we use an example with two possible referring expressions, as long as $P(w|r)$ is constant across all referents and words, it does not make a difference to the computation in (5) how many competing words we assume for each referent.

To estimate the salience of a referent, $P(r)$, our framework employs factors such as referent frequency or recency. Although there are other important factors such as topicality of the referent (Orita et al., 2014) that are not incorporated in our simulations, this model sets up a framework to test the role and interaction of various potential factors suggested in the discourse literature.

Salience of the referent is computed differently depending on its information status: old or new. The following illustrates the speaker's assumptions about the listener's discourse model:

For each referent $r \in [1, R_d]$:

1. If $r = old$, choose r in proportion to N_r (the number of times referent r has been referred to in the preceding discourse).
2. Otherwise, $r = new$ with probability proportional to α (a hyperparameter that controls how likely the speaker is to refer to a new referent).
3. If $r = new$, sample that new referent r from the base distribution over entities with probability $\frac{1}{U.}$ (count $U.$ denotes a total number of unseen entities that is estimated from a named entity list (Bergsma and Lin, 2006)).

The above discourse model is frequency-based. We can replace the term N_r for the old referent with $f(d_{i,j}) = e^{-d_{i,j}/a}$ that captures recency, where the recency function $f(d_{i,j})$ decays exponentially with the distance between the current referent r_i and the same referent r_j that has previously been referred to. This framework for frequency and recency of new and old referents exactly corresponds to priors in the Chinese Restaurant Process (Teh et al., 2006) and the distance-dependent Chinese Restaurant Process (Blei and Frazier, 2011).

The denominator in (5) represents the sum of potential referents that could be referred to by word w. We assume that a pronoun can refer to a large number of unseen referents if gender and number match, but a proper name cannot. For example, 'he' could refer to all singular and male referents, but 'Barack Obama' can only refer to *Barack Obama*. This assumption is reflected as a probability of *unseen referents* for the pronoun as illustrated in (10) below.

In our simulations, the speaker's cost function C_w is estimated based on word length as in (9). We assume that longer words are costly to produce.

$$C_w = \text{length}(w) \tag{9}$$

Suppose that the speaker is considering using 'he' to refer to *Barack Obama*, which has been referred to N_O times in the preceding discourse, and there is another singular and male entity, *Joe Biden*, in the preceding discourse that has been referred to N_B times. In this situation, the model computes the probability that the speaker uses 'he' to refer to *Barack Obama* as follows:

$$\begin{aligned}
&P_{\text{S}}(\text{`he'}|\textit{Obama}) \\
&\propto P_{\text{L}}(\textit{Obama}|\text{`he'}) \cdot \tfrac{1}{C_{\text{`he'}}} \\
&= \tfrac{P(\text{`he'}|\textit{Obama})P(\textit{Obama})}{\Sigma_{r'} P(\text{`he'}|r')P(r')} \cdot \tfrac{1}{C_{\text{`he'}}} \\
&= \tfrac{\frac{1}{V} \cdot N_{\text{O}}}{(\frac{1}{V} \cdot N_{\text{O}}) + (\frac{1}{V} \cdot N_{\text{B}}) + (\frac{1}{V} \cdot \alpha \cdot \frac{U_{\text{sing\&masc}}}{U.})} \cdot \tfrac{1}{C_{\text{`he'}}}
\end{aligned} \tag{10}$$

where count $U_{\text{sing\&masc}}$ in the denominator of the last line denotes the number of unseen singular & male entities that could be referred to by 'he'. We estimate this number for each type of pronoun we evaluate (singular-female, singular-male, singular-neuter, and plural) based on the named entity list in Bergsma and Lin (2006). The term ($\frac{1}{V} \cdot \alpha \cdot \frac{U_{\text{sing\&masc}}}{U.}$) is the sum of probabilities of unseen referents that could be referred to by the pronoun 'he'. The unseen referents can be interpreted as a penalty for the inexplicitness of pronouns. In the case of proper names, the denominator is always the same as the numerator, under the assumption that each entity has one unique proper name.

4 Data

4.1 Corpora

Our model was run on both adult-directed speech and child-directed speech. We chose to use the SemEval-2010 Task 1 subset of OntoNotes (Recasens et al., 2011), a corpus of news text, as our corpus of adult-directed speech. The Gleason et al. (1984) subset of CHILDES (MacWhinney, 2000) was chosen as our corpus of child-directed speech.

The model requires coreference chains, agreement information, grammatical position, and part of speech. These were extracted from each corpus, either manually or automatically. The coreference chains let us easily count how many times/how recently each referent is mentioned in the discourse, which is necessary for computing discourse salience. The agreement information (gender and number of each referent) is required so that the model can identify all possible competing referents for pronouns. For instance, *Barack Obama* will be ruled out as a possible competitor for the pronoun *she*. The grammatical position that each proper name occupies[2] determines the form of the alternative pronoun that could be used there. For example, the difference between *he* and *him* is the grammatical position that each can appear in. The part of speech is used to identify the form of the referring expression (pronouns and proper names), which is what our model aims to predict.[3]

OntoNotes includes information about coreference chains, part of speech, and grammatical dependencies. Gleason CHILDES has parsed part of speech and grammatical dependencies (Sagae et al., 2010), but it does not have coreference chains. Neither corpus has agreement information. The following section describes manual annotations that we have done for this study. Due to time constraints, we annotated only a part of the CHILDES Gleason corpus, 9 out of 70 scripts.

4.2 Annotation

4.2.1 Mention annotation

We considered only maximally spanning noun phrases as mentions, ignoring nested NPs and nested coreference chains. For the sentence "Both Al Gore and George W. Bush have different ideas on how to spend that extra money" from OntoNotes, the extracted NPs are *Both Al Gore and George W. Bush* and *different ideas about how to spend that extra money*.

These maximally spanning NPs were automatically extracted from the OntoNotes data, but were manually annotated for the CHILDES data using brat (Stenetorp et al., 2012) by two annotators.[4]

4.2.2 Agreement annotation

Many mentions (46,246 out of 56,575 mentions in OntoNotes and 10,141 out of 10,530 mentions in CHILDES Gleason) were automatically annotated using agreement information from the named entity list in Bergsma and Lin (2006), leaving 10,329 to be manually annotated from OntoNotes (about 18%) and 389 from CHILDES (about 4%).[5]

The guidelines we followed for this manual agreement annotation were largely based on pronoun replacement tests. NPs that referred to a single man and could be replaced with *he* or *him* were labeled 'male singular', NPs that could be replaced by *it*, such as *the comment*, were labeled 'neuter singular', and so on. NPs that could not be replaced with a pronoun, such as *about 30 years earnings for the average peasant, who makes $145 a year*, were excluded from the analysis.

4.2.3 Coreference annotation

We used the provided coreference chains for the OntoNotes data, but for the CHILDES data, it was necessary to do this manually using brat. The guidelines we followed for determining whether mentions coreferred came from the OntoNotes corefer-

[2] Dependency tags used were 'SUBJ', 'OBJ', and 'PMOD' in OntoNotes and 'SBJ' and 'OBJ' in CHILDES.

[3] The part of speech used to extract the target NPs were 'PRP' (pronoun), 'NNP' (proper name), and 'NNPS' (plural proper name) from OntoNotes and 'pro' (pronoun) and 'n:prop' (proper name) from CHILDES.

[4] Interannotator agreement for the CHILDES mention annotation was: precision 0.97, recall 0.98, F-score 0.97 (for two scripts).

[5] Interannotator agreement for the manual annotation of agreement information was 97% (for 500 mentions).

ence guidelines (BBN Technologies, 2007).[6]

5 Experiments

Our experiments are designed to quantify the contributions of the various components of the complete model described in Section 3.2 that incorporates discourse salience, cost, and unseen referents. We contrast the complete model with three impoverished models that lack precisely one of these components. The comparison model without discourse uses a uniform discourse salience distribution. The model without cost uses constant speech cost. The model without good estimates of unseen referents always assigns probability $\frac{1}{V} \cdot \alpha \cdot \frac{1}{C.}$ to unseen referents in the denominator of (5), regardless of whether the word is a proper name or pronoun. In other words, this model does not have good estimates of unseen referents like the complete model does.

We use the adult- and child-directed corpora to examine to what extent each model captures speakers' referring expressions. We selected pronouns and proper names in each corpus according to several criteria. First, the referring expression had to be in a coreference chain that had at least one proper name, in order to facilitate computing the cost of the proper name alternative. Second, pronouns were only included if they were third person pronouns in subject or object position, and indexicals and reflexives were excluded. Finally, for the CHILDES corpus, children's utterances were excluded.

After filtering pronouns and proper names according to these criteria, 553 pronouns and 1,332 proper names (total 1,885 items) in the OntoNotes corpus, and 165 pronouns and 149 proper names (total 314 items) in the CHILDES Gleason corpus remained for use in the analysis.

Each model chooses referring expressions given information extracted from each corpus as described in Section 4.1. For evaluation, we computed accuracies (total, pronoun, and proper name) and model log likelihood (summing $\log P_S(w|r)$ for the words in the corpus) for each model.

5.1 Results

Table 1 summarizes the results of each model with the OntoNotes and CHILDES datasets. The new referent hyperparameter α and the decay parameter for discourse recency salience were fixed at 0.1 and 3.0, respectively.[7]

5.1.1 News

Overall, the recency salience measure provides a better fit than the frequency salience measure with respect to accuracies, suggesting that recency better captures speakers' representations of discourse salience that influence choices of referring expressions. On the other hand, the models with frequency discourse salience have higher model log likelihood than the models with recency do. This is because of the peakiness of the recency models. Model log likelihood computed over pronouns and proper names (complete model) were -1022.33 and -222.76, respectively, with recency, and -491.81 and -467.06 with frequency. The recency model tends to return a higher probability for a proper name than the frequency model does. Some pronouns receive a very low probability for this reason, and this lowers the model log likelihood.

The model without discourse and the model without cost consistently failed to predict pronouns (these models predicted all proper names). This happens because in the model without discourse, the information content of pronouns is extremely low due to the large number of consistent unseen referents. In the model without cost, pronouns are disfavored because they always convey less information than proper names. The log likelihoods of these models were also below that of the complete model. These results show that pronominalization depends on subtle interaction between discourse salience and speech cost. Neither of them is sufficient to explain the distribution of pronouns and nouns on its own.

The total accuracy of the model without good estimates of unseen referents was the worst among the four models, but this model did predict pronouns to some extent. Because the number of proper names is larger than the number of pronouns in this dataset, the difference in total accuracies between the model without good estimates of unseen referents and the models without discourse or cost reflects this asymmetry. Comparison between the complete model and the model without good estimates of unseen referents also suggests that having knowledge of unseen referents helps correctly pre-

[6] Interannotator agreement for CHILDES coreference annotation was computed using B^3 (Bagga and Baldwin, 1998): precision: 0.99, recall: 1.00 (for one script).

[7] We chose the best parameter values based on multiple runs, but results were qualitatively consistent across a range of parameter values.

Corpus	Model	Discourse	Total accuracy	Pronoun accuracy	Proper name accuracy	Log-lhood
OntoNotes	complete	recency	80.27%	59.49%	88.89%	-1245.09
		frequency	73.10%	62.74%	77.40%	-958.87

dict the use of proper names in the first mention of a referent.

5.1.2 Child-directed speech

Unlike the adult-directed news text, neither recency nor frequency discourse salience provides a good fit to the data. The low accuracies of pronouns and the high accuracies of proper names in all models indicate that the models are more likely to predict proper names than pronouns. There are several possible reasons for this. First, the CHILDES transcripts involve long conversations in a natural settings. Compared to the news, interlocutors are not focusing on a specific topic, but rather they often switch topics (e.g., a child interrupts her parents' conversation about her father's coworker to talk about her eggs). This topic switching makes it difficult for the model to estimate discourse salience using simple frequency or recency measures. Second, interlocutors are a family and they share a good deal of common knowledge/background (e.g., a mother said *she* as the first mention of her child's friend's mother). The current model is not able to incorporate this kind of background knowledge. Third, many referents are visually available. The current model is not able to use visual salience. In general, these problems arise due to our impoverished estimates of salience, and we would expect a more sophisticated discourse model that accurately measured salience to show better performance.

5.2 Summary

Experiments with the adult-directed news corpus show a close match between speakers' utterances and model predictions. On the other hand, experiments with child-directed speech show that the models were more likely to predict proper names where pronouns were used, suggesting that the estimates of discourse salience using simple measures were not sufficient to capture a conversation.

6 Discussion

This paper proposes a language production model that extends the rational speech act model from Frank and Goodman (2012) to incorporate updates to listeners' beliefs as discourse proceeds. We show that the predictions suggested from UID in this domain can be derived from our speaker model, providing an explanation from first principles for the relation between discourse salience and speakers' choices of referring expressions. Experiments with an adult-directed news corpus show a close match between speakers' utterances and model predictions, and experiments with child-directed speech show a qualitatively similar pattern. This suggests that speakers' behavior can be modeled in a principled way by considering the probabilities of referents in the discourse and the information conveyed by each word.

A controversial issue in language production is to what extent speakers consider a listener's discourse model (Fukumura and van Gompel, 2012). By incorporating an explicit model of listeners, our model provides a way to explore this question. For example, the speaker's listener model $P_L(r|w)$ in (4) might differ between contexts and could also be extended to sum over possible listener identity q in mixed contexts, as in (11).

$$P_L(r|w) = \Sigma_q P(r|w, q)P(q) \qquad (11)$$

This provides a way to probe speakers' sensitivity to differences in listener characteristics across situations.

Although the simulations in this paper employed simple measures for discourse salience (referent frequency and recency), the discourse models used by speakers are likely to be more complex. Studies show that semantic information that cannot be captured with these simple measures, such as topicality (Orita et al., 2014) and animacy (Vogels et al., 2013a), affects speakers' choices of referring expressions. Future work will test to what extent this latent discourse information could affect the model predictions.

Our model predicts a tight coupling between the probability of a referent being mentioned, $p(r)$, and the choice of referring expression. However, these two quantities appear to be dissociated in some cases. For example, Fukumura and Van Gompel (2010) show that semantic bias (as a measure of predictability) affects *what* to refer to (i.e., the referent), but not *how* to refer (i.e., the referring expression), while grammatical position does affect *how* you refer. One way of dissociating the probability of mention from the choice of referring expression in our model would be through the likelihood term, the word probability $p(w|r)$. While we have assumed this word probability to be constant across words and referents, Kehler et al. (2008) use grammatical position to define this probability and show that their model captures experimental data. Syntactic constraints (such as Binding principles) also influence form choices, and this kind of knowledge may also be reflected in the word probability. Examining the role of the word probability $p(w|r)$ more closely would allow us to further explore these issues.

Despite these limitations, our model provides a principled explanation for speakers' choices of referring expressions. In future work we hope to look at a broader range of referring expressions, such as null pronouns and definite descriptions, and to explore the extent to which our model can be applied to other linguistic phenomena that rely on discourse information.

Linguistic Harbingers of Betrayal: A Case Study on an Online Strategy Game

Abstract

Interpersonal relations are fickle, with close friendships often dissolving into enmity. In this work, we explore linguistic cues that presage such transitions by studying dyadic interactions in an online strategy game where players form alliances and break those alliances through betrayal. We characterize friendships that are unlikely to last and examine temporal patterns that foretell betrayal.

We reveal that subtle signs of imminent betrayal are encoded in the conversational patterns of the dyad, even if the victim is not aware of the relationship's fate. In particular, we find that lasting friendships exhibit a form of balance that manifests itself through language. In contrast, sudden changes in the balance of certain conversational attributes—such as positive sentiment, politeness, or focus on future planning—signal impending betrayal.

1 Introduction

A major focus in computational social science has been the study of interpersonal relations through data. However, social interactions are complicated, and we rarely have access all of the data that define the relationship between friends or enemies. As an alternative, thought experiments like the prisoner's dilemma (Axelrod and Dion, 1988) are used to explain behavior. Two prisoners—denied communication—must decide whether to cooperate with each other or defect. Such simple and elegant tools initially helped understand many real world scenarios from pricing products (Rosenthal, 1981) to athletes doping (Buechel et al., 2013). Despite its power, the prisoner's dilemma remains woefully unrealistic. Cooperation and betrayal do not happen in a cell cut off from the rest of the world. Instead, real interactions are mediated by communication: promises are made, then broken, and met with recriminations.

To study the complex social phenomenon of betrayal, we turn to data and observe the players of **Diplomacy** (Sharp, 1978), a war-themed strategy game where friendships and betrayals are orchestrated primarily through language. Diplomacy, like the prisoner's dilemma, is a repeated game where players choose to either cooperate or betray other players. Diplomacy is so engaging that it is played around the world, not only casually as a board game but also over the Internet and in formal settings such as world championships.[1] Players converse throughout the game and victory hinges on enlisting others' support through persuasiveness and cunning duplicity. To illustrate the social relations that carry out throughout the game, consider the following exchange between two Diplomacy allies:

> Germany: Can I suggest you move your armies east and then I will support you? Then next year you move *[there]* and dismantle Turkey. I will deal with England and France, you take out Italy.
>
> Austria: Sounds like a perfect plan! Happy to follow through. And—thank you Bruder!

Austria is very polite and positive in its reply, and appreciates Germany's support and generosity. They have been good allies for the better part of the game. However, immediately after this exchange, Austria suddenly invades German territory. The intention to do so was so well concealed that Germany did not see the betrayal coming; otherwise it would have taken advantage first. Indeed, if we follow their conversation after the attack, we find Germany surprised:

> Germany: Not really sure what to say, except that I regret you did what you did.

[1] A recent episode of *This American Life* describes the Diplomacy game in a competitive offline setting: `http://www.thisamericanlife.org/radio-archives/episode/531/got-your-back?act=1`

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1650–1659,
Beijing, China, July 26-31, 2015.

Such scenarios suggest an important research challenge: is the forthcoming betrayal signaled by linguistic cues appearing in the (ostensibly friendly) conversation between the betrayer and the eventual victim? A positive answer would suggest not only that the betrayer unknowingly reveals their future treachery, but also that the eventual victim fails to notice these signals. Capturing these signals computationally would therefore mean outperforming the human players.

In this work, we provide a framework for analyzing a dyad's evolving communication patterns and provide evidence of subtle but consistent conversational patterns that foretell the unilateral dissolution of a friendship. In particular, imminent betrayal is signaled by sudden changes in the balance of conversational attributes such as positive sentiment, politeness, and structured discourse. Furthermore, we show that by exploiting these cues in a prediction setting we can anticipate imminent betrayal better than the human players.

After briefly describing the game (Section 2), we focus on how the structure of the game provides convenient, reliable indicators of whether pairs of participants are friends or foes (Section 3). Given these labels, we explore linguistic features that are predictive of whether friendships will end in betrayal (Section 4) and, if so, when the betrayal will happen (Section 5).

While our focus is on a single popular game, we choose methods that generalize to other domains, revealing dynamics present in other social interactions (Section 6). We discuss how automatically predicting stable relationships and betrayal can more broadly help advance the study of trust and relationships using computational linguistics.

2 Communication and Conflict in Diplomacy

A game of Diplomacy begins in 1901 with players casting themselves as the European powers at the eve of the first world war: England, Germany, France, Russia, Austria, Italy, and the Ottoman Empire. The goal of the game (like other war games such as Risk or Axis & Allies) is to capture all of the territories on the game board (Figure 1). The games are divided into years starting from 1901 and each year is divided into two seasons—Spring and Fall. Each season consists of two alternating phases: *diplomacy*—the players communicate to form strategies—and *orders*—the players submit their moves for the season. Seasons are therefore the main unit of game time.

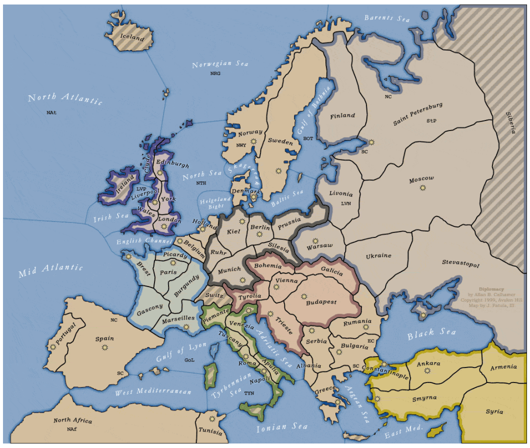

Figure 1: The full Diplomacy board representing Europe circa 1914. The seven nations struggle to control the map.

2.1 Movement, Orders, and Battles

On the board, each player can operate a unit for each city they control. During each turn, these pieces have the option of moving to an adjacent territory. What makes Diplomacy unique is that all players submit their written (or electronic) orders; these orders are executed simultaneously; and *there is no randomness* (e.g., dice). Thus, the outcome of the game depends only on the communication, cooperation, and movements of players.

When two units end their turn in the same territory, it implies a battle. Who wins the battle is decided purely based on numerical superiority (ties go to defenders). Instead of moving, a unit can support another unit; large armies can be created through intricate networks of support. The side with the largest army wins the battle.

The process of *supporting* a unit is thus critical for both a successful offensive move and a successful defense. Often, a lone player lacks the units to provide enough support to his attacks and thus needs the help of others.[2] Because these orders (both movement and support) are machine readable, we have a clear indication of when players are working together (supporting each other) or working against each other (attacking each other); we will use this to define relationships between

[2] While support can come from a player's own units, allies often combine resources. For example, if an English army in Belgium is attacking a Germany Army in Ruhr, a French army in Burgundy could strengthen that attack. This is accomplished by the French player submitting a move explicitly stating "I support England's attack from Belgium to Ruhr".

players (Section 3). However, coordinating these actions between players requires cooperation and *diplomacy*.

2.2 Communication

In the *diplomacy* phase of the game, players talk to each other. These conversations are either public or—more typically—one-on-one. Conversations include greetings, extra-game discussions (e.g., "did you see Game of Thrones?"), low-level tactics ("if you attack Armenia, I'll support you"), and high-level strategy ("we need to control Central Europe"). The content of these messages forms the object of our study.

Because of the centrality of language to Diplomacy, we can learn the rhetorical and social devices players use to build and break trust. Because this language is embedded in every game, it has convenient properties: similar situations are repeated, the goals are clear, and machine-readable orders confirm which players are enemies and which are friends. In the next section, we explore the Diplomacy data.

2.3 Preprocessing

We use games from two popular online platforms for playing Diplomacy.[3] The average season of an online Diplomacy game lasts nine days. We remove non-standard games caused by differences between the two platforms, as well as games that are still in progress. Moreover, in each game, we filter out setup messages, regulatory messages to and from the administrator of the game and messages declaring the state of the game, keeping only messages between the players. This leaves 249 games with 145.000 total messages.

The dataset confirms that communication is an essential part of Diplomacy: half of the games have over 515 messages exchanged between the players, while the top quartile has over 750 messages per game. Also, non-trivial messages (with at least one sentence) tend to be complex: over half of them have at least five sentences, and the top quartile consists of messages with eight or more sentences.

3 Relationships and Their Stability

In this section, we explore how interactions within the game of Diplomacy define the relationships between players. While such dyadic relationships can be undefined (e.g., England and Turkey are in opposite corners of the map), specific interactions between players indicate whether they are friendly or hostile to each other.

Event	Time	What happened
F_1	4	B supports V's army in Vienna
F_2	3	V supports B's attack from Warsaw to Silesia
F_3	3	B again supports V in Vienna
F_4	1	V supports B's move from Venice to Tyrolia
H_5	0	B attacks V in Vienna
H_6	-1	V retaliates, attacking B in Warsaw

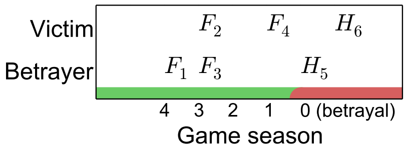

Figure 2: A friendship between Player B (eventual betrayer) and Player V (eventual victim) unravels. For the first four events, the players exchange **F**riendly acts (in green). Eventually B's unilateral hostile act betrays V's trust, leading to hostility (in red). The dissolution takes place at the time of the first hostile act ($t = 0$) and we index game seasons going back from the betrayal, such that lower indices mean betrayal is nearer.

Friendships and hostilities. Alliances are a natural part of the game of Diplomacy. While the best outcome for a player is a *solo victory* against all other players, this is rare and difficult to achieve without any cooperation and assistance. Instead, the game's structure encourages players to form long-term alliances. Allies often settle for (less prestigious) team victories, but these coalitions can also crumble as players seek a (more prestigious) solo victory for themselves. This game dynamic naturally leads to the formation of *friendly and hostile dyads*, which are relatively easy to identify through post-hoc analysis of the game, as explained next.

Acts of friendship. Diplomacy provides a *support* option for players to help each other: this game mechanism (discussed in Section 2) provides unequivocal evidence of friendship. When two players engage in a series of such friendly acts, we will say that the two are in a relation of *friendship*.

Acts of hostility. Unlike support, hostile actions are not explicitly marked in Diplomacy. We consider two players to be hostile if they get involved in any unambiguous belligerent action, such as invading one another's territory, or if one supports an enemy of the other.[4]

[3] Anonymized transcripts and more information available at `http://vene.ro/betrayal/`

[4] In Diplomacy all game actions are simultaneous, and this can lead to ambiguous interpretation of the nature of a

Betrayal. As in real life, friendships can be broken unilaterally: an individual can *betray* his friend by engaging in a hostile act towards her. Figure 2 shows two players who started out as friends (green) but became hostile (red) after a betrayal. Importantly, until the last act of friendship (game season $t = 1$), the *victim* is unaware that she will be betrayed (otherwise she would not have engaged in an act of friendship) and the *betrayer* has no interest in signaling his planned duplicity to his partner.

This setting poses the following research challenge: are there linguistic cues that appear during the friendly conversations and portend the upcoming betrayal? A positive answer would have two implications: the betrayer unknowingly hints at his future treachery, and the victim could have noticed it, but did not. We will explore this question in the following sections.

Relationship stability. Before venturing into the linguistic analysis of betrayals, we briefly explore the dynamics underlying these state transitions. We find that, as in real life, friendships are much more likely to collapse into hostilities than the reverse: in Diplomacy, the probability of a friendship to dissolve into enmity is about five times greater than that of hostile players becoming friends. The history of the relationship also matters. A friendship built on the foundation of many cooperative acts is more likely to endure than friendship with a short history, and long-lasting conflict is less likely to become a friendship. In numbers, the probability that a two season long friendship ends is 35%, while for pairs who have helped each other for ten or more seasons, the probability of betrayal is only 23%. Similarly, the probability that a two season long conflict resolves is 7%, while players at war for over ten seasons have only a 5% chance to make up. These numbers aren't particularly shocking—the idea that the passage of time has an effect on the strength of a relationship is intuitive. For the purposes of this study, we control for such effects in order to capture purely linguistic hints of betrayal.

Starting from the relationship definitions discussed in this section, in what follows we show how subtle linguistic patterns of in-game player conversations can reveal whether or not a friendship will turn hostile or not.

4 Language Foretelling Betrayal

In this section, we examine whether the conversations between two Diplomacy allies contain linguistic cues foretelling if their friendship will last or end in betrayal. We expect these cues to be subtle, since we only consider messages exchanged when the two individuals are being ostensibly friendly; when at least one of them—the eventual victim—is unaware of the relationship's fate.

4.1 What Constitutes a Betrayal

To find betrayals, we must first find friendships. Building on the discussion from Section 3, we consider a friendship to be *stable* if it is ongoing, established, and reciprocal. Thus, we focus on relationships that contain at least two consecutive and reciprocated acts of friendships that span at last at least three seasons in game time. We also check that no more than five seasons pass between two acts of friendships, as friendships can fade.

Betrayals are established and reciprocal friendships that end with at least two hostile acts. The person initiating the first of these hostile acts is the *betrayer*, while the other person is the *victim*.[5]

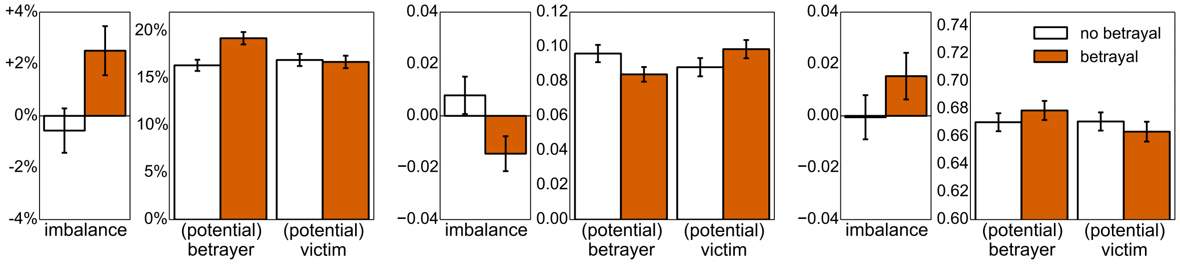
For each betrayal instance, we find the most similar stable friendship that was *never* dissolved by betrayal. Using a greedy heuristic, we select friendships that match the betrayals on two statistics: the length of the friendship and number of seasons since the start of the game. After this matching process, we find no significant difference in either of the two variables (Mann-Whitney $p > 0.3$). Matching betrayals with lasting friendships in this fashion removes historical and relationship-type effects such as those discussed in Section 3, and focuses the comparison on the variable of interest: whether a given stable friendship will end in a betrayal or not.

4.2 Linguistic Harbingers of Betrayal

Now we switch to exploring linguistic features that correlate with future betrayal in the controlled setting described above. We start from the intuition that a stable relationship should be balanced (Jung et al., 2012): friends will help each other

pair's interactions. Our definition of hostility intentionally discards such ambiguous evidence. For instance, if two players attempt to move into the same unoccupied territory, this is not necessarily aggressive: allies sometimes use this tactic ("bouncing") to ensure that a territory remains unoccupied.

[5] In rare cases, the betrayal can be mutual (i.e., both players start attacking each other in the same season). In such cases, we consider both betrayals.



(a) Positive sentiment
(percentage of sentences)

(b) Planning discourse markers
(avg. number per sentence)

(c) Politeness
(avg. message score)

Figure 3: Friendships that will end in betrayal are imbalanced. The eventual betrayer is more positive, more polite, but plans less than the victim. The white bars correspond to matched lasting friendships, where the roles of potential betrayer and victim are arbitrarily assigned; in these cases, the imbalances disappear. Error bars mark bootstrapped standard errors (Efron, 1979).

while enemies will fight each other. A precarious friendship might feel one-sided, while a conflict may turn to friendship through a magnanimous olive branch. Therefore, we focus our attention on linguistic features that have the potential to signal an imbalance in the communication patterns of the dyad.

To ensure that we are studying conversational patterns that occur *only* when the two individuals in the dyad are ostensibly being friends, we only extract features from the messages exchanged before the last act of friendship, that is, before the season labeled 1 in Figure 2. Considering the nature of this setting, we can only hope for subtle linguistic cues: if there were salient linguistic signals, then the victim would notice and preempt the betrayal. Instead, they are taken by surprise; the following is a typical reaction of a player after having been betrayed by a friend:

> Well that move was sour. I'm guessing France put you up to it, citing my large growth. This was a pity, as I was willing to give you the lion's share of centers in the west. [...] If you voiced your concerns I would have supported you in most of the western centers. Unfortunately now you have jumped out of the pan into the fire.

Sentiment. Changes in the sentiment expressed in conversation can reflect emotional responses, social affect, as well as the status of the relationship as a whole (Gottman and Levenson, 2000; Wang and Cardie, 2014). We quantify the proportion of exchanged sentences that transmit positive, neutral and negative sentiment using the Stanford Sentiment Analyzer (Socher et al., 2013).[6] Example sentences with these features, as well as all other features we consider, can be found in Table 1.

We find that an imbalance in the amount of positive sentiment expressed by the two individuals is a subtle sign that the relation will end in betrayal (Figure 3a, left; one-sample t-test on the imbalance, $p = 0.008$). When looking closer at who is the source of this imbalance (Figure 3a, right), we find that that it is the eventual betrayer that uses significantly *more positive sentiment* than the control counterpart in the matched friendship (two-sample t-test, $p = 0.001$). This is somewhat surprising, and we speculate that this is the betrayer overcompensating for his forthcoming actions.

Argumentation and Discourse. Structured discourse and well-made arguments are essential in persuasion (Cialdini, 2000; Anand et al., 2011). To capture discourse complexity, we measure the average number of explicit discourse connectors per sentence (Prasad et al., 2008).[7] These markers belong to four coarse classes: *comparison*, *contingency*, *expansive*, and *temporal*. To capture *planning*, we group temporal markers that refer to the future (e.g.,"next", "thereafter") in a separate category. To quantify the level of argumentation, we calculate average number of claim and premise markers per sentence, as identified by Stab and Gurevych (2014). We also measure the number of request sentences in each message, as identified by the heuristics in the Stanford Politeness classifier (Danescu-Niculescu-Mizil et al., 2013).

The structure of the discourse offers clues to whether the friendship will last. For example, Figure 3b shows that in friendships doomed to end in betrayal, the victim uses planning discourse markers significantly more often than the betrayer (one-sample t-test on the imbalance, $p = 0.03$), who is

[6] We collapse the few examples classified as *extreme positive* and *extreme negative* examples into *positive* and *negative*, respectively.

[7] We remove the connectors that appear in over 20% of the messages (*and*, *for*, *but*, *if*, *as*, *or*, and *so*).

Feature	Example sentence from the data
Positive sentiment	I will still be thrilled if it turns out you win this war.
Negative sentiment	It's not a great outcome, but still an OK one.
Neutral sentiment	Do you concur with my assumption?
Claim	But **I believe** that E/F have discarded him and so **I think** he might bite.
Premise	I put Italy out **because** I wanted to work with you.
Comparison	We can trade centers **as much as** we like **after** that.
Contingency	He did not, **thus** we are **indeed** in fine shape to continue as planned.
Expansion	Would you **rather** see WAR-UKR, or GAL-UKR?
Temporal	I think he can **still** be effective to help me take TUN **while** you take ROM.
Planning	HOL should fall **next** year, and **then** MUN and KIE shortly **thereafter**.
Number of requests	
Politeness	I wonder if you shouldn't try to support Italy into MAR ... What do you think?
Subjectivity	I'm **just curious** what you **think**.
Talkativeness	

Table 1: Summary of the linguistic cues we consider.

likely to be aware that the cooperation has no future. (More argumentation and discourse features will be discussed in the following sections.)

Politeness. Pragmatic information can also be informative of the relation between two individuals; for example Danescu-Niculescu-Mizil et al. (2013) show that differences in levels of politeness can echo differences in status and power. We measure the politeness of each message using the Stanford Politeness classifier and find that friendships that end in betrayal show a slight imbalance between the level of politeness used by the two individuals (one-sample t-test on the imbalance, $p = 0.09$) and that in those cases the future victim is the one that is less polite.

Subjectivity. We explored phrases expressing opinion, accusation, suspicion, and speculation taken from an automatically collected lexicon (Riloff and Wiebe, 2003), but did not find significant differences between betrayals and control friendships.

Talkativeness. Another conversational aspect is the amount of communication flowing between the players, in each direction. To quantify this, we simply use the number of messages sent, the average number of sentences per message, and the average number of words per sentence. Abnormal communication patterns can indicate a relationship breakdown. For example, friendships that dissolve are characterized by an imbalance in the number of messages exchanged between the two players (one-sample t-test, $p < 0.001$).

These results show that there are indeed subtle linguistic imbalance signals that are indicative of an forthcoming betrayal, even in a setting in which the victim is not aware of the impending betrayal.

4.3 Predictive Power

To test whether these linguistic cues have any predictive power and to explore how they interact, we turn to a binary classification setting in which we try to detect whether a player V will be betrayed by a player B. (We will call player V the potential victim and player B the potential betrayer.) Expert humans—the actual victims—performed poorly on this task and were not able to tell that they will be betrayed: by virtue of how the dataset is constructed, the performance of the human players is at chance level.

We use the same balanced dataset of matched betrayals and lasting friendships as before and consider as classification instances all the seasons coming from each of the two classes (663 betrayal seasons and 712 from lasting friendships). As features, we use the cues described above and summarized in Table 1, differentiated by source: V or B. We use logistic regression after univariate feature selection. The best setting for the model parameters[8] is selected via 5-fold cross validation, ensuring that instances from the same game are never found in both train and validation folds. The resulting model achieves a cross-validation accuracy of 57% and a Matthews correlation coefficient of 0.14, significantly above chance (52% accuracy and 0 Matthews correlation coefficient), with 95% bootstrapped confidence. This indicates

[8] We optimize the number of features selected, the scoring function used (ANOVA or χ^2), whether to automatically reweigh the classes, the regularizer (ℓ_1 or ℓ_2), and the value of the regularization parameter C between 10^{-12} and 10^{12}.

From	Positive feature	From	Negative feature
B	Positive sentiment	B	Expansion
B	Sentences	B	Comparison
		B	Contingency
		B	No. Words
		B	Planning
		B	Negative sentiment

Table 2: Selected features for recognizing upcoming betrayal, in decreasing order of the absolute value of their coefficients. The *From* column indicates whether the message containing the feature was sent by the potential **B**etrayer or the potential **V**ictim. (In this case, only betrayer features were selected.) Positive features indicate that a friendship is more likely to end in betrayal.

that, unlike the actual players, the classifier is able to exploit subtle linguistic signals that surface in the conversation.[9]

The selected features and their coefficients are reported in Table 2. On top of the observations we previously made, the feature ranking reveals that writing more sentences per message is more common when one will betray. Discourse features also prove relevant: more complex discourse indicates a lower likelihood of the player betraying (e.g., Figure 3b).

Overall, the selected linguistic features capture a consistent signal that characterizes people's language when they are about to betray: they tend to plan less than their victims, use less structure in their communication, and are overly positive.

5 Sudden yet Inevitable Betrayal

The results from Section 4 suggest that language cues can be subtle signs of future relationship disruption. Even though people are aware that most relationships eventually end, one would still prefer to reap their benefits as long as possible. In Diplomacy, despite the common knowledge that everyone prefers to win alone, players still take chances on long-lasting alliances. This leads to an alternate research question: assuming that a relationship will be disrupted, how soon can one expect to be betrayed? This is still just as challenging for the expert human players, as they were not able to anticipate and thereby avoid betrayal.

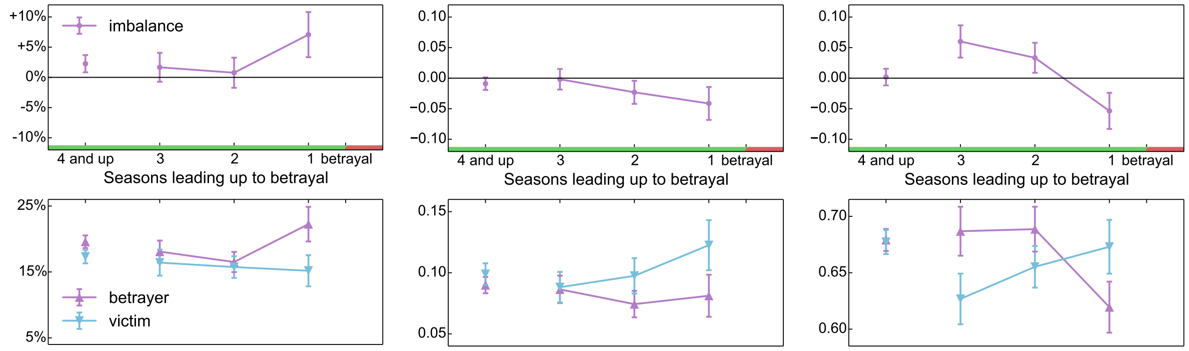
Next we investigate if the variation of the linguistic cues over time can predict imminent change in the relationship. We consider only the subset of betrayals used in Section 4, and label each individual game season with its distance from the end of the friendship (as in Figure 2). We prevent short alliances of circumstance from distorting the features close to betrayal by keeping only friendships lasting at least four seasons.

We consider the same cues described in Table 1, and train a classifier to discriminate between the season preceding the last friendly interaction and all the older seasons. This learning task is imbalanced, with only 14% of the seasons being immediately before the betrayal. Thus, we optimize F_1 score and also measure the Matthews correlation coefficient, which takes a value of 0 for uninformative predictions (random or majority). The best model achieves an F_1 score of 0.31 and a Matthews correlation coefficient of 0.17, significantly better than chance with 95% bootstrapped confidence. This shows that we can capture signs of imminent betrayal, something that even the skilled human players have failed to do. Furthermore, 39% of the predicted false positives are within two seasons of the last friendly act. This suggests that sometimes the warning signs can appear slightly earlier.

The selected features, displayed in Table 3, reflect some of the effects identified in Section 4, such as the importance of positive sentiment and planning discourse markers. Betrayers have a tendency to use more positive sentiment during the last moment of purported friendliness (Figure 4a). Also, expressing more opinions through claims is a sign that one will not betray right away. Three of the discourse features (comparison, contingency and expansion) are selected as *imbalance* features (they have near-opposite coefficients for the betrayer and for the victim), indicating that as betrayal approaches, victims are less eloquent than betrayers. Interestingly, some predictive signals come only from the victim: a partner using increasingly more planning words is at higher risk of being betrayed (Figure 4b). This could be explained by the pressure that making plans for the future can put on a relationship. A similar reasoning applies for making many requests.

We also find that a decrease in a partner's politeness presages their imminent betrayal. The change in politeness over time (Figure 4c) reveals a reversal in the politeness imbalance of the pair. This explains why politeness is not a good enough feature in detecting long-term betrayal. The behav-

[9] Since our focus is on understanding linguistic aspects of betrayal, rather than on achieving the best possible performance on this particular Diplomacy task, we do not use game-specific information, such as the players' position on the map, or any information not accessible to both players.



(a) Positive sentiment (percentage of sentences)

(b) Planning discourse markers (avg. number per sentence)

(c) Politeness (avg. message score)

Figure 4: Changes in balance can mark imminent betrayal. As the breakdown approaches, the betrayer becomes more positive but less polite, and the victim tends to make more requests and become more polite. Error bars mark bootstrapped standard errors (Efron, 1979).

From	Positive feature	From	Negative feature
V	Comparison	B	Claims
V	Positive sentiment	B	Politeness
V	Contingency	B	Contingency
V	Planning	B	Subjectivity
V	Requests	B	Expansion
V	Expansion	B	No. Sentences
		B	Comparison

Table 3: Selected features for recognizing imminent betrayal, in decreasing order of the absolute value of their coefficients. The *From* column indicates whether the message containing the feature comes from the potential **B**etrayer or the potential **V**ictim. Positive features indicate that an exchange is more likely to be followed by immediate betrayal.

ior could have two intuitive explanations. On one hand, if the betrayer has planned the act in advance, politeness can be a strategy for deception. On the other hand, if the betrayer receives impolite requests, the value of the relationship can decrease, hastening a betrayal. We observe a similar dynamic for the average number of sentences per message sent by the betrayer; the feature is selected in both prediction tasks, but with opposite signs: more complex messages suggest that betrayal *will* happen, but *not right away*.

Studying language change as betrayal draws nearer uncovers effects that cannot be seen when looking at an entire friendship on average. For example, while excessively positive and polite partners are potential betrayers, people who have themselves suddenly become more polite are likely to become victims soon.

6 Relevance Beyond the Game

While discovering betrayal in one online game is a fun and novel task, our work connects with broader research in computational social science. In this section we describe how our work tackles issues that previous research on alliances, negotiation, and relationships have faced.

Cooperation and relationship building are an essential part of many activities: completing a group project, opening a business, or forging a new relationship. Each of these has been the subject of extensive research to understand what makes for effective relationships. Jung et al. (2012) show that a balanced working relationship is more likely to lead to better performance on tasks like pair programming. Imai and Gelfand (2010) show that understanding cultural norms improves negotiations. While these data are elicited in the lab, our “found” data are inexpensive because Diplomacy games are fun and inherently anonymized.

Romance is a popular and more real-world phenomenon that helps us understand how relationships form and dissolve. The research that tells us how language shapes early dating (Ranganath et al., 2009) and whether an existing relationship will continue (Slatcher and Pennebaker, 2006; Gottman and Levenson, 2000; Ireland et al., 2011) is formed from an incomplete sample of a course of a relationship. In contrast, a game of Diplomacy is shorter than almost any marriage and we have a complete account of all interactions throughout the entire relationship. Furthermore, this work focuses on the unilateral and asymmetric act of betrayal, rather than on the question of whether a relation will last.

Playing Diplomacy online is less tangible than a romantic relationship, but understanding trust and deception in online interactions (Riegelsberger et al., 2003; Newman et al., 2003; Hancock et al., 2007; Ott et al., 2011; Feng et al., 2012) is particularly important because the Internet marketplace is a growing driver of economic growth (Boyd, 2003). Diplomacy offers a setting in which deception occurs spontaneously in the context of complex relationships.

7 Conclusions

Despite people's best effort to hide it, the intention to betray can leak through the language one uses. Detecting it is not a task that we expect to be solvable with high accuracy, as that would entail a reliable "recipe" for avoiding betrayal in relationships; in this unrealistic scenario, betrayals would be unlikely to exist. While the effects we find are subtle, they bring new insights into the relation between linguistic balance and stability in relationships.

Although we use one game to develop our methodology, the framework developed here can be extended to be applied to a wide range of social interaction. Social dynamics in collaborative settings can bear striking similarities to those present in war games. For example, in Wikipedia "edit wars"—where attacks correspond to edit reverts—are common on issues relating to politics, religion, history and nationality, among others (Kittur et al., 2007). As in Diplomacy, Wikipedia editors form alliances, argue and negotiate about possible compromises. A challenge for future work is to find reliable linguistic cues that generalize well between such settings.

Abstract

The development and proliferation of social media services has led to the emergence of new approaches for surveying the population and addressing social issues. One popular application of social media data is health surveillance, e.g., predicting the outbreak of an epidemic by recognizing diseases and symptoms from text messages posted on social media platforms. In this paper, we propose a novel task that is crucial and generic from the viewpoint of health surveillance: estimating a subject (carrier) of a disease or symptom mentioned in a Japanese tweet. By designing an annotation guideline for labeling the subject of a disease/symptom in a tweet, we perform annotations on an existing corpus for public surveillance. In addition, we present a supervised approach for predicting the subject of a disease/symptom. The results of our experiments demonstrate the impact of subject identification on the effective detection of an episode of a disease/symptom. Moreover, the results suggest that our task is independent of the type of disease/symptom.

1 Introduction

Social media services, including Twitter and Facebook, provide opportunities for individuals to share their experiences, thoughts, and opinions. The wide use of social media services has led to the emergence of new approaches for surveying the population and addressing social issues. One popular application of social media data is flu surveillance, i.e., predicting the outbreak of influenza epidemics by detecting mentions of flu infections on social media platforms (Culotta, 2010; Lampos and Cristianini, 2010; Aramaki et al., 2011; Paul and Dredze, 2011; Signorini et al., 2011; Collier, 2012; Dredze et al., 2013; Gesualdo et al., 2013; Stoové and Pedrana, 2014).

Previous studies mainly relied on shallow textual clues in Twitter posts in order to predict the number of flu infections, e.g., the number of occurrences of specific keywords (such as “flu” or “influenza”) on Twitter. However, such a simple approach can lead to incorrect predictions. Broniatowski et al. (2013) argued that media attention increases chatter, i.e., the number of tweets that mention the flu without the poster being actually infected. Examples include, “I don’t wish the flu on anyone” and “A Harry Potter actor hospitalised after severe flu-like syndromes.” Lazer et al. (2014) reported large errors in Google Flu Trends (Carneiro and Mylonakis, 2009) on the basis of a comparison with the proportion of doctor visits for influenza-like illnesses.

Lamb et al. (2013) aimed to improve the accuracy of detecting mentions of flu infections. Their method trains a binary classifier to distinguish tweets reporting flu infections from those expressing concern or awareness about the flu, e.g., “Starting to get worried about swine flu.” Accordingly, they reported encouraging results (e.g., better correlations with CDC trends), but their approach requires supervision data and a lexicon (word class features) specially designed for the flu. Moreover, even though this method is a reasonable choice for improving the accuracy, it is not readily applicable to other types of diseases (e.g., dengue fever) and symptoms (e.g., runny nose), which are also important for public health (Velardi et al., 2014).

In this paper, we propose a more generalized task setting for public surveillance. In other words, our objective is to *estimate the subject (carrier) of a disease or symptom mentioned in a Japanese tweet.* More specifically, we are interested in determining who has a disease/symptom

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1660–1670,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

(if any) in order to examine whether the poster suffers from the disease or symptom. For example, given the sentence "I caught a cold," we would predict that the first person ("I," i.e., the poster) is the subject (carrier) of the cold. On the other hand, we can ignore the sentence, "The TV presenter caught a cold" only if we predict that the subject of the cold is the third person, who is at a different location from the poster.

Although the task setting is simple and intuitive, we identify several key challenges in this study.

1. **Novel task setting.** The task of identifying the subject of a disease/symptom is similar to predicate-argument structure (PAS) analysis for nominal predicates (Meyers et al., 2004; Sasano et al., 2004; Komachi et al., 2007; Gerber and Chai, 2010). However, these studies do not treat diseases (e.g., "influenza") and symptoms (e.g., "headache") as nominal predicates. To the best of our knowledge, this task has not been explored in natural language processing (NLP) thus far.

2. **Identifying whether the subject has a disease/symptom.** Besides the work on PAS analysis for nominal predicates, the most relevant work is PAS analysis for verb predicates. However, our task is not as simple as predicting the subject of the verb governing a disease/symptom-related noun. For example, the subject of the verb "beat" is the first person "I" in the sentence "I beat the flu," but this does not imply that the poster has the flu. At the same time, we can use a variety of expressions for indicating an infection, e.g., "I'm still sick!! This flu is just incredible...," "I can feel the flu bug in me," and "I tested positive for the flu."

3. **Omitted subjects.** We often come across tweets with omitted subjects, e.g., "Down with the flu feel" and "Thanks the flu for striking in hard this week" even in English tweets. Because the first person is omitted frequently, it is important to predict omitted subjects from the viewpoint of the application (public surveillance).

In this paper, we present an approach for identifying the subjects of various types of diseases and symptoms. The contributions of this paper are three-fold.

1. In order to explore a novel and general task setting, we design an annotation guideline for labeling a subject of a disease/symptom in a tweet, and we deliver annotations in an existing corpus for public surveillance. Further, we propose a method for predicting the subject of a disease/symptom by using the annotated corpus.

2. The experimental results show that the task of identifying subjects is independent of the type of diseases/symptom. We verify the possibility of transferring supervision data to different targets of diseases and symptoms. In other words, we verify that it is possible to utilize the supervision data for a particular disease/symptom to improve the accuracy of predicting subjects of another disease/symptom.

3. In addition, the experimental results demonstrate the impact of identifying subjects on improving the accuracy of the downstream application (identification of an episode of a disease/symptom).

The remainder of this paper is organized as follows. Section 2 describes the corpus used in this study as well as our annotation work for identifying subjects of diseases and symptoms. Section 3.1 presents our method for predicting subjects on the basis of the annotated corpus. Sections 3.2 and 3.3 report the performance of the proposed method. Section 3.4 describes the contributions of this study toward identifying episodes of diseases and symptoms. Section 4 reviews some related studies. Finally, Section 5 summarizes our findings and concludes the paper with a brief discussion on the scope for future work.

2 Corpus

2.1 Target corpus

We used a Japanese corpus for public surveillance of diseases and symptoms (Aramaki et al., 2011). The corpus targets seven types of diseases and symptoms: *cold*, *cough*, *headache*, *chill*, *runny nose*, *fever*, and *sore throat*. Tweets containing keywords for each disease/symptom were collected using the Twitter Search API: for example, tweets about *sore throat* were collected using the query "(sore OR pain) AND throat". Further,

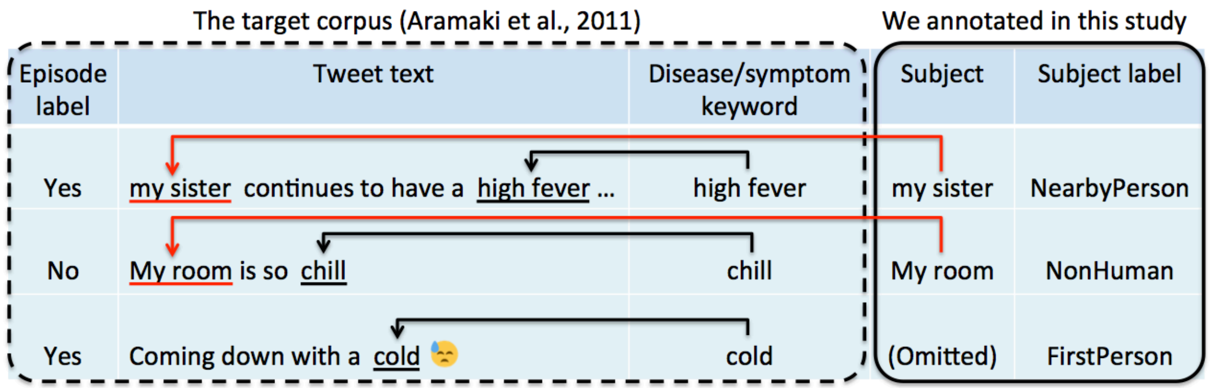

Figure 1: Examples of annotations of subject labels.

Subject label	Definition	Example
FirstPerson	The subject of the disease/symptom is the poster of the tweet.	I wish I have fever or something so that I don't have to go to school.
NearbyPerson	The subject of the disease/symptom is a person whom the poster can directly see or hear.	my sister continues to have a high fever...
FarawayPerson	The subject of the disease/symptom is a person who is at a different location from the poster.	@***** does sour stuff give you a headache?
NonHuman	The subject of the disease/symptom is not a person. Alternatively, the sentence does not describe a disease/symptom but a phenomenon or event related to the disease/symptom.	My room is so chill. But I like it.
None	The subject of the disease/symptom does not exist. Alternatively, the sentence does not mention an occurrence of a disease/symptom.	I hate buyin cold medicine cuz I never know which one to buy

Table 1: Definitions of subject labels and example tweets.

the corpus consists of 1,000 tweets for each disease/symptom besides *cold*, and 5,000 tweets for *cold*. The corpus was collected through whole years 2007-2008. This period was not in the A/H1N1 flu pandemic season.

An instance in this corpus consists of a tweet text (in Japanese) and a binary label (*episode label*, hereafter) indicating whether someone near the poster has the target disease/symptom[1]. A positive episode indicates an occurrence of the disease/symptom. In this study, we disregarded instances of *sore throat* in the experiments because most such instances were positive episodes[2].

2.2 Annotating subjects

In this study, we annotated the subjects of diseases and symptoms in the corpus described in Section 2.1. Specifically, we annotated the subjects in 500 tweets for each disease/symptom (except for *sore throat*). Thus, our corpus includes a total of 3,000 tweets in which the subjects of diseases and symptoms are annotated.

Figure 1 shows examples of annotations in this study. Episode labels, tweet texts, and disease/symptom keywords were annotated by Aramaki et al. (2011) in the corpus.

We annotated the subject labels of the diseases/symptoms in each tweet and identified those who had the target disease/symptom. The subject labels indicate those who have the corresponding disease/symptom; they are described in detail

[1] This label is positive if someone mentioned in the tweet is in the same prefecture as the poster. This is because the corpus was designed to survey the spread of a disease/symptom in every prefecture.

[2] In Japanese tweets, *sore throat* or *throat pain* mostly describes the health condition of the poster.

Label	FirstPerson	NearbyPerson	FarawayPerson	NonHuman	None	Total
# tweets	2,153	129	201	40	401	2,924
# explicit subjects	70 (3.3%)	112 (86.8%)	175 (87.1%)	38 (95.0%)	0 (0.0%)	395
# positive episodes	1,833	99	2	0	16	1,950
# negative episodes	320	30	199	40	385	974
Positive ratio	85.1%	76.7%	1.0%	0.0%	4.0%	66.7%

Table 2: Associations between subject labels and positive/negative episodes of diseases and symptoms.

herein.

In addition to the subject labels, we annotated the text span that indicates a subject. However, the subjects of diseases/symptoms are often omitted in tweet texts. Example 3 in Figure 1 shows a case in which the subject is omitted. The information as to whether the subject is omitted is useful for analyzing the difficulty in predicting the subject of a disease/symptom.

Table 1 lists the definitions of the subject labels with tweeted examples. Because it is important to distinguish the primary information (information that is observed and experienced by the poster) from the secondary information (information that is broadcasted by the media) for the application of public surveillance, we introduced five labels: FirstPerson, NearbyPerson, FarawayPerson, NonHuman, and None.

FirstPerson is assigned when the subject of the disease/symptom is the poster of the tweet. When annotating this label, we ignore the modality or factuality of the event of acquiring the disease/symptom. For example, the example tweet corresponding to FirstPerson in Table 1 does not state that the poster has a fever but only that the poster has a desire to have a fever. Although such tweets may be inappropriate for identifying a disease/symptom, this study focuses on identifying the possessive relation between a subject and a disease/symptom. The concept underlying this decision is to divide the task of public surveillance into several sub-tasks that are sufficiently generalized for use in other NLP applications. Therefore, the task of analyzing the modality lies beyond of scope of this study (Kitagawa et al.,). We apply the same criterion to the labels NearbyPerson, FarawayPerson, and NonHuman.

NearbyPerson is assigned when the subject of the disease/symptom is a person whom the poster can directly see or hear. In the original corpus (Aramaki et al., 2011), a tweet is labeled as positive if the person having a disease/symptom is in the same prefecture as the poster. However, it is extremely difficult for annotators to judge from a tweet whether the person mentioned in the tweet is in the same prefecture as the poster. Nevertheless, we would like to determine from a tweet whether the poster can directly see or hear a patient. For these reasons, we introduced the label NearbyPerson in this study.

FarawayPerson applies to all cases in which the subject is a human, but not classified as FirstPerson or NearbyPerson. This category frequently includes tweeted replies, as in the case of the example corresponding to FarawayPerson in Table 1. We assign FarawayPerson to such sentences because we are unsure whether the subject of the symptom is a person whom the poster can physically see or hear.

NonHuman applies to cases in which the subject is not a human but an object or a concept. For example, a sentence with the phrase "My room is so chill" is annotated with this label.

None indicates that the sentence does not mention a target disease or symptom even though it includes a keyword for the disease/symptom.

In order to investigate the inter-annotator agreement, we sampled 100 tweets of *cold* at random, and examined the Cohen's κ statistic by two annotators. The κ statistic is 0.83, indicating a high level agreement (Carletta, 1996).

Table 2 reports the distribution of subject labels in the corpus annotated in this study. When the subject of a disease/symptom is FirstPerson, only 3.3% of the tweets have explicit textual clues for the first person[3]. In other words, when the subject of a disease/symptom is FirstPerson, we rarely find textual clues in tweets. In contrast, there is a greater likelihood of finding explicit clues for NearbyPerson, FarawayPerson, and NonHuman subjects.

Table 2 also lists the probability of positive episodes given a subject label, i.e., the positive ratio. The likelihood of a positive episode

[3] This ratio may appear to be extremely low, but it is very common to omit first person pronouns in Japanese sentences.

is extremely high when the subject label of a disease/symptom is FirstPerson (85.1%) or NearbyPerson (76.7%). In contrast, FarawayPerson, NonHuman, and None subjects represent negative episodes (less than 5.0%). These facts suggest that identifying subject labels can improve the accuracy of predicting patient labels for diseases and symptoms.

3 Experiment

3.1 Subject classifier

We built a classifier to predict a subject label for a disease/symptom mentioned in a sentence by using the corpus described in the previous section. In our experiment, we merged training instances having the label NonHuman with those having the label None because the number of NonHuman instances was small and we did not need to distinguish the label NonHuman from the label None in the final episode detection task. Thus, the classifier was trained to choose a subject label from among FirstPerson, NearbyPerson, FarawayPerson, and None. We discarded instances in which multiple diseases or symptoms are mentioned in a tweet as well as those in which multiple subjects are associated with a disease/symptom in a tweet. In addition, we removed text spans corresponding to retweets, replies, and URLs; the existence of these spans was retained for firing features. We trained an L2-regularized logistic regression model using Classias 1.1[4]. The following features were used.

Bag-of-Words (BoW). Nine words included before and after a disease/symptom keyword. We split a Japanese sentence into a sequence of words using a Japanese morphological analyzer, MeCab (ver.0.98) with IPADic (ver.2.7.0)[5].

Disease/symptom word (Keyword). The surface form of the disease/symptom keyword (e.g. “cold” and “headache”).

2,3-gram. Character-based bigrams and trigrams before and after the disease/symptom keyword within a window of six letters.

URL. A boolean feature indicating whether the tweet includes a URL.

Feature	Micro F1	Macro F1
BoW (baseline)	77.2	42.2
BoW + Keyword	81.9	53.6
BoW + 2,3-gram	79.1	46.1
BoW + URL	77.3	42.7
BoW + RT & reply	80.0	47.1
BoW + NearWord	77.6	46.8
BoW + FarWord	77.3	42.7
BoW + Title word	77.1	42.7
BoW + Tweet length	77.4	43.3
BoW + Is-head	77.6	43.5
All features	**84.0**	**61.8**

Table 3: Performance of the subject classifier.

RT & reply. Boolean features indicating whether the tweet is a reply or a retweet.

Word list for NearbyPerson (NearWord). A boolean feature indicating whether the tweet contains a word that is included in the lexicon for NearbyPerson. We manually collected words that may refer to a person who is near the poster, e.g., “girlfriend,” “sister,” and “staff.” The NearWord list includes 97 words.

Word list for FarawayPerson (FarWord). A boolean feature indicating whether the tweet contains a word that is included in the lexicon for FarawayPerson. Similarly to the NearWord list, we manually collected 50 words (e.g., “infant”) for compiling this list.

