Also, Jeong and Lee (2009) presented a transfer learning approach in multi-domain NLU, where the model jointly learns slot taggers in multiple domains and simultaneously predicts domain detection and slot tagging results.[2] To share parameters across domains, they added an additional node for domain prediction on top of the slot sequence. However, this framework also limited to a setting in which the label set remains invariant. In contrast, our method is restricted to this setting without any modification of models.

3 Sequence Modeling Technique

The proposed techniques in Section 4 and 5 are generic methodologies and not tied to any particular models such as any sequence models and instanced based models. However, because of superior performance over CRF, we use a hidden unit CRF (HUCRF) of Maaten et al. (2011).

[1] Multilingual learning (Kim et al., 2011; Kim and Snyder, 2012; Kim and Snyder, 2013) has same setting.

[2] Jeong and Lee (2009) pointed out that if the domain is given, their method is the same as that of Daumé III (2007).

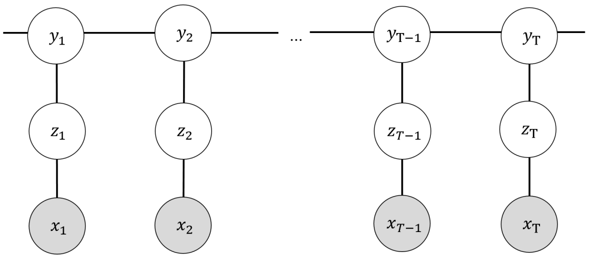

Figure 1: Graphical representation of hidden unit CRFs.

While popular and effective, a CRF is still a linear model. In contrast, a HUCRF benefits from nonlinearity, leading to superior performance over CRF (Maaten et al., 2011). Thus we will focus on HUCRFs to demonstrate our techniques in experiments.

3.1 Hidden Unit CRF (HUCRF)

A HUCRF introduces a layer of binary-valued hidden units $z = z_1 \ldots z_n \in \{0, 1\}$ for each pair of label sequence $y = y_1 \ldots y_n$ and observation sequence $x = x_1 \ldots x_n$. A HUCRF parametrized by $\theta \in \mathbb{R}^d$ and $\gamma \in \mathbb{R}^{d'}$ defines a joint probability of y and z conditioned on x as follows:

$$p_{\theta,\gamma}(y, z|x) = \frac{\exp(\theta^\top \Phi(x, z) + \gamma^\top \Psi(z, y))}{\sum_{\substack{z' \in \{0,1\}^n \\ y' \in \mathcal{Y}(x,z')}} \exp(\theta^\top \Phi(x, z') + \gamma^\top \Psi(z', y'))} \tag{1}$$

where $\mathcal{Y}(x, z)$ is the set of all possible label sequences for x and z, and $\Phi(x, z) \in \mathbb{R}^d$ and $\Psi(z, y) \in \mathbb{R}^{d'}$ are global feature functions that decompose into local feature functions:

$$\Phi(x, z) = \sum_{j=1}^{n} \phi(x, j, z_j)$$

$$\Psi(z, y) = \sum_{j=1}^{n} \psi(z_j, y_{j-1}, y_j)$$

HUCRF forces the interaction between the observations and the labels at each position j to go through a latent variable z_j: see Figure 1 for illustration. Then the probability of labels y is given by marginalizing over the hidden units,

$$p_{\theta,\gamma}(y|x) = \sum_{z \in \{0,1\}^n} p_{\theta,\gamma}(y, z|x)$$

As in restricted Boltzmann machines (Larochelle and Bengio, 2008), hidden units are conditionally independent given observations and labels. This allows for efficient inference with HUCRFs despite their richness (see Maaten et al. (2011) for details). We use a perceptron-style algorithm of Maaten et al. (2011) for training HUCRFs.

4 Transfer learning between domains with different label sets

In this section, we describe three methods for utilizing annotations in domains with different label types. First two methods are about transferring features and last method is about transferring model parameters. Each of these methods requires some sort of *mapping* for label types. A fine-grained label type needs to be mapped to a coarse one; a label type in one domain needs to be mapped to the corresponding label type in another domain. We will provide a solution to obtaining these label mappings automatically in Section 5.

4.1 Coarse-to-fine prediction

This approach has some similarities to the method of Li et al. (2011) in that shared slots are used to transfer information between domains. In this two-stage approach, we train a model on the source domain, make predictions on the target domain, and then use the predicted labels as additional features to train a final model on the target domain. This can be helpful if there is some correlation between the label types in the source domain and the label types in the target domain.

However, it is not desirable to directly use the label types in the source domain since they can be highly specific to that particular domain. An effective way to combat this problem is to reduce the original label types such `start-time`, `contract-info`, and `restaurant` as to a set of coarse label types such as `name`, `date`, `time`, and `location` that are universally shared across all domains. By doing so, we can use the first model to predict generic labels such as `time` and then use the second model to use this information to predict fine-grained labels such as `start-time` and `end-time`.

4.2 Method of Daumé III (2007)

In this popular technique for domain adaptation, we train a model on the union of the source domain data and the target domain data but with the following preprocessing step: each feature is duplicated and the copy is conjoined with a domain indicator. For example, in a `WEATHER` domain dataset, a feature that indicates the identity of the string "Sunny" will generate both $w(0) = Sunny$ and $(w(0) = Sunny) \wedge (domain = WEATHER)$ as feature types. This preprocessing allows the model to utilize all data through the common features and at the same time specialize to specific domains through the domain specific features. This is especially helpful when there is label ambiguity on particular features (e.g., "Sunny" might be a `weather-condition` in a `WEATHER` domain dataset but a `music-song-name` in a `MUSIC` domain dataset).

Note that a straightforward application of this technique is in general not feasible in our situation. This is because we have features conjoined with label types and our domains do *not* share label types. This breaks the sharing of features across domains: many feature types in the source domain are disjoint from those in the target domain due to different labeling.

Thus it is necessary to first map source domain label types to target domain label type. After the mapping, features are shared across domains and we can apply this technique.

4.3 Transferring model parameter

In this approach, we train HUCRF on the source domain and transfer the learned parameters to initialize the training process on the target domain. This can be helpful for at least two reasons:

1. The resulting model will have parameters for feature types observed in the source domain as well as the target domain. Thus it has better feature coverage.

2. If the training objective is non-convex, this initialization can be helpful in avoiding bad local optima.

Since the training objective of HUCRFs is non-convex, both benefits can apply. We show in our experiments that this is indeed the case: the model benefits from both better feature coverage and better initialization.

Note that in order to use this approach, we need to map source domain label types to target domain label type so that we know which parameter in the source domain corresponds to which parameter in the target domain. This can be a many-to-one, one-to-many, one-to-one mapping depending on the label sets.

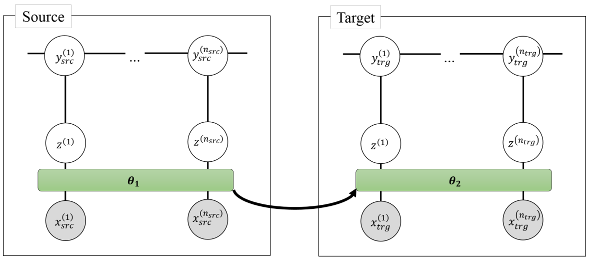

Figure 2: Illustration of a pretraining scheme for HUCRFs.

4.3.1 Pretraining with HUCRFs

In fact, pretraining HUCRFs in the source domain can be done in various ways. Recall that there are two parameter types: $\theta \in \mathbb{R}^d$ for scoring observations and hidden states and $\gamma \in \mathbb{R}^{d'}$ for scoring hidden states and labels (Eq. (1)). In pretraining, we first train a model (θ_1, γ_1) on the source data $\{(x_{src}^{(i)}, y_{src}^{(i)})\}_{i=1}^{n_{src}}$:

$$(\theta_1, \gamma_1) \approx \arg\max_{\theta,\gamma} \sum_{i=1}^{n_{src}} \log p_{\theta,\gamma}(y_{src}^{(i)} | x_{src}^{(i)})$$

Then we train a model (θ_2, γ_2) on the target data $\{(x_{trg}^{(i)}, y_{trg}^{(i)})\}_{i=1}^{n_{trg}}$ by initializing $(\theta_2, \gamma_2) \leftarrow (\theta_1, \gamma_1)$:

$$(\theta_2, \gamma_2) \approx \arg\max_{\theta,\gamma} \sum_{i=1}^{n_{trg}} \log p_{\theta,\gamma}(y_{trg}^{(i)} | x_{trg}^{(i)})$$

Here, we can choose to initialize only $\theta_2 \leftarrow \theta_1$ and discard the parameters for hidden states and labels since they may not be the same. The θ_1 parameters model the hidden structures in the source domain data and serve as a good initialization point for learning the θ_2 parameters in the target domain. This can be helpful if the mapping between the label types in the source data and the label types in the target data is unreliable. This process is illustrated in Figure 2.

5 Automatic generation of label mappings

All methods described in Section 4 require a way to propagate the information in label types across different domains. A straightforward solution would be to manually construct such mappings by inspection. For instance, we can specify that `start-time` and `end-time` are grouped as the same label `time`, or that the label `public-transportation-route` in the `PLACES` domain maps to the label `implicit-location` in the `CALENDAR` domain.

Instead, we propose a technique that automatically generates the label mappings. We induce vector representations for all label types through canonical correlation analysis (CCA) — a powerful and flexible technique for deriving low-dimensional representation. We give a review of CCA in Section 5.1 and describe how we use the technique to construct label mappings in Section 5.2.

5.1 Canonical Correlation Analysis (CCA)

CCA is a general technique that operates on a pair of multi-dimensional variables. CCA finds k dimensions (k is a parameter to be specified) in which these variables are maximally correlated.

Let $x_1 \ldots x_n \in \mathbb{R}^d$ and $y_1 \ldots y_n \in \mathbb{R}^{d'}$ be n samples of the two variables. For simplicity, assume that these variables have zero mean. Then CCA computes the following for $i = 1 \ldots k$:

$$\underset{\substack{u_i \in \mathbb{R}^d,\, v_i \in \mathbb{R}^{d'}:\\ u_i^\top u_{i'} = 0 \;\; \forall i' < i \\ v_i^\top v_{i'} = 0 \;\; \forall i' < i}}{\arg\max} \frac{\sum_{l=1}^n (u_i^\top x_l)(v_i^\top y_l)}{\sqrt{\sum_{l=1}^n (u_i^\top x_l)^2}\sqrt{\sum_{l=1}^n (v_i^\top y_l)^2}}$$

In other words, each (u_i, v_i) is a pair of projection vectors such that the *correlation* between the projected variables $u_i^\top x_l$ and $v_i^\top y_l$ (now scalars) is maximized, under the constraint that this projection is *uncorrelated* with the previous $i - 1$ projections.

This is a non-convex problem due to the interaction between u_i and v_i. Fortunately, a method based on singular value decomposition (SVD) provides an efficient and exact solution to this problem (Hotelling, 1936). The resulting solution $u_1 \ldots u_k \in \mathbb{R}^d$ and $v_1 \ldots v_k \in \mathbb{R}^{d'}$ can be used to project the variables from the original d- and d'-dimensional spaces to a k-dimensional space:

$$x \in \mathbb{R}^d \longrightarrow \bar{x} \in \mathbb{R}^k : \bar{x}_i = u_i^\top x$$
$$y \in \mathbb{R}^{d'} \longrightarrow \bar{y} \in \mathbb{R}^k : \bar{y}_i = v_i^\top y$$

The new k-dimensional representation of each variable now contains information about the other variable. The value of k is usually selected to be much smaller than d or d', so the representation is typically also low-dimensional.

5.2 Inducing label embeddings

We now describe how to use CCA to induce vector representations for label types. Using the same notation, let n be the number of instances of labels in the entire data. Let $x_1 \ldots x_n$ be the original representations of the label samples and $y_1 \ldots y_n$ be the original representations of the associated words set contained in the labels.

We employ the following definition for the original representations for reasons we explain below. Let d be the number of distinct label types and d' be the number of distinct word types.

- $x_l \in \mathbb{R}^d$ is a zero vector in which the entry corresponding to the label type of the l-th instance is set to 1.
- $y_l \in \mathbb{R}^{d'}$ is a zero vector in which the entries corresponding to words spanned by the label are set to 1.

The motivation for this definition is that similar label types often have similar or same word.

For instance, consider two label types `start-time`, (start time of a calendar event) and `end-time`, meaning (the end time of a calendar event). Each type is frequently associated with phrases about time. The phrases {"9 pm", "7", "8 am"} might be labeled as `start-time`; the phrases {"9 am", "7 pm"} might be labeled as `end-time`. In these examples, both label types share words "am", "pm", "9", and "7" even though phrases may not match exactly.

Figure 3 gives the CCA algorithm for inducing label embeddings. It produces a k-dimensional vector for each label type corresponding to the CCA projection of the one-hot encoding of that label.

5.3 Discussion on alternative label representations

We point out that there are other options for inducing label representations besides CCA. For instance, one could simply use the sparse feature vector representation of each label. However, CCA's low-dimensional projection is computationally more convenient and arguably more generalizable. One can also consider training a predictive model similar to `word2vec` (Mikolov

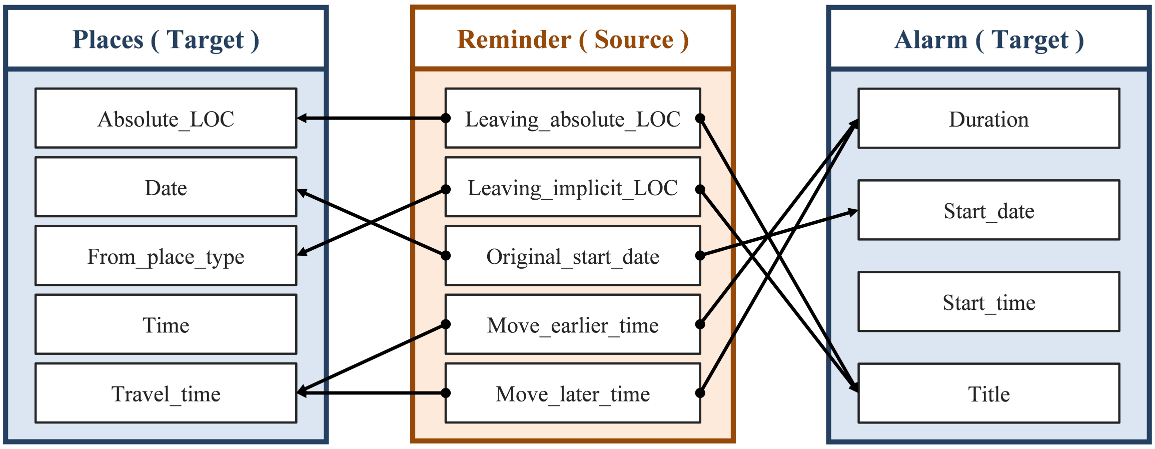

Figure 4: Bijective mapping: labels in REMINDER domain (orange box) are mapped into those in PLACES and ALARM domains.

CCA-LABEL
Input: labeled sequences $\{(x^{(i)}, y^{(i)})\}_{i=1}^{n}$, dimension k
Output: label vector $v \in \mathbb{R}^k$ for each label type

1. For each label type $l \in \{1 \dots d\}$ and word type $w \in \{1 \dots d\}$ present in the sequences, calculate
    - **count**(l) = number of times label l occurs
    - **count**(w) = number of times word w occurs
    - **count**(l, w) = number of times word w occurs under label l
2. Define a matrix $\Omega \in \mathbb{R}^{d \times d'}$ where:

$$\Omega_{l,w} = \frac{\textbf{count}(l, w)}{\sqrt{\textbf{count}(l)\textbf{count}(w)}}$$

3. Perform rank-k SVD on Ω. Let $U \in \mathbb{R}^{d \times k}$ be a matrix where the i-th column is the left singular vector of Ω corresponding to the i-th largest singular value.
4. For each label l, set the l-th normalized row of U to be its vector representation.

Figure 3: CCA algorithm for inducing label embeddings.

et al., 2013). But this requires significant efforts in implementation and also very long training time. In contrast, CCA is simple, efficient, and effective and can be readily implemented. Also, CCA is theoretically well understood while methods inspired by neural networks are not.

5.4 Constructing label mappings

Vector representations of label types allow for natural solutions to the task of constructing label mappings.

5.4.1 Mapping to a coarse label set

Given a domain and the label types that occur in the domain, we can reduce the number of label types by simply clustering their vector representations. For instance, if the embeddings for start-time and end-time are close together, they will be grouped as a single label type. We run the k-means algorithm on the label embeddings to obtain this coarse label set.

Table 1 shows examples of this clustering. It demonstrates that the CCA representations obtained by the procedure described in Section 5.2 are indeed informative of the labels' properties.

Cluster	Labels	Cluster	Labels
Time	start_time end_time original_start_time travel_time	Person	contact_info artist from_contact_name relationship_name
Loc	absolute_loc leaving_loc from_loc position_ref	Loc_ATTR	prefer_route public_trans_route nearby distance

Table 1: Some of cluster examples

5.4.2 Bijective mapping between label sets

Given a pair of domains and their label sets, we can create a bijective label mapping by finding the nearest neighbor of each label type. Figure 4 shows some actual examples of CCA-based bijective maps, where the label set in the REMINDER domain is mapped to the PLACES and ALARM domains. One particularly interesting example is that move_earlier_time in REMINDER domain is mapped to Travel_time in PLACES and Duration in ALARM domain. This is a tag used in a user utterance requesting to move an

Domains	# of label	Source Training	Test	Description
Alarm	7	27865	3334	Set alarms
Calendar	20	50255	7017	Set appointments & meetings in the calendar
Communication	18	104881	14484	Make calls, send texts, and communication related user request
Note	4	17445	2342	Note taking
Ondevice	7	60847	9704	Phone settings
Places	32	150348	20798	Find places & get direction
Reminder	16	62664	8235	Setting time, person & place based reminder
Weather	9	53096	9114	Weather forecasts & historical information about weather patterns

Table 2: Size of number of label, labeled data set size and description for Alarm, Calendar, Communication, Note, Ondevice, Places, Reminder and Weather domains partitioned into training and test set.

appointment to an earlier time. For example, in the query "move the dentist's appointment up by 30 minutes.", the phrase "30 minutes" is tagged with `move_earlier_time`. The role of this tag is very similar to the role of `Travel_time` in `PLACES` (not `Time`) and `Duration` in `ALARMS` (not `Start_date`), and CCA is able to recover this relation.

6 Experiments

In this section, we turn to experimental findings to provide empirical support for our proposed methods.

6.1 Setup

To test the effectiveness of our approach, we apply it to a suite of eight Cortana personal assistant domains for slot sequence tagging tasks, where the goal is to find the correct semantic tagging of the words in a given user utterance.

The data statistics and short descriptions are shown in Table 2. As the table indicates, the domains have very different granularity and diverse semantics.

6.2 Baselines

In all our experiments, we trained HUCRF and only used n-gram features, including unigram, bigram, and trigram within a window of five words (±2 words) around the current word as binary feature functions. With these features, we compare the following methods for slot tagging:

- *NoAdapt*: train only on target training data.
- *Union*: train on the union of source and target training data.
- *Daume*: train with the feature duplication method described in 4.2.
- *C2F*: train with the coarse-to-fine prediction method described in 4.1.
- *Pretrain*: train with the pretraining method described in 4.3.1.

To apply these methods except for *Target*, we treat each of the eight domains in turn as the test domain, with one of remaining seven domain as the source domain. As in general domain adaptation setting, we assume that the source domain has a sufficient amount of labeled data but the target domain has an insufficient amount of labeled data. Specifically, For each test or target domain, we only use 10% of the training examples to simulate data scarcity. In the following experiments, we report the slot F-measure, using the standard CoNLL evaluation script [3]

6.3 Results on mappings

	Mapping technique

Table 5: Slot F1 scores of using Union, Daume, Coarse-to-Fine and pretraining on all pairs of source and target data. The numbers in boldface are the best performing adaptation technique in each pair.

by two experienced annotators who have PhD in linguistics and machine learning. Each annotator first assigned mapping slot labels independently and then both annotators collaborated to reduce disagreement of their mapping results. Initially, the disagreement of their mapping rate between two annotators was about 30% because labels of slot tagging are very diverse; furthermore, in some cases it is not clear for human annotators if there exists a valid mapping.