Title word. A boolean feature indicating whether the tweet contains a title word accompanied by a proper noun. The list of title words includes expressions such as “さん” and “くん” (roughly corresponding to “Ms” and “Mr”) that describe the title of a person.

Tweet length. Three types of boolean features that fire when the tweet has less than 11 words, 11 to 30 words, and more than 30 words, respectively.

Is-head. A boolean feature indicating whether the word following a disease/symptom keyword is a noun. In Japanese, when the word following a disease/symptom keyword is a noun, the disease/symptom keyword is unlikely to be the head of the noun phrase.

Correct/predicted label	FirstPerson		Nearby.		Faraway.		None		Total
FirstPerson	**2,084**	**(−15)**	6	(+1)	25	(+21)	38	(−7)	2,153
NearbyPerson	80	(−20)	**41**	**(+29)**	4	(−5)	4	(−4)	129
FarawayPerson	88	(−49)	8	(+2)	**89**	**(+46)**	16	(+1)	201
None	174	(−158)	2	(+1)	10	(+4)	**255**	**(+153)**	441
Total predictions	2,426	(−237)	57	(+33)	128	(+66)	313	(+137)	2,924

Table 4: Confusion matrix between predicted and correct subject labels.

3.2 Evaluation of the subject classifier

Table 3 reports the performance of the subject classifier measured via five-fold cross validation. We used 3,000 tweets corresponding to six types of diseases and symptoms for this experiment. The Bag-of-Words (BoW) feature achieved micro and macro F1 scores of 77.2 and 42.2, respectively. When all the features were used, the performance was boosted, i.e., micro and macro F1 scores of 84.0 and 61.8 were achieved. Features such as disease/symptom keywords, retweet & reply, and the lexicon for NearbyPerson were particularly effective in improving the performance.

The surface form of the disease/symptom keyword was found to be the most effective feature in this task, the reasons for which are discussed in Section 3.3.

A retweet or reply tweet provides evidence that the poster has interacted with another person. Such meta-linguistic features may facilitate semantic and discourse analysis in web texts. However, this feature is mainly limited to tweets.

The lexicon for NearbyPerson provided an improvement of 4.6 points in terms of the macro F1 score. This is because (i) around 90% of the subjects for NearbyPerson were explicitly stated in the tweets and (ii) the vocabulary of people near the poster was limited.

Table 4 shows the confusion matrix between the correct labels and the predicted labels. The diagonal elements (in bold face) represent the number of correct predictions. The figures in parentheses denote the number of instances for which the baseline feature set made incorrect predictions, but the full feature set made correct predictions. For example, the classifier predicted NearbyPerson subjects 48 times; 34 out of 48 predictions were correct. The full feature set increased the number of correct predictions by 22.

From the diagonal elements (in bold face), we can confirm that the number of correct predictions increased significantly from the baseline case, except for FirstPerson. One of the reasons for the improved accuracy of None prediction is the imbalanced label ratio of each disease/symptom. None accounts for 14% of the entire corpus, but only 5% of the *runny nose* corpus. On the other hand, None accounts for more than 30% of the *chill* corpus. The disease/symptom keyword feature adjusts the ratio of the subject labels for each disease/symptom, and the accuracy of subject identification is improved.

As compared to the baseline case, the number of FirstPerson cases that were predicted as FarawayPerson increased. Such errors may be attributed to the reply feature. According to our annotation scheme, FarawayPerson contains many reply tweets. Because the reply & retweet features make the second-largest contribution in our experiment, the subject classifier tends to output FarawayPerson if the tweet is a reply.

Table 5 summarizes the subject classification results comparing the case in which the subject of a disease/symptom exists in the tweet with that in which the subject does not exist. The prediction of FirstPerson is not affected by the presence of the subject because FirstPerson subjects are often omitted (especially in Japanese tweets). The prediction of NearbyPerson and FarawayPerson is difficult if the subject is not stated explicitly. In contrast, it is easy to correctly predict None even though the subject is not expressed explicitly. This is because it is not easy to capture a variety of human-related subjects using Bag-of-Words, N-gram, or other simple features used in this experiment.

3.3 Dependency on diseases/symptoms

The experiments described in Section 3.2 use training instances for all types of diseases and symptoms. However, each disease/symptom may have a set of special expressions for describing the state of an episode. For example, even though “catch a cold” is a common expression, we cannot

Subject	FirstPerson	NearbyPerson	FarawayPerson	None
# Explicit	66/69 (95.7%)	40/112 (35.7%)	79/174 (45.4%)	1/26 (3.8%)
# Omitted	2,018/2,084 (96.8%)	1/17 (5.9%)	10/27 (37.0%)	254/415 (61.2%)
# Total	2,084/2,153 (96.8%)	41/129 (31.8%)	89/201 (44.3%)	255/441 (57.8%)

Table 5: Subject classification results comparing explicit subjects with omitted subjects.

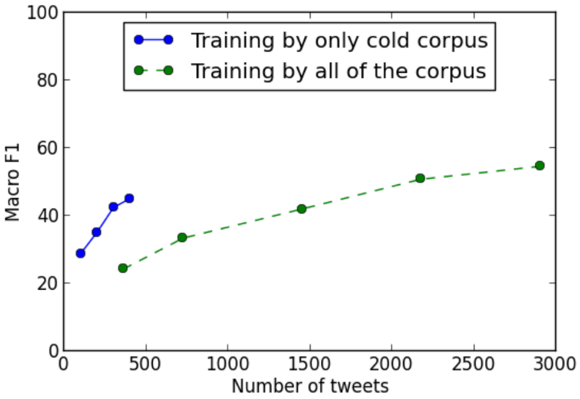

Figure 2: F1 scores for predicting subjects of *cold* with different types and sizes of training data.

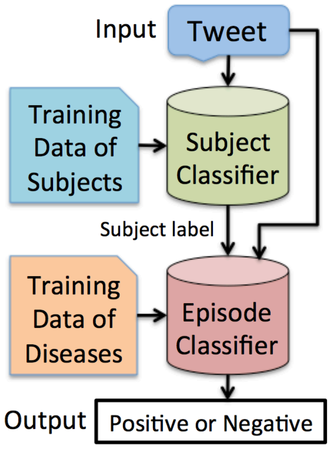

Figure 3: Overall structure of the system.

say "catch a fever" by combining the verb "catch" and the disease "fever." The corpus developed in Section 2.2 can be considered as the supervision data for weighting linguistic patterns that connect diseases/symptoms with their subjects. This viewpoint raises another question: how strongly does the subject classifier depend on specific diseases and symptoms?

In order to answer this question, we compare the performance of recognizing subjects of *cold* when using the training instances for all types of diseases and symptoms with that when using only the training instances for the target disease/symptom. Figure 2 shows the macro F1 scores with all training instances (dotted line) and with only *cold* training instances (solid line)[6].

In this case, training with *cold* instances is naturally more efficient than training with other types of diseases/symptoms. When trained with 400 instances only for *cold*, the classifier achieved an F1 score of 45.2. Moreover, we confirmed that adding training instances for other types of diseases/symptoms improved the F1 score: the maximum F1 score was 54.6 with 2,900 instances. These results indicate the possibility of building a subject classifier that is independent of specific diseases/symptoms but applicable to a variety of diseases/symptoms. We observed a similar tendency for other types of diseases/symptoms.

3.4 Contributions to the episode classifier

The ultimate objective of this study is to detect outbreaks of epidemics by recognizing diseases and symptoms. In order to demonstrate the contributions of this study, we built an *episode classifier* that judges whether the poster or a person close to the poster suffers from a target disease/symptom. Figure 3 shows the overall structure of the system. Given a tweet, the system predicts the subject label for a disease/symptom, and integrates the predicted subject label as a feature for the episode classifier. In addition to the features used in Aramaki et al. (2011), we included binary features, each of which corresponds to a subject label predicted by the proposed method. We trained an L2-regularized logistic regression model using Classias 1.1.

Table 6 summarizes the performance of the episode classifier with different settings: without subject labels (baseline), with predicted subject la-

[6] For the solid line, we used 500 instances of "cold" as a test set, and we plotted the learning curve by increasing the number of training instances for other diseases/symptoms. For the dotted line, we fixed 100 instances for a test set, and we plotted the learning curve by increasing the number of training instances (100, 200, 300, and 400).

Setting	Cold	Cough	Headache	Chill	Runny nose	Fever	Macro F1
Baseline (BL)	84.4	88.5	90.8	75.9	89.2	78.1	84.5
BL + predicted subjects	85.0	88.3	90.7	81.4	89.4	80.2	85.8
BL + gold-standard subjects	87.7	92.6	93.5	88.5	91.4	88.6	90.4

Table 6: Performance of the episode classifier.

bels , and with gold-standard subject labels. We measured the F1 scores via five-fold cross validation[7]. Further, we confirmed the contribution of subject label prediction, which achieved an improvement of 1.3 points over the baseline method (85.8 vs. 84.5). When using the gold-standard subject labels, the episode classifier achieved an improvement of 5.9 points. These results highlight the importance of recognizing a subject who has a disease/symptom using the episode classifier.

Considering the F1 score for each disease/symptom, we observed the largest improvement for *chill*. This is because the Japanese word for "chill" has another meaning *a cold air mass*. When the word "chill" stands for *a cold air mass* in a tweet, the subject for "chill" is NONE. Therefore, the episode classifier can disambiguate the meaning of "chill' on the basis of the subject labels. Similarly, the subject labels improved the performance for "fever".

In contrast, the subject labels did not improve the performance for *headache* and *runny nose* considerably. This is because the subjects for these symptoms are mostly FIRSTPERSON, as we seldom mention the symptoms of another person in such cases. In other words, the episode classifier can predict a positive label for these symptoms without knowing the subjects of these symptoms.

4 Related Work

4.1 Twitter and NLP

NLP researchers have addressed two major directions for Twitter: adapting existing NLP technologies to noisy texts and extracting useful knowledge from Twitter. The former includes improving the accuracy of part-of-speech tagging (Gimpel et al., 2011) and named entity recognition (Plank et al., 2014), as well as normalizing ill-formed words into canonical forms (Han and Baldwin, 2011; Chrupała, 2014). Even though we did not incorporate the findings of these studies, they could be beneficial to our work in the future.

The latter has led to the development of several interesting applications besides health surveillance. These include prediction of future revenue (Asur and Huberman, 2010) and stock market trends (Si et al., 2013), mining of public opinion (O'Connor et al., 2010), event extraction and summarization (Sakaki et al., 2010; Thelwall et al., 2011; Marchetti-Bowick and Chambers, 2012; Shen et al., 2013; Li et al., 2014a), user profiling (Bergsma et al., 2013; Han et al., 2013; Li et al., 2014b; Zhou et al., 2014), disaster management (Varga et al., 2013), and extraction of common-sense knowledge (Williams and Katz, 2012). Our work can directly contribute to these applications, e.g., sentiment analysis, user profiling, event extraction, and disaster management.

4.2 Semantic analysis for nouns

Our work can be considered as a semantic analysis that identifies an argument (subject) for a disease/symptom-related noun. NomBank (Meyers et al., 2004) provides annotations of noun arguments in a similar manner to PropBank (Palmer et al., 2005), which provides annotations of verbs. In NomBank, nominal predicates and their arguments are identified: for example, ARG0 (typically, subject or agent) is "customer" and ARG1 (typically, objects, patients, themes) is "issue" for the nominal predicate "complaints" in the sentence "There have been no customer complaints about that issue." Gerber and Chai (2010) improved the coverage of NomBank by handling implicit arguments. Some studies have addressed the task of identifying implicit and omitted arguments for nominal predicates in Japanese (Komachi et al., 2007; Sasano et al., 2008).

Our work shares a similar goal with the abovementioned studies, i.e., identifying an implicit ARG0 for a disease and symptom. However, these studies do not regard a disease/symptom as a nominal predicate because they consider verb nominalizations as nominal predicates. In addition,

[7] For the "predicted" setting, first, we predicted the subject labels in a similar manner to five-fold cross validation, and we used the predicted labels as features for the episode classifier.

they use a corpus that consists of newswire text, the writing style and word usage of which differ considerably from those of tweets. For these reasons, we proposed a novel task setting for identifying subjects of diseases and symptoms, and we built an annotated corpus for developing the subject classifier and analyzing the challenges of this task.

5 Conclusion

In this paper, we presented a novel approach to the identification of subjects of various types of diseases and symptoms. First, we constructed an annotated corpus based on an existing corpus for public surveillance. Then, we trained a classifier for predicting the subject of a disease/symptom. The results of our experiments showed that the task of identifying the subjects is independent of the type of disease/symptom. In addition, the results demonstrated the contributions of our work toward identifying an episode of a disease/symptom from a tweet.

In the future, we plan to consider a greater variety of diseases and symptoms in order to develop applications for public health, e.g., monitoring the mental condition of individuals. Thus, we can not only improve the accuracy of subject identification but also enhance the generality of this task.

Acknowledgments

This study was partly supported by Japan Science and Technology Agency (JST). We are grateful to the anonymous referees for their constructive reviews. We are also grateful to Takayuki Sato and Yasunobu Asakura for their annotation efforts. This study was inspired by Project Next NLP[8], a workshop for error analysis on various NLP tasks. We appreciate Takenobu Tokunaga, Satoshi Sekine, and Kentaro Inui for their helpful comments.

Abstract

In this paper, we model conversational roles in terms of distributions of turn level behaviors, including conversation acts and stylistic markers, as they occur over the whole interaction. This work presents a lightly supervised approach to inducing role definitions over sets of contributions within an extended interaction, where the supervision comes in the form of an outcome measure from the interaction. The identified role definitions enable a mapping from behavior profiles of each participant in an interaction to limited sized feature vectors that can be used effectively to predict the teamwork outcome. An empirical evaluation applied to two Massive Open Online Course (MOOCs) datasets demonstrates that this approach yields superior performance in learning representations for predicting the teamwork outcome over several baselines.

1 Introduction

In language technologies research seeking to model conversational interactions, modeling approaches have aimed to identify conversation acts (Paul, 2012; Wallace et al., 2013; Bhatia et al., 2014) on a per turn basis, or to identify stances (Germesin and Wilson, 2009; Mukherjee et al., 2013; Piergallini et al., 2014; Hasan and Ng, 2014) that characterize the nature of a speaker's orientation within an interaction over several turns. What neither of these two perspectives quite offer is a notion of a conversational role. And yet, conversational role is a concept with great utility in current real world applications where language technologies may be applied.

Important teamwork is achieved through collaboration where discussion is an important medium for accomplishing work. For example, distributed work teams are becoming increasingly the norm in the business world where creating innovative products in the networked world is a common practice. This work requires the effective exchange of expertise and ideas. Open source and open collaboration organizations have successfully aggregated the efforts of millions of volunteers to produce complex artifacts such as GNU/Linux and Wikipedia. Discussion towards decision making about how to address problems that arise or how to extend work benefit from effective conversational interactions. With a growing interest in social learning in large online platforms such as Massive Open Online Courses (MOOCs), students form virtual study groups and teams to complete a course project, and thus may need to coordinate and accomplish the work through discussion. In all such environments, discussions serve a useful purpose, and thus the effectiveness of the interaction can be measured in terms of the quality of the resulting product.

We present a modeling approach that leverages the concept of latent conversational roles as an intermediary between observed discussions and a measure of interaction success. While a stance identifies speakers in terms of their positioning with respect to one another, roles associate speakers with rights and responsibilities, associated with common practices exhibited by performers of that role within an interaction, towards some specific interaction outcome. That outcome may be achieved through strategies characterized in terms of conversation acts or language with particular stylistic characteristics. However, individual acts by themselves lack the power to achieve a complex outcome. We argue that roles make up for this decontextualized view of a conversational contribution by identifying distributions of conversation acts and stylistic features as behavior profiles indicative of conversational roles. These

profiles have more explanatory power to identify strategies that lead to successful outcomes.

In the remainder of the paper we first review related work that lays the foundation for our approach. Then we describe a series of role identification models. Experimental results are analyzed quantitatively and qualitatively in Section 4, followed by conclusions and future work.

2 Related Work

The concept of *social role* has long been used in social science fields to describe the intersection of behavioral, symbolic, and structural attributes that emerge regularly in particular contexts. Theory on coordination in groups and organizations emphasizes role differentiation, division of labor and formal and informal management (Kittur and Kraut, 2010). However, identification of roles as such has not had a corresponding strong emphasis in the language technologies community, although there has been work on related notions. For example, there has been much previous work modeling disagreement and debate framed as stance classification (Thomas et al., 2006; Walker et al., 2012). Another similar line of work studies the identification of personas (Bamman et al., 2013; Bamman et al., 2014) in the context of a social network, e.g. celebrity, newbie, lurker, flamer, troll and ranter, etc, which evolve through user interaction (Forestier et al., 2012).

What is similar between stances and personas on the one hand and roles on the other is that the unit of analysis is the person. On the other hand, they are distinct in that stances (e.g., liberal) and personas (e.g., lurker) are not typically defined in terms of what they are meant to accomplish, although they may be associated with kinds of things they do. Teamwork roles are defined in terms of what the role holder is meant to accomplish.

The notion of a natural outcome associated with a role suggests a modeling approach utilizing the outcome as light supervision towards identification of the latent roles. However, representations of other notions such as stances or strategies can similarly be used to predict outcomes. Cadilhac et al. maps strategies based on verbal contributions of participants in a win-lose game into a prediction of exactly which players, if any, trade with each other (Cadilhac et al., 2013). Hu et al. (Hu et al., 2009) predict the outcome of featured article nominations based on user activeness, discussion consensus and user co-review relations. In other work, the authors of (Somasundaran and Wiebe, 2009) adopt manually annotated characters and leaders to predict which participants will achieve success in online debates. The difference is the interpretation of the latent constructs. The latent construct of a role, such as team leader, is defined in terms of a distribution of characteristics that describe how that role should ideally be carried out. However, in the case of stances, the latent constructs are learned in order to distinguish one stance from another or in order to predict who will win. This approach will not necessarily offer insight into what marks the most staunch proponents of a stance, but instead distinguish those proponents of a stance who are persuasive from those who are not.

Roles need not only be identified with the substance of the text uttered by role holders. Previous work discovers roles in social networks based on the network structure (Hu and Liu, 2012; Zhao et al., 2013). Examples include such things as mixed membership stochastic blockmodels (MMSB) (Airoldi et al., 2008), similar unsupervised matrix factorization methods (Hu and Liu, 2012), or semi-supervised role inference models (Zhao et al., 2013). However, these approaches do not standardly utilize an outcome as supervision to guide the clustering.

Many open questions exist about what team roles and in what balance would make the ideal group composition (Neuman et al., 1999), and how those findings interact with other contextual factors (Senior, 1997; Meredith Belbin, 2011). Thus, a modeling approach that can be applied to new contexts in order to identify roles that are particularly valuable given the context would potentially have high practical value.

3 Role Identification Models

The context of this work is team based MOOCs using the NovoEd platform. In this context, we examine the interaction between team members as they work together to achieve instructional goals in their project work. Our modeling goal is to identify behavior profiles that describe the emergent roles that team members take up in order to work towards a successful group grade for their team project. Identification of effective role based behavior profiles would enable work towards supporting effective team formation in subsequent work. This approach would be similar to prior work where constraints that describe successful teams were used to group participants into teams in which each member's expertise is modeled so that an appropriate mixture of expertise can be achieved in the assignment (Anagnostopoulos et al., 2010).

In this section, we begin with an introduction of some basic notations. Then we present an iterative model, which involves two stages: teamwork quality prediction and student role matching. Furthermore, we generalize this model to a constrained version which provides more interpretable role assignments. In the end, we describe how to construct student behavior representations from their teamwork collaboration process.

3.1 Notation

Suppose we have C teams where students collaborate to finish a course project together. The number of students in the j-th team is denoted as N_j, $(1 \leq j \leq N_j)$. There are K roles across C teams that we want to identify, where $1 \leq K \leq N_j, \forall j \in [1, C]$. That is, the number of roles is smaller than or equal to the number of students in a team, which means that each role should have one student assigned to it, but not every student needs to be assigned to a role. Each role is associated with a weight vector $W_k \in \mathcal{R}^D$ to be learned, $1 \leq k \leq K$ and D is the number of dimensions. Each student i in a team j is associated with a behavior vector $B_{j,i} \in \mathcal{R}^D$. The measurement of teamwork quality is denoted as Q_j for team j, and $\hat{Q}_j$ is the predicted quality. Here, $\hat{Q}_j$ is determined by the inner product of the behavior vectors of students who are assigned to different roles and the corresponding weight vectors.

Teamwork Role Identification Our goal is to find a proper teamwork role assignment that positively contributes to the collaboration outcome as much as possible.

3.2 Role Identification

Here we describe our role identification model. Our role identification process is iterative and involves two stages. The first stage adjusts the weight vectors to predict the teamwork quality, given a fixed role assignment that assumes students are well matched to roles; the second stage iterates the possible assignments and finds a matching to maximize our objective measure. The two stages run iteratively until both role assignment and teamwork quality prediction converge.

Figure 1: Weighted Bipartite Graph for a Team

Teamwork Quality Prediction: Given the identified role assignment, i.e. we know who is assigned to which roles in a team, the focus is to accurately predict the teamwork quality under this role assignment. $p_{j,k}$ refers to the student who is assigned to role k in team j. We minimize the following objective function to update the role weight vector W:

$$\min_{W} \frac{1}{2} \sum_{j=1}^{C} (Q_j - \sum_{k=1}^{K} {W_k}^T \cdot B_{j,p_{j,k}}) + \lambda \cdot \|W\|^2 \quad (1)$$

Here, λ is the regularization parameter; large λ leads to higher complexity penalization. To give the optimal solution to Equation 1, which is a classical ridge regression task (Hoerl and Kennard, 2000), we can easily compute the optimal solution by its closed form representation, as shown in the Algorithm 1.

Matching Members to Roles: Once the weight vector W is updated, we iterate over all the possible assignments and find the best role assignment, where the goal is to maximize the predicted teamwork quality since we want our assignment of students and roles to be associated with improvement in the quality of teamwork. The complexity of brute-force enumeration of all possible role assignments is exponential. To avoid such an expensive computational cost, we design a weighted bipartite graph and apply a maximum weighted matching algorithm (Ravindra et al., 1993) to find the best matching under the objective of maximizing $\sum_{j=1}^{C} \hat{Q}_j$. Because this objective is a summation, we can further separate it into C iso-

Algorithm 1: Role Identification

```
Heuristicly initialize the role assignment $p_{j,k}$
while assignments have not converged do
    // Teamwork Quality Prediction
    $X \leftarrow$ a $C \times (K \cdot D)$ matrix
    for $j = 1$ to $C$ do
        $X_{j,*} \leftarrow (B_{j,p_{j,1}}, B_{j,p_{j,2}}, \ldots, B_{j,p_{j,K}})$
    // optimal solution to Eq. 1
    $(W_1, \ldots, W_C) \leftarrow (X^T X + \lambda I)^{-1} X^T Q$
    // Student and Role Matching
    // maximize $\sum_j \hat{Q}_j$
    for $j = 1$ to $C$ do
        $(p_{j,*}) \leftarrow$ maximum weighted bipartite
        matching on Figure  1
```

lated components for C teams by maximizing each $\hat{Q}_j$. For each team, a weighted bipartite graph is created as specified in Figure 1. By applying the maximum weighted matching algorithm on this graph, we can obtain the best role assignment for each team.

The two stage role identification model is solved in detail in Algorithm 1.

3.3 Role Identification with Constraints

The above role identification model puts no constraints on the roles that we want to identify in teamwork. This might result in more effort to explain how different roles collaborate to produce the teamwork success. Therefore, we introduce a constrained role identification model, which is able to integrate external constraints on roles. For example, we can require our extracted role set to contain a role that makes a positive contribution to the project success and a role that contributes relatively negatively, instead of extracting several generic roles. To address such constraints, in the stage of teamwork quality prediction, we reformulate the Equation 2 as follows:

$$
\begin{aligned}
L = \frac{1}{2} \sum_{j=1}^{C} (Q_j - \sum_{k=1}^{K} {W_k}^T \cdot B_{j,p_{j,k}}) + \lambda \|W\|^2 \\
- \mu_+ \sum_{k \in S_+} \sum_{d=1}^{D} log(W_{kd}) \\
- \mu_- \sum_{k \in S_-} \sum_{d=1}^{D} log(-W_{kd})
\end{aligned} \tag{2}
$$

Algorithm 2: Identification with Constraints

```
Heuristicly initialize the role assignment $p_{j,k}$
while assignments have not converged do
    // Teamwork Quality Prediction
    $X \leftarrow$ a $C \times (K \cdot D)$ matrix
    for $j = 1$ to $C$ do
        $X_j \leftarrow (B_{j,p_{j,1}}, B_{j,p_{j,2}}, \ldots, B_{j,p_{j,K}})$
    // gradient descent solution to
       Eq. 2
    $\mu_+, \mu_- \leftarrow$ large enough values
    while $\mu_+, \mu_- > \epsilon$ do
        while not converge do
            for $k = 1$ to $K$ do
                $W_k \leftarrow W_k - \eta \cdot \frac{\partial L}{\partial W_k}$
        $\mu_+ \leftarrow \theta \cdot \mu_+$
        $\mu_- \leftarrow \theta \cdot \mu_-$
    // Students and Roles Matching
    // maximize $\sum_j \hat{Q}_j$
    for $j = 1$ to $C$ do
        $(p_{j,*}) \leftarrow$ maximum weighted bipartite
        matching on Figure 1
```

The external constraints are handled by the log barrier terms (Ahuja et al., 1993). Here, μ_+ and μ_- are positive parameters used to penalize the violation of role constraints. S_+ is the set of roles that we want to assign students who contribute positively to the group outcome (i.e. above average level), and S_- contains the roles that we want to capture students who contribute negatively to the group outcome (i.e. below average level). The solving of Equation 2 cannot directly apply the previous ridge regression algorithm, thus we use the Interior Point Method (Potra and Wright, 2000) to solve it. The detailed procedure is illustrated in Algorithm 2, where the θ is a constant to control the shrinkage and η is the learning rate.

3.4 Behavior Construction

One essential component in our teamwork role identification models is the student behavior representation. To some extent, a proper behavior representation is essential for facilitating the interpretation of identified roles. We construct the representation of student behavior from the following feature types:

Team Member Behaviors: How a team functions can be reflected in their team communication messages. To understand how students collaborate

Type	Behavior Definition	Example Messages
Team Building	Invite or accept users to join the group	*Lauren, We would love to have you. Jill and I are both ESL specialists in Boston.*
Task Management	Initiate a task or assign subtask to a team member	*Housekeeping Task 3 is optional but below are the questions I summarize and submit for our team.*
Collaboration	Collaborate with teammates, provide help or feedback	*I figured out how to use the Google Docs. Let's use it to share our lesson plans.*

Table 1: Three Different Types of Team Member Behaviors

to contribute to teamwork success, we identified three main team member behaviors based on messages sent between team members as shown in Table 1. These annotations, which came from prior qualitative work analysing discussion contributions in the same dataset (Wen et al., 2015), are used to define component behaviors in this work. We design four variables to characterize the above collaboration behaviors:

1. *Collaboration*: the number of Collaboration messages sent by this team member.

2. *Task Management*: the number of Task Management messages sent by this team member.

3. *Team Building*: the number of Team Building messages sent by this team member.

4. *Other Strategies*: the number of messages that do not belong to the listed behavior categories.

Communication Languages: Teams that work successfully typically exchange more knowledge and establish good social relations. To capture such evidence that is indicated in the language choice and linguistic styles of each team member, we design the following features:

5. *Personal Pronouns*: the proportion of first person and second person pronouns.

6. *Negation*: counts of negation words.

7. *Question Words*: counts of question related words in the posts, e.g. why, what, question, problem, how, answer, etc.

8. *Discrepancy*: number of occurrences of words, such as should, would, could, etc as defined in LIWC (Tausczik and Pennebaker, 2010).

9. *Social Process*: number of words that denote social processes and suggest human interaction, e.g. talking, sharing, etc.

10. *Cognitive Process*: number of occurrences of words that reflect thinking and reasoning, e.g. cause, because, thus, etc.

11-14. *Polarity*: four variables that measure the portion of Positive, Negative, Neutral, Both polarity words (Wilson et al., 2005) in the posts.

15-16. *Subjectivity*: two count variables of occurrences of Strong Subjectivity words and Weak Subjectivity words.

Activities: We also introduce several variables to measure the activeness level of team members.

17-18. *Messages*: two variables that measure the total number of messages sent, and the number of tokens contained in the messages.

19-20. *Videos*: the number of videos a student has watched and total duration of watched videos.

21. *Login Times*: times that a student logins to the course.

4 Experiments

In this section, we begin with the dataset description, and then we compare our models with several competitive baselines by performing 10-fold cross validation on two MOOCs, followed by a series of quantitative and qualitative analyses.

4.1 Dataset

Our datasets come from a MOOC provider NovoEd, and consist of two MOOC courses. Both courses are teacher professional development courses about Constructive Classroom Conversations; one is in elementary education and another is about secondary education. Students in a NovoEd MOOC have to initiate or join a team in the beginning of the course. A NovoEd team homepage consists of blog posts, comments and other content shared within the group. The performance measure we use is the final team project score, which is in the range of 0 to 40. There are 57 teams (163 students) who survived until the end in the Elementary education course, and 77 teams (262 students) who survived for the Secondary course. The surviving teams are the ones in which none of the team members dropped out of the course, and who finished all the course requirements. For the purpose of varying teamwork roles K, we only keep the teams with at least 3 members. Self-identified team leader are labeled in the dataset.

4.2 Baselines

We propose several baselines to extract possible roles and predict the teamwork quality for comparison with our models. Preprocessing is identical for baselines as for our approach.

Top K Worst/Best: The worst performing student is often the bottleneck in a team, while the success of a team project largely depends on the outstanding students. Therefore, we use the top K worst/best performing students as our identified K roles. Their behavior representation are then used to predict the teamwork quality. The performing scores are only accessible after the course.

K-Means Clustering: Students who are assigned to the same roles tend to have similar activity profiles. To capture the similarities of student behavior, we adopt a clustering method to group students in a team into K clusters, and then assign students to roles based on their distances to the centroid of clusters. Prediction is then performed on the basis of those corresponding behavior vectors. Here, we use K-Means method for clustering. That is, each cluster is a latent representation of a role and each student is assigned to its closest cluster (role).

Leader: Leaders play important roles for the smooth functioning of teams, and thus might have substantial predictive power of team success. We input our role identification model with only the identified leader's behavior representation and conduct our role identification algorithm as illustrated in Algorithm 1. Each team in our courses have a predefined leader.

Average: The average representation of all team members is a good indication of team ability level and thus teamwork success. Here, we average all team members' behavior feature vectors and use that to predict the teamwork quality.

4.3 Teamwork Quality Prediction Results

The purpose of our role identification is to find a role assignment that minimizes the prediction error, thus we measure the performance of our models using RMSE (Rooted Mean Square Error). 10-fold Cross Validation is employed to test the overall performance. Table 2 and Table 3 presents the results of our proposed models and baselines on our two courses. Our role identification model shown in Algorithm 1, is denoted as **RI**. θ is set as 0.9 and we vary the role number K from 1 to 3 in order to assess the added value of each additional role over the first one.

4.3.1 Who Matters Most In a Team

If we set the number of roles K as 1, what will the role identification pick as the most important person to the teamwork outcome? From Table 2 and 3, we find that, RI performs better than Leader, and either Top K Best gives a good RMSE in one course and Top K Worst gives a good RMSE in the other course. This indicates that, the predefined leader is not always functioning well in facilitating the teamwork, thus we need a more fair mechanism to select the proper leading role. Besides, Top K worst has quite good performance on the Elementary course, which reflects that the success of a teamwork is to some extent dependent on the worst performing student in that team. The best performing student matters for the teamwork outcome on the Secondary course.

4.3.2 Multi-Role Collaboration

From Table 2 and 3, in the setting of K=3, RI achieved better results compared to Top K Best, Top K Worst and K-means methods. One explanation is that our RI model not only considers individual student's behaviors, but also takes into account the collaboration patterns through all teamwork. Besides, RI achieves better performance compared to our baselines as K becomes larger. We also noticed that Top K Best gives a quite good approximation to the teamwork quality on both courses. However, such performing scores that are used to rank students are not accessible until the course ends, and have high correlation with team score. Thus an advantage of our RI model is that it does not make use of that information. Compared with all other results, our RI has a good generalization ability, and achieves both a smallest RMSE of around 10 across both MOOCs.

4.4 Role Assignment Validation

We demonstrate the predicative power of our identified roles to team success above. In this part, we interpret the identified roles guided by different constraints in a team qualitatively, and show how different roles are distributed in a team, how each role contributes to teamwork, and how collaboration happens among the roles.

Table 2: RMSE Comparison of Different Methods on the Elementary Course

	Average	Leader	K-Means	K Worst	K Best	RI	RIC	RIC$_-$	RIC$_+$
K = 1	13.945	16.957	14.212	13.092	20.464	14.982	N/A	N/A	N/A
K = 2	N/A	N/A	13.160	13.428	15.591	11.581	N/A	N/A	N/A
K = 3	N/A	N/A	12.291	15.460	14.251	**9.517**	10.486	27.314	10.251

Table 3: RMSE Comparison of Different Methods on the Secondary Course

	Average	Leader	K-Means	K Worst	K Best	RI	RIC	RIC$_-$	RIC$_+$

4.4.1 Constraint Exploration

By incorporating constraints into the role identification process, we expect to guide the model using human intuition such that the results will be more interpretable, although the prediction error might increase because of the limitation of the search space. We present three alternative possible constrained models here. The **RIC** model emphasizes picking one best member, one worst member and another generic member, which is achieved by putting one role to S$_+$ and one to S$_-$ as defined in Equation 2. **RIC$_+$** aims at picking three best team members who collaborate to make the best contribution to the team success, achieved by putting three roles into S$_+$. Similarly, **RIC$_-$** rewards poorly performing students to contribute to teamwork quality, i.e. putting all roles into S$_-$.

Based on results shown in Table 2 and 3, we found that RIC$_+$ and RIC work similar as RI even though RI is slightly better. RIC$_-$ gives quite unsatisfying performance which shows that examining the behavior of a set of poorly performing students is not very helpful in predicting teamwork success. The comparison of RIC$_+$ and RIC$_-$ can be shown clearly in Figure 2, which presents the behavior representation of each role identified by RIC$_+$ and RIC$_-$. Obviously, RIC$_+$ produces positive roles that contribute largely to the teamwork quality across all feature dimensions; such behaviors are what we want to encourage. Those identified roles are diverse and not symmetrical because each role achieves peaks at different feature dimensions. On the contrary, roles identified by RIC$_-$ works negatively towards teamwork quality and they have homogeneous behavior representation curves. Therefore, our constrained models can provide much interpretation, with a little loss of accuracy compared to RI.

4.4.2 Role Assignment Interpretation

Leading Role Validation: As a validation, we found that one of our identified roles has substantial overlap with team leaders. For instance, in the Elementary course, around 70% of students who are assigned to Role 0 are actual leaders for RIC and RIC$_+$ models. On the Secondary course, around 86% students who are in the position of Role 0 are real team leaders. When it comes to RIC$_-$, such ratio drops to around 2% for all roles. This validates the ability of our models in producing role definitions that make sense.

Information Diffusion: Figure 3 compares the information diffusion among different identified roles of RI, RIC, RIC$_+$ and RIC$_-$. The darker the node, the better grade it achieves. The number associated with each role indicates the average final grades (scale 0-100) of all students who are assigned to this role. The edge represents how many messages sent from one node to another. The thicker the edge, the more information it conveys. From the figure, we found that, RI performs similarly with RIC and roles in RIC$_+$ have much higher grades compared to RIC$_-$. One explanation is that RIC actually does not incorporate many constraints and is less interpretable compared to RIC$_+$ and RIC$_-$. As shown in (c), RIC$_+$ Role 0 contributes more information to Role 1 with an average of 5.5 messages and to Role 2 with weight 6.1. Role 1 and Role 2 also have many messages communicated with others in their team. However, less communication happens in RIC$_-$ roles. This comparison comes much easier when it comes to each role's behaviors on different normalized feature representations as shown in Figure 2 for

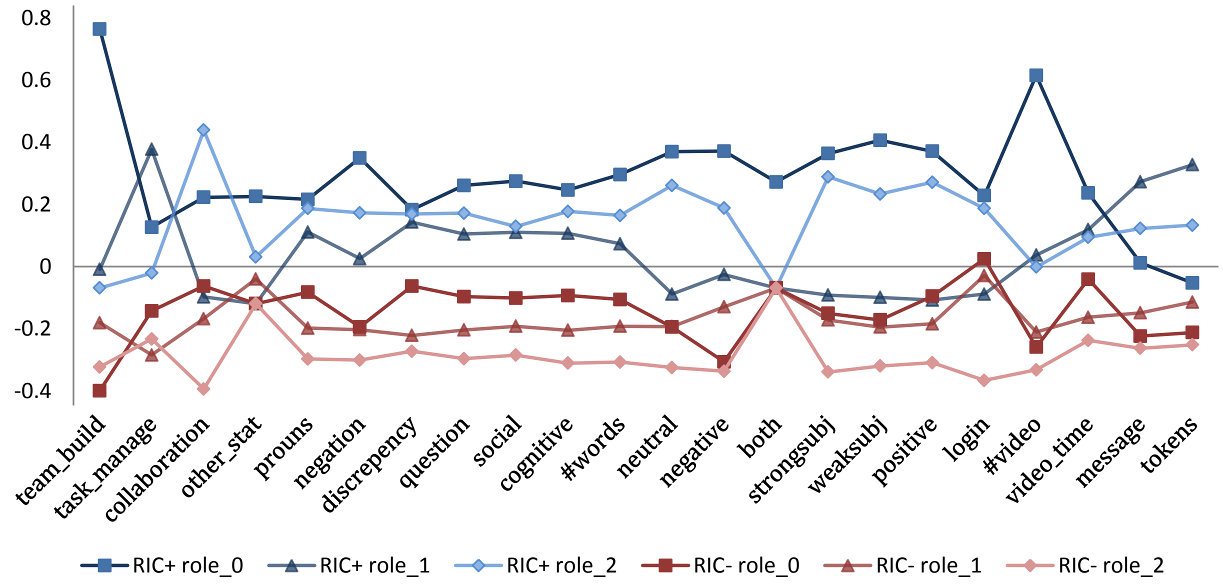

Figure 2: Beahvior Representation of Each Role on the Secondary Course

	Typical Behavior	Representative Post
RIC$_+$	Team Building	I *started a new doc* ... Let me *know your email* if you didn't get the invite.
	Positive	*Great* job team!! Our lesson plan is *amazing* and I learned so much ...
	Collaboration	We plan to meet on Monday to *figure out exactly how to complete* the assignment ...
	Task Management	Here's *what I propose*: *1) to save time, use ... 2) Tara, do you have plans* ... 3) *once* a lesson plan outline is up, *we can* each go in and add modifications..

	Negation	I'm *not* able to ... the pictures *don't* show up...I *don't understand* how to create a link..

Table 4: Representative Posts and Corresponding Behavior Feature Comparison on the Secondary Course

RIC$_+$ and RIC$_-$ models. It can be concluded that by incorporating rewarding and penalizing constraints, our model works effectively in picking the behavior profiles we want to encourage and avoid in a teamwork.

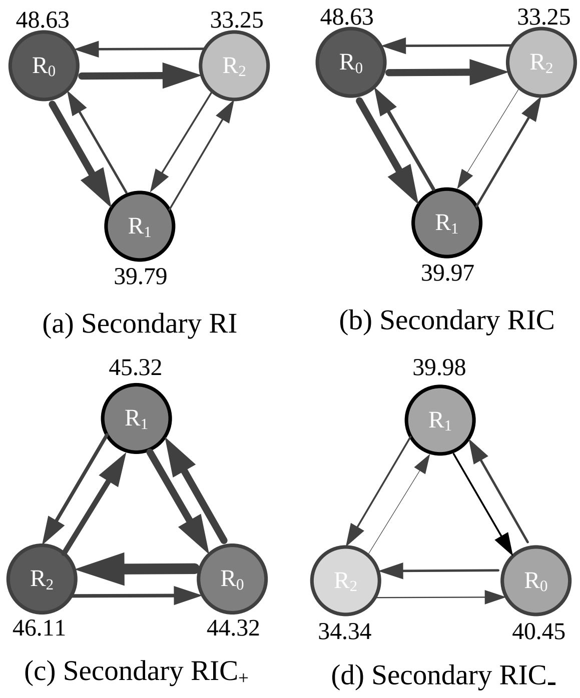
Behavior Comparison: Table 4 presents several representative posts and their corresponding behavior features for our identified roles. Most features shown in Table 4 correspond to the peak behaviors associated with roles in Figure 2, which is consistent with our previous interpretation. For example, RIC$_+$ picks the well performing student who adds calmness to the teamwork as indicated by using positive words and adopting collaborative strategies. On the contrary, RIC$_-$ reflects a less cooperative teamwork, such as strong subjectivity, negation and negativity indicated in their posts.

In summary, our role identification models provide quite interpretable identified roles as discussed above, as well as accurate prediction of teamwork quality. More interpretability can be achieved by incorporating intuitive constraints and sacrificing a bit of accuracy.

5 Conclusion

In this work, we propose a role identification model, which iteratively optimizes a team member role assignment that can predict the teamwork quality to the utmost extent. Furthermore, we extend it to a general constrained version that enables humans to incorporate external constraints to guide the identification of roles. The experimental results on two MOOCs show that both of our proposed role identification models can not only perform accurate predictions of teamwork quality, but also provide interpretable student role assignment results ranging from leading role validation to information diffusion.

Even though we have only explored up to 3 roles in this work that would enable us to use most



(a) Secondary RI

(b) Secondary RIC

(c) Secondary RIC_+

(d) Secondary RIC_-

Figure 3: Information Diffusion among Roles

of our data, our role identification method is capable to experiment with a larger range of values of K, such as in the context of Wikipedia (Ferschke et al., 2015). Furthermore, our model can be directly applied to other online collaboration scenarios to help identify the roles that contribute to collaboration, not limited in the context of MOOCs. In the future, we are interested in relaxing the assumptions that people can take only one role and roles are taken up by only one person and incorporating mixed membership role matching strategies into our method. Furthermore, nonlinear relationship between roles and performance as well as the dependencies between roles should be explored. Last but not least, we plan to take advantage of our identified roles to provide guidance and recommendation to those weakly performing teams for better collaboration and engagement in online teamworks.

Abstract

Many existing deep learning models for natural language processing tasks focus on learning the *compositionality* of their inputs, which requires many expensive computations. We present a simple deep neural network that competes with and, in some cases, outperforms such models on sentiment analysis and factoid question answering tasks while taking only a fraction of the training time. While our model is syntactically-ignorant, we show significant improvements over previous bag-of-words models by deepening our network and applying a novel variant of dropout. Moreover, our model performs better than syntactic models on datasets with high syntactic variance. We show that our model makes similar errors to syntactically-aware models, indicating that for the tasks we consider, nonlinearly transforming the input is more important than tailoring a network to incorporate word order and syntax.

1 Introduction

Vector space models for natural language processing (NLP) represent words using low dimensional vectors called embeddings. To apply vector space models to sentences or documents, one must first select an appropriate *composition function*, which is a mathematical process for combining multiple words into a single vector.

Composition functions fall into two classes: *unordered* and *syntactic*. Unordered functions treat input texts as bags of word embeddings, while syntactic functions take word order and sentence structure into account. Previously published experimental results have shown that syntactic functions outperform unordered functions on many tasks (Socher et al., 2013b; Kalchbrenner and Blunsom, 2013).

However, there is a tradeoff: syntactic functions require more training time than unordered composition functions and are prohibitively expensive in the case of huge datasets or limited computing resources. For example, the recursive neural network (Section 2) computes costly matrix/tensor products and nonlinearities at every node of a syntactic parse tree, which limits it to smaller datasets that can be reliably parsed.

We introduce a deep unordered model that obtains near state-of-the-art accuracies on a variety of sentence and document-level tasks with just minutes of training time on an average laptop computer. This model, the deep averaging network (**DAN**), works in three simple steps:

1. take the vector average of the embeddings associated with an input sequence of tokens
2. pass that average through one or more feed-forward layers
3. perform (linear) classification on the final layer's representation

The model can be improved by applying a novel dropout-inspired regularizer: for each training instance, randomly drop some of the tokens' embeddings before computing the average.

We evaluate **DAN**s on sentiment analysis and factoid question answering tasks at both the sentence and document level in Section 4. Our model's successes demonstrate that for these tasks, the choice of composition function is not as important as initializing with pretrained embeddings and using a deep network. Furthermore, **DAN**s, unlike more complex composition functions, can be effectively trained on data that have high syntactic variance. A

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 1681–1691,
Beijing, China, July 26-31, 2015.

qualitative analysis of the learned layers suggests that the model works by magnifying tiny but meaningful differences in the vector average through multiple hidden layers, and a detailed error analysis shows that syntactically-aware models actually make very similar errors to those of the more naïve DAN.

2 Unordered vs. Syntactic Composition

Our goal is to marry the speed of unordered functions with the accuracy of syntactic functions. In this section, we first describe a class of unordered composition functions dubbed "neural bag-of-words models" (NBOW). We then explore more complex syntactic functions designed to avoid many of the pitfalls associated with NBOW models. Finally, we present the deep averaging network (DAN), which stacks nonlinear layers over the traditional NBOW model and achieves performance on par with or better than that of syntactic functions.

2.1 Neural Bag-of-Words Models

For simplicity, consider text classification: map an input sequence of tokens X to one of k labels. We first apply a composition function g to the sequence of word embeddings $\boldsymbol{v}_w$ for $w \in X$. The output of this composition function is a vector $\boldsymbol{z}$ that serves as input to a logistic regression function.

In our instantiation of NBOW, g averages word embeddings[1]

$$\boldsymbol{z} = g(w \in X) = \frac{1}{|X|} \sum_{w \in X} \boldsymbol{v}_w. \qquad (1)$$

Feeding $\boldsymbol{z}$ to a softmax layer induces estimated probabilities for each output label

$$\hat{y} = \text{softmax}(\mathbf{W}_s \cdot \boldsymbol{z} + \boldsymbol{b}), \qquad (2)$$

where the softmax function is

$$\text{softmax}(\boldsymbol{q}) = \frac{\exp \boldsymbol{q}}{\sum_{j=1}^{k} \exp \boldsymbol{q}_j} \qquad (3)$$

$\mathbf{W}_s$ is a $k \times d$ matrix for a dataset with k output labels, and $\boldsymbol{b}$ is a bias term.

We train the NBOW model to minimize cross-entropy error, which for a single training instance with ground-truth label y is

$$\ell(\hat{y}) = \sum_{p=1}^{k} y_p \log(\hat{y}_p). \qquad (4)$$

Before we describe our deep extension of the NBOW model, we take a quick detour to discuss syntactic composition functions. Connections to other representation frameworks are discussed further in Section 4.

2.2 Considering Syntax for Composition

Given a sentence like "You'll be more entertained getting hit by a bus", an unordered model like NBOW might be deceived by the word "entertained" to return a positive prediction. In contrast, syntactic composition functions rely on the order and structure of the input to learn how one word or phrase affects another, sacrificing computational efficiency in the process. In subsequent sections, we argue that this complexity is not matched by a corresponding gain in performance.

Recursive neural networks (RecNNs) are syntactic functions that rely on natural language's inherent structure to achieve state-of-the-art accuracies on sentiment analysis tasks (Tai et al., 2015). As in NBOW, each word type has an associated embedding. However, the composition function g now depends on a *parse tree* of the input sequence. The representation for any internal node in a binary parse tree is computed as a nonlinear function of the representations of its children (Figure 1, left). A more powerful RecNN variant is the recursive neural tensor network (RecNTN), which modifies g to include a costly tensor product (Socher et al., 2013b).

While RecNNs can model complex linguistic phenomena like negation (Hermann et al., 2013), they require much more training time than NBOW models. The nonlinearities and matrix/tensor products at each node of the parse tree are expensive, especially as model dimensionality increases. RecNNs also require an error signal at *every* node. One root softmax is not strong enough for the model to learn compositional relations and leads to worse accuracies than standard bag-of-words models (Li, 2014). Finally, RecNNs require relatively consistent syntax between training and test data due to their reliance on parse trees and thus cannot effectively incorporate out-of-domain data, as we show in our question-answering experiments. Kim (2014) shows that some of these issues can be avoided by using a convolutional network instead of a RecNN, but the computational complexity increases even further (see Section 4 for runtime comparisons).

What contributes most to the power of syntactic

[1] Preliminary experiments indicate that averaging outperforms the vector sum used in NBOW from Kalchbrenner et al. (2014).

Figure 1: On the left, a RecNN is given an input sentence for sentiment classification. Softmax layers are placed above every internal node to avoid vanishing gradient issues. On the right is a two-layer DAN taking the same input. While the RecNN has to compute a nonlinear representation (purple vectors) for every node in the parse tree of its input, this DAN only computes two nonlinear layers for every possible input.

functions: the compositionality or the nonlinearities? Socher et al. (2013b) report that removing the nonlinearities from their RecNN models drops performance on the Stanford Sentiment Treebank by over 5% absolute accuracy. Most unordered functions are linear mappings between bag-of-words features and output labels, so might they suffer from the same issue? To isolate the effects of syntactic composition from the nonlinear transformations that are crucial to RecNN performance, we investigate how well a deep version of the NBOW model performs on tasks that have recently been dominated by syntactically-aware models.

3 Deep Averaging Networks

The intuition behind deep feed-forward neural networks is that each layer learns a more abstract representation of the input than the previous one (Bengio et al., 2013). We can apply this concept to the NBOW model discussed in Section 2.1 with the expectation that each layer will increasingly magnify small but meaningful differences in the word embedding average. To be more concrete, take s_1 as the sentence “I really loved Rosamund Pike’s performance in the movie Gone Girl” and generate s_2 and s_3 by replacing “loved” with “liked” and then again by “despised”. The vector averages of these three sentences are almost identical, but the averages associated with the synonymous sentences s_1 and s_2 are slightly more similar to each other than they are to s_3’s average.

Could adding depth to NBOW make small such distinctions as this one more apparent? In Equation 1, we compute $\boldsymbol{z}$, the vector representation for input text X, by averaging the word vectors $\boldsymbol{v}_{w \in X}$. Instead of directly passing this representation to an output layer, we can further transform $\boldsymbol{z}$ by adding more layers before applying the softmax. Suppose we have n layers, $\boldsymbol{z}_{1 \dots n}$. We compute each layer

$$\boldsymbol{z}_i = g(\boldsymbol{z}_{i-1}) = f(\mathbf{W}_i \cdot \boldsymbol{z}_{i-1} + \boldsymbol{b}_i) \qquad (5)$$

and feed the final layer’s representation, $\boldsymbol{z}_n$, to a softmax layer for prediction (Figure 1, right).

This model, which we call a deep averaging network (DAN), is still unordered, but its depth allows it to capture subtle variations in the input better than the standard NBOW model. Furthermore, computing each layer requires just a single matrix multiplication, so the complexity scales with the number of layers rather than the number of nodes in a parse tree. In practice, we find no significant difference between the training time of a DAN and that of the shallow NBOW model.

3.1 Word Dropout Improves Robustness

Dropout regularizes neural networks by randomly setting hidden and/or input units to zero with some probability p (Hinton et al., 2012; Srivastava et al., 2014). Given a neural network with n units, dropout prevents overfitting by creating an ensemble of 2^n different networks that share parameters, where each network consists of some combination of dropped and undropped units. Instead of dropping units, a natural extension for the DAN model is to randomly drop word tokens’ entire *word embeddings* from the vector average. Using this method, which we call *word dropout*, our network theoretically sees $2^{|X|}$ different token sequences for each input X.

We posit a vector $\boldsymbol{r}$ with $|X|$ independent Bernoulli trials, each of which equals 1 with probability p. The embedding $\boldsymbol{v}_w$ for token w in X is dropped from the average if $\boldsymbol{r}_w$ is 0, which exponentially increases the number of unique examples the network sees during training. This allows us to modify Equation 1:

$$\boldsymbol{r}_w \sim \text{Bernoulli}(p) \tag{6}$$

$$\hat{X} = \{w | w \in X \text{ and } \boldsymbol{r}_w > 0\} \tag{7}$$

$$\boldsymbol{z} = g(w \in X) = \frac{\sum_{w \in \hat{X}} \boldsymbol{v}_w}{|\hat{X}|}. \tag{8}$$

Depending on the choice of p, many of the "dropped" versions of an original training instance will be very similar to each other, but for shorter inputs this is less likely. We might drop a very important token, such as "horrible" in "the crab rangoon was especially horrible"; however, since the number of word types that are predictive of the output labels is low compared to non-predictive ones (e.g., neutral words in sentiment analysis), we always see improvements using this technique.

Theoretically, word dropout can also be applied to other neural network-based approaches. However, we observe no significant performance differences in preliminary experiments when applying word dropout to leaf nodes in **RecNN**s for sentiment analysis (dropped leaf representations are set to zero vectors), and it slightly hurts performance on the question answering task.

4 Experiments

We compare **DAN**s to both the shallow **NBOW** model as well as more complicated syntactic models on sentence and document-level sentiment analysis and factoid question answering tasks. The **DAN** architecture we use for each task is almost identical, differing across tasks only in the type of output layer and the choice of activation function. Our results show that **DAN**s outperform other bag-of-words models and many syntactic models with very little training time.[2] On the question-answering task, **DAN**s effectively train on out-of-domain data, while **RecNN**s struggle to reconcile the syntactic differences between the training and test data.

Table 1: **DAN**s achieve comparable sentiment accuracies to syntactic functions (bottom third of table) but require much less training time (measured as time of a single epoch on the SST fine-grained task). Asterisked models are initialized either with different pretrained embeddings or randomly.

4.1 Sentiment Analysis

Recently, syntactic composition functions have revolutionized both fine-grained and binary (positive or negative) sentiment analysis. We conduct sentence-level sentiment experiments on the Rotten Tomatoes (RT) movie reviews dataset (Pang and Lee, 2005) and its extension with phrase-level labels, the Stanford Sentiment Treebank (SST) introduced by Socher et al. (2013b). Our model is also effective on the document-level IMDB movie review dataset of Maas et al. (2011).

4.1.1 Neural Baselines

Most neural approaches to sentiment analysis are variants of either recursive or convolutional networks. Our recursive neural network baselines include standard **RecNN**s (Socher et al., 2011b), **RecNTN**s, the deep recursive network (**DRecNN**) proposed by İrsoy and Cardie (2014), and the **TREE-LSTM** of (Tai et al., 2015). Convolutional network baselines include the dynamic convolutional network (Kalchbrenner et al., 2014, **DCNN**) and the convolutional neural network multichannel (Kim, 2014, **CNN-MC**). Our other neural baselines are the sliding-window based paragraph vector (Le and Mikolov, 2014, **PVEC**)[3] and

[2] Code at `http://github.com/miyyer/dan`.

[3] **PVEC** is computationally expensive at both training and test time and requires enough memory to store a vector for every paragraph in the training data.

the word-representation restricted Boltzmann machine (Dahl et al., 2012, **WRRBM**), which only works on the document-level IMDB task.[4]

4.1.2 Non-Neural Baselines

We also compare to non-neural baselines, specifically the bigram naïve Bayes (**BINB**) and naïve Bayes support vector machine (**NBSVM-BI**) models introduced by Wang and Manning (2012), both of which are memory-intensive due to huge feature spaces of size $|V|^2$.

4.1.3 DAN Configurations

In Table 1, we compare a variety of **DAN** and **NBOW** configurations[5] to the baselines described above. In particular, we are interested in not only comparing **DAN** accuracies to those of the baselines, but also how initializing with pretrained embeddings and restricting the model to only root-level labels affects performance. With this in mind, the **NBOW-RAND** and **DAN-RAND** models are initialized with random 300-dimensional word embeddings, while the other models are initialized with publicly-available 300-d GloVe vectors trained over the Common Crawl (Pennington et al., 2014). The **DAN-ROOT** model only has access to sentence-level labels for SST experiments, while all other models are trained on labeled phrases (if they exist) in addition to sentences. We train all **NBOW** and **DAN** models using AdaGrad (Duchi et al., 2011).

We apply **DAN**s to documents by averaging the embeddings for all of a document's tokens and then feeding that average through multiple layers as before. Since the representations computed by **DAN**s are always d-dimensional vectors regardless of the input size, they are efficient with respect to both memory and computational cost. We find that the hyperparameters selected on the SST also work well for the IMDB task.

4.1.4 Dataset Details

We evaluate over both fine-grained and binary sentence-level classification tasks on the SST, and just the binary task on RT and IMDB. In the fine-grained SST setting, each sentence has a label from zero to five where two is the neutral class. For the binary task, we ignore all neutral sentences.[6]

4.1.5 Results

The **DAN** achieves the second best reported result on the RT dataset, behind only the significantly slower **CNN-MC** model. It's also competitive with more complex models on the SST and outperforms the **DCNN** and **WRRBM** on the document-level IMDB task. Interestingly, the **DAN** achieves good performance on the SST when trained with only sentence-level labels, indicating that it does not suffer from the vanishing error signal problem that plagues **RecNN**s. Since acquiring labelled phrases is often expensive (Sayeed et al., 2012; Iyyer et al., 2014b), this result is promising for large or messy datasets where fine-grained annotation is infeasible.

4.1.6 Timing Experiments

DANs require less time per epoch and—in general—require fewer epochs than their syntactic counterparts. We compare **DAN** runtime on the SST to publicly-available implementations of syntactic baselines in the last column of Table 1; the reported times are for a single epoch to control for hyperparameter choices such as learning rate, and all models use 300-d word vectors. Training a **DAN** on just sentence-level labels on the SST takes under five minutes on a single core of a laptop; when labeled phrases are added as separate training instances, training time jumps to twenty minutes.[7] All timing experiments were performed on a single core of an Intel I7 processor with 8GB of RAM.

4.2 Factoid Question Answering

DANs work well for sentiment analysis, but how do they do on other NLP tasks? We shift gears to a paragraph-length factoid question answering task and find that our model outperforms other unordered functions as well as a more complex syntactic **RecNN** model. More interestingly, we find that unlike the **RecNN**, the **DAN** significantly benefits from out-of-domain Wikipedia training data.

Quiz bowl is a trivia competition in which players are asked four-to-six sentence questions about entities (e.g., authors, battles, or events). It is an ideal task to evaluate **DAN**s because there is prior

[4] The **WRRBM** is trained using a slow Metropolis-Hastings algorithm.

[5] Best hyperparameters chosen by cross-validation: three 300-d ReLu layers, word dropout probability $p = 0.3$, L2 regularization weight of 1e-5 applied to all parameters

[6] Our fine-grained SST split is {train: 8,544, dev: 1,101, test: 2,210}, while our binary split is {train: 6,920, dev:872, test:1,821}. Split sizes increase by an order of magnitude when labeled phrases are added to the training set. For RT, we do 10-fold CV over a balanced binary dataset of 10,662 sentences. Similarly, for the IMDB experiments we use the provided balanced binary training set of 25,000 documents.

[7] We also find that **DAN**s take significantly fewer epochs to reach convergence than syntactic models.

Model	Pos 1	Pos 2	Full	Time(s)
BoW-DT	35.4	57.7	60.2	—
IR	37.5	65.9	71.4	N/A
QANTA	47.1	72.1	73.7	314
DAN	46.4	70.8	71.8	**18**
IR-WIKI	53.7	**76.6**	**77.5**	N/A
QANTA-WIKI	46.5	72.8	73.9	1,648
DAN-WIKI	**54.8**	75.5	77.1	119

Table 2: The DAN achieves slightly lower accuracies than the more complex QANTA in much less training time, even at early sentence positions where compositionality plays a bigger role. When Wikipedia is added to the training set (bottom half of table), the DAN outperforms QANTA and achieves comparable accuracy to a state-of-the-art information retrieval baseline, which highlights a benefit of ignoring word order for this task.

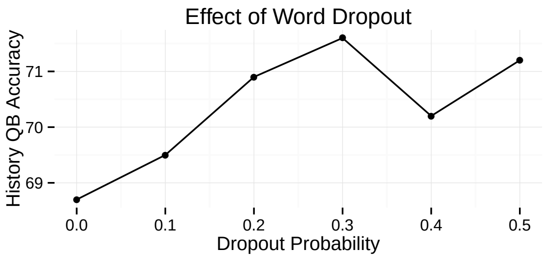

Figure 2: Randomly dropping out 30% of words from the vector average is optimal for the quiz bowl task, yielding a gain in absolute accuracy of almost 3% on the quiz bowl question dataset compared to the same model trained with no word dropout.

work using both syntactic and unordered models for quiz bowl question answering. In Boyd-Graber et al. (2012), naïve Bayes bag-of-words models (BOW-DT) and sequential language models work well on easy questions but poorly on harder ones. A dependency-tree RecNN called QANTA proposed in Iyyer et al. (2014a) shows substantial improvements, leading to the hypothesis that correctly modeling compositionality is crucial for answering hard questions.

4.2.1 Dataset and Experimental Setup

To test this, we train a DAN over the history questions from Iyyer et al. (2014a).[8] This dataset is augmented with 49,581 sentence/page-title pairs from the Wikipedia articles associated with the answers in the dataset. For fair comparison with QANTA, we use a normalized tanh activation function at the last layer instead of ReLu, and we also change the output layer from a softmax to the margin ranking loss (Weston et al., 2011) used in QANTA. We initialize the DAN with the same pretrained 100-d word embeddings that were used to initialize QANTA.

We also evaluate the effectiveness of word dropout on this task in Figure 2. Cross-validation indicates that $p = 0.3$ works best for question answering, although the improvement in accuracy is negligible for sentiment analysis. Finally, continuing the trend observed in the sentiment experiments, DAN converges much faster than QANTA.