The results are shown at Table 3. Vector representation of Li et al. (2011) increases the F1 score slightly from 75.13 to 75.69 in *C2F*, but it does not help as much in cases that require bijective mapping: *Daume*, *Union* and *Pretrain*.

In contrast, the proposed CCA based technique consistently outperforms the *NoAdapt* baselines by significant margins. More importantly, it also outperforms manual results under all conditions. It is perhaps not so surprising – the CCA derived mapping is completely data driven, while human annotators have nothing but the prior linguistic knowledge about the slot tags and the domain.

6.4 Main Results

The full results are shown in Table 5, where all pairs of source and target languages are considered for domain adaptation. It is clear from the table that we can always achieve better results using adaptation techniques than the non-adapted models trained only on the target data. Also, our proposed pretraining method outperforms other types of adaptation in most cases.

The overall result of our experiments are shown in Table 4. In this experiment, we compare different adaptation techniques using our suggested CCA-based mapping. Here, except for *NoAdapt*, we use both the target and the nearest source domain data. To find the nearest domain, we first map fine grained label set to coarse label set by using the method described in Section 5.4.1 and then count how many coarse labels are used in a domain. And then we can find the nearest source domain by calculating the l_2 distance between the multinomial distributions of the source domain and the target domain over the set of coarse labels.

For example, for `CALENDAR`, we identify `REMINDER` as the nearest domain and vice versa because most of their labels are attributes related to `time`. In all experiments, the domain adapted models perform better than using only target domain data which achieves 75.1% F1 score. Simply combining source and target domain using our automatically mapped slot labels performs slightly better than baseline. *C2F* boosts the performance up to 77.61% and *Daume* is able to reach 78.99%.[4] Finally, our proposed method, *pretrain* achieves nearly 81.02% F1 score.

7 Conclusion

We presented an approach to take advantage of existing annotations when the data are similar but the label sets are different. This approach was based on label embeddings from CCA, which reduces the setting to a standard domain adaptation problem. Combined with a novel pretraining scheme applied to hidden-unit CRFs, our approach is shown to be superior to strong baselines in extensive experiments for slot tagging on eight distinct personal assistant domains.

[4] It is known that *Daume* is less beneficial when the source and target domains are similar due to the increased number of features.

Abstract

Spoken dialogue systems (SDS) typically require a predefined semantic ontology to train a spoken language understanding (SLU) module. In addition to the annotation cost, a key challenge for designing such an ontology is to define a coherent slot set while considering their complex relations. This paper introduces a novel matrix factorization (MF) approach to learn latent feature vectors for utterances and semantic elements without the need of corpus annotations. Specifically, our model learns the semantic slots for a domain-specific SDS in an unsupervised fashion, and carries out semantic parsing using latent MF techniques. To further consider the global semantic structure, such as inter-word and inter-slot relations, we augment the latent MF-based model with a knowledge graph propagation model based on a slot-based semantic graph and a word-based lexical graph. Our experiments show that the proposed MF approaches produce better SLU models that are able to predict semantic slots and word patterns taking into account their relations and domain-specificity in a joint manner.

1 Introduction

A key component of a spoken dialogue system (SDS) is the spoken language understanding (SLU) module—it parses the users' utterances into semantic representations; for example, the utterance "*find a cheap restaurant*" can be parsed into (price=*cheap*, target=*restaurant*) (Pieraccini et al., 1992). To design the SLU module of a SDS, most previous studies relied on predefined slots[1] for training the decoder (Seneff, 1992; Dowding et al., 1993; Gupta et al., 2006; Bohus and Rudnicky, 2009). However, these predefined semantic slots may bias the subsequent data collection process, and the cost of manually labeling utterances for updating the ontology is expensive (Wang et al., 2012).

In recent years, this problem led to the development of unsupervised SLU techniques (Heck and Hakkani-Tür, 2012; Heck et al., 2013; Chen et al., 2013b; Chen et al., 2014b). In particular, Chen et al. (2013b) proposed a frame-semantics based framework for automatically inducing semantic slots given raw audios. However, these approaches generally do not explicitly learn the latent factor representations to model the measurement errors (Skrondal and Rabe-Hesketh, 2004), nor do they jointly consider the complex lexical, syntactic, and semantic relations among words, slots, and utterances.

Another challenge of SLU is the inference of the hidden semantics. Considering the user utterance "*can i have a cheap restaurant*", from its surface patterns, we can see that it includes explicit semantic information about "price (cheap)" and "target (restaurant)"; however, it also includes hidden semantic information, such as "food" and "seeking", since the SDS needs to infer that the user wants to "find" some cheap "food", even though they are not directly observed in the surface patterns. Nonetheless, these implicit semantics are important semantic concepts for domain-specific SDSs. Traditional SLU models use discriminative classifiers (Henderson et al., 2012) to predict whether the predefined slots occur in the utterances or not, ignoring the unobserved concepts and the hidden semantic information.

In this paper, we take a rather radical approach: we propose a novel matrix factorization (MF) model for learning latent features for SLU, taking account of additional information such as the word relations, the induced slots, and the slot relations. To further consider the global coherence of induced slots, we combine the MF model with

[1] A slot is defined as a basic semantic unit in SLU, such as "price" and "target" in the example.

a knowledge graph propagation based model, fusing both a word-based lexical knowledge graph and a slot-based semantic graph. In fact, as it is shown in the Netflix challenge, MF is credited as the most useful technique for recommendation systems (Koren et al., 2009). Also, the MF model considers the unobserved patterns and estimates their probabilities instead of viewing them as negative examples. However, to the best of our knowledge, the MF technique is not yet well understood in the SLU and SDS communities, and it is not very straight-forward to use MF methods to learn latent feature representations for semantic parsing in SLU. To evaluate the performance of our model, we compare it to standard discriminative SLU baselines, and show that our MF-based model is able to produce strong results in semantic decoding, and the knowledge graph propagation model further improves the performance. Our contributions are three-fold:

- We are among the first to study matrix factorization techniques for unsupervised SLU, taking account of additional information;
- We augment the MF model with a knowledge graph propagation model, increasing the global coherence of semantic decoding using induced slots;
- Our experimental results show that the MF-based unsupervised SLU outperforms strong discriminative baselines, obtaining promising results.

In the next section, we outline the related work in unsupervised SLU and latent variable modeling for spoken language processing. Section 3 introduces our framework. The detailed MF approach is explained in Section 4. We then introduce the global knowledge graphs for MF in Section 5. Section 6 shows the experimental results, and Section 7 concludes.

2 Related Work

Unsupervised SLU Tur et al. (2011; 2012) were among the first to consider unsupervised approaches for SLU, where they exploited query logs for slot-filling. In a subsequent study, Heck and Hakkani-Tür (2012) studied the Semantic Web for an unsupervised intent detection problem in SLU, showing that results obtained from the unsupervised training process align well with the performance of traditional supervised learning. Following their success of unsupervised SLU, recent studies have also obtained interesting results on the tasks of relation detection (Hakkani-Tür et al., 2013; Chen et al., 2014a), entity extraction (Wang et al., 2014), and extending domain coverage (El-Kahky et al., 2014; Chen and Rudnicky, 2014). However, most of the studies above do not explicitly learn latent factor representations from the data—while we hypothesize that the better robustness in noisy data can be achieved by explicitly modeling the measurement errors (usually produced by automatic speech recognizers (ASR)) using latent variable models and taking additional local and global semantic constraints into account.

Latent Variable Modeling in SLU Early studies on latent variable modeling in speech included the classic hidden Markov model for statistical speech recognition (Jelinek, 1997). Recently, Celikyilmaz et al. (2011) were the first to study the intent detection problem using query logs and a discrete Bayesian latent variable model. In the field of dialogue modeling, the partially observable Markov decision process (POMDP) (Young et al., 2013) model is a popular technique for dialogue management, reducing the cost of handcrafted dialogue managers while producing robustness against speech recognition errors. More recently, Tur et al. (2013) used a semi-supervised LDA model to show improvement on the slot filling task. Also, Zhai and Williams (2014) proposed an unsupervised model for connecting words with latent states in HMMs using topic models, obtaining interesting qualitative and quantitative results. However, for unsupervised learning for SLU, it is not obvious how to incorporate additional information in the HMMs. To the best of our knowledge, this paper is the first to consider MF techniques for learning latent feature representations in unsupervised SLU, taking various local and global lexical, syntactic, and semantic information into account.

3 The Proposed Framework

This paper introduces a matrix factorization technique for unsupervised SLU,. The proposed framework is shown in Figure 1(a). Given the utterances, the task of the SLU model is to decode their surface patterns into semantic forms and differentiate the target semantic concepts from the generic semantic space for task-oriented SDSs simultaneously. Note that our model does not require any human-defined slots and domain-specific semantic representations for utterances.

In the proposed model, we first build a feature matrix to represent the training utterances, where each row represents an utterance, and each column refers to an observed surface pattern or a induced slot candidate. Figure 1(b) illustrates an example

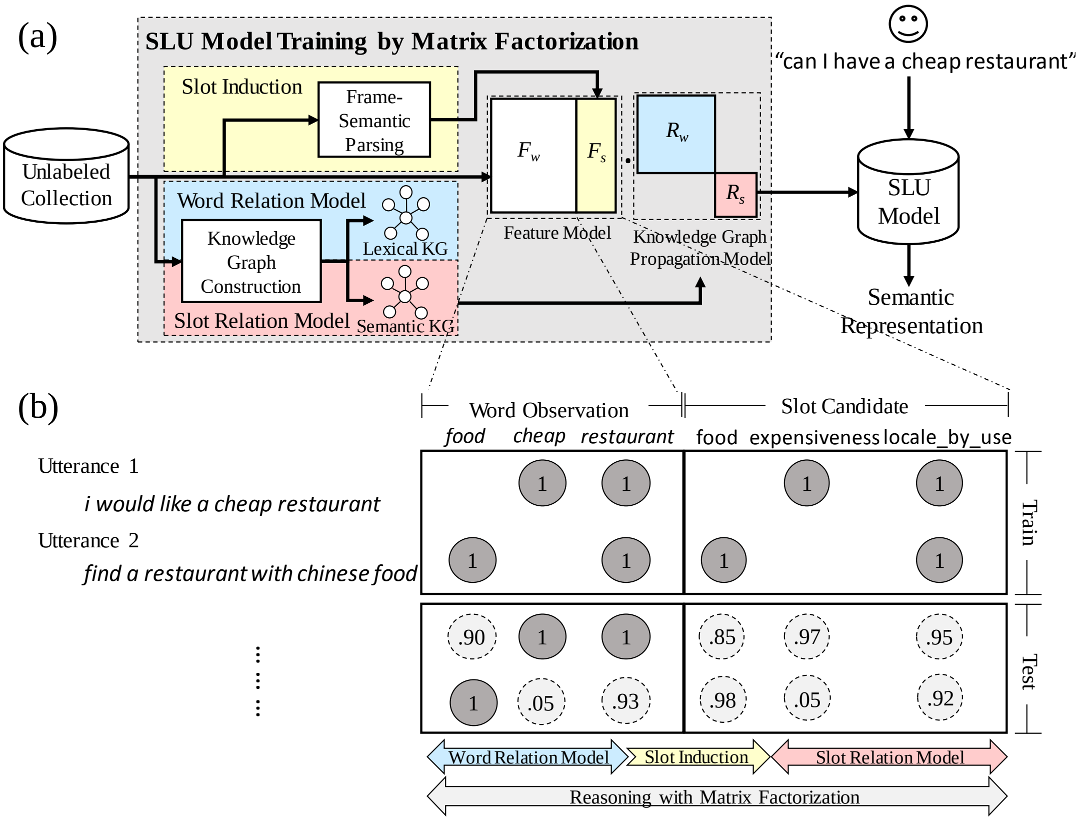

Figure 1: (a): The proposed framework. (b): Our matrix factorization method completes a partially-missing matrix for implicit semantic parsing. Dark circles are observed facts, shaded circles are inferred facts. The slot induction maps (yellow arrow) observed surface patterns to semantic slot candidates. The word relation model (blue arrow) constructs correlations between surface patterns. The slot relation model (pink arrow) learns the slot-level correlations based on propagating the automatically derived semantic knowledge graphs. Reasoning with matrix factorization (gray arrow) incorporates these models jointly, and produces a coherent, domain-specific SLU model.

of the matrix. Given a testing utterance, we convert it into a vector based on the observed surface patterns, and then fill in the missing values of the slots. In the first utterance in the figure, although the semantic slot food is not observed, the utterance implies the meaning facet food. The MF approach is able to learn the latent feature vectors for utterances and semantic elements, inferring implicit semantic concepts to improve the decoding process—namely, by filling the matrix with probabilities (lower part of the matrix).

The feature model is built on the observed word patterns and slot candidates, where the slot candidates are obtained from the slot induction component through frame-semantic parsing (the yellow block in Figure 1(a)) (Chen et al., 2013b). Section 4.1 explains the detail of the feature model.

In order to consider the additional inter-word and inter-slot relations, we propose a knowledge graph propagation model based on two knowledge graphs, which includes a word relation model (blue block) and a slot relation model (pink block), described in Section 4.2. The method of automatic knowledge graph construction is introduced in Section 5, where we leverage distributed word embeddings associated with typed syntactic dependencies to model the relations (Mikolov et al., 2013b; Mikolov et al., 2013c; Levy and Goldberg, 2014; Chen et al., 2015).

Finally, we train the SLU model by learning latent feature vectors for utterances and slot candidates through MF techniques. Combining with a knowledge graph propagation model based on word/slot relations, the trained SLU model estimates the probability that each semantic slot occurs in the testing utterance, and how likely each slot is domain-specific simultaneously. In other words, the SLU model is able to transform the testing utterances into domain-specific semantic representations without human involvement.

4 The Matrix Factorization Approach

Considering the benefits brought by MF techniques, including 1) modeling the noisy data, 2) modeling hidden semantics, and 3) modeling the

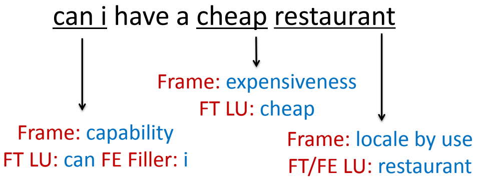

Figure 2: An example of probabilistic frame-semantic parsing on ASR output. FT: frame target. FE: frame element. LU: lexical unit.

long-range dependencies between observations, in this work we apply an MF approach to SLU modeling for SDSs. In our model, we use U to denote the set of input utterances, W as the set of word patterns, and S as the set of semantic slots that we would like to predict. The pair of an utterance $u \in U$ and a word pattern/semantic slot $x \in \{W + S\}$, $\langle u, x \rangle$, is a *fact*. The input to our model is a set of observed facts $\mathcal{O}$, and the observed facts for a given utterance is denoted by $\{\langle u, x \rangle \in \mathcal{O}\}$. The goal of our model is to estimate, for a given utterance u and a given word pattern/semantic slot x, the probability, $p(M_{u,x} = 1)$, where $M_{u,x}$ is a binary random variable that is true if and only if x is the word pattern/domain-specific semantic slot in the utterance u. We introduce a series of exponential family models that estimate the probability using a natural parameter $\theta_{u,x}$ and the logistic sigmoid function:

$$p(M_{u,x} = 1 \mid \theta_{u,x}) = \sigma(\theta_{u,x}) = \frac{1}{1 + \exp(-\theta_{u,x})} \tag{1}$$

We construct a matrix $M_{|U| \times (|W| + |S|)}$ as observed facts for MF by integrating a feature model and a knowledge graph propagation model below.

4.1 Feature Model

First, we build a word pattern matrix F_w with binary values based on observations, where each row represents an utterance and each column refers to an observed unigram. In other words, F_w carries the basic word vectors for the utterances, which is illustrated as the left part of the matrix in Figure 1(b).

To induce the semantic elements, we parse all ASR-decoded utterances in our corpus using SEMAFOR[2], a state-of-the-art semantic parser for frame-semantic parsing (Das et al., 2010; Das et al., 2013), and extract all frames from semantic parsing results as slot candidates (Chen et al., 2013b; Dinarelli et al., 2009). Figure 2 shows an example of an ASR-decoded output parsed by SEMAFOR. Three FrameNet-defined frames (capability, expensiveness, and locale_by_use) are generated for the utterance, which we consider as slot candidates for a domain-specific dialogue system (Baker et al., 1998). Then we build a slot matrix F_s with binary values based on the induced slots, which also denotes the slot features for the utterances (right part of the matrix in Figure 1(b)).

To build the feature model M_F, we concatenate two matrices:

$$M_F = [\ F_w \quad F_s\ ], \tag{2}$$

which is the upper part of the matrix in Figure 1(b) for training utterances. Note that we do not use any annotations, so all slot candidates are included.

4.2 Knowledge Graph Propagation Model

Since SEMAFOR was trained on FrameNet annotation, which has a more generic frame-semantic context, not all the frames from the parsing results can be used as the actual slots in the domain-specific dialogue systems. For instance, in Figure 2, we see that the frames "expensiveness" and "locale_by_use" are essentially the key slots for the purpose of understanding in the restaurant query domain, whereas the "capability" frame does not convey particularly valuable information for SLU.

Assuming that domain-specific concepts are usually related to each other, considering global relations between semantic slots induces a more coherent slot set. It is shown that the relations on knowledge graphs help make decisions on domain-specific slots (Chen et al., 2015). Considering two directed graphs, semantic and lexical knowledge graphs, each node in the semantic knowledge graph is a slot candidate s_i generated by the frame-semantic parser, and each node in the lexical knowledge graph is a word w_j.

- **Slot-based semantic knowledge graph** is built as $G_s = \langle V_s, E_{ss} \rangle$, where $V_s = \{s_i \in S\}$ and $E_{ss} = \{e_{ij} \mid s_i, s_j \in V_s\}$.
- **Word-based lexical knowledge graph** is built as $G_w = \langle V_w, E_{ww} \rangle$, where $V_w = \{w_i \in W\}$ and $E_{ww} = \{e_{ij} \mid w_i, w_j \in V_w\}$.

The edges connect two nodes in the graphs if there is a typed dependency between them. Figure 3 is a simplified example of a slot-based semantic knowledge graph. The structured graph helps define a coherent slot set. To model the relations between words/slots based on the knowledge graphs, we define two relation models below.

[2] http://www.ark.cs.cmu.edu/SEMAFOR/

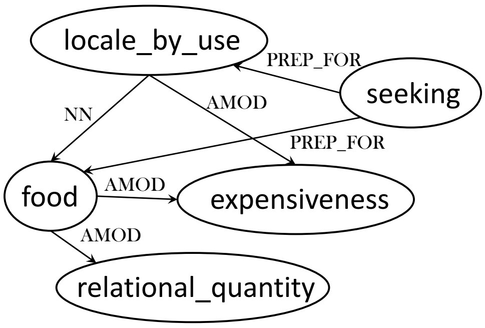

Figure 3: A simplified example of the automatically derived knowledge graph.

- Semantic Relation
  For modeling word semantic relations, we compute a matrix $R_w^S = [Sim(w_i, w_j)]_{|W| \times |W|}$, where $Sim(w_i, w_j)$ is the cosine similarity between the dependency embeddings of the word patterns w_i and w_j after normalization. For slot semantic relations, we compute $R_s^S = [Sim(s_i, s_j)]_{|S| \times |S|}$ similarly[3]. The matrices R_w^S and R_s^S model not only the semantic but functional similarity since we use dependency-based embeddings (Levy and Goldberg, 2014).

- Dependency Relation
  Assuming that important semantic slots are usually mutually related to each other, that is, connected by syntactic dependencies, our automatically derived knowledge graphs are able to help model the dependency relations. For word dependency relations, we compute a matrix $R_w^D = [\hat{r}(w_i, w_j)]_{|W| \times |W|}$, where $\hat{r}(w_i, w_j)$ measures the dependency between two word patterns w_i and w_j based on the word-based lexical knowledge graph, and the detail is described in Section 5. For slot dependency relations, we similarly compute $R_s^D = [\hat{r}(s_i, s_j)]_{|S| \times |S|}$ based on the slot-based semantic knowledge graph.