4.2.2 DANs Improve with Noisy Data

Table 2 shows that while DAN is slightly worse than QANTA when trained only on question-answer pairs, it improves when trained on additional out-of-domain Wikipedia data (DAN-WIKI), reaching performance comparable to that of a state-of-the-art information retrieval system (IR-WIKI). QANTA, in contrast, barely improves when Wikipedia data is added (QANTA-WIKI) possibly due to the syntactic differences between Wikipedia text and quiz bowl question text.

The most common syntactic structures in quiz bowl sentences are imperative constructions such as "Identify this British author who wrote Wuthering Heights", which are almost never seen in Wikipedia. Furthermore, the subject of most quiz bowl sentences is a pronoun or pronomial mention referring to the answer, a property that is not true of Wikipedia sentences (e.g., "Little of Emily's work from this period survives, except for poems spoken by characters."). Finally, many Wikipedia sentences do not uniquely identify the title of the page they come from, such as the following sentence from Emily Brontë's page: "She does not seem to have made any friends outside her family." While noisy data affect both DAN and QANTA, the latter is further hampered by the syntactic divergence between quiz bowl questions and Wikipedia, which may explain the lack of improvement in accuracy.

[8] The training set contains 14,219 sentences over 3,761 questions. For more detail about data and baseline systems, see Iyyer et al. (2014a).

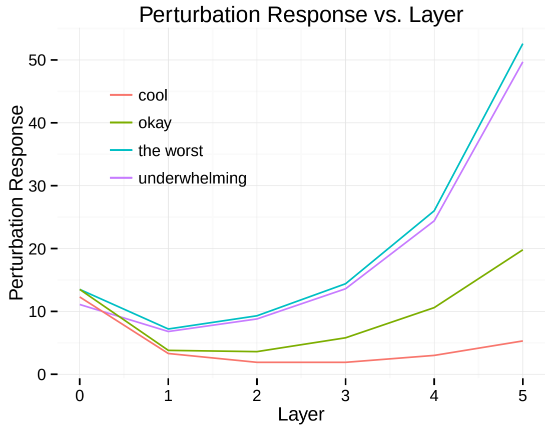

Figure 3: Perturbation response (difference in 1-norm) at each layer of a 5-layer **DAN** after replacing *awesome* in *the film's performances were awesome* with four words of varying sentiment polarity. While the shallow **NBOW** model does not show any meaningful distinctions, we see that as the network gets deeper, negative sentences are increasingly different from the original positive sentence.

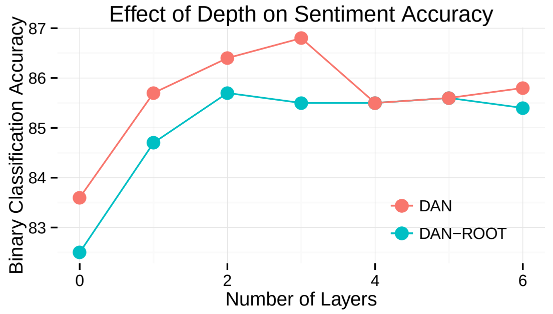

Figure 4: Two to three layers is optimal for the **DAN** on the SST binary sentiment analysis task, but adding any depth at all is an improvement over the shallow **NBOW** model.

5 How Do DANs Work?

In this section we first examine how the deep layers of the **DAN** amplify tiny differences in the vector average that are predictive of the output labels. Next, we compare **DAN**s to **DRecNN**s on sentences that contain negations and contrastive conjunctions and find that both models make similar errors despite the latter's increased complexity. Finally, we analyze the predictive ability of unsupervised word embeddings on a simple sentiment task in an effort to explain why initialization with these embeddings improves the **DAN**.

5.1 Perturbation Analysis

Following the work of İrsoy and Cardie (2014), we examine our network by measuring the response at each hidden layer to perturbations in an input sentence. In particular, we use the template *the film's performances were awesome* and replace the final word with increasingly negative polarity words (*cool*, *okay*, *underwhelming*, *the worst*). For each perturbed sentence, we observe how much the hidden layers differ from those associated with the original template in 1-norm.

Figure 3 shows that as a **DAN** gets deeper, the differences between negative and positive sentences become increasingly amplified. While nonexistent in the shallow **NBOW** model, these differences are visible even with just a single hidden layer, thus explaining why deepening the **NBOW** improves sentiment analysis as shown in Figure 4.

5.2 Handling Negations and "but": Where Syntax is Still Needed

While **DAN**s outperform other bag-of-words models, how can they model linguistic phenomena such as negation without considering word order? To evaluate **DAN**s over tougher inputs, we collect 92 sentences, each of which contains at least one negation and one contrastive conjunction, from the dev and test sets of the SST.[9] Our fine-grained accuracy is *higher* on this subset than on the full dataset, improving almost five percent absolute accuracy to 53.3%. The **DRecNN** model of İrsoy and Cardie (2014) obtains a similar accuracy of 51.1%, contrary to our intuition that syntactic functions should outperform unordered functions on sentences that clearly require syntax to understand.[10]

Are these sentences truly difficult to classify? A close inspection reveals that both the **DAN** and the **DRecNN** have an overwhelming tendency to predict negative sentiment (60.9% and 55.4% of the time for the **DAN** and **DRecNN** respectively) when they see a negation compared to positive sentiment (35.9% for **DAN**s, 34.8% for **DRecNN**s). If we further restrict our subset of sentences to only those with positive ground truth labels, we find that while both models struggle, the **DRecNN** obtains 41.7% accuracy, outperforming the **DAN**'s 37.5%.

To understand why a negation or contrastive conjunction triggers a negative sentiment prediction,

[9] We search for non-neutral sentences containing *not* / *n't*, and *but*. 48 of the sentences are positive while 44 are negative.

[10] Both models are initialized with pretrained 300-d GloVe embeddings for fair comparison.

Sentence	DAN	DRecNN	Ground Truth
a lousy movie that's not merely unwatchable, but also unlistenable	negative	negative	negative
if you're not a prepubescent girl, you'll be laughing at britney spears' movie-starring debut whenever it does n't have you impatiently squinting at your watch	negative	negative	negative
blessed with immense physical prowess he may well be, but ahola is simply not an actor	positive	neutral	negative
who knows what exactly godard is on about in this film, but his words and images do n't have to add up to mesmerize you.	positive	positive	positive
it's so good that its relentless, polished wit can withstand not only inept school productions, but even oliver parker's movie adaptation	negative	positive	positive
too bad, but thanks to some lovely comedic moments and several fine performances, it's not a total loss	negative	negative	positive
this movie was not good	negative	negative	negative
this movie was good	positive	positive	positive
this movie was bad	negative	negative	negative
the movie was not bad	negative	negative	positive

Table 3: Predictions of DAN and DRecNN models on real (top) and synthetic (bottom) sentences that contain negations and contrastive conjunctions. In the first column, words colored red individually predict the negative label when fed to a DAN, while blue words predict positive. The DAN learns that the negators *not* and *n't* are strong negative predictors, which means it is unable to capture double negation as in the last real example and the last synthetic example. The DRecNN does slightly better on the synthetic double negation, predicting a lower negative polarity.

we show six sentences from the negation subset and four synthetic sentences in Table 3, along with both models' predictions. The token-level predictions in the table (shown as colored boxes) are computed by passing each token through the DAN as separate test instances. The tokens *not* and *n't* are strongly predictive of negative sentiment. While this simplified "negation" works for many sentences in the datasets we consider, it prevents the DAN from reasoning about double negatives, as in "this movie was not bad". The DRecNN does slightly better in this case by predicting a lesser negative polarity than the DAN; however, we theorize that still more powerful syntactic composition functions (and more labelled instances of negation and related phenomena) are necessary to truly solve this problem.

5.3 Unsupervised Embeddings Capture Sentiment

Our model consistently converges slower to a worse solution (dropping 3% in absolute accuracy on coarse-grained SST) when we randomly initialize the word embeddings. This does not apply to just DANs; both convolutional and recursive networks do the same (Kim, 2014; İrsoy and Cardie, 2014). Why are initializations with these embeddings so crucial to obtaining good performance? Is it possible that unsupervised training algorithms are already capturing sentiment?

We investigate this theory by conducting a simple experiment: given a sentiment lexicon containing both positive and negative words, we train a logistic regression to discriminate between the associated word embeddings (without any fine-tuning). We use the lexicon created by Hu and Liu (2004), which consists of 2,006 positive words and 4,783 negative words. We balance and split the dataset into 3,000 training words and 1,000 test words. Using 300-dimensional GloVe embeddings pretrained over the Common Crawl, we obtain over 95% accuracy on the unseen test set, supporting the hypothesis that unsupervised pretraining over large corpora can capture properties such as sentiment.

Intuitively, after the embeddings are fine-tuned during DAN training, we might expect a decrease in the norms of stopwords and an increase in the norms of sentiment-rich words like “awesome” or “horrible”. However, we find no significant differences between the L_2 norms of stopwords and words in the sentiment lexicon of Hu and Liu (2004).

6 Related Work

Our DAN model builds on the successes of both simple vector operations and neural network-based models for compositionality.

There are a variety of element-wise vector operations that could replace the average used in the DAN. Mitchell and Lapata (2008) experiment with many of them to model the compositionality of short phrases. Later, their work was extended to take into account the syntactic relation between words (Erk and Padó, 2008; Baroni and Zamparelli, 2010; Kartsaklis and Sadrzadeh, 2013) and grammars (Coecke et al., 2010; Grefenstette and Sadrzadeh, 2011). While the average works best for the tasks that we consider, Banea et al. (2014) find that simply summing `word2vec` embeddings outperforms all other methods on the SemEval 2014 phrase-to-word and sentence-to-phrase similarity tasks.

Once we compute the embedding average in a DAN, we feed it to a deep neural network. In contrast, most previous work on neural network-based methods for NLP tasks explicitly model word order. Outside of sentiment analysis, RecNN-based approaches have been successful for tasks such as parsing (Socher et al., 2013a), machine translation (Liu et al., 2014), and paraphrase detection (Socher et al., 2011a). Convolutional networks also model word order in local windows and have achieved performance comparable to or better than that of RecNNs on many tasks (Collobert and Weston, 2008; Kim, 2014). Meanwhile, feedforward architectures like that of the DAN have been used for language modeling (Bengio et al., 2003), selectional preference acquisition (Van de Cruys, 2014), and dependency parsing (Chen and Manning, 2014).

7 Future Work

In Section 5, we showed that the performance of our DAN model worsens on sentences that contain lingustic phenomena such as double negation. One promising future direction is to cascade classifiers such that syntactic models are used only when a DAN is not confident in its prediction. We can also extend the DAN’s success at incorporating out-of-domain training data to sentiment analysis: imagine training a DAN on labeled tweets for classification on newspaper reviews. Another potentially interesting application is to add gated units to a DAN,as has been done for recurrent and recursive neural networks (Hochreiter and Schmidhuber, 1997; Cho et al., 2014; Sutskever et al., 2014; Tai et al., 2015), to drop useless words rather than randomly-selected ones.

8 Conclusion

In this paper, we introduce the deep averaging network, which feeds an unweighted average of word vectors through multiple hidden layers before classification. The DAN performs competitively with more complicated neural networks that explicitly model semantic and syntactic compositionality. It is further strengthened by word dropout, a regularizer that reduces input redundancy. DANs obtain close to state-of-the-art accuracy on both sentence and document-level sentiment analysis and factoid question-answering tasks with much less training time than competing methods; in fact, all experiments were performed in a matter of minutes on a single laptop core. We find that both DANs and syntactic functions make similar errors given syntactically-complex input, which motivates research into more powerful models of compositionality.

Abstract

Traditional learning to rank methods learn ranking models from training data in a *batch* and *offline* learning mode, which suffers from some critical limitations, e.g., poor scalability as the model has to be re-trained from scratch whenever new training data arrives. This is clearly non-scalable for many real applications in practice where training data often arrives sequentially and frequently. To overcome the limitations, this paper presents SOLAR — a new framework of Scalable Online Learning Algorithms for Ranking, to tackle the challenge of scalable learning to rank. Specifically, we propose two novel SOLAR algorithms and analyze their IR measure bounds theoretically. We conduct extensive empirical studies by comparing our SOLAR algorithms with conventional learning to rank algorithms on benchmark testbeds, in which promising results validate the efficacy and scalability of the proposed novel SOLAR algorithms.

1 Introduction

Learning to rank [27, 8, 29, 31, 7] aims to learn some ranking model from training data using machine learning methods, which has been actively studied in information retrieval (IR). Specifically, consider a document retrieval task, given a query, a ranking model assigns a relevance score to each document in a collection of documents, and then ranks the documents in decreasing order of relevance scores. The goal of learning to rank is to build a ranking model from training data of a set of queries by optimizing some IR performance measures using machine learning techniques. In literature, various learning to rank techniques have been proposed, ranging from early pointwise approaches [15, 30, 28], to popular pairwise [26, 18, 3], and recent listwise approaches [5, 38]. Learning to rank has many applications, including document retrieval, collaborative filtering, online ad, answer ranking for online QA in NLP [33], etc.

Most existing learning to rank techniques follow batch and offline machine learning methodology, which typically assumes all training data are available prior to the learning task and the ranking model is trained by applying some batch learning method, e.g., neural networks [3] or SVM [4]. Despite being studied extensively, the batch learning to rank methodology has some critical limitations. One of serious limitations perhaps is its poor scalability for real-world web applications, where the ranking model has to be re-trained from scratch whenever new training data arrives. This is apparently inefficient and non-scalable since training data often arrives sequentially and frequently in many real applications [33, 7]. Besides, batch learning to rank methodology also suffers from slow adaption to fast-changing environment of web applications due to the static ranking models pre-trained from historical batch training data.

To overcome the above limitations, this paper investigates SOLAR — a new framework of Scalable Online Learning Algorithms for Ranking, which aims to learn a ranking model from a sequence of training data in an online learning fashion. Specifically, by following the pairwise learning to rank framework, we formally formulate the learning problem, and then present two different SOLAR algorithms to solve the challenging task together with the analysis of their theoretical properties. We conduct an extensive set of experiments by evaluating the performance of the proposed algorithms under different settings by comparing them with both online and batch algorithms on benchmark testbeds in literature.

As a summary, the key contributions of this pa-

per include: (i) we present a new framework of Scalable Online Learning Algorithms for Ranking, which tackles the pairwise learning to ranking problem via a scalable online learning approach; (ii) we present two SOLAR algorithms: a first-order learning algorithm (SOLAR-I) and a second-order learning algorithm (SOLAR-II); (iii) we analyze the theoretical bounds of the proposed algorithms in terms of standard IR performance measures; and (iv) finally we examine the efficacy of the proposed algorithms by an extensive set of empirical studies on benchmark datasets.

The rest of this paper is organized as follows. Section 2 reviews related work. Section 3 gives problem formulations of the proposed framework and presents our algorithms, followed by theoretical analysis in Section 4. Section 5 presents our experimental results, and Section 6 concludes this work and indicates future directions.

2 Related Work

In general, our work is related to two topics in information retrieval and machine learning: *learning to rank* and *online learning*. Both of them have been extensively studied in literature. Below we briefly review important related work in each area.

2.1 Learning to Rank

Most of the existing approaches to learning to rank can be generally grouped into three major categories: (i) pointwise approaches, (ii) pairwise approaches, and (iii) listwise approaches.

The pointwise approaches treat ranking as a classification or regression problem for predicting the ranking of individual objects. For example, [12, 19] formulated ranking as a regression problem in diverse forms. [30] formulated ranking a binary classification of relevance on document objects, and solved it by discriminative models (e.g., SVM). In [15], Perceptron [32] ranking (known as "Prank") [15] formulated it as online binary classification. [28] cast ranking as multiple classification or multiple ordinal classification tasks.

The pairwise approaches treat the document pairs as training instances and formulate ranking as a classification or regression problem from a collection of pairwise document instances. Example of pairwise learning to rank algorithms include: neural network approaches such as RankNet [3] and LambdaRank [2], SVM approaches such as RankSVM [26], boosting approaches such as RankBoost [18], regression algorithms such as GBRank [43], and probabilistic ranking algorithms such as FRank [35]. The pairwise group is among one of widely and successfully applied approaches. Our work generally belongs to this group.

The listwise approaches treat a list of documents for a query as a training instance and attempt to learn a ranking model by optimizing some loss defined on the predicted list and the ground-truth list. In general, there are two types of approaches. The first is to directly optimize some IR metrics, such as Mean Average Precision (MAP) and Normalized Discounted Cumulative Gain (NDCG) [25]. Examples include AdaRank by boosting [39], SVM-MAP by optimizing MAP [42], PermuRank [40], and SoftRank [34] based on a smoothed approximation to NDCG, and NDCG-Boost by optimizing NDCG [37], etc. The other is to indirectly optimize the IR metrics by defining some listwise loss function, such as ListNet [5] and ListMLE [38].

Despite being studied actively, most existing works generally belong to batch learning methods, except a few online learning studies. For example, Prank [15] is probably the first online pointwise learning to ranking algorithm. Unlike Prank, our work focuses online pairwise learning to rank technique, which significantly outperforms Prank as observed in our empirical studies. Besides, our work is also related to another existing work in [10], but differs considerably in several aspects: (i) they assume the similarity function is defined in a bi-linear form which is inappropriate for document retrieval applications; (ii) their training data is given in the form of triplet-image instance (p_1, p_2, p_3), while our training data is given in a pairwise query-document instance (q_t, d_t^1, d_t^2); (iii) they only apply first order online learning algorithms, while we explore both first-order and second-order online algorithms. Finally, we note that our work differs from another series of online learning to rank studies [21, 22, 23, 36, 41] which attempt to explore reinforcement learning or multi-arm bandit techniques for learning to rank from implicit/partial feedback, whose formulation and settings are very different.

2.2 Online Learning

Our work is closely related to studies of online learning [24], representing a family of efficient and scalable machine learning algorithms. In literature, a variety of online algorithms have been proposed, mainly in two major categories: first-order algorithms and second-order algorithms. The notable examples of first-order online learning methods include classical Perceptron [32], and Passive-Aggressive (PA) learning algorithms [13]. Unlike first-order algorithms, second-order online learning [6], e.g., Confidence-Weighted (CW) learning [16], usually assumes the weight vector follows a Gaussian distribution and attempts to update the mean and covariance for each received instance. In addition, Adaptive Regularization of Weights Learning (AROW) [14] was proposed to improve robustness of CW. More other online learning methods can be found in [24]. In this work, we apply both first-order and second-order online learning methods for online learning to rank.

3 SOLAR — Online Learning to Rank

We now present SOLAR — a framework of Scalable Online Learning Algorithms for Ranking, which applies online learning to build ranking models from sequential training instances.

3.1 Problem Formulation

Without loss of generality, consider an online learning to rank problem for document retrieval, where training data instances arrive sequentially. Let us denote by $\mathcal{Q}$ a query space and denote by $\mathcal{D}$ a document space. Each instance received at time step t is represented by a triplet $(q_t^{(i)}, d_t^{(1)}, d_t^{(2)})$, where $q_t^{(i)} \in \mathcal{Q}$ denotes the i-th query in the entire collection of queries $\mathcal{Q}$, $d_t^{(1)} \in \mathcal{D}$ and $d_t^{(2)} \in \mathcal{D}$ denote a pair of documents for prediction of ranking w.r.t. the query $q_t^{(i)}$. Without loss of clarity, for the rest of this paper, we simplify the notation $q_t^{(i)}, d_t^{(1)}, d_t^{(2)}$ as q_t^i, d_t^1, d_t^2, respectively.

We also denote by $y_t \in \{+1, -1\}$ the true ranking order of the pairwise instances at step t such that if $y_t = +1$, document d_t^1 is ranked before d_t^2; otherwise d_t^1 is ranked after d_t^2. We introduce a mapping function $\phi : \mathcal{Q} \times \mathcal{D} \to \mathbb{R}^n$ that creates a n-dimensional feature vector from a query-document pair. For example, consider $\phi(q, d) \in \mathbb{R}^n$, one way to extract one of the n features is based on term frequency, which counts the number of times the query term of q occurs in document d. We also introduce $\mathbf{w}_t \in \mathbb{R}^n$ as the ranking model to be learned at step t, which is used to form the target ranking function below:

$$f(q_t^i, d_t^1, d_t^2) = \mathbf{w}_t^\top \phi(q_t^i, d_t^1, d_t^2) = \mathbf{w}_t{}^\top(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))$$

Assume that we have a total of Q queries $\{q^{(i)}\}_{i=1}^{Q}$, each of which is associated with a total of D_i documents and a total of T_i training triplet instances. In a practical document retrieval task, the online learning to rank framework operates in the following procedure:

(i) Given a query q_1, an initial model $\mathbf{w}_1$ is first applied to rank the set of documents for the query, which are then returned to users;

(ii) We then collect user's feedback (e.g., clickthrough data) as the ground truth labels for the ranking orders of a collection of T_1 triplet training instances;

(iii) We then apply an online learning algorithm to update the ranking model from the sequence of T_1 triplet training instances;

(iv) We repeat the above by applying the updated ranking model to process the next query.

For a sequence of T triplet training instances, the goal of online learning to rank is to optimize the sequence of ranking models $\mathbf{w}_1, \ldots, \mathbf{w}_T$ during the entire online learning process. In general, the proposed online learning to rank scheme is evaluated by measuring the online cumulative MAP [1] or online cumulative NDCG [25]. Let us denote by NDCG$_i$ and MAP$_i$ the NDCG and MAP values for query q_i, respectively, which are defined as follows:

$$\text{NDCG}_i = \frac{1}{N_n} \sum_{r=1}^{D_i} G(l(\pi_f(r)))D(r) \qquad (1)$$

$$\text{MAP}_i = \frac{1}{m} \sum_{s:l(\pi_f(s))=1} \frac{\sum_{j \le s} \mathbb{I}_{\{l(\pi_f(j))=1\}}}{s} \qquad (2)$$

where $\mathbb{I}_{\{\cdot\}}$ is an indicator function that outputs 1 when the statement is true and 0 otherwise; $G(K) = 2^K - 1$,$D(K) = \frac{1}{\log_2(1+K)}$, $N_n = \max_\pi \sum_{r=1}^{m} G(l(\pi(r)))D(r)$, $l(r)$ is the corresponding labels as K-level ratings, π_f denote a rank list produced by ranking function f, m is the number of relevant documents. The online cumulative IR measure is defined as the average of the measure over a sequence of Q queries:

$$\text{NDCG} = \frac{1}{Q} \sum_{i=1}^{Q} \text{NDCG}_i \qquad \text{MAP} = \frac{1}{Q} \sum_{i=1}^{Q} \text{MAP}_i \qquad (3)$$

3.2 First-order SOLAR Algorithm

The key challenge of online learning to rank is how to optimize the ranking model $\mathbf{w}_t$ when receiving a training instance (q_t^i, d_t^1, d_t^2) and its true label y_t at each time step t. In the following, we apply the passive-aggressive online learning technique [13] to solve this challenge. First of all, we formulate the problem as an optimization:

$$\mathbf{w}_{t+1} = \arg\min_{\mathbf{w}} \frac{1}{2}\|\mathbf{w} - \mathbf{w}_t\|^2 + C\ell(\mathbf{w}; (q_t^i, d_t^1, d_t^2), y_t)^2 \quad (4)$$

where $\ell(\mathbf{w}_t)$ is a hinge loss defined as $\ell(\mathbf{w}_t) = \max(0, 1 - y_t\mathbf{w}_t{}^\top(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)))$, and C is a penalty cost parameter.

The above optimization formulation aims to achieve a trade-off between two concerns: (i) the updated ranking model should not be deviated too much from the previous ranking model $\mathbf{w}_t$; and (ii) the updated ranking model should suffer a small loss on the triplet instance (q_t^i, d_t^1, d_t^2). Their trade-off is essentially controlled by the penalty cost parameter C. Finally, we can derive the following proposition for the solution to the above.

Proposition 1. *This optimization in (4) has the following closed-form solution:*

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \lambda_t y_t(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)) \quad (5)$$

where λ_t is computed as follows:

$$\lambda_t = \frac{\max(0, 1 - \mathbf{w}_t{}^\top y_t(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)))}{\|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\|^2 + \frac{1}{2C}} \quad (6)$$

It is not difficult to derive the result in the above proposition by following the similar idea of passive aggressive online learning [13]. We omit the detailed proof here. We can see that if $\mathbf{w}_t{}^\top y_t(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)) \geq 1$, then the model remains unchanged, which means that if the current ranking model can correctly rank the order of d_t^1 and d_t^2 w.r.t. query q_t^i at a large margin, we can keep our model unchanged at this round; otherwise, we will update the current ranking model by the above proposition. Figure 1 gives the framework of the proposed online learning to rank algorithms. We denote by the first-order learning to rank algorithm as "SOLAR-I" for short.

3.3 Second-order SOLAR Algorithm

The previous algorithm only exploits first-order information of the ranking model $\mathbf{w}_t$. Inspired by recent studies in second-order online learning [6, 16, 14], we explore second-order algorithms for online learning to rank.

```
Algorithm 1: SOLAR — Scalable Online Learning to Rank
Initialize $\mathbf{w}_1 = 0, t = 1$
for $i = 1, 2, \ldots, Q$ do
    receive a query $q_i$ and documents for ranking
    rank the documents by current model $\mathbf{w}_t$
    acquire user's feedback in triplet instances
    for $j = 1, \ldots, T_i$ do
        update $\mathbf{w}_{t+1}$ with $(q_t^i, d_t^1, d_t^2)$ and $y_t$ by
        Eqn. (5) (SOLAR-I) or by Eqn.(8) (SOLAR-II)
        t = t + 1
    end for
end for
```

Figure 1: SOLAR: scalable online learning to rank

Specifically, we cast the online learning to ranking problem into a probabilistic framework, in which we model feature confidence for a linear ranking model $\mathbf{w}$ with a Gaussian distribution with mean $\mathbf{w} \in \mathbb{R}^d$ and covariance $\Sigma \in \mathbb{R}^{d\times d}$. The mean vector $\mathbf{w}$ is used as the model of the ranking function, and the covariance matrix Σ represents our confidence on the model: the smaller the value of $\Sigma_{p,p}$, the more confident the learner has over the p-th feature w_p of the ranking model $\mathbf{w}$.

Following the similar intuition of the above section, we want to optimize our ranking model $\mathcal{N}(\mathbf{w}, \Sigma)$ by achieving the following trade-off: (i) to avoid being deviated too much from the previous model $\mathcal{N}(w_t, \Sigma_t)$; (ii) to ensure that it suffers a small loss on current triplet instance; and (iii) to attain a large confidence on the current instance. Similar to [16], we employ the Kullback-Leibler divergence to measure the distance between the current model $\mathbf{w}$ to be optimized and the previous model $\mathbf{w}_t$, and the regularization terms include both the loss suffered at current triplet instance and the confidence on current triplet instance.

Specifically, we formulate the optimization of second-order online learning to rank as:

$$\begin{aligned}\{\mathbf{w}_{t+1}, \Sigma_{t+1}\} &= \arg\min_{\mathbf{w},\Sigma} D_{KL}(\mathcal{N}(\mathbf{w}, \Sigma)||\mathcal{N}(\mathbf{w}_t, \Sigma_t)) \\ &\quad + \frac{\ell(\mathbf{w})^2 + \Omega(\Sigma)}{2\gamma} \qquad (7)\\ \Omega(\Sigma) &= (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))^\top\Sigma(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\end{aligned}$$

where γ is the trade-off parameter. The following proposition gives the closed-form solution.

Proposition 2. *This optimization problem in (7) has the following closed-form solution:*

$$\begin{aligned}\mathbf{w}_{t+1} &= \mathbf{w}_t + \alpha_t\Sigma_t y_t(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)) \quad (8)\\ \Sigma_{t+1} &= \Sigma_t - (1/\beta_t)\Sigma_t A\Sigma_t \quad (9)\end{aligned}$$

where A, β_t, and α_t are computed as follows:

$$\begin{aligned}A &= (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))^\top \\ \beta_t &= (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))^\top\Sigma_t(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)) + \gamma \\ \alpha_t &= \max(0, 1 - y_t\mathbf{w}_t{}^\top(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)))/\beta_t\end{aligned}$$

The above can be proved by following [14]. We omit the details. We denote the above algorithm as "SOLAR-II" for short.

4 Theoretical Analysis

In this section, we theoretically analyze the two proposed algorithms by proving some online cumulative IR measure bounds for both of them.

In order to prove the IR measure bounds for the proposed algorithms, we first need to draw the relationships between the cumulative IR measures and the sum of pairwise squared hinge losses. To this purpose, we introduce the following Lemma.

Lemma 4.1. *For one query q_i and its related documents, the NDCG and MAP is lower bounded by its sum of pairwise squared hinge loss suffered by rank model w.*

$$\mathit{NDCG}_i \geq 1 - \gamma_{\mathit{NDCG}} \sum_t \ell^2(w, (q_t^i, d_t^1, d_t^2))$$

$$\mathit{MAP}_i \geq 1 - \gamma_{\mathit{MAP}} \sum_t \ell^2(w, (q_t^i, d_t^1, d_t^2))$$

where γ_{NDCG} and γ_{MAP} are constant specified by the properties of IR measures: $\gamma_{\mathit{NDCG}} = \frac{G(K-1)D(1)}{N_n}$ and $\gamma_{\mathit{MAP}} = \frac{1}{m}$, $G(K) = 2^K - 1, D(K) = \frac{1}{\log_2(1+K)}$, $N_n = \max_\pi \sum_{r=1}^m G(l(\pi(r)))D(r)$, $l(r)$ is the corresponding labels as K-level ratings, π is rank list, m is the number of relevant documents.

Sketch Proof. Using the $essential\ loss$ idea defined in [11], from Theorem 1 of [11] we could see the $essential\ loss$ is an upper bound of measure-based ranking errors; besides, the $essential\ loss$ is the lower bound of the sum of pairwise squared hinge loss, using the properties of squared hinge loss, which is non-negative, non-increasing and satisfy $\ell^2(0) = 1$.

The above lemma indicates that if we could prove bounds for the online cumulative squared hinge loss compared to the best ranking model with all data beforehand, we could obtain the cumulative IR measures bounds. Fortunately there are strong theoretical loss bounds for the proposed online learning to ranking algorithms. The following shows the theorem of such loss bounds for the proposed SOLAR algorithms.

Theorem 1. *For the SOLAR-I algorithm with Q queries, for any rank model u, suppose $R = \max_{i,t} \|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\|$, the cumulative squared hinge loss is bounded by*

$$\sum_{i=1}^{Q}\sum_{t=1}^{T_i} \ell_t^2(w_t) \leq (R^2 + \frac{1}{2C})(\|u\|^2 + 2C\sum_{i=1}^{Q}\sum_{t=1}^{T_i} \ell_t^2(u)) \quad (10)$$

The proof for Theorem 1 can be found in Appendix A. By combining the results of Lemma 1 and Theorem 1, we can easily derive the cumulative IR measure bound of the SOLAR-I algorithm.

Theorem 2. *For the SOLAR-I algorithm with Q queries, for any ranking model u, the NDCG and MAP performances are respectively bounded by*

$$\mathit{NDCG} \geq 1 - \frac{\gamma_{\mathit{NDCG}}}{Q}(R^2 + \frac{1}{2C})(\|u\|^2 + 2C\sum_{i}^{Q}\sum_{t=1}^{T_i} \ell_t^2(u))$$

$$\mathit{MAP} \geq 1 - \frac{\gamma_{\mathit{MAP}}}{Q}(R^2 + \frac{1}{2C})(\|u\|^2 + 2C\sum_{i}^{Q}\sum_{t=1}^{T_i} \ell_t^2(u))$$

The analysis of the SOLAR-II algorithm would be much more complex. Let us denote by $\mathcal{M}(M = |\mathcal{M}|)$ the set of example indices for which the algorithm makes a mistake, and by $\mathcal{U}(U = |\mathcal{U}|)$ the set of example indices for which there is an update but not a mistake. Let $X_A = \sum_{(q_t^i, d_t^1, d_t^2) \in \mathcal{M} \cup \mathcal{U}} (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))(\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))^T$. The theorem below give the squared hinge loss bound.

Theorem 3. *For the SOLAR-II algorithm with Q queries, Let $\chi_t = (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))^T \Sigma_t (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))$ of examples in $\mathcal{M} \cup \mathcal{U}$ at time t, K and k is the maximum and minimum value of χ_t, respectively. Σ_T be the final covariance matrix and u_T be the final mean vector. For any ranking model u, the squared hinge loss is bounded by*

$$\begin{aligned}\sum_{i=1}^{Q}\sum_{t=1}^{T_i} \ell_t^2(w_t) \leq{}& \frac{K+\gamma}{k+\gamma}(a + \sum_{i=1}^{Q}\sum_{t=1}^{T_i} \ell_t(u)) \\ &+(K+\gamma)(\log\det(\Sigma_T^{-1}) - \frac{a^2}{\gamma^2 u^T \Sigma_T^{-1} u})\end{aligned}$$

$$\text{where } a = \sqrt{\gamma\|u\|^2 + u^t X_A u}\sqrt{\log(\det(I + \frac{1}{\gamma}X_A)) + U}$$

The proof for Theorem 3 can be found in Appendix B. Now, by combining the Lemma 1 and Theorem 3, we can derive the cumulative IR measure bound achieved by the proposed SOLAR-II algorithm.

Theorem 4. *For the SOLAR-II algorithm with Q queries, for any ranking model u, the NDCG and MAP performances are respectively bounded by*

$$\mathit{NDCG} \geq 1 - \frac{\gamma_{\mathit{NDCG}}(K+\gamma)}{Q(k+\gamma)}(a + \sum_{i}^{Q}\sum_{t=1}^{T_i} \ell_t(u)) - \frac{\gamma_{\mathit{NDCG}} b}{Q}$$

$$\mathit{MAP} \geq 1 - \frac{\gamma_{\mathit{MAP}}(K+\gamma)}{Q(k+\gamma)}(a + \sum_{i}^{Q}\sum_{t=1}^{T_i} \ell_t(u)) - \frac{\gamma_{\mathit{MAP}} b}{Q}$$

where $b = (K+\gamma)(\log\det(\Sigma_T^{-1}) - \frac{a^2}{\gamma^2 u^T \Sigma_T^{-1} u})$

The above theorems show that our online algorithm is no much worse than that of the best ranking model u with all data beforehand.

5 Experiments

We conduct extensive experiments to evaluate the efficacy of our algorithms in two major aspects: (i) to examine the learning efficacy of the proposed SOLAR algorithms for online learning to rank tasks; (ii) to directly compare the proposed SOLAR algorithms with the state-of-the-art batch learning to rank algorithms. Besides, we also show an application of our algorithms for transfer learning to rank tasks to demonstrate the importance of capturing changing search intention timely in real web applications. The results are in the supplemental file due to space limitation.

5.1 Experimental Testbed and Metrics

We adopt the popular benchmark testbed for learning to rank: LETOR[1] [31]. To make a comprehensive comparison, we perform experiments on all the available datasets in LETOR3.0 and LETOR4.0. The statistics are shown in Table 1. For performance evaluation metrics, we adopt the standard IR measures, including ”MAP”, ”NDCG@1”, ”NDCG@5”, and ”NDCG@10”.

Table 1: LETOR datasets used in the experiments.

5.2 Evaluation of Online Rank Performance

This experiment evaluates the online learning performance of the proposed algorithms for online learning to rank tasks by comparing them with the existing “Prank” algorithm [15], a Perceptron-based pointwise online learning to rank algorithm, and a recently proposed “Committee Perceptron (Com-P)” algorithm [17], which explores the ensemble learning for Perceptron. We evaluate the performance in terms of both online cumulative NDCG and MAP measures. As it is an online learning task, the parameter C of SOLAR-I is fixed to 10^{-5} and the parameter γ of SOLAR-II is fixed to 10^{4} for all the datasets, as suggested by [17], we set the number of experts in “Com-P” to 20. All experiments were conducted over 10 random permutations of each dataset, and all results were averaged over the 10 runs.

Table 2 give the results of NDCG on all the datasets, where the best results were bolded. Several observations can be drawn as follows.

First of all, among all the algorithms, we found that both SOLAR-I and SOLAR-II achieve significantly better performance than Prank, which proves the efficacy of the proposed pairwise algorithms. Second, we found that Prank (pointwise) performs extremely poor on several datasets (HP2003, HP2004, NP2003, NP2004, TD2003, TD2004). By looking into the details, we found that it is likely because Prank (pointwise), as a pointwise algorithm, is highly sensitive to the imbalance of training data, and the above datasets are indeed highly imbalanced in which very few documents are labeled as relevant among about 1000 documents per query. By contrast, the pairwise algorithm performs much better. This observation further validates the importance of the proposed pairwise SOLAR algorithms that are insensitive to imbalance issue. Last, by comparing the two SOLAR algorithms, we found SOLAR-II outperforms SOLAR-I in most cases, validating the efficacy of exploiting second-order information.

5.3 Batch v.s. Online Learning

5.3.1 Comparison of ranking performance

This experiment aims to directly compare the proposed algorithms with the state-of-the-art batch algorithms in a standard learning to rank setting. We choose four of the most popular and cutting-edge batch algorithms that cover both pairwise and listwise approaches, including RankSVM [20], AdaRank [39], RankBoost [18], and ListNet [5]. For comparison, we follow the standard setting: each dataset is divided into 3 parts: 60% for training, 20% for validation to select the best parameters, and 20% for testing. We use the training data to learn the ranking model by the proposed SOLAR algorithms, the validation data to select the best parameters, and use the test data to evaluate performance. For SOLAR-I, we choose the best parameter C from $[10^{-3.5}, 10^{-6.5}]$ via grid search on the validation set; and similarly for SOLAR-II, we choose the best parameter γ from $[10^{3}, 10^{6}]$. Following [31], we adopt 5 division versions of all the datasets, and report the average performance. The results are shown in Table 3, where the best performances were bolded[2]. Several observations can drawn from the results.

2003NP 2004NP 2003TD 2004TD

Figure 2: Evaluation of MAP performances of Online Learning to Rank algorithms

First of all, we found that no single algorithm beats all the others on all the datasets. Second, on all the datasets, we found that the SOLAR algorithms are generally achieve comparable to the state-of-the-art batch algorithms. On some datasets, e.g., ”MQ2008”, ”MQ2007” ”HP2003”, ”TD2003”, the proposed online algorithms can even achieve best performances in terms of MAP. This encouraging result proves the efficacy of the proposed algorithms as an efficient and scalable online solution to train ranking models. Second, among the two proposed online algorithms, SOLAR-II still outperforms SOLAR-I in most cases, which again shows the importance of exploiting second-order information.

5.3.2 Scalability Evaluation

This experiment aims to examine the scalability of the proposed SOLAR algorithms. We compare it with RankSVM [20], a widely used and efficient batch algorithm. For implementation, we adopt the code from [9] [3], which is known to be the fastest implementation. Figure 3 illustrates the scalability evaluation on “2008MQ” dataset. From the results, we observe that SOLAR is much faster (e.g., 100+ times faster on this dataset)and significantly more scalable than RankSVM.

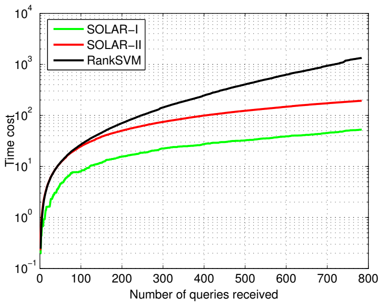

Figure 3: Scalability Evaluation on “2008MQ”

6 Conclusions and Future Work

This paper presented SOLAR — a new framework of Scalable Online Learning Algorithms for Ranking. SOLAR overcomes the limitations of traditional batch learning to rank for real-world online applications. Our empirical results concluded that SOLAR algorithms share competitive efficacy as the state-of-the-art batch algorithms, but enjoy salient properties which are critical to many applications. Our future work include (i) extending our techniques to the framework of listwise learning to rank; (ii) modifying the framework to handle learning to ranking with ties; and (iii) conducting more in-depth analysis and comparisons to other types of online learning to rank algorithms in diverse settings, e.g., partial feedback [41, 22].

Appendix Proof of Theorem 1

Proof. Let $\Delta_t = \|w_t - u\|^2 - \|w_{t+1} - u\|^2$, then

$$\sum_{t=1}^{T} \Delta_t = \|u\|^2 - \|w_{T+1} - u\|^2 \le \|u\|^2$$

Further, Δ_t can be expressed as:

$$\begin{aligned}\Delta_t &= -2\lambda_t y_t (w_t - u) \cdot (\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)) \\ &\quad -\lambda_t \|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\|^2 \\ &\ge \lambda_t (2\ell_t(w_t) - \lambda_t - 2\ell_t(u)).\end{aligned}$$

We thus have

$$\|u\|^2 \quad \ge \quad \sum_{t=1}^{T} (2\lambda_t \ell_t(w_t) - \lambda_t^2 \|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\|^2 - 2\lambda_t \ell_t(u))$$

$$\ge \sum_{t=1}^{T} (2\lambda_t \ell_t(w_t) - \lambda_t^2 \|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\|^2 - 2\lambda_t \ell_t(u)$$

$$-(\frac{\lambda_t}{\sqrt{2C}} - \sqrt{2C}\ell_t(u))^2)$$

$$\ge \sum_{t=1}^{T} (2\lambda_t \ell_t(w_t) - \lambda_t^2 (\|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2)\|^2 + \frac{1}{2C}) - 2C\ell_t(u)^2)$$

$$= \sum_{t=1}^{T} (\frac{\ell_t(w_t)^2}{\|\phi(q_t^i, d_t^1) - \phi(q_t^i, d_t^2))\|^2 + \frac{1}{2C}} - 2C\ell_t(u)^2)$$

Combining the above concludes the theorem. □

Appendix B: Proof of Theorem 3

Proof. Using the Cauchy-Schwarz inequality, we have $u_T^T \Sigma_T^{-1} u_T \ge \frac{(u^T \Sigma_T^{-1} u_T)^2}{u^T \Sigma_T^{-1} u}$. Notice that some inequalities could be easily obtained by extending the Lemma3, Lemma 4 and Theorem 2 of [14] to the pairwise setting as follows:

$$u^T \Sigma_T^{-1} u_T \ge \frac{M + U - \sum_{t \in \mathcal{M} \cup \mathcal{U}} \ell_t(u)}{\gamma},$$

$$\sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{\chi_t}{r(\chi_t + \gamma)} \le \log(\det(\Sigma_T^{-1}))$$

$$u_T^T \Sigma_T^{-1} u_T = \sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{\chi_t}{r(\chi_t + \gamma)} + \sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{1 - \ell_t^2(w_t)}{\chi_t + \gamma},$$

$$M + U \le a + \sum_{t \in \mathcal{M} \cup \mathcal{U}} \ell_t(u)$$

where $a = \sqrt{\gamma \|u\|^2 + u^t X_A u} \sqrt{\log(\det(I + \frac{1}{\gamma} X_A)) + U}$.

We thus have

$$\begin{aligned}\sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{\ell_t^2(w_t)}{\chi_t + \gamma} \quad &\le \quad \sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{\chi_t}{r(\chi_t + \gamma)} + \sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{1}{\chi_t + \gamma} \\ &\quad - \frac{(M + U - \sum_{t \in \mathcal{M} \cup \mathcal{U}} \ell_t(u))^2}{r^2 u^T \Sigma_T^{-1} u} \\ &\le \log(\det(\Sigma_T^{-1})) + \sum_{t \in \mathcal{M} \cup \mathcal{U}} \frac{1}{\chi_t + \gamma} - \frac{a^2}{r^2 u^T \Sigma_T^{-1} u} \\ &\le \log(\det(\Sigma_T^{-1})) - \frac{a^2}{r^2 u^T \Sigma_T^{-1} u} + \frac{M + U}{k + \gamma} \\ &\le \log(\det(\Sigma_T^{-1})) - \frac{a^2}{r^2 u^T \Sigma_T^{-1} u} + \frac{a + \sum_{t \in \mathcal{M} \cup \mathcal{U}} \ell_t(u)}{k + \gamma}\end{aligned}$$

Combining the above, we achieve the final result:

$$\begin{aligned}\sum_{i=1}^{Q} \sum_{t=1}^{T_i} \ell_t^2(w_t) \quad &\le \quad \frac{K + \gamma}{k + \gamma} (a + \sum_{i=1}^{Q} \sum_{t=1}^{T_i} \ell_t(u)) \\ &\quad + (K + \gamma)(\log\det(\Sigma_T^{-1}) - \frac{a^2}{\gamma^2 u^T \Sigma_T^{-1} u})\end{aligned}$$

Text Categorization as a Graph Classification Problem

François Rousseau **Emmanouil Kiagias** **Michalis Vazirgiannis**

LIX, École Polytechnique, France

Abstract

In this paper, we consider the task of text categorization as a graph classification problem. By representing textual documents as graph-of-words instead of historical n-gram bag-of-words, we extract more discriminative features that correspond to long-distance n-grams through frequent subgraph mining. Moreover, by capitalizing on the concept of k-core, we reduce the graph representation to its densest part – its main core – speeding up the feature extraction step for little to no cost in prediction performances. Experiments on four standard text classification datasets show statistically significant higher accuracy and macro-averaged F1-score compared to baseline approaches.

1 Introduction

The task of text categorization finds applications in a wide variety of domains, from news filtering and document organization to opinion mining and spam detection. With the ever-growing quantity of information available online nowadays, it is crucial to provide effective systems capable of classifying text in a timely fashion. Compared to other application domains of classification, its specificity lies in its high number of features, its sparse feature vectors and its skewed multiclass scenario. For instance, when dealing with thousands of news articles, it is not uncommon to have millions of n-gram features, only a few hundreds actually present in each document and tens of class labels – some of them with thousands of articles and some others will only a few hundreds. These particularities have to be taken into account when envisaging a different representation for a document and in our case when considering the task as a graph classification problem.

Graphs are powerful data structures that are used to represent complex information about entities and interaction between them and we think text makes no exception. Historically, following the traditional bag-of-words representation, unigrams have been considered as the natural features and later extended to n-grams to capture some *word dependency* and *word order*. However, n-grams correspond to sequences of words and thus fail to capture *word inversion* and *subset matching* (e. g., “article about news” vs. “news article”). We believe graphs can help solve these issues like they did for instance with chemical compounds where repeating substructure patterns are good indicators of belonging to one particular class, e. g., predicting carcinogenicity in molecules (Helma et al., 2001). Graph classification has received a lot of attention this past decade and various techniques have been developed to deal with the task but rarely applied on textual data and at its scale.

In our work, we explored a graph representation of text, namely graph-of-words, to challenge the traditional bag-of-words representation and help better classify textual documents into categories. We first trained a classifier using frequent subgraphs as features for increased effectiveness. We then reduced each graph-of-words to its main core before mining the features for increased efficiency. Finally, we also used this technique to reduce the total number of n-gram features considered in the baselines for little to no loss in prediction performances.

The rest of the paper is organized as follows. Section 2 provides a review of the related work. Section 3 defines the preliminary concepts upon which our work is built. Section 4 introduces the proposed approaches. Section 5 describes the experimental settings and presents the results we obtained on four standard datasets. Finally, Section 6 concludes our paper and mentions future work directions.

2 Related work

In this section, we present the related work in *text categorization*, *graph classification* and the combination of the two fields like in our case.

2.1 Text categorization

Text categorization, a.k.a. *text classification*, corresponds to the task of automatically predicting the class label of a given textual document. We refer to (Sebastiani, 2002) for an in-depth review of the earliest works in the field and (Aggarwal and Zhai, 2012) for a survey of the more recent works that capitalize on additional meta-information. We note in particular the seminal work of Joachims (1998) who was the first to propose the use of a linear SVM with TF×IDF term features for the task. This approach is one of the standard baselines because of its simplicity yet effectiveness (unsupervised n-gram feature mining followed by standard supervised learning). Another popular approach is the use of Naive Bayes and its multiple variants (McCallum and Nigam, 1998), in particular for the subtask of *spam detection* (Androutsopoulos et al., 2000). Finally, there are a couple of works such as (Hassan et al., 2007) that used the graph-of-words representation to propose alternative weights for the n-gram features but still without considering the task as a graph classification problem.

2.2 Graph classification

Graph classification corresponds to the task of automatically predicting the class label of a given graph. The learning part in itself does not differ from other supervised learning problems and most proposed methods deal with the feature extraction part. They fall into two main categories: approaches that consider *subgraphs as features* and *graph kernels*.

2.2.1 Subgraphs as features

The main idea is to mine frequent subgraphs and use them as features for classification, be it with Adaboost (Kudo et al., 2004) or a linear SVM (Deshpande et al., 2005). Indeed, most datasets that were used in the associated experiments correspond to chemical compounds where repeating substructure patterns are good indicators of belonging to one particular class. Some popular graph pattern mining algorithms are gSpan (Yan and Han, 2002), FFSM (Huan et al., 2003) and Gaston (Nijssen and Kok, 2004). The number of frequent subgraphs can be enormous, especially for large graph collections, and handling such a feature set can be very expensive. To overcome this issue, recent works have proposed to retain or even only mine the discriminative subgraphs, i. e. features that contribute to the classification decision, in particular gBoost (Saigo et al., 2009), CORK (Thoma et al., 2009) and GAIA (Jin et al., 2010). However, when experimenting, gBoost did not converge on our larger datasets while GAIA and CORK consider subgraphs of node size at least 2, which exclude unigrams, resulting in poorer performances. Moreover, all these approaches have been developed for binary classification, which meant mining features as many times as the number of classes instead of just once (*one-vs-all* learning strategy). In this paper, we tackle the scalability issue differently through an unsupervised feature selection approach to reduce the size of the graphs and a fortiori the number of frequent subgraphs.

2.2.2 Graph kernels

Gärtner et al. (2003) proposed the first kernels *between* graphs (as opposed to previous kernels *on* graphs, i. e. between nodes) based on either random walks or cycles to tackle the problem of classification between graphs. In parallel, the idea of marginalized kernels was extended to graphs by Kashima et al. (2003) and by Mahé et al. (2004). We refer to (Vishwanathan et al., 2010) for an in-depth review of the topic and in particular its limitations in terms of number of unique node labels, which make them unsuitable for our problem as tested in practice (limited to a few tens of unique labels compared to hundreds of thousands for us).

2.3 Similar works

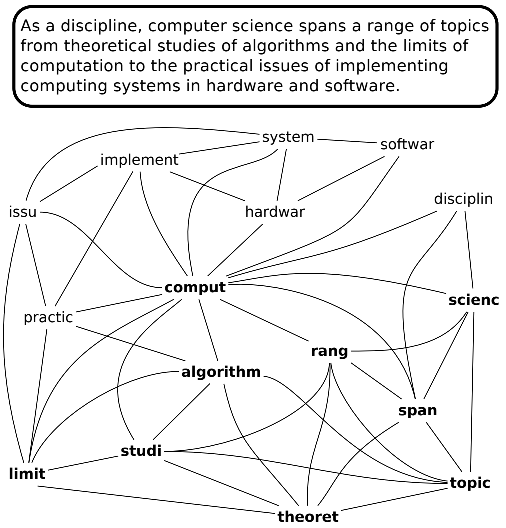
The work of Markov et al. (2007) is perhaps the closest to ours since they also perform subgraph feature mining on graph-of-words representations but with non-standard datasets and baselines. The works of Jiang et al. (2010) and Arora et al. (2010) are also related but their representations are different and closer to parse and dependency trees used as base features for text categorization by Kudo and Matsumoto (2004) and Matsumoto et al. (2005). Moreover, they do not discuss the choice of the support value, which controls the total number of features and can potentially lead to millions of subgraphs on standard datasets.

3 Preliminary concepts

In this section, we introduce the preliminary concepts upon which our work is built.

3.1 Graph-of-words

We model a textual document as a *graph-of-words*, which corresponds to a graph whose vertices represent unique terms of the document and whose edges represent co-occurrences between the terms within a fixed-size sliding window. The underlying assumption is that all the words present in a document have some undirected relationships with the others, modulo a window size outside of which the relationship is not considered. This representation was first used in keyword extraction and summarization (Ohsawa et al., 1998; Mihalcea and Tarau, 2004) and more recently in ad hoc IR (Blanco and Lioma, 2012; Rousseau and Vazirgiannis, 2013). We refer to (Blanco and Lioma, 2012) for an in-depth review of the graph representations of text in NLP.



As a discipline, computer science spans a range of topics from theoretical studies of algorithms and the limits of computation to the practical issues of implementing computing systems in hardware and software.

Figure 1: Graph-of-words representation of a textual document – in bold font, its main core.

Figure 1 illustrates the graph-of-words representation of a textual document. The vertices correspond to the remaining terms after standard preprocessing steps have been applied (tokenization, stop word removal and stemming). The undirected edges were drawn between terms co-occurring within a sliding window over the processed text of size 4, value consistently reported as working well in the references aforementioned and validated in our experiments. Edge direction was used by Filippova (2010) so as to extract valid sentences but not here in order to capture some word inversion.

Note that for small-enough window sizes (which is typically the case in practice), we can consider that two terms linked represent a *long-distance bigram* (Bassiou and Kotropoulos, 2010), if not a bigram. Furthermore, by extending the denomination, we can consider that a subgraph of size n is a *long-distance n-gram*, if not an n-gram. Indeed, the nodes belonging to a subgraph do not necessarily appear in a sequence in the document like for a n-gram. Moreover, this enables us to "merge" together n-grams that share the same terms but maybe not in the same order. In the experiments, by abusing the terminology, we will refer to them as n-grams to adopt a common terminology with the baseline approaches.

3.2 Node/edge labels and subgraph matching

In graph classification, it is common to introduce a node labeling function μ to map a node id to its label. For instance, consider the case of chemical compounds (e. g., the benzene C_6H_6). Then in its graph representation (its "structural formula"), it is crucial to differentiate between the multiple nodes labeled the same (e. g., C or H). In the case of graph-of-words, node labels are unique inside a graph since they represent unique terms of the document and we can therefore omit these functions since they are injective in our case and we can substitute node ids for node labels. In particular, the general problem of *subgraph matching*, which defines an isomorphism between a graph and a subgraph and is NP-complete (Garey and Johnson, 1990), can be reduced to a polynomial problem when node labels are unique. In our experiments, we used the standard algorithm VF2 developed by Cordella et al. (2001).

3.3 K-core and main core

Seidman (1983) defined the k-core of a graph as the maximal connected subgraph whose vertices are at least of degree k within the subgraph. The non-empty k-core of largest k is called the *main core* and corresponds to the most cohesive set(s) of vertices. The corresponding value of k may differ from one graph to another. Batagelj and Zaveršnik (2003) proposed an algorithm to extract the main core of an unweighted graph in time linear in the number of edges, complexity similar in our case to the other NLP preprocessing steps. Bold font on Figure 1 indicates that a vertex belongs to the main core of the graph.

4 Graph-of-words classification

In this section, we present our work and the several approaches we explored, from unsupervised feature mining using gSpan to propose more discriminative features than standard n-grams to unsupervised feature selection using k-core to reduce the total number of subgraph and n-gram features.

4.1 Unsupervised feature mining using gSpan

We considered the task of text categorization as a graph classification problem by representing textual documents as graph-of-words and then extracting subgraph features to train a graph classifier. Each document is a separate graph-of-words and the collection of documents thus corresponds to a set of graphs. Therefore, for larger datasets, the total number of graphs increases but not the average graph size (the average number of unique terms in a text), assuming homogeneous datasets.

Because the total number of unique node labels corresponds to the number of unique terms in the collection in our case, graph kernels are not suitable for us as verified in practice using the MATLAB code made available by Shervashidze (2009). We therefore only explored the methods that consider subgraphs as features. Repeating substructure patterns between graphs are intuitively good candidates for classification since, at least for chemical compounds, shared subparts of molecules are good indicators of belonging to one particular class. We assumed it would the same for text. Indeed, subgraphs of graph-of-words correspond to sets of words co-occurring together, just not necessarily always as the same sequence like for n-grams – it can be seen as a relaxed definition of a n-gram to capture additional variants.

We used gSpan (graph-based Substructure pattern (Yan and Han, 2002)) as frequent subgraph miner like (Jiang et al., 2010; Arora et al., 2010) mostly because of its fast available C++ implementation from gBoost (Saigo et al., 2009). Briefly, the key idea behind gSpan is that instead of enumerating all the subgraphs and testing for isomorphism throughout the collection, it first builds for each graph a lexicographic order of all the edges using depth-first-search (DFS) traversal and assigns to it a unique minimum DFS code. Based on all these DFS codes, a hierarchical search tree is constructed at the collection-level. By pre-order traversal of this tree, gSpan discovers all frequent subgraphs with required support.

Consider the set of all subgraphs in the collection of graphs, which corresponds to the set of all potential features. Note that there may be overlapping (subgraphs sharing nodes/edges) and redundant (subgraphs included in others) features. Because its size is exponential in the number of edges (just like the number of n-grams is exponential in n), it is common to only retain/mine the most frequent subgraphs (again just like for n-grams with a minimum document frequency (Fürnkranz, 1998; Joachims, 1998)). This is controlled via a parameter known as the *support*, which sets the minimum number of graphs in which a given subgraph has to appear to be considered as a feature, i. e. the number of subgraph matches in the collection. Here, since node labels are unique inside a graph, we do not have to consider multiple occurrences of the same subgraph in a given graph. The lower the support, the more features selected/considered but the more expensive the mining and the training (not only in time spent for the learning but also for the feature vector generation).

4.2 Unsupervised support selection

The optimal value for the support can be learned through cross-validation so as to maximize the prediction accuracy of the subsequent classifier, making the whole feature mining process *supervised*. But if we consider that the classifier can only improve its goodness of fit with more features (the sets of features being nested as the support varies), it is likely that the lowest support will lead to the best test accuracy; assuming subsequent regularization to prevent overfitting. However, this will come at the cost of an exponential number of features as observed in practice. Indeed, as the support decreases, the number of features increases slightly up until a point where it increases exponentially, which makes both the feature vector generation and the learning expensive, especially with multiple classes. Moreover, we observed that the prediction performances did not benefit that much from using all the possible features (support of 1) as opposed to a more manageable number of features corresponding to a higher support. Therefore, we propose to select the support using the so-called *elbow method*. This is an unsupervised empirical method initially developed for selecting the number of clusters in k-means (Thorndike, 1953). Figure 3 (upper plots) in Section 5 illustrates this process.

4.3 Considered classifiers

In text categorization, standard baseline classifiers include k-nearest neighbors (kNN) (Larkey and Croft, 1996), Naive Bayes (NB) (McCallum and Nigam, 1998) and linear Support Vector Machines (SVM) (Joachims, 1998) with the latter performing the best on n-gram features as verified in our experiments. Since our subgraph features correspond to "long-distance n-grams", we used linear SVMs as our classifiers in all our experiments – the goal of our work being to explore and propose better features rather than a different classifier.

4.4 Multiclass scenario

In standard binary graph classification (e. g., predicting chemical compounds' carcinogenicity as either positive or negative (Helma et al., 2001)), feature mining is performed on the whole graph collection as we expect the mined features to be able to discriminate between the two classes (thus producing a good classifier). However, for the task of text categorization, there are usually more than two classes (e. g., 118 categories of news articles for the Reuters-21578 dataset) and with a skewed class distribution (e. g., a lot more news related to "acquisition" than to "grain"). Therefore, a single support value might lead to some classes generating a tremendous number of features (e. g., hundreds of thousands of frequent subgraphs) and some others only a few (e. g., a few hundreds subgraphs) resulting in a skewed and non-discriminative feature set. To include discriminative features for these *minority* classes, we would need an extremely low support resulting in an exponential number of features because of the *majority* classes. For these reasons, we decided to mine frequent subgraphs per class using the same relative support (%) and then aggregating each feature set into a global one at the cost of a *supervised* process (but which still avoids cross-validated parameter tuning). This was not needed for the tasks of spam detection and opinion mining since the corresponding datasets consist of only two balanced classes.

4.5 Main core mining using gSpan

Since the main drawback of mining frequent subgraphs for text categorization rather than chemical compound classification is the very high number of possible subgraphs because of the size of the graphs and the total number of graphs (more than 10x in both cases), we thought of ways to reduce the graphs' sizes while retaining as much classification information as possible.

The graph-of-words representation is designed to capture dependency between words, i. e. dependency between features in the context of machine learning but at the document-level. Initially, we wanted to capture recurring sets of words (i. e. take into account word inversion and subset matching) and not just sequences of words like with n-grams. In terms of subgraphs, this means words that co-occur with each other and form a dense subgraph as opposed to a path like for a n-gram. Therefore, when reducing the graphs, we need to keep their densest part(s) and that is why we considered extracting their main cores. Compared to other density-based algorithms, retaining the main core of a graph has the advantage of being linear in the number of edges, i. e. in the number of unique terms in a document in our case (the number of edges is at most the number of nodes times the fixed size of the sliding window, a small constant in practice).

4.6 Unsupervised n-gram feature selection

Similarly to (Hassan et al., 2007) that used graph-of-words to propose alternative weights for the n-gram features, we can capitalize on main core retention to still extract binary n-gram features for classification but considering only the terms belonging to the main core of each document. Because some terms never belong to any main core of any document, the dimension of the overall feature space decreases. Additionally, since a document is only represented by a subset of its original terms, the number of non-zero feature values per document also decreases, which matters for SVM, even for the linear kernel, when considering the dual formulation or in the primal with more recent optimization techniques (Joachims, 2006).

Compared to most existing feature selection techniques in the field (Yang and Pedersen, 1997), it is *unsupervised* and *corpus-independent* as it does not rely on any labeled data like IG, MI or χ^2 nor any collection-wide statistics like IDF, which can be of interest for large-scale text categorization in order to process documents in parallel, independently of each other. In some sense, it is similar to what Özgür et al. (2005) proposed with corpus-based and class-based keyword selection for text classification except that we use here *document-based* keyword selection following the approach from Rousseau and Vazirgiannis (2015).

5 Experiments

In this section we present the experiments we conducted to validate our approaches.

5.1 Datasets

We used four standard text datasets: two for multiclass document categorization (WebKB and R8), one for spam detection (LingSpam) and one for opinion mining (Amazon) so as to cover all the main subtasks of text categorization:

- `WebKB`: 4 most frequent categories among labeled webpages from various CS departments – split into 2,803 for training and 1,396 for test (Cardoso-Cachopo, 2007, p. 39–41).

- `R8`: 8 most frequent categories of Reuters-21578, a set of labeled news articles from the 1987 Reuters newswire – split into 5,485 for training and 2,189 for test (Debole and Sebastiani, 2005).

- `LingSpam`: 2,893 emails classified as spam or legitimate messages – split into 10 sets for 10-fold cross validation (Androutsopoulos et al., 2000).

- `Amazon`: 8,000 product reviews over four different sub-collections (books, DVDs, electronics and kitchen appliances) classified as positive or negative – split into 1,600 for training and 400 for test each (Blitzer et al., 2007).

5.2 Implementation

We developed our approaches mostly in Python using the `igraph` library (Csardi and Nepusz, 2006) for the graph representation and main core extraction. For unsupervised subgraph feature mining, we used the C++ implementation of gSpan from gBoost (Saigo et al., 2009). Finally for classification and standard n-gram text categorization we used `scikit` (Pedregosa et al., 2011), a standard Python machine learning library.

5.3 Evaluation metrics

To evaluate the performance of our proposed approaches over standard baselines, we computed on the test set both the micro- and macro-average F1-score. Because we are dealing with single-label classification, the micro-average F1-score corresponds to the accuracy and is a measure of the overall prediction effectiveness (Manning et al., 2008, p. 281). Conversely, the macro-average F1-score takes into account the skewed class label distributions by weighting each class uniformly. The statistical significance of improvement in accuracy over the n-gram SVM baseline was assessed using the micro sign test ($p < 0.05$) (Yang and Liu, 1999). For the Amazon dataset, we report the average of each metric over the four sub-collections.

Dataset	# subgraphs before	# subgraphs after	reduction
WebKB	30,868	10,113	67 %
R8	39,428	11,373	71 %
LingSpam	54,779	15,514	72 %
Amazon	16,415	8,745	47 %

Dataset	# n-grams before	# n-grams after	reduction
WebKB	1,849,848	735,447	60 %
R8	1,604,280	788,465	51 %
LingSpam	2,733,043	1,016,061	63 %
Amazon	583,457	376,664	35 %

Table 1: Total number of features (n-grams or subgraphs) vs. number of features present only in main cores along with the reduction of the dimension of the feature space on all four datasets.

5.4 Results

Table 2 shows the results on the four considered datasets. The first three rows correspond to the baselines: unsupervised n-gram feature extraction and then supervised learning using kNN, NB (Multinomial but Bernoulli yields similar results) and linear SVM. The last three rows correspond to our approaches.

In our first approach, denoted as "gSpan + SVM", we mine frequent subgraphs (gSpan) as features and then train a linear SVM. These features correspond to long-distance n-grams. This leads to the best results in text categorization on almost all datasets (all if we compare to baseline methods), in particular on multiclass document categorization (R8 and WebKB).

In our second approach, denoted as "MC + gSpan + SVM", we repeat the same procedure except that we mine frequent subgraphs (gSpan) from the main core (MC) of each graph-of-words and then train an SVM on the resulting features. Main cores can vary from 1-core to 12-core depending on the graph structure, 5-core and 6-core being the most frequent (more than 60%). This yields results similar to the SVM baseline for a faster mining and training compared to gSpan + SVM. Table 1 (upper table) shows the reduction in the dimension of the feature space and we see

Table 2: Test accuracy and macro-average F1-score on four standard datasets. Bold font marks the best performance in a column. * indicates statistical significance at $p < 0.05$ using micro sign test with regards to the SVM baseline of the same column. MC corresponds to unsupervised feature selection using the main core of each graph-of-words to extract n-gram and subgraph features. gSpan mining support values are 1.6% (WebKB), 7% (R8), 4% (LingSpam) and 0.5% (Amazon).

Dataset / Method	WebKB		R8		LingSpam		Amazon	
	Accuracy	F1-score	Accuracy	F1-score	Accuracy	F1-score	Accuracy	F1-score
kNN (k=5)	0.679	0.617	0.894	0.705	0.910	0.774	0.512	0.644
NB (Multinomial)	0.866	0.861	0.934	0.839	0.990	0.971	0.768	0.767
linear SVM	0.889	0.871	0.947	0.858	**0.991**	**0.973**	0.792	0.790
gSpan + SVM	**0.912***	**0.882**	**0.955***	**0.864**	**0.991**	0.972	0.798*	0.795
MC + gSpan + SVM	0.901*	0.871	0.949*	0.858	0.990	**0.973**	**0.800***	**0.798**
MC + SVM	0.872	0.863	0.937	0.849	0.990	0.972	0.786	0.774

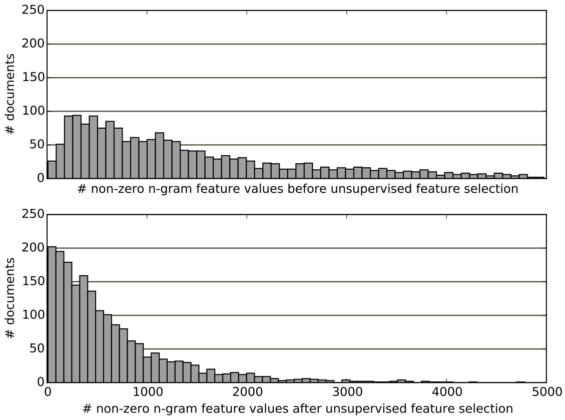


Figure 2: Distribution of non-zero n-gram feature values before and after unsupervised feature selection (main core retention) on R8 dataset.

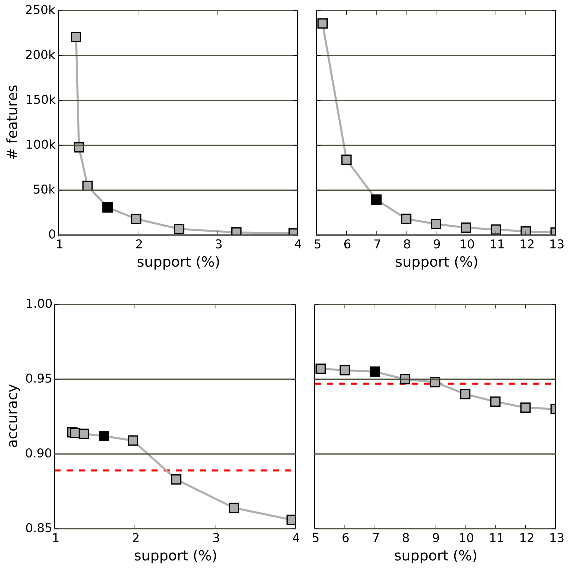

Figure 3: Number of subgraph features/accuracy in test per support (%) on WebKB (left) and R8 (right) datasets: in black, the selected support value chosen via the elbow method and in red, the accuracy in test for the SVM baseline.

that on average less than 60% of the subgraphs are kept for little to no cost in prediction effectiveness.

In our final approach, denoted as "MC + SVM", we performed unsupervised feature selection by keeping the terms appearing in the main core (MC) of each document's graph-of-words representation and then extracted standard n-gram features. Table 1 (lower table) shows the reduction in the dimension of the feature space and we see that on average less than half the n-grams remain. Figure 2 shows the distribution of non-zero features before and after the feature selection on the R8 dataset. Similar changes in distribution can be observed on the other datasets, from a right-tail Gaussian to a power law distribution as expected from the main core retention. Table 2 shows that the main core retention has little to no cost in accuracy and F1-score but can reduce drastically the feature space and the number of non-zero values per document.

5.5 Unsupervised support selection

Figure 3 above illustrates the unsupervised heuristic (elbow method) we used to select the support value, which corresponds to the minimum number of graphs in which a subgraph has to appear to be considered frequent. We noticed that as the support decreases, the number of features increases slightly up until a point where it increases exponentially. This support value, highlighted in black on the figure and chosen before taking into account the class label, is the value we used in our experiments and for which we report the results in Table 1 and 2. The lower plots provide evidence

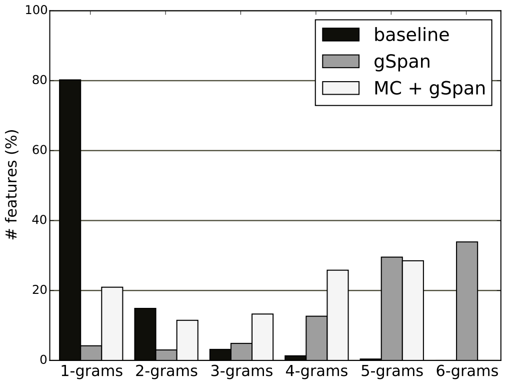

Figure 4: Distribution of n-grams (standard and long-distance ones) among all the features on WebKB dataset.

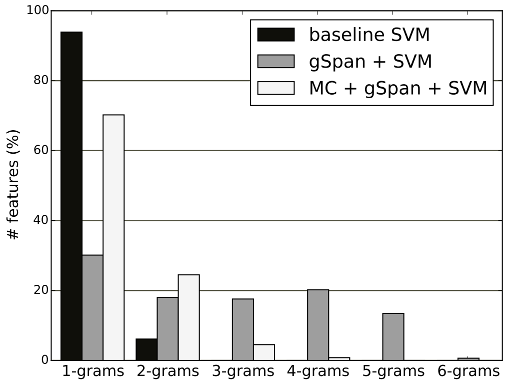

Figure 5: Distribution of n-grams (standard and long-distance ones) among the top 5% most discriminative features for SVM on WebKB dataset.

that the elbow method helps selecting in an unsupervised manner a support that leads to the best or close to the best accuracy.

5.6 Distribution of mined n-grams

In order to gain more insights on why the long-distance n-grams mined with gSpan result in better classification performances than the baseline n-grams, we computed the distribution of the number of unigrams, bigrams, etc. up to 6-grams in the traditional feature set and ours (Figure 4) as well as in the top 5% features that contribute the most to the classification decision of the trained SVM (Figure 5). Again, a long-distance n-gram corresponds to a subgraph of size n in a graph-of-words and can be seen as a relaxed definition of the traditional n-gram, one that takes into account word inversion for instance. To obtain comparable results, we considered for the baseline n-grams with a minimum document frequency equal to the support. Otherwise, by definition, there are at least as many bigrams as there are unigrams and so forth.

Figure 4 shows that our approaches mine way more n-grams than unigrams compared to the baseline. This happens because with graph-of-words a subgraph of size n corresponds to a set of n terms while with bag-of-words a n-gram corresponds to a sequence of n terms. Note that even when restricting the subgraphs to the main cores, there are still more higher order n-grams mined.

Figure 5 shows that the higher order n-grams still contribute indeed to the classification decision and in higher proportion than with the baseline, even when restricting to the main cores. For instance, on the R8 dataset, {bank, base, rate} was a discriminative (top 5% SVM features) long-distance 3-gram for the category "interest" and occurred in documents in the form of "barclays bank cut its base lending rate", "midland bank matches its base rate" and "base rate of natwest bank dropped", pattern that would be hard to capture with traditional n-gram bag-of-words.

5.7 Timing

With an Intel Core i5-3317U clocking at 2.6GHz and 8GB of RAM, mining the subgraph features with gSpan takes on average 30s for the selected support. It can take several hours with lower support and goes down to 5s using the main cores.

6 Conclusion

In this paper, we tackled the task of text categorization by representing documents as graph-of-words and then considering the problem as a graph classification one. We were able to extract more discriminative features that correspond to long-distance n-grams through frequent subgraph mining. Experiments on four standard datasets show statistically significant higher accuracy and macro-averaged F1-score compared to baselines.

To the best of our knowledge, graph classification has never been tested at that scale – thousands of graphs and tens of thousands of unique node labels – and also in the multiclass scenario. For these reasons, we could not capitalize on all standard methods. In particular, we believe new kernels that support a very high number of unique node labels could yield even better performances.

Abstract

We present a novel, count-based approach to obtaining inter-lingual word representations based on inverted indexing of Wikipedia. We present experiments applying these representations to 17 datasets in document classification, POS tagging, dependency parsing, and word alignment. Our approach has the advantage that it is simple, computationally efficient and almost parameter-free, and, more importantly, it enables multi-source cross-lingual learning. In 14/17 cases, we improve over using state-of-the-art bilingual embeddings.

1 Introduction

Linguistic resources are hard to come by and unevenly distributed across the world's languages. Consequently, transferring linguistic resources or knowledge from one language to another has been identified as an important research problem. Most work on cross-lingual transfer has used English as the source language. There are two reasons for this; namely, the availability of English resources and the availability of parallel data for (and translations between) English and most other languages.

In cross-lingual syntactic parsing, for example, two approaches to cross-lingual learning have been explored, namely annotation projection and delexicalized transfer. Annotation projection (Hwa et al., 2005) uses word-alignments in human translations to project predicted source-side analyses to the target language, producing a noisy syntactically annotated resource for the target language. On the other hand, delexicalized transfer (Zeman and Resnik, 2008; McDonald et al., 2011; Søgaard, 2011) simply removes lexical features from mono-lingual parsing models, but assumes reliable POS tagging for the target language. Delexicalized transfer works particularly well when resources from several source languages are used for training; learning from multiple other languages prevents over-fitting to the peculiarities of the source language. Some authors have also combined annotation projection and delexicalized transfer, e.g., McDonald et al. (2011). Others have tried to augment delexicalized transfer models with bilingual word representations (Täckström et al., 2013; Xiao and Guo, 2014).

In cross-lingual POS tagging, mostly annotation projection has been explored (Fossum and Abney, 2005; Das and Petrov, 2011), since all features in POS tagging models are typically lexical. However, using bilingual word representations was recently explored as an alternative to projection-based approaches (Gouws and Søgaard, 2015).

The major drawback of using bi-lexical representations is that it limits us to using a single source language. Täckström et al. (2013) obtained significant improvements using bilingual word clusters over a single source delexicalized transfer model, for example, but even better results were obtained with delexicalized transfer in McDonald et al. (2011) by simply using several source languages.

This paper introduces a simple method for obtaining *truly* inter-lingual word representations in order to train models with lexical features on several source languages at the same time. Briefly put, we represent words by their occurrence in clusters of Wikipedia articles linking to the same concept. Our representations are competitive with

and the 7th International Joint Conference on Natural Language Processing*, pages 1713–1722,
Beijing, China, July 26-31, 2015.

state-of-the-art neural net word embeddings when using only a single source language, but also enable us to exploit the availability of resources in multiple languages. This also makes it possible to explore multi-source transfer for POS tagging. We evaluate the method across POS tagging and dependency parsing datasets in four languages in the Google Universal Treebanks v. 1.0 (see §3.2.1), as well as two document classification datasets and four word alignment problems using a hand-aligned text. Finally, we also directly compare our results to Xiao and Guo (2014) on parsing data for four languages from CoNLL 2006 and 2007.

Contribution

- We present a novel approach to cross-lingual word representations with several advantages over existing methods: (a) It does not require training neural networks, (b) it does not rely on the availability of parallel data between source and target language, and (c) it enables multi-source transfer with lexical representations.
- We present an evaluation of our inter-lingual word representations, based on inverted indexing, across four tasks: document classification, POS tagging, dependency parsing, and word alignment, comparing our representations to two state-of-the-art neural net word embeddings. For the 17 datasets, for which we can make this comparison, our system is better than these embedding models on 14 datasets. The word representations are made publicly available at `https://bitbucket.org/lowlands/`

2 Distributional word representations

Most NLP models rely on lexical features. Encoding the presence of words leads to high-dimensional and sparse models. Also, simple bag-of-words models fail to capture the relatedness of words. In many tasks, synonymous words should be treated alike, but their bag-of-words representations are as different as those of *dog* and *therefore*.

Distributional word representations are supposed to capture distributional similarities between words. Intuitively, we want similar words to have similar representations. Known approaches focus on different kinds of similarity, some more syntactic, some more semantic. The representations are typically either clusters of distributionally similar words, e.g., Brown et al. (1992), or vector representations. In this paper, we focus on vector representations. In vector-based approaches, similar representations are vectors close in some multi-dimensional space.

2.1 Count-based and prediction-based representations

There are, briefly put, two approaches to inducing vector-based distributional word representations from large corpora: count-based and prediction-based approaches (Baroni et al., 2014). Count-based approaches represent words by their co-occurrences. Dimensionality reduction is typically performed on a raw or weighted co-occurrence matrix using methods such as singular value decomposition (SVD), a method for maximizing the variance in a dataset in few dimensions. In our inverted indexing, we use raw co-occurrence data.

Prediction-based methods use discriminative learning techniques to learn how to predict words from their context, or vice versa. They rely on a neural network architecture, and once the network converges, they use word representations from a middle layer as their distributional representations. Since the network learns to predict contexts from this representation, words occurring in the same contexts will get similar representations. In §2.1.2, we briefly introduce the skip-gram and CBOW models (Mikolov et al., 2013; Collobert and Weston, 2008).

Baroni et al. (2014) argue in favor of prediction-based representations, but provide little explanation why prediction-based representations should be better. One key finding, however, is that prediction-based methods tend to be more robust than count-based methods, and one reason for this seems to be better regularization.

2.1.1 Monolingual representations

Count-based representations rely on co-occurrence information in the form of binary matrices, raw counts, or point-wise mutual information (PMI). The PMI between two words is

$$P(w_i; w_j) = \log \frac{P(w_i \mid w_j)}{P(w_i)}$$

and PMI representations associate a word w_i with a vector of its PMIs with all other words w_j. Dimensionality reduction is typically performed using SVD. We will refer to two prediction-based approaches to learning word vectors, below: the

Table 1: Three nearest neighbors in the English training data of six words occurring in the Spanish test data, in the embeddings used in our experiments. Only 2/6 words were in the German data.

skip-gram model and CBOW. The two models both rely on three level architectures with input, output and a middle layer for intermediate target word representations. The major difference is that skip-gram uses the target word as input and the context as output, whereas the CBOW model does it the other way around. Learning goes by back-propagation, and random target words are used as negative examples. Levy and Goldberg (2014) show that prediction-based representations obtained with the skip-gram model can be related to count-based ones obtained with PMI. They argue that which is best, varies across tasks.

2.1.2 Bilingual representations

Klementiev et al. (2012) learn distinct embedding models for the source and target languages, but while learning to minimize the sum of the two models' losses, they jointly learn a regularizing interaction matrix, enforcing word pairs aligned in parallel text to have similar representations. Note that Klementiev et al. (2012) rely on word-aligned parallel text, and thereby on a large-coverage soft mapping of source words to target words. Other approaches rely on small coverage dictionaries with hard 1:1 mappings between words. Klementiev et al. (2012) do not use skip-gram or CBOW, but the language model presented in Bengio et al. (2003).

Chandar et al. (2014) also rely on sentence-aligned parallel text, but do not make use of word alignments. They begin with bag-of-words representations of source and target sentences. They then use an auto-encoder architecture. Auto-encoders for document classification typically try to reconstruct bag-of-words input vectors at the output layer, using back-propagation, passing the representation through a smaller middle layer. This layer then provides a dimensionality reduction. Chandar et al. (2014) instead replace the output layer with the target language bag-of-words reconstruction. In their final set-up, they simultaneously minimize the loss of a source-source, a target-target, a source-target, and a target-source auto-encoder, which corresponds to training a single auto-encoder with randomly chosen instances from source-target pairs. The bilingual word vectors can now be read off the auto-encoder's middle layer.

Xiao and Guo (2014) use a CBOW model and random target words as negative examples. The trick they introduce to learn bilingual embeddings, relies on a bilingual dictionary, in their case obtained from Wiktionary. They only use the unambiguous translation pairs for the source and target languages in question and simply force translation equivalents to have the same representation. This corresponds to replacing words from unambiguous translation pairs with a unique dummy symbol.

Gouws and Søgaard (2015) present a much simpler approach to learning prediction-based bilingual representations. They assume a list of source-target pivot word pairs that should obtain similar representations, i.e., translations or words with similar representations in some knowledge base. They then present a generative model for constructing a mixed language corpus by randomly selecting sentences from source and target corpora, and randomly replacing pivot words with their equivalent in the other language. They show that running the CBOW model on such a mixed corpus suffices to learn competitive bilingual embeddings. Like Xiao and Guo (2014), Gouws and Søgaard (2015) only use unambiguous translation pairs.

There has, to the best of our knowledge, been no previous work on count-based approaches to bilingual representations.

2.2 Inverted indexing

In this paper, we introduce a new count-based approach, INVERTED, to obtaining cross-lingual word representations using inverted indexing, comparing it with bilingual word representations learned using discriminative techniques. The main advantage of this approach, apart for its simplicity, is that it provides *truly* inter-lingual representations.

Our idea is simple. Wikipedia is a cross-lingual, crowd-sourced encyclopedia with more than 35 million articles written in different languages. At the time of writing, Wikipedia contains more than 10,000 articles in 129 languages. 52 languages had more than 100,000 articles. Several articles are written on the same topic, but in different languages, and these articles all link to the same node in the Wikipedia ontology, the same Wikipedia concept. If for a set of languages, we identify the common subset of Wikipedia concepts, we can thus describe each concept by the set of terms used in the corresponding articles. Each term set will include terms from each of the different languages.

We can now present a word by the corresponding row in the inverted indexing of this concept-to-term set matrix. Instead of representing a Wikipedia concept by the terms used across languages to describe it, we describe a word by the Wikipedia concepts it is used to describe. Note that because of the cross-lingual concepts, this vector representation is by definition cross-lingual. So, for example, if the word *glasses* is used in the English Wikipedia article on Harry Potter, and the English Wikipedia article on Google, and the word *Brille* occurs in the corresponding German ones, the two words are likely to get similar representations.

In our experiments, we use the common subset of available German, English, French, Spanish, and Swedish Wikipedia dumps.[1] We leave out words occurring in more than 5000 documents and perform dimensionality reduction using stochastic, two-pass, rank-reduced SVD - specifically, the latent semantic indexing implementation in Gensim using default parameters.[2]

2.3 Baseline embeddings

We use the word embedding models of Klementiev et al. (2012)[3] (KLEMENTIEV), and Chandar et al. (2014) (CHANDAR) as baselines in the experiments below. We also ran some of our experiments with the embeddings provided by Gouws and Søgaard (2015), but results were very similar to Chandar et al. (2014). We compare the nearest cross-language neighbors in the various representations in Table 1. Specifically, we selected five words from the Spanish test data and searched for its three nearest neighbors in KLEMENTIEV, CHANDAR and INVERTED. The nearest neighbors are presented left to right. We note that CHANDAR and INVERTED seem to contain less noise. KLEMENTIEV is the only model that relies on word-alignments. Whether the noise originates from alignments, or just model differences, is unclear to us.

2.4 Parameters of the word representation models

For KLEMENTIEV and CHANDAR, we rely on embeddings provided by the authors. The only parameter in inverted indexing is the fixed dimensionality in SVD. Our baseline models use 40 dimensions. In document classification, we also use 40 dimensions, but for POS tagging and dependency parsing, we tune the dimensionality parameter $\delta \in \{40, 80, 160\}$ on Spanish development data when possible. For document clas-

sification and word alignment, we fix the number of dimensions to 40. For both our baselines and systems, we also tune a scaling factor $\sigma \in \{1.0, 0.1, 0.01, 0.001\}$ for POS tagging and dependency parsing, using the scaling method from Turian et al. (2010), also used in Gouws and Søgaard (2015). We do not scale our embeddings for document classification or word alignment.

3 Experiments

The data set characteristics are found in Table 2.3.

3.1 Document classification

Data Our first document classification task is topic classification on the cross-lingual multi-domain sentiment analysis dataset AMAZON in Prettenhofer and Stein (2010).[4] We represent each document by the average of the representations of those words that we find both in the documents and in our embeddings. Rather than classifying reviews by sentiment, we classify by topic, trying to discriminate between book reviews, music reviews and DVD reviews, as a three-way classification problem, training on English and testing on German. Unlike in the other tasks below, we always use unscaled word representations, since these are our only features. All word representations have 40 dimensions.

The other document classification task is a four-way classification problem distinguishing between four topics in RCV corpus.[5] See Klementiev et al. (2012) for details. We use exactly the same set-up as for AMAZON.

Baselines We use the default parameters of the implementation of logistic regression in Sklearn as our baseline.[6] The feature representation is the average embedding of non-stopwords in KLEMENTIEV, resp., CHANDAR. Out-of-vocabulary words do not affect the feature representation of the documents.

System For our system, we replace the above neural net word embeddings with INVERTED representations. Again, out-of-vocabulary words do not affect the feature representation of the documents.

3.2 POS tagging

Data We use the coarse-grained part-of-speech annotations in the Google Universal Treebanks v. 1.0

[4] http://www.webis.de/research/corpora/

[5] http://www.ml4nlp.de/code-and-data

[6] http://scikit-learn.org/stable/

(McDonald et al., 2013).[7] Out of the languages in this set of treebanks, we focus on five languages (de, en, es, fr, sv), with English only used as training data. Those are all treebanks of significant size, but more importantly, we have baseline embeddings for four of these languages, as well as tag dictionaries (Li et al., 2012) needed for the POS tagging experiments.

Baselines One baseline method is a type-constrained structured perceptron with only ortographic features, which are expected to transfer across languages. The type constraints come from Wiktionary, a crowd-sourced tag dictionary.[8] Type constraints from Wiktionary were first used by Li et al. (2012), but note that their set-up is unsupervised learning. Täckström et al. (2013) also used type constraints in a supervised set-up. Our learning algorithm is the structured perceptron algorithm originally proposed by Collins (2002). In our POS tagging experiments, we always do 10 passes over the data. We also present two other baselines, where we augment the feature representation with different embeddings for the target word, KLEMENTIEV and CHANDAR. With all the embeddings in POS tagging, we assign a mean vector to out-of-vocabulary words.

System For our system, we simply augment the delexicalized POS tagger with the INVERTED distributional representation of the current word. The best parameter setting on Spanish development data was $\sigma = 0.01, \delta = 160$.

3.3 Dependency parsing

Data We use the same treebanks from the Google Universal Treebanks v. 1.0 as used in our POS tagging experiments. We again use the Spanish development data for parameter tuning. For compatibility with Xiao and Guo (2014), we also present results on CoNLL 2006 and 2007 treebanks for languages for which we had baseline and system word representations (de, es, sv). Our parameter settings for these experiments were the same as those tuned on the Spanish development data from the Google Universal Treebanks v. 1.0.

Baselines The most obvious baseline in our experiments is delexicalized transfer (DELEX) (McDonald et al., 2011; Søgaard, 2011). This baseline system simply learns models without lexical features. We use a modified version of the first-order Mate parser (Bohnet, 2010) that also takes continuous-valued embeddings as input an disregards features that include lexical items.

For our embeddings baselines, we augment the feature space by adding embedding vectors for head h and dependent d. We experimented with different versions of combining embedding vectors, from firing separate h and d per-dimension features (Bansal et al., 2014) to combining their information. We found that combining the embeddings of h and d is effective and consistently use the absolute difference between the embedding vectors, since that worked better than addition and multiplication on development data.

Delexicalized transfer (DELEX) uses three (3) iterations over the data in both the single-source and the multi-source set-up, a parameter set on the Spanish development data. The remaining parameters were obtained by averaging over performance with different embeddings on the Spanish development data, obtaining: $\sigma = 0.005, \delta = 20, i = 3$, and absolute difference for vector combination. With all the embeddings in dependency parsing, we assign a POS-specific mean vector to out-of-vocabulary words, i.e., the mean of vectors for words with the input word's POS.

System We use the same parameters as those used for our baseline systems. In the single-source set-up, we use absolute difference for combining vectors, while addition in the multi-source set-up.

3.4 Word alignment

Data We use the manually word-aligned English-Spanish Europarl data from Graca et al. (2008). The dataset contains 100 sentences. The annotators annotated whether word alignments were certain or possible, and we present results with *all* word alignments and with only the certain ones. See Graca et al. (2008) for details.

Baselines For word alignment, we simply align every aligned word in the gold data, for which we have a word embedding, to its (Euclidean) nearest neighbor in the target sentence. We evaluate this strategy by its precision (P@1).

System We compare INVERTED with KLEMENTIEV and CHANDAR. To ensure a fair comparison, we use the subset of words covered by all three embeddings.

Table 6: Dependency parsing for CoNLL 2006/2007 datasets. Parameters same as on the Google Universal Treebanks.

4 Results

4.1 Document classification

Our document classification results in Table 3 are mixed, but we note that both Klementiev et al. (2012) and Chandar et al. (2014) developed their methods using development data from the RCV corpus. It is therefore not surprising that they obtain good results on this data. On AMAZON, INVERTED is superior to both KLEMENTIEV and CHANDAR.

4.2 POS tagging

In POS tagging, INVERTED leads to significant improvements over using KLEMENTIEV and CHANDAR. See Table 4 for results. Somewhat surprisingly, we see no general gain from using multiple source languages. This is very different from what has been observed in dependency parsing (McDonald et al., 2011), but may be explained by treebank sizes, language similarity, or the noise introduced by the word representations.

4.3 Dependency parsing

In dependency parsing, distributional word representations do not lead to significant improvements, but while KLEMENTIEV and CHANDAR hurt performance, the INVERTED representations lead to small improvements on some languages. The fact that improvements are primarily seen on Spanish suggest that our approach is parameter-sensitive. This is in line with previous observations that count-based methods are more parameter-sensitive than prediction-based ones (Baroni et al., 2014).

For comparability with Xiao and Guo (2014), we also did experiments with the CoNLL 2006 and CoNLL 2007 datasets for which we had embeddings (Table 6). Again, we see little effects from using the word representations, and we also see that our baseline model is weaker than the one in Xiao and Guo (2014) (DELEX-XIAO). See §5 for further discussion.

4.4 Word alignment

The word alignment results are presented in Table 7. On the certain alignments, we see an accuracy of more than 50% with INVERTED in one case. KLEMENTIEV and CHANDAR have the advantage of having been trained on the English-Spanish Europarl data, but nevertheless we see consistent improvements with INVERTED over their off-the-shelf embeddings.

5 Related Work

As noted in §1, there has been some work on learning word representations for cross-lingual parsing lately. Täckström et al. (2013) presented a bilingual clustering algorithm and used the word clusters to augment a delexicalized transfer baseline. Bansal et al. (2014), in the context of monolingual dependency parsing, investigate continuous word representation for dependency parsing in a monolingual cross-domain setup and compare them to word clusters. However, to make the embeddings work, they had to i) bucket real values and perform hierarchical clustering on them, ending up with word clusters very similar to those of Täckström et al. (2013); ii) use syntactic context to estimate embeddings. In the cross-lingual setting, syntactic context is not available for the target language, but doing clustering on top of inverted indexing is an interesting option we did not explore in this paper.

Xiao and Guo (2014) is, to the best of our knowledge, the only parser using bilingual embeddings for unsupervised cross-lingual parsing. They evaluate their models on CoNLL 2006 and CoNLL 2007, and we compare our results to theirs in §4. They obtain much better relative improvements on dependency parsing that we do - comparable to those we observe in document classification and POS tagging. It is not clear to us what is the explanation for this improvement. The approach relies on a bilingual dictionary as in Klementiev et al. (2012) and Gouws and Søgaard (2015), but none of these embeddings led to improvements. Unfortunately, we did not have the code or embeddings of Xiao and Guo (2014). One possible explanation is that they use the embeddings in a very different way in the parser. They use the MSTParser. Unfortunately, they do not say exactly how they combine the embeddings with their baseline feature model.

The idea of using inverted indexing in Wikipedia for modelling language is not entirely new either. In cross-lingual information retrieval, this technique, sometimes referred to as *explicit semantic analysis*, has been used to measure source and target language document relatedness (Potthast et al., 2008; Sorg and Cimiano, 2008). Gabrilovich and Markovitch (2009) also use this technique to model documents, and they evaluate their method on text categorization and on computing the degree of semantic relatedness between text fragments. See also Müller and Gurevych (2009) for an application of explicit semantic analysis to modelling documents. This line of work is very different from ours, and to the best of our knowledge, we are the first to propose to use inverted indexing of Wikipedia for cross-lingual word representations.

6 Conclusions

We presented a simple, scalable approach to obtaining cross-lingual word representations that enables multi-source learning. We compared these representations to two state-of-the-art approaches to neural net word embeddings across four tasks and 17 datasets, obtaining better results than *both* approaches in 14/17 of these cases.

Abstract

In this paper, we investigate the problem of learning a machine translation model that can simultaneously translate sentences from one source language to multiple target languages. Our solution is inspired by the recently proposed neural machine translation model which generalizes machine translation as a sequence learning problem. We extend the neural machine translation to a multi-task learning framework which shares source language representation and separates the modeling of different target language translation. Our framework can be applied to situations where either large amounts of parallel data or limited parallel data is available. Experiments show that our multi-task learning model is able to achieve significantly higher translation quality over individually learned model in both situations on the data sets publicly available.

1 Introduction

Translation from one source language to multiple target languages at the same time is a difficult task for humans. A person often needs to be familiar with specific translation rules for different language pairs. Machine translation systems suffer from the same problems too. Under the current classic statistical machine translation framework, it is hard to share information across different phrase tables among different language pairs. Translation quality decreases rapidly when the size of training corpus for some minority language pairs becomes smaller. To conquer the problems described above, we propose a multi-task learning framework based on a sequence learning model to conduct machine translation from one source language to multiple target languages, inspired by the recently proposed neural machine translation(NMT) framework proposed by Bahdanau et al. (2014). Specifically, we extend the recurrent neural network based encoder-decoder framework to a multi-task learning model that shares an encoder across all language pairs and utilize a different decoder for each target language.

The neural machine translation approach has recently achieved promising results in improving translation quality. Different from conventional statistical machine translation approaches, neural machine translation approaches aim at learning a radically end-to-end neural network model to optimize translation performance by generalizing machine translation as a sequence learning problem. Based on the neural translation framework, the lexical sparsity problem and the long-range dependency problem in traditional statistical machine translation can be alleviated through neural networks such as long short-term memory networks which provide great lexical generalization and long-term sequence memorization abilities.

The basic assumption of our proposed framework is that many languages differ lexically but are closely related on the semantic and/or the syntactic levels. We explore such correlation across different target languages and realize it under a multi-task learning framework. We treat a separate translation direction as a sub RNN encode-decoder task in this framework which shares the same encoder (i.e. the same source language representation) across different translation directions, and use a different decoder for each specific target language. In this way, this proposed multi-task learning model can make full use of the source language corpora across different language pairs. Since the encoder part shares the same source language representation

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1723–1732,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

across all the translation tasks, it may learn semantic and structured predictive representations that can not be learned with only a small amount of data. Moreover, during training we jointly model the alignment and the translation process simultaneously for different language pairs under the same framework. For example, when we simultaneously translate from English into Korean and Japanese, we can jointly learn latent similar semantic and structure information across Korea and Japanese because these two languages share some common language structures.

The contribution of this work is three folds. First, we propose a unified machine learning framework to explore the problem of translating one source language into multiple target languages. To the best of our knowledge, this problem has not been studied carefully in the statistical machine translation field before. Second, given large-scale training corpora for different language pairs, we show that our framework can improve translation quality on each target language as compared with the neural translation model trained on a single language pair. Finally, our framework is able to alleviate the data scarcity problem, using language pairs with large-scale parallel training corpora to improve the translation quality of those with few parallel training corpus.

The following sections will be organized as follows: in section 2, related work will be described, and in section 3, we will describe our multi-task learning method. Experiments that demonstrate the effectiveness of our framework will be described in section 4. Lastly, we will conclude our work in section 5.

2 Related Work

Statistical machine translation systems often rely on large-scale parallel and monolingual training corpora to generate translations of high quality. Unfortunately, statistical machine translation system often suffers from data sparsity problem due to the fact that phrase tables are extracted from the limited bilingual corpus. Much work has been done to address the data sparsity problem such as the pivot language approach (Wu and Wang, 2007; Cohn and Lapata, 2007) and deep learning techniques (Devlin et al., 2014; Gao et al., 2014; Sundermeyer et al., 2014; Liu et al., 2014).

On the problem of how to translate one source language to many target languages within one model, few work has been done in statistical machine translation. A related work in SMT is the pivot language approach for statistical machine translation which uses a commonly used language as a ”bridge” to generate source-target translation for language pair with few training corpus. Pivot based statistical machine translation is crucial in machine translation for resource-poor language pairs, such as Spanish to Chinese. Considering the problem of translating one source language to many target languages, pivot based SMT approaches does work well given a large-scale source language to pivot language bilingual corpus and large-scale pivot language to target languages corpus. However, in reality, language pairs between English and many other target languages may not be large enough, and pivot-based SMT sometimes fails to handle this problem. Our approach handles one to many target language translation in a different way that we directly learn an end to multi-end translation system that does not need a pivot language based on the idea of neural machine translation.

Neural Machine translation is a emerging new field in machine translation, proposed by several work recently (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014), aiming at end-to-end machine translation without phrase table extraction and language model training. Different from traditional statistical machine translation, neural machine translation encodes a variable-length source sentence with a recurrent neural network into a fixed-length vector representation and decodes it with another recurrent neural network from a fixed-length vector into variable-length target sentence. A typical model is the RNN encoder-decoder approach proposed by Bahdanau et al. (2014), which utilizes a bidirectional recurrent neural network to compress the source sentence information and fits the conditional probability of words in target languages with a recurrent manner. Moreover, soft alignment parameters are considered in this model. As a specific example model in this paper, we adopt a RNN encoder-decoder neural machine translation model for multi-task learning, though all neural network based model can be adapted in our framework.

In the natural language processing field, a notable work related with multi-task learning was proposed by Collobert et al. (2011) which shared common representation for input words and solve different traditional NLP tasks such as part-of-Speech tagging, name entity recognition and semantic role labeling within one framework, where the convolutional neural network model was used. Hatori et al. (2012) proposed to jointly train word segmentation, POS tagging and dependency parsing, which can also be seen as a multi-task learning approach. Similar idea has also been proposed by Li et al. (2014) in Chinese dependency parsing. Most of multi-task learning or joint training frameworks can be summarized as parameter sharing approaches proposed by Ando and Zhang (2005) where they jointly trained models and shared center parameters in NLP tasks. Researchers have also explored similar approaches (Sennrich et al., 2013; Cui et al., 2013) in statistical machine translation which are often refered as domain adaption. Our work explores the possibility of machine translation under the multi-task framework by using the recurrent neural networks. To the best of our knowledge, this is the first trial of end to end machine translation under multi-task learning framework.

3 Multi-task Model for Multiple Language Translation

Our model is a general framework for translating from one source language to many targets. The model we build in this section is a recurrent neural network based encoder-decoder model with multiple target tasks, and each task is a specific translation direction. Different tasks share the same translation encoder across different language pairs. We will describe model details in this section.

3.1 Objective Function

Given a pair of training sentence $\{\mathbf{x}, \mathbf{y}\}$, a standard recurrent neural network based encoder-decoder machine translation model fits a parameterized model to maximize the conditional probability of a target sentence $\mathbf{y}$ given a source sentence $\mathbf{x}$, i.e., $\mathrm{argmax}\, p(\mathbf{y}|\mathbf{x})$. We extend this into multiple languages setting. In particular, suppose we want to translate from English to many different languages, for instance, French(Fr), Dutch(Nl), Spanish(Es). Parallel training data will be collected before training, i.e. En-Fr, En-Nl, En-Es parallel sentences. Since the English representation of the three language pairs is shared in one encoder, the objective function we optimize is the summation of several conditional probability terms conditioned on representation generated from the same encoder.

$$L(\Theta) = \underset{\Theta}{\mathrm{argmax}}(\sum_{T_p}(\frac{1}{N_p}\sum_{i}^{N_p}\log p(\mathbf{y_i}^{T_p}|\mathbf{x_i}^{T_p};\Theta)) \tag{1}$$

where $\Theta = \{\Theta_{src}, \Theta_{trg_{T_p}}, T_p = 1, 2, \cdots, T_m\}$, Θ_{src} is a collection of parameters for source encoder. And $\Theta_{trg_{T_p}}$ is the parameter set of the T_pth target language. N_p is the size of parallel training corpus of the pth language pair. For different target languages, the target encoder parameters are seperated so we have T_m decoders to optimize. This parameter sharing strategy makes different language pairs maintain the same semantic and structure information of the source language and learn to translate into target languages in different decoders.

3.2 Model Details

Suppose we have several language pairs $(\mathbf{x}^{T_p}, \mathbf{y}^{T_p})$ where T_p denotes the index of the T_pth language pair. For a specific language pair, given a sequence of source sentence input $(x_1^{T_p}, x_2^{T_p}, \cdots, x_n^{T_p})$, the goal is to jointly maximize the conditional probability for each generated target word. The probability of generating the tth target word is estimated as:

$$p(y_t^{T_p}|y_1^{T_p}, \cdots, y_{t-1}^{T_p}, \mathbf{x}^{T_p}) = g(y_{t-1}^{T_p}, s_t^{T_p}, c_t^{T_p}) \tag{2}$$

where the function g is parameterized by a feedforward neural network with a softmax output layer. And g can be viewed as a probability predictor with neural networks. $s_t^{T_p}$ is a recurrent neural network hidden state at time t, which can be estimated as:

$$s_t^{T_p} = f(s_{t-1}^{T_p}, y_{t-1}^{T_p}, c_t^{T_p}) \tag{3}$$

the context vector $c_t^{T_p}$ depends on a sequence of annotations $(h_1, \cdots, h_{L_x})$ to which an encoder maps the input sentence, where L_x is the number of tokens in $\mathbf{x}$. Each annotation h_i is a bidirectional recurrent representation with forward and backward sequence information around the ith word.

$$\mathbf{c_t}^{T_p} = \sum_{j=1}^{L_x} a_{ij}^{T_p} \mathbf{h_j} \tag{4}$$

where the weight $a_{tj}^{T_p}$ is a scalar computed by

$$a_{tj}^{T_p} = \frac{exp(e_{tj}^{T_p})}{\sum_{k=1}^{L_x^{T_p}} exp(e_{tk}^{T_p})} \tag{5}$$

$$e_{tj}^{T_p} = \phi(\mathbf{s_{t-1}}^{T_p}, \mathbf{h_j}) \tag{6}$$

$a_{tj}^{T_p}$ is a normalized score of e_{tj} which is a soft alignment model measuring how well the input context around the jth word and the output word in the tth position match. e_{tj} is modeled through a perceptron-like function:

$$\phi(\mathbf{x}, \mathbf{y}) = \mathbf{v}^T tanh(\mathbf{W}\mathbf{x} + \mathbf{U}\mathbf{y}) \tag{7}$$

To compute $\mathbf{h_j}$, a bidirectional recurrent neural network is used. In the bidirectional recurrent neural network, the representation of a forward sequence and a backward sequence of the input sentence is estimated and concatenated to be a single vector. This concatenated vector can be used to translate multiple languages during the test time.

$$\mathbf{h_j} = [\overrightarrow{\mathbf{h_j}}; \overleftarrow{\mathbf{h_j}}]^T \tag{8}$$

From a probabilistic perspective, our model is able to learn the conditional distribution of several target languages given the same source corpus. Thus, the recurrent encoder-decoders are jointly trained with several conditional probabilities added together. As for the bidirectional recurrent neural network module, we adopt the recently proposed gated recurrent neural network (Cho et al., 2014). The gated recurrent neural network is shown to have promising results in several sequence learning problem such as speech recognition and machine translation where input and output sequences are of variable length. It is also shown that the gated recurrent neural network has the ability to address the gradient vanishing problem compared with the traditional recurrent neural network, and thus the long-range dependency problem in machine translation can be handled well. In our multi-task learning framework, the parameters of the gated recurrent neural network in the encoder are shared, which is formulated as follows.

$$\mathbf{h_t} = (\mathbf{I} - \mathbf{z_t}) \odot \mathbf{h_{t-1}} + \mathbf{z_t} \odot \hat{\mathbf{h_t}} \tag{9}$$

$$\mathbf{z_t} = \sigma(\mathbf{W_z x_t} + \mathbf{U_z h_{t-1}}) \tag{10}$$

$$\hat{\mathbf{h_t}} = tanh(\mathbf{W x_t} + \mathbf{U}(\mathbf{r_t} \odot \mathbf{h_{t-1}})) \tag{11}$$

$$\mathbf{r_t} = \sigma(\mathbf{W_r x_t} + \mathbf{U_r h_{t-1}}) \tag{12}$$

Where $\mathbf{I}$ is identity vector and $\odot$ denotes element wise product between vectors. $tanh(x)$ and $\sigma(x)$ are nonlinear transformation functions that can be applied element-wise on vectors. The recurrent computation procedure is illustrated in 1, where x_t denotes one-hot vector for the tth word in a sequence.

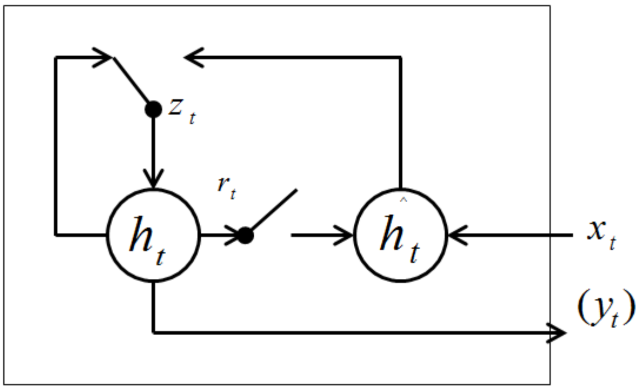

Figure 1: Gated recurrent neural network computation, where r_t is a reset gate responsible for memory unit elimination, and z_t can be viewed as a soft weight between current state information and history information.

$$\tanh(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \tag{13}$$

$$\sigma(x) = \frac{1}{1 + e^{-x}} \tag{14}$$

The overall model is illustrated in Figure 2 where the multi-task learning framework with four target languages is demonstrated. The soft alignment parameters A_i for each encoder-decoder are different and only the bidirectional recurrent neural network representation is shared.

3.3 Optimization

The optimization approach we use is the mini-batch stochastic gradient descent approach (Bottou, 1991). The only difference between our optimization and the commonly used stochastic gradient descent is that we learn several mini-batches within a fixed language pair for several mini-batch iterations and then move onto the next language pair. Our optimization procedure is shown in Figure 3.

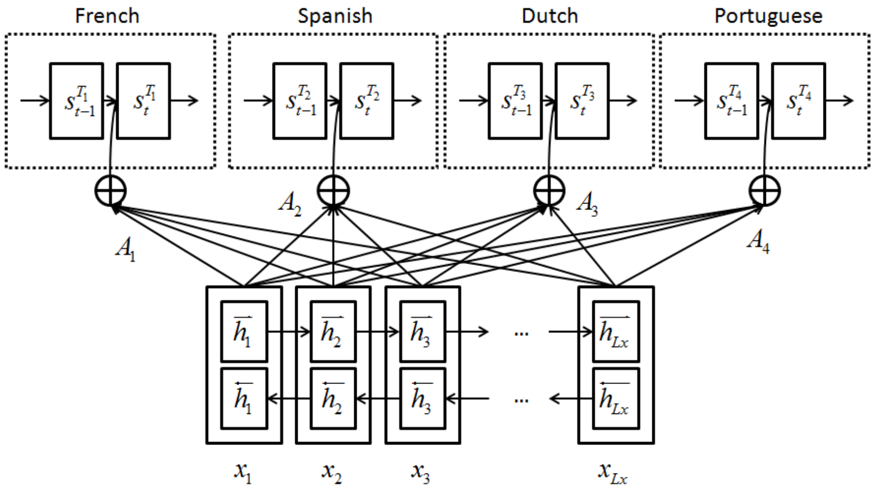

Figure 2: Multi-task learning framework for multiple-target language translation

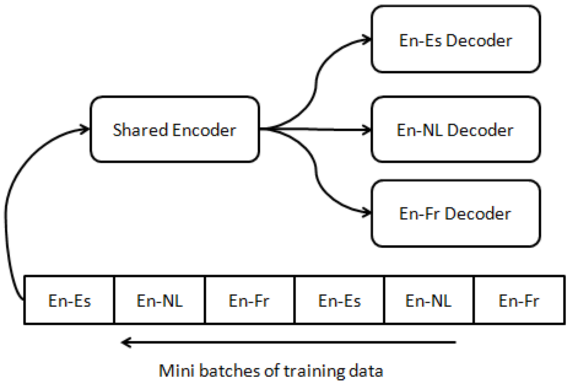

Figure 3: Optimization for end to multi-end model

3.4 Translation with Beam Search

Although parallel corpora are available for the encoder and the decoder modeling in the training phrase, the ground truth is not available during test time. During test time, translation is produced by finding the most likely sequence via beam search.

$$\hat{\mathbf{Y}} = \operatorname*{argmax}_{\mathbf{Y}} p(\mathbf{Y}^{T_p}|\mathbf{S}^{T_p}) \qquad (15)$$

Given the target direction we want to translate to, beam search is performed with the shared encoder and a specific target decoder where search space belongs to the decoder T_p. We adopt beam search algorithm similar as it is used in SMT system (Koehn, 2004) except that we only utilize scores produced by each decoder as features. The size of beam is 10 in our experiments for speedup consideration. Beam search is ended until the end-of-sentence **eos** symbol is generated.

4 Experiments

We conducted two groups of experiments to show the effectiveness of our framework. The goal of the first experiment is to show that multi-task learning helps to improve translation performance given enough training corpora for all language pairs. In the second experiment, we show that for some resource-poor language pairs with a few parallel training data, their translation performance could be improved as well.

4.1 Dataset

The Europarl corpus is a multi-lingual corpus including 21 European languages. Here we only choose four language pairs for our experiments. The source language is English for all language pairs. And the target languages are Spanish (Es), French (Fr), Portuguese (Pt) and Dutch (Nl). To demonstrate the validity of our learning framework, we do some preprocessing on the training set. For the source language, we use 30k of the most frequent words for source language vocabulary which is shared across different language pairs and 30k most frequent words for each target language. Out-of-vocabulary words are denoted as unknown words, and we maintain different unknown word labels for different languages. For test sets, we also restrict all words in the test set to be from our training vocabulary and mark the OOV words as the corresponding labels as in the training data. The size of training corpus in experiment 1 and 2 is listed in Table 1 where

Training Data Information						
Lang	En-Es	En-Fr	En-Nl	En-Pt	En-Nl-sub	En-Pt-sub
Sent size	1,965,734	2,007,723	1,997,775	1,960,407	300,000	300,000
Src tokens	49,158,635	50,263,003	49,533,217	49,283,373	8,362,323	8,260,690
Trg tokens	51,622,215	52,525,000	50,661,711	54,996,139	8,590,245	8,334,454

Table 1: Size of training corpus for different language pairs

En-Nl-sub and En-Pt-sub are sub-sampled data set of the full corpus. The full parallel training corpus is available from the EuroParl corpus, downloaded from EuroParl public websites[1]. We mimic the situation that there are only a small-scale parallel corpus available for some language pairs by randomly sub-sampling the training data. The parallel corpus of English-Portuguese and English-Dutch are sub-sampled to approximately 15% of the full corpus size. We select two data sets as our test data. One is the EuroParl Common test set[2] in European Parliament Corpus, the other is WMT 2013 data set[3]. For WMT 2013, only En-Fr, En-Es are available and we evaluate the translation performance only on these two test sets. Information of test sets is shown in Table 2.

Language pair	En-Es	En-Fr	En-Nl	En-Pt
Common test	1755	1755	1755	1755
WMT2013	3000	3000	-	-

Table 2: Size of test set in EuroParl Common testset and WMT2013

4.2 Training Details

Our model is trained on Graphic Processing Unit K40. Our implementation is based on the open source deep learning package Theano (Bastien et al., 2012) so that we do not need to take care about gradient computations. During training, we randomly shuffle our parallel training corpus for each language pair at each epoch of our learning process. The optimization algorithm and model hyper parameters are listed below.

- Initialization of all parameters are from uniform distribution between -0.01 and 0.01.
- We use stochastic gradient descent with recently proposed learning rate decay strategy Ada-Delta (Zeiler, 2012).
- Mini batch size in our model is set to 50 so that the convergence speed is fast.
- We train 1000 mini batches of data in one language pair before we switch to the next language pair.
- For word representation dimensionality, we use 1000 for both source language and target language.
- The size of hidden layer is set to 1000.

We trained our multi-task model with a multi-GPU implementation due to the limitation of Graphic memory. And each target decoder is trained within one GPU card, and we synchronize our source encoder every 1000 batches among all GPU card. Our model costs about 72 hours on full large parallel corpora training until convergence and about 24 hours on partial parallel corpora training. During decoding, our implementation on GPU costs about 0.5 second per sentence.

4.3 Evaluation

We evaluate the effectiveness of our method with EuroParl Common testset and WMT 2013 dataset. BLEU-4 (Papineni et al., 2002) is used as the evaluation metric. We evaluate BLEU scores on EuroParl Common test set with multi-task NMT models and single NMT models to demonstrate the validity of our multi-task learning framework. On the WMT 2013 data sets, we compare performance of separately trained NMT models, multi-task NMT models and Moses. We use the EuroParl Common test set as a development set in both neural machine translation experiments and Moses experiments. For single NMT models and multi-task NMT models, we select the best model with the highest BLEU score in the EuroParl Common testset and apply it to the WMT 2013 dataset. Note that our experiment settings in NMT is equivalent with Moses, considering the same training corpus, development sets and test sets.

4.4 Experimental Results

We report our results of three experiments to show the validity of our methods. In the first experiment, we train multi-task learning model jointly on all four parallel corpora and compare BLEU scores with models trained separately on each parallel corpora. In the second experiment, we utilize the same training procedures as Experiment 1, except that we mimic the situation where some parallel corpora are resource-poor and maintain only 15% data on two parallel training corpora. In experiment 3, we test our learned model from experiment 1 and experiment 2 on WMT 2013 dataset. Table 3 and 4 show the case-insensitive BLEU scores on the Europarl common test data. Models learned from the multi-task learning framework significantly outperform the models trained separately. Table 4 shows that given only 15% of parallel training corpus of English-Dutch and English-Portuguese, it is possible to improve translation performance on all the target languages as well. This result makes sense because the correlated languages benefit from each other by sharing the same predictive structure, e.g. French, Spanish and Portuguese, all of which are from Latin. We also notice that even though Dutch is from Germanic languages, it is also possible to increase translation performance under our multi-task learning framework which demonstrates the generalization of our model to multiple target languages.

Lang-Pair	En-Es	En-Fr	En-Nl	En-Pt
Single NMT	26.65	21.22	28.75	20.27
Multi Task	28.03	22.47	29.88	20.75
Delta	**+1.38**	**+1.25**	**+1.13**	**+0.48**

Table 3: Multi-task neural translation v.s. single model given large-scale corpus in all language pairs

We tested our selected model on the WMT 2013 dataset. Our results are shown in Table 5 where Multi-Full is the model with Experiment 1 setting and the model of Multi-Partial uses the same setting in Experiment 2. The English-French and English-Spanish translation performances are improved significantly compared with models trained separately on each language pair. Note that this result is not comparable with the result reported in (Bahdanau et al., 2014) as we use much less training corpus. We also compare our trained models with Moses. On the WMT 2013 data set, we utilize parallel corpora for Moses training without any extra resource such as large-scale monolingual corpus. From Table 5, it is shown that neural machine translation models have comparable BLEU scores with Moses. On the WMT 2013 test set, multi-task learning model outperforms both single model and Moses results significantly.

Lang-Pair	En-Es	En-Fr	En-Nl*	En-Pt*
Single NMT	26.65	21.22	26.59	18.26
Multi Task	28.29	21.89	27.85	19.32
Delta	**+1.64**	**+0.67**	**+1.26**	**+1.06**

Table 4: Multi-task neural translation v.s. single model with a small-scale training corpus on some language pairs. * means that the language pair is sub-sampled.

4.5 Model Analysis and Discussion

We try to make empirical analysis through learning curves and qualitative results to explain why multi-task learning framework works well in multiple-target machine translation problem.

From the learning process, we observed that the speed of model convergence under multi-task learning is faster than models trained separately especially when a model is trained for resource-poor language pairs. The detailed learning curves are shown in Figure 4. Here we study the learning curve for resource-poor language pairs, i.e. English-Dutch and En-Portuguese, for which only 15% of the bilingual data is sampled for training. The BLEU scores are evaluated on the Europarl common test set. From Figure 4, it can be seen that in the early stage of training, given the same amount of training data for each language pair, the translation performance of the multi-task learning model is improved more rapidly. And the multi-task models achieve better translation quality than separately trained models within three iterations of training. The reason of faster and better convergence in performance is that the encoder parameters are shared across different language pairs, which can make full use of all the source language training data across the language pairs and improve the source language

	Nmt Baseline	Nmt Multi-Full	Nmt Multi-Partial	Moses
En-Fr	23.89	26.02(**+2.13**)	25.01(**+1.12**)	23.83
En-Es	23.28	25.31(**+2.03**)	25.83(**+2.55**)	23.58

Table 5: Multi-task NMT v.s. single model v.s. moses on the WMT 2013 test set

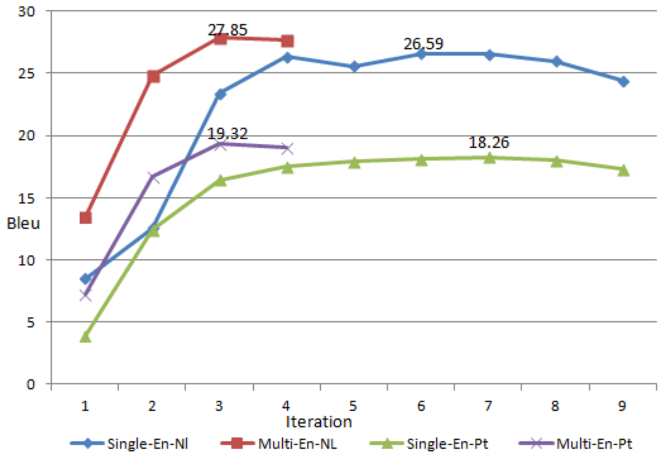

Figure 4: Faster and Better convergence in Multi-task Learning in multiple language translation

representation.

The sharing of encoder parameters is useful especially for the resource-poor language pairs. In the multi-task learning framework, the amount of the source language is not limited by the resource-poor language pairs and we are able to learn better representation for the source language. Thus the representation of the source language learned from the multi-task model is more stable, and can be viewed as a constraint that leverages translation performance of all language pairs. Therefore, the overfitting problem and the data scarcity problem can be alleviated for language pairs with only a few training data. In Table 6, we list the three nearest neighbors of some source words whose similarity is computed by using the cosine score of the embeddings both in the multi-task learning framework (from Experiment two) and in the single model (the resource-poor English-Portuguese model). Although the nearest neighbors of the high-frequent words such as numbers can be learned both in the multi-task model and the single model, the overall quality of the nearest neighbors learned by the resource-poor single model is much poorer compared with the multi-task model.

The multi-task learning framework also generates translations of higher quality. Some examples are shown in Table 7. The examples are from the WMT 2013 test set. The French and Spanish translations generated by the multi-task learning model and the single model are shown in the table.

MultiTask	**Nearest neighbors**

recently proposed recurrent neural network based encoder-decoder framework. We train a unified neural machine translation model under the multi-task learning framework where the encoder is shared across different language pairs and each target language has a separate decoder. To the best of our knowledge, the problem of learning to translate from one source to multiple targets has seldom been studied. Experiments show that given large-scale parallel training data, the multi-task neural machine translation model is able to learn good predictive structures in translating multiple targets. Significant improvement can be observed from our experiments on the data sets publicly available. Moreover, our framework is able to address the data scarcity problem of some resource-poor language pairs by utilizing large-scale parallel training corpora of other language pairs to improve the translation quality. Our model is efficient and gets faster and better convergence for both resource-rich and resource-poor language pair under the multi-task learning.

In the future, we would like to extend our learning framework to more practical setting. For example, train a multi-task learning model with the same target language from different domains to improve multiple domain translation within one model. The correlation of different target languages will also be considered in the future work.

Abstract

This paper proposes an *embedding matching* approach to Chinese word segmentation, which generalizes the traditional sequence labeling framework and takes advantage of distributed representations. The training and prediction algorithms have linear-time complexity. Based on the proposed model, a greedy segmenter is developed and evaluated on benchmark corpora. Experiments show that our greedy segmenter achieves improved results over previous neural network-based word segmenters, and its performance is competitive with state-of-the-art methods, despite its simple feature set and the absence of external resources for training.

1 Introduction

Chinese sentences are written as character sequences without word delimiters, which makes word segmentation a prerequisite of Chinese language processing. Since Xue (2003), most work has formulated Chinese word segmentation (CWS) as *sequence labeling* (Peng et al., 2004) with character position tags, which has lent itself to structured discriminative learning with the benefit of allowing rich features of *segmentation configurations*, including (i) *context* of character/word n-grams within local windows, (ii) *segmentation history* of previous characters, or the combinations of both. These feature-based models still form the backbone of most state-of-the art systems.