With the built word relation models (R_w^S and R_w^D) and slot relation models (R_s^S and R_s^D), we combine them as a knowledge graph propagation matrix M_R[4].

$$M_R = \begin{bmatrix} R_w^{SD} & 0 \\ 0 & R_s^{SD} \end{bmatrix}, \qquad (3)$$

where $R_w^{SD} = R_w^S + R_w^D$ and $R_s^{SD} = R_s^S + R_s^D$ to integrate semantic and dependency relations. The goal of this matrix is to propagate scores between nodes according to different types of relations in the knowledge graphs (Chen and Metze, 2012).

4.3 Integrated Model

With a feature model M_F and a knowledge graph propagation model M_R, we integrate them into a single matrix.

$$\begin{aligned} M &= M_F \cdot (\alpha I + \beta M_R) \qquad (4) \\ &= \begin{bmatrix} \alpha F_w + \beta F_w R_w & 0 \\ 0 & \alpha F_s + \beta F_s R_s \end{bmatrix}, \end{aligned}$$

where M is the final matrix and I is the identity matrix. α and β are the weights for balancing original values and propagated values, where $\alpha + \beta = 1$. The matrix M is similar to M_F, but some weights are enhanced through the knowledge graph propagation model, M_R. The word relations are built by $F_w R_w$, which is the matrix with internal weight propagation on the lexical knowledge graph (the blue arrow in Figure 1(b)). Similarly, $F_s R_s$ models the slot correlations, and can be treated as the matrix with internal weight propagation on the semantic knowledge graph (the pink arrow in Figure 1(b)). The propagation models can be treated as running a random walk algorithm on the graphs.

F_s contains all slot candidates generated by SEMAFOR, which may include some generic slots (such as capability), so the original feature model cannot differentiate the domain-specific and generic concepts. By integrating with R_s, the semantic and dependency relations can be propagated via the knowledge graph, and the domain-specific concepts may have higher weights based on the assumption that the slots for dialogue systems are often mutually related (Chen et al., 2015). Hence, the structure information can be automatically involved in the matrix. Also, the word relation model brings the same function, but now on the word level. In conclusion, for each utterance, the integrated model not only predicts the probability that semantic slots occur but also considers whether the slots are domain-specific. The following sections describe the learning process.

4.4 Parameter Estimation

The proposed model is parameterized through weights and latent component vectors, where the parameters are estimated by maximizing the log

[3] For each column in R_w^S and R_s^S, we only keep top 10 highest values, which correspond the top 10 semantically similar nodes.

[4] The values in the diagonal of M_R are 0 to model the propagation from other entries.

likelihood of observed data (Collins et al., 2001).

$$\begin{aligned}\theta^* &= \arg\max_\theta \prod_{u\in U} p(\theta \mid M_u) \qquad (5)\\ &= \arg\max_\theta \prod_{u\in U} p(M_u \mid \theta)p(\theta)\\ &= \arg\max_\theta \sum_{u\in U} \ln p(M_u \mid \theta) - \lambda_\theta,\end{aligned}$$

where M_u is the vector corresponding to the utterance u from $M_{u,x}$ in (1), because we assume that each utterance is independent of others.

To avoid treating unobserved facts as designed negative facts, we consider our positive-only data as *implicit feedback*. Bayesian Personalized Ranking (BPR) is an optimization criterion that learns from implicit feedback for MF, which uses a variant of the ranking: giving observed true facts higher scores than unobserved (true or false) facts (Rendle et al., 2009). Riedel et al. (2013) also showed that BPR learns the implicit relations for improving the relation extraction task.

4.4.1 Objective Function

To estimate the parameters in (5), we create a dataset of *ranked pairs* from M in (4): for each utterance u and each observed fact $f^+ = \langle u, x^+\rangle$, where $M_{u,x} \geq \delta$, we choose each word pattern/slot x^- such that $f^- = \langle u, x^-\rangle$, where $M_{u,x} < \delta$, which refers to the word pattern/slot we have not observed to be in utterance u. That is, we construct the observed data $\mathcal{O}$ from M. Then for each pair of facts f^+ and f^-, we want to model $p(f^+) > p(f^-)$ and hence $\theta_{f^+} > \theta_{f^-}$ according to (1). BPR maximizes the summation of each ranked pair, where the objective is

$$\sum_{u\in U} \ln p(M_u \mid \theta) = \sum_{f^+\in\mathcal{O}} \sum_{f^-\notin\mathcal{O}} \ln \sigma(\theta_{f^+} - \theta_{f^-}). \quad (6)$$

The BPR objective is an approximation to the per utterance AUC (area under the ROC curve), which directly correlates to what we want to achieve – well-ranked semantic slots per utterance.

4.4.2 Optimization

To maximize the objective in (6), we employ a stochastic gradient descent (SGD) algorithm (Rendle et al., 2009). For each randomly sampled observed fact $\langle u, x^+\rangle$, we sample an unobserved fact $\langle u, x^-\rangle$, which results in $|\mathcal{O}|$ fact pairs $\langle f^-, f^+\rangle$. For each pair, we perform an SGD update using the gradient of the corresponding objective function for matrix factorization (Gantner et al., 2011).

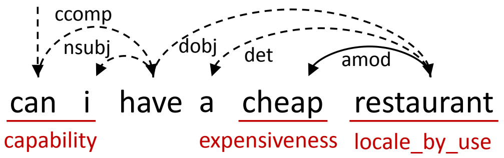

Figure 4: The dependency parsing result.

5 Knowledge Graph Construction

This section introduces the procedure of constructing knowledge graphs in order to estimate $\hat{r}(w_i, w_j)$ for building R_w^D and $\hat{r}(s_i, s_j)$ for R_s^D in Section 4.2. Considering the relations in the knowledge graphs, the edge weights for E_{ww} and E_{ss} are measured as $\hat{r}(w_i, w_j)$ and $\hat{r}(s_i, s_j)$ based on the dependency parsing results respectively.

The example utterance "*can i have a cheap restaurant*" and its dependency parsing result are illustrated in Figure 4. The arrows denote the dependency relations from headwords to their dependents, and words on arcs denote types of the dependencies. All typed dependencies between two words are encoded in triples and form a word-based dependency set $\mathcal{T}_w = \{\langle w_i, t, w_j\rangle\}$, where t is the typed dependency between the headword w_i and the dependent w_j. For example, Figure 4 generates $\langle$*restaurant*, AMOD, *cheap*$\rangle$, $\langle$*restaurant*, DOBJ, *have*$\rangle$, etc. for $\mathcal{T}_w$, Similarly, we build a slot-based dependency set $\mathcal{T}_s = \{\langle s_i, t, s_j\rangle\}$ by transforming dependencies between slot-fillers into ones between slots. For example, $\langle$*restaurant*, AMOD, *cheap*$\rangle$ from $\mathcal{T}_w$ is transformed into $\langle$locale_by_use, AMOD, expensiveness$\rangle$ for building $\mathcal{T}_s$, because both sides of the non-dotted line are parsed as slot-fillers by SEMAFOR.

5.1 Relation Weight Estimation

For the edges in the knowledge graphs, we model the relations between two connected nodes x_i and x_j as $\hat{r}(x_i, x_j)$, where x is either a slot s or a word pattern w. Since the weights are measured based on the relations between nodes regardless of the directions, we combine the scores of two directional dependencies:

$$\hat{r}(x_i, x_j) = r(x_i \to x_j) + r(x_j \to x_i), \quad (7)$$

where $r(x_i \to x_j)$ is the score estimating the dependency including x_i as a head and x_j as a dependent. We propose a scoring function for $r(\cdot)$ using dependency-based embeddings.

Table 1: The example contexts extracted for training dependency-based word/slot embeddings.

	Typed Dependency Relation	Target Word	Contexts
Word	$\langle$*restaurant*, AMOD, *cheap*$\rangle$	*restaurant* *cheap*	*cheap*/AMOD *restaurant*/AMOD^{-1}
Slot	$\langle$locale_by_use, AMOD, expensiveness$\rangle$	locale_by_use expansiveness	expensiveness/AMOD locale_by_use/AMOD^{-1}

5.1.1 Dependency-Based Embeddings

Most neural embeddings use linear bag-of-words contexts, where a window size is defined to produce contexts of the target words (Mikolov et al., 2013c; Mikolov et al., 2013b; Mikolov et al., 2013a). However, some important contexts may be missing due to smaller windows, while larger windows capture broad topical content. A dependency-based embedding approach was proposed to derive contexts based on the syntactic relations the word participates in for training embeddings, where the embeddings are less topical but offer more functional similarity compared to original embeddings (Levy and Goldberg, 2014).

Table 1 shows the extracted dependency-based contexts for each target word from the example in Figure 4, where headwords and their dependents can form the contexts by following the arc on a word in the dependency tree, and -1 denotes the directionality of the dependency. After replacing original bag-of-words contexts with dependency-based contexts, we can train dependency-based embeddings for all target words (Yih et al., 2014; Bordes et al., 2011; Bordes et al., 2013).

For training dependency-based word embeddings, each target x is associated with a vector $\mathbf{v_x} \in \mathbb{R}^d$ and each context c is represented as a context vector $\mathbf{v_c} \in \mathbb{R}^d$, where d is the embedding dimensionality. We learn vector representations for both targets and contexts such that the dot product $\mathbf{v_x} \cdot \mathbf{v_c}$ associated with "good" target-context pairs belonging to the training data $\mathcal{D}$ is maximized, leading to the objective function:

$$\arg\max_{\mathbf{v_x},\mathbf{v_c}} \sum_{(w,c)\in\mathcal{D}} \log \frac{1}{1+\exp(-\mathbf{v_c}\cdot\mathbf{v_x})}, \quad (8)$$

which can be trained using stochastic-gradient updates (Levy and Goldberg, 2014). Then we can obtain the dependency-based slot and word embeddings using $\mathcal{T}_s$ and $\mathcal{T}_w$ respectively.

5.1.2 Embedding-Based Scoring Function

With trained dependency-based embeddings, we estimate the probability that x_i is the headword and x_j is its dependent via the typed dependency t as

$$P(x_i \underset{t}{\rightarrow} x_j) = \frac{Sim(x_i, x_j/t) + Sim(x_j, x_i/t^{-1})}{2}, \quad (9)$$

where $Sim(x_i, x_j/t)$ is the cosine similarity between word/slot embeddings $\mathbf{v_{x_i}}$ and context embeddings $\mathbf{v_{x_j/t}}$ after normalizing to $[0, 1]$.

Based on the dependency set $\mathcal{T}_x$, we use $t^*_{x_i \rightarrow x_j}$ to denote the most possible typed dependency with x_i as a head and x_j as a dependent.

$$t^*_{x_i \rightarrow x_j} = \arg\max_t C(x_i \underset{t}{\rightarrow} x_j), \quad (10)$$

where $C(x_i \underset{t}{\rightarrow} x_j)$ counts how many times the dependency $\langle x_i, t, x_j\rangle$ occurs in the dependency set $\mathcal{T}_x$. Then the scoring function $r(\cdot)$ in (7) that estimates the dependency $x_i \rightarrow x_j$ is measured as

$$r(x_i \rightarrow x_j) = C(x_i \xrightarrow[t^*_{x_i \rightarrow x_j}]{} x_j) \cdot P(x_i \xrightarrow[t^*_{x_i \rightarrow x_j}]{} x_j), \quad (11)$$

which is equal to the highest observed frequency of the dependency $x_i \rightarrow x_j$ among all types from $\mathcal{T}_x$ and additionally weighted by the estimated probability. The estimated probability smoothes the observed frequency to avoid overfitting due to the smaller dataset. Figure 3 is a simplified example of an automatically derived semantic knowledge graph with the most possible typed dependencies as edges based on the estimated weights. Then the relation weights $\hat{r}(x_i, x_j)$ can be obtained by (7) in order to build R^D_w and R^D_s matrices.

6 Experiments

6.1 Experimental Setup

In this experiment, we used the Cambridge University SLU corpus, previously used on several other SLU tasks (Henderson et al., 2012; Chen et al., 2013a). The domain of the corpus is about restaurant recommendation in Cambridge; subjects were asked to interact with multiple SDSs in an in-car setting. The corpus contains a total number of 2,166 dialogues, including 15,453 utterances (10,571 for self-training and 4,882 for

Table 2: The MAP of predicted slots (%); † indicates that the result is significantly better than the Logistic Regression (row (b)) with $p < 0.05$ in t-test.

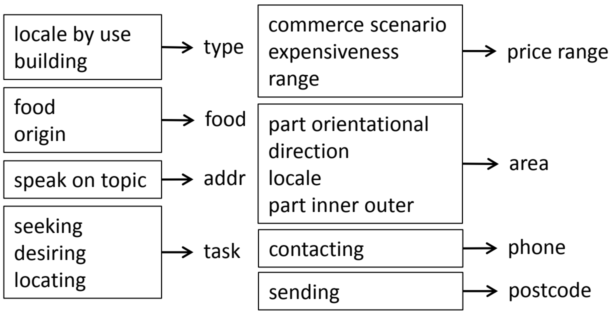

Figure 5: The mappings from induced slots (within blocks) to reference slots (right sides of arrows).

testing). The data is gender-balanced, with slightly more native than non-native speakers. The vocabulary size is 1868. An ASR system was used to transcribe the speech; the word error rate was reported as 37%. There are 10 slots created by domain experts: addr, area, food, name, phone, postcode, price range, signature, task, and type.

For parameter setting, the weights for balancing feature models and propagation models, α and β, are set as 0.5 to give the same influence, and the threshold for defining the unobserved facts δ is set as 0.5 for all experiments. We use the Stanford Parser[5] to obtain the collapsed typed syntactic dependencies (Socher et al., 2013) and set the dimensionality of embeddings $d = 300$ in all experiments.

6.2 Evaluation Metrics

To evaluate the accuracy of the automatically decoded slots, we measure their quality as the proximity between predicted slots and reference slots. Figure 5 shows the mappings that indicate semantically related induced slots and reference slots (Chen et al., 2013b).

To eliminate the influence of threshold selection when predicting semantic slots, in the following metrics, we take the whole ranking list into account and evaluate the performance by the metrics that are independent of the selected threshold. For each utterance, with the predicted probabilities of all slot candidates, we can compute an average precision (AP) to evaluate the performance of SLU by treating the slots with mappings as positive. AP scores the ranking result higher if the correct slots are ranked higher, which also approximates to the area under the precision-recall curve (Boyd et al., 2012). Mean average precision (MAP) is the metric for evaluating all utterances. For all experiments, we perform a paired t-test on the AP scores of the results to test the significance.

6.3 Evaluation Results

Table 2 shows the MAP performance of predicted slots for all experiments on ASR and manual transcripts. For the first baseline using explicit semantics, we use the observed data to self-train models for predicting the probability of each semantic slot by support vector machine (SVM) with a linear kernel and multinomial logistic regression (MLR) (row (a)-(b)) (Pedregosa et al., 2011; Henderson et al., 2012). It is shown that SVM and MLR perform similarly, and MLR is slightly better than SVM because it has better capability of estimating probabilities. For modeling implicit semantics, two baselines are performed as references, Random (row (c)) and Majority (row (d)), where the former assigns random probabilities for all slots, and the later assigns probabilities for the slots based on their frequency distribution. To improve probability estimation, we further integrate the results from implicit semantics with the better result from explicit approaches, MLR (row (b)), by averaging the probability distribution from two results.

Two baselines, Random and Majority, cannot model the implicit semantics, producing poor results. The results of Random integrated with MLR significantly degrades the performance of

MLR for both ASR and manual transcripts. Also, the results of Majority integrated with MLR does not produce any difference compared to the MLR baseline. Among the proposed MF approaches, only using feature model for building the matrix (row (e)) achieves 24.2% and 22.6% of MAP for ASR and manual results respectively, which are worse than two baselines using explicit semantics. However, with the combination of explicit semantics, using only the feature model significantly outperforms the baselines, where the performance comes from about 34.0% to 37.6% and from 38.8% to 45.3% for ASR and manual results respectively. Additionally integrating a knowledge graph propagation (KGP) model (row (e)) outperforms the baselines for both ASR and manual transcripts, and the performance is further improved by combining with explicit semantics (achieving MAP of 43.5% and 53.4%). The experiments show that the proposed MF models successfully learn the implicit semantics and consider the relations and domain-specificity simultaneously.

6.4 Discussion and Analysis

With promising results obtained by the proposed models, we analyze the detailed difference between different relation models in Table 3.

6.4.1 Effectiveness of Semantic and Dependency Relation Models

To evaluate the effectiveness of semantic and dependency relations, we consider each of them individually in M_R of (3) (columns (b) and (c) in Table 3). Comparing to the original model (column (a)), both modeling semantic relations and modeling dependency relations significantly improve the performance for ASR and manual results. It is shown that semantic relations help the SLU model infer the implicit meaning, and then the prediction becomes more accurate. Also, dependency relations successfully differentiate the generic concepts from the domain-specific concepts, so that the SLU model is able to predict more coherent set of semantic slots (Chen et al., 2015). Integrating two types of relations (column (f)) further improves the performance.

6.4.2 Comparing Word/ Slot Relation Models

To analyze the performance results from inter-word and inter-slot relations, the columns (d) and (e) show the results considering only word relations and only slot relations respectively. It can be seen that the inter-slot relation model significantly improves the performance for both ASR and manual results. However, the inter-word relation model only performs slightly better results for ASR output (from 37.6% to 39.2%), and there is no difference after applying the inter-word relation model on manual transcripts. The reason may be that inter-slot relations carry high-level semantics that align well with the structure of SDSs, but inter-word relations do not. Nevertheless, combining two relations (column (f)) outperforms both results for ASR and manual transcripts, showing that different types of relations can compensate each other and then benefit the SLU performance.

7 Conclusions

This paper presents an MF approach to self-train the SLU model for semantic decoding in an unsupervised way. The purpose of the proposed model is not only to predict the probability of each semantic slot but also to distinguish between generic semantic concepts and domain-specific concepts that are related to an SDS. The experiments show that the MF-based model obtains promising results, outperforming strong discriminative baselines.

Abstract

Automatic speech recognition (ASR) outputs often contain various disfluencies. It is necessary to remove these disfluencies before processing downstream tasks. In this paper, an efficient disfluency detection approach based on right-to-left transition-based parsing is proposed, which can efficiently identify disfluencies and keep ASR outputs grammatical. Our method exploits a global view to capture long-range dependencies for disfluency detection by integrating a rich set of syntactic and disfluency features with linear complexity. The experimental results show that our method outperforms state-of-the-art work and achieves a 85.1% f-score on the commonly used English Switchboard test set. We also apply our method to in-house annotated Chinese data and achieve a significantly higher f-score compared to the baseline of CRF-based approach.

1 Introduction

With the development of the mobile internet, speech inputs have become more and more popular in applications where automatic speech recognition (ASR) is the key component to convert speech into text. ASR outputs often contain various disfluencies which create barriers to subsequent text processing tasks like parsing, machine translation and summarization. Usually, disfluencies can be classified into uncompleted words, filled pauses (e.g. "uh", "um"), discourse markers (e.g. "I mean"), editing terms (e.g. "you know") and repairs. To identify and remove disfluencies, straightforward rules can be designed to tackle the former four classes of disfluencies since they often belong to a closed set. However, the repair type disfluency poses particularly more difficult problems as their form is more arbitrary. Typically, as shown in Figure 1, a repair disfluency type consists of a reparandum ("to Boston") and a filled pause ("um"), followed by its repair ("to Denver"). This special structure of disfluency constraint, which exists in many languages such as English and Chinese, reflects the scenarios of spontaneous speech and conversation, where people often correct preceding words with following words when they find that the preceding words are wrong or improper. This procedure might be interrupted and inserted with filled pauses when people are thinking or hesitating. The challenges of detecting repair disfluencies are that reparandums vary in length, may occur everywhere, and are sometimes nested.

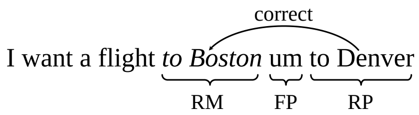

Figure 1: A typical example of repair type disfluency consists of FP (Filled Pause), RM (Reparandum), and RP (Repair). The preceding RM is corrected by the following RP.