Nevertheless, many feature weights in such models are inevitably poorly estimated because the number of parameters is so large with respect to the limited amount of training data. This has motivated the introduction of low-dimensional, real-valued vectors, known as *embeddings*, as a tool to deal with the sparseness of the input. Embeddings allow linguistic units appearing in similar contexts to share similar vectors. The success of embeddings has been observed in many NLP tasks. For CWS, Zheng et al. (2013) adapted Collobert et al. (2011) and uses character embeddings in local windows as input for a two-layer network. The network predicts individual character position tags, the transitions of which are learned separately. Mansur et al. (2013) also developed a similar architecture, which labels individual characters and uses character bigram embeddings as additional features to compensate the absence of sentence-level modeling. Pei et al. (2014) improved upon Zheng et al. (2013) by capturing the combinations of context and history via a tensor neural network.

Despite their differences, these CWS approaches are all sequence labeling models. In such models, the target character can only influence the prediction as features. Consider the the segmentation configuration in (1), where the dot appears before the target character in consideration and the box (□) represents any character that can occur in the configuration. In that example, the known history is that the first two characters 中国 'China' are joined together, which is denoted by the underline.

(1) 中国·□ 格外 (where □ ∈ {风, 规, ...})

(2) 中国风 格外 'China-style especially'

(3) 中国 规格 外 'besides Chinese spec.'

For possible target characters, 风 'wind' and 规 'rule', the correct segmentation decisions for them are *opposite*, as shown in (2) and (3), respectively. In order to correctly predict both, current models can set higher weights for target character-specific features. However, in general, 风 is more likely to start a new word instead of joining the existing one as in this example. Given such conflicting evidence, models can rarely find optimal feature weights, if they exist at all.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1733–1743,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

The crux of this *conflicting evidence* problem is that similar configurations can suggest opposite decisions, depending on the target character and vice versa. Thus it might be useful to treat segmentation decisions for distinct characters separately. And instead of predicting general segmentation decisions given configurations, it could be beneficial to model the *matching* between configurations and *character-specific* decisions.

To this end, this paper proposes an embedding matching approach (Section 2) to CWS, in which embeddings for both input and output are learned and used as representations to counteract sparsities. Thanks to embeddings of character-specific decisions (actions) serving as both input features and output, our hidden-layer-free architecture (Section 2.2) is capable of capturing prediction histories in similar ways as the hidden layers in recurrent neural networks (Mikolov et al., 2010). We evaluate the effectiveness of the model via a linear-time greedy segmenter (Section 3) implementation. The segmenter outperforms previous embedding-based models (Section 4.2) and achieves state-of-the-art results (Section 4.3) on a benchmark dataset. The main contributions of this paper are:

- A novel embedding matching model for Chinese word segmentation.
- Developing a greedy word segmenter, which is based on the matching model and achieves competitive results.
- Introducing the idea of character-specific segmentation action embeddings as both feature and output, which are cornerstones of the model and the segmenter.

2 Embedding Matching Models for Chinese Word Segmentation

We propose an embedding based matching model for CWS, the architecture of which is shown in Figure 1. The model employs trainable embeddings to represent both sides of the matching, which will be specified shortly, followed by details of the architecture in Section 2.2.

2.1 Segmentation as Configuration-Action Matching

Output. The word segmentation output of a character sequence can be described as a sequence of *character-specific segmentation actions*. We use **separation** (***s***) and **combination** (***c***) as possible actions for each character, where a separation action starts a new word with the current character, while a combination action appends the character to the preceding ones. We model character-action *combinations* instead of atomic, character independent actions. As a running example, sentence (4b) is the correct segmentation for (4a), which can be represented as the sequence (猫 -***s***, 占 -***s***, 领 -***c***, 了 -***s***, 婴 -***s***, 儿 -***c***, 床 -***c***) .

(4) a. 猫占领了婴儿床
    b. 猫 占领 了 婴儿床
    c. ‘The cat occupied the crib’

Input. The input are the segmentation configurations for each character under consideration, which are described by context and history features. The *context features* of captures the characters that are in the same sentence of the current character and the *history features* encode the segmentation actions of previous characters.

- **Context features**. These refer to character *unigrams* and *bigrams* that appear in the local context window of h characters that centers at c_i, where c_i is 领 in example (4) and $h = 5$ is used in this paper. The template for features are shown in Table 1. For our example, the uni- and bi-gram features would be: 猫, 占, 领, 了, 婴 and 猫占, 占领, 领了, 了婴, respectively.
- **History features**. To make inference tractable, we assume that only previous l character-specific actions are relevant, where $l = 2$ for this study. In our example, 猫 -***s*** and 战 -***s*** are the history features. Such features capture partial information of syntactic and semantic dependencies between previous *words*, which are clues for segmentation that pure character contexts could not provide. A dummy character START is used to represent the absent (left) context characters in the case of the first l characters in a sentence. And the predicted action for the START symbol is always ***s***.

Matching. CWS is now modeled as the matching of the input (segmentation configuration) and output (two possible character-specific actions) for each character. Formally, a matching model learns

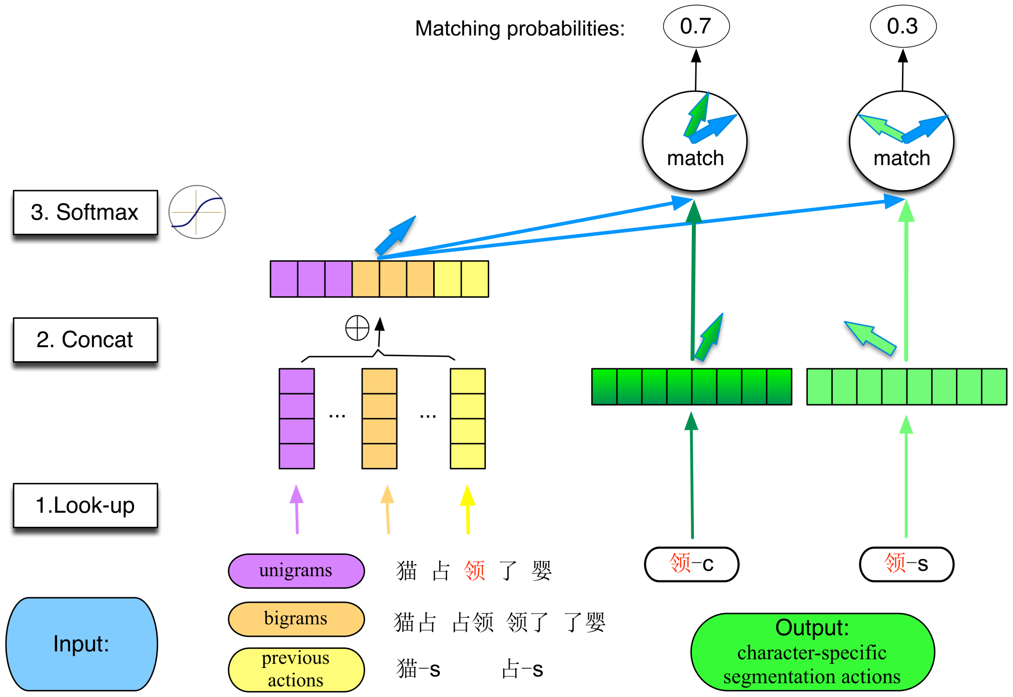

Figure 1: **The architecture of the embedding matching model for CWS**. The model predicts the segmentation for the character 领 in sentence (4), which is the second character of word 占领 'occupy'. Both feature and output embeddings are trainable parameters of the model.

Group	Feature template
unigram	$c_{i-2}, c_{i-1}, c_i, c_{i+1}, c_{i+2}$
bigram	$c_{i-2}c_{i-1}, c_{i-1}c_i, c_ic_{i+1}, c_{i+1}c_{i+2}$

Table 1: Uni- and bi-gram feature template

the following function:

$$g\,(\,b_1b_2...b_n, a_1a_2...a_n) = \prod_{j=1}^{n} f\left(b_j(a_{j-2}, a_{j-1}; c_{j-\frac{h}{2}}...c_{j+\frac{h}{2}}), a_j\right) \quad (1)$$

where $c_1c_2...c_n$ is the character sequence, b_j and a_j are the segmentation configuration and action for character c_j, respectively. In (1), $b_j(a_{j-2}, a_{j-1}; c_{j-\frac{h}{2}}...c_{j+\frac{h}{2}})$ indicates that the configuration for each character is a function that depends on the actions of the previous l characters and the characters in the local window of size h.

Why embedding. The above matching model would suffer from sparsity if these outputs (character-specific action a_j) were directly encoded as one-hot vectors, since the matching model can be seen as a sequence labeling model with $C \times L$ outputs, where L is the number of original labels while C is the number of unique characters. For Chinese, C is at the order of $10^3 - 10^4$. The use of embeddings, however, can serve the matching model well thanks to their low dimensionality.

2.2 The Architecture

The proposed architecture (Figure 1) has three components, namely look-up table, concatenation and softmax function for matching. We will go through each of them in this section.

Look-up table. The mapping between features/outputs to their corresponding embeddings are kept in a *look-up table*, as in many previous embedding related work (Bengio et al., 2003; Pei et al., 2014). Such features are extracted from the training data. Formally, the embedding for each distinct feature d is denoted as $Embed(d) \in \mathbb{R}^N$, which is a real valued vector of dimension N. Each feature is retrieved by its unique index. The retrieval of the embeddings for the output actions is similar.

Concatenation. To predict the segmentation for the target character c_j, its feature vectors are *concatenated* into a single vector, the *input embedding*, $\mathbf{i}(b_j) \in \mathbb{R}^{N \times K}$, where K is the number of features used to describe the configuration b_j.

Softmax. The model then computes the dot product of the input embedding $\mathbf{i}(b_j)$ and each of the two *output embeddings*, $\mathbf{o}(a_{j,1})$ and $\mathbf{o}(a_{j,2})$, which represent the two possible segmentation actions for the target character c_j, respectively. The exponential of the two raw scores are normalized to obtain probabilistic values $\in [0,1]$.

We call the resulting scores *matching probabilities*, which denote probabilities that actions match the given segmentation configuration. In our example, 领 -***c*** has the probability of 0.7 to be the correct action, while 领 -***s*** is less likely with a lower probability of 0.3. Formally, the above matching procedure can be described as a *softmax* function, as shown in (2), which is also an individual *f* term in (1).

$$f(\,b_j, a_{j,k}) = \frac{exp\,(\mathbf{i}(b_j)\cdot\mathbf{o}(a_{j,k}))}{\sum_{k'} exp\,\big(\mathbf{i}(b_j)\cdot\mathbf{o}(a_{j,k'})\big)} \qquad (2)$$

In (2), $a_{j,k}$ ($1 \le k \le 2$) represent two possible actions, such as 领 -***c*** and 领 -***s*** for 领 in our example. Note that, to ensure the input and output are of the same dimension, for each character specific action, the model trains two distinct embeddings, one $\in \mathbb{R}^N$ as feature and the other $\in \mathbb{R}^{N\times K}$ as output, where K is the number of features for each input.

Best word segmentation of sentence. After plugging (2) into (1) and applying (and then dropping) logarithms for computational convenience, finding the best segmentation for a sentence becomes an optimization problem as shown in (3). In the formula, $\hat{Y}$ is the best action sequence found by the model among all the possible ones, $Y = a_1a_2...a_n$, where a_j is the predicted action for the character c_j ($1 \le j \le n$), which is either c_j-***s*** or c_j-***c***, such as 领 -***s*** and 领 -***c***.

$$\hat{Y} = \underset{Y}{\text{argmax}} \sum_{j=1}^{n} \frac{exp\,(\mathbf{i}(b_j)\cdot\mathbf{o}(a_j))}{\sum_k exp\,(\mathbf{i}(b_j)\cdot\mathbf{o}(a_{j,k}))} \qquad (3)$$

3 The Greedy Segmenter

Our model depends on the actions predicted for the previous two characters as history features. Traditionally, such scenarios call for dynamic programming for exact inference. However, preliminary experiments showed that, for our model, a Viterbi search based segmenter, even supported by conditional random field (Lafferty et al., 2001) style training, yields similar results as the greedy search based segmenter in this section. Since the greedy segmenter is much more efficient in training and testing, the rest of the paper will focus on the proposed greedy segmenter, the details of which will be described in this section.

3.1 Greedy Search

Initialization. The first character in the sentence is made to have two left side characters that are dummy symbols of START, whose predicted actions are always START-***s***, i.e. separation.

Iteration. The algorithms predicts the action for each character c_j, one at a time, in a left-to-right, incremental manner, where $1 \le j \le n$ and n is the sentence length. To do so, it first extracts context features and history features, the latter of which are the predicted character-specific actions for the previous two characters. Then the model matches the concatenated feature embedding with embeddings of the two possible character-specific actions, c_j-***s*** and c_i-***c***. The one with higher matching probability is predicted as segmentation action for the character, which is irreversible. After the action for the last character is predicted, the segmented word sequence of the sentence is built from the predicted actions deterministically.

Hybrid matching. Character-specific embeddings are capable of capturing subtle word formation tendencies of individual characters, but such representations are incapable of covering matching cases for unknown target characters. Another minor issue is that the action embeddings for certain low frequent characters may not be sufficiently trained. To better deal with these scenarios, We also train two embeddings to represent character-independent segmentation actions, ALL-***s*** and ALL-***c***, and use them to average with or substitute embeddings of infrequent or unknown characters, which are either insufficiently trained or nonexistent. Such strategy is called *hybrid matching*, which can improve accuracy.

Complexity. Although the total number of actions is large, the matching for each target character only requires the two actions that correspond to that specific character, such as 领 -***s*** and 领 -***c*** for 领 in our example. Each prediction is thus similar to a softmax computation with two outputs, which costs constant time C. Greedy search ensures that the total time for predicting a sentence of n characters is $n \times C$, i.e. *linear time complexity*, with a minor overhead for mapping actions to segmentations.

3.2 Training

The training procedure first predicts the action for the current character with current parameters, and then optimizes the log likelihood of correct segmentation actions in the gold segmentations to update parameters. Ideally, the matching probability for the correct action embedding should be 1 while that of the incorrect one should be 0. We minimize the *cross-entropy loss function* as in (4) for the segmentation prediction of each character c_j to pursue this goal. The loss function is convex, similar to that of maximum entropy models.

$$J = -\sum_{k=1}^{K} \delta\left(a_{j,k}\right) \log \frac{exp\left(\mathbf{i} \cdot \mathbf{o}(a_{j,k})\right)}{\sum_{k'} exp\left(\mathbf{i} \cdot \mathbf{o}(a_{j,k'})\right)} \quad (4)$$

where $a_{j,k}$ denotes a possible action for c_j and $\mathbf{i}$ is a compact notation for $\mathbf{i}(b_j)$. In (4), $\delta(a_{j,k})$ is an *indicator function* defined by the following formula, where $\hat{a_j}$ denotes the correct action.

$$\delta(a_{j,k}) = \begin{cases} 1, & \text{if } a_{j,k} = \hat{a_j} \\ 0, & \text{otherwise} \end{cases}$$

To counteract over-fitting, we add L2 regularization term to the loss function, as follows:

$$J = J + \sum_{k=1}^{K} \frac{\lambda}{2} \left(||\mathbf{i}||^2 + ||\mathbf{o}(a_{j,k})||^2 \right) \quad (5)$$

The formula in (4) and (5) are similar to that of a standard softmax regression, except that both input and output embeddings are parameters to be trained. We perform *stochastic gradient descent* to update input and output embeddings in turn, each time considering the other as constant. We give the gradient (6) and the update rule (7) for the input embedding $\mathbf{i}(b_j)$ ($\mathbf{i}$ for short), where $\mathbf{o}_k$ is a short notation for $\mathbf{o}(a_{j,k})$. The gradient and update for output embeddings are similar. The α in (7) is the learning rate, which we use a linear decay scheme to gradually shrink it from its initial value to zero. Note that the update for the input embedding $\mathbf{i}$ is actually performed for the feature embeddings that form $\mathbf{i}$ in the concatenation step.

$$\frac{\partial J}{\partial \mathbf{i}} = \sum_{k} \left(f\left(b_j, a_{j,k}\right) - \delta\left(a_{j,k}\right)\right) \cdot \mathbf{o}_k + \lambda \mathbf{i} \quad (6)$$

$$\mathbf{i} = \mathbf{i} - \alpha \frac{\partial J}{\partial \mathbf{i}} \quad (7)$$

Complexity. For each iteration of the training process, the time complexity is also linear to the input character number, as compared with search, only a few constant time operations of gradient computation and parameter updates are performed for each character.

4 Experiments

4.1 Data and Evaluation Metric

In the experiments, we use two widely used and freely available[1] manually word-segmented corpora, namely, **PKU** and **MSR**, from the second SIGHAN international Chinese word segmentation bakeoff (Emerson, 2005). Table 2 shows the details of the two dataset. All evaluations in this paper are conducted with official training/testing set split using official scoring script.[2]

	PKU	**MSR**
Word types	5.5×10^4	8.8×10^4
Word tokens	1.1×10^6	2.4×10^6
Character types	5×10^3	5×10^3
Character tokens	1.8×10^6	4.1×10^6

Table 2: Corpus details of PKU and MSR

The segmentation accuracy is evaluated by precision (P), recall (R), **F-score** and **R**$_{oov}$, the recall for out-of-vocabulary words. Precision is defined as the number of correctly segmented words divided by the total number of words in the segmentation result. Recall is defined as the number of correctly segmented words divided by the total number of words in the gold standard segmentation. In particular, R$_{oov}$ reflects the model generalization ability. The metric for overall performance, the evenly-weighted F-score is calculated as in (8):

$$F = \frac{2 \times P \times R}{P + R} \quad (8)$$

To comply with CWS evaluation conventions and make comparisons fair, we distinguish the following two settings:

- *closed-set*: no extra resource other than training corpora is used.
- *open-set*: additional lexicon, raw corpora, etc are used.

[1] http://www.sighan.org/bakeoff2005/

[2] http://www.sighan.org/bakeoff2003/score

We will report the final results of our model[3] on PKU and MSR corpora in comparison with previous embedding based models (Section 4.2) and state-of-the-art systems (Section 4.3), before going into detailed experiments for model analyses (Section 4.5).

4.2 Comparison with Previous Embedding-Based Models

Table 3 shows the results of our greedy segmenter on the PKU and MSR datasets, which are compared with embedding-based segmenters in previous studies.[4] In the table, results for both closed-set and open-set setting are shown for previous models. In the open-set evaluations, all three previous work use *pre-training* to train character ngram embeddings from large unsegmented corpora to initialize the embeddings, which will be later trained with the manually word-segmented training data. For our model, we report the close-set results only, as pre-training does not significant improve the results in our experiments (Section 4.5).

As shown in Table 3, under close-set evaluation, our model significantly outperform previous embedding based models in all metrics. Compared with the previous best embedding-based model, our greedy segmenter has achieved up to 2.2% and 25.8% absolute improvements (MSR) on F-score and R_{oov}, respectively. Surprisingly, our close-set results are also comparable to the best *open-set* results of previous models. As we will see in (Section 4.4), when using same or less character uni- and bi-gram features, our model still outperforms previous embedding based models in closed-set evaluation, which shows the effectiveness of our matching model.

Significance test. Table 4 shows the 95% confidence intervals (CI) for close-set results of our model and the best performing previous model (Pei et al., 2014), which are computed by formula (9), following (Emerson, 2005).

$$CI = 2\sqrt{\frac{F(1-F)}{N}} \tag{9}$$

where F is the F-score value and the N is the word token count of the testing set, which is 104,372 and 106,873 for PKU and MSR, respectively. We see that the confidence intervals of our results do *not* overlap with that of (Pei et al., 2014), meaning that our improvements are statistically significant.

4.3 Comparison with the State-of-the-Art Systems

Table 5 shows that the results of our greedy segmenter are competitive with the state-of-the-art supervised systems (Best05 closed-set, Zhang and Clark, 2007), although our feature set is much simpler. More recent state-of-the-art systems rely on both extensive feature engineering and extra raw corpora to boost performance, which are semi-supervised learning. For example, Zhang et al (2013) developed 8 types of static and dynamic features to maximize the co-training system that used extra corpora of Chinese Gigaword and Baike, each of which contains more than 1 billion character tokens. Such systems are not directly comparable with our supervised model. We leave the development of semi-supervised learning methods for our model as future work.

4.4 Features Influence

Table 6 shows the F-scores of our model on PKU dataset when different features are removed ('w/o') or when only a subset of features are used. Features complement each other and removing any group of features leads to a limited drop of F-score up to 0.7%. Note that features of previous (two) actions are even more informative than all unigram features combined, suggesting that intra- an inter-word dependencies reflected by action features are strong evidence for segmentation. Moreover, using same or less character ngram features, our model outperforms previous embedding based models, which shows the effectiveness of our matching model.

4.5 Model Analysis

Learning curve. Figure 2 shows that the training procedure coverages quickly. After the first iteration, the testing F-scores are already 93.5% and 95.7% for PKU and MSR, respectively, which then gradually reach their maximum within the next 9 iterations before the curve flats out.

Speed. With an unoptimized single-thread Python implementation running on a laptop with intel Core-i5 CPU (1.9 GHZ), each iteration of the training procedure on PKU dataset takes about 5 minutes, or 6,000 characters per second. The pre-

diction speed is above 13,000 character per second.

Hyper parameters. The hyper parameters used in the experiments are shown in Table 7. We initialized hyper parameters with recommendations in literature before tuning with dev-set experiments, each of which change one parameter by a magnitude. We fixed the hyper parameter to the current setting without spending too much time on tuning, since that is not the main purpose of this paper.

Feature	F-score	Feature	F-score
All features	**95.1**	uni-&bi-gram	94.6
w/o action	94.6	only action	93.3
w/o unigram	94.8	only unigram	92.1
w/o bigram	94.4	only bigram	94.2

Table 6: The influence of features. F-score in percentage on the PKU corpus.

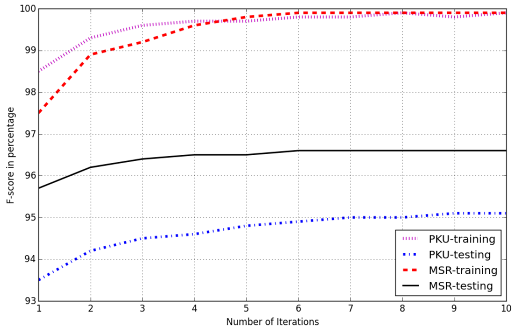

Figure 2: The learning curve of our model.

- **Embedding size** determines the number of parameters to be trained, thus should fit the training data size to achieve good performance. We tried the size of 30 and 100, both of which performs worse than 50. A possible tuning is to use different embedding size for different groups of features instead of setting $N_1 = 50$ for all features.
- **Context window size**. A window size of 3-5 characters achieves comparable results. Zheng et al. (2013) suggested that context window larger than 5 may lead to inferior results.
- **Initial Learning rate**. We found that several learning rates between 0.04 to 0.15 yielded very similar results as the one reported here. The training is not very sensitive to reason-

able values of initial learning rate. However, Instead of our simple linear decay of learning rate, it might be useful to try more sophisticated techniques, such as *AdaGrad* and exponential decaying (Tsuruoka et al., 2009; Sun et al., 2013).

- **Regularization**. Our model suffers a little from over-fitting, if no regularization is used. In that case, the F-score on PKU drops from 95.1% to 94.7%.
- **Pre-training**. We tried pre-training character embeddings using *word2vec*[5] with Chinese Gigaword Corpus[6] and use them to initialize the corresponding embeddings in our model, as previous work did. However, we were only able to see insignificant F-score improvements within 0.1% and observed that the training F-score reached 99.9% much earlier. We hypothesize that pre-training leads to sub-optimal local maximums for our model.
- **Hybrid matching**. We tried applying hybrid matching (Section 3.1) for target characters which are less frequent than the top f_{top} characters, including unseen characters, which leads to about 0.15% of F-score improvements.

Size of feature embed'	$N_1 = 50$
Size of output embed'	$N_2 = 550$
Window size	$h = 5$
Initial learning rate	$\alpha = 0.1$
Regularization	$\lambda = 0.001$
Hybrid matching	$f_{top} = 8\%$

5 Related Work

Word segmentation. Most modern segmenters followed Xue (2003) to model CWS as sequence labeling of character position tags, using conditional random fields (Peng et al. 2004), structured perceptron (Jiang et al., 2008), etc. Some notable exceptions are (Zhang and Clark, 2007; Zhang et al., 2012), which exploited rich word-level features and (Ma et al., 2012; Ma, 2014; Zhang et al., 2014), which explicitly model word structures. Our work generalizes the sequence labeling to a more flexible framework of matching, and predicts actions as in (Zhang and Clark, 2007; Zhang et al., 2012) instead of position tags to prevent the greedy search from suffering tag inconsistencies. To better utilize resources other than training data, our model might benefit from techniques used in recent state-of-the-art systems, such as semi-supervised learning (Zhao and Kit, 2008; Sun and Xu, 2011; Zhang et al., 2013; Zeng et al., 2013), joint models (Li and Zhou, 2012; Qian and Liu, 2012), and partial annotations (Liu et al., 2014; Yang and Vozila, 2014).

Distributed representation and CWS. Distributed representation are useful for various NLP tasks, such as POS tagging (Collobert et al., 2011), machine translation (Devlin et al., 2014) and parsing (Socher et al., 2013). Influenced by Collobert et al. (2011), Zheng et al. (2013) modeled CWS as tagging and treated *sentence-level* tag sequence as the combination of individual tag predictions and context-independent tag transition. Mansur et al. (2013) was inspired by Bengio et al. (2003) and used character bigram embeddings to compensate for the absence of sentence level optimization. To model interactions between tags and characters, which are absent in these two CWS models, Pei et al. (2014) introduced the tag embedding and used a tensor hidden layer in the neural net. In contrast, our work uses character-specific action embeddings to *explicitly* capture such interactions. In addition, our work gains efficiency by avoiding hidden layers, similar as Mikolov et al. (2013).

Learning to match. Matching heterogeneous objects has been studied in various contexts before, and is currently flourishing, thanks to embedding-based deep (Gao et al., 2014) and convolutional (Huang et al., 2013; Hu et al., 2014) neural networks. This work develops a matching model for CWS and differs from others in its “shallow” yet effective architecture.

6 Discussion

Simple architecture. It is possible to adopt standard feed-forward neural network for our embedding matching model with character-action embeddings as both feature and output. Nevertheless, we designed the proposed architecture to avoid hidden layers for simplicity, efficiency and easy-tuning, inspired by *word2vec*. Our simple architecture is effective, demonstrated by the improved results over previous neural-network word seg-

[5] https://code.google.com/p/word2vec/

[6] https://catalog.ldc.upenn.edu/LDC2005T14

menters, all of which use feed-forward architecture with different features and/or layers. It might be interesting to directly compare the performances of our model with same features on the current and feed-forward architectures, which we leave for future work.

Greedy and exact search-based models. As mentioned in Section 3, we implemented and preliminarily experimented with a segmenter that trains a similar model with exact search via Viterbi algorithm. On the PKU corpus, its F-score is 0.944, compared with greedy segmenter's 0.951. Its training and testing speed are up to 7.8 times slower than that of the greedy search segmenter. It is counter-intuitive that the performance of the exact-search segmenter is no better or even worse than that of the greedy-search segmenter. We hypothesize that since the training updates parameters with regard to search errors, the final model is "tailored" for the specific search method used, which makes the model-search combination of greedy search segmenter not necessarily worse than that of exact search segmenter. Another way of looking at it is that search is less important when the model is accurate. In this case, most step-wise decisions are correct in the first place, which requires no correction from the search algorithm. Empirically, Zhang and Clark (2011) also reported exact-search segmenter performing worse than beam-search segmenters.

Despite that the greedy segmenter is incapable of considering future labels, this rarely causes problems in practice. Our greedy segmenter has good results, compared with the exact-search segmenter above and previous approaches, most of which utilize exact search. Moreover, the greedy segmenter has additional advantages of faster training and prediction.

Sequence labeling and matching. A traditional sequence labeling model such as CRF has K (number of labels) target-character-independent weight vectors, where the target character influences the prediction via the weights of the features that contain it. In a way, a matching model can be seen as a family of "sub-models", which keeps a group of weight vectors (the output embeddings) for *each* unique target character. Different target characters activate different sub-models, allowing opposite predictions for similar input features, as the target weight vectors used are different.

7 Conclusion and Future Work

In this paper, we have introduced the matching formulation for Chinese word segmentation and proposed an embedding matching model to take advantage of distributed representations. Based on the model, we have developed a greedy segmenter, which outperforms previous embedding-based methods and is competitive with state-of-the-art systems. These results suggest that it is promising to model CWS as configuration-action matching using distributed representations. In addition, linear-time training and testing complexity of our simple architecture is very desirable for industrial application. To the best of our knowledge, this is the first greedy segmenter that is competitive with the state-of-the-art discriminative learning models.

In the future, we plan to investigate methods for our model to better utilize external resources. We would like to try using convolutional neural network to automatically encode ngram-like features, in order to further shrink parameter space. It is also interesting to study whether extending our model with deep architectures can benefit CWS. Lastly, it might be useful to adapt our model to tasks such as POS tagging and name entity recognition.

Abstract

Recently, neural network models for natural language processing tasks have been increasingly focused on for their ability of alleviating the burden of manual feature engineering. However, the previous neural models cannot extract the complicated feature compositions as the traditional methods with discrete features. In this paper, we propose a gated recursive neural network (GRNN) for Chinese word segmentation, which contains reset and update gates to incorporate the complicated combinations of the context characters. Since GRNN is relative deep, we also use a supervised layer-wise training method to avoid the problem of gradient diffusion. Experiments on the benchmark datasets show that our model outperforms the previous neural network models as well as the state-of-the-art methods.

1 Introduction

Unlike English and other western languages, Chinese do not delimit words by white-space. Therefore, word segmentation is a preliminary and important pre-process for Chinese language processing. Most previous systems address this problem by treating this task as a sequence labeling problem and have achieved great success. Due to the nature of supervised learning, the performance of these models is greatly affected by the design of features. These features are explicitly represented by the different combinations of context characters, which are based on linguistic intuition and statistical information. However, the number of features could be so large that the result models are too large to use in practice and prone to overfit on training corpus.

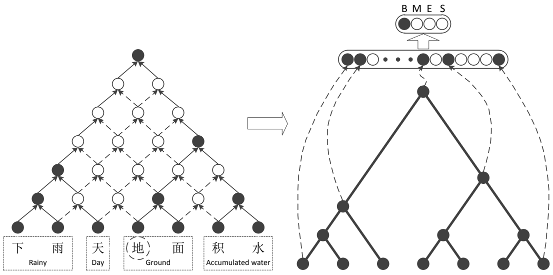

Figure 1: Illustration of our model for Chinese word segmentation. The solid nodes indicate the active neurons, while the hollow ones indicate the suppressed neurons. Specifically, the links denote the information flow, where the solid edges denote the acceptation of the combinations while the dashed edges means rejection of that. As shown in the right figure, we receive a score vector for tagging target character "地" by incorporating all the combination information.

Recently, neural network models have been increasingly focused on for their ability to minimize the effort in feature engineering. Collobert et al. (2011) developed a general neural network architecture for sequence labeling tasks. Following this work, many methods (Zheng et al., 2013; Pei et al., 2014; Qi et al., 2014) applied the neural network to Chinese word segmentation and achieved a performance that approaches the state-of-the-art methods.

However, these neural models just concatenate the embeddings of the context characters, and feed them into neural network. Since the concatenation operation is relatively simple, it is difficult to model the complicated features as the traditional discrete feature based models. Although the complicated interactions of inputs can be modeled by the deep neural network, the previous neural model shows that the deep model cannot outperform the one with a single non-linear model. Therefore, the

neural model only captures the interactions by the simple transition matrix and the single non-linear transformation . These dense features extracted via these simple interactions are not nearly as good as the substantial discrete features in the traditional methods.

In this paper, we propose a gated recursive neural network (GRNN) to model the complicated combinations of characters, and apply it to Chinese word segmentation task. Inspired by the success of gated recurrent neural network (Chung et al., 2014), we introduce two kinds of gates to control the combinations in recursive structure. We also use the layer-wise training method to avoid the problem of gradient diffusion, and the dropout strategy to avoid the overfitting problem.

Figure 1 gives an illustration of how our approach models the complicated combinations of the context characters. Given a sentence "雨 (Rainy) 天 (Day) 地面 (Ground) 积水 (Accumulated water)", the target character is "地". This sentence is very complicated because each consecutive two characters can be combined as a word. To predict the label of the target character "地" under the given context, GRNN detects the combinations recursively from the bottom layer to the top. Then, we receive a score vector of tags by incorporating all the combination information in network.

The contributions of this paper can be summarized as follows:

- We propose a novel GRNN architecture to model the complicated combinations of the context characters. GRNN can select and preserve the useful combinations via reset and update gates. These combinations play a similar role in the feature engineering of the traditional methods with discrete features.

- We evaluate the performance of Chinese word segmentation on PKU, MSRA and CTB6 benchmark datasets which are commonly used for evaluation of Chinese word segmentation. Experiment results show that our model outperforms other neural network models, and achieves state-of-the-art performance.

2 Neural Model for Chinese Word Segmentation

Chinese word segmentation task is usually regarded as a character-based sequence labeling problem. Each character is labeled as one of {B, M, E, S} to indicate the segmentation. {B, M, E} represent *Begin*, *Middle*, *End* of a multi-character segmentation respectively, and S represents a *Single* character segmentation.

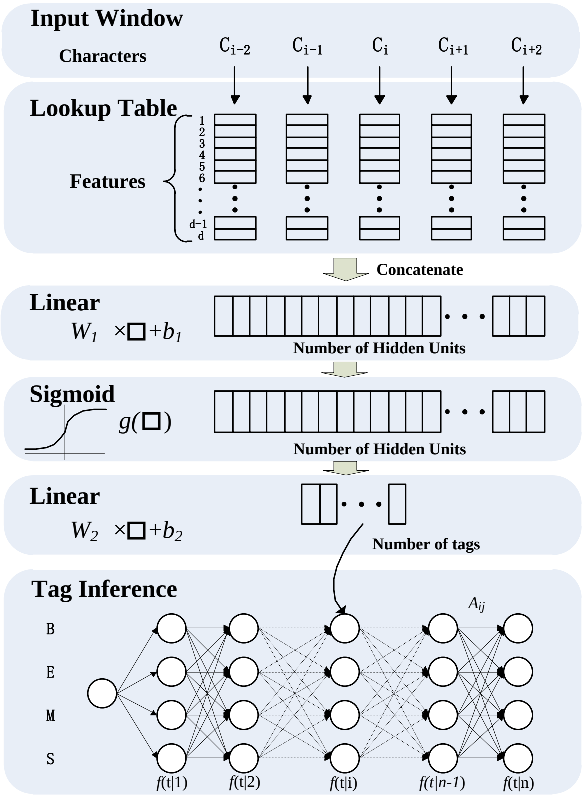

Figure 2: General architecture of neural model for Chinese word segmentation.

The general neural network architecture for Chinese word segmentation task is usually characterized by three specialized layers: (1) a character embedding layer; (2) a series of classical neural network layers and (3) tag inference layer. A illustration is shown in Figure 2.

The most common tagging approach is based on a local window. The window approach assumes that the tag of a character largely depends on its neighboring characters.

Firstly, we have a character set $\mathcal{C}$ of size $|\mathcal{C}|$. Then each character $c \in \mathcal{C}$ is mapped into an d-dimensional embedding space as $\mathbf{c} \in \mathbb{R}^d$ by a lookup table $\mathbf{M} \in \mathbb{R}^{d\times|\mathcal{C}|}$.

For each character c_i in a given sentence $c_{1:n}$, the context characters $c_{i-w1:i+w2}$ are mapped to their corresponding character embeddings as $\mathbf{c}_{i-w_1:i+w_2}$, where w_1 and w_2 are left and right context lengths respectively. Specifically, the unknown characters and characters exceeding the sentence boundaries are mapped to special symbols, "unknown", "start" and "end" respectively. In addition, w_1 and w_2 satisfy the constraint $w_1 + w_2 + 1 = w$, where w is the window size of the model. As an illustration in Figure 2, w_1, w_2 and w are set to 2, 2 and 5 respectively.

The embeddings of all the context characters are then concatenated into a single vector $\mathbf{a}_i \in \mathbb{R}^{H_1}$ as input of the neural network, where $H_1 = w \times d$ is the size of Layer 1. And $\mathbf{a}_i$ is then fed into a conventional neural network layer which performs a linear transformation followed by an element-wise activation function g, such as tanh.

$$\mathbf{h}_i = g(\mathbf{W}_1\mathbf{a}_i + \mathbf{b}_1), \tag{1}$$

where $\mathbf{W}_1 \in \mathbb{R}^{H_2 \times H_1}$, $\mathbf{b}_1 \in \mathbb{R}^{H_2}$, $\mathbf{h}_i \in \mathbb{R}^{H_2}$. H_2 is the number of hidden units in Layer 2. Here, w, H_1 and H_2 are hyper-parameters chosen on development set.

Then, a similar linear transformation is performed without non-linear function followed:

$$f(t|c_{i-w_1:i+w_2}) = \mathbf{W}_2\mathbf{h}_i + \mathbf{b}_2, \tag{2}$$

where $\mathbf{W}_2 \in \mathbb{R}^{|T| \times H_2}$, $\mathbf{b}_2 \in \mathbb{R}^{|T|}$ and T is the set of 4 possible tags. Each dimension of vector $f(t|c_{i-w_1:i+w_2}) \in \mathbb{R}^{|T|}$ is the score of the corresponding tag.

To model the tag dependency, a transition score $\mathbf{A}_{ij}$ is introduced to measure the probability of jumping from tag $i \in T$ to tag $j \in T$ (Collobert et al., 2011).

3 Gated Recursive Neural Network for Chinese Word Segmentation

To model the complicated feature combinations, we propose a novel gated recursive neural network (GRNN) architecture for Chinese word segmentation task (see Figure 3).

3.1 Recursive Neural Network

A recursive neural network (RNN) is a kind of deep neural network created by applying the same set of weights recursively over a given structure(such as parsing tree) in topological order (Pollack, 1990; Socher et al., 2013a).

In the simplest case, children nodes are combined into their parent node using a weight matrix $\mathbf{W}$ that is shared across the whole network, followed by a non-linear function $g(\cdot)$. Specifically, if $\mathbf{h}_L$ and $\mathbf{h}_R$ are d-dimensional vector representations of left and right children nodes respectively, their parent node $\mathbf{h}_P$ will be a d-dimensional vector as well, calculated as:

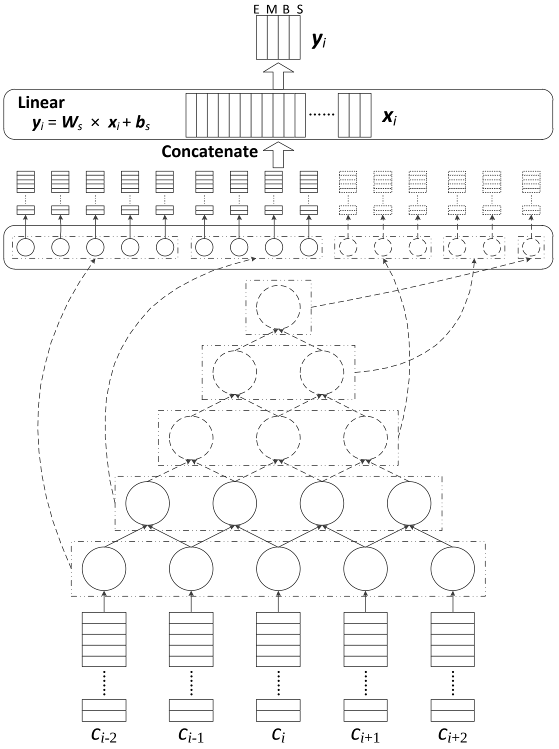

Figure 3: Architecture of Gated Recursive Neural Network for Chinese word segmentation.

$$\mathbf{h}_P = g\left(\mathbf{W}\begin{bmatrix}\mathbf{h}_L \\ \mathbf{h}_R\end{bmatrix}\right), \tag{3}$$

where $\mathbf{W} \in \mathbb{R}^{d \times 2d}$ and g is a non-linear function as mentioned above.

3.2 Gated Recursive Neural Network

The RNN need a topological structure to model a sequence, such as a syntactic tree. In this paper, we use a directed acyclic graph (DAG), as showing in Figure 3, to model the combinations of the input characters, in which two consecutive nodes in the lower layer are combined into a single node in the upper layer via the operation as Eq. (3).

In fact, the DAG structure can model the combinations of characters by continuously mixing the information from the bottom layer to the top layer. Each neuron can be regarded as a complicated feature composition of its governed characters, similar to the discrete feature based models. The difference between them is that the neural one automatically learns the complicated combinations while the conventional one need manually design them.

When the children nodes combine into their parent node, the combination information of two children nodes is also merged and preserved by their parent node.

Although the mechanism above seem to work well, it can not sufficiently model the complicated combination features for its simplicity in practice.

Inspired by the success of the gated recurrent neural network (Cho et al., 2014b; Chung et al., 2014), we propose a gated recursive neural network (GRNN) by introducing two kinds of gates, namely “reset gate” and “update gate”. Specifically, there are two reset gates, $\mathbf{r}_L$ and $\mathbf{r}_R$, partially reading the information from left child and right child respectively. And the update gates $\mathbf{z}_N$, $\mathbf{z}_L$ and $\mathbf{z}_R$ decide what to preserve when combining the children’s information. Intuitively, these gates seems to decide how to update and exploit the combination information.

In the case of word segmentation, for each character c_i of a given sentence $c_{1:n}$, we first represent each context character c_j into its corresponding embedding $\mathbf{c}_j$, where $i - w_1 \leq j \leq i + w_2$ and the definitions of w_1 and w_2 are as same as mentioned above.

Then, the embeddings are sent to the first layer of GRNN as inputs, whose outputs are recursively applied to upper layers until it outputs a single fixed-length vector.

The outputs of the different neurons can be regarded as the different feature compositions. After concatenating the outputs of all neurons in the network, we get a new big vector $\mathbf{x}_i$. Next, we receive the tag score vector $\mathbf{y}_i$ for character c_j by a linear transformation of $\mathbf{x}_i$:

$$\mathbf{y}_i = \mathbf{W}_s \times \mathbf{x}_i + \mathbf{b}_s, \tag{4}$$

where $b_s \in \mathbb{R}^{|T|}$, $\mathbf{W}_s \in \mathbb{R}^{|T| \times Q}$. $Q = q \times d$ is dimensionality of the concatenated vector $\mathbf{x}_i$, where q is the number of nodes in the network.

3.3 Gated Recursive Unit

GRNN consists of the minimal structures, gated recursive units, as showing in Figure 4.

By assuming that the window size is w, we will have recursion layer $l \in [1, w]$. At each recursion layer l, the activation of the j-th hidden node $\mathbf{h}_j^{(l)} \in \mathbb{R}^d$ is computed as

$$\mathbf{h}_j^{(l)} = \begin{cases} \mathbf{z}_N \odot \hat{\mathbf{h}}_j^l + \mathbf{z}_L \odot \mathbf{h}_{j-1}^{l-1} + \mathbf{z}_R \odot \mathbf{h}_j^{l-1}, & l > 1, \\ \mathbf{c}_j, & l = 1, \end{cases} \tag{5}$$

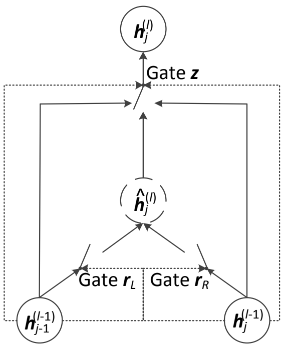

Figure 4: Our proposed gated recursive unit.

where $\mathbf{z}_N$, $\mathbf{z}_L$ and $\mathbf{z}_R \in \mathbb{R}^d$ are update gates for new activation $\hat{\mathbf{h}}_j^l$, left child node $\mathbf{h}_{j-1}^{l-1}$ and right child node $\mathbf{h}_j^{l-1}$ respectively, and $\odot$ indicates element-wise multiplication.

The update gates can be formalized as:

$$\mathbf{z} = \begin{bmatrix} \mathbf{z}_N \\ \mathbf{z}_L \\ \mathbf{z}_R \end{bmatrix} = \begin{bmatrix} 1/Z \\ 1/Z \\ 1/Z \end{bmatrix} \odot \exp(\mathbf{U} \begin{bmatrix} \hat{\mathbf{h}}_j^l \\ \mathbf{h}_{j-1}^{l-1} \\ \mathbf{h}_j^{l-1} \end{bmatrix}), \tag{6}$$

where $\mathbf{U} \in \mathbb{R}^{3d \times 3d}$ is the coefficient of update gates, and $Z \in \mathbb{R}^d$ is the vector of the normalization coefficients,

$$Z_k = \sum_{i=1}^{3} [\exp(\mathbf{U} \begin{bmatrix} \hat{\mathbf{h}}_j^l \\ \mathbf{h}_{j-1}^{l-1} \\ \mathbf{h}_j^{l-1} \end{bmatrix})]_{d \times (i-1)+k}, \tag{7}$$

where $1 \leq k \leq d$.

Intuitively, three update gates are constrained by:

$$\begin{cases} [\mathbf{z}_N]_k + [\mathbf{z}_L]_k + [\mathbf{z}_R]_k = 1, & 1 \leq k \leq d; \\ [\mathbf{z}_N]_k \geq 0, & 1 \leq k \leq d; \\ [\mathbf{z}_L]_k \geq 0, & 1 \leq k \leq d; \\ [\mathbf{z}_R]_k \geq 0, & 1 \leq k \leq d. \end{cases} \tag{8}$$

The new activation $\hat{\mathbf{h}}_j^l$ is computed as:

$$\hat{\mathbf{h}}_j^l = \tanh(\mathbf{W}_{\hat{\mathbf{h}}} \begin{bmatrix} \mathbf{r}_L \odot \mathbf{h}_{j-1}^{l-1} \\ \mathbf{r}_R \odot \mathbf{h}_j^{l-1} \end{bmatrix}), \tag{9}$$

where $\mathbf{W}_{\hat{\mathbf{h}}} \in \mathbb{R}^{d \times 2d}$, $\mathbf{r}_L \in \mathbb{R}^d$, $\mathbf{r}_R \in \mathbb{R}^d$. $\mathbf{r}_L$ and $\mathbf{r}_R$ are the reset gates for left child node $\mathbf{h}_{j-1}^{l-1}$ and right child node $\mathbf{h}_j^{l-1}$ respectively, which can be formalized as:

$$\begin{bmatrix} \mathbf{r}_L \\ \mathbf{r}_R \end{bmatrix} = \sigma(\mathbf{G} \begin{bmatrix} \mathbf{h}_{j-1}^{l-1} \\ \mathbf{h}_{j}^{l-1} \end{bmatrix}), \tag{10}$$

(11)

where $\mathbf{G} \in \mathbb{R}^{2d \times 2d}$ is the coefficient of two reset gates and σ indicates the sigmoid function.

Intuiativly, the reset gates control how to select the output information of the left and right children, which results to the current new activation $\hat{\mathbf{h}}$.

By the update gates, the activation of a parent neuron can be regarded as a choice among the the current new activation $\hat{\mathbf{h}}$, the left child, and the right child. This choice allows the overall structure to change adaptively with respect to the inputs.

This gating mechanism is effective to model the combinations of the characters.

3.4 Inference

In Chinese word segmentation task, it is usually to employ the Viterbi algorithm to inference the tag sequence $t_{1:n}$ for a given input sentence $c_{1:n}$.

In order to model the tag dependencies, the previous neural network models (Collobert et al., 2011; Zheng et al., 2013; Pei et al., 2014) introduce a transition matrix $\mathbf{A}$, and each entry $\mathbf{A}_{ij}$ is the score of the transformation from tag $i \in T$ to tag $j \in T$.

Thus, the sentence-level score can be formulated as follows:

$$s(c_{1:n}, t_{1:n}, \theta) = \sum_{i=1}^{n} \left(\mathbf{A}_{t_{i-1}t_i} + f_\theta(t_i | c_{i-w_1:i+w_2}) \right), \tag{12}$$

where $f_\theta(t_i | c_{i-w_1:i+w_2})$ is the score for choosing tag t_i for the i-th character by our proposed GRNN (Eq. (4)). The parameter set of our model is $\theta = (\mathbf{M}, \mathbf{W}_s, \mathbf{b}_s, \mathbf{W}_{\hat{\mathbf{h}}}, \mathbf{U}, \mathbf{G}, \mathbf{A})$.

4 Training

4.1 Layer-wise Training

Deep neural network with multiple hidden layers is very difficult to train for its problem of gradient diffusion and risk of overfitting.

Following (Hinton and Salakhutdinov, 2006), we employ the layer-wise training strategy to avoid problems of overfitting and gradient vanishing. The main idea of layer-wise training is to train the network with adding the layers one by one. Specifically, we first train the neural network with the first hidden layer only. Then, we train at the network with two hidden layers after training at first layer is done and so on until we reach the top hidden layer. When getting convergency of the network with layers 1 to l , we preserve the current parameters as initial values of that in training the network with layers 1 to $l + 1$.

4.2 Max-Margin Criterion

We use the Max-Margin criterion (Taskar et al., 2005) to train our model. Intuitively, the Max-Margin criterion provides an alternative to probabilistic, likelihood based estimation methods by concentrating directly on the robustness of the decision boundary of a model. We use $Y(x_i)$ to denote the set of all possible tag sequences for a given sentence x_i and the correct tag sequence for x_i is y_i. The parameter set of our model is θ. We first define a structured margin loss $\Delta(y_i, \hat{y})$ for predicting a tag sequence $\hat{y}$ for a given correct tag sequence y_i:

$$\Delta(y_i, \hat{y}) = \sum_{j}^{n} \eta \mathbf{1}\{y_{i,j} \neq \hat{y_j}\}, \tag{13}$$

where n is the length of sentence x_i and η is a discount parameter. The loss is proportional to the number of characters with an incorrect tag in the predicted tag sequence. For a given training instance (x_i, y_i), we search for the tag sequence with the highest score:

$$y^* = \arg\max_{\hat{y} \in Y(x)} s(x_i, \hat{y}, \theta), \tag{14}$$

where the tag sequence is found and scored by the proposed model via the function $s(\cdot)$ in Eq. (12). The object of Max-Margin training is that the tag sequence with highest score is the correct one: $y^* = y_i$ and its score will be larger up to a margin to other possible tag sequences $\hat{y} \in Y(x_i)$:

$$s(x, y_i, \theta) \geq s(x, \hat{y}, \theta) + \Delta(y_i, \hat{y}). \tag{15}$$

This leads to the regularized objective function for m training examples:

$$J(\theta) = \frac{1}{m} \sum_{i=1}^{m} l_i(\theta) + \frac{\lambda}{2} \|\theta\|_2^2, \tag{16}$$

$$l_i(\theta) = \max_{\hat{y} \in Y(x_i)} (s(x_i, \hat{y}, \theta) + \Delta(y_i, \hat{y})) - s(x_i, y_i, \theta). \tag{17}$$

By minimizing this object, the score of the correct tag sequence y_i is increased and score of the highest scoring incorrect tag sequence $\hat{y}$ is decreased. The objective function is not differentiable due to the hinge loss. We use a generalization of gradient descent called subgradient method (Ratliff et al., 2007) which computes a gradient-like direction.

Following (Socher et al., 2013a), we minimize the objective by the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs. The parameter update for the i-th parameter $\theta_{t,i}$ at time step t is as follows:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i}, \qquad (18)$$

where α is the initial learning rate and $g_\tau \in \mathbb{R}^{|\theta_i|}$ is the subgradient at time step τ for parameter θ_i.

5 Experiments

We evaluate our model on two different kinds of texts: newswire texts and micro-blog texts. For evaluation, we use the standard Bakeoff scoring program to calculate precision, recall, F1-score.

5.1 Word Segmentation on Newswire Texts

5.1.1 Datasets

We use three popular datasets, PKU, MSRA and CTB6, to evaluate our model on newswire texts. The PKU and MSRA data are provided by the second International Chinese Word Segmentation Bakeoff (Emerson, 2005), and CTB6 is from Chinese TreeBank 6.0 (LDC2007T36) (Xue et al., 2005), which is a segmented, part-of-speech tagged, and fully bracketed corpus in the constituency formalism. These datasets are commonly used by previous state-of-the-art models and neural network models. In addition, we use the first 90% sentences of the training data as training set and the rest 10% sentences as development set for PKU and MSRA datasets, and we divide the training, development and test sets according to (Yang and Xue, 2012) for the CTB6 dataset.

All datasets are preprocessed by replacing the Chinese idioms and the continuous English characters and digits with a unique flag.

5.1.2 Hyper-parameters

We set the hyper-parameters of the model as list in Table 1 via experiments on development set. In addition, we set the batch size to 20. And we find that it is a good balance between model performance and efficiency to set character embedding size $d = 50$. In fact, the larger embedding size leads to higher cost of computational resource, while lower dimensionality of the character embedding seems to underfit according to the experiment results.

Window size	$k = 5$
Character embedding size	$d = 50$
Initial learning rate	$\alpha = 0.3$
Margin loss discount	$\eta = 0.2$
Regularization	$\lambda = 10^{-4}$
Dropout rate on input layer	$p = 20\%$

Table 1: Hyper-parameter settings.

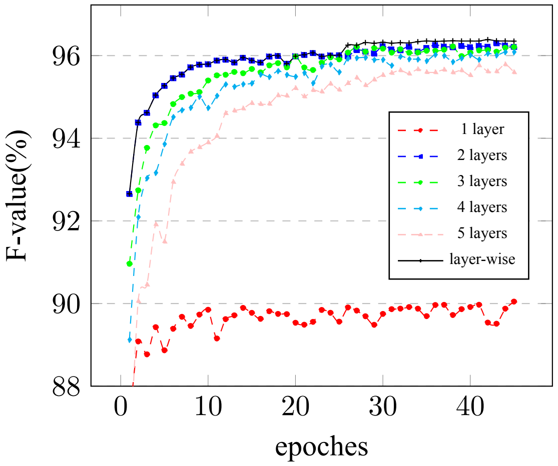

Figure 5: Performance of different models with or without layer-wise training strategy on PKU development set.

Deep neural networks contain multiple non-linear hidden layers are always hard to train for it is easy to overfit. Several methods have been used in neural models to avoid overfitting, such as early stop and weight regularization. Dropout (Srivastava et al., 2014) is also one of the popular strategies to avoid overfitting when training the deep neural networks. Hence, we utilize the dropout strategy in this work. Specifically, dropout is to temporarily remove the neuron away with a fixed probability p independently, along with the incoming and outgoing connections of it. As a result, we find dropout on the input layer with probability $p = 20\%$ is a good tradeoff between model efficiency and performance.

GRNN (5 layers)	95.3	94.7	95.0	96.1	95.7	95.9

Table 2: Performance of different models with or without layer-wise training strategy on PKU test set.

5.1.3 Layer-wise Training

We first investigate the effects of the layer-wise training strategy. Since we set the size of context window to five, there are five recursive layers in our architecture. And we train the networks with the different numbers of recursion layers. Due to the limit of space, we just give the results on PKU dataset.

Figure 5 gives the convergence speeds of the five models with different numbers of layers and the model with layer-wise training strategy on development set of PKU dataset. The model with one layer just use the neurons of the lowest layer in final linear score function. Since there are no non-linear layer, its seems to underfit and perform poorly. The model with two layers just use the neurons in the lowest two layers, and so on. The model with five layers use all the neurons in the network. As we can see, the layer-wise training strategy lead to the fastest convergence and the best performance.

Table 2 shows the performances on PKU test set. The performance of the model with layer-wise training strategy is always better than that without layer-wise training strategy. With the increase of the number of layers, the performance also increases and reaches the stable high performance until getting to the top layer.

5.1.4 Results

We first compare our model with the previous neural approaches on PKU, MSRA and CTB6 datasets as showing in Table 3. The character embeddings of the models are random initialized. The performance of word segmentation is significantly boosted by exploiting the gated recursive architecture, which can better model the combinations of the context characters than the previous neural models.

Previous works have proven it will greatly improve the performance to exploit the pre-trained character embeddings instead of that with random initialization. Thus, we pre-train the embeddings on a huge unlabeled data, the Chinese Wikipedia corpus, with word2vec toolkit (Mikolov et al., 2013). By using these obtained character embeddings, our model receives better performance and still outperforms the previous neural models with pre-trained character embeddings. The detailed results are shown in Table 4 (1st to 3rd rows).

Inspired by (Pei et al., 2014), we utilize the bigram feature embeddings in our model as well. The concept of feature embedding is quite similar to that of character embedding mentioned above. Specifically, each context feature is represented as a single vector called feature embedding. In this paper, we only use the simply bigram feature embeddings initialized by the average of two embeddings of consecutive characters element-wisely.

Although the model of Pei et al. (2014) greatly benefits from the bigram feature embeddings, our model just obtains a small improvement with them. This difference indicates that our model has well modeled the combinations of the characters and do not need much help of the feature engineering. The detailed results are shown in Table 4 (4-th and 6-th rows).

Table 5 shows the comparisons of our model with the state-of-the-art systems on F-value. The model proposed by Zhang and Clark (2007) is a word-based segmentation method, which exploit features of complete words, while remains of the list are all character-based word segmenters, whose features are mostly extracted from the context characters. Moreover, some systems (such as Sun and Xu (2011) and Zhang et al. (2013)) also exploit kinds of extra information such as the unlabeled data or other knowledge. Although our model only uses simple bigram features, it outperforms the previous state-of-the-art methods which use more complex features.

5.2 Word Segmentation on Micro-blog Texts

5.2.1 Dataset

We use the NLPCC 2015 dataset[1] (Qiu et al., 2015) to evaluate our model on micro-blog texts. The NLPCC 2015 data are provided by the shared task in the 4th CCF Conference on Natural Language Processing & Chinese Computing (NLPCC 2015): Chinese Word Segmentation and POS Tagging for micro-blog Text. Different with the popular used newswire dataset, the NLPCC 2015 dataset is collected from Sina Weibo[2], which consists of the relatively informal texts from micro-blog with the various topics, such as finance, sports, entertainment, and so on. The information of the dataset is shown in Table 6.

To train our model, we also use the first 90% sentences of the training data as training set and the rest 10% sentences as development set.

Here, we use the default setting of CRF++ toolkit with the feature templates as shown in Table 7. The same feature templates are also used for FNLP.

5.2.2 Results

Since the NLPCC 2015 dataset is a new released dataset, we compare our model with the two popular open source toolkits for sequence labeling task: FNLP[3] (Qiu et al., 2013) and CRF++[4]. Our model uses pre-trained and bigram character embeddings.

Table 8 shows the comparisons of our model with the other systems on NLPCC 2015 dataset.

6 Related Work

Chinese word segmentation has been studied with considerable efforts in the NLP community. The most popular word segmentation method is based on sequence labeling (Xue, 2003). Recently, researchers have tended to explore neural network

based approaches (Collobert et al., 2011) to reduce efforts of the feature engineering (Zheng et al., 2013; Qi et al., 2014). However, the features of all these methods are the concatenation of the embeddings of the context characters.

Pei et al. (2014) also used neural tensor model (Socher et al., 2013b) to capture the complicated interactions between tags and context characters. But the interactions depend on the number of the tensor slices, which cannot be too large due to the model complexity. The experiments also show that the model of (Pei et al., 2014) greatly benefits from the further bigram feature embeddings, which shows that their model cannot even handle the interactions of the consecutive characters. Different with them, our model just has a small improvement with the bigram feature embeddings, which indicates that our approach has well modeled the complicated combinations of the context characters, and does not need much help of further feature engineering.

More recently, Cho et al. (2014a) also proposed a gated recursive convolutional neural network in machine translation task to solve the problem of varying lengths of sentences. However, their approach only models the update gate, which can not tell whether the information is from the current state or from sub notes in update stage without reset gate. Instead, our approach models two kinds of gates, reset gate and update gate, by incorporating which we can better model the combinations of context characters via selection function of reset gate and collection function of update gate.

7 Conclusion

In this paper, we propose a gated recursive neural network (GRNN) to explicitly model the combinations of the characters for Chinese word segmentation task. Each neuron in GRNN can be regarded as a different combination of the input characters. Thus, the whole GRNN has an ability to simulate the design of the sophisticated features in traditional methods. Experiments show that our proposed model outperforms the state-of-the-art methods on three popular benchmark datasets.

Despite Chinese word segmentation being a specific case, our model can be easily generalized and applied to other sequence labeling tasks. In future work, we would like to investigate our proposed GRNN on other sequence labeling tasks.

Abstract

Social media content can be used as a complementary source to the traditional methods for extracting and studying collective social attributes. This study focuses on the prediction of the occupational class for a public user profile. Our analysis is conducted on a new annotated corpus of Twitter users, their respective job titles, posted textual content and platform-related attributes. We frame our task as classification using latent feature representations such as word clusters and embeddings. The employed linear and, especially, non-linear methods can predict a user's occupational class with strong accuracy for the coarsest level of a standard occupation taxonomy which includes nine classes. Combined with a qualitative assessment, the derived results confirm the feasibility of our approach in inferring a new user attribute that can be embedded in a multitude of downstream applications.

1 Introduction

The growth of online social networks provides the opportunity to analyse user text in a broader context (Tumasjan et al., 2010; Bollen et al., 2011; Lampos and Cristianini, 2012). This includes the social network (Sadilek et al., 2012), spatio-temporal information (Lampos and Cristianini, 2010) and personal attributes (Al Zamal et al., 2012). Previous research has analysed language differences in user attributes like location (Cheng et al., 2010), gender (Burger et al., 2011), impact (Lampos et al., 2014) and age (Rao et al., 2010), showing that language use is influenced by them. Therefore, user text allows us to infer these properties. This *user profiling* is important not only for sociolinguistic studies, but also for other applications: recommender systems to provide targeted advertising, analysts who study different opinions in each social class or integration in text regression tasks such as voting intention (Lampos et al., 2013).