There are many related works on disfluency detection, that mainly focus on detecting repair type of disfluencies. Straightforwardly, disfluency detection can be treated as a sequence labeling problem and solved by well-known machine learning algorithms such as conditional random fields (CRF) or max-margin markov network (M^3N) (Liu et al., 2006; Georgila, 2009; Qian and Liu, 2013), and prosodic features are also concerned in (Kahn et al., 2005; Zhang et al., 2006). These methods achieve good performance, but are not powerful enough to capture complicated disfluencies with longer spans or distances. Recently, syntax-based models such as transition-based parser have been used for detecting disflu-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 495–503,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

encies (Honnibal and Johnson, 2014; Rasooli and Tetreault, 2013). These methods can jointly perform dependency parsing and disfluency detection. But in these methods, great efforts are made to distinguish normal words from disfluent words as decisions cannot be made imminently from left to right, leading to inefficient implementation as well as performance loss.

In this paper, we propose detecting disfluencies using a right-to-left transition-based dependency parsing (R2L parsing), where the words are consumed from right to left to build the parsing tree based on which the current word is predicted to be either disfluent or normal. The proposed models cater to the disfluency constraint and integrate a rich set of features extracted from contexts of lexicons and partial syntactic tree structure, where the parsing model and disfluency predicting model are jointly calculated in a cascaded way. As shown in Figure 2(b), while the parsing tree is being built, disfluency tags are predicted and attached to the disfluency nodes. Our models are quite efficient with linear complexity of $2*N$ (N is the length of input).

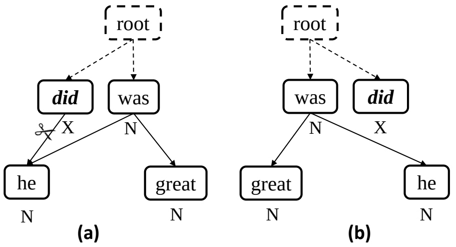

Figure 2: An instance of the detection procedure where 'N' stands for a normal word and 'X' a disfluency word. Words with italic font are Reparandums. (a) is the L2R detecting procedure and (b) is the R2L procedure.

Intuitively, compared with previous syntax-based work such as (Honnibal and Johnson, 2014) that uses left-to-right transition-based parsing (L2R parsing) model, our proposed approach simplifies disfluency detection by sequentially processing each word, without going back to modify the pre-built tree structure of disfluency words. As shown in Figure 2(a), the L2R parsing based joint approach needs to cut the pre-built dependency link between "did" and "he" when "was" is identified as the repair of "did", which is never needed in our method as Figure 2(b). Furthermore, our method overcomes the deficiency issue in decoding of L2R parsing based joint method, meaning the number of parsing transitions for each hypothesis path is not identical to $2*N$, which leads to the failure of performing optimal search during decoding. For example, the involvement of the extra cut operation in Figure 2(a) destroys the competition scoring that accumulates over $2*N$ transition actions among hypotheses in the standard transition-based parsing. Although the heuristic score, such as the normalization of transition count (Honnibal and Johnson, 2014), can be introduced, the total scores of all hypotheses are still not statistically comparable from a global view.

We conduct the experiments on English Switchboard corpus. The results show that our method can achieve a 85.1% f-score with a gain of 0.7 point over state-of-the-art M^{3}N labeling model in (Qian and Liu, 2013) and a gain of 1 point over state-of-the-art joint model proposed in (Honnibal and Johnson, 2014). We also apply our method on Chinese annotated data. As there is no available public data in Chinese, we annotate 25k Chinese sentences manually for training and testing. We achieve 71.2% f-score with 15 points gained compared to the CRF-based baseline, showing that our models are robust and language independent.

2 Transition-based dependency parsing

In a typical transition-based parsing, the Shift-Reduce decoding algorithm is applied and a queue and stack are maintained (Zhang and Clark, 2008). The queue stores the stream of the input and the front of the queue is indexed as the current word. The stack stores the unfinished words which may be linked to the current word or a future word in the queue. When words in the queue are consumed in sequential order, a set of transition actions is applied to build a parsing tree. There are four kinds of transition actions in the parsing process (Zhang and Clark, 2008), as described below.

- *Shift* : Removes the front of the queue and pushes it to the stack.
- *Reduce* : Pops the top of the stack.
- *LeftArc* : Pops the top of the stack, and links the popped word to the front of the queue.
- *RightArc* : Links the front of the queue to the top of the stack and, removes the front of the queue and pushes it to the stack.

The choice of each transition action during parsing is scored by a generalized perceptron (Collins,

2002) which can be trained over a rich set of non-local features. In decoding, beam search is performed to search the optimal sequence of transition actions. As each word must be pushed to the stack once and popped off once, the number of actions needed to parse a sentence is always $2 * N$, where N is the length of the sentence.

Transition-based dependency parsing (Zhang and Clark, 2008) can be performed in either a left-to-right or a right-to-left way, both of which have a performance that is comparable as illustrated in Section 4. However, when they are applied to disfluency detection, their behaviors are very different due to the disfluency structure constraint. We prove that right-to-left transition-based parsing is more efficient than left-to-right transition-based parsing for disfluency detection.

3 Our method

3.1 Model

Unlike previous joint methods (Honnibal and Johnson, 2014; Rasooli and Tetreault, 2013), we introduce dependency parsing into disfluency detection from theory. In the task of disfluency detection, we are given a stream of unstructured words from automatic speech recognition (ASR). We denote the word sequence with $W_1^n := w_1$, w_2,w_3,...,w_n, which is actually the inverse order of ASR words that should be w_n, w_{n-1},w_{n-2},...,w_1. The output of the task is a sequence of binary tags denoted as $D_1^n = d_1$, d_2,d_3,...,d_n, where each d_i corresponds to w_i, indicating whether w_i is a disfluency word (X) or not (N).[1]

Our task can be modeled as formula (1), which is to search the best sequence D^* given the stream of words W_1^n.

$$D^* = argmax_D P(D_1^n|W_1^n) \tag{1}$$

The dependency parsing tree is introduced into model (1) to guide detection. The rewritten formula is shown below:

$$D^* = argmax_D \sum_T P(D_1^n, T|W_1^n) \tag{2}$$

We jointly optimize disfluency detection and parsing with form (3), rather than considering all possible parsing trees:

$$(D^*, T^*) = argmax_{(D,T)} P(D_1^n, T|W_1^n) \tag{3}$$

As both the dependency tree and the disfluency tags are generated word by word, we decompose formula (3) into:

$$(D^*, T^*) = argmax_{(D,T)} \prod_{i=1}^{n} P(d_i, T_1^i|W_1^i, T_1^{i-1}) \tag{4}$$

where T_1^i is the partial tree after word w_i is consumed, d_i is the disfluency tag of w_i.

We simplify the joint optimization in a cascaded way with two different forms (5) and (6).

$$(D^*, T^*) = argmax_{(D,T)} \prod_{i=1}^{n} P(T_1^i|W_1^i, T_1^{i-1}) \times P(d_i|W_1^i, T_1^i) \tag{5}$$

$$(D^*, T^*) = argmax_{(D,T)} \prod_{i=1}^{n} P(d_i|W_1^i, T_1^{i-1}) \times P(T_1^i|W_1^i, T_1^{i-1}, d_i) \tag{6}$$

Here, $P(T_1^i|.)$ is the parsing model, and $P(d_i|.)$ is the disfluency model used to predict the disluency tags on condition of the contexts of partial trees that have been built.

In (5), the parsing model is calculated first, followed by the calculation of the disfluency model. Inspired by (Zhang et al., 2013), we associate the disfluency tags to the transition actions so that the calculation of $P(d_i|W_1^i, T_1^i)$ can be omitted as d_i can be inferred from the partial tree T_1^i. We then get

$$(D^*, T^*) = argmax_{(D,T)} \prod_{i=1}^{n} P(d_i, T_1^i|W_1^i, T_1^{i-1}) \tag{7}$$

Where the parsing and disfluency detection are unified into one model. We refer to this model as the Unified Transition(UT) model.

While in (6), the disfluency model is calculated first, followed by the calculation of the parsing model. We model $P(d_i|.)$ as a binary classifier to classify whether a word is disfluent or not. We refer to this model as the binary classifier transition (BCT) model.

3.2 Unified transition-based model (UT)

In model (7), in addition to the standard 4 transition actions mentioned in Section 2, the UT model

[1] We just use tag ’N’ to represent a normal word, in practice normal words will not be tagged anything by default.

adds 2 new transition actions which extend the original *Shift* and *RightArc* transitions as shown below:

- *Dis_Shift*: Performs what *Shift* does then marks the pushed word as disfluent.
- *Dis_RightArc*: Adds a virtual link from the front of the queue to the top of the stack which is similar to *Right_Arc*, marking the front of the queue as disfluenct and pushing it to the stack.

Figure 3 shows an example of how the UT model works. Given an input "*he did great was great*", the optimal parsing tree is predicted by the UT model. According to the parsing tree, we can get the disfluency tags "N X X N N" which have been attached to each word. To ensure the normal words are built grammatical in the parse tree, we apply a constraint to the UT model.

UT model constraint: When a word is marked disfluent, all the words in its left and right subtrees will be marked disfluent and all the links of its descendent offsprings will be converted to virtual links, no matter what actions are applied to these words.

For example, the italic word "*great*" will be marked disfluent, no matter what actions are performed on it.

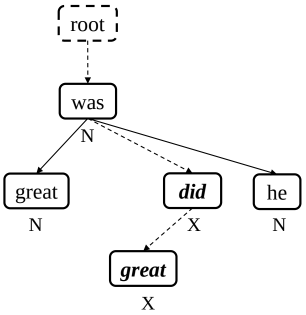

Figure 3: An example of UT model, where 'N' means the word is a fluent word and 'X' means it is disfluent. Words with italic font are Reparandums.

3.3 A binary classifier transition-based model (BCT)

In model (6), we perform the binary classifier and the parsing model together by augmenting the Shift-Reduce algorithm with a binary classifier transition(BCT) action:

- *BCT* : Classifies whether the current word is disfluent or not. If it is, remove it from the queue, push it into the stack which is similar to *Shift* and then mark it as disfluent, otherwise the original transition actions will be used.

It is noted that when BCT is performed, the next action must be *Reduce*. This constraint guarantees that any disfluent word will not have any descendent offspring. Figure 2(b) shows an example of the BCT model. When the partial tree "*great was*" is built, the next word "*did*" is obviously disfluent. Unlike UT model, the BCT will not link the word "*did*" to any word. Instead only a virtual link will add it to the virtual root.

3.4 Training and decoding

In practice, we use the same linear model for both models (6) and (7) to score a parsing tree as:

$$Score(T) = \sum_{action} \phi(action) \cdot \vec{\lambda}$$

Where $\phi(action)$ is the feature vector extracted from partial hypothesis T for a certain $action$ and $\vec{\lambda}$ is the weight vector. $\phi(action) \cdot \vec{\lambda}$ calculates the score of a certain transition action. The score of a parsing tree T is the sum of $action$ scores.

In addition to the basic features introduced in (Zhang and Nivre, 2011) that are defined over bag of words and POS-tags as well as tree-based context, our models also integrate three classes of new features combined with Brown cluster features (Brown et al., 1992) that relate to the right-to-left transition-based parsing procedure as detailed below.

Simple repetition function

- $\delta_I(a, b)$: A logic function which indicates whether a and b are identical.

Syntax-based repetition function

- $\delta_L(a, b)$: A logic function which indicates whether a is a left child of b.
- $\delta_R(a, b)$: A logic function which indicates whether a is a right child of b.

Longest subtree similarity function

- $N_I(a, b)$: The count of identical children on the left side of the root node between subtrees rooted at a and b.
- $N_\#(a_{0..n}, b)$: The count of words among a_0 .. a_n that are on the right of the subtree rooted at b.

Table 1 summarizes the features we use in the model computation, where w_s denotes the top word of the stack, w_0 denotes the front word of the queue and $w_{0..2}$ denotes the top three words of the queue. Every p_i corresponds to the POS-tag of w_i and $p_{0..2}$ represents the POS-tags of $w_{0..2}$. In addition, w_ic means the Brown cluster of w_i. With these symbols, several new feature templates are defined in Table 1. Both our models have the same feature templates.

Basic features	All templates in (Zhang and Nivre, 2011)
New disfluency features	
Function unigrams	$\delta_I(w_s, w_0)$;$\delta_I(p_s, p_0)$; $\delta_L(w_0, w_s)$;$\delta_L(p_0, p_s)$; $\delta_R(w_0, w_s)$;$\delta_R(p_0, p_s)$; $N_I(w_0, w_s)$;$N_I(p_0, p_s)$; $N_{\#}(w_{0..2}, w_s)$;$N_{\#}(p_{0..2}, p_s)$;
Function bigrams	$\delta_I(w_s, w_0)\delta_I(p_s, p_0)$; $\delta_L(w_0, w_s)\delta_L(p_0, p_s)$; $\delta_R(w_0, w_s)\delta_R(p_0, p_s)$; $N_I(w_0, w_s)N_I(p_0, p_s)$; $N_{\#}(w_{0..2}, w_s)N_{\#}(p_{0..2}, p_s)$; $\delta_I(w_s, w_0)w_sc$; $\delta_I(w_s, w_0)w_0c$;
Function trigrams	$w_sw_0\delta_I(w_s, w_0)$; $w_sw_0\delta_I(p_s, p_0)$;

Table 1: Feature templates designed for disfluency detection and dependency parsing.

Similar to the work in (Zhang and Clark, 2008; Zhang and Nivre, 2011), we train our models by averaged perceptron (Collins, 2002). In decoding, beam search is performed to get the optimal parsing tree as well as the tag sequence.

4 Experiments

4.1 Experimental setup

Our training data is the Switchboard portion of the English Penn Treebank (Marcus et al., 1993) corpus, which consists of telephone conversations about assigned topics. As not all the Switchboard data has syntactic bracketing, we only use the subcorpus of PAESED/MRG/SWBD. Following the experiment settings in (Charniak and Johnson, 2001), the training subcorpus contains directories 2 and 3 in PAESED/MRG/SWBD and directory 4 is split into test and development sets. We use the Stanford dependency converter (De Marneffe et al., 2006) to get the dependency structure from the Switchboard corpus, as Honnibal and Johnson (2014) prove that Stanford converter is robust to the Switchboard data.

For our Chinese experiments, no public Chinese corpus is available. We annotate about 25k spoken sentences with only disfluency annotations according to the guideline proposed by Meteer et al. (1995). In order to generate similar data format as English Switchboard corpus, we use Chinese dependency parsing trained on the Chinese Treebank corpus to parse the annotated data and use these parsed data for training and testing . For our Chinese experiment setting, we respectively select about 2k sentences for development and testing. The rest are used for training.

To train the UT model, we create data format adaptation by replacing the original *Shift* and *RightArc* of disfluent words with *Dis_Shift* and *Dis_RightArc*, since they are just extensions of *Shift* and *RightArc*. For the BCT model, disfluent words are directly depended to the root node and all their links and labels are removed. We then link all the fluent children of disfluent words to parents of disfluent words. We also remove partial words and punctuation from data to simulate speech recognizer results where such information is not available (Johnson and Charniak, 2004). Additionally, following Honnibal and Johnson (2014), we remove all one token sentences as these sentences are trivial for disfluency detection, then lowercase the text and discard filled pauses like "um" and "uh".

The evaluation metrics of disfluency detection are precision (Prec.), recall (Rec.) and f-score (F1). For parsing accuracy metrics, we use unlabeled attachment score (UAS) and labeled attachment score (LAS). For our primary comparison, we evaluate the widely used CRF labeling model, the state-of-the-art M^{3}N model presented by Qian and Liu (2013) which has been commonly used as baseline in previous works and the state-of-the-art L2R parsing based joint model proposed by Honnibal and Johnson (2014).

4.2 Experimental results

4.2.1 Performance of disfluency detection on English Swtichboard corpus

The evaluation results of both disfluency detection and parsing accuracy are presented in Table 2. The accuracy of M^{3}N directly refers to the re-

	Disfluency detection accuracy			Parsing accuracy	
Method	Prec.	Rec.	F1	UAS	LAS
CRF(BOW)	81.2%	44.9%	57.8%	88.7%	84.7%
CRF(BOW+POS)	88.3%	62.2%	73.1%	89.2%	85.6%
M^3N	N/A	N/A	84.1%	N/A	N/A
$M^3N^\dagger$	90.5%	79.1%	84.4%	91%	88.2%
H&J	N/A	N/A	84.1%	90.5%	N/A
UT(basic features)	86%	72.5%	78.7%	91.9%	89.0%
UT(+new features)	88.8%	75.1%	81.3%	92.1%	89.4%
BCT(basic features)	88.2%	77.9%	82.7%	92.1%	89.3%
BCT(+new features)	90.3%	80.5%	85.1%	92.2%	89.6%

Table 2: Disfluency detection and parsing accuracies on English Switchboard data. The accuracy of M^3N refers to the result reported in (Qian and Liu, 2013). H&J is the L2R parsing based joint model in (Honnibal and Johnson, 2014). The results of $M^3N^\dagger$ come from the experiments with toolkit released by Qian and Liu (2013) on our pre-processed corpus.

sults reported in (Qian and Liu, 2013). The results of $M^3N^\dagger$ come from our experiments with the toolkit[2] released by Qian and Liu (2013) which uses our data set with the same pre-processing. It is comparable between our models and the L2R parsing based joint model presented by Honnibal and Johnson (2014), as we all conduct experiments on the same pre-processed data set. In order to compare parsing accuracy, we use the CRF and $M^3N^\dagger$ model to pre-process the test set by removing all the detected disfluencies, then evaluate the parsing performance on the processed set. From the table, our BCT model with new disfluency features achieves the best performance on disfluency detection as well as dependency parsing.

The performance of the CRF model is low, because the local features are not powerful enough to capture long span disfluencies. Our main comparison is with the $M^3N^\dagger$ labeling model and the L2R parsing based model by Honnibal and Johnson (2014). As illustrated in Table 2, the BCT model outperforms the $M^3N^\dagger$ model (we got an accuracy of 84.4%, though 84.1% was reported in their paper) and the L2R parsing based model respectively by 0.7 point and 1 point on disfluency detection, which shows our method can efficiently tackle disfluencies. This is because our method can cater extremely well to the disfluency constraint and perform optimal search with identical transition counts over all hypotheses in beam search. Furthermore, our global syntactic and disfluency features can help capture long-range dependencies for disfluency detection. However, the UT model does not perform as well as BCT. This is because the UT model suffers from the risk that normal words may be linked to disfluencies which may bring error propagation in decoding. In addition our models with only basic features respectively score about 3 points below the models adding new features, which shows that these features are important for disfluency detection. In comparing parsing accuracy, our BCT model outperforms all the other models, showing that this model is more robust on disfluent parsing.

4.2.2 Performance of disfluency detection on different part-of-speeches

In this section, we further analyze the frequency of different part-of-speeches in disfluencies and test the performance on different part-of-speeches. Five classes of words take up more than 73% of all disfluencies as shown in Table 3, which are pronouns (contain PRP and PRP$), verbs (contain VB,VBD,VBP,VBZ,VBN), determiners (contain DT), prepositions (contain IN) and conjunctions (contain CC). Obviously, these classes of words appear frequently in our communication.

	Pron.	Verb	Dete.	Prep.	Conj.	Others
Dist.	30.2%	14.7%	13%	8.7%	6.7%	26.7%

Table 3: Distribution of different part-of-speeches in disfluencies. Conj.=conjunction; Dete.=determiner; Pron.=pronoun; Prep.= preposition.

[2] The toolkit is available at https://code.google.com/p/disfluency-detection/downloads.

Table 4 illustrates the performance (f-score) on these classes of words. The results of L2R parsing based joint model in (Honnibal and Johnson, 2014) are not listed because we cannot get such detailed data.

	CRF (BOW)	CRF (BOW +POS)	$M^3N^\dagger$	UT (+feat.)	BCT (+feat.)
Pron.	73.9%	85%	92%	91.5%	93.8%
Verb	38.2%	64.8%	84.2%	82.3%	84.7%
Dete.	66.8%	80%	88%	83.7%	87%
Prep.	60%	71.5%	79.1%	76.1%	79.3%
Conj.	75.2%	82.2%	81.6%	79.5%	83.2%
Others	43.2%	61%	78.4%	72.3%	79.1%

Table 4: Performance on different classes of words. Dete.=determiner; Pron.=pronoun; Conj.=conjunction; Prep.= preposition. feat.=new disfluency features

As shown in Table 4, our BCT model outperforms all other models except that the performance on determiner is lower than $M^3N^\dagger$, which shows that our algorithm can significantly tackle common disfluencies.

4.2.3 Performance of disfluency detection on Chinese annotated corpus

In addition to English experiments, we also apply our method on Chinese annotated data. As there is no standard Chinese corpus, no Chinese experimental results are reported in (Honnibal and Johnson, 2014; Qian and Liu, 2013). We only use the CRF-based labeling model with lexical and POS-tag features as baselines. Table 5 shows the results of Chinese disfluency detection.

Model	Prec.	Rec.	F1
CRF(BOW)	89.5%	35.6%	50.9%
CRF(BOW+POS)	83.4%	41.6%	55.5%
UT(+new features)	86.7%	59.5%	70.6%
BCT(+new features)	85.5%	61%	71.2%

Table 5: Disfluency detection performance on Chinese annotated data.

Our models outperform the CRF model with bag of words and POS-tag features by more than 15 points on f-score which shows that our method is more effective. As shown latter in 4.2.4, the standard transition-based parsing is not robust in parsing disfluent text. There are a lot of parsing errors in Chinese training data. Even though we are still able to get promising results with less data and un-golden parsing annotations. We believe that if we were to have the golden Chinese syntactic annotations and more data, we would get much better results.

4.2.4 Performance of transition-based parsing

In order to show whether the advantage of the BCT model is caused by the disfluency constraint or the difference between R2L and L2R parsing models, in this section, we make a comparison between the original left-to-right transition-based parsing and right-to-left parsing. These experiments are performed with the Penn Treebank (PTB) Wall Street Journal (WSJ) corpus. We follow the standard approach to split the corpus as 2-21 for training, 22 for development and section 23 for testing (McDonald et al., 2005). The features for the two parsers are basic features in Table 1. The POS-tagger model that we implement for a pre-process before parsing also uses structured perceptron for training and can achieve a competitive accuracy of 96.7%. The beam size for both POS-tagger and parsing is set to 5. Table 6 presents the results on WSJ test set and Switchboard (SWBD) test set.

Data sets	Model	UAS	LAS
WSJ	L2R Parsing	92.1%	89.8%
	R2L Parsing	92.0%	89.6%
SWBD	L2R Parsing	88.4%	84.4%
	R2L Parsing	88.7%	84.8%

Table 6: Performance of our parsers on different test sets.

The parsing accuracy on SWBD is lower than WSJ which means that the parsers are more robust on written text data. The performances of R2L and L2R parsing are comparable on both SWBD and WSJ test sets. This demonstrates that the effectiveness of our disfluency detection model mainly relies on catering to the disfluency constraint by using R2L parsing based approach, instead of the difference in parsing models between L2R and R2L parsings.

5 Related work

In practice, disfluency detection has been extensively studied in both speech processing field and natural language processing field. Noisy channel models have been widely used in the past to detect disfluencies. Johnson and Charniak (2004) proposed a TAG-based noisy channel model where the TAG model was used to find rough copies. Thereafter, a language model and MaxEnt reranker were added to the noisy channel model by Johnson et al. (2004). Following their framework, Zwarts and Johnson (2011) extended this model using minimal expected f-loss oriented n-best reranking with additional corpus for language model training.

Recently, the max-margin markov networks (M^3N) based model has achieved great improvement in this task. Qian and Liu (2013) presented a multi-step learning method using weighted M^3N model for disfluency detection. They showed that M^3N model outperformed many other labeling models such as CRF model. Following this work, Wang et al. (2014) used a beam-search decoder to combine multiple models such as M^3N and language model, they achieved the highest f-score. However, direct comparison with their work is difficult as they utilized the whole SWBD data while we only use the subcorpus with syntactic annotation which is only half the SWBD corpus and they also used extra corpus for language model training.

Additionally, syntax-based approaches have been proposed which concern parsing and disfluency detection together. Lease and Johnson (2006) involved disfluency detection in a PCFG parser to parse the input along with detecting disfluencies. Miller and Schuler (2008) used a right corner transform of syntax trees to produce a syntactic tree with speech repairs. But their performance was not as good as labeling models. There exist two methods published recently which are similar to ours. Rasooli and Tetreault (2013) designed a joint model for both disfluency detection and dependency parsing. They regarded the two tasks as a two step classifications. Honnibal and Johnson (2014) presented a new joint model by extending the original transition actions with a new "Edit" transition. They achieved the state-of-the-art performance on both disfluency detection and parsing. But this model suffers from the problem that the number of transition actions is not identical for different hypotheses in decoding, leading to the failure of performing optimal search. In contrast, our novel right-to-left transition-based joint method caters to the disfluency constraint which can not only overcome the decoding deficiency in previous work but also achieve significantly higher performance on disfluency detection as well as dependency parsing.

6 Conclusion and Future Work

In this paper, we propose a novel approach for disfluency detection. Our models jointly perform parsing and disfluency detection from right to left by integrating a rich set of disfluency features which can yield parsing structure and difluency tags at the same time with linear complexity. The algorithm is easy to implement without complicated backtrack operations. Experiential results show that our approach outperforms the baselines on the English Switchboard corpus and experiments on the Chinese annotated corpus also show the language independent nature of our method. The state-of-the-art performance on disfluency detection and dependency parsing can benefit the downstream tasks of text processing.

In future work, we will try to add new classes of features to further improve performance by capturing the property of disfluencies. We would also like to make an end-to-end MT test over transcribed speech texts with disfluencies removed based on the method proposed in this paper.

Abstract

Non-linear models recently receive a lot of attention as people are starting to discover the power of statistical and embedding features. However, tree-based models are seldom studied in the context of structured learning despite their recent success on various classification and ranking tasks. In this paper, we propose S-MART, a tree-based structured learning framework based on multiple additive regression trees. S-MART is especially suitable for handling tasks with dense features, and can be used to learn many different structures under various loss functions.

We apply S-MART to the task of tweet entity linking — a core component of tweet information extraction, which aims to identify and link name mentions to entities in a knowledge base. A novel inference algorithm is proposed to handle the special structure of the task. The experimental results show that S-MART significantly outperforms state-of-the-art tweet entity linking systems.

1 Introduction

Many natural language processing (NLP) problems can be formalized as structured prediction tasks. Standard algorithms for structured learning include Conditional Random Field (CRF) (Lafferty et al., 2001) and Structured Supported Vector Machine (SSVM) (Tsochantaridis et al., 2004). These algorithms, usually equipped with a linear model and sparse lexical features, achieve state-of-the-art performances in many NLP applications such as part-of-speech tagging, named entity recognition and dependency parsing.

This classical combination of linear models and sparse features is challenged by the recent emerging usage of dense features such as statistical and embedding features. Tasks with these low dimensional dense features require models to be more sophisticated to capture the relationships between features. Therefore, non-linear models start to receive more attention as they are often more expressive than linear models.

Tree-based models such as boosted trees (Friedman, 2001) are flexible non-linear models. They can handle categorical features and count data better than other non-linear models like Neural Networks. Unfortunately, to the best of our knowledge, little work has utilized tree-based methods for structured prediction, with the exception of TreeCRF (Dietterich et al., 2004).

In this paper, we propose a novel structured learning framework called S-MART (**S**tructured **M**ultiple **A**dditive **R**egression **T**rees). Unlike TreeCRF, S-MART is very versatile, as it can be applied to tasks beyond sequence tagging and can be trained under various objective functions. S-MART is also powerful, as the high order relationships between features can be captured by non-linear regression trees.

We further demonstrate how S-MART can be applied to tweet entity linking, an important and challenging task underlying many applications including product feedback (Asur and Huberman, 2010) and topic detection and tracking (Mathioudakis and Koudas, 2010). We apply S-MART to entity linking using a simple logistic function as the loss function and propose a novel inference algorithm to prevent overlaps between entities.

Our contributions are summarized as follows:

- We propose a novel structured learning framework called S-MART. S-MART combines non-linearity and efficiency of tree-based models with structured prediction, leading to a family of new algorithms. (Section 2)

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 504–513,
Beijing, China, July 26-31, 2015.

- We apply S-MART to tweet entity linking. Building on top of S-MART, we propose a novel inference algorithm for non-overlapping structure with the goal of preventing conflicting entity assignments. (Section 3)

- We provide a systematic study of evaluation criteria in tweet entity linking by conducting extensive experiments over major data sets. The results show that S-MART significantly outperforms state-of-the-art entity linking systems, including the system that is used to win the NEEL 2014 challenge (Cano and others, 2014). (Section 4)

2 Structured Multiple Additive Regression Trees

The goal of a structured learning algorithm is to learn a joint scoring function S between an input $\mathbf{x}$ and an output structure $\mathbf{y}$, $S : (\mathbf{x}, \mathbf{y}) \rightarrow \mathbb{R}$. The structured output $\mathbf{y}$ often contains many interdependent variables, and the number of the possible structures can be exponentially large with respect to the size of $\mathbf{x}$. At test time, the prediction $\mathbf{y}$ for $\mathbf{x}$ is obtained by

$$\arg\max_{\mathbf{y} \in Gen(\mathbf{x})} S(\mathbf{x}, \mathbf{y}),$$

where $Gen(\mathbf{x})$ represents the set of all valid output structures for $\mathbf{x}$.

Standard learning algorithms often directly optimize the model parameters. For example, assume that the joint scoring function S is parameterized by θ. Then, gradient descent algorithms can be used to optimize the model parameters θ iteratively. More specifically,

$$\theta_m = \theta_{m-1} - \eta_m \frac{\partial L(\mathbf{y}^*, S(\mathbf{x}, \mathbf{y}; \theta))}{\partial \theta_{m-1}}, \quad (1)$$

where $\mathbf{y}^*$ is the gold structure, $L(\mathbf{y}^*, S(\mathbf{x}, \mathbf{y}; \theta))$ is a loss function and η_m is the learning rate of the m-th iteration.

In this paper, we propose a framework called **Structured Multiple Additive Regression Trees (S-MART)**, which generalizes Multiple Additive Regression Trees (MART) for structured learning problems. Different from Equation (1), S-MART does *not* directly optimize the model parameters; instead, it approximates the optimal scoring function that minimize the loss by adding (weighted) regression tree models iteratively.

Due to the fact that there are exponentially many input-output pairs in the training data, S-MART assumes that the joint scoring function can be decomposed as

$$S(\mathbf{x}, \mathbf{y}) = \sum_{k \in \Omega(\mathbf{x})} F(\mathbf{x}, \mathbf{y}_k),$$

where $\Omega(\mathbf{x})$ contains the set of the all factors for input $\mathbf{x}$ and $\mathbf{y}_k$ is the sub-structure of $\mathbf{y}$ that corresponds to the k-th factor in $\Omega(\mathbf{x})$. For instance, in the task of word alignment, each factor can be defined as a pair of words from source and target languages respectively. Note that we can recover $\mathbf{y}$ from the union of $\{\mathbf{y}_k\}_1^K$.

The factor scoring function $F(\mathbf{x}, \mathbf{y}_k)$ can be optimized by performing gradient descent in the function space in the following manner:

$$F_m(\mathbf{x}, \mathbf{y}_k) = F_{m-1}(\mathbf{x}, \mathbf{y}_k) - \eta_m g_m(\mathbf{x}, \mathbf{y}_k) \quad (2)$$

where function $g_m(\mathbf{x}, \mathbf{y}_k)$ is the functional gradient.

Note that g_m is a *function* rather than a vector. Therefore, modeling g_m theoretically requires an infinite number of data points. We can address this difficulty by approximating g_m with a finite number of point-wise functional gradients

$$g_m(\mathbf{x}, \mathbf{y}_k = u_k) = \quad (3)$$
$$\left[\frac{\partial L(\mathbf{y}^*, S(\mathbf{x}, \mathbf{y}_k = u_k))}{\partial F(\mathbf{x}, \mathbf{y}_k = u_k)}\right]_{F(\mathbf{x}, \mathbf{y}_k) = F_{m-1}(\mathbf{x}, \mathbf{y}_k)}$$

where u_k index a valid sub-structure for the k-th factor of $\mathbf{x}$.

The key point of S-MART is that it approximates $-g_m$ by modeling the point-wise negative functional gradients using a regression tree h_m. Then the factor scoring function can be obtained by

$$F(\mathbf{x}, \mathbf{y}_k) = \sum_{m=1}^{M} \eta_m h_m(\mathbf{x}, \mathbf{y}_k),$$

where $h_m(\mathbf{x}, \mathbf{y}_k)$ is also called a basis function and η_m can be simply set to 1 (Murphy, 2012).

The detailed S-MART algorithm is presented in Algorithm 1. The factor scoring function $F(\mathbf{x}, \mathbf{y}_k)$ is simply initialized to zero at first (line 1). After this, we iteratively update the function by adding regression trees. Note that the scoring function is shared by all the factors. Specifically, given the current decision function F_{m-1}, we can consider line 3 to line 9 a process of generating the pseudo