Social status reflected through a person's occupation is a factor which influences language use (Bernstein, 1960; Bernstein, 2003; Labov, 2006). Therefore, our hypothesis is that language use in social media can be indicative of a user's occupational class. For example, executives may write more frequently about business or financial news, while people in manufacturing positions could refer more to their personal interests and less to job related activities. Similarly, we expect some categories of people, like those working in sales and customer services, to be more social or to use more informal language.

Focusing on the microblogging platform of Twitter, we explore our hypothesis by studying the task of predicting a user's occupational class given platform-related attributes and generated content, i.e. tweets. That has direct applicability in a broad range of areas from sociological studies, which analyse the behaviour of different occupations, to recruiting companies that target people for new job opportunities. For this study, we created a publicly available data set of users, including their profile information and historical text content as well as a label to an occupational class from the "Standard Occupational Classification" taxonomy (see Section 2).

We frame our task as classification, aiming to identify the most likely job class for a given user based on profile and a variety of textual features: general word embeddings and clusters (or 'topics'). Both linear and non-linear classification methods are applied with a focus on those that can assist interpretation and offer qualitative insights. We find that text features, especially word clusters, lead to good predictive performance. Accuracy for our best model is well above 50% for 9-way classifi-

Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

cation, outperforming competitive methods. The best results are obtained using the Bayesian non-parametric framework of Gaussian Processes (Rasmussen and Williams, 2006), which also accommodates feature interpretation via the Automatic Relevance Determination. This allows us to get insight into differences in language use across job classes and, finally, assess our original hypothesis about the thematic divergence across them.

2 Standard Occupational Classification

To enable the user occupation study, we adopt a standardised job classification taxonomy for mapping Twitter users to occupations. The Standard Occupational Classification (SOC)[1] is a UK government system developed by the Office of National Statistics for classifying occupations. Jobs are categorised hierarchically based on skill requirements and content. The SOC scheme includes nine major groups coded with a digit from 1 to 9. Each major group is divided into sub-major groups coded with 2 digits, where the first digit indicates the major group. Each sub-major group is further divided into minor groups coded with 3 digits and finally, minor groups are divided into unit groups, coded with 4 digits. The unit groups are the leaves of the hierarchy and represent specific jobs related to the group.

Table 1 shows a part of the SOC hierarchy. In total, there are 9 major groups, 25 sub-major groups, 90 minor groups and 369 unit groups. Although other hierarchies exist, we use the SOC because it has been published recently (in 2010), includes newly introduced jobs, has a balanced hierarchy and offers a wide variety of job titles that were crucial in our data set creation.

3 Data

To the best of our knowledge there are no publicly available data sets suitable for the task we aim to investigate. Thus, we have created a new one consisting of Twitter users mapped to their occupation, together with their profile information and historical tweets. We use the account's profile information to capture users with self-disclosed occupations. The potential self-selection bias is acknowledged, but filtering content via self disclosure is widespread when extracting large-scale data for user attribute inference (Pennacchiotti and Popescu, 2011; Coppersmith et al., 2014).

- Major Group 1 (**C1**): Managers, Directors and Senior Officials
  - Sub-major Group 11: Corporate Managers and Directors
    - Minor Group 111: Chief Executives and Senior Officials
      - Unit Group 1115: Chief Executives and Senior Officials
      - •Job: chief executive, bank manager
      - Unit Group 1116: Elected Officers and Representatives
    - Minor Group 112: Production Managers and Directors
    - Minor Group 113: Functional Managers and Directors
    - Minor Group 115: Financial Institution Managers and Directors
    - Minor Group 116: Managers and Directors in Transport and Logistics
    - Minor Group 117: Senior Officers in Protective Services
    - Minor Group 118: Health and Social Services Managers and Directors
    - Minor Group 119: Managers and Directors in Retail and Wholesale
  - Sub-major Group 12: Other Managers and Proprietors
- Major Group (**C2**): Professional Occupations
  - •Job: mechanical engineer, pediatrist
- Major Group (**C3**): Associate Professional and Technical Occupations
  - •Job: system administrator, dispensing optician
- Major Group (**C4**): Administrative and Secretarial Occupations
  - •Job: legal clerk, company secretary
- Major Group (**C5**): Skilled Trades Occupations
  - •Job: electrical fitter, tailor
- Major Group (**C6**): Caring, Leisure and Other Service Occupations
  - •Job: nursery assistant, hairdresser
- Major Group (**C7**): Sales and Customer Service Occupations
  - •Job: sales assistant, telephonist
- Major Group (**C8**): Process, Plant and Machine Operatives
  - •Job: factory worker, van driver
- Major Group (**C9**): Elementary Occupations
  - •Job: shelf stacker, bartender

Table 1: Subset of the SOC classification hierarchy.

Similarly to Hecht et al. (2011), we first assess the proportion of Twitter accounts with a clear mention to their occupation by annotating the user description field of a random set of 500 users. There were chosen from the random 1% sample, having at least 200 tweets in their history and with a majority of English tweets. There, we can identify the following categories: no description (12.2%), random information (22%), user information but not occupation related (45.8%), and job related information (20%).

To create our data set, we thus use the user description field to search for self-disclosed job titles provided by the 4-digit SOC unit groups, since they contain specific job titles. We queried Twitter's Search API to retrieve for each job title a maximum of 200 accounts which best matched occupation keywords. Then, we aggregated the accounts into the 3-digit (minor) categories. To remove potential ambiguity in the retrieved set, we manually inspected accounts in each minor category and filtered out those that belong to companies, contain no description or the description provided does not indicate that the user has a job corresponding to the minor category. In total, around 50% of the accounts were removed by manual inspection per-

[1] `http://www.ons.gov.uk/ons/guide-method/classifications/current-standard-classifications/soc2010/index.html`; accessed on 24/02/2015.

formed by the authors. We also removed users in multiple categories and or users that have tweeted less than 50 times in their history. Finally, we eliminated all 3-digit categories that contained less than 45 user accounts after this filtering. This process produced a total number of 5,191 users from 55 minor groups (22 sub-major groups), spread across all nine major SOC groups. The distribution of users across these nine groups is: 9.7%, 34.5%, 20.6%, 3.8%, 16.7%, 6.1%, 1.4%, 4.2%, and 3% (following the ordering of Table 1). In our data set the most well represented minor occupational groups are 'Functional Managers and Directors' (184 users – code 113), 'Therapy Professionals' (159 users – code 222) and 'Quality and Regulatory Professionals' (158 users – code 246), whereas the least represented ones are 'Textile and Garment Trades' (45 users – code 541), 'Elementary Security Occupations' (46 users – code 924), 'Elementary Cleaning Occupations' (47 users – code 923). The mean number of users in the minor classes is equal to 94.4 with a standard deviation of 35.6. For these users, we have collected all their tweets, going as far back as the latest 3,200, and their profile information. The final data set consists of 10,796,836 tweets collected around 5 August 2014 and is openly available.[2]

A separate Twitter data set is used as a reference corpus in order to build the feature representations detailed in Section 4. This data set is an extract from the Twitter Gardenhose stream (a 10% representative sample of the entire Twitter stream) from 2 January to 28 February 2011. Based on this content, we also build the vocabulary for the text features, containing the most frequent 71,555 words. We tokenise and filter for English using the Trendminer preprocessing pipeline (Preoţiuc-Pietro et al., 2012).

4 Features

In this section, we overview the features used in the occupational class prediction task. They are divided into two types: (1) user level features, (2) textual features.

4.1 User Level Features (UserLevel)

The user level features are based on the general user information or aggregated statistics about the tweets. Table 2 introduces the 18 features in this category.

u_1	number of followers
u_2	number of friends
u_3	number of times listed
u_4	follower/friend ratio
u_5	proportion of non-duplicate tweets
u_6	proportion of retweeted tweets
u_7	average no. of retweets/tweet
u_8	proportion of retweets done
u_9	proportion of hashtags
u_{10}	proportion of tweets with hashtags
u_{11}	proportion of tweets with @-mentions
u_{12}	proportion of @-replies
u_{13}	no. of unique @-mentions in tweets
u_{14}	proportion of tweets with links
u_{15}	no. of favourites the account made
u_{16}	avg. number of tweets/day
u_{17}	total number of tweets
u_{18}	proportion of tweets in English

Table 2: User level attributes for a Twitter user.

4.2 Textual Features

The textual features are derived from the aggregated set of user's tweets. We use our reference corpus to represent each user as a distribution over these features. We ignore the bio field from building textual features to avoid introducing biases from our data collection method. While this is a restriction, our analysis showed that in less than 20% of the cases the information in the bio is directly relevant to the occupation.

4.2.1 SVD Word Embeddings (SVD-E)

We use a more abstract representation of words than simple unigram counts in order to aid interpretability of our analysis. We compute a word to word similarity matrix from our reference corpus. Normalised Pointwise Mutual Information (NPMI) (Bouma, 2009) is used to compute word to word similarity. NPMI is an information theoretic measure indicating which words co-occur in the same context, where the context is represented by a whole tweet:

$$\text{NPMI}(x, y) = -\log \text{P}(x, y) \cdot \log \frac{\text{P}(x, y)}{\text{P}(x) \cdot \text{P}(y)}. \tag{1}$$

We then perform singular value decomposition (SVD) on the word to word similarity matrix and obtain an embedding of words into a low dimensional space. In our experiments we tried the following dimensionalities: 30, 50, 100 and 200. The feature representation for each user is obtained summing over each of the embedding dimensions across all words.

[2] http://www.sas.upenn.edu/~danielpr/jobs.tar.gz

4.2.2 NPMI Clusters (SVD-C)

We use the NPMI matrix described in the previous paragraph to create hard clusters of words. These clusters can be thought as 'topics', i.e. words that are semantically similar. From a variety of clustering techniques we choose spectral clustering (Shi and Malik, 2000; Ng et al., 2002), a hard-clustering approach which deals well with high-dimensional and non-convex data (von Luxburg, 2007). Spectral clustering is based on applying SVD to the graph Laplacian and aims to perform an optimal graph partitioning on the NPMI similarity matrix. The number of clusters needs to be pre-specified. We use 30, 50, 100 and 200 clusters – numbers were chosen a priori based on previous work (Lampos et al., 2014). The feature representation is the standardised number of words from each cluster.

Although there is a loss of information compared to the original representation, the clusters are very useful in the model analysis step. Embeddings are hard to interpret because each dimension is an abstract notion, while the clusters can be interpreted by presenting a list of the most frequent or representative words. The latter are identified using the following centrality metric:

$$\mathrm{C}_w = \frac{\sum_{x \in c} \mathrm{NPMI}(w, x)}{|c| - 1}, \qquad (2)$$

where c denotes the cluster and w the target word.

4.2.3 Neural Embeddings (W2V-E)

Recently, there has been a growing interest in neural language models, where the words are projected into a lower dimensional dense vector space via a hidden layer (Mikolov et al., 2013b). These models showed they can provide a better representation of words compared to traditional language models (Mikolov et al., 2013c) because they capture syntactic information rather than just bag-of-context, handling non-linear transformations. In this low dimensional vector space, words with a small distance are considered semantically similar. We use the skip-gram model with negative sampling (Mikolov et al., 2013a) to learn word embeddings on the Twitter reference corpus. In that case, the skip-gram model is factorising a word-context PMI matrix (Levy and Goldberg, 2014). We use a layer size of 50 and the Gensim implementation.[3]

4.2.4 Neural Clusters (W2V-C)

Similar to the NPMI cluster, we use the neural embeddings in order to obtain clusters of related words, i.e. 'topics'. We derive a word to word similarity matrix using cosine similarity on the neural embeddings. We apply spectral clustering on this matrix to obtain 30, 50, 100 and 200 word clusters.

5 Classification with Gaussian Processes

In this section, we briefly overview Gaussian Process (GP) for classification, highlighting our motivation for using this method. GPs formulate a Bayesian non-parametric machine learning framework which defines a prior on functions (Rasmussen and Williams, 2006). The properties of the functions are given by a kernel which models the covariance in the response values as a function of its inputs. Although GPs form a powerful learning tool, they have only recently been used in NLP research (Cohn and Specia, 2013; Preoţiuc-Pietro and Cohn, 2013) with classification applications limited to (Polajnar et al., 2011).

Formally, GP methods aim to learn a function $f : \mathbb{R}^d \rightarrow \mathbb{R}$ drawn from a GP prior given the inputs $\boldsymbol{x} \in \mathbb{R}^d$:

$$f(\boldsymbol{x}) \sim \mathcal{GP}(m(\boldsymbol{x}), k(\boldsymbol{x}, \boldsymbol{x}')), \qquad (3)$$

where $m(\cdot)$ is the mean function (here 0) and $k(\cdot, \cdot)$ is the covariance kernel. Usually, the Squared Exponential (SE) kernel (a.k.a. RBF or Gaussian) is used to encourage smooth functions. For the multidimensional pair of inputs $(\boldsymbol{x}, \boldsymbol{x}')$, this is:

$$k_{\text{ard}}(\boldsymbol{x}, \boldsymbol{x}') = \sigma^2 \exp\left[\sum_i^d -\frac{(x_i - x_i')^2}{2l_i^2}\right], \qquad (4)$$

where l_i are lengthscale parameters learnt only using training data by performing gradient ascent on the type-II marginal likelihood. Intuitively, the lengthscale parameter l_i controls the variation along the i input dimension, i.e. a low value makes the output very sensitive to input data, thus making that input more useful for the prediction. If the lengthscales are learnt separately for each input dimension the kernel is named SE with Automatic Relevance Determination (ARD) (Neal, 1996).

Binary classification using GPs 'squashes' the real valued latent function $f(x)$ output through a logistic function: $\pi(\boldsymbol{x}) \triangleq \mathrm{P}(y = 1|\boldsymbol{x}) = \sigma(f(\boldsymbol{x}))$ in a similar way to logistic regression classification. The object of the GP inference is the distribution

[3] http://radimrehurek.com/gensim/models/word2vec.html

of the latent variable corresponding to a test case x_*:

$$\mathrm{P}(f_*|\boldsymbol{x}, \boldsymbol{y}, x_*) = \int \mathrm{P}(f_*|\boldsymbol{x}, x_*, f)\mathrm{P}(f|\boldsymbol{x}, \boldsymbol{y})df \,, \tag{5}$$

where $\mathrm{P}(f|\boldsymbol{x}, \boldsymbol{y}) = \mathrm{P}(\boldsymbol{y}|f)\mathrm{P}(f|\boldsymbol{x})/\mathrm{P}(\boldsymbol{y}|\boldsymbol{x})$ is the posterior over the latent variables. If the likelihood $\mathrm{P}(\boldsymbol{y}|f)$ is Gaussian, the combination with a GP prior $\mathrm{P}(f|\boldsymbol{x})$ gives a posterior GP over functions. In binary classification, the distribution over the latent f_* is combined with the logistic function to produce the prediction:

$$\bar{\pi}_* = \int \sigma(f_*)\mathrm{P}(f_*|\boldsymbol{x}, \boldsymbol{y}, x_*)df_*. \tag{6}$$

This results in a non-Gaussian likelihood in the posterior formulation and therefore, exact inference is infeasible for classification models. Multiple approximations exist that make the computation tractable (Gibbs and Mackay, 1997; Williams and Barber, 1998; Neal, 1999). In our experiments we opt to use the Expectation Propagation (EP) method (Minka, 2001) which approximates the non-Gaussian joint posterior with a Gaussian one. EP offers very good empirical results for many different likelihoods, although it has no proof of convergence. The complexity for the inference step is $\mathcal{O}(n^3)$. Given that our data set is very large and the number of features is high, we conduct inference using the fully independent training conditional (FITC) approximation (Snelson and Ghahramani, 2006) with 500 random inducing points. We refer the interested reader to Rasmussen and Williams (2006) for further information on GP classification.

Although we could use multi-class classification methods, in order to provide insight, we perform a separate one-vs-all classification for each class and then determine a label through the occupational class that has the highest likelihood.

6 Experiments

This section presents the experimental results for our task. We first compare the accuracy of our classification methods on held out data using each feature set and conduct a standard error analysis. We then use the interpretability of the ARD lengthscales from the GP classifier to further analyse the relevant features.

6.1 Predictive Accuracy

We assign users to one of nine possible classes (see the 'Major Groups' on Table 1) using one set of features at a time. Experiments combining features yielded only minor improvements. We apply common linear and non-linear methods together with our proposed **GP** classifier. The linear method is logistic regression (**LR**) with Elastic Net regularisation (Freedman, 2009) and the non-linear one is formulated by a Support Vector Machine (**SVM**) with an RBF kernel (Vapnik, 1998). The accuracy of our classifiers is measured on held-out data. Our data set is divided into stratified training (80%), validation (10%) and testing (10%) sets. The validation set was used to learn the LR and SVM hyperparameters, while the GP did not use this set at all. We report results using all three methods and all feature sets in Table 3.

Feature	**LR**	**SVM**	**GP**
Most frequent class	34.4%	34.4%	34.4%
UserLevel	34.0%	31.5%	34.2%
SVD-E-30	36.3%	35.0%	39.8%
SVD-E-50	36.7%	36.9%	38.6%
SVD-E-100	40.8%	41.9%	40.9%
SVD-E-200	40.0%	43.1%	43.8%
SVD-C-30	36.9%	36.5%	38.2%
SVD-C-50	37.7%	38.3%	40.5%
SVD-C-100	40.4%	42.1%	44.6%
SVD-C-200	44.2%	47.9%	48.2%
W2V-E-50	42.5%	49.0%	48.4%
W2V-C-30	40.0%	46.0%	47.1%
W2V-C-50	42.3%	48.5%	47.9%
W2V-C-100	44.4%	48.7%	51.3%
W2V-C-200	**46.9%**	**51.7%**	**52.7%**

Table 3: 9-way classification accuracy on held-out data for our 3 methods. Textual features are obtained using **SVD** or Word2Vec (**W2V**). **E** represents embeddings, **C** clusters. The final number denotes the amount of clusters or the size of the embedding.

We first observe that user level features (UserLevel; see Section 4.1) are not useful for predicting the job class. This finding indicates that general social behaviour or user impact are likely to be spread evenly across classes. It also highlights the difficulty of the task and motivates the use of deeper textual features.

The textual features (see Section 4.2) improve performance as compared to the most frequent class baseline. We also notice that the embeddings (SVD-E and W2V-E) have lower performance than the clusters (SVD-C and W2V-C) in most of the cases. This is expected, as adding word vectors to represent a user's text may overemphasise common words. The size of the embedding also increases performance. The W2V features show better ac-

Rank	**Topic #**	**Label**	**Topic** (most central words; *most frequent words*)	MRR	$\mu(l)$
1	116	Arts	archival, stencil, canvas, minimalist, illustration, paintings, abstract, designs, lettering, steampunk; *art, design, print, collection, poster, painting, custom, logo, printing, drawing*	.43	1.35
2	105	Health	chemotherapy, diagnosis, disease, inflammation, diseases, arthritis, symptoms, patients, mrsa, colitis; *risk, cancer, mental, stress, patients, treatment, surgery, disease, drugs, doctor*	.20	2.76
3	153	Beauty Care	exfoliating, cleanser, hydrating, moisturizer, moisturiser, shampoo, lotions, serum, moisture, clarins; *beauty, natural, dry, skin, massage, plastic, spray, facial, treatments, soap*	.19	3.69
4	21	Higher Education	undergraduate, doctoral, academic, students, curriculum, postgraduate, enrolled, master's, admissions, literacy; *students, research, board, student, college, education, library, schools, teaching, teachers*	.18	3.21
5	158	Software Engineering	integrated, data, implementation, integration, enterprise, configuration, open-source, cisco, proprietary, avaya; *service, data, system, services, access, security, development, software, testing, standard*	.17	3.10
7	186	Football	bardsley, etherington, gallas, heitinga, assou-ekotto, lescott, pienaar, warnock, ridgewell, jenas; *van, foster, cole, winger, terry, reckons, youngster, rooney, fielding, kenny*	.16	3.11
8	124	Corporate	consortium, institutional, firm's, acquisition, enterprises, subsidiary, corp, telecommunications, infrastructure, partnership; *patent, industry, reports, global, survey, leading, firm, 2015, innovation, financial*	.15	2.44
9	96	Cooking	parmesan, curried, marinated, zucchini, roasted, coleslaw, salad, tomato, spinach, lentils; *recipe, meat, salad, egg, soup, sauce, beef, served, pork, rice*	.15	3.00
12	164	Elongated Words	yaaaay, wooooo, woooo, yayyyyy, yaaaaay, yayayaya, yayy, yaaaaaaay, wooohooo, yaayyy; *wait, till, til, yay, ahhh, hoo, woo, woot, whoop, woohoo*	.11	3.47
16	176	Politics	religious, colonialism, christianity, judaism, persecution, fascism, marxism, nationalism, communism, apartheid; *human, culture, justice, religion, democracy, religious, humanity, tradition, ancient, racism*	.08	3.09

Table 4: Topics, represented by their most central and most frequent 10 words, sorted by their ARD lengthscale MRR across the nine GP-based occupation classifiers. $\mu(l)$ denotes the average lengthscale for a topic across these classifiers. Topic labels are manually created.

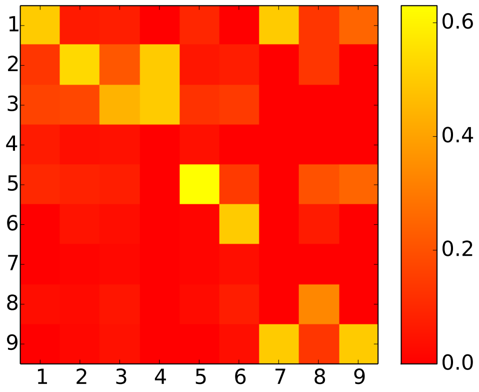

Figure 1: Confusion matrix of the prediction results. Rows represent the actual occupational class (**C** 1–9) and columns the predicted class.

curacy than the SVD on the NPMI matrix. This is consistent with previous work that showed the efficiency of word2vec and the ability of those embeddings to capture non-linear relationships and syntactic features (Mikolov et al., 2013a; Mikolov et al., 2013b; Mikolov et al., 2013c).

LR has a lower performance than the non-linear methods, especially when using clusters as features. GPs usually outperform SVMs by a small margin. However, these offer the advantages of not using the validation set and the interpretability properties we highlight in the next section. Although we only draw our focus on major occupational classes, the data set allows the study of finer granularities of occupation classes in future work. For example, prediction performance for sub-major groups reaches 33.9% accuracy (15.6% majority class, 22 classes) and 29.2% accuracy for minor groups (3.4% majority class, 55 classes).

6.2 Error Analysis

To illustrate the errors made by our classifiers, Figure 1 shows the confusion matrix of the classification results. First, we observe that class 4 is many times classified as class 2 or 3. This can be explained by the fact that classes 2, 3 and 4 contain similar types of occupations, e.g. doctors and nurses or accountants and assistant accountants. However, with very few exceptions, we notice that only adjacent classes get misclassified, suggesting that our model captures the general user skill level.

6.3 Qualitative Analysis

The word clusters that were built from a reference corpus and then used as features in the GP classifier, give us the opportunity to extract some qualitative derivations from our predictive task. For the rest of the section we use the best performing model of this type (W2V-C-200) in order to analyse the results. Our main assumption is that there might be a divergence of language and topic usage across occupational classes following previous studies in sociology (Bernstein, 1960; Bernstein, 2003). Knowing that the inferred GP lengthscale hyperparameters are inversely proportional to feature (i.e. topic) relevance (see Section 5), we can use them to rank the topic importance and give answers to our hypothesis.

Table 4 shows 10 of the most informative topics (represented by the top 10 most central and frequent words) sorted by their ARD lengthscale Mean Reciprocal Rank (MRR) (Manning et al., 2008) across the nine classifiers. Evidently, they cover a broad range of thematic subjects, including potentially work specific topics in different domains such as 'Corporate' (Topic #124), 'Software Engineering' (#158), 'Health' (#105), 'Higher Education' (#21) and 'Arts' (#116), as well as topics covering recreational interests such as 'Football' (#186), 'Cooking' (#96) and 'Beauty Care' (#153).

The highest ranked MRR GP lengthscales only highlight the topics that are the most discriminative of the particular learning task, i.e. which topic used alone would have had the best performance. To examine the difference in topic usage across occupations, we illustrate how six topics are covered by the users of each class. Figure 2 shows the Cumulative Distribution Functions (CDFs) across the nine different occupational classes for these six topics. CDFs indicate the fraction of users having at least a certain topic proportion in their tweets. A topic is more prevalent in a class, if the CDF line leans towards the bottom-right corner of the plot.

'Higher Education' (#21) is more prevalent in classes 1 and 2, but is also discriminative for classes 3 and 4 compared to the rest. This is expected because the vast majority of jobs in these classes require a university degree (holds for all of the jobs in classes 2 and 3) or are actually jobs in higher education. On the other hand, classes 5 to 9 have a similar behaviour, tweeting less on this topic. We also observe that words in 'Corporate' (#124) are used more as the skill required for a job gets higher. This topic is mainly used by people in classes 1 and 2 and with less extent in classes 3 and 4, indicating that people in these occupational classes are more likely to use social media for discussions about corporate business.

There is a clear trend of people with more skilled jobs to talk about 'Politics' (#176). Indeed, highly ranked politicians and political philosophers are parts of classes 1 and 2 respectively. Nevertheless, this pattern expands to the entire spectrum of the investigated occupational classes, providing further proof-of-concept for our methodology, under the assumption that the theme of politics is more attractive to the higher skilled classes rather than the lower skilled occupations. By examining 'Arts' (#116), we see that it clearly separates class 5, which includes artists, from all others. This topic appears to be relevant to most of the classification tasks and it is ranked first according to the MRR metric. Moreover, we observe that people with higher skilled jobs and education (classes 1–3) post more content about arts. Finally, we examine two topics containing words that can be used in more informal occasions, i.e. 'Elongated Words' (#164) and 'Beauty Care' (#153). We observe a similar pattern in both topics by which users with lower skilled jobs tweet more often.

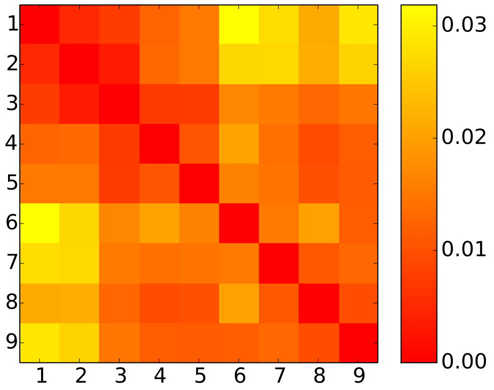

Figure 3: Jensen-Shannon divergence in the topic distributions between the different occupational classes (**C** 1–9).

The main conclusion we draw from Figure 2 is that there exists a topic divergence between users in the lower vs. higher skilled occupational classes. To examine this distinction better, we use the Jensen-Shannon divergence (JSD) to quantify the difference between the topic distributions across every

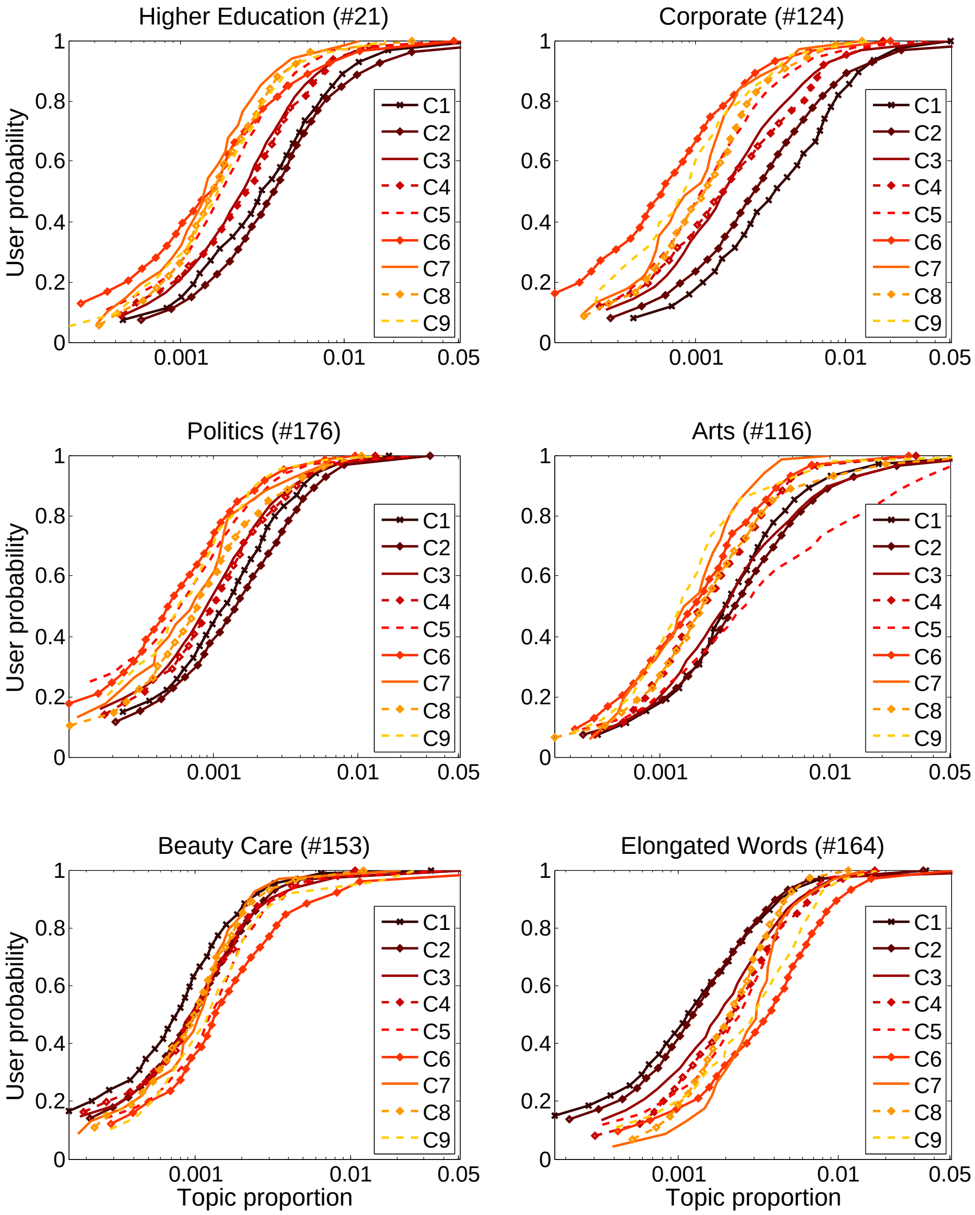

Figure 2: CDFs for six of the most important topics; the x-axis is on the log-scale for display purposes. A point on a CDF line indicates the fraction of users (y-axis point) with a topic proportion in their tweets lower or equal to the corresponding x-axis point. The topic is more prevalent in a class, if the CDF line leans closer to the bottom-right corner of the plot.

class pair. Figure 3 visualises these differences. There, we confirm that adjacent classes use similar topics of discussion. We also notice that JSD increases as the classes are further apart. Two main groups of related classes, with a clear separation from the rest, are identified: classes 1–2 and 6–9. For the users belonging to these two groups, we compute their topic usage distribution (for the top topics listed in Table 4). Then, we assess whether the topic usage distributions of those super-classes of occupations have a statistically significant difference by performing a two-sample Kolmogorov-Smirnov test. We enumerate the group topic usage means in Table 5; all differences were indeed statistically significant ($p < 10^{-5}$). From this comparison, we conclude that users in the higher skilled classes have a higher representation in all top topics but ‘Beauty Care’ and ‘Elongated Words’. Hence, the original hypothesis about the difference in the usage of language between upper and lower occupational classes is reconfirmed in this more generic testing. A very noticeable difference occurs for the

Topics	C 1–2	C 6–9
Arts	4.95	2.79
Health	4.45	2.13
Beauty Care	1.40	2.24
Higher Education	6.04	2.56
Software Engineering	6.31	2.54
Football	0.54	0.52
Corporate	5.15	1.41
Cooking	2.81	2.49
Elongated Words	1.90	3.78
Politics	2.14	1.06

'Corporate' topic, whereas 'Football' registers the lowest distance.

7 Related Work

Occupational class prediction has been studied in the past in the areas of psychology and economics. French (1959) investigated the relation between various measures on 232 undergraduate students and their future occupations. This study concluded that occupational membership can be predicted from variables such as the ability of subjects in using mathematical and verbal symbols, their family economic status, body-build and personality components. Schmidt and Strauss (1975) also studied the relationship between job types (five classes) and certain demographic attributes (gender, race, experience, education, location). Their analysis identified biases or discrimination which possibly exist in different types of jobs. Sociolinguistic and sociology studies deduct that social status is an important factor in determining the use of language (Bernstein, 1960; Bernstein, 2003; Labov, 2006). Differences arise either due to language use or due to the topics people discuss as parts of various social domains. However, a large scale investigation of this hypothesis has never been attempted.

Relevant to our task is a relation extraction approach proposed by Li et al. (2014) aiming to extract user profile information on Twitter. They used a weakly supervised approach to obtain information for job, education and spouse. Nonetheless, the information relevant to the job attribute regards the employer of a user (i.e. the name of a company) rather than the type of occupation. In addition, Huang et al. (2014) proposed a method to classify Sina Weibo users to twelve predefined occupations using content based and network features. However, there exist significant differences from our task since this inference is based on a distinct platform, with an ambiguous distribution over occupations (e.g. more than 25% related to media), while the occupational classes are not generic (e.g. media, welfare and electronic are three of the twelve categories). Most importantly, the applied model did not allow for a qualitative interpretation. Filho et al. (2014) inferred the social class of social media users by combining geolocation information derived from Foursquare and Twitter posts. Recently, Sloan et al. (2015) introduced tools for the automated extraction of demographic data (age, occupation and social class) from the profile descriptions of Twitter users using a similar method to our data set extraction approach. They showed that it is feasible to build a data set that matches the real-world UK occupation distribution as given by the SOC.

8 Conclusions

Our paper presents the first large-scale systematic study on language use on social media as a factor for inferring a user's occupational class. To address this problem, we have also introduced an extensive labelled data set extracted from Twitter. We have framed prediction as a classification task and, to this end, we used the powerful, non-linear GP framework that combines strong predictive performance with feature interpretability. Results show that we can achieve a good predictive accuracy, highlighting that the occupation of a user influences text use. Through a qualitative analysis, we have shown that the derived topics capture both occupation specific interests as well as general class-based behaviours. We acknowledge that the derivations of this study, similarly to other studies in the field, are reflecting the Twitter population and may experience a bias introduced by users self-mentioning their occupations. However, the magnitude, occupational diversity and face validity of our conclusions suggest that the presented approach is useful for future downstream applications.

Abstract

Tracking topics on social media streams is non-trivial as the number of topics mentioned grows without bound. This complexity is compounded when we want to track such topics against other fast moving streams. We go beyond traditional small scale topic tracking and consider a stream of topics against another document stream. We introduce two tracking approaches which are fully applicable to true streaming environments. When tracking 4.4 million topics against 52 million documents in constant time and space, we demonstrate that counter to expectations, simple single-pass clustering can outperform locality sensitive hashing for nearest neighbour search on streams.

1 Introduction

The emergence of massive social media streams has sparked a growing need for systems able to process them. While previous research (Hassan et al., 2009; Becker et al., 2009; Petrovic et al., 2010; Cataldi et al., (2010); Weng et al., (2011); Petrovic 2013) has focused on detecting new topics in unbounded textual streams, less attention was paid to following (tracking) the steadily growing set of topics. Standard topic tracking (Allan, 2002) deals with helping human analysts follow and monitor ongoing events on massive data streams. By pairing topics with relevant documents, topic tracking splits a noisy stream of documents into sub-streams grouped by their target topics. This is a crucial task for financial and security analysts who are interested in pulling together relevant information from unstructured and noisy data streams. Other fields like summarization or topic modeling benefit from topic tracking as a mean to generate their data sources.

In todays data streams however, new topics emerge on a continual basis and we are interested in following all instead of just a small fraction of newly detected topics. Since its introduction (Allan, 2002), standard topic tracking typically operates on a small scale and against a static set of predefined target topics. We go beyond such approaches and deal for the first time with massive, unbounded topic streams. Examples of unbounded topic streams include all events reported by news agencies each day across the world; popular examples of unbounded document streams include social media services such as Twitter. Tracking streams of topics allows research tasks like topic-modeling or summarization to be applied to millions of topics, a scale that is several orders of magnitude larger than those of current publications. We present two massive scale topic tracking systems capable of tracking unbounded topic streams. One is based on locality sensitive hashing (LSH) and the other on clustering. Since we operate on two unbounded data sources we are subject to the streaming model of computation (Muthukrishnan, 2005), which requires instant and single-pass decision making in constant time and space. Contrary to expectations, we find that nearest neighbour search on a stream based on clustering performs faster than LSH for the same level of accuracy. This is surprising as LSH is widely believed to be the fastest way of nearest neighbour search. Our experiments reveal how simple single-pass clustering outperforms LSH in terms of effectiveness and efficiency. Our results are general and apply to any setting where we have massive or infinite numbers of topics, matched against unboundedly large document streams.

Contributions

- For the first time we show how it is possible to track an unbounded stream of topics in constant time and space, while maintaining a level of effectiveness that is statistically indistinguishable from an exact tracking system
- We show how single-pass clustering can outperform locality sensitive hashing in terms of effectiveness and efficiency for identifying nearest neighbours in a stream
- We demonstrate that standard measures of similarity are sub-optimal when matching short documents against long documents

2 Related Work

Topic or event tracking was first introduced in the Topic Detection and Tracking (TDT) program (Allan, 2002). In TDT, topic tracking involves monitoring a stream of news documents with the intent to identify those documents relevant to a small predefined set of target topics. During the course of TDT, research focused extensively on the effectiveness of tracking systems, neglecting scale and efficiency. The three official data sets only range from 25k to 74k documents with a few hundred topics (Allan, 2002).

More recently, the rise of publicly available real-time social media streams triggered new research on topic detection and tracking, intended to apply the technology to those high volume document streams. The novel data streams differ from the TDT data sets in their volume and level of noise. To provide real-time applications, traditional methods need to be overhauled to keep computation feasible. It became common practice to limit data sets to cope with the computational effort. Popular strategies involve reducing the number of tracked topics (Lin et al., 2011; Nichols et al., 2012;) as well as sampling the document stream (Ghosh et al., 2013). These approaches have proven to be efficient in cutting down workload but they also limit an application's performance. Furthermore, Sayyadi et al. (2009) discovered and tracked topics in social streams based on keyword graphs. They applied the sliding window principle to keep the computation feasible, although their data set only contained 18k documents. Yang et al. 2012 tracked topics in tweet streams using language models. To cope with the computational effort they assume a small set of topics of only a few dozen, which are defined in advance. Tang et al. (2011) tracked a single topic on a few thousand blogs based on semantic graph topic models. Pon et al. (2007) recommend news by tracking multiple topics for a user but their data sets only span several thousand documents and a few topics.

Further related work includes the real-time filtering task, introduced as part of TREC's Microblog Track in 2012 (Soboroff et al., 2012). Hong et al. (2013) explore topic tracking in tweet streams in relation to the TREC real-time filtering task by relying on a sliding window principle, while focusing on the cold start problem.

3 Topic Tracking

3.1 Traditional Approach

Numerous approaches to topic tracking have emerged, spanning from probabilistic retrieval to statistical classification frameworks. While there is no single general approach, we define the traditional approach to tracking from a high-level perspective covering the basic principle of all previous approaches. We do not make any assumptions about the kind of topics, documents or distance functions used. As defined by TDT (Allan, 2002), we assume, we operate on an unbounded document stream with the goal of tracking a fixed set of target topics. Although topics are allowed to drift conceptually and evolve over time, new topics would always trigger the start of a new tracking system.

Algorithm 1 Traditional Tracking

```
INPUT:
TOPIC-SET $\{t \epsilon T\}$
DOCUMENT-STREAM $\{d \epsilon D\}$
OUTPUT:
relevant topic-document pairs $\{t, d\}$

while documents d in stream D do
    for all topics t in set T do
        similarity = computeSimilarity(d,t)
        if similarity > threshold then
            emit relevant $\{t, d\}$
```

As seen in Algorithm 1, documents arrive one at a time, requiring instant decision making through single pass processing. Each document is compared to all topics representations to identify the closest topic. The tracking decision is based on the similarity to the closest topic and usually defined by a thresholding strategy. Because incoming documents can be relevant to more than one topic, we need to match it against all of them. Due to its simplicity, the traditional tracking approach is highly efficient when applied to a fairly low number of topics.

3.2 Shortcomings of the traditional approach

The traditional approach - though low in computational effort - becomes challenging when scaling up the number of target topics. The computational effort arises from the number of comparisons made (the number of documents times topics). That explains, why researches following the traditional approach have either lowered the number of documents or topics. Heuristics and indexing methods increase the performance but offer no solution scalable to true streaming environments because they only allow for one-side scaling (either a large number of documents or topics). Increasing either of the two components by a single document, increases the computational effort by the magnitude of the other one. For the extreme case of pushing to an infinite number of topics, tracking in constant space is a necessity.

4 Tracking at scale

Before directly turning to a full streaming set up in constant space, we approach tracking a topic stream on a document stream in unbounded space. The key to scale up documents and topics, lies in reducing the number of necessary comparisons. Throughout the remainder of this paper we represent documents and topics arriving from a steady high volume stream by term-weighted vectors in the vector space.

In order to cut down the search space, we encapsulate every topic vector by a hypothetical region marking its area of proximity. Those regions are intend to capture documents that are more likely to be relevant. Ideally, these regions form a hypersphere centred around every topic vector with a radius equal to the maximum distance to relevant documents. The tracking procedure is then reduced to determining whether an incoming document is also enclosed by any of the hyperspheres.

4.1 Approximated Tracking

Our first attempt to reach sub-linear execution time uses random segmentation of the vector space using hashing techniques. We frame the tracking process as a nearest neighbour search problem, as defined by Gionis et al. (1999). Documents arriving from a stream are seen as queries and the closest topics are the nearest neighbours to be identified. We explore locality sensitive hashing (LSH), as described by Indyk et al. (1998), to approach high dimensional nearest neighbour search for topic tracking in sub-linear time. LSH, which has been used to speed up NLP applications (Ravichandran et al., 2005), provides hash functions that guarantee that similar documents are more likely to be hashed to the same binary hash key than distant ones. Hash functions capture similarities between vectors in high dimensions and represent them on a low dimensional binary level. We apply the scheme by Charikar (2002), which describes the probabilistic bounds for the cosine similarity between two vectors. Each bit in a hash key represents a documents position with respect to a randomly placed hyperplane. Those planes segment the vector space, forming high dimensional polygon shaped buckets. Documents and topics are placed into a bucket by determining on which side of each the hyperplanes they are positioned. We interpret these buckets as regions of proximity as the collision probability is directly proportional to the cosine similarity between two vectors.

Algorithm 2 LSH-based Tracking

```
INPUT:
TOPIC-STREAM $\{T\}$
DOCUMENT-STREAM $\{D\}$
OUTPUT:
relevant topic-document pairs $\{t, d\}$

while document d in T, D do
    if d $\epsilon$ T then
        hashKeys = $hash_{LSH}$(d)
        store hashKeys in hashTables
    else if d $\epsilon$ D then
        candidateSet = lookupHashtables($hash_{LSH}$(d))
        for all topics t in candidateSet do
            if similarity(d,t) $>$ threshold then
                emit relevant $\{t, d\}$
```

Algorithm 2 outlines the pseudo code to LSH-based tracking. Whenever a topic arrives, it is hashed, placing it into a bucket. To increase collision probability with similar documents, we repeat the hashing process with different hash functions, storing a topic and hash-key tuple in a hash table. On each arrival of a new document the same hash functions are applied and the key is matched against the hash tables, yielding a set of candidate topics. The probabilistic bounds of the hashing scheme guarantee that topics in the candidate set are on average more likely to be similar to the document than others.

We then match each topic in the candidate set against the document to lower the false positive rate of LSH (Gionis, et al., 1999). The number of exact comparisons necessary is reduced to the number of topics in the candidate set.

4.2 Cluster based Tracking

LSH based tracking segments the vector-space randomly without consideration of the data's distribution. In contrast, we now propose a data dependent approach through document clustering. The main motivation for data dependent space segmentation is increased effectiveness resulting from taking the topic distribution within the vector space into account when forming the regions of proximity. We construct these regions by grouping similar topics to form clusters represented by a centroid. When tracking a document, it is matched against the centroids instead of all topics, yielding a set of candidate topics. This allows reducing the number of comparisons necessary to only the number of centroids plus the number of topics captured by the closest cluster.

Algorithm 3 Cluster based Tracking

```
INPUT:
INITIAL-CLUSTER-SET $\{c \epsilon C\}$
TOPIC-STREAM $\{T\}$
DOCUMENT-STREAM $\{D\}$
threshold for spawning a new cluster $\{thr_{spawn}\}$
threshold for adapting an existing cluster $\{thr_{adapt}\}$
OUTPUT:
relevant topic-document pairs $\{t, d\}$

while document d in T, D do
    if d $\epsilon$ T then
        $c_{min} = argmin_c\{distances(d, c \epsilon C)\}$
        if distance(d,$c_{min}$) $> thr_{spawn}$ then
            spawnNewCluster(d $\rightarrow$ C)
        else if distance(d,$c_{min}$) $< thr_{adapt}$ then
            contribute,assign($c_{min}$,d)
        else
            assign($c_{min}$,d)
    else if d $\epsilon$ D then
        $c_{min} = argmin_c\{$distances(d,c $\epsilon$ $C)\}$
        candidateSet = $\{t \epsilon c_{min}\}$
        for all topics t in candidateSet do
            if similarity(d,t) $>$ threshold then
                emit relevant $\{t, d\}$
```

While the literature provides a vast diversity of clustering methods for textual documents, our requirements regarding tracking streams of topics naturally reduce the selection to lightweight single-pass algorithms. Yang et al. (2012) provided evidence that in extreme settings simple approaches work well in terms of balancing effectiveness, efficiency and scalability. We identified ArteCM by Carullo et al. (2008), originally intended to cluster documents for the web, as suitable. Algorithm 3 outlines our approach for cluster based tracking. Given an initial set of 4 random centroids, we compare each arriving topic to all centroids. We associate the new topic with the cluster whenever it is close enough. Particularly close documents contribute to a cluster, allowing it to drift towards topic dense regions. If the document is distant to all existing clusters, we spawn a new cluster based on the document.

Documents arriving from the document stream are exactly matched against all centroids to determine the k-closest clusters. Topics associated with those clusters are subsequently exhaustively compared with the document, yielding topic-document pairs considered to be relevant. Probing more than one cluster increases the probability of finding similar topics. This does not correlate with soft-clustering methods as multiple probing happens at querying time while topics are assigned under a hard clustering paradigm.

4.3 Algorithm Comparison

Both the LSH- and the cluster-based tracking algorithm provide two parameters that are conceptually directly comparable to each other. The number of bits per hash key and the threshold for spawning new clusters directly determine the size of the candidate set by either varying the bucket size or the cluster radius. The size of the candidate set trades a gain in efficiency against a loss in effectiveness. Fewer topics in the candidate set heavily reduce the search space for the tracking process but increase the chance of missing a relevant topic. Bigger sets are more likely to cover relevant topics but require more computational effort during the exact comparison step. The proposed algorithms allow continuously adjusting the candidate set size between two extremes of having all topics in a single set and having a separate set for each topic.

The second parameter both algorithms have in common, is the number of probes to increase the probability of identifying similar topics. While LSH-based tracking offers the number of hash tables, cluster-based tracking provides the number of clusters probed. We again encounter a trade-off between gains in efficiency at the cost of effectiveness. Each additionally probed cluster or looked up table increases the chance of finding relevant topics as well as the computational effort.

5 Tracking Streams in Constant Space

Operation in constant space is crucial when tracking topic streams. We ensure this by placing an upper limit on the number of concurrently tracked topics. Whenever the limit is reached, an active topic is deleted and subsequently not considered any longer. The strategy for selecting deletion candidates is heavily application dependant. To handle topic streams, LSH-based tracking replaces the entries of an active topic in its hash-tables by the values of the new topic, whenever the maximum number of topics is reached. Cluster-based tracking requires more adaptation because we allow clusters to drift conceptually. Whenever the maximum number of topics is reached, the contribution of the deletion candidate to its cluster is reverted and it is removed, freeing space for a new topic.

6 Experiments

We evaluate the three algorithms in terms of effectiveness and efficiency. Starting out with tracking a small set of topics using the traditional approach, we evaluate various similarity metrics to ensure high effectiveness. We then conduct scaling experiments on massive streams in bounded and unbounded space.

Corpora

Traditional tracking datasets are unsuitable to approach tracking at scale as they consist of only a few thousand documents and several hundred topics (Allan, 2002). We created a new data set consisting of two streams (document and topic stream). The document stream consists of 52 million tweets gathered through Twitter's streaming API [1]. The tweets are order by their time-stamps. Since we are advocating a high volume topic stream, we require millions of topics. To ensure a high number of topics, we treat the entire English part (4.4 mio articles) of Wikipedia[2] as a proxy for a collection of topics and turn it into a stream. Each article is considered to be an unstructured textual representation of a topic time-stamped by its latest verified update.

Relevance Judgements

The topics we picked range from natural disasters, political and financial events to news about celebrities, as seen in table 3. We adopted the search-guided-annotation process used by NIST (Fiscus et al., 2002) and followed NIST's TDT annotation guidelines. According to the definition of TDT, a document is relevant to a topic if it speaks about it (Allan, 2002). In total we identified 14,436 tweets as relevant to one of 30 topics.

total number of topics	4.4 mio
annotated topics	30
total number of documents	52 mio
documents relevant to one of the 30 annotated topics	14.5k

Table 1: Data set statistics

Baseline

We use an exact tracking system as a baseline. To speed up runtime, we implement an inverted index in conjunction with term-at-a-time query execution. Additionally, we provide a trade off between effectiveness and efficiency by randomly down sampling the Twitter stream. Note that this closely resembles previous approaches to scale topic tracking (Ghosh et al., 2013).

Evaluation Metrics

We evaluate effectiveness by recall and precision and combine them using F1 scores. Efficiency is evaluated using two different metrics. We provide a theoretical upper bound by computing the number of dot products required for tracking (Equations 1-4).

$$DP_{traditional} = n_D * n_T \quad (1)$$

$$DP_{LSH-based} = (n_D + n_T) * (k * L) + DP_{cs} \quad (2)$$

$$DP_{cluster-based} = (n_D + n_T) * c + DP_{cs} \quad (3)$$

$$DP_{cs} = n_D * n_C \quad (4)$$

Variables	Definition
n_D	total number of documents
n_T	total number of topics
k	number of bits per hash
L	total number of hash tables
c	total number of clusters
n_C	total number of topics in all candidate sets

Table 2: Definition of variables for equation 1-4

[1] http://stream.twitter.com

[2] http://en.wikipedia.org/wiki/Wikipedia_database

Topic-Title	Topic description	Number of relevant tweets
Amy Winehouse	Amy Winehouse dies	3265
Prince William	William and Kate arrive in Canada	1021
Floods in Seoul	Floods and landslides in North and South Korea	432
Flight 4896	Flight 4896 crashed	11
Bangladesh-India border	Bangladesh and India sign a border pact	4
Goran Hadzic	War criminal Goran Hadzic got arrested	2

Table 3: Showing 6 example topics plus a short summary of relevant tweets, as well as the number of relevant tweets per topic

They therefore indicate performance without system- or implementation-dependent distortions. Equations 2 and 3 represent the cost to identify the candidate set for the LSH- and cluster-based algorithm plus the cost resulting from exhaustively comparing the candidate sets with the documents (Equation 4).

Because we compute the dot products for a worst case scenario, we also provide the runtime in seconds. All run-times are averaged over 5 runs, measured on the same idle machine. To ensure fair comparison, all algorithms are implemented in C using the same libraries, compiler, compiler optimizations and run as a single process using 4 GB of memory. Because the runtime of the traditional approach ($\sim$171 days) exceeds our limits, we estimate it based on extrapolating 50 runs using up to 25,000 topics. Note that this extrapolation favours the efficiency of the baseline system as it ignores hardware dependent slowdowns when scaling up the number of topics.

6.1 Exact tracking

In our first experiment we track 30 annotated topics on 52 million tweets using the traditional approach. We compare various similarity measures (Table 4) and use the best-performing one in all following experiments. Our data set differs from the TREC and TDT corpora, which used news-wire articles. Allan et al. (2000) report that the cosine similarity constantly performed as the best distance function for TDT. The use of Wikipedia and Twitter causes a different set of similarity measures to perform best. This results from the imbalance in average document length between Wikipedia articles (590 terms) and tweets (11 terms). The term weights in short tweets (many only containing a single term) are inflated by the cosine's length normalization. Those short tweets are however not uniquely linkable to target topics and consequently regarded as non-relevant by annotators, which explains the drop in performance. The similarity function chosen for all subsequent experiments is a BM25 weighted dot product, which we found to perform best.

	F1 score
tf-idf weighted cosine	0.147
tf-idf weighted dot product	0.149
BM25 weighted cosine	0.208
BM25 weighted dot product	0.217

Table 4: Comparing the effectiveness of similarity measures when matching 30 Wikipedia articles against 52 million tweets

6.2 Tracking at scale, using Wikipedia and Twitter

Previously, we conducted small scale experiments, now we are looking to scale them up, by tracking 4.4 million Wikipedia articles on 52 million tweets without limiting the number of topics tracked. The resulting trade-off between effectiveness and efficiency is shown in Figure 1 and 2. The right-most point corresponds to exhaustive comparison of every document against every topic – this results in highest possible effectiveness (F1 score) and highest computational cost. All runs use optimal tracking thresholds determined by sweeping them while optimizing on F1 score as an objective function. We also show the performance resulting from the traditional approach when randomly down-sampling the document (Twitter) stream, which resembles previous attempts to scale tracking (Ghosh et al., 2013). Every point on the LSH-based tracking curve in Figure 1 and 2 represents a different number of bits per hash key (varying between 4 and 20) and tables (ranging from 6 to 200). The points on the cluster-based tracking curves result from varying the number of clusters (ranging from 1 to 100,000) and probes. The resulting bucket sizes span from a few dozen to over a million topics.

As expected, the graphs in Figure 1 closely resembles those in Figure 2. The two figures also show that the performance of all three algorithms is continuously adjustable. Unsurprisingly, LSH- and cluster-based tracking clearly outperform

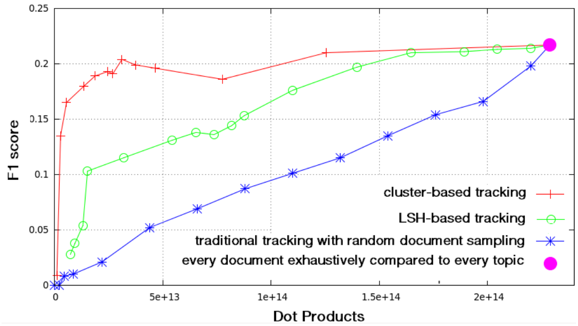

Figure 1: Trade-off between efficiency and dot-products for LSH- and cluster-based tracking as well as a random downsampling approach for traditional tracking

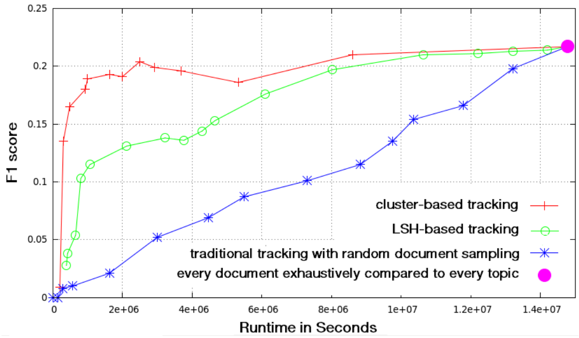

Figure 2: Trade-off between efficiency and runtime for LSH- and cluster-based tracking as well as a random downsampling approach for traditional tracking;

random document sampling for the traditional approach, based on their more effective search space reduction strategies. More surprisingly, we also observe that cluster-based tracking outperforms tracking based on LSH in terms of efficiency for F1 scores between 10% and 20%. To understand why tracking based on clustering is faster than randomized tracking, we further investigate their abilities in cutting down the search space.

Figure 3 presents the candidate set size necessary to find a certain ratio of relevant topics. The graph also illustrates the impact of probing multiple clusters. When focusing on a recall up to 60%, LSH-based tracking requires a significantly larger candidate set size in comparison with tracking through clustering. For example, LSH-based tracking needs to examine 30% of all topics to reach a recall of 50%, while the cluster based approach only needs to look at 9%. This effect diminishes for higher recall values. Furthermore, we observe an impressive performance gain in recall from 20% to 60%, resulting from additionally probing the k-closest clusters instead

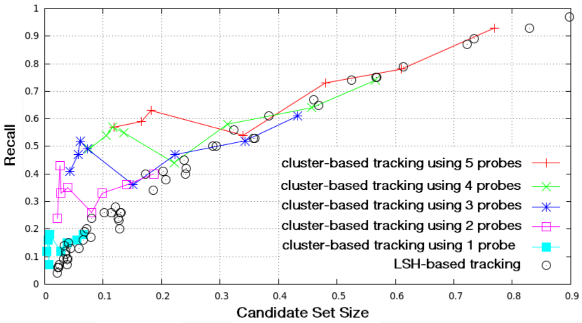

Figure 3: Comparing the candidate set size with the Recall of LSH- with cluster-based tracking without the exact evaluation phase; The magnitude of the candidate set size represents the ratio between the number of candidate topics and the total number of topics;

of just the closest one. While data dependent segmentation is expected to outperform LSH in terms of effectiveness, we were surprised by the magnitude of its impact on efficiency.

The lack in effectiveness of LSH has a direct negative implication on its efficiency for tracking. In order to make up for its suboptimal space segmentation, it requires substantially bigger candidate sets to reach the same level of recall as the cluster-based approach. The size of the candidate set is critical because we assume a subsequent exact comparison phase to lower the false positive rate. The overhead of both algorithms is outweighed by the cost of exact comparison for the candidate set.

Table 5, which compares the performance of the three algorithms, reveals a drastic reduction in runtime of up to 80%, at the cost of only a minor decrease in F1 score. The differences of 6% and 10% percent in F1 score are statistically not significant according to a sign test (p<=0.362 and p<=0.2). Consequently, both algorithms achieve substantial runtime reduction, while maintaining a level of effectiveness that is statistically indistinguishable from the traditional (exact) approach.

6.3 Tracking Wikipedia on Twitter in constant space

Tracking a stream of topics in bounded space is highly application specific due to the deletion procedure. We know from previous studies (Nichols et al., 2012) that a topic's popularity within Twitter fades away over time. We are interested in keeping currently active topics and delete those that attract the least number of recent documents. This set-up has the interesting aspect that the doc-

Algorithm	F1 score	Dot Products	Runtime (sec)
traditional approach	0.217	$2.3 * 10^{14}$	$1.5 * 10^{7}$
LSH-based tracking	0.196 (-10%)	$1.4 * 10^{14}$ (-39%)	$8.0 * 10^{6}$ (-46%)
cluster-based tracking	0.204 (-6%)	$3.1 * 10^{13}$ (-86%)	$2.5 * 10^{6}$ (-83%)

Table 5: Effectiveness and efficiency of LSH- and cluster-based tracking to the traditional approach

Algorithm	Space	F1 score	dot products	runtime (sec)
LSH-based tracking	unbounded	0.196	$1.4 * 10^{14}$	$8.0 * 10^{6}$
	bounded	0.173 (-12%)	$5.1 * 10^{11}$ (-99%)	$4.1 * 10^{4}$ (-99%)
cluster-based tracking	unbounded	0.204	$3.1 * 10^{13}$	$2.5 * 10^{6}$
	bounded	0.189 (-7%)	$1.8 * 10^{11}$ (-99%)	$3.3 * 10^{4}$ (-98%)

Table 6: Effectiveness and efficiency for tracking in bounded and unbounded space

ument stream dictates the lifespan of each topic in the topic stream. Table 6 contains the results of cluster- and LSH-based tracking and compares them to their bounded versions using the same set up. Note that the hit in performance is solely defined by the amount of memory provided and therefore continuously adjustable.

For this particular experiment, we chose an upper bound of 25k concurrent topics. The table represents a substantial drop in runtime, following the reduced search space, at a fairly low expense in effectiveness. Based on our observations, we hypothesise that significant topics are more likely to be discussed during random Twitter chatter than the average Wikipedia topic. It is interesting to notice that the runtime also indicates a lower overhead for LSH-based tracking in comparison with the cluster-based approach. This difference was hidden in the unbounded tracking experiments but carries now more weight.

7 Conclusion

We extended traditional topic tracking by demonstrating that it is possible to track an unbounded stream of topics in constant space and time. We also presented two approaches to tracking, based on LSH and clustering that efficiently scale to a high number of topics and documents while maintaining a level of effectiveness that is statistically indistinguishable from an exact tracking system. While they trade gains in efficiency against a loss in effectiveness, we showed that cluster based tracking does so more efficiently due to more effective space segmentation, which allows a higher reduction of the search space. Contrary to common believes this showed how nearest neighbour search in data streams based on clustering performs faster than LSH, for the same level of accuracy. Furthermore, we showed that standard measures of similarity (cosine) are sub-optimal when tracking Wikipedia against Twitter.