11:     $F_m(\mathbf{x}, \mathbf{y}_k) = F_{m-1}(\mathbf{x}, \mathbf{y}_k) + h_m(\mathbf{x}, \mathbf{y}_k)$
12: end for
```

training data D for modeling the regression tree. For each training example, S-MART first computes the point-wise functional gradients according to Equation (3) (line 6). Here we use g_{ku} as the abbreviation for $g_m(\mathbf{x}, \mathbf{y}_k = u_k)$. In line 7, for each sub-structure u_k, we create a new training example for the regression problem by the feature vector $\Phi(\mathbf{x}, \mathbf{y}_k = u_k)$ and the negative gradient $-g_{ku}$. In line 10, a regression tree is constructed by minimizing differences between the prediction values and the point-wise negative gradients. Then a new basis function (modeled by a regression tree) will be added into the overall F (line 11).

It is crucial to note that S-MART is *a family of algorithms* rather than a single algorithm. S-MART is flexible in the choice of the loss functions. For example, we can use either logistic loss or hinge loss, which means that S-MART can train probabilistic models as well as non-probabilistic ones. Depending on the choice of factors, S-MART can handle various structures such as linear chains, trees, and even the semi-Markov chain (Sarawagi and Cohen, 2004).

S-MART versus MART There are two key differences between S-MART and MART. First, S-MART decomposes the joint scoring function $S(\mathbf{x}, \mathbf{y})$ into factors to address the problem of the exploding number of input-output pairs for structured learning problems. Second, S-MART models a single scoring function $F(\mathbf{x}, \mathbf{y}_k)$ over inputs and output variables directly rather than O different functions $F^o(\mathbf{x})$, each of which corresponds to a label class.

S-MART versus TreeCRF TreeCRF can be viewed as a special case of S-MART, and there are two points where S-MART improves upon TreeCRF. First, the model designed in (Dietterich et al., 2004) is tailored for sequence tagging problems. Similar to MART, for a tagging task with O tags, they choose to model O functions $F^o(\mathbf{x}, o')$ instead of directly modeling the joint score of the factor. This imposes limitations on the feature functions, and TreeCRF is consequently unsuitable for many tasks such as entity linking.[1] Second, S-MART is more general in terms of the objective functions and applicable structures. In the next section, we will see how S-MART can be applied to a non-linear-chain structure and various loss functions.

3 S-MART for Tweet Entity Linking

We first formally define the task of tweet entity linking. As *input*, we are given a tweet, an entity database (*e.g.*, Wikipedia where each article is an entity), and a lexicon[2] which maps a surface form into a set of entity candidates. For each incoming tweet, all n-grams of this tweet will be used to find matches in the lexicon, and each match will form a mention candidate. As *output*, we map every mention candidate (*e.g.*, "new york giants") in the message to an entity (*e.g.*, NEW YORK GIANTS) or to **Nil** (*i.e.*, a non-entity). A mention candidate can often potentially link to multiple entities, which we call possible *entity assignments*.

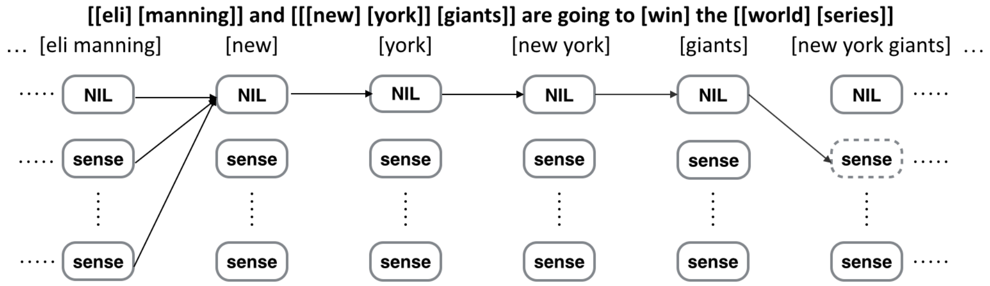
This task is a structured learning problem, as the final entity assignments of a tweet should not overlap with each other.[3] We decompose this learning problem as follows: we make each mention candidate a factor, and the score of the entity assignments of a tweet is the sum of the score of each entity and mention candidate pair. Although all mention candidates are decomposed, the non-overlapping constraint requires the system to perform global inference.

Consider the example tweet in Figure 1, where we show the tweet with the mention candidates in brackets. To link the mention candidate "new york giants" to a non-**Nil** entity, the system has to link previous overlapping mention candidates to **Nil**. It is important to note that this is **not** a linear chain problem because of the non-overlapping constraint, and the inference algorithm needs to be

[1] For example, entity linking systems need to model the similarity between an entity and the document. The TreeCRF formulation does not support such features.

[2] We use the standard techniques to construct the lexicon from anchor texts, redirect pages and other information resources.

[3] We follow the common practice and do not allow embedded entities.



[[eli] [manning]] and [[[new] [york]] [giants]] are going to [win] the [[world] [series]]
... [eli manning]
[new]
[york]
[new york]
[giants]
[new york giants] ...
NIL
sense

Figure 1: Example tweet and its mention candidates. Each mention candidate is marked as a pair of brackets in the original tweet and forms a column in the graph. The graph demonstrates the non-overlapping constraint. To link the mention candidate "new york giants" to a non-**Nil** entity, the system has to link previous four overlapping mention candidates to **Nil**. The mention candidate "eli manning" is not affected by "new york giants". **Note that this is not a standard linear chain problem.**

carefully designed.

3.1 Applying S-MART

We derive specific model for tweet entity linking task with S-MART and use logistic loss as our running example. The hinge loss version of the model can be derived in a similar way.

Note that the tweet and the mention candidates are given. Let x be the tweet, u_k be the entity assignment of the k-th mention candidate. We use function $F(\mathbf{x}, y_k = u_k)$ to model the score of the k-th mention candidate choosing entity u_k.[4] The overall scoring function can be decomposed as follows:

$$S(\mathbf{x}, \mathbf{y} = \{u_k\}_{k=1}^{K}) = \sum_{k=1}^{K} F(\mathbf{x}, y_k = u_k)$$

S-MART utilizes regression trees to model the scoring function $F(\mathbf{x}, y_k = u_k)$, which requires point-wise functional gradient for each entity of every mention candidate. Let's first write down the logistic loss function as

$$\begin{aligned} L(\mathbf{y}^*, S(\mathbf{x}, \mathbf{y})) &= -\log P(\mathbf{y}^*|\mathbf{x}) \\ &= \log Z(\mathbf{x}) - S(\mathbf{x}, \mathbf{y}^*) \end{aligned}$$

where $Z(\mathbf{x}) = \sum_{\mathbf{y}} \exp(S(\mathbf{x}, \mathbf{y}))$ is the potential function. Then the point-wise gradients can be computed as

$$\begin{aligned} g_{ku} &= \frac{\partial L}{\partial F(\mathbf{x}, y_k = u_k)} \\ &= P(y_k = u_k|\mathbf{x}) - \mathbf{1}[y_k^* = u_k], \end{aligned}$$

where $\mathbf{1}[\cdot]$ represents an indicator function. The conditional probability $P(y_k = u_k|\mathbf{x})$ can be computed by a variant of the forward-backward algorithm, which we will detail in the next subsection.

3.2 Inference

The non-overlapping structure is distinct from linear chain and semi-Markov chain (Sarawagi and Cohen, 2004) structures. Hence, we propose a carefully designed forward-backward algorithm to calculate $P(y_k = u_k|\mathbf{x})$ based on current scoring function $F(\mathbf{x}, y_k = u_k)$ given by the regression trees. The non-overlapping constraint distinguishes our inference algorithm from other forward-backward variants.

To compute the forward probability, we sort[5] the mention candidates by their end indices and define forward recursion by

$$\begin{aligned} \alpha(u_1, 1) =& \exp(F(\mathbf{x}, y_1 = u_1)) \\ \alpha(u_k, k) =& \exp(F(\mathbf{x}, y_k = u_k)) \\ & \cdot \prod_{p=1}^{P-1} \exp(F(\mathbf{x}, y_{k-p} = \textbf{Nil})) \\ & \cdot \sum_{u_{k-P}} \alpha(u_{k-P}, k-P) \qquad (4) \end{aligned}$$

where $k - P$ is the index of the previous non-overlapping mention candidate. Intuitively, for the k-th mention candidate, we need to identify its nearest non-overlapping fellow and recursively compute the probability. The overlapping mention candidates can only take the **Nil** entity.

Similarly, we can sort the mention candidates by their start indices and define backward recur-

[4] Note that each mention candidate has different own entity sets.

[5] Sorting helps the algorithms find non-overlapping candidates.

sion by

$$\begin{aligned}\beta(u_K, K) =& 1\\ \beta(u_k, k) =& \sum_{u_{k+Q}} \exp(F(\mathbf{x}, y_{k+Q} = u_{k+Q}))\\ &\cdot \prod_{q=1}^{Q-1} \exp(F(\mathbf{x}, y_{k+q} = \textbf{Nil}))\\ &\cdot \beta(u_{k+Q}, k+Q) \qquad (5)\end{aligned}$$

where $k + Q$ is the index of the next non-overlapping mention candidate. Note that the third terms of equation (4) or (5) will vanish if there are no corresponding non-overlapping mention candidates.

Given the potential function can be computed by $Z(\mathbf{x}) = \sum_{u_k} \alpha(u_k, k)\beta(u_k, k)$, for entities that are not **Nil**,

$$\begin{aligned}P(y_k = u_k|\mathbf{x}) =& \frac{\exp(F(\mathbf{x}, y_k = u_k)) \cdot \beta(u_k, k)}{Z(\mathbf{x})}\\ &\cdot \prod_{p=1}^{P-1} \exp(F(\mathbf{x}, y_{k-p} = \textbf{Nil}))\\ &\cdot \sum_{u_{k-P}} \alpha(u_{k-P}, k-P) \qquad (6)\end{aligned}$$

The probability for the special token **Nil** can be obtained by

$$P(y_k = \textbf{Nil}|\mathbf{x}) = 1 - \sum_{u_k \neq \textbf{Nil}} P(y_k = u_k|\mathbf{x}) \quad (7)$$

In the worst case, the total cost of the forward-backward algorithm is $\mathcal{O}(\max\{TK, K^2\})$, where T is the number of entities of a mention candidate.[6]

Finally, at test time, the decoding problem $\arg\max_{\mathbf{y}} S(\mathbf{x}, \mathbf{y})$ can be solved by a variant of the Viterbi algorithm.

3.3 Beyond S-MART: Modeling entity-entity relationships

It is important for entity linking systems to take advantage of the entity-to-entity information while making local decisions. For instance, the identification of entity "eli manning" leads to a strong clue for linking "new york giants" to the NFL team.

Instead of defining a more complicated structure and learning everything jointly, we employ a two-stage approach as the solution for modeling entity-entity relationships after we found that S-MART achieves high precision and reasonable recall. Specifically, in the first stage, the system identifies all possible entities with basic features, which enables the extraction of entity-entity features. In the second stage, we re-train S-MART on a union of basic features and entity-entity features. We define entity-entity features based on the Jaccard distance introduced by Guo et al. (2013).

Let $\Gamma(e_i)$ denotes the set of Wikipedia pages that contain a hyperlink to an entity e_i and $\Gamma(t_{-i})$ denotes the set of pages that contain a hyperlink to any identified entity e_j of the tweet t in the first stage excluding e_i. The Jaccard distance between e_i and t is

$$Jac(e_i, t) = \frac{|\Gamma(e_i) \cap \Gamma(t_{-i})|}{|\Gamma(e_i) \cup \Gamma(t_{-i})|}.$$

In addition to the Jaccard distance, we add one additional binary feature to indicate if the current entity has the highest Jaccard distance among all entities for this mention candidate.

4 Experiments

Our experiments are designed to answer the following three research questions in the context of tweet entity linking:

- Do non-linear learning algorithms perform better than linear learning algorithms?
- Do structured entity linking models perform better than non-structured ones?
- How can we best capture the relationships between entities?

4.1 Evaluation Methodology and Data

We evaluate each entity linking system using two evaluation policies: Information Extraction (IE) driven evaluation and Information Retrieval (IR) driven evaluation. For both evaluation settings, precision, recall and F1 scores are reported. Our data is constructed from two publicly available sources: Named Entity Extraction & Linking (NEEL) Challenge (Cano et al., 2014) datasets, and the datasets released by Fang and Chang (2014). Note that we gather two datasets from Fang and Chang (2014) and they are used in two different evaluation settings. We refer to these two datasets as TACL-IE and TACL-IR, respectively. We perform some data cleaning and unification on

[6] The cost is $\mathcal{O}(K^2)$ only if every mention candidate of the tweet overlaps other mention candidates. In practice, the algorithm is nearly linear w.r.t K.

these sets.[7] The statistics of the datasets are presented in Table 1.

IE-driven evaluation The IE-driven evaluation is the standard evaluation for an end-to-end entity linking system. We follow Carmel et al. (2014) and relax the definition of the correct mention boundaries, as they are often ambiguous. A mention boundary is considered to be correct if it overlaps (instead of being the same) with the gold mention boundary. Please see (Carmel et al., 2014) for more details on the procedure of calculating the precision, recall and F1 score.

The NEEL and TACL-IE datasets have different annotation guidelines and different choices of knowledge bases, so we perform the following procedure to clean the data and unify the annotations. We first filter out the annotations that link to entities excluded by our knowledge base. We use the same knowledge base as the ERD 2014 competition (Carmel et al., 2014), which includes the union of entities in Wikipedia and Freebase. Second, we follow NEEL annotation guideline and re-annotate TACL-IE dataset. For instance, in order to be consistent with NEEL, all the user tags (e.g. @BarackObama) are re-labeled as entities in TACL-IE.

We train all the models with NEEL Train dataset and evaluate different systems on NEEL Test and TACL-IE datasets. In addition, we sample 800 tweets from NEEL Train dataset as our development set to perform parameter tuning.

IR-driven evaluation The IR-driven evaluation is proposed by Fang and Chang (2014). It is motivated by a key application of entity linking — retrieval of relevant tweets for target entities, which is crucial for downstream applications such as product research and sentiment analysis. In particular, given a query entity we can search for tweets based on the match with some potential surface forms of the query entity. Then, an entity linking system is evaluated by its ability to correctly identify the presence or absence of the query entity in every tweet. Our IR-driven evaluation is based on the TACL-IR set, which includes 980 tweets sampled for ten query entities of five entity types (roughly 100 tweets per entity). About 37% of the sampled tweets did not mention the query entity due to the anchor ambiguity.

Data	#Tweet	#Entity	Date
NEEL Train	2340	2202	Jul. ~Aug. 11
NEEL Test	1164	687	Jul. ~Aug. 11
TACL-IE	500	300	Dec. 12
TACL-IR	980	NA	Dec. 12

Table 1: Statistics of data sets.

4.2 Experimental Settings

Features We employ a total number of 37 dense features as our basic feature set. Most of the features are adopted from (Guo et al., 2013)[8], including various statistical features such as the probability of the surface to be used as anchor text in Wikipedia. We also add additional Entity Type features correspond to the following entity types: Character, Event, Product and Brand. Finally, we include several NER features to indicate each mention candidate belongs to one the following NER types: Twitter user, Twitter hashtag, Person, Location, Organization, Product, Event and Date.

Algorithms Table 2 summarizes all the algorithms that are compared in our experiments. First, we consider two linear structured learning algorithms: Structured Perceptron (Collins, 2002) and Linear Structured SVM (SSVM) (Tsochantaridis et al., 2004).

For non-linear models, we consider polynomial SSVM, which employs polynomial kernel inside the structured SVM algorithm. We also include LambdaRank (Quoc and Le, 2007), a neural-based learning to rank algorithm, which is widely used in the information retrieval literature. We further compare with MART, which is designed for performing multiclass classification using log loss without considering the structured information. Finally, we have our proposed log-loss S-MART algorithm, as described in Section 3. [9]

Note that our baseline systems are quite strong. Linear SSVM has been used in one of the state-of-the-art tweet entity linking systems (Guo et al., 2013), and the system based on MART is the winning system of the 2014 NEEL Challenge (Cano and others, 2014)[10].

Table 2 summarizes several properties of the algorithms. For example, most algorithms are struc-

[7] We plan to release the cleaned data and evaluation code if license permitted.

[8] We consider features of Base, Capitalization Rate, Popularity, Context Capitalization and Entity Type categories.

[9] Our pilot experiments show that the log-loss S-MART consistently outperforms the hinge-loss S-MART.

[10] Note that the numbers we reported here are different from the results in NEEL challenge due to the fact that we have cleaned the datasets and the evaluation metrics are slightly different in this paper.

Model	Structured	Non-linear	Tree-based
Structured Perceptron	✓		
Linear SSVM	✓		
Polynomial SSVM	✓	✓	
LambdaRank		✓	
MART		✓	✓
S-MART	✓	✓	✓

Table 2: Included algorithms and their properties.

tured (e.g. they perform dynamic programming at test time) except for MART and LambdaRank, which treat mention candidates independently.

Parameter tuning All the hyper-parameters are tuned on the development set. Then, we re-train our models on full training data (including the dev set) with the best parameters. We choose the soft margin parameter C from $\{0.5, 1, 5, 10\}$ for two structured SVM methods. After a preliminary parameter search, we fixed the number of trees to 300 and the minimum number of documents in a leaf to 30 for all tree-based models. For LambdaRank, we use a two layer feed forward network. We select the number of hidden units from $\{10, 20, 30, 40\}$ and learning rate from $\{0.1, 0.01, 0.001\}$.

It is widely known that F1 score can be affected by the trade-off between precision and recall. In order to make the comparisons between all algorithms fairer in terms of F1 score, we include a post-processing step to balance precision and recall for all the systems. Note the tuning is only conducted for the purpose of robust evaluation. In particular, we adopt a simple tuning strategy that works well for all the algorithms, in which we add a bias term b to the scoring function value of **Nil**:

$$F(\mathbf{x}, y_k = \textbf{Nil}) \leftarrow F(\mathbf{x}, y_k = \textbf{Nil}) + b.$$

We choose the bias term b from values between -3.0 to 3.0 on the dev set and apply the same bias term at test time.

4.3 Results

Table 3 presents the empirical findings for S-MART and competitive methods on tweet entity linking task in both IE and IR settings. In the following, we analyze the empirical results in details.

Linear models vs. non-linear models Table 3 clearly shows that linear models perform worse than non-linear models when they are restricted to the IE setting of the tweet entity linking task. The story is similar in IR-driven evaluation, with the exception of LambdaRank. Among the linear models, linear SSVM demonstrates its superiority over Structured Perceptron on all datasets, which aligns with the results of (Tsochantaridis et al., 2005) on the named entity recognition task.

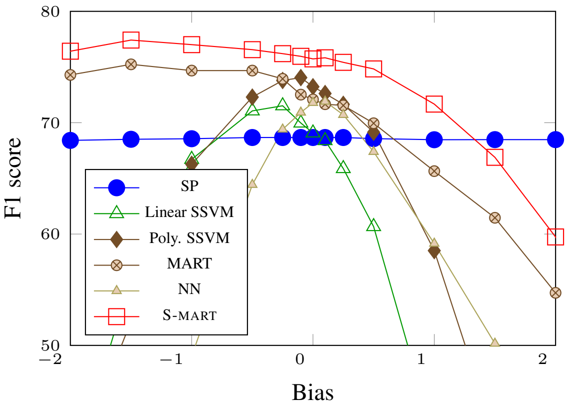


Figure 2: Balance precisions and recalls. X-axis corresponds to values of the bias terms for the special token **Nil**. Note that S-MART is still the overall winning system without tuning the threshold.

We have many interesting observations on the non-linear models side. First, by adopting a polynomial kernel, the non-linear SSVM further improves the entity linking performances on the NEEL datasets and TACL-IR dataset. Second, LambdaRank, a neural network based model, achieves better results than linear models in IE-driven evaluation, but the results in IR-driven evaluation are worse than all the other methods. We believe the reason for this dismal performance is that the neural-based method tends to overfit the IR setting given the small number of training examples. Third, both MART and S-MART significantly outperform alternative linear and non-linear methods in IE-driven evaluation and performs better or similar to other methods in IR-driven evaluation. This suggests that tree-based non-linear models are suitable for tweet entity linking task. Finally, S-MART outperforms previous state-of-the-art method Structured SVM by a surprisingly large margin. In the NEEL Test dataset, the difference is more than 10% F1. Overall, the results show that the shallow linear models are not expressive enough to capture the complex patterns in the data, which are represented by a few dense features.

Structured learning models To showcase structured learning technique is crucial for entity linking with non-linear models, we compare S-MART against MART directly. As shown in

Model	NEEL Dev			NEEL Test			TACL-IE			TACL-IR		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1
Structured Perceptron	75.8	62.8	68.7	79.1	64.3	70.9	74.4	63.0	68.2	86.2	43.8	58.0
Linear SSVM	78.0	66.1	71.5	80.5	67.1	73.2	**78.2**	64.7	70.8	86.7	48.5	62.2
Polynomial SSVM	77.7	70.7	74.0	81.3	69.0	74.6	76.8	64.0	69.8	91.1	48.8	63.6
LambdaRank	75.0	69.0	71.9	80.3	71.2	75.5	77.8	66.7	71.8	85.8	42.4	56.8
MART	76.2	74.3	75.2	76.8	78.0	77.4	73.4	71.0	72.2	**98.1**	46.4	63.0
S-MART	**79.1**	**75.8**	**77.4**	**83.2**	**79.2**	**81.1**	76.8	**73.0**	**74.9**	95.1	**52.2**	**67.4**
+ entity-entity	79.2	75.8	77.5	81.5	76.4	78.9	77.3	73.7	75.4	95.5	56.7	71.1

Table 3: IE-driven and IR-driven evaluation results for different models. The best results with basic features are in **bold**. The results are underlined if adding entity-entity features gives the overall best results.

Table 3, S-MART can achieve higher precision and recall points compared to MART on all datasets in terms of IE-driven evaluation, and can improve F1 by 4 points on NEEL Test and TACL-IR datasets. The task of entity linking is to produce non-overlapping entity assignments that match the gold mentions. By adopting structured learning technique, S-MART is able to automatically take into account the non-overlapping constraint during learning and inference, and produce global optimal entity assignments for mention candidates of a tweet. One effect is that S-MART can easily eliminate some common errors caused by popular entities (e.g. new york in Figure 1).

Modeling entity-entity relationships Entity-entity relationships provide strong clues for entity disambiguation. In this paper, we use the simple two-stage approach described in Section 3.3 to capture the relationships between entities. As shown in Table 3, the significant improvement in IR-driven evaluation indicates the importance of incorporating entity-entity information.

Interestingly, while IR-driven results are significantly improved, IE-driven results are similar or even worse given entity-entity features. We believe the reason is that IE-driven and IR-driven evaluations focus on different aspects of tweet entity linking task. As Guo et al. (2013) shows that most mentions in tweets should be linked to the most popular entities, IE setting actually pays more attention on mention detection sub-problem. In contrast to IE setting, IR setting focuses on entity disambiguation, since we only need to decide whether the tweet is relevant to the query entity. Therefore, we believe that both evaluation policies are needed for tweet entity linking.

Balance Precision and Recall Figure 2 shows the results of tuning the bias term for balancing precision and recall on the dev set. The results show that S-MART outperforms competitive approaches without any tuning, with similar margins to the results after tuning. Balancing precision and recall improves F1 scores for all the systems, which suggests that the simple tuning method performs quite well. Finally, we have an interesting observation that different methods have various scales of model scores.

5 Related Work

Linear structured learning methods have been proposed and widely used in the literature. Popular models include Structured Perceptron (Collins, 2002), Conditional Random Field (Lafferty et al., 2001) and Structured SVM (Taskar et al., 2004; Tsochantaridis et al., 2005). Recently, many structured learning models based on neural networks have been proposed and are widely used in language modeling (Bengio et al., 2006; Mikolov et al., 2010), sentiment classification (Socher et al., 2013), as well as parsing (Socher et al., 2011). Cortes et al. (2014) recently proposed a boosting framework which treats different structured learning algorithms as base learners to ensemble structured prediction results.

Tree-based models have been shown to provide more robust and accurate performances than neural networks in some tasks of computer vision (Roe et al., 2005; Babenko et al., 2011) and information retrieval (Li et al., 2007; Wu et al., 2010), suggesting that it is worth to investigate tree-based non-linear models for structured learning problems. To the best of our knowledge, TreeCRF (Dietterich et al., 2004) is the only work that explores tree-based methods for structured learning problems. The relationships between TreeCRF and our work have been discussed in Section 2.