Abstract

We propose a nonparametric Bayesian model for joint unsupervised word segmentation and part-of-speech tagging from raw strings. Extending a previous model for word segmentation, our model is called a Pitman-Yor Hidden Semi-Markov Model (PYHSMM) and considered as a method to build a class n-gram language model directly from strings, while integrating character and word level information. Experimental results on standard datasets on Japanese, Chinese and Thai revealed it outperforms previous results to yield the state-of-the-art accuracies. This model will also serve to analyze a structure of a language whose words are not identified a priori.

1 Introduction

Morphological analysis is a staple of natural language processing for broad languages. Especially for some East Asian languages such as Japanese, Chinese or Thai, word boundaries are not explicitly written, thus morphological analysis is a crucial first step for further processing. Note that also in Latin and old English, scripts were originally written with no word indications (*scripta continua*), but people felt no difficulty reading them. Here, morphological analysis means word segmentation and part-of-speech (POS) tagging.

For this purpose, supervised methods have often been employed for training. However, to train such supervised classifiers, we have to prepare a large amount of training data with correct annotations, in this case, word segmentation and POS tags. Creating and maintaining these data is not only costly but also very difficult, because generally there are no clear criteria for either "correct" segmentation or POS tags. In fact, since there are different standards for Chinese word segmentation, widely used SIGHAN Bakeoff dataset (Emerson, 2005) consists of multiple parts employing different annotation schemes.

Lately, this situation has become increasingly important because there are strong demands for processing huge amounts of text in consumer generated media such as Twitter, Weibo or Facebook (Figure 1). They contain a plethora of colloquial expressions and newly coined words, including sentiment expressions such as emoticons that cannot be covered by fixed supervised data.

To automatically recognize such linguistic phenomena beyond small "correct" supervised data, we have to extract linguistic knowledge from the statistics of strings themselves in an unsupervised fashion. Needless to say, such methods will also contribute to analyzing speech transcripts, classic texts, or even unknown languages. From a scientific point of view, it is worth while to find "words" and their part-of-speech purely from a collection of strings without any preconceived assumptions.

To achieve that goal, there have been two kinds of approaches: heuristic methods and statistical generative models. Heuristic methods are based on basic observations such that word boundaries will often occur at the place where predictive entropy of characters is large (i.e. the next character cannot be predicted without assuming

the next word). By formulating such ideas as search or MDL problems of given coding length[1], word boundaries are found in an algorithmic fashion (Zhikov et al., 2010; Magistry and Sagot, 2013). However, such methods have difficulty incorporating higher-order statistics beyond simple heuristics, such as word transitions, word spelling formation, or word length distribution. Moreover, they usually depends on tuning parameters like thresholds that cannot be learned without human intervention.

In contrast, statistical models are ready to incorporate all such phenomena within a consistent statistical generative model of a string, and often prove to work better than heuristic methods (Goldwater et al., 2006; Mochihashi et al., 2009). In fact, the statistical methods often include the criteria of heuristic methods at least in a conceptual level, which is noted in (Mochihashi et al., 2009) and also explained later in this paper. In a statistical model, each word segmentation $\mathbf{w}$ of a string s is regarded as a hidden stochastic variable, and the unsupervised learning of word segmentation is formulated as a maximization of a probability of $\mathbf{w}$ given s:

$$\operatorname*{argmax}_{\mathbf{w}} p(\mathbf{w}|s)\,. \tag{1}$$

This means that we want the most "natural" segmentation $\mathbf{w}$ that have a high probability in a language model $p(\mathbf{w}|s)$.

Lately, Chen et al. (2014) proposed an intermediate model between heuristic and statistical models as a product of character and word HMMs. However, these two models do not have information shared between the models, which is not the case with generative models.

So far, these approaches only find word segmentation, leaving part-of-speech information behind. These two problems are not actually independent but interrelated, because knowing the part-of-speech of some infrequent or unknown word will give contextual clues to word segmentation, and vice versa. For example, in Japanese

すもももももも

can be segmented into not only すもも/も/もも/も (plum/too/peach/too), but also into すもも/もも/もも (plum/peach/peach), which is ungrammatical. However, we could exclude the latter case if we leverage knowledge that a state sequence N/P/N/P is much more plausible in Japanese than N/N/N from the part-of-speech information. Sirts and Alumäe (2012) treats a similar problem of POS induction with unsupervised morphological segmentation, but they know the words in advance and only consider segmentation within a word.

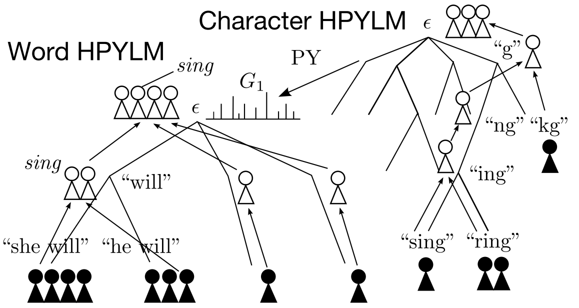

Figure 2: NPYLM represented in a hierarchical Chinese restaurant process. Here, a character ∞-gram HPYLM is embedded in a word n-gram HPYLM and learned jointly during inference.

For this objective, we attempt to maximize the joint probability of words and tags:

$$\operatorname*{argmax}_{\mathbf{w},\mathbf{z}} \; p(\mathbf{w},\mathbf{z}|s) \propto p(\mathbf{w},\mathbf{z},s) \tag{2}$$

From the expression above, this amounts to building a generative model of a string s with words $\mathbf{w}$ and tags $\mathbf{z}$ along with an associated inference procedure. We solve this problem by extending previous generative model of word segmentation. Note that heuristic methods are never able to model the hidden tags, and only statistical generative models can accommodate this objective.

This paper is organized as follows. In Section 2, we briefly introduce NPYLM (Mochihashi et al., 2009) on which our extension is based. Section 3 extends it to include hidden states to yield a hidden semi-Markov models (Murphy, 2002), and we describe its inference procedure in Section 4. We conduct experiments on some East Asian languages in Section 5. Section 6 discusses implications of our model and related work, and Section 7 concludes the paper.

2 Nested Pitman-Yor Language Model

Our joint model of words and states is an extension of the Nested Pitman-Yor Language Model (Mochihashi et al., 2009) of a string, which in turn is an extension of a Bayesian n-gram language model called Hierarchical Pitman-Yor Language Model (HPYLM) (Teh, 2006).

[1] For example, Zhikov et al. (2010) defined a coding length using character n-grams plus MDL penalty. Since this can be interpreted as a crude "likelihood" and a prior, its essence is similar but driven by a quite simplistic model.

HPYLM is a nonparametric Bayesian model of n-gram distribution based on the Pitman-Yor process (Pitman and Yor, 1997) that generates a discrete distribution G as $G \sim \mathrm{PY}(G_0, d, \theta)$. Here, d is a discount factor, “parent” distribution G_0 is called a base measure and θ controls how similar G is to G_0 in expectation. In HPYLM, n-gram distribution $G_n = \{p(w_t|w_{t-1} \cdots w_{t-(n-1)})\}$ is assumed to be generated from the Pitman-Yor process

$$G_n \sim \mathrm{PY}(G_{n-1}, d_n, \theta_n)\,, \tag{3}$$

where the base measure G_{n-1} is an $(n-1)$-gram distribution generated recursively in accordance with (3). Note that there are different G_n for each n-gram history $h = w_{t-1} \cdots w_{t-(n-1)}$. When we reach the unigram G_1 and need to use a base measure G_0, i.e. prior probabilities of words, HPYLM usually uses a uniform distribution over the lexicon.

However, in the case of unsupervised word segmentation, every sequence of characters could be a word, thus the size of the lexicon is unbounded. Moreover, prior probability of forming a word should not be uniform over all sequences of characters: for example, English words rarely begin with ‘gme’ but tend to end with ’-ent’ like in *segment*. To model this property, NPYLM assumes that word prior G_0 is generated from character HPYLM to model a well-formedness of w. In practice, to avoid dependency on n in the character model, we used an ∞-gram VPYLM (Mochihashi and Sumita, 2008) in this research. Finally, NPYLM gives an n-gram probability of word w given a history h recursively by integrating out G_n,

$$p(w|h) = \frac{c(w|h) - d \cdot t_{hw}}{\theta + c(h)} + \frac{\theta + d \cdot t_{h\cdot}}{\theta + c(h)}\, p(w|h')\,, \tag{4}$$

where h' is the shorter history of $(n-1)$-grams. $c(w|h), c(h) = \sum_w c(w|h)$ are n-gram counts of w appearing after h, and $t_{hw}, t_{h\cdot} = \sum_w t_{hw}$ are associated latent variables explained below. In case the history h is already empty at the unigram, $p(w|h') = p_0(w)$ is computed from the character ∞-grams for the word $w = c_1 \cdots c_k$:

$$\begin{aligned} p_0(w) &= p(c_1 \cdots c_k) & (5)\\ &= \textstyle\prod_{i=1}^{k} p(c_i|c_{i-1} \cdots c_1)\,. & (6)\end{aligned}$$

In practice, we further corrected (6) so that a word length follows a mixture of Poisson distributions. For details, see (Mochihashi et al., 2009).

When we know word segmentation $\mathbf{w}$ of the data, the probability above can be computed by adding each n-gram count of w given h to the model, i.e. increment $c(w|h)$ in accordance with a hierarchical Chinese restaurant process associated with HPYLM (Figure 2). When each n-gram count called a customer is inferred to be actually generated from $(n-1)$-grams, we send its proxy customer for smoothing to the parent restaurant and increment t_{hw}, and this process will recurse. Notice that if a word w is never seen in $\mathbf{w}$, its proxy customer is eventually sent to the parent restaurant of unigrams. In that case[2], w is decomposed to its character sequence $c_1 \cdots c_k$ and this is added to the character HPYLM in the same way, making it a little “clever” about possible word spellings.

Inference Because we do not know word segmentation $\mathbf{w}$ beforehand, we begin with a trivial segmentation in which every sentence is a single word[3]. Then, we iteratively refine it by sampling a new word segmentation $\mathbf{w}(s)$ of a sentence s in a Markov Chain Monte Carlo (MCMC) framework using a dynamic programming, as is done with PCFG by (Johnson et al., 2007) shown in Figure 3 where we omit MH steps for computational reasons. Further note that every hyperparameter d_n, θ_n of NPYLM can be sampled from the posterior in a Bayesian fashion, as opposed to heuristic methods that rely on a development set for tuning. For details, see Teh (2006).

3 Pitman-Yor Hidden Semi-Markov Models

NPYLM is a complete generative model of a string, that is, a hierarchical Bayesian n-gram lan-

```
Input: a collection of strings $S$
Add initial segmentation $\mathbf{w}(s)$ to $\Theta$
for $j = 1 \cdots J$ do
    for $s$ in randperm ($S$) do
        Remove customers of $\mathbf{w}(s)$ from $\Theta$
        Sample w(s) according to $p(\mathbf{w}|s, \Theta)$
        Add customers of w(s) to $\Theta$
    end for
    Sample hyperparameters of $\Theta$
end for
```

Figure 3: MCMC inference of NPYLM Θ.

[2] To be precise, this occurs whenever t_{hw} is incremented in the unigram restaurant.

[3] Note that a child first memorizes what his mother says as a single word and gradually learns the lexicon.

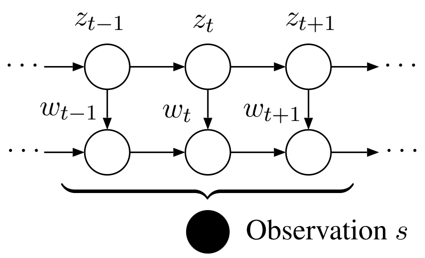

Figure 4: Graphical model of PYHSMM in a bigram case. White nodes are latent variables, and the shaded node is the observation. We only observe a string s that is a concatenation of hidden words $w_1 \cdots w_T$.

guage model combining words and characters. It can also be viewed as a way to build a Bayesian word n-gram language model directly from a sequence of characters, without knowing "words" a priori.

One possible drawback of it is a lack of part-of-speech: as described in the introduction, grammatical states will contribute much to word segmentation. Also, from a computational linguistics point of view, it is desirable to induce not only words from strings but also their part-of-speech purely from the usage statistics (imagine applying it to an unknown language or colloquial expressions). In classical terms, it amounts to building a class n-gram language model where both class and words are unknown to us. Is this really possible?

Yes, we can say it is possible. The idea is simple: we augment the latent states to include a hidden part-of-speech z_t for each word w_t, which is again unknown as displayed in Figure 4. Assuming w_t is generated from z_t'-th NPYLM, we can draw a generative model of a string s as follows:

```
$z_0 = \text{BOS}$; $s = \epsilon$ (an empty string).
**for** $t = 1 \cdots T$ **do**
    Draw $z_t \sim p(z_t | z_{t-1})$ ,
    Draw $w_t \sim p(w_t | w_1 \cdots w_{t-1}, z_t)$ ,
    Append $w_t$ to $s$ .
**end for**
```

Here, $z_0 = \text{BOS}$ and $z_{T+1} = \text{EOS}$ are distinguished states for beginning and end of a sentence, respectively. For the transition probability of hidden states, we put a HPY process prior as (Blunsom and Cohn, 2011):

$$p(z_t | z_{t-1}) \sim \text{HPY}(d, \theta) \tag{7}$$

with the final base measure being a uniform distribution over the states. The word boundaries are known in (Blunsom and Cohn, 2011), but in our case it is also learned from data at the same time. Note that because w_t depends on already generated words $w_1 \cdots w_{t-1}$, our model is considered as an autoregressive HMM rather than a vanilla HMM, as shown in Figure 4 ($w_{t-1} \rightarrow w_t$ dependency).

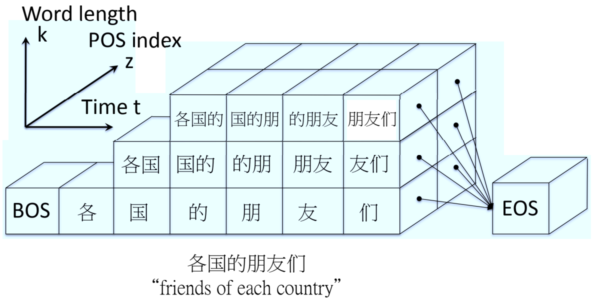

Figure 5: Graphical representation of sampling words and POSs. Each cell corresponds to an inside probability $\alpha[t][k][z]$. Note each cell is not always connected to adjacent cells, because of an overlap of substrings associated with each cell.

Since segment models like NPYLM have segment lengths as hidden states, they are called semi-Markov models (Murphy, 2002). In contrast, our model also has hidden part-of-speech, thus we call it a Pitman-Yor Hidden Semi-Markov model (PYHSMM).[4] Note that this is considered as a generative counterpart of a discriminative model known as a hidden semi-Markov CRF (Sarawagi and Cohen, 2005).

4 Inference

Inference of PYHSMM proceeds in almost the same way as NPYLM in Figure 3: For each sentence, first remove the customers associated with the old segmentation similarly to adding them. After sampling a new segmentation and states, the model is updated by adding new customers in accordance with the new segmentation and hidden states.

4.1 Sampling words and states

To sample words and states (part-of-speech) jointly, we first compute inside probabilities forward from BOS to EOS and sample backwards from EOS according to the Forward filtering-Backward sampling algorithm (Scott, 2002). This

[4] Lately, Johnson et al. (2013) proposed a nonparametric Bayesian hidden semi-Markov models for general state spaces. However, it depends on a separate distribution for a state duration, thus is clealy different from ours for a natural language.

can be regarded as a "stochastic Viterbi" algorithm that has the advantage of not being trapped in local minima, since it is a valid move of a Gibbs sampler in a Bayesian model.

For a word bigram case for simplicity, inside variable $\alpha[t][k][z]$ is a probability that a substring $c_1 \cdots c_t$ of a string $s = c_1 \cdots c_N$ is generated with its last k characters being a word, generated from state z as shown in Figure 5. From the definition of PYHSMM, this can be computed recursively as follows:

$$\alpha[t][k][z] = \sum_{j=1}^{L}\sum_{y=1}^{K} p(c_{t-k}^{t}|c_{t-k-j+1}^{t-k}, z) \\ p(z|y)\alpha[t-k][j][y]\,. \quad (8)$$

Here, c_s^t is a substring $c_s \cdots c_t$ and L $(\leq t)$ is the maximum length of a word, and K is the number of hidden states.[5]

In Figure 5, each cell represents $\alpha[t][k][z]$ and a single path connecting from EOS to BOS corresponds to a word sequence $\mathbf{w}$ and its state sequence $\mathbf{z}$. Note that each cell is not always connected to adjacent cells (we omit the arrows), because the length-k substring associated with each cell already subsumes that of neighborhood cells.

Once $\mathbf{w}$ and $\mathbf{z}$ are sampled, each w_t is added to z_t'-th NPYLM to update its statistics.

4.2 Efficient computation by the Negative Binomial generalized linear model

Inference algorithm of PYHSMM has a computational complexity of $O(K^2L^2N)$, where N is a length of the string to analyze. To reduce computations it is effective to put a small L of maximum word length, but it might also ignore occasionally long words. Since these long words are often predictable from some character level information including suffixes or character types, in a semi-supervised setting we employ a Negative Binomial generalized linear model (GLM) for setting L_t adaptively for each character position t in the corpus.

Type	Feature
c_i	Character at time $t-i$ $(0 \leq i \leq 1)$
t_i	Character type at time $t-i$ $(0 \leq i \leq 4)$
cont	# of the same character types before t
ch	# of times character types changed within 8 characters before t

Table 1: Features used for the Negative Binomial generalized linear model for maximum word length prediction.

Specifically, we model the word length ℓ by a Negative Binomial distribution (Cook, 2009):

$$\ell \sim \mathrm{NB}(\ell|r,p) = \frac{\Gamma(r+\ell)}{\Gamma(r)\,\ell!}\, p^{\ell}(1-p)^r\,. \quad (9)$$

This counts the number of failures of Bernoulli draws with probability $(1-p)$ before r'th success. For our model, note that Negative Binomial is obtained from a Poisson distribution $\mathrm{Po}(\lambda)$ whose parameter λ again follows a Gamma distribution $\mathrm{Ga}(r,b)$ and integrated out:

$$p(\ell|r,b) = \int \mathrm{Po}(\ell|\lambda)\mathrm{Ga}(\lambda|r,b)d\lambda \quad (10)$$

$$= \frac{\Gamma(r+\ell)}{\Gamma(r)\,\ell!}\left(\frac{b}{1+b}\right)^{\ell}\left(\frac{1}{1+b}\right)^{r}. \quad (11)$$

This construction exactly mirrors the Poisson-Gamma word length distribution in (Mochihashi et al., 2009) with sampled λ. Therefore, our Negative Binomial is basically a continuous analogue of the word length distribution in NPYLM.[6]

Since $r > 0$ and $0 \leq p \leq 1$, we employ an exponential and sigmoidal linear regression

$$r = \exp(\mathbf{w}_r^T\mathbf{f}),\;\; p = \sigma(\mathbf{w}_p^T\mathbf{f}) \quad (12)$$

where $\sigma(x)$ is a sigmoid function and $\mathbf{w}_r, \mathbf{w}_p$ are weight vectors to learn. $\mathbf{f}$ is a feature vector computed from the substring $c_1 \cdots c_t$, including $f_0 \equiv 1$ for a bias term. Table 1 shows the features we used for this Negative Binomial GLM. Since Negative Binomial GLM is not convex in $\mathbf{w}_r$ and $\mathbf{w}_p$, we endow a Normal prior $\mathrm{N}(0, \sigma^2 I)$ for them and used a random walk MCMC for inference.

Predicting L_t Once the model is obtained, we can set L_t adaptively as the time where the cumulative probability of ℓ exceeds some threshold θ (we used $\theta = 0.99$). Table 2 shows the precision of predicting maximum word length learned from 10,000 sentences from each set: it measures whether the correct word boundary in test data is included in the predicted L_t.

Overall it performs very well with high precision, and works better for longer words that cannot be accommodated with a fixed maximum length.

[5] For computational reasons, we do not pursue using a Dirichlet process to yield an infinite HMM (Van Gael et al., 2009), but it is straightforward to extend our PYHSMM to iHMM.

[6] Because NPYLM employs a mixture of Poisson distributions for each character type of a substring, this correspondence is not exact.

Lang	Dataset	Training	Test
Ja	Kyoto corpus	37,400	1,000
	BCCWJ OC	20,000	1,000
Zh	SIGHAN MSR	86,924	3,985
	SIGHAN CITYU	53,019	1,492
	SIGHAN PKU	19,056	1,945
Th	InterBEST Novel	1,000	1,000

Table 3: Datasets used for evaluation. Abbreviations: Ja=Japanese, Zh=Chinese, Th=Thai language.

Figure 6 shows the distribution of predicted maximum lengths for Japanese. Although we used $\theta = 0.99$, it is rather parsimonious but accurate that makes the computation faster.

Because this cumulative Negative Binomial prediction is language independent, we believe it might be beneficial for other natural language processing tasks that require some maximum lengths within which to process the data.

5 Experiments

To validate our model, we conducted experiments on several corpora of East Asian languages with no word boundaries.

Datasets For East Asian languages, we used standard datasets in Japanese, Chinese and Thai as shown in Table 3. The Kyoto corpus is a collection of sentences from Japanese newspaper (Kurohashi and Nagao, 1998) with both word segmentation and part-of-speech annotations. BCCWJ (Balanced Corpus of Contemporary Written Japanese) is a balanced corpus of written Japanese (Maekawa, 2007) from the National Institute of Japanese Language and Linguistics, also with both word segmentation and part-of-speech annotations from slightly different criteria. For experiments on colloquial texts, we used a random subset of "OC" register from this corpus that is comprised of Yahoo!Japan Answers from users. For Chinese, experiments are conducted on standard datasets of SIGHAN Bakeoff 2005 (Emerson, 2005); for comparison we used MSR and PKU datasets for simplified Chinese, and the CITYU dataset for traditional Chinese. SIGHAN datasets have word boundaries only, and we conformed to original training/test splits provided with the data. InterBEST is a dataset in Thai used in the InterBEST 2009 word segmentation contest (Kosawat, 2009). For contrastive purposes, we used a "Novel" subset of it with a random sampling without replacement for training and test data. Accuracies are measured in token F-measures computed as follows:

$$F = \frac{2PR}{P+R}, \tag{13}$$

$$P = \frac{\textit{\# of correct words}}{\textit{\# of words in output}}, \tag{14}$$

$$R = \frac{\textit{\# of correct words}}{\textit{\# of words in gold standard}}. \tag{15}$$

Unsupervised word segmentation In Table 4, we show the accuracies of unsupervised word segmentation with previous figures. We used bigram PYHSMM and set $L = 4$ for Chinese, $L = 5, 8, 10, 21$ for Japanese with different types of contiguous characters, and $L = 6$ for Thai. The number of hidden states are $K = 10$ (Chinese and Thai), $K = 20$ (Kyoto) and $K = 30$ (BCCWJ).

We can see that our PYHSMM outperforms on all the datasets. Huang and Zhao (2007) reports that the maximum possible accuracy in unsupervised Chinese word segmentation is 84.8%, derived through the inconsistency between different segmentation standards of the SIGHAN dataset. Our PYHSMM performs nearer to this best possible accuracy, leveraging both word and character knowledge in a consistent Bayesian fashion. Further note that in Thai, quite high performance is achieved with a very small data compared to previous work.

Unsupervised part-of-speech induction As stated above, Kyoto, BCCWJ and Weibo datasets

Dataset	Kyoto	BCCWJ	MSR	CITYU	BEST
Precision (All)	99.9	99.9	99.6	99.9	99.0
Precision (≥ 5)	96.7	98.4	73.6	87.0	91.7
Maximum length	15	48	23	12	21

Table 2: Precision of maximum word length prediction with a Negative Binomial generalized linear model (in percent). ≥ 5 are figures for word length ≥ 5. Final row is the maximum length of a word found in each dataset.

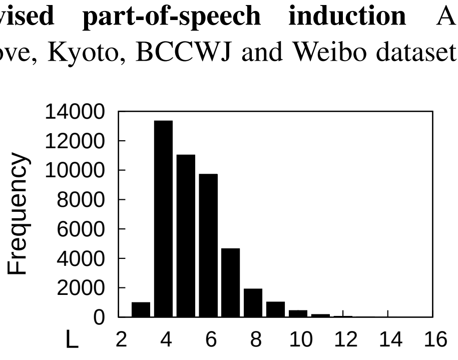

Figure 6: Distribution of predicted maximum word lengths on the Kyoto corpus.

Dataset	PYHSMM	NPY	BE	HMM^2
Kyoto	**71.5**	62.1	71.3	NA
BCCWJ	**70.5**	NA	NA	NA
MSR	**82.9**	80.2	78.2	81.7
CITYU	**82.6***	82.4	78.7	NA
PKU	**81.6**	NA	80.8	81.1
BEST	**82.1**	NA	**82.1**	NA

Table 4: Accuracies of unsupervised word segmentation. BE is a Branching Entropy method of Zhikov et al. (2010), and HMM^2 is a product of word and character HMMs of Chen et al. (2014). * is the accuracy decoded with $L=3$: it becomes 81.7 with $L=4$ as MSR and PKU.

have part-of-speech annotations as well. For these data, we also evaluated the precision of part-of-speech induction on the output of unsupervised word segmentation above. Note that the precision is measured only over correct word segmentation that the system has output. Table 5 shows the precisions; to the best of our knowledge, there are no previous work on joint unsupervised learning of words and tags, thus we only compared with Bayesian HMM (Goldwater and Griffiths, 2007) on both NPYLM segmentation and gold segmentation. In this evaluation, we associated each tag of supervised data with a latent state that cooccurred most frequently with that tag. We can see that the precision of joint POS tagging is better than NPYLM+HMM, and even better than HMM that is run over the gold segmentation.

For colloquial Chinese, we also conducted an experiment on the Leiden Weibo Corpus (LWC), a corpus of Chinese equivalent of Twitter[7]. We used random 20,000 sentences from this corpus, and results are shown in Figure 7. In many cases plausible words are found, and assigned to syntactically consistent states. States that are not shown here are either just not used or consists of a mixture of different syntactic categories. Guiding our model to induce more accurate latent states is a common problem to all unsupervised part-of-speech induction, but we show some semi-supervised results next.

Dataset	PYHSMM	NPY+HMM	HMM
Kyoto	**57.4**	53.8	49.5
BCCWJ	**50.2**	44.1	44.2
LWC	33.0	30.9	32.9

Table 5: Precision of POS tagging on correctly segmented words.

Semi-supervised experiments Because our PYHSMM is a generative model, it is easily amenable to semi-supervised segmentation and tagging. We used random 10,000 sentences from supervised data on Kyoto, BCCWJ, and LWC datasets along with unsupervised datasets in Table 3.

Results are shown in Table 6: segmentation accuracies came close to 90% but do not go beyond. By inspecting the segmentation and POS that PYHSMM has output, we found that this is not necessarily a fault of our model, but it came from the often inconsistet or incorrect tagging of the dataset. In many cases PYHSMM found more "natural" segmentations, but it does not always conform to the gold annotations. On the other hand, it often oversegments emotional expressions (sequence of the same character, for example) and this is one of the major sources of errors.

Finally, we note that our proposed model for unsupervised learning is most effective for the language which we do not know its syntactic behavior but only know raw strings as its data. In Figure 8, we show an excerpt of results to model a Japanese local dialect (*Mikawa-ben* around Nagoya district) collected from a specific Twitter. Even from the surface appearance of characters, we can see that similar words are assigned to the same state including some emoticons (states 9,29,32), and in fact we can identify a state of postpositions specific to that dialect (state 3). Notice that the words themselves are not trivial before this analysis. There are also some name of local places (state 41) and general Japanese postpositions (2) or nouns (11,18,25,27,31). Because of the sparsity promoting prior (7) over the hidden states, actually used states are sparse and the results can be considered quite satisfactory.

6 Discussion

The characteristics of NPYLM is a Baysian integration of character and word level information, which is related to (Blunsom and Cohn, 2011) and the adaptor idea of (Goldwater et al., 2011). This

is different from (and misunderstood in) a joint model of Chen et al. (2014), where word and character HMMs are just multiplied. There are no information shared from the model structure, and in fact it depends on a BIO-like heuristic tagging scheme in the character HMM.

In the present paper, we extended it to include a hidden state for each word. Therefore, it might be interesting to introduce a hidden state also for each character. Unlike western languages, there are many kinds of Chinese characters that work quite differently, and Japanese uses several distinct kinds of characters, such as a Chinese character, Hiragana, Katakana, whose mixture would constitute a single word. Therefore, statistical modeling of different types of characters is an important research venue for the future.

NPYLM has already applied and extended to speech recognition (Neubig et al., 2010), statistical machine translation (Nguyen et al., 2010), or even robotics (Nakamura et al., 2014). For all these research area, we believe PYHSMM would be beneficial for their extension.

7 Conclusion

In this paper, we proposed a Pitman-Yor Hidden Semi-Markov model for joint unsupervised word segmentation and part-of-speech tagging on a raw sequence of characters. It can also be viewed as a way to build a class n-gram language model directly on strings, without any "word" information a priori.

We applied our PYHSMM on several standard datasets on Japanese, Chinese and Thai, and it outperformed previous figures to yield the state-of-the-art results, as well as automatically induced word categories. It is especially beneficial for colloquial text, local languages or speech transcripts, where not only words themselves are unknown but their syntactic behavior is a focus of interest.

In order to adapt to human standards given in supervised data, it is important to conduct a semi-supervised learning with discriminative classifiers. Since semi-supervised learning requires generative models in advance, our proposed Bayesian generative model will also lay foundations to such an extension.

Abstract

In order to effectively utilize multiple datasets with heterogeneous annotations, this paper proposes a coupled sequence labeling model that can directly learn and infer two heterogeneous annotations simultaneously, and to facilitate discussion we use Chinese part-of-speech (POS) tagging as our case study. The key idea is to bundle two sets of POS tags together (e.g. "$[NN, n]$"), and build a conditional random field (CRF) based tagging model in the enlarged space of bundled tags with the help of *ambiguous labelings*. To train our model on two non-overlapping datasets that each has only one-side tags, we transform a one-side tag into a set of bundled tags by considering all possible mappings at the missing side and derive an objective function based on ambiguous labelings. The key advantage of our coupled model is to provide us with the flexibility of 1) incorporating joint features on the bundled tags to implicitly learn the loose mapping between heterogeneous annotations, and 2) exploring separate features on one-side tags to overcome the data sparseness problem of using only bundled tags. Experiments on benchmark datasets show that our coupled model significantly outperforms the state-of-the-art baselines on both one-side POS tagging and annotation conversion tasks. The codes and newly annotated data are released for non-commercial usage.[1]

1 Introduction

The scale of available labeled data significantly affects the performance of statistical data-driven models. As a widely-used structural classification problem, sequence labeling is prone to suffer from the data sparseness issue. However, the heavy cost of manual annotation typically limits one labeled resource in both scale and genre. As a promising research line, semi-supervised learning for sequence labeling has been extensively studied. Huang et al. (2009) show that standard self-training can boost the performance of a simple hidden Markov model (HMM) based part-of-speech (POS) tagger. Søgaard (2011) apply tri-training to English POS tagging, boosting accuracy from 97.27% to 97.50%. Sun and Uszkoreit (2012) derive word clusters from large-scale unlabeled data as extra features for Chinese POS tagging. Recently, the use of natural annotation has becomes a hot topic in Chinese word segmentation (Jiang et al., 2013; Liu et al., 2014; Yang and Vozila, 2014). The idea is to derive segmentation boundaries from implicit information encoded in web texts, such as anchor texts and punctuation marks, and use them as partially labeled training data in sequence labeling models.

The existence of multiple annotated resources opens another door for alleviating data sparseness. For example, Penn Chinese Treebank (*CTB*) contains about 20 thousand sentences annotated with word boundaries, POS tags, and syntactic structures (Xue et al., 2005), which is widely used for research on Chinese word segmentation and POS tagging. People's Daily corpus (*PD*)[2] is a large-scale corpus annotated with word segments and POS tags, containing about 300 thousand sentences from the first half of 1998 of People's

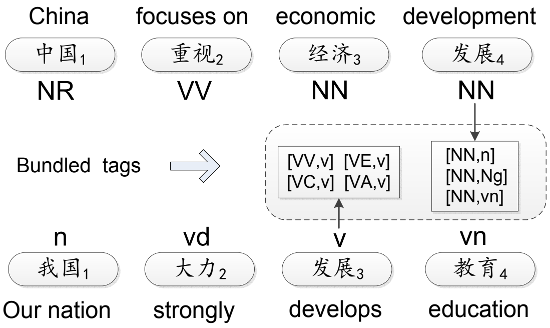

Figure 1: An example to illustrate the annotation differences between *CTB* (above) and *PD* (below), and how to transform a one-side tag into a set of bundled tags. "*NN*" and "*n*" represent nouns; "*VV*"and "*v*" represent verbs.

Daily newspaper (see Table 2). The two resources were independently built for different purposes. *CTB* was designed to serve syntactic analysis, whereas *PD* was developed to support information extraction systems. However, the key challenge of exploiting the two resources is that they adopt different sets of POS tags which are impossible to be precisely converted from one to another based on heuristic rules. Figure 1 shows two example sentences from *CTB* and *PD*. Please refer to Table B.3 in Xia (2000) for detailed comparison of the two guidelines.

Previous work on exploiting heterogeneous data (*CTB* and *PD*) mainly focuses on indirect guide-feature based methods. The basic idea is to use one resource to generate extra guide features on another resource (Jiang et al., 2009; Sun and Wan, 2012), which is similar to stacked learning (Nivre and McDonald, 2008). First, *PD* is used as source data to train a source model *Tagger$_{PD}$*. Then, *Tagger$_{PD}$* generates automatic POS tags on the target data *CTB*, called *source annotations*. Finally, a target model *Tagger$_{CTB\text{-}guided}$* is trained on *CTB*, using source annotations as extra guide features. Although the guide-feature based method is effective in boosting performance of the target model, we argue that it may have two potential drawbacks. First, the target model *Tagger$_{CTB\text{-}guided}$* does not directly use *PD* as training data, and therefore fails to make full use of rich language phenomena in *PD*. Second, the method is more complicated in real applications since it needs to parse a test sentence twice to get the final results.

This paper proposes a coupled sequence labeling model that can directly learn and infer two heterogeneous annotations simultaneously. We use Chinese part-of-speech (POS) tagging as our case study.[3] The key idea is to bundle two sets of POS tags together (e.g. "[*NN*, *n*]"), and build a conditional random field (CRF) based tagging model in the enlarged space of bundled tags. To make use of two non-overlapping datasets that each has only one-side tags, we transform a one-side tag into a set of bundled tags by considering all possible mappings at the missing side and derive an objective function based on *ambiguous labelings*. During training, the CRF-based coupled model is supervised by such ambiguous labelings. The advantages of our coupled model are to provide us the flexibility of 1) incorporating joint features on the bundled tags to implicitly learn the loose mapping between two sets of annotations, and 2) exploring separate features on one-side tags to overcome the data sparseness problem of using bundled tags. In summary, this work makes two major contributions:

1. We propose a coupled model which can more effectively make use of multiple resources with heterogeneous annotations, compared with both the baseline and guide-feature based method. Experiments show our approach can significantly improve POS tagging accuracy from 94.10% to 95.00% on *CTB*.

2. We have manually annotated *CTB* tags for $1,000$ *PD* sentences, which is the first dataset with two-side annotations and can be used for annotation-conversion evaluation. Experiments on the newly annotated data show that our coupled model also works effectively on the annotation conversion task, improving conversion accuracy from 90.59% to 93.90% ($+3.31\%$).

2 Traditional POS Tagging (*Tagger$_{CTB}$*)

Given an input sentence of n words, denoted by $\mathbf{x} = w_1...w_n$, POS tagging aims to find an optimal tag sequence $\mathbf{t} = t_1...t_n$, where $t_i \in \mathcal{T}$ ($1 \leq i \leq n$) and $\mathcal{T}$ is a predefined tag set. As a log-linear probabilistic model (Lafferty et al., 2001), CRF

[3] There are some slight differences in the word segmentation guidelines between *CTB* and *PD*, which are ignored in this work for simplicity.

01: $t_i \circ t_{i-1}$	02: $t_i \circ w_i$
03: $t_i \circ w_{i-1}$	04: $t_i \circ w_{i+1}$
05: $t_i \circ w_i \circ c_{i-1,-1}$	06: $t_i \circ w_i \circ c_{i+1,0}$
07: $t_i \circ c_{i,0}$	08: $t_i \circ c_{i,-1}$
09: $t_i \circ c_{i,k}, 0 < k < \#c_i - 1$	
10: $t_i \circ c_{i,0} \circ c_{i,k}, 0 < k < \#c_i - 1$	
11: $t_i \circ c_{i,-1} \circ c_{i,k}, 0 < k < \#c_i - 1$	
12: **if** $\#c_i = 1$ **then** $t_i \circ w_i \circ c_{i-1,-1} \circ c_{i+1,0}$	
13: **if** $c_{i,k} = c_{i,k+1}$ **then** $t_i \circ c_{i,k} \circ$ *"consecutive"*	
14: $t_i \circ \mathsf{prefix}(w_i, k), 1 \le k \le 4, k \le \#c_i$	
15: $t_i \circ \mathsf{suffix}(w_i, k), 1 \le k \le 4, k \le \#c_i$	

Table 1: POS tagging features $\mathbf{f}(\mathbf{x}, i, t_{i-1}, t_i)$. $\circ$ means string concatenation; $c_{i,k}$ denotes the k^{th} Chinese character of w_i; $c_{i,0}$ is the first Chinese character; $c_{i,-1}$ is the last Chinese character; $\#c_i$ is the total number of Chinese characters contained in w_i; prefix/suffix(w_i, k) denote the k-Character prefix/suffix of w_i.

defines the probability of a tag sequence as:

$$P(\mathbf{t}|\mathbf{x};\theta) = \frac{\exp(Score(\mathbf{x}, \mathbf{t}; \theta))}{\sum_{\mathbf{t}'} \exp(Score(\mathbf{x}, \mathbf{t}'; \theta))}$$
$$Score(\mathbf{x}, \mathbf{t}; \theta) = \sum_{1 \le i \le n} \theta \cdot \mathbf{f}(\mathbf{x}, i, t_{i-1}, t_i) \quad (1)$$

where $\mathbf{f}(\mathbf{x}, i, t_{i-1}, t_i)$ is the feature vector at the i^{th} word and θ is the weight vector. We adopt the state-of-the-art tagging features in Table 1 (Zhang and Clark, 2008).

3 Coupled POS Tagging (*Tagger*$_{\textit{CTB\&PD}}$)

In this section, we introduce our coupled model, which is able to learn and predict two heterogeneous annotations simultaneously. The idea is to bundle two sets of POS tags together and let the CRF-based model work in the enlarged tag space. For example, a *CTB* tag "*NN*" and a *PD* tag "*n*" would be bundled into "[*NN,n*]". Figure 2 shows the graphical structure of our model.

Different from the traditional model in Eq. (1), our coupled model defines the score of a bundled tag sequence as follows:

$$Score(\mathbf{x}, [\mathbf{t}^a, \mathbf{t}^b]; \theta) = \sum_{1 \le i \le n} \theta \cdot \begin{bmatrix} \mathbf{f}(\mathbf{x}, i, [t^a_{i-1}, t^b_{i-1}], [t^a_i, t^b_i]) \\ \mathbf{f}(\mathbf{x}, i, t^a_{i-1}, t^a_i) \\ \mathbf{f}(\mathbf{x}, i, t^b_{i-1}, t^b_i) \end{bmatrix} \quad (2)$$

where the first item of the enlarged feature vector is called *joint features*, which can be obtained by instantiating Table 1 by replacing t_i with bundled tags $[t^a_i, t^b_i]$; the second and third items are called *separate features*, which are based on single-side tags. The advantages of our coupled model over the traditional model are to provide us with the flexibility of using both kinds of features, which significantly contributes to the accuracy improvement as shown in the following experiments.

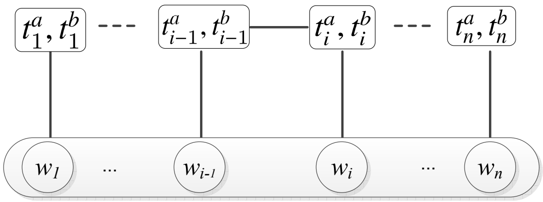

Figure 2: Graphical structure of our coupled CRF model.

3.1 Mapping Functions

The key challenge of our idea is that both *CTB* and *PD* are non-overlapping and each contains only one-side POS tags. Therefore, the problem is how to construct training data for our coupled model. We denote the tag set of *CTB* as $\mathcal{T}^a$, and that of *PD* as $\mathcal{T}^b$, and the bundled tag set as $\mathcal{T}^{a\&b}$. Since the full Cartetian $\mathcal{T}^a \times \mathcal{T}^b$ would lead to a very large number of bundled tags, making the model very slow, we would like to come up with a much smaller $\mathcal{T}^{a\&b} \subseteq \mathcal{T}^a \times \mathcal{T}^b$, based on linguistic insights of the annotation guidelines of the two datasets.

To obtain a proper $\mathcal{T}^{a\&b}$, we introduce a mapping function between the two sets of tags as $\mathbf{m} : \mathcal{T}^a \times \mathcal{T}^b \rightarrow \{0, 1\}$, which only allow specific tag pairs to be bundled together.

$$\mathbf{m}(t^a, t^b) = \begin{cases} 1 & \textit{if the two tags can be bundled} \\ 0 & \textit{otherwise} \end{cases} \quad (3)$$

where one mapping function $\mathbf{m}$ corresponds to one $\mathcal{T}^{a\&b}$. When the mapping function becomes looser, the tag set size $|\mathcal{T}^{a\&b}|$ becomes larger.

Then, based on the mapping function, we can map a single-side POS tag into a set of bundled tags by considering all possible tags at the missing side, as illustrated in Figure 1. The word "发展$_4$" is tagged as "*NN*" at the *CTB* side. Suppose that the mapping function $\mathbf{m}$ tells that "*NN*" can be mapped into three tags at the *PD* side, i.e., "*n*", "*Ng*", and "*vn*". Then, we create three bundled tags for the word, i.e., "[*NN, n*]", "[*NN, Ng*]", “[*NN, vn*]” as its gold-standard references during training. It is known as *ambiguous labelings* when a training instance has multiple gold-standard labels. Similarly, we can obtain bundled tags for all other words in sentences of *CTB* and *PD.* After such transformation, the two datasets are now in the same tag space.

At the beginning of this work, our intuition is that the coupled model would achieve the best performance if we build a tight and linguistically motivated mapping function. However, our preliminary experiments show that our intuitive assumption is actually incorrect. Therefore, we experiment with the following four mapping functions to manage to figure out the reasons behind and to better understand our coupled model.

- The **tight** mapping function produces 145 tags, and is constructed by strictly following linguistic principles and our careful study of the two guidelines and datasets.

- The **relaxed** mapping function results in 179 tags, which is an looser version of the tight mapping function by including extra 34 weak mapping relationships.

- The **automatic** mapping function generates 346 tags. We use the baseline *Tagger$_{CTB}$* to parse *PD*, and collect all automatic mapping relationships.

- The **complete** mapping function obtains $1,254$ tags ($|\mathcal{T}^a| \times |\mathcal{T}^b| = 33 \times 38$).

3.2 Training Objective with Ambiguous Labelings

So far, we have formally defined a coupled model and prepared both *CTB* and *PD* in the same bundled tag space. The next problem is how to learn the model parameters θ. Note that after our transformation, a sentence in *CTB* or *PD* have many tag sequences as gold-standard references due to the loose mapping function, known as *ambiguous labelings*. Here, we derive a training objective based on ambiguous labelings. For simplicity, we illustrate the idea based on the notations of the baseline CRF model in Eq. (1).

Given a sentence $\mathbf{x}$, we denote a set of ambiguous tag sequences as $\mathcal{V}$. Then, the probability of $\mathcal{V}$ is the sum of probabilities of all tag sequences contained in $\mathcal{V}$:

$$p(\mathcal{V}|\mathbf{x};\theta) = \sum_{\mathbf{t}\in\mathcal{V}} p(\mathbf{t}|\mathbf{x};\theta) \tag{4}$$

Algorithm 1 SGD training with two labeled datasets.

```
Input: Two labeled datasets: $\mathcal{D}^{(1)} = \{(\mathbf{x}_i^{(1)}, \mathcal{V}_i^{(1)})\}_{i=1}^{N}$, $\mathcal{D}^{(2)} = \{(\mathbf{x}_i^{(2)}, \mathcal{V}_i^{(2)})\}_{i=1}^{M}$;
    Parameters: $I$, $N'$, $M'$, $b$
Output: $\theta$
Initialization: $\theta_0 = \mathbf{0}$, $k = 0$;
for $i = 1$ to $I$ do {iterations}
    Randomly select $N'$ instances from $\mathcal{D}^{(1)}$ and $M'$ instances from $\mathcal{D}^{(2)}$ to compose a new dataset $\mathcal{D}_i$, and shuffle it.
    Traverse $\mathcal{D}_i$, and use a small batch $\mathcal{D}_k^b \subseteq \mathcal{D}_i$ at one step.
        $\theta_{k+1} = \theta_k + \eta_k \frac{1}{b} \nabla \mathcal{L}(\mathcal{D}_k^b; \theta_k)$
        $k = k + 1$
end for
```

Suppose the training data is $\mathcal{D} = \{(\mathbf{x}_i, \mathcal{V}_i)\}_{i=1}^{N}$. Then the log likelihood is:

$$\mathcal{L}(\mathcal{D};\theta) = \sum_{i=1}^{N} \log p(\mathcal{V}_i|\mathbf{x}_i;\theta) \tag{5}$$

After derivation, the gradient is:

$$\frac{\partial \mathcal{L}(\mathcal{D};\theta)}{\partial \theta} = \sum_{i=1}^{N} \left(E_{\mathbf{t}\in\mathcal{V}_i}[\mathbf{f}(\mathbf{x}_i, \mathbf{t})] - E_{\mathbf{t}}[\mathbf{f}(\mathbf{x}_i, \mathbf{t})]\right) \tag{6}$$

where $\mathbf{f}(\mathbf{x}_i, \mathbf{t})$ is an aggregated feature vector for tagging $\mathbf{x}_i$ as $\mathbf{t}$; $E_{\mathbf{t}\in\mathcal{V}_i}[.]$ means model expectation of the features in the constrained space of $\mathcal{V}_i$; $E_{\mathbf{t}}[.]$ is model expectation with no constraint. This function can be efficiently solved by the forward-backward algorithm. Please note that the training objective of a traditional CRF model can be understood as a special case where $\mathcal{V}_i$ contains one sequence.

3.3 SGD Training with Two Datasets

We adopt stochastic gradient descent (SGD) to iteratively learn θ for our baseline and coupled models. However, we have two separate training data, and *CTB* may be overwhelmed by *PD* if directly merging the two datasets into one, since *PD* is 15 times larger than *CTB* (see Table 2), Therefore, we propose a simple corpus-weighting strategy, as shown in Algorithm 1, where $\mathcal{D}_k^b$ is a subset of training data used in k^{th} step update; b is the batch size; η_k is a update step. The idea is to randomly sample instances from each training data in a certain proportion before each iteration.

The sampled data is then used for one-iteration training. Later experiments will investigate the effect of the weighting proportion. In this work, we use $b = 30$, and follow the implementation in CRFsuite[4] to decide η_k.

4 Manually Annotating *PD* Sentences with *CTB* Tags

To evaluate different methods on annotation conversion, we build the first dataset that contains $1,000$ sentences with POS tags on both sides of *CTB* and *PD*. The sentences are randomly sampled from *PD*. To save annotation effort, we only select 20% most difficult tokens to manually annotate. The difficulty of a word w_i is measured based on marginal probabilities produced by the baseline Tagger$_{CTB}$. $p(t_i|\mathbf{x}, w_i; \theta)$ denotes the marginal probability of tagging w_i as t_i. The basic assumption is that w_i is more difficult to annotate if its most likely tag candidate $(\arg\max_t p(t|\mathbf{x}, w_i; \theta))$ gets lower marginal probability.

We build a visualized online annotation system to facilitate manual labeling. The annotation task is designed in such way that at a time an annotator is provided with a sentence and one focus word, and is required to decide the *CTB* POS tag of the word. To further simplify annotation, we provide two or three most likely tag candidates as well, so that annotators can choose one either among the candidates or from a full list. We employ 8 undergraduate students as our annotators. Annotators are trained on simulated tasks from *CTB* data for several hours, and and start real annotation once reaching certain accuracy. To guarantee annotation quality, we adopt *multiple annotation*. Initially, one task is randomly assigned to two annotators. Later, if the two annotators submit different results, the system will assign the task to two more annotators. To aggregate annotation results, we only retain annotation tasks that the first two annotators agree (91.0%) or three annotators among four agree (5.6%), and discard other tasks (3.4%). Finally, we obtain $5,769$ words with both *CTB* and *PD* tags, with each annotator's detailed submissions, and could be used as a non-synthesized dataset for studying aggregating submissions from non-expert annotators in crowdsourcing platforms (Qing et al., 2014). The data is also fully released for non-commercial usage.

5 Experiments

In this section, we conduct experiments to verify the effectiveness of our approach. We adopt *CTB* (version 5.1) with the standard data split, and randomly split *PD* into four sets, among which one set is 20% *partially* annotated with *CTB* tags. The data statistics is shown in Table 2. The main concern of this work is to improve accuracy on *CTB* by exploring large-scale *PD*, since *CTB* is relatively small, but is widely-used benchmark data in the research community.

We use the standard token-wise tagging accuracy as the evaluation metric. For significance test, we adopt Dan Bikel's randomized parsing evaluation comparator (Noreen, 1989).[5].

The baseline CRF is trained on either *CTB* training data with 33 tags, or *PD* training data with 38 tags. The coupled CRF is trained on both two separate training datasets with bundled tags (179 tags for the relaxed mapping function). During evaluation, the coupled CRF is not directly evaluated on bundled tags, since bundled tags are unavailable in either *CTB* or *PD* test data. Instead, the coupled and baseline CRFs are both evaluated on one-side tags.

5.1 Model Development

Our coupled model has two major parameters to be decided. The first parameter is to determine the mapping function between *CTB* and *PD* annotations, and the second parameter is the relative weights of the two datasets during training (N' vs. M': number of sentences in each dataset used for training at one iteration).

Effect of mapping functions (described in Subsection 3.1) is illustrated in Figure 3. Empirically, we adopt $N' = 5K$ vs. $M' = 20K$ to merge the two training datasets at each iteration. Our intuition is that using this proportion, *CTB* should not be overwhelmed by *PD*, and both training data can be used up in relatively similar speed. Specifically, all training data of *CTB* can be consumed in about 3 iterations, whereas *PD* can be consumed in about 14 iterations. We also present the results of the baseline model trained using $5K$ sentences in one iteration for better comparison.

Contrary to our intuitive assumption, it actually leads to very bad performance when using the

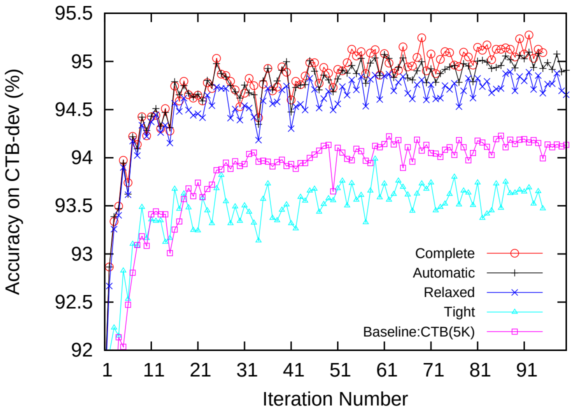

Figure 3: Accuracy on *CTB*-dev regarding to mapping functions.

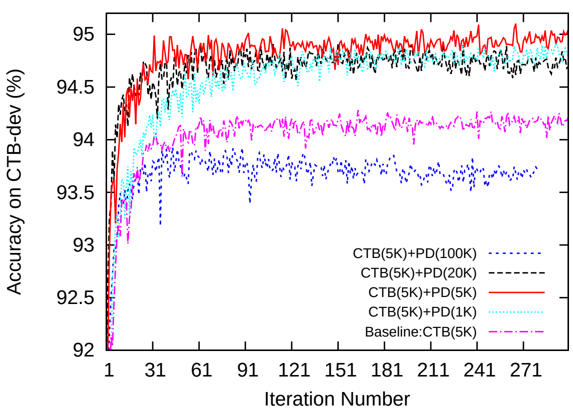

Figure 4: Accuracy on *CTB*-dev with different weighting settings.

tight mapping function that is carefully created based on linguistic insights, which is even inferior to the baseline model. The relaxed mapping function outperforms the tight function by large margin. The automatic function works slightly better than the relaxed one. The complete function achieves similar accuracy with the automatic one. In summary, we can conclude that our coupled model achieves much better performance when the mapping function becomes looser. In other words, this suggests that *our coupled model can effectively learn the implicit mapping between heterogeneous annotations, and does not rely on a carefully designed mapping function.*

Since a looser mapping function leads to a larger number of bundled tags and makes the model slower, we implement a paralleled training procedure based on Algorithm 1, and run each experiment with five threads. However, it still takes about 20 hours for one iteration when using the complete mapping function; whereas the other three mapping functions need about 6, 2, and 1 hours respectively. Therefore, as a compromise, *we adopt the relaxed mapping function in the following experiments*, which achieves slightly lower accuracy than the complete mapping function, but is much faster.

Effect of weighting *CTB* and *PD* is investigated in Figure 4 and 5. Since the scale of *PD* is much larger than *CTB*, we adopt Algorithm 1 to merge the training data in a certain proportion (N' *CTB* sentences and M' *PD* sentences) at each iteration. We use $N' = 5K$, and vary $M' = 1K/5K/20K/100K$. Figure 4 shows the accuracy curves on *CTB* development data. We find that when $M' = 100K$, our coupled model achieve very low accuracy, which is even worse than the baseline model. The reason should be that the training instances in *CTB* are overwhelmed by those in *PD* when M' is large. In contrast, when $M' = 1K$, the accuracy is also inferior to the case of $M' = 5K$, which indicates that *PD* is not effectively utilized in this setting. Our model works best when $M' = 5K$, which is slightly better than the case of $M' = 1K/20K$.

Figure 5 shows the accuracy curves on *PD* development data. The baseline model is trained using $100K$ sentences in one iteration. We find

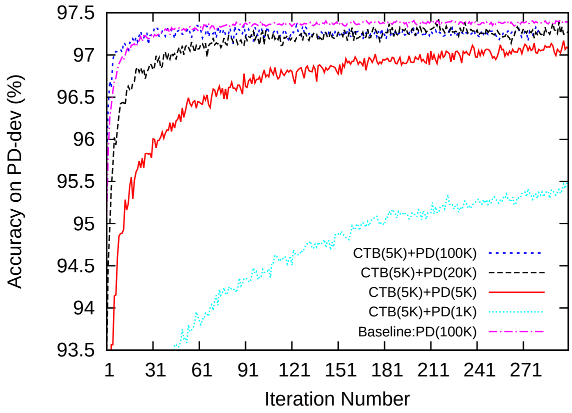

Figure 5: Accuracy on *PD*-dev with different weighting settings.

that when $M' = 100K$, our coupled model achieves similar accuracy with the baseline model. When M' becomes smaller, our coupled model becomes inferior to the baseline model. Particularly, when $M' = 1K$, the model converges very slowly. However, from the trend of the curves, we expect that the accuracy gap between our coupled model with $M' = 5K/20K$ and the baseline model should be much smaller when reaching convergence. Based on the above observation, *we adopt $N' = 5K$ and $M' = 5K$ in the following experiments.* Moreover, we select the best iteration on the development data, and use the corresponding model to parse the test data.

5.2 Final Results

Table 3 shows the final results on the *CTB* test data. We re-implement the guide-feature based method of Jiang et al. (2009), referred to as two-stage CRF. Li et al. (2012) jointly models Chinese POS tagging and dependency parsing, and report the best tagging accuracy on *CTB*. The results show that *our coupled model outperforms the baseline model by large margin, and also achieves slightly higher accuracy than the guide-feature based method.*

5.3 Feature Study

We conduct more experiments to measure individual contribution of each feature set, namely the joint features based on bundled tags and separate features based on single-side tags, as defined in Eq. (2). Table 4 shows the results. We can see that when only using separate features, our coupled model achieves only slightly better accuracy than the baseline model. This is because there is little connection and help between the two sets annotations. When only using joint features, our coupled model becomes largely inferior to the baseline, which is due to the data sparseness problem for the joint features. However, when the two sets of features are combined, the coupled model largely outperforms the baseline model. These results indicate that *both joint features and separate features are indispensable components and complementary to each other for the success of our coupled model.*

	Accuracy
Baseline CRF	94.10
Two-stage CRF (guide-feature)	94.81 (+0.71) †
Coupled CRF	**95.00** (+0.90) †‡
Best result (Li et al., 2012)	94.60

Table 3: Final results on *CTB* test data. † means the corresponding approach significantly outperforms the baseline at confidence level of $p < 10^{-5}$; whereas ‡ means the accuracy difference between the two-stage CRF and the coupled CRF is significant at confidence level of $p < 10^{-2}$.

	dev	test
Baseline CRF	94.28	94.10
Coupled CRF (w/ separate feat)	94.36	94.43 (+0.33)
Coupled CRF (w/ joint feat)	92.92	92.90 (-1.20)
Coupled CRF (full)	**95.10**	**95.00** (+0.90)

5.4 Results on Annotation Conversion

In this subsection, we evaluate different methods on the annotation conversion task using our newly annotated $1,000$ sentences. The gold-standard

	PD-to-*CTB* conversion
Baseline CRF	90.59
Two-stage CRF (guide-feature)	93.22 (+2.63) †
Coupled CRF	**93.90** (+3.31) †‡

Table 5: Conversion accuracy on our annotated data. † means the corresponding approach significantly outperforms the baseline at confidence level of $p < 10^{-5}$; whereas ‡ means the accuracy difference between the two-stage CRF and the coupled CRF is significant at confidence level of $p < 10^{-2}$.

	dev	test
Baseline CRF	94.28	94.10
Coupled CRF	**95.10**	**95.00** (+0.90) †
Baseline CRF + converted *PD*	95.01	94.81 (+0.71) †‡

Table 6: Accuracy on *CTB*: using converted *PD*. † means the corresponding approach significantly outperforms the baseline at confidence level of $p < 10^{-5}$; whereas ‡ means the accuracy difference between the coupled CRF and the baseline CRF with converted *PD* is significant at confidence level of $p < 10^{-2}$.

PD-side tags are provided, and the goal is to obtain the *CTB*-side tags via annotation conversion. We evaluate accuracy on the $5,769$ words having manually annotated *CTB*-side tags.

Our coupled model can be naturally used for annotation conversion. The idea is to perform constrained decoding on the test data, using the *PD*-side tags as hard constraints. The guide-feature based method can also perform annotation conversion by using the gold-standard *PD*-side tags to compose guide features. Table 5 shows the results. The accuracy is much lower than those in Table 3, because the $5,769$ words used for evaluation are 20% most ambiguous tokens in the $1,000$ test sentence (partial annotation to save annotation effort). From Table 5, we can see that *our coupled model outperforms both the baseline and guide-feature based methods by large margin*.

5.5 Results of Training with Converted Data

One weakness of our coupled model is the inefficiency problem due to the large bundled tag set. In practice, we usually only need results following one annotation style. Therefore, we employ our coupled model to convert *PD* into the style of *CTB*, and train our baseline model with two training data with homogeneous annotations. Again, Algorithm 1 is used to merge the two data with $N' = 5K$ and $M' = 5K$. The results are shown in the bottom row in Table 6. We can see that *with the extra converted data, the baseline model can achieve slightly lower accuracy with the coupled model and avoid the inefficiency problem at the meantime.*

6 Related Work

This work is partially inspired by Qiu et al. (2013), who propose a model that performs heterogeneous Chinese word segmentation and POS tagging and produces two sets of results following *CTB* and *PD* styles respectively. Different from our CRF-based coupled model, their approach adopts a linear model, which directly combines two separate sets of features based on single-side tags, without considering the interacting joint features between the two annotations. They adopt an approximate decoding algorithm which tries to find the best single-side tag sequence with reference to tags at the other side. In contrast, our approach is a direct extension of traditional CRF, and is more theoretically simple from the perspective of modelling. The use of both joint and separate features is proven to be crucial for the success of our coupled model. In addition, their work indicates that their model relies on a hand-crafted loose mapping between annotations, which is opposite to our findings. The naming of the "coupled" CRF is borrowed from the work of Qiu et al. (2012), which treats the joint task of Chinese word segmentation and POS tagging as two coupled sequence labeling problems.

Zhang et al. (2014) propose a shift-reduce dependency parsing model which can simultaneously learn and produce two heterogeneous parse trees. However, their approach assumes the existence of data with annotations at both sides, which is obtained by converting phrase-structure trees into dependency trees with different heuristic rules.

This work is also closely related with multi-task learning, which aims to jointly learn multiple related tasks with the benefit of using interactive features under a share representation (Ben-David and Schuller, 2003; Ando and Zhang, 2005; Parameswaran and Weinberger, 2010). However, according to our knowledge, multi-task learning typically assumes the existence of data with labels for multiple tasks at the same time, which is unavailable in our situation.

As one reviewer kindly pointed out that our model is a factorial CRF (Sutton et al., 2004), in the sense that the bundled tags can be factorized two connected latent variables. Initially, factorial CRFs are designed to jointly model two related (and typically hierarchical) sequential labeling tasks, such as POS tagging and chunking. In this work, our coupled CRF jointly models two same tasks which have different annotation schemes. Moreover, this work provides a natural way to learn from incomplete annotations where one sentence only contains one-side labels. The reviewer also suggests that our objective can be optimized with the latent variable structured perceptron of Sun et al. (2009), which we leave as future work.