Early research on entity linking has focused on well written documents (Bunescu and Pasca, 2006; Cucerzan, 2007; Milne and Witten, 2008). Due to the raise of social media, many techniques have been proposed or tailored to short texts including tweets, for the problem of entity linking (Ferragina and Scaiella, 2010; Meij et al., 2012; Guo et al., 2013) as well as the related problem of named entity recognition (NER) (Ritter et al., 2011). Recently, non-textual information such as spatial and temporal signals have also been used to improve entity linking systems (Fang and Chang, 2014). The task of entity linking has attracted a lot of attention, and many shared tasks have been hosted to promote entity linking research (Ji et al., 2010; Ji and Grishman, 2011; Cano and others, 2014; Carmel et al., 2014).

Building an end-to-end entity linking system involves in solving two interrelated sub-problems: mention detection and entity disambiguation. Earlier research on entity linking has been largely focused on the entity disambiguation problem, including most work on entity linking for well-written documents such as news and encyclopedia articles (Cucerzan, 2007) and also few for tweets (Liu et al., 2013). Recently, people have focused on building systems that consider mention detection and entity disambiguation jointly. For example, Cucerzan (2012) delays the mention detection decision and consider the mention detection and entity linking problem jointly. Similarly, Sil and Yates (2013) proposed to use a reranking approach to obtain overall better results on mention detection and entity disambiguation.

6 Conclusion and Future Work

In this paper, we propose S-MART, a family of structured learning algorithms which is flexible on the choices of the loss functions and structures. We demonstrate the power of S-MART by applying it to tweet entity linking, and it significantly outperforms the current state-of-the-art entity linking systems. In the future, we would like to investigate the advantages and disadvantages between tree-based models and other non-linear models such as deep neural networks or recurrent neural networks.

Abstract

We propose that entity queries are generated via a two-step process: users first select entity facts that can distinguish target entities from the others; and then choose words to describe each selected fact. Based on this query generation paradigm, we propose a new entity representation model named as entity factoid hierarchy. An entity factoid hierarchy is a tree structure composed of factoid nodes. A factoid node describes one or more facts about the entity in different information granularities. The entity factoid hierarchy is constructed via a factor graph model, and the inference on the factor graph is achieved by a modified variant of Multiple-try Metropolis algorithm. Entity retrieval is performed by decomposing entity queries and computing the query likelihood on the entity factoid hierarchy. Using an array of benchmark datasets, we demonstrate that our proposed framework significantly improves the retrieval performance over existing models.

1 Introduction

Entity retrieval, which aims at returning specific entities to directly answer a user's query, has drawn much attention these years. Various entity retrieval tasks have been proposed, such as TREC Entity (Balog et al., 2012; Wang et al., 2011) and INEX-LD (Wang et al., 2012; Wang and Kang, 2012). Many existing entity retrieval models follow the document retrieval assumption: when issuing queries, users choose the words that may appear in the "entity pseudo-document". Based on the assumption, these models construct internal entity representations by combining various entity descriptions, and use these representations to compute the rank of the candidate entities for a given entity query. These models include fielded versions of BM25 and Mixture of Language Models (Neumayer et al., 2012), Entity Language Model (Raghavan et al., 2004), Hierarchical Expert Model (Petkova and Croft, 2006), Structured Positional Entity Language Model (Lu et al., 2013).

However, a closer examination of entity queries reveals that most of them are not simple uniform word samples from the "entity pseudo-document". Instead, they can be decomposed into multiple parts, where each part describes a fact about target entities. For example, the query "National capitals situated on islands" describes two facts regarding a target entity: it is a national capital; it is located on an island. Compared to the assumption in document retrieval models, where query terms are assumed to be generated from a single document, these query terms can be regarded to be independently generated from two underlying documents. According to this observation, we propose that an entity query is generated via a two-step process: users first select facts that can distinguish target entities from the others; and then choose words that describe the selected facts. Based on the proposed query generation paradigm, we design a new entity retrieval framework. On one hand, an entity is modeled to have multiple internal representations, each regarding one or more closely related facts. On the other hand, an entity query is decomposed into one or more subqueries, each describing a fact about target entities. In this way, entity retrieval can be performed by combining the probabilities of subqueries being satisfied for each candidate entity.

One of the central components of our proposed

retrieval framework is a novel entity representation known as entity factoid hierarchy. An entity factoid hierarchy is a tree structure composed of factoid nodes, which is automatically constructed from a collection of entity descriptions. We abuse the term "factoid" to denote a single piece of information regarding an entity. A factoid node in the hierarchy describes one or more factoids. Factoid nodes in different levels capture the information of different levels of detail (referred to as information granularities hereafter), where lower level nodes contain more detailed information and higher level nodes abstract the details away. The entity factoid hierarchy is constructed via a factor graph model, and the inference on the factor graph is achieved by a modified variant of Multiple-try Metropolis algorithm. Each factoid node is indexed separately as a pseudo-document. During retrieval, the query likelihood for a candidate entity are computed by transversing the factoid hierarchy. Compared to exiting entity retrieval models, our proposed framework exhibits two advantages:

- By organizing entity descriptions in a hierarchical structure, detailed entity information is preserved and we can return finer confidence value. Suppose that the entity "Barack Obama" is only described by one sentence: "born in 1961". Traditional entity models, which model an entity as a pseudo-document, would return high confidence value for the query "who is born in 1961". However, as we add more and more sentences to describe "Barack Obama", the confidence value returned for the query decreases due to the longer entity pseudo-document. This result is not desirable for entity retrieval, since adding more descriptions about other facts should not affect the confidence of existing facts. Our factoid hierarchy avoids this problem by preserving all the entity descriptions in a hierarchical structure. When performing retrieval, entity factoid hierarchy can be traversed to locate the best supporting description for the query.
- By separating entity facts in different factoid nodes, our model prevent ambiguity caused by mixing terms describing different facts. Suppose "Barack Obama" is described by two sentences: "Barack Obama is a president of United States" and "Barack Obama is a graduate of Harvard Law School", and our query is "Who is a president of Harvard Law School". A traditional document retrieval model with a bag-of-word entity pseudo-document would return "Barack Obama" with high confidence, since all the query terms appear in the entity descriptions. But obviously, this result is not correct. In our factoid hierarchy, these two facts are separated in lower level factoid nodes. While higher level nodes are still mixed with terms from child nodes, they are penalized to avoid giving high confidence value.

2 Factoid Hierarchy

2.1 Hierarchy Representation

As mentioned in the previous section, all the information regarding an entity is organized in a particular factoid hierarchy. We denote the term "factoid" as a single piece of information regarding an entity, such as the birth date of Barack Obama. A factoid node in the hierarchy describes one or more factoids. Each factoid node is associated with a bag-of-words vector to represent the factoid description. Factoid nodes in different depth encode information in different granularities.

An example of an entity factoid hierarchy, regarding two factoids (birth date and birth place) about Barack Obama, is given in Figure 1. The example hierarchy is constructed from three sentences about Barack Obama: he was born in 1961; he was born in August 1961; he was born in Honolulu Hawaii. These three sentences correspond to the leaf nodes A, B, and C respectively in Figure 1. In general, a leaf node in the factoid hierarchy comes directly from a sentence or a RDF triple describing the entity. Since it is extracted either from human written texts or from manually crafted structured databases, a leaf node represents the most exact representation regarding one or more factoids. During the construction of the hierarchy, intermediate nodes are formed as parents for nodes that contain closely related factoids. The factoid description for an intermediate node is the sum of bag-of-words vectors of its child nodes. In this way, intermediate nodes capture the words that are used more frequently with higher weights to describe the underlying factoids in a more general form. As we merge more nodes and move up in the hierarchy, intermediate nodes become blended with more different factoids. Node D in Figure 1 is an intermediate factoid node, as a parent node for nodes A and B both describing the birth date. The root node in an entity factoid hierarchy summarizes all the descriptions regarding an entity, which is similar to the "entity pseudo-document" used in some existing entity retrieval models. Each entity factoid hierarchy has only one root node. For example, node E in Figure 1 is the root node, and it contains words from all the three sentences.

Note that the depth of a leaf node varies with the number of descriptions associated with the factoids. Some factoids may be associated with lots of detailed information and are expressed in many sentences, while others are only expressed in one or two sentences. For example, the factoid that Obama is elected president in 2008 may be described in many sentences and in different contexts; while the factoid that Obama is born in Kapiolani Maternity & Gynecological Hospital is only mentioned in a few sentences. In this case, factoid nodes associated with more details may have deeper hierarchical structure.

2.2 Factor Graph Model

To construct the entity factoid hierarchy, we make use of a hierarchical discriminative factor graph model. A similar factor graph model has been proposed to solve the coreference resolution in (Singh et al., 2011; Wick et al., 2012). Here we design a factor graph model corresponding to the entity factoid hierarchy, together with new factor types and inference mechanism.

Generally speaking, a factor graph is composed of two parts: a set of random variables and a set of factors that model the dependencies between random variables. An example of the factor graph construction corresponding to the factoid hierarchy involved in Figure 1 is given in Figure 2. In our factor graph approach, each factoid is represented as a random variable f_i, corresponding to a rounded square node in Figure 2. The pairwise binary decision variable y_{ij}, denotes whether a factoid f_i is a child of another factoid f_j corresponding to a circle node in Figure 2. The set of factoids F plus the set of decision variables $\mathbf{y}$ are the random variables in our factor graph model. To model the dependency between factoids, we consider two types of factors. Ψ_p is the set of factors that consider the compatibility between two factoid nodes, i.e., to indicate whether two nodes have parent-child relationship. Ψ_u is the set of factors that measure the compatibility of the factoid node itself. Such factor is used to check whether a new intermediate node should be created. Factors are represented as square nodes in Figure 2. Given a factor graph model $\mathbf{m}$, our target is to find the best assignments for the decision variable $\mathbf{y}$ that maximizes the objective function in Equation (1).

$$P(\mathbf{y}, F|\mathbf{m}) = \prod_{f \in \mathcal{F}} \Psi_p(f, f^p)\Psi_u(f) \qquad (1)$$

2.3 Factors Design

The pairwise factors Ψ_p and unit-wise factors Ψ_u compute the compatibility scores among factoid nodes. Each factor type is associated with a weight w to indicate the importance of the factor during inference. For the notation, the bag-of-words representation for a factoid node is denoted as d. We use superscripts p and c to denote the variables of parent nodes and child nodes. To capture the interrelations between factoid nodes, the following factors are used in our factor graph model.

Bag-of-words similarity To check whether two factoid nodes refer to the same fact, we compare the similarity between their bag-of-words descriptions. We choose Kullback-Leibler divergence (KL divergence) as the similarity measure. By definition, the KL divergence of Q from P, denoted $D_{KL}(P||Q)$, is a measure of the informa-

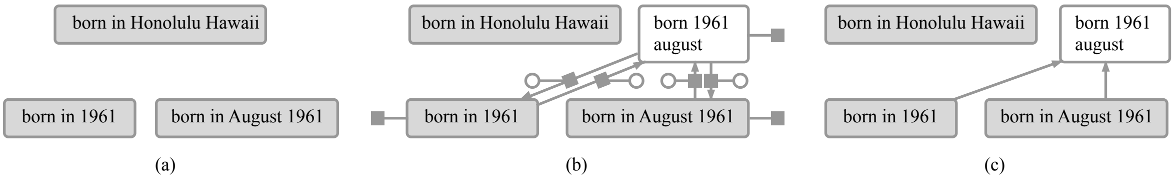

Figure 2: Generation of an factoid hierarchy via factor graph inference. Factoid nodes are initialized as singletons in (a). During one step of sampling in (b), two factoid nodes are selected and one proposal is to add a common parent. If we accept the proposal, we end up with the factoid hierarchy in (c).

tion lost when Q is used to approximate P. It is a non-symmetric measure and fits in our problem nicely, i.e., measuring whether a parent node is a more abstract representation of its child node. The compatibility score is computed as:

$$\begin{aligned} & - w_1 \cdot D_{KL}(d^p || d^q) \\ = & - w_1 \cdot \sum_{i=1}^{m} d_i^p \times \log\left(\frac{d_i^p}{d_i^c}\right), \end{aligned} \quad (2)$$

where d_i^p is the smoothed term frequency of the factoid description for the parent node; d_i^c is for the child node; w_1 is a global weighting parameter among different factors. In fact, we have also explored other popular text similarity metrics summarized in (Huang, 2008), and find that KL divergence performs the best.

Entropy penalty We penalize the entropy of the factoid description to encourage a smaller vocabulary of words describing the underlying factoids:

$$-w_2 \cdot \frac{H(d)}{\log ||d||_0}, \quad (3)$$

where $H(d)$ denotes the Shannon entropy for the bag-of-words representation of the factoid description d; $||d||_0$ is the number of unique terms in the factoid description.

Structure penalty The depth of a factoid node indicates the level of information granularity. However, we also need to control the depth of the factoid hierarchy. A factoid node should not have too many levels. We define the depth penalty as:

$$-w_3 \cdot |n_d - \frac{||d||_0}{s}|, \quad (4)$$

where n_d is the depth of a factoid node and s is the parameter that controls the average depth of factoid nodes per term. In this way, we can control the average depth of factoid nodes in the entity factoid hierarchy.

2.4 Inference

Exact inference is impossible for our factor graph model due to the large state space. Here we adopt a modified variant of Multiple-try Metropolis algorithm to conduct maximum probability estimation for inference, following the work in (Wick et al., 2013). At each sampling step, multiple changes to the current setting are proposed. The acceptance probability for a given proposal is equal to the likelihood ratio of the proposed hypothesis to the current hypothesis. In our case, we initialize the MCMC procedure to the singleton configuration, where each entity description, such as a sentence or a RDF triple, forms its own factoid hierarchy initially. At each sampling step, we randomly select two nodes and propose several alternative local modifications. If f_i and f_j are not connected, i.e., sharing no common child nodes, the following changes are proposed:

- Add factoid f_i as the parent of f_j, if f_j has no parent node;
- Remove f_j from its current parent, if f_j has a parent;
- Create a new common parent for f_i and f_j, if both f_i and f_j have no parent.

Otherwise, if f_i and f_j are in the same cluster, the following changes are proposed:

- Remove f_j from its current parent;
- Move f_j's children to f_j's parent and delete f_j, if f_j is an intermediate node.

A sampling step of the inference process is illustrated in Figure 2. Initially, all the decision variables $\mathbf{y}$ are set to zero. That is, each factoid node is regarded as forming its own factoid hierarchy, as illustrated in Figure 2(a). During the inference, local modifications are proposed to the current factor graph hypothesis. For example, in Figure 2(b), the two factoid nodes at the bottom are selected and proposed to add a new intermediate factoid as their common parent. If we accept the proposal, we get an intermediate factoid hierarchy as illustrated in Figure 2(c).

The sampling process is iterated until no proposal has been accepted in a certain number of successive steps, or a maximum number of steps has been reached. Each entity factoid hierarchy is inferred separately, allowing us to parallelize the inference across multiple machines.

3 Entity Retrieval

3.1 Retrieval Model

After we preprocess available information sources and construct the entity factoid hierarchy, we are ready to answer entity queries. Our retrieval model is based on the query likelihood model. Using Bayes' rule, the probability that an entity e is a target entity for a query q can be written as:

$$p(e|q) = \frac{p(q|e)p(e)}{p(q)}. \tag{5}$$

The probability of the query $p(q)$ is the same for all entities and can be ignored. Furthermore, we assume that the prior probability of an entity being a target entity is uniform. Thus, $p(e)$ can also be ignored. The task is to rank an entity e in response to a query q by estimating the query generation probability $p(q|e)$.

To compute $p(q|e)$, recall that our two-step query generation process assumes that users generate queries by first selecting facts and then choosing query words for each fact. Based on the query generation process, we first decompose the query q into m subqueries q_i (discussed in Section 3.2). Then the probability $p(q|e)$ can be computed as:

$$\begin{aligned} p(q|e) &= \prod_{i=1}^{m} p(q_i|e) && (6) \\ &= \prod_{i=1}^{m} \sum_{k=1}^{n} p(q_i|f_k)p(f_k|e) && (7) \\ &\simeq \prod_{i=1}^{m} \max_k p(q_i|f_k). && (8) \end{aligned}$$

Equation (6) decomposes the query into subqueries, assuming that all the subqueries are independent. Equation (7) iterates through all the factoid nodes f_k in the factoid hierarchy of an entity e. Equation (8) simplifies the computation by assuming that the underlying factoid generating subquery q_i is the factoid f_k with the highest query generation probability.

To compute $p(q_i|f_k)$, the probability of the factoid f_k generating the subquery q_i, we use the multinomial unigram language model:

$$p(q_i|f_k) = e(f_k) \prod_j p(t_i^j|f_k), \tag{9}$$

where t_i^j is the term j in the subquery q_i. $e(f_k)$ is the penalty term for factoids containing many children:

$$e(f_k) = w \cdot \frac{1}{c(f_k)}, \tag{10}$$

where $c(f_k)$ is the number of child nodes for f_k. To understand why we add this penalty term, consider a query "who is born in 2008". Suppose "Barack Obama" is described by two sentences: "born in 1961" and "elected president in 2008". When computing $p(q_i|f_k)$ for the root node, although it contains both the terms "born" and "2008", it should be penalized since the terms come from two different child nodes.

3.2 Query analysis

As mentioned earlier, we decompose the original query q into multiple factoid subqueries q_i. For long queries issued in a verbose sentence, such as "which presidents were born in 1945", dependency parsing is performed (Klein and Manning, 2003) and the resulting dependency tree is used to split the original query. For short queries issued in keywords, such as "vietnam war movies", we decompose it based on possible key concepts expressed in the query. Usually a short query only contains a single entity, which is used to segment the original query into subqueries.

Furthermore, stop structures in verbose queries is removed, following the method proposed in (Huston and Croft, 2010). Here a stop structure is defined as a phrase which provides no information regarding the information needs, such as "tell me the". We also inject target entity type information by replacing the leading "who " as "person", and "where" as "place" for all the queries.

3.3 Retrieval Process

For the purpose of retrieval, each node in the entity factoid hierarchy is regarded as a pseudo-document describing one or more factoids about the entity, and is indexed as a bag-of-words document during the preprocessing. The retrieval is performed in a two-step process. First, for each individual subquery, we retrieve top 1000 candidate entities by performing retrieval on all root nodes. This gives us an initial pool of candidate entities by merging the returned entities for subqueries. After that, for each candidate entity, we traverse its factoid hierarchy and compute the query generation probability $p(q|e)$ using Equations (8) and (9). Top ranked entities are returned as retrieval results.

4 Experiments

4.1 Dataset

We perform entity retrieval experiments using the DBpedia-Entity dataset used in (Balog and Neumayer, 2013). The dataset is a mixture of multiple entity retrieval datasets, covering entity queries of various styles such as keyword queries like "vietnam war movies" and verbose queries like "What is the capital of Canada". Some query statistics are shown in Table 2.

Query set	#query	avg($|q|$)	avg(#rel)
INEX-XER	55	5.5	29.7
TREC Entity	17	6.7	12.9
SemSearch ES	130	2.7	8.6
SemSearch LS	43	5.4	12.5
QALD-2	140	7.9	41.2
INEX-LD	100	4.8	36.8
Total	485	5.3	26.7

Table 2: DBpedia-Entity dataset statistics

The data corpus we use are DBpedia 3.9 and the corresponding English Wikipedia data dump on April 4, 2013. It should be noted that the original DBpedia-Entity benchmark only uses DBpedia for entity modeling (Balog and Neumayer, 2013). In our experiments, we also conducted another set of experiments which include full-text Wikipedia articles as additional entity descriptions, to evaluate the capacity of different models on handling free texts as information sources.

4.2 Comparison models and variants of our model

For comparison, we have implemented the following two existing models:

- **BM25**. BM25 is a popular document retrieval method and also used to perform entity retrieval (Balog and Neumayer, 2013). All the descriptions about an entity are aggregated into an entity pseudo-document. We use $k_1 = 1.2, b = 0.8$ for the model parameter, similar to the original papers.

- **MLM-tc**. The Mixture of Language Model represents an entity as a document with multiple fields, where each field is given a different weight for generating the query terms. MLM is often adopted to do entity retrieval (Neumayer et al., 2012). Here we adopt the MLM-tc model used in (Balog and Neumayer, 2013), where two fields are considered: title and content fields (described in Section 4.3). The parameters used are 0.8 for the title field and 0.2 for the content field.

Note that both MLM-tc and BM25 are also compared in (Balog and Neumayer, 2013), and have shown the best MAP performances among all the compared models.

For our models, the following two variants are implemented and compared.

- **Factoid Retrieval Model with Hierarchy (FRMwH)**. Our full model uses entity factoid graph as entity representation. Each factoid node is indexed as a bag-of-words document. The retrieval model described in Section 3 is employed.