Learning with ambiguous labelings are previously explored for classification (Jin and Ghahramani, 2002), sequence labeling (Dredze et al., 2009), parsing (Riezler et al., 2002; Täckström et al., 2013; Li et al., 2014a; Li et al., 2014b). Recently, researchers derive natural annotations from web data, transform them into ambiguous labelings to supervise Chinese word segmentation models (Jiang et al., 2013; Liu et al., 2014; Yang and Vozila, 2014).

7 Conclusions

This paper proposes an effective coupled sequence labeling model for exploiting multiple non-overlapping datasets with heterogeneous annotations. Please note that our model can also be naturally trained on datasets with both-side annotations if such data exists. Experimental results demonstrate that our model work better than the baseline and guide-feature based methods on both one-side POS tagging and annotation conversion. Specifically, detailed analysis shows several interesting findings. First, both the separate features and joint features are indispensable components for the success of our coupled model. Second, our coupled model does not rely on a carefully hand-crafted mapping function. Our linguistically motivated mapping function is only used to reduce the size of the bundled tag set for the sake of efficiency. Finally, using the extra training data converted with our coupled model, the baseline tagging model achieves similar accuracy improvement. In this way, we can avoid the inefficiency problem of our coupled model in real application.

For future, our immediate plan is to annotate more data with both *CTB* and *PD* tags (a few thousand sentences), and to investigate our coupled model with small amount of such annotation as extra training data. Meanwhile, Algorithm 1 is empirically effective in merging two training data, but still needs manual tuning of the weighting factor on held-out data. Thus, we would like to find a more principled and theoretically sound method to merge multiple training data.

Acknowledgments

The authors would like to thank the undergraduate students Fangli Lu and Xiaojing Wang for building our annotation system, and Le Lu, Die Hu, Yue Zhang, Jian Zhang, Qiuyi Yan, Xinzhou Jiang for data annotation. We are also grateful that Yu Ding kindly shared her earlier codes on which our annotation system was built. We also thank the helpful comments from our anonymous reviewers. AutoExtend: Extending Word Embeddings to Embeddings for Synsets and Lexemes

Sascha Rothe and Hinrich Schütze
Center for Information & Language Processing
University of Munich
sascha@cis.lmu.de

Abstract

We present *AutoExtend*, a system to learn embeddings for synsets and lexemes. It is flexible in that it can take any word embeddings as input and does not need an additional training corpus. The synset/lexeme embeddings obtained live in the same vector space as the word embeddings. A sparse tensor formalization guarantees efficiency and parallelizability. We use WordNet as a lexical resource, but AutoExtend can be easily applied to other resources like Freebase. AutoExtend achieves state-of-the-art performance on word similarity and word sense disambiguation tasks.

1 Introduction

Unsupervised methods for word embeddings (also called “distributed word representations”) have become popular in natural language processing (NLP). These methods only need very large corpora as input to create sparse representations (e.g., based on local collocations) and project them into a lower dimensional dense vector space. Examples for word embeddings are SENNA (Collobert and Weston, 2008), the hierarchical log-bilinear model (Mnih and Hinton, 2009), word2vec (Mikolov et al., 2013c) and GloVe (Pennington et al., 2014). However, there are many other resources that are undoubtedly useful in NLP, including lexical resources like WordNet and Wiktionary and knowledge bases like Wikipedia and Freebase. We will simply call these *resources* in the rest of the paper. Our goal is to enrich these valuable resources with embeddings for those data types that are not words; e.g., we want to enrich WordNet with embeddings for synsets and lexemes. A *synset* is a set of synonyms that are interchangeable in some context. A *lexeme* pairs a particular spelling or pronunciation with a particular meaning, i.e., a lexeme is a conjunction of a word and a synset. Our premise is that many NLP applications will benefit if the non-word data types of resources – e.g., synsets in WordNet – are also available as embeddings. For example, in machine translation, enriching and improving translation dictionaries (cf. Mikolov et al. (2013b)) would benefit from these embeddings because they would enable us to create an enriched dictionary for word senses. Generally, our premise is that the arguments for the utility of embeddings for word forms should carry over to the utility of embeddings for other data types like synsets in WordNet.

The insight underlying the method we propose is that *the constraints of a resource can be formalized as constraints on embeddings and then allow us to extend word embeddings to embeddings of other data types like synsets.* For example, the hyponymy relation in WordNet can be formalized as such a constraint.

The advantage of our approach is that it decouples embedding learning from the extension of embeddings to non-word data types in a resource. If somebody comes up with a better way of learning embeddings, these embeddings become immediately usable for resources. And we do not rely on any specific properties of embeddings that make them usable in some resources, but not in others.

An alternative to our approach is to train embeddings on annotated text, e.g., to train synset embeddings on corpora annotated with synsets. However, successful embedding learning generally requires very large corpora and sense labeling is too expensive to produce corpora of such a size.

Another alternative to our approach is to add up all word embedding vectors related to a particular node in a resource; e.g., to create the synset vector of *lawsuit* in WordNet, we can add the word vectors of the three words that are part of the synset (*lawsuit*, *suit*, *case*). We will call this approach

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1793–1803,
Beijing, China, July 26-31, 2015.

naive and use it as a baseline ($\mathrm{S}_{\mathrm{naive}}$ in Table 3).

We will focus on WordNet (Fellbaum, 1998) in this paper, but our method – based on a formalization that exploits the constraints of a resource for extending embeddings from words to other data types – is broadly applicable to other resources including Wikipedia and Freebase.

A word in WordNet can be viewed as a composition of several lexemes. Lexemes from different words together can form a synset. When a synset is given, it can be decomposed into its lexemes. And these lexemes then join to form words. These observations are the basis for the formalization of the constraints encoded in WordNet that will be presented in the next section: *we view words as the sum of their lexemes and, analogously, synsets as the sum of their lexemes.*

Another motivation for our formalization stems from the analogy calculus developed by Mikolov et al. (2013a), which can be viewed as a group theory formalization of word relations: we have a set of elements (our vectors) and an operation (addition) satisfying the properties of a mathematical group, in particular, associativity and invertibility. For example, you can take the vector of *king*, subtract the vector of *man* and add the vector of *woman* to get a vector near *queen*. In other words, you remove the properties of *man* and add the properties of *woman*. We can also see the vector of *king* as the sum of the vector of *man* and the vector of a gender-neutral ruler. The next thing to notice is that this does not only work for words that combine several *properties*, but also for words that combine several *senses*. The vector of *suit* can be seen as the sum of a vector representing *lawsuit* and a vector representing *business suit*. AutoExtend is designed to take word vectors as input and unravel the word vectors to the vectors of their lexemes. The lexeme vectors will then give us the synset vectors.

The main contributions of this paper are: (i) We present AutoExtend, a flexible method that extends word embeddings to embeddings of synsets and lexemes. AutoExtend is completely general in that it can be used for any set of embeddings and for any resource that imposes constraints of a certain type on the relationship between words and other data types. (ii) We show that AutoExtend achieves state-of-the-art word similarity and word sense disambiguation (WSD) performance. (iii) We publish the AutoExtend code for extending word embeddings to other data types, the lexeme and synset embeddings and the software to replicate our WSD evaluation.

This paper is structured as follows. Section 2 introduces the model, first as a general tensor formulation then as a matrix formulation making additional assumptions. In Section 3, we describe data, experiments and evaluation. We analyze AutoExtend in Section 4 and give a short summary on how to extend our method to other resources in Section 5. Section 6 discusses related work.

2 Model

We are looking for a model that extends standard embeddings for words to embeddings for the other two data types in WordNet: synsets and lexemes. We want all three data types – words, lexemes, synsets – to live in the same embedding space.

The basic premise of our model is: (i) words are sums of their lexemes and (ii) synsets are sums of their lexemes. We refer to these two premises as *synset constraints*. For example, the embedding of the word *bloom* is a sum of the embeddings of its two lexemes *bloom(organ)* and *bloom(period)*; and the embedding of the synset *flower-bloom-blossom(organ)* is a sum of the embeddings of its three lexemes *flower(organ)*, *bloom(organ)* and *blossom(organ)*.

The synset constraints can be argued to be the simplest possible relationship between the three WordNet data types. They can also be motivated by the way many embeddings are learned from corpora – for example, the counts in vector space models are additive, supporting the view of words as the sum of their senses. The same assumption is frequently made; for example, it underlies the group theory formalization of analogy discussed in Section 1.

We denote word vectors as $w^{(i)} \in \mathbb{R}^n$, synset vectors as $s^{(j)} \in \mathbb{R}^n$, and lexeme vectors as $l^{(i,j)} \in \mathbb{R}^n$. $l^{(i,j)}$ is that lexeme of word $w^{(i)}$ that is a member of synset $s^{(j)}$. We set lexeme vectors $l^{(i,j)}$ that do not exist to zero. For example, the non-existing lexeme *flower(truck)* is set to zero. We can then formalize our premise that the two constraints (i) and (ii) hold as follows:

$$w^{(i)} = \sum_j l^{(i,j)} \tag{1}$$

$$s^{(j)} = \sum_i l^{(i,j)} \tag{2}$$

These two equations are underspecified. We therefore introduce the matrix $E^{(i,j)} \in \mathbb{R}^{n \times n}$:

$$l^{(i,j)} = E^{(i,j)} w^{(i)} \tag{3}$$

We make the assumption that the dimensions in Eq. 3 are independent of each other, i.e., $E^{(i,j)}$ is a diagonal matrix. Our motivation for this assumption is: (i) This makes the computation technically feasible by significantly reducing the number of parameters and by supporting parallelism. (ii) Treating word embeddings on a per-dimension basis is a frequent design choice (e.g., Kalchbrenner et al. (2014)). Note that we allow $E^{(i,j)} < 0$ and in general the distribution weights for each dimension (diagonal entries of $E^{(i,j)}$) will be different. Our assumption can be interpreted as word $w^{(i)}$ distributing its embedding activations to its lexemes on each dimension separately. Therefore, Eqs. 1-2 can be written as follows:

$$w^{(i)} = \sum_j E^{(i,j)} w^{(i)} \tag{4}$$

$$s^{(j)} = \sum_i E^{(i,j)} w^{(i)} \tag{5}$$

Note that from Eq. 4 it directly follows that:

$$\sum_j E^{(i,j)} = I_n \quad \forall i \tag{6}$$

with I_n being the identity matrix.

Let W be a $|W| \times n$ matrix where n is the dimensionality of the embedding space, $|W|$ is the number of words and each row $w^{(i)}$ is a word embedding; and let S be a $|S| \times n$ matrix where $|S|$ is the number of synsets and each row $s^{(j)}$ is a synset embedding. W and S can be interpreted as linear maps and a mapping between them is given by the rank 4 tensor $\mathbf{E} \in \mathbb{R}^{|S| \times n \times |W| \times n}$. We can then write Eq. 5 as a tensor product:

$$S = \mathbf{E} \otimes W \tag{7}$$

while Eq. 6 states, that

$$\sum_j \mathbf{E}^{i,d_1}_{j,d_2} = 1 \quad \forall i, d_1, d_2 \tag{8}$$

Additionally, there is no interaction between different dimensions, so $\mathbf{E}^{i,d_1}_{j,d_2} = 0$ if $d_1 \neq d_2$. In other words, we are creating the tensor by stacking the diagonal matrices $E^{(i,j)}$ over i and j. Another sparsity arises from the fact that many lexemes do not exist: $\mathbf{E}^{i,d_1}_{j,d_2} = 0$ if $l^{(i,j)} = 0$; i.e., $l^{(i,j)} \neq 0$ only if word i has a lexeme that is a member of synset j. To summarize the sparsity:

$$\mathbf{E}^{i,d_1}_{j,d_2} = 0 \Leftarrow d_1 \neq d_2 \lor l^{(i,j)} = 0 \tag{9}$$

2.1 Learning

We adopt an autoencoding framework to learn embeddings for lexemes and synsets. To this end, we view the tensor equation $S = \mathbf{E} \otimes W$ as the encoding part of the autoencoder: the synsets are the encoding of the words. We define a corresponding decoding part that decodes the synsets into words as follows:

$$s^{(j)} = \sum_i \bar{l}^{(i,j)}, \quad \overline{w}^{(i)} = \sum_j \bar{l}^{(i,j)} \tag{10}$$

In analogy to $E^{(i,j)}$, we introduce the diagonal matrix $D^{(j,i)}$:

$$\bar{l}^{(i,j)} = D^{(j,i)} s^{(j)} \tag{11}$$

In this case, it is the synset that distributes itself to its lexemes. We can then rewrite Eq. 10 to:

$$s^{(j)} = \sum_i D^{(j,i)} s^{(j)}, \; \overline{w}^{(i)} = \sum_j D^{(j,i)} s^{(j)} \tag{12}$$

and we also get the equivalent of Eq. 6 for $D^{(j,i)}$:

$$\sum_i D^{(j,i)} = I_n \quad \forall j \tag{13}$$

and in tensor notation:

$$\overline{W} = \mathbf{D} \otimes S \tag{14}$$

Normalization and sparseness properties for the decoding part are analogous to the encoding part:

$$\sum_i \mathbf{D}^{j,d_2}_{i,d_1} = 1 \quad \forall j, d_1, d_2 \tag{15}$$

$$\mathbf{D}^{j,d_2}_{i,d_1} = 0 \Leftarrow d_1 \neq d_2 \lor l^{(i,j)} = 0 \tag{16}$$

We can state the learning objective of the autoencoder as follows:

$$\underset{\mathbf{E},\mathbf{D}}{\operatorname{argmin}} \|\mathbf{D} \otimes \mathbf{E} \otimes W - W\| \tag{17}$$

under the conditions Eq. 8, 9, 15 and 16.

Now we have an autoencoder where input and output layers are the word embeddings and the hidden layer represents the synset vectors. A simplified version is shown in Figure 1. The tensors $\mathbf{E}$

and $\mathbf{D}$ have to be learned. They are rank 4 tensors of size $\approx 10^{15}$. However, we already discussed that they are very sparse, for two reasons: (i) We make the assumption that there is no interaction between dimensions. (ii) There are only few interactions between words and synsets (only when a lexeme exists). In practice, there are only $\approx 10^{7}$ elements to learn, which is technically feasible.

2.2 Matrix formalization

Based on the assumption that each dimension is fully independent from other dimensions, a separate autoencoder for each dimension can be created and trained in parallel. Let $W \in \mathbb{R}^{|W| \times n}$ be a matrix where each row is a word embedding and $w^{(d)} = W_{\cdot,d}$ the d-th column of W, i.e., a vector that holds the d-th dimension of each word vector. In the same way, $s^{(d)} = S_{\cdot,d}$ holds the d-th dimension of each synset vector and $E^{(d)} = \mathbf{E}^{\cdot,d}_{\cdot,d} \in \mathbb{R}^{|S| \times |W|}$. We can write $S = \mathbf{E} \otimes W$ as:

$$s^{(d)} = E^{(d)} w^{(d)} \quad \forall d \tag{18}$$

with $E^{(d)}_{i,j} = 0$ if $l^{(i,j)} = 0$. The decoding equation $\overline{W} = \mathbf{D} \otimes S$ takes this form:

$$\overline{w}^{(d)} = D^{(d)} s^{(d)} \quad \forall d \tag{19}$$

where $D^{(d)} = \mathbf{D}^{\cdot,d}_{\cdot,d} \in \mathbb{R}^{|W| \times |S|}$ and $D^{(d)}_{j,i} = 0$ if $l^{(i,j)} = 0$. So E and D are symmetric in terms of non-zero elements. The learning objective becomes:

$$\underset{E^{(d)},D^{(d)}}{\operatorname{argmin}} \|D^{(d)} E^{(d)} w^{(d)} - w^{(d)}\| \quad \forall d \tag{20}$$

2.3 Lexeme embeddings

The hidden layer S of the autoencoder gives us synset embeddings. The lexeme embeddings are defined when transitioning from W to S, or more explicitly by:

$$l^{(i,j)} = E^{(i,j)} w^{(i)} \tag{21}$$

However, there is also a second lexeme embedding in AutoExtend when transitioning form S to $\overline{W}$:

$$\overline{l}^{(i,j)} = D^{(j,i)} s^{(j)} \tag{22}$$

Aligning these two representations seems natural, so we impose the following *lexeme constraints*:

$$\underset{E^{(i,j)},D^{(j,i)}}{\operatorname{argmin}} \left\| E^{(i,j)} w^{(i)} - D^{(j,i)} s^{(j)} \right\| \quad \forall i,j \tag{23}$$

	noun	verb	adj	adv

similarity	0	0	21,434	0
verb group	0	1,744	0	0

Table 1: # of WN relations by part-of-speech

This can also be expressed dimension-wise. The matrix formulation is given by:

$$\underset{E^{(d)},D^{(d)}}{\operatorname{argmin}} \left\| E^{(d)} \operatorname{diag}(w^{(d)}) - \left(D^{(d)} \operatorname{diag}(s^{(d)})\right)^{T} \right\| \forall d \tag{24}$$

with $\operatorname{diag}(x)$ being a square matrix having x on the main diagonal and vector $s^{(d)}$ defined by Eq. 18. While we try to align the embeddings, there are still two different lexeme embeddings. In all experiments reported in Section 4 we will use the average of both embeddings and in Section 4 we will analyze the weighting in more detail.

2.4 WN relations

Some WordNet synsets contain only a single word (lexeme). The autoencoder learns based on the synset constraints, i.e., lexemes being shared by different synsets (and also words); thus, it is difficult to learn good embeddings for single-lexeme synsets. To remedy this problem, we impose the constraint that *synsets related by WordNet (WN) relations should have similar embeddings*. Table 1 shows relations we used. WN relations are entered in a new matrix $R \in \mathbb{R}^{r \times |S|}$, where r is the number of WN relation tuples. For each relation tuple, i.e., row in R, we set the columns corresponding to the first and second synset to 1 and -1, respectively. The values of R are not updated during training. We use a squared error function and 0 as target value. This forces the system to find similar values for related synsets. Formally, the *WN relation constraints* are:

$$\underset{E^{(d)}}{\operatorname{argmin}} \|R E^{(d)} w^{(d)}\| \quad \forall d \tag{25}$$

2.5 Implementation

Our training objective is minimization of the sum of synset constraints (Eq. 20), weighted by α, the lexeme constraints (Eq. 24), weighted by β, and the WN relation constraints (Eq. 25), weighted by $1 - \alpha - \beta$.

The training objective cannot be solved analytically because it is subject to constraints Eq. 8,

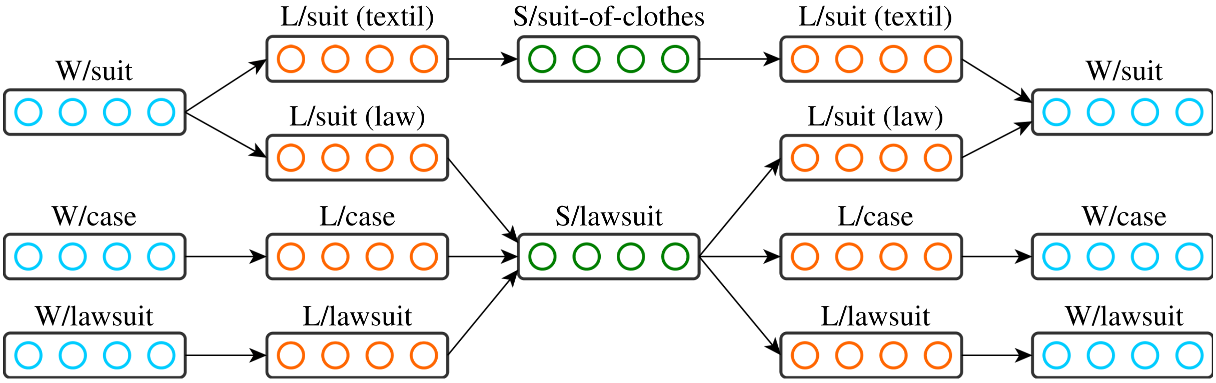

Figure 1: A small subgraph of WordNet. The circles are intended to show four different embedding dimensions. These dimensions are treated as independent. The synset constraints align the input and the output layer. The lexeme constraints align the second and fourth layers.

Eq. 9, Eq. 15 and Eq. 16. We therefore use backpropagation. We do not use regularization since we found that all learned weights are in $[-2, 2]$.

AutoExtend is implemented in MATLAB. We run 1000 iterations of gradient descent. On an Intel Xeon CPU E7-8857 v2 3.00GHz, one iteration on one dimension takes less than a minute because the gradient computation ignores zero entries in the matrix.

2.6 Column normalization

Our model is based on the premise that a word is the sum of its lexemes (Eq. 1). From the definition of $E^{(i,j)}$, we derived that $\mathbf{E} \in \mathbb{R}^{|S|\times n\times|W|\times n}$ is normalized over the first dimension (Eq. 8). So $E^{(d)} \in \mathbb{R}^{|S|\times|W|}$ is also normalized over the first dimension. In other words, $E^{(d)}$ is a column normalized matrix. Another premise of the model is that a synset is the sum of its lexemes. Therefore, $D^{(d)}$ is also column normalized. A simple way to implement this is to start the computation with column normalized matrices and normalize them again after each iteration as long as the error function still decreases. When the error function starts increasing, we stop normalizing the matrices and continue with a normal gradient descent. This respects that while $E^{(d)}$ and $D^{(d)}$ should be column normalized in theory, there are a lot of practical issues that prevent this, e.g., OOV words.

3 Data, experiments and evaluation

We downloaded 300-dimensional embeddings for 3,000,000 words and phrases trained on Google News, a corpus of $\approx 10^{11}$ tokens, using word2vec CBOW (Mikolov et al., 2013c). Many words in the word2vec vocabulary are not in WordNet, e.g., inflected forms (*cars*) and proper nouns (*Tony Blair*). Conversely, many WordNet lemmas are not in the word2vec vocabulary, e.g., *42* (digits were converted to 0). This results in a number of empty synsets (see Table 2). Note however that AutoExtend can produce embeddings for empty synsets because we use WN relation constraints in addition to synset and lexeme constraints.

We run AutoExtend on the word2vec vectors. As we do not know anything about a suitable weighting for the three different constraints, we set $\alpha = \beta = 0.33$. Our main goal is to produce compatible embeddings for lexemes and synsets. Thus, we can compute nearest neighbors across all three data types as shown in Figure 2.

We evaluate the embeddings on WSD and on similarity performance. Our results depend directly on the quality of the underlying word embeddings, in our case word2vec embeddings. We would expect even better evaluation results as word representation learning methods improve. Using a new and improved set of underlying embeddings is simple: it is a simple switch of the input file that contains the word embeddings.

3.1 Word Sense Disambiguation

For WSD we use the shared tasks of Senseval-2 (Kilgarriff, 2001) and Senseval-3 (Mihalcea et al., 2004) and a system named IMS (Zhong and

	WordNet	$\cap$ word2vec

Figure 2: Five nearest word (W/), lexeme (L/) and synset (S/) neighbors for three items, ordered by cosine

Ng, 2010). Senseval-2 contains 139, Senseval-3 57 different words. They provide 8,611, respectively 8,022 training instances and 4,328, respectively 3,944 test instances. For the system, we use the same setting as in the original paper. Preprocessing consists of sentence splitting, tokenization, POS tagging and lemmatization; the classifier is a linear SVM. In our experiments (Table 3), we run IMS with *each feature set by itself* to assess the relative strengths of feature sets (lines 1–7) and on *feature set combinations* to determine which combination is best for WSD (lines 8, 12–15).

IMS implements three standard WSD feature sets: part of speech (POS), surrounding word and local collocation (lines 1–3).

Let w be an ambiguous word with k senses. The three feature sets on lines 5–7 are based on the AutoExtend embeddings $s^{(j)}$, $1 \leq j \leq k$, of the synsets of w and the centroid c of the sentence in which w occurs. The centroid is simply the sum of all word2vec vectors of the words in the sentence, excluding stop words.

The **S-cosine** feature set consists of the k cosines of centroid and synset vectors:

$$< \cos(c, s^{(1)}), \cos(c, s^{(2)}), \ldots, \cos(c, s^{(k)}) >$$

The **S-product** feature set consists of the nk element-wise products of centroid and synset vectors:

$$< c_1 s_1^{(1)}, \ldots, c_n s_n^{(1)}, \ldots, c_1 s_1^{(k)}, \ldots, c_n s_n^{(k)} >$$

where c_i (resp. $s_i^{(j)}$) is element i of c (resp. $s^{(j)}$). The idea is that we let the SVM estimate how important each dimension is for WSD instead of giving all equal weight as in S-cosine.

The **S-raw** feature set simply consists of the $n(k+1)$ elements of centroid and synset vectors:

$$< c_1, \ldots, c_n, s_1^{(1)}, \ldots, s_n^{(1)}, \ldots, s_1^{(k)}, \ldots, s_n^{(k)} >$$

Our main goal is to determine if AutoExtend features improve WSD performance when added to standard WSD features. To make sure that improvements we get are not solely due to the power of word2vec, we also investigate a simple word2vec baseline. For S-product, the AutoExtend feature set that performs best in the experiment (cf. lines 6 and 14), we test the alternative word2vec-based **$\mathbf{S_{naive}}$-product** feature set. It has the same definition as S-product except that we replace the synset vectors $s^{(j)}$ with naive synset vectors $z^{(j)}$, defined as the sum of the word2vec vectors of the words that are members of synset j.

Lines 1–7 in Table 3 show the performance of each feature set by itself. We see that the synset feature sets (lines 5–7) have a comparable performance to standard feature sets. S-product is the strongest of them.

Lines 8–16 show the performance of different feature set combinations. MFS (line 8) is the most frequent sense baseline. Lines 9&10 are the winners of Senseval. The standard configuration of IMS (line 11) uses the three feature sets on lines 1–3 (POS, surrounding word, local collocation) and achieves an accuracy of 65.2% on the English lexical sample task of Senseval-2 and 72.3% on Senseval-3.[1] Lines 12–16 add one additional feature set to the IMS system on line 11; e.g., the system on line 14 uses POS, surrounding word, local collocation and S-product feature sets. The system on line 14 outperforms all previous systems, most of them significantly. While S-raw performs quite reasonably as a feature set alone, it hurts the performance when used as an additional feature set. As this is the feature set that contains the largest number of features ($n(k+1)$), overfitting is the likely reason. Conversely, S-cosine only adds k features and therefore may suffer from underfitting.

We do a grid search (step size .1) for optimal values of α and β, optimizing the average score of Senseval-2 and Senseval-3. The best performing feature set combination is **$\mathbf{S_{optimized}}$-product** with

[1] Zhong and Ng (2010) report accuracies of 65.3% / 72.6% for this configuration.

[†] In Table 3 and Table 4, results significantly worse than the best (bold) result in each column are marked † for $\alpha = .05$ and ‡ for $\alpha = .10$ (one-tailed Z-test).

Table 3: WSD accuracy for different feature sets and systems. Best result (excluding line 16) in each column in bold.

$\alpha = 0.2$ and $\beta = 0.5$, with only a small improvement (line 16).

The main result of this experiment is that we achieve an improvement of more than 1% in WSD performance when using AutoExtend.

3.2 Synset and lexeme similarity

We use SCWS (Huang et al., 2012) for the similarity evaluation. SCWS provides not only isolated words and corresponding similarity scores, but also a context for each word. SCWS is based on WordNet, but the information as to which synset a word in context came from is not available. However, the dataset is the closest we could find for sense similarity. Synset and lexeme embeddings are obtained by running AutoExtend. Based on the results of the WSD task, we set $\alpha = 0.2$ and $\beta = 0.5$. Lexeme embeddings are the natural choice for this task as human subjects are provided with two words and a context for each and then have to assign a similarity score. But for completeness, we also run experiments for synsets.

For each word, we compute a context vector c by adding all word vectors of the context, excluding the test word itself. Following Reisinger and Mooney (2010), we compute the lexeme (resp. synset) vector l either as the simple average of the lexeme (resp. synset) vectors $l^{(ij)}$ (method AvgSim, no dependence on c in this case) or as the average of the lexeme (resp. synset) vectors weighted by cosine similarity to c (method AvgSimC).

Table 4 shows that AutoExtend lexeme embeddings (line 7) perform better than previous work, including (Huang et al., 2012) and (Tian et al., 2014). Lexeme embeddings perform better than synset embeddings (lines 7 vs. 6), presumably because using a representation that is specific to the actual word being judged is more precise than using a representation that also includes synonyms.

		AvgSim	AvgSimC
1	Huang et al. (2012)	62.8†	65.7†
2	Tian et al. (2014)	–	65.4†
3	Neelakantan et al. (2014)	67.2	69.3
4	Chen et al. (2014)	66.2†	68.9
5	words (word2vec)	66.6‡	66.6†
6	synsets	62.6†	63.7†
7	lexemes	**68.9**	**69.8**

Table 4: Spearman correlation ($\rho \times 100$) on SCWS. Best result per column in bold.

A simple baseline is to use the underlying word2vec embeddings directly (line 5). In this case, there is only one embedding, so there is no difference between AvgSim and AvgSimC. It is interesting that even if we do not take the context into account (method AvgSim) the lexeme embeddings outperform the original word embeddings. As AvgSim simply adds up all lexemes of a word, this is equivalent to the constraint we proposed in the beginning of the paper (Eq. 1). Thus, replacing a word's embedding by the sum of the embeddings of its senses could generally improve the quality of embeddings (cf. Huang et al. (2012) for a similar point). We will leave a deeper evaluation of this topic for future work.

4 Analysis

We first look at the impact of the parameters α, β (Section 2.5) that control the weighting of synset constraints vs lexeme constraints vs WN relation constraints. We investigate the impact for three different tasks. **WSD-alone:** accuracy of IMS (average of Senseval-2 and Senseval-3) if only S-product is used as a feature set (line 6 in Table 3). **WSD-additional:** accuracy of IMS (average of Senseval-2 and Senseval-3) if S-product is used together with the feature sets POS, surrounding word and local collocation (line 14 in Table 3). **SCWS:** Spearman correlation on SCWS (line 7 in Table 4).

For WSD-alone (Figure 3, center), the best performing weightings (red) all have high weights for WN relations and are therefore at the top of triangle. Thus, WN relations are very important for WSD-alone and adding more weight to the synset and lexeme constraints does not help. However, all three constraints are important in WSD-additional: the red area is in the middle (corresponding to nonzero weights for all three constraints) in the left panel of Figure 3. Apparently, strongly weighted lexeme and synset constraints enable learning of representations that in their interaction with standard WSD feature sets like local collocation increase WSD performance. For SCWS (right panel), we should not put too much weight on WN relations as they artificially bring related, but not similar lexemes together. So the maximum for this task is located in the lower part of the triangle.

The main result of this analysis is that AutoExtend never achieves its maximum performance when using only one set of constraints. All three constraints are important – synset, lexeme and WN relation constraints – with different weights for different applications.

We also analyzed the impact of the four different WN relations (see Table 1) on performance. In Table 3 and Table 4, all four WN relations are used together. We found that any combination of three relation types performs worse than using all four together. A comparison of different relations must be done carefully as they differ in the POS they affect and in quantity (see Table 1). In general, relation types with more relations outperformed relation types with fewer relations.

Finally, the relative weighting of $l^{(i,j)}$ and $\bar{l}^{(i,j)}$ when computing lexeme embeddings is also a parameter that can be tuned. We use simple averaging ($\theta = 0.5$) for all experiments reported in this paper. We found only small changes in performance for $0.2 \leq \theta \leq 0.8$.

5 Resources other than WordNet

AutoExtend is broadly applicable to lexical and knowledge resources that have certain properties. While we only run experiments with WordNet in this paper, we will briefly address other resources. For *Freebase* (Bollacker et al., 2008), we could replace the synsets with Freebase entities. Each entity has several aliases, e.g. Barack Obama, President Obama, Obama. The role of words in WordNet would correspond to these aliases in Freebase. This will give us the synset constraint, as well as the lexeme constraint of the system. Relations are given by Freebase types; e.g., we can add a constraint that entity embeddings of the type ”President of the US” should be similar.

To explorer multilingual word embeddings we require the word embeddings of different languages to live in the same vector space, which can easily be achieved by training a transformation matrix L between two languages using known translations (Mikolov et al., 2013b). Let X be a matrix where each row is a word embedding in language 1 and Y a matrix where each row is a word embedding in language 2. For each row the words of X and Y are a translation of each other. We then want to minimize the following objective:

$$\underset{L}{\operatorname{argmin}} \| LX - Y \| \qquad (26)$$

We can use a gradient descent to solve this but a matrix inversion will run faster. The matrix L is given by:

$$L = (X^T * X)^{-1}(X^T * Y) \qquad (27)$$

The matrix L can be used to transform unknown embeddings into the new vector space, which enables us to use a multilingual WordNet like *BabelNet* (Navigli and Ponzetto, 2010) to compute synset embeddings. We can add cross-linguistic relationships to our model, e.g., aligning German and English synset embeddings of the same concept.

6 Related Work

Rumelhart et al. (1988) introduced distributed word representations, usually called word embeddings today. There has been a resurgence of work on them recently (e.g., Bengio et al. (2003) Mnih and Hinton (2007), Collobert et al. (2011), Mikolov et al. (2013a), Pennington et al. (2014)). These models produce only a single embedding for each word. All of them can be used as input for AutoExtend.

There are several approaches to finding embeddings for senses, variously called meaning, sense and multiple word embeddings. Schütze (1998) created sense representations by clustering context representations derived from co-occurrence. The representation of a sense is simply the centroid of its cluster. Huang et al. (2012) improved this by learning single-prototype embeddings before performing word sense discrimination on them. Bordes et al. (2011) created similarity measures for relations in WordNet and Freebase to learn entity embeddings. An energy based model was

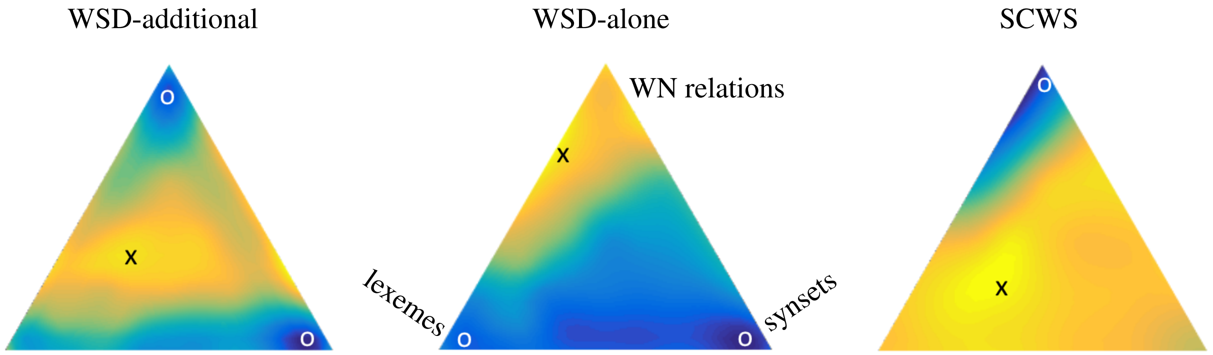

Figure 3: Performance of different weightings of the three constraints (WN relations:top, lexemes:left, synsets:right) on the three tasks WSD-additional, WSD-alone and SCWS. "x" indicates the maximum; "o" indicates a local minimum.

proposed by Bordes et al. (2012) to create disambiguated meaning embeddings and Neelakantan et al. (2014) and Tian et al. (2014) extended the Skip-gram model (Mikolov et al., 2013a) to learn multiple word embeddings. While these embeddings can correspond to different word senses, there is no clear mapping between them and a lexical resource like WordNet. Chen et al. (2014) also modified word2vec to learn sense embeddings, each corresponding to a WordNet synset. They use glosses to initialize sense embedding, which in turn can be used for WSD. The sense disambiguated data can again be used to improve sense embeddings.

This prior work needs a training step to learn embeddings. In contrast, we can "AutoExtend" any set of given word embeddings – without (re)training them.

There is only little work on taking existing word embeddings and producing embeddings in the same space. Labutov and Lipson (2013) tuned existing word embeddings in supervised training, not to create new embeddings for senses or entities, but to get better predictive performance on a task while not changing the space of embeddings.

Lexical resources have also been used to improve word embeddings. In the Relation Constrained Model, Yu and Dredze (2014) use word2vec to learn embeddings that are optimized to predict a related word in the resource, with good evaluation results. Bian et al. (2014) used not only semantic, but also morphological and syntactic knowledge to compute more effective word embeddings.

Another interesting approach to create sense specific word embeddings uses bilingual resources (Guo et al., 2014). The downside of this approach is that parallel data is needed.

We used the SCWS dataset for the word similarity task, as it provides a context. Other frequently used datasets are WordSim-353 (Finkelstein et al., 2001) or MEN (Bruni et al., 2014).

And while we use cosine to compute similarity between synsets, there are also a lot of similarity measures that only rely on a given resource, mostly WordNet. These measures are often functions that depend on the provided information like gloss or the topology like shortest-path. Examples include (Wu and Palmer, 1994) and (Leacock and Chodorow, 1998); Blanchard et al. (2005) give a good overview.

7 Conclusion

We presented AutoExtend, a flexible method to learn synset and lexeme embeddings from word embeddings. It is completely general and can be used for any other set of embeddings and for any other resource that imposes constraints of a certain type on the relationship between words and other data types. Our experimental results show that AutoExtend achieves state-of-the-art performance on word similarity and word sense disambiguation. Along with this paper, we will publish AutoExtend for extending word embeddings to other data types; the lexeme and synset embeddings used in the experiments; and the code needed to replicate our WSD evaluation[2].

Abstract

Quality estimation evaluation commonly takes the form of measurement of the error that exists between predictions and gold standard labels for a particular test set of translations. Issues can arise during comparison of quality estimation prediction score distributions and gold label distributions, however. In this paper, we provide an analysis of methods of comparison and identify areas of concern with respect to widely used measures, such as the ability to gain by prediction of aggregate statistics specific to gold label distributions or by optimally conservative variance in prediction score distributions. As an alternative, we propose the use of the unit-free Pearson correlation, in addition to providing an appropriate method of significance testing improvements over a baseline. Components of WMT-13 and WMT-14 quality estimation shared tasks are replicated to reveal substantially increased conclusivity in system rankings, including identification of outright winners of tasks.

1 Introduction

Machine Translation (MT) Quality Estimation (QE) is the automatic prediction of machine translation quality without the use of reference translations (Blatz et al., 2004; Specia et al., 2009). Human assessment of translation quality in theory provides the most meaningful evaluation of systems, but human assessors are known to be inconsistent and this causes challenges for quality estimation evaluation. For instance, there is a general lack of consensus both with respect to what provides the most meaningful gold standard representation, as well as best method of comparison of gold labels and system predictions. For example, in the 2014 Workshop on Statistical Machine Translation (WMT), which since 2012 has provided a main venue for evaluation of systems, sentence-level systems were evaluated with respect to three distinct gold standard representations and each of those compared to predictions using four different measures, resulting in a total of 12 different system rankings, 6 identified as official rankings (Bojar et al., 2014).

Although the aim of several methods of evaluation is to provide more insight into performance of systems, this also produces conflicting results and raises the question which method of evaluation really identifies the system(s) or method(s) that best predicts translation quality. For example, an extreme case in WMT-14 occurred for sentence-level quality estimation for English-to-Spanish. In each of the 12 system rankings, many systems were tied and this resulted in a total of 22 official winning systems for this language pair. Besides leaving potential users of quality estimation systems at a loss as to what the best system may be, a large number of inconclusive evaluation methodologies is also likely to lead to confusion about which evaluation methods should be applied in general in QE research, or worse still, researchers simply choosing the methodology that favors their system from among the many different methodologies.

In this paper, we provide an analysis of each of the methodologies used in WMT and widely applied to evaluation of quality estimation systems in general. Our analysis reveals potential flaws in existing methods and we subsequently provide detail of a single method that overcomes previous challenges. To demonstrate, we replicate com-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1804–1813,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

ponents of evaluations previously carried out at WMT-13 and WMT-14 sentence-level quality estimation shared tasks. Results reveal substantially more conclusive system rankings, revealing outright winners that had not previously been identified.

2 Relevant Work

The Workshop on Statistical Machine Translation (WMT) provides a main venue for evaluation of quality estimation systems, in addition to the rare and highly-valued effort of provision of publicly available data sets to facilitate further research. We provide an analysis of current evaluation methodologies applied not only in the most recent WMT shared task but also widely within quality estimation research.

2.1 WMT-style Evaluation

WMT-14 quality estimation evaluation at the sentence-level, Task 1, is comprised of three subtasks. In Task 1.1, human gold labels comprise three levels of translation quality or "perceived post-edit effort" (1 = perfect translation; 2 = near miss translation; 3 = very low quality translation). A possible downside of the evaluation methodology applied in Task 1.1 is firstly that the gold standard representation may be overly coarse-grained. Considering the vast range of possible errors occurring in translations, limiting the levels of translation quality to only three may impact negatively on systems' ability to discriminate between translations of various quality.

More importantly, however, the combination of such coarse-grained gold labels (1, 2 or 3) and comparison of gold labels and system predictions by mean absolute error (MAE) has a counter-intuitive effect on system rankings, as systems that produce continuous predictions are at an advantage over those that produce discrete predictions even though gold labels are also discrete. Figure 1(a) shows discrete gold label distributions for the scoring variant of Task 1.1 in WMT-14 and Figure 1(b) prediction distributions for an example system that was at a disadvantage because it restricted its predictions to discrete ratings like those of gold labels, and Figure 1(c) a system that achieves apparent better performance (lower MAE) despite prediction representations mismatching the discrete nature of gold labels.

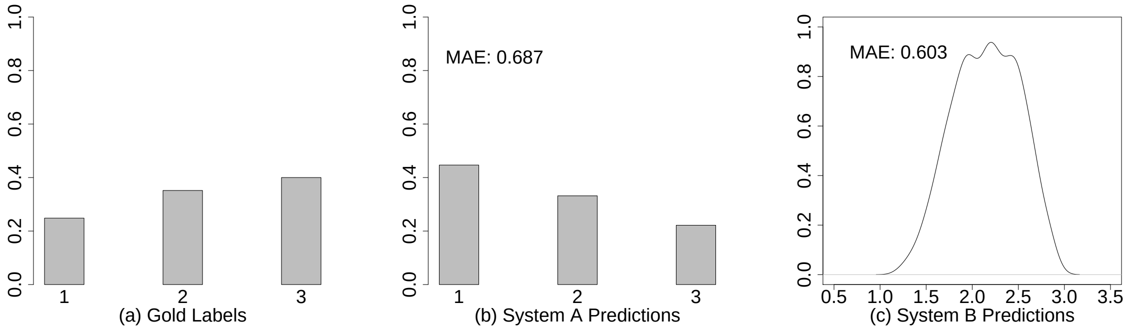
Evaluation of the ranking variant of Task 1.1 again includes a significant mismatch between representations used as gold labels, which again were limited to the ratings 1, 2 or 3, while systems were required to provide a total-order ranking of test set translations, for example ranks 1-600 or 1-450, depending on language pair. Evaluation methodologies applied to ranking tasks may be better facilitated by application of more fine-grained gold standard labels that more closely represent total-order rankings of system predictions.

	r
Post-edit Time	0.36
Post-edit Rate	0.69^{***}

Table 1: Pearson correlation with HTER scores of post-edit times (PETs) and post-edit rates (PERs) for WMT-14 Task 1.2 and Task 1.3 gold labels, correlation marked with *** is significantly greater at $p < 0.001$.

Evaluation methodologies applied in Task 1.3 employ the more fine-grained post-edit times (PETs) as translation quality gold labels. PETs potentially provide a good indication of the underlying quality of translations, as a translation that takes longer to manually correct is thought to have lower quality. However, we propose what may correspond more directly to translation quality is an alteration of this, a post-edit rate (PER), where PETs are normalized by the number of words in translations. This takes into account the fact that, all else being equal, longer translations simply take a greater amount of time to post-edit than shorter ones. To investigate to what degree PERs may correspond better to translation quality than PETs, we compute correlations of each with HTER gold labels of translations from Task 1.2. Table 6 reveals a significantly higher correlation that exists between PER and HTER compared to PET and HTER ($p < 0.001$) , and we conclude therefore that the PER of a translation provides a more faithful representation of translation quality than PET, and convert PETs for both predictions and gold labels to PERs (in seconds per word) in our later replication of Task 1.3.

In Task 1.2 of WMT-14, gold standard labels used to evaluate systems were in the form of human translation error rates (HTERs) (Snover et al., 2009). HTER scores provide an effective representation for evaluation of quality estima-



(a) Gold Labels (b) System A Predictions (c) System B Predictions

Figure 1: WMT-14 English-to-German quality estimation Task 1.1 where mismatched prediction/gold labels achieves apparent better performance, where (a) gold label distribution; (b) example system disadvantaged by its discrete predictions; (c) example system gaining advantage by its continuous predictions.

tion systems, as scores are individually computed per translation using custom post-edited reference translations, avoiding the bias that can occur with metrics that employ generic reference translations. In our later evaluation, we therefore use HTER scores in addition to PERs as suitable gold standard labels.

2.2 Mean Absolute Error

Mean absolute error is likely the most widely applied comparison measure of quality estimation system predictions and gold labels, in addition to being the official measure applied to scoring variants of tasks in WMT (Bojar et al., 2014). MAE is the average absolute difference that exists between a system's predictions and gold standard labels for translations, and a system achieving a lower MAE is considered a better system. Significant issues arise for evaluation of quality estimation systems with MAE when comparing distributions for predictions and gold labels, however. Firstly, a system's MAE can be lowered not only by individual predictions closer to corresponding gold labels, but also by prediction of aggregate statistics specific to the distribution of gold labels in the particular test set used for evaluation. MAE is most susceptible in this respect when gold labels have a unimodal distribution with relatively low standard deviation. For example, Figure 2(a) shows test set gold label HTER distribution for Task 1.2 in WMT-14 where the bulk of HTERs are located around one main peak with relatively low variance in the distribution. Unfortunately with MAE, a system that correctly predicts the location of the mode of the test set gold distribution and centers predictions around it with an optimally conservative variance can achieve lower MAE and apparent better performance. Figure 2(b) shows a lower MAE can be achieved by rescaling the original prediction distribution for an example system to a distribution with lower variance.

A disadvantage of an ability to gain in performance by prediction of such features of a given test set is that prediction of aggregates is, in general, far easier than individual predictions. In addition, inclusion of confounding test set aggregates such as these in evaluations will likely lead to both an overestimate of the ability of some systems to predict the quality of unseen translations and an underestimate of the accuracy of systems that courageously attempt to predict the quality of translations in the tails of gold distributions, and it follows that systems optimized for MAE can be expected to perform badly when predicting the quality of translations in the tails of gold label distributions (Moreau and Vogel, 2014).

Table 2 shows how MAEs of original predicted score distributions for *all systems* participating in Task 1.2 WMT-14 can be reduced by shifting and rescaling the prediction score distribution according to gold label aggregates. Table 3 shows that for similar reasons other measures commonly applied to evaluation of quality estimation systems, such as root mean squared error (RMSE), that are also not unit-free, encounter the same problem.

2.3 Significance Testing

In quality estimation, it is common to apply bootstrap resampling to assess the likelihood that a decrease in MAE (an improvement) has occurred by chance. In contrast to other areas of MT, where the accuracy of randomized methods of signifi-

cance testing such as bootstrap resampling in combination with BLEU and other metrics have been empirically evaluated (Koehn, 2004; Graham et al., 2014), to the best of our knowledge no research has been carried out to assess the accuracy of similar methods specifically for quality estimation evaluation. In addition, since data used for evaluation of quality estimation systems are not independent, methods of significance testing differences in performance will be inaccurate unless the dependent nature of the data is taken into account.

3 Quality Estimation Evaluation by Pearson Correlation

The Pearson correlation is a measure of the linear correlation between two variables, and in the case of quality estimation evaluation this amounts to the linear correlation between system predictions and gold labels. Pearson's r overcomes the outlined challenges of previous approaches, such as mean absolute error, for several reasons. Firstly, Pearson's r is a unit-free measure with a key property being that the correlation coefficient is invariant to separate changes in location and scale in either of the two variables. This has the obvious advantage over MAE that the coefficient cannot be altered by shifting or rescaling prediction score distributions according to aggregates specific to the test set.

To illustrate, Figure 3 depicts a pair of systems for which the baseline system appears to outperform the other when evaluated with MAE, but this is only due to the conservative variance in its pre-

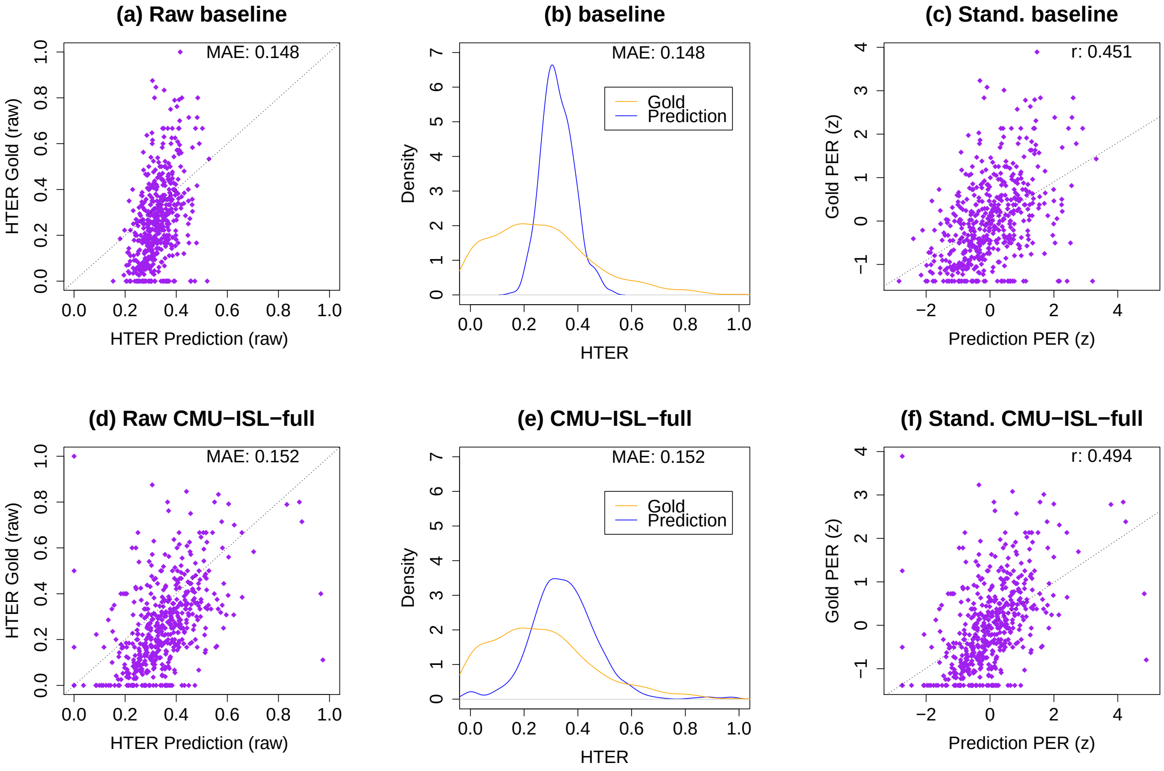

Figure 3: WMT-13 Task 1.1 systems showing baseline with better MAE than CMU-ISL-FULL only due to conservative variance in prediction distribution and despite its weaker correlation with gold labels.

diction score distribution, as can be seen by the narrow blue spike in Figure 3(b). Figure 3(e) shows how the prediction distribution of CMU-ISL-FULL, on the other hand, has higher variance, and subsequently higher MAE. Figures 3(c) and 3(f) depict what occurs in computation of the Pearson correlation where raw prediction and gold label scores are replaced by standardized scores, i.e. numbers of standard deviations from the mean of each distribution, where CMU-ISL-FULL in fact achieves a significantly higher correlation than the baseline system at $p < 0.001$.

An additional advantage of the Pearson correlation is that coefficients do not change depending on the representation used in the gold standard in the way they do with MAE, making possible a comparison of performance across evaluations that employ different gold label representations. Additionally, there is no longer a need for training and test representations to directly correspond to one another. To demonstrate, in our later evaluation we include the evaluation of systems trained on both HTER and PETs for prediction of both HTER and PERs.

Finally, when evaluated with the Pearson correlation significance tests can be applied without resorting to randomized methods, in addition to taking into account the dependent nature of data used in evaluations.

The fact that the Pearson correlation is invariant to separate shifts in location and scale of either of the two variables is nonproblematic for evaluation of quality estimation systems. Take, for instance, the possible counter-argument: a pair of systems, one of which predicts the precise gold distribution, and another system predicting the gold distribution + 1, would unfairly receive the same Pearson correlation coefficient. Firstly, it is just as difficult to predict the gold distribution + 1, as it is to predict the gold distribution itself. More importantly, however, the scenario is extremely unlikely to occur in practice, it is highly unlikely that a system would ever accurately predict the gold distribution + 1, as opposed to the actual gold distribution unless training labels were adjusted in the same manner, or indeed predict the gold distribution shifted or rescaled by any other constant value. It is important to understand that invariance of the Pearson correlation to a shift in location or scale means that the measure is only invariant to a shift in location or scale applied to the entire distribution (of either of the two variables), such as the shift in location and scale that can be used to boost apparent performance of systems when measures like MAE and RMSE, that are not unit-free, are employed. Increasing the distance between system predictions and gold labels for anything less than the entire distribution, a more realistic scenario, or by something other than a constant across the entire distribution, will result in an appropriately weaker Pearson correlation.

4 Quality Estimation Significance Testing

Previous work has shown the suitability of Williams significance test (Williams, 1959) for evaluation of automatic MT metrics (Graham and Baldwin, 2014; Graham et al., 2015), and, for similar reasons, Williams test is appropriate for significance testing differences in performance of competing quality estimation systems which we detail further below.

Evaluation of a given quality estimation system, P_{new}, by Pearson correlation takes the form of quantifying the correlation, $r(P_{new}, G)$, that exists between system prediction scores and corresponding gold standard labels, and contrasting this correlation with the correlation for some baseline system, $r(P_{base}, G)$.

At first it might seem reasonable to perform significance testing in the following manner when an increase in correlation with gold labels is observed: apply a significance test separately to the correlation of each quality estimation system with gold labels, with the hope that the new system will achieve a significant correlation where the baseline system does not. The reasoning here is flawed however: the fact that one correlation is significantly higher than zero ($r(P_{new}, G)$) and that of another is not, does not necessarily mean that the *difference* between the two correlations is significant. Instead, a specific test should be applied to the difference in correlations on the data. For this same reason, confidence intervals for individual correlations with gold labels are also not useful.

In psychology, it is often the case that samples that data are drawn from are independent, and differences in correlations are computed on independent data sets. In such cases, the Fisher r to z transformation is applied to test for significant differences in correlations. Data used for evaluation of quality estimation systems are not independent, however, and this means that if $r(P_{base}, G)$ and $r(P_{new}, G)$ are both > 0, the correlation between both sets of predictions themselves, $r(P_{base}, P_{new})$, must also be > 0. The strength of this correlation, directly between predictions of pairs of quality estimation systems, should be taken into account using a significance test of the difference in correlation between $r(P_{base}, G)$ and $r(P_{new}, G)$.

Williams test [1] (Williams, 1959) evaluates the significance of a difference in dependent correlations (Steiger, 1980). It is formulated as follows as a test of whether the population correlation between X_1 and X_3 equals the population correlation between X_2 and X_3:

$$t(n-3) = \frac{(r_{13} - r_{23})\sqrt{(n-1)(1+r_{12})}}{\sqrt{2K\frac{(n-1)}{(n-3)} + \frac{(r_{23}+r_{13})^2}{4}(1-r_{12})^3}},$$

where r_{ij} is the correlation between X_i and X_j, n is the size of the population, and:

$$K = 1 - {r_{12}}^2 - {r_{13}}^2 - {r_{23}}^2 + 2r_{12}r_{13}r_{23}$$

As part of this research, we have made available an open-source implementation of statistical tests tailored to the assessment of quality estimation systems, at `https://github.com/ygraham/mt-qe-eval`.

5 Evaluation and Discussion

To demonstrate the use of the Pearson correlation as an effective mechanism for evaluation of quality estimation systems, we rerun components of previous evaluations originally carried out at WMT-13 and WMT-14.

Table 4 shows Pearson correlations for systems participating in WMT-13 Task 1.1 where gold labels were in the form of HTER scores. System rankings diverge considerably from original rankings, notably the top system according to the Pearson correlation is tied in fifth place when evaluated with MAE.

Table 5 shows Pearson correlations of systems that took part in Task 1.2 of WMT-14, where gold labels were again in the form of HTER scores,

and to demonstrate the ability of evaluation of systems trained on a representation distinct from that of gold labels made possible by the unit-free Pearson correlation, we also include evaluation of systems originally trained on PET labels to predict HTER scores. Since PET systems also produce predictions in the form of PET, we convert predictions for all systems to PERs prior to computation of correlations, as PERs more closely correspond to translation quality. Results reveal that systems originally trained on PETs in general perform worse than HTER trained systems, and this is not all that surprising considering the training representation did not correspond well to translation quality. Again system rankings diverge from MAE rankings with the second best system according to MAE moved to the initial position.

Table 6 shows Pearson correlations for predictions of PER for systems trained on either PETs or HTER, and predictions for systems trained on PETs are converted to PER for evaluation. System rankings diverge most for this data set from the original rankings by MAE, as the system holding initial position according to MAE moves to position 13 according to the Pearson correlation.

Many of the differences in correlation between systems in Tables 4, 5 and 6 are small and instead of assuming that an increase in correlation of one system over another corresponds to an improvement in performance, we first apply significance testing to differences in correlation with gold labels that exist between correlations for each pair

of systems.

5.1 Significance Tests

When an increase in correlation with gold labels is present for a pair of systems, significance tests provide insight into the likelihood that such an increase has occurred by chance. As described in detail in Section 4, the Williams test (Williams, 1959), a test also appropriate for MT metrics evaluated by the Pearson correlation (Graham and Baldwin, 2014), is appropriate for testing the significance of a difference in dependent correlations and therefore provides a suitable method of significance testing for quality estimation systems. Figure 4 provides an example of the strength of correlations that commonly exist between predictions of quality estimation systems.

Figure 5 shows significance test outcomes of the Williams test for systems originally taking part in WMT-13 Task 1.1, with systems ordered by strongest to least Pearson correlation with gold labels, where a green cell in (row i, column j) signifies a significant win for row i system over column j system, where darker shades of green signify conclusions made with more certainty. Test outcomes allow identification of significant increases in correlation with gold labels of one system over another, and subsequently the systems shown to outperform others. Test outcomes in Figure 5 reveal substantially increased conclusivity in system rankings made possible with the application of the Pearson correlation and Williams test, with almost an unambiguous total-order ranking of systems and an outright winner of the task.

Figure 6 shows outcomes of Williams significance tests for prediction of HTER and Figure 7 shows outcomes of tests for PER prediction for WMT-14 English-to-Spanish, again showing substantially increased conclusivity in system rankings for tasks.

It is important to note that the number of competing systems a system significantly outperforms should not be used as the criterion for ranking competing quality estimation systems, since the power of the Williams test changes depending on the degree to which predictions of a pair of systems correlate with each other. A system with predictions that happen to correlate strongly with predictions of many other systems would be at an unfair advantage, were numbers of significant wins to be used to rank systems. For this reason, it is

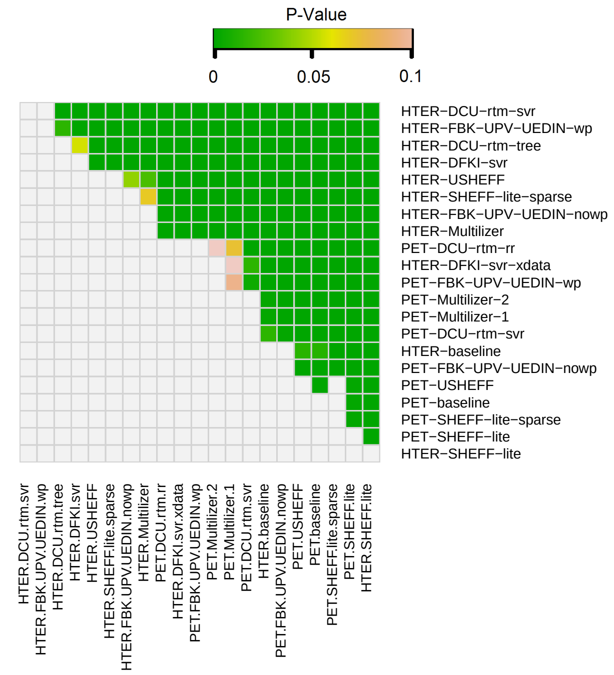

Figure 6: HTER prediction significance test outcomes for all pairs of systems from English-to-Spanish WMT-14 Task 1.2, colored cells denote a significant increase in correlation with gold labels for row i system over column j system.

best to interpret pairwise system tests in isolation.

6 Conclusion

We have provided a critique of current widely used methods of evaluation of quality estimation systems and highlighted potential flaws in existing methods, with respect to the ability to boost scores by prediction of aggregate statistics specific to the particular test set in use or conservative variance in prediction distributions. We provide an alternate mechanism, and since the Pearson correlation is a unit-free measure, it can be applied to evaluation of quality estimation systems avoiding the previous vulnerabilities of measures such as MAE and RMSE. Advantages also outlined are that training and test representations no longer need to directly correspond in evaluations as long as labels comprise a representation that closely reflects translation quality. We demonstrated the suitability of the proposed measures through replication of components of WMT-13 and WMT-14 quality estimation shared tasks, revealing substantially increased conclusivity of system rankings.