- **Factoid Retrieval Model (FRM)**. This model does not use entity factoid hierarchy as entity representation. Instead, K-Means clustering algorithm is used to cluster the sentences into text clusters. Each text cluster is then indexed as a document. Compared to the FRMwH model, an entity only has a flat cluster of factoid descriptions. The same retrieval model is used.

All the four models use the same query preprocessing techniques.

4.3 Setup

The entity descriptions come from texts in Wikipedia articles and structured information from DBpedia. For DBpedia information, we consider top 1000 most frequent predicates as fields. We convert RDF predicates to free text by breaking the camelcase predicate name to terms, for example "birthPlace" is converted to "birth place". For Wikipedia texts, we first remove all markup text such as images, categories. Infoboxes are also

Table 1: Retrieval performance for various models

removed since the information is already well captured in DBpedia. Each Wikipedia article is then segmented to a list of sentences, which are considered as factoid descriptions regarding the entity.

For the BM25 model, all the descriptions about an entity are aggregated into an entity pseudo-document. For the MLMtc model, the *title* field is constructed by combining DBpedia properties whose property names are ending with "title", "name" or "label", such as "fullName" (Neumayer et al., 2012), and the *content* field is the same as the entity pseudo-document used in the BM25 model.

The inference algorithm for the entity factoid hierarchy is implemented based on the factorie package (McCallum et al., 2009). The parameters used in the inference are manually tuned on a small set of entities. The retrieval algorithms, including BM25 and Language Modeling, are implemented based on Apache Lucene[1]. For language models, Bayesian smoothing with Dirichlet priors is used, with parameter $\mu = 2000$. For FRM, to cluster the entity descriptions, we use the K-Means clustering algorithm implemented in Carrot2[2].

4.4 Results

We report two standard retrieval measures: mean average precision (MAP) and precision at 10 (P@10). Top 100 ranked entities are evaluated for each query. Two set of experiments are conducted: experiments with only DBpedia information; experiments with both DBpedia and Wikipedia information. The experiment result is shown in Table 1. To conduct the statistical significance analysis, we use two-tailed paired t-test at the 0.05 level. The symbols underline and wave underline are used to indicate significant improvement of our model compared with the BM25 and MLM-tc models respectively.

The first set of rows in Table 1 show the performance of four models using only DBpedia information. Both of our models have better overall performance. On datasets with verbose queries, such as INEX-XER and TREC Entity, both our models outperform the baseline models. One reason is that our retrieval model relies on the assumption that verbose queries can be decomposed into multiple subqueries. The second set of rows show the performance of four models using both DBpedia and Wikipedia information. After adding the additional information from Wikipedia articles, MLM-tc attains much worse performance, while BM25 performs roughly the same. One possible reason is that Wikipedia articles contain much irrelevant information regarding entities, and these two existing models cannot easily make use of additional information. In contrast, with Wikipedia full-text available, both of our proposed models achieve obviously better performances.

Our full model, FRMwH, has shown consistently better overall performance compared with the FRM model. It demonstrates that it is worthwhile to employ our proposed entity hierarchical structure for entity representation.

4.5 Analysis

For the retrieval performance, we also perform a topic-level analysis between our model FRMwH and the baseline model BM25, shown in Figure 3. The X-axis represents individual query topics, ordered by average precision difference (shown on the Y-axis). Positive Y value indicates that FRMwH performs better than the BM25 model for the query. From the figure, most of

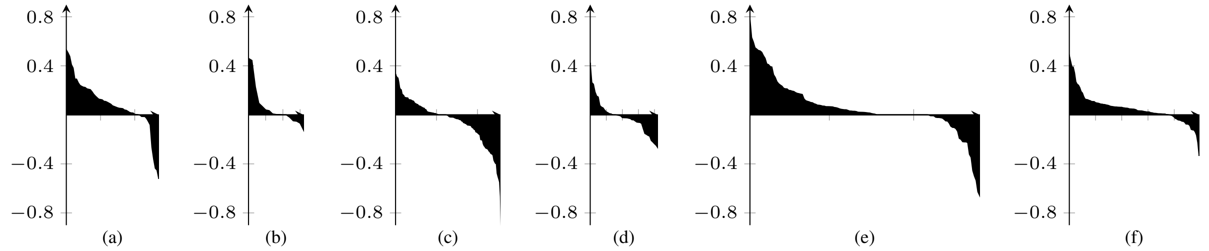

Figure 3: Topic-level differences between FRMwH and BM25. Positive values mean FRMwH is better. (a) INEX-XER; (b) TREC Entity; (c) SemSearch ES; (d) SemSearch LS; (e) QALD-2; (f) INEX-LD.

queries are affected by using FRMwH model. On the datasets with verbose queries, such as INEX-XER and TREC Entity, we can see most of the query are improved. FRMwH performs slightly worse for datasets like SemSearch ES which is mostly composed of keyword queries. For the queries that show little or no performance differences, manual inspection shows that both models fail to find any relevant results, due to the lack of supporting descriptions in Wikipedia and DBpedia.

5 Related Work

Besides the entity retrieval models reviewed in Section 1, there are models that do not maintain an explicit entity representation. Instead, they compute the entity relevance score based on the co-occurance between entities and query terms in the documents directly. Most of these models are originally proposed for expertise retrieval, where the appearance of a person name indicates the association with the expertise mentioned in the same document. Typical models include voting model (Macdonald and Ounis, 2006), graph model (Serdyukov et al., 2008), etc. However, it is not easy to generalize these models for open domain entity retrieval.

Entity models are also used in other fields besides entity retrieval. For example, entity topic models are used to perform entity prediction, classification of entity pairs, construction of entity-entity network (Newman et al., 2006), as well as entity linking (Han and Sun, 2012). These models are not suitable for our retrieval framework.

The decomposing of entity queries into factoid queries is related to query segmentation. Query segmentation has been used by search engines to support inverse lookup of words and phrases (Risvik et al., 2003; Bergsma and Wang, 2007). Our use of query decomposition is quite different compared to query segmentation. Besides query segmentation, query decomposition has also been used to facilitate the acquisition and optimization of high-order contextual term associations (Song et al., 2012).

Our work is also related to the information extraction and knowledge representation field since our framework involves extraction and aggregation of knowledge from free texts. However, most existing approaches takes two extreme ways: either extract relations based on pre-defined ontology, such as DBpedia (Lehmann et al., 2014); or cluster relation without referring to some ontology, such as OpenIE (Etzioni et al., 2011). Though our main goal is not on constructing a complete knowledge base, we do leverage both existing knowledge bases as well as free text data.

Semantic search also targets on returning answers directly (Pound et al., 2010; Blanco et al., 2011; Tonon et al., 2012; Kahng and Lee, 2012). However, they are mainly based on structured linked data, as well as structured query language like SPARQL. While this is an effective approach if we have a powerful thorough knowledge base, in practice many facts cannot be effectively represented as linked data. Only a small set of relations (thousands in DBpedia) have been defined in the ontology, such as “birthPlace”. Furthermore, even if we can define a formal representation of human knowledge, retrieve them effectively is still a problem due to the difficulty of transforming the human query into a structured query on a knowledge base.

6 Conclusions

We propose that an entity query is generated in a two-step process: users first select the facts that can distinguish target entities from the others; then choose words to express those facts. Following this motivation, we propose a retrieval framework by decomposing the original query into factoid queries. We also propose to construct an entity factoid hierarchy as the entity model for the purpose of entity retrieval. Our entity factoid hierarchy can integrate information of different granularities from both free text and structured data. Extensive experiments demonstrate the effectiveness of our framework.

Abstract

Document enrichment focuses on retrieving relevant knowledge from external resources, which is essential because text is generally replete with gaps. Since conventional work primarily relies on special resources, we instead use triples of *Subject, Predicate, Object* as knowledge and incorporate distributional semantics to rank them. Our model first extracts these triples automatically from raw text and converts them into real-valued vectors based on the word semantics captured by Latent Dirichlet Allocation. We then represent these triples, together with the source document that is to be enriched, as a graph of triples, and adopt a global iterative algorithm to propagate relevance weight from source document to these triples so as to select the most relevant ones. Evaluated as a ranking problem, our model significantly outperforms multiple strong baselines. Moreover, we conduct a task-based evaluation by incorporating these triples as additional features into document classification and enhances the performance by 3.02%.

1 Introduction

Document enrichment is the task of acquiring relevant background knowledge from external resources for a given document. This task is essential because, during the writing of text, some basic but well-known information is usually omitted by the author to make the document more concise. For example, *Baghdad is the capital of Iraq* is omitted in Figure 1a. A human will fill these gaps automatically with the background knowledge in his mind. However, the machine lacks both the necessary background knowledge and the ability to select. The task of document enrichment is proposed to tackle this problem, and has been proved helpful in many NLP tasks such as web search (Pantel and Fuxman, 2011), coreference resolution (Bryl et al., 2010), document cluster (Hu et al., 2009) and entity disambiguation (Sen, 2012).

We can classify previous work into two classes according to the resources they rely on. The first line of work uses *Wikipedia*, the largest on-line encyclopedia, as a resource and introduces the content of Wikipedia pages as external knowledge (Cucerzan, 2007; Kataria et al., 2011; He et al., 2013). Most research in this area relies on the text similarity (Zheng et al., 2010; Hoffart et al., 2011) and structure information (Kulkarni et al., 2009; Sen, 2012; He et al., 2013) between the mention and the Wikipedia page. Despite the apparent success of these methods, most Wikipedia pages contain too much information, most of which is not relevant enough to the source document, and this causes a noise problem. Another line of work tries to improve the accuracy by introducing ontologies (Fodeh et al., 2011; Kumar and Salim, 2012) and structured knowledge bases such as WordNet (Nastase et al., 2010), which provide semantic information about words such as synonym (Sun et al., 2011) and antonym (Sansonnet and Bouchet, 2010). However, these methods primarily rely on special resources constructed with supervision or even manually, which are difficult to expand and in turn limit their applications in practice.

In contrast, we wish to seek the benefits of both coverage and accuracy from a better representation of background knowledge: triples of *Subject, Predicate, Object* (SPO). According to Hoffart et al. (2013), these triples, such as *LeonardCohen, wasBornIn, Montreal*, can be extracted automatically from Wikipedia and other sources, which is compatible with the RDF data model (Staab and Studer, 2009). Moreover, by extracting these

(a) Source document: air strike aiming at Saddam in Baghdad

(b) Two omitted relevant pieces of background knowledge

Figure 1: An example of document enrichment: A source document about a U.S. air strike omitting two important pieces of background knowledge which are acquired by our framework.

triples from multiple sources, we also get better coverage. Therefore, one can expect that this representation is helpful for better document enrichment by incorporating both accuracy and coverage. In fact, there is already evidence that this representation is helpful. Zhang et al. (2014) proposed a triple-based document enrichment framework which uses triples of SPO as background knowledge. They first proposed a search engine–based method to evaluate the relatedness between every pair of triples, and then an iterative propagation algorithm was introduced to select the most relevant triples to a given source document (see Section 2), which achieved a good performance.

However, to evaluate the semantic relatedness between two triples, Zhang et al. (2014) primarily relied on the text of triples and used search engines, which makes their method difficult to re-implement and in turn limits its application in practice. Moreover, they did not carry out any task-based evaluation, which makes it uncertain whether their method will be helpful in real applications. Therefore, we instead use topic models, especially *Latent Dirichlet Allocation* (LDA), to encode distributional semantics of words and convert every triple into a real-valued vector, which is then used to evaluate the relatedness between a pair of triples. We then incorporate these triples into the given source document and represent them together as a graph of triples. Then a modified iterative propagation is carried out over the entire graph to select the most relevant triples of background knowledge to the given source document.

To evaluate our model, we conduct two series of experiments: (1) evaluation as a ranking problem, and (2) task-based evaluation. We first treat this task as a ranking problem which inputs one document and outputs the top N most-relevant triples of background knowledge. Second, we carry out a task-based evaluation by incorporating these relevant triples acquired by our model into the original model of document classification as additional features. We then perform a direct comparison between the classification models with and without these triples, to determine whether they are helpful or not. On the first series of experiments, we achieve a *MAP* of 0.6494 and a *P@N* of 0.5597 in the best situation, which outperforms the strongest baseline by 5.87% and 17.21%. In the task-based evaluation, the enriched model derived from the triples of background knowledge performs better by 3.02%, which demonstrates the effectiveness of our framework in real NLP applications.

2 Background

The most closely related work in this area is our own (Zhang et al., 2014), which used the triples of *SPO* as background knowledge. In that work, we first proposed a *triple graph* to represent the source document and then used a search engine–based iterative algorithm to rank all the triples. We describe this work in detail below.

Triple graph Zhang et al. (2014) proposed the *triple graph* as a document representation, where the triples of *SPO* serve as nodes, and the edges between nodes indicate their semantic relatedness. There are two kinds of nodes in the triple graph: (1) source document nodes (*sd-nodes*), which are triples extracted from source documents, and (2) background knowledge nodes (*bk-nodes*), which are triples extracted from external sources. Both of them are extracted automatically with *Reverb*, a well-known *Open Information Extraction* system (Etzioni et al., 2011). There are also two kinds of edges: (1) an edge between a pair of sd-nodes, and (2) an edge between one sd-node and another bk-node, both of which are unidirectional. In the original representation, there are no edges between two bk-nodes because they treat the bk-nodes as recipients of relevance weight only. In this paper, we modify this setup and connect every pair of bk-nodes with an edge, so the bk-nodes serve as intermediate nodes during the iterative propagation process and contribute to the final performance too as shown in our experiments (see Section 5.1).

Relevance evaluation To compute the weight of a edge, Zhang et al. (2014) evaluate the semantic relatedness between two nodes with a search engine–based method. They first convert every node, which is a triple of *SPO*, into a query by combining the text of *Subject* and *Object* together. Then for every pair of nodes t_i and t_j, they construct three queries: p, q, and $p \cap q$, which correspond to the queries of t_i, t_j, and $t_j \cap t_j$, the combination of t_i and t_j. All these queries are put into a search engine to get $H(p)$, $H(q)$, and $H(p \cap q)$, the numbers of returned pages for query p, p, and $p \cap q$. Then the *WebJaccard Coefficient* (Bollegala et al., 2007) is used to evaluate $r(i, j)$, the relatedness between t_i and t_j, according to Formula 1.

$$r(i,j) = WebJaccard(p,q) = \begin{cases} 0 & \text{if } H(p \cap q) \leq C \\ \dfrac{H(p \cap q)}{H(p) + H(q) - H(p \cap q)} & \text{otherwise.} \end{cases} \tag{1}$$

Using $r(i, j)$, Zhang et al. (2014) further define $p(i, j)$, the probability of t_i and t_j propagating to each other, as shown in Formula 2. Here N is the set of all nodes, and $\delta(i, j)$ denotes whether an edge exists between two nodes or not.

$$p(i,j) = \frac{r(i,j) \times \delta(i,j)}{\sum_{n \in N} r(n,j) \times \delta(n,j)} \tag{2}$$

Iterative propagation Considering that the source document D is represented as a graph of sd-nodes, so the relevance of background knowledge t_b to D is naturally converted into that of t_b to the graph of sd-nodes. Zhang et al. (2014) evaluate this relevance by propagating relevance weight from sd-nodes to t_b iteratively. After convergence, the relevance weight of t_b will be treated as the final relevance to D. There are in total $n \times n$ pairs of nodes, and their $p(i, j)$ are stored in a matrix P. Zhang et al. (2014) use $\vec{W} = (w_1, w_2, \ldots, w_n)$ to denote the relevance weights of nodes, where w_i indicates the relevance of t_i to D. At the beginning, each w_i of bk-nodes is initialized to 0, and each that of sd-nodes is initialized to its importance to D. Then $\vec{W}$ is updated to $\vec{W}'$ after every iteration according to Formula 3. They keep updating the weights of both sd-nodes and bk-nodes until convergence and do not distinguish them explicitly.

$$\begin{aligned} \vec{W}' &= \vec{W} \times P \\ &= \vec{W} \times \begin{bmatrix} p(1,1) & p(1,2) & \ldots & p(1,n) \\ p(2,1) & p(2,2) & \ldots & p(2,n) \\ \ldots & \ldots & \ldots & \ldots \\ p(n,1) & p(n,2) & \ldots & p(n,n) \end{bmatrix} \end{aligned} \tag{3}$$

3 Methodology

The key idea behind this work is that every document is composed of several units of information, which can be extracted into triples automatically. For every unit of background knowledge b, the more units that are relevant to b and the more relevant they are, the more relevant b will be to the source document. Based on this intuition, we first present both source document information and background knowledge together as a document-level triple graph as illustrated in Section 2. Then we use LDA to capture the distributional semantics of a triple by representing it as a vector of distributional probabilities over k topics and evaluate the relatedness between two triples with cosine-similarity. Finally, we propose a modified iterative process to propagate the relevance score from the source document information to the background knowledge and select the top n relevant ones.

3.1 Encoding distributional semantics

LDA LDA is a popular generative probabilistic model, which was first introduced by Blei et al. (2003). LDA views every document as a mixture over underlying topics, and each topic as a distribution over words. Both the document-topic and the topic-word distributions are assumed to have a *Dirichlet prior*. Given a set of documents and a number of topics, the model returns θ_d, the topic distribution for each document d, and ϕ_z, the word distribution for every topic z.

LDA assumes the following generative process for each document in a corpus D:

1. Choose $N \sim Poisson(\xi)$.
2. Choose $\theta \sim Dir(\alpha)$.
   (a) Choose a topic $z_n \sim Multinomial(\theta)$.
   (b) Choose a word w_n from $p(w_n|z_n, \beta)$ conditioned on the topic z_n.

Here the dimensionality k of the Dirichlet distribution (and thus the dimensionality of the topic vari-

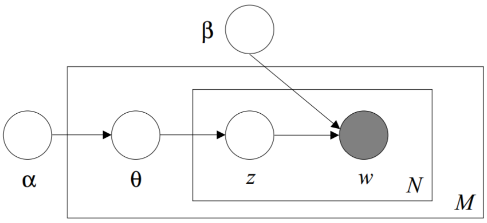

Figure 2: Graphical representation of LDA. The boxes represents replicates, where the inner box represents the repeated choice of N topics and words within a document, while the outer one represents the repeated generation of M documents.

able z) is assumed to be known and fixed; θ is a k-dimensional Dirichlet random variable, where the parameter α is a k-vector with components $\alpha_i > 0$; and the β indicates the word probabilities over topics, which is a matrix with $\beta_{ij} = p(w^j = 1|z^i = 1)$. Figure 2 shows the representation of LDA as a probabilistic graphical model with three levels. There are two corpus-level parameters α and β , which are assumed to be sampled once in the process of generating a corpus; one document-level variable θ_d, which is sampled once per document; and two word-level variables z_{dn} and w_{dn}, which are sampled once for each word in each document.

We employ the publicly available implementation of LDA, JGibbLDA2[1] (Phan et al., 2008), which has two main execution methods: parameter estimation (model building) and inference for new data (classification of a new document).

Relevance evaluation Given a set of documents and the number of topics k, LDA will return ϕ_z, the word distribution over the topic z. So for every word w_n, we get k distributional probabilities over k topics. We use $p_{w_n z_i}$ to denote the probability that w_n appears in the i^{th} topic z_i, where $i \leq k$, $z_i \in Z$, the set of k topics. Then we combine these k possibilities together as a real-valued vector $\vec{v}_{w_n}$ to represent w_n as shown in Formula 4.

$$\vec{v}_{w_n} = (p_{w_n z_1}, p_{w_n z_2}, \ldots, p_{w_n z_k}) \tag{4}$$

After getting the vectors of words, we employ an intuitive method to compute the vector of a triple t, by accumulating all the corresponding vectors of words appearing in t according to Formula 5. Considering that the elements of this newly generated vector indicate the distributional probabilities of t over k topics, we then normalize it according to Formula 6 so that its elements sum to 1. This gives us $\vec{v}_t$, the real-valued vector of triple t, which captures its distributional probabilities over k topics. Here t corresponds to a triple of background knowledge or of source document, p_{tz_i} indicates the possibility of t to appear in the i^{th} topic z_i, and $w_n \in t$ means that w_n appears in t.

$$p_{tz_i} = \sum_{w_n \in t} p_{w_n z_i} \tag{5}$$

$$\vec{v}_t = \frac{(p_{tz_1}, p_{tz_2}, \ldots, p_{tz_k})}{\sum_{i=1}^{k} p_{tz_i}} \tag{6}$$

Using the vectors of triples, we can easily compute the semantic relatedness between a pair of triples as their cosine-similarity according to Formula 7. Here A, B correspond to the real-valued vectors of two triples, $r(A,B)$ denotes their semantic relatedness, and k is the number of topics, which is also the length of A (or B). A high value of $r(A,B)$ usually indicates a close relatedness between A and B, and thus a higher probability of propagating to each other in the following modified iterative propagation illustrated in Section 3.2.

$$\begin{aligned} r(A,B) = &\cos(A,B) = \frac{AB}{\|A\|\|B\|} \\ = &\frac{\sum_{i=1}^{k} A_i B_i}{\sqrt{\sum_{i=1}^{k}(A_i)^2}\sqrt{\sum_{i=1}^{k}(B_i)^2}} \end{aligned} \tag{7}$$

3.2 Modified iterative propagation

In this part, we propose a modified iterative propagation based ranking model to select the most-relevant triples of background knowledge. There are three primary modifications to the original model of Zhang et al. (2014), all of which are shown more powerful in our experiments.

First of all, the original model (Zhang et al., 2014) does not reset the relevance weight of sd-nodes after every iteration. This results in a continued decrease of the relevance weight of sd-nodes, which weakens the effect of sd-nodes during the iterative propagation and in turn affects the final performance. To tackle this problem, we decrease the relevance weight of bk-nodes and increase that of sd-nodes according to a fixed ratio after every iteration, so as to ensure that the total weight of sd-nodes is always higher than that of bk-nodes. Note that although the relevance weights of bk-nodes are changed after the redistribution, the corresponding ranking of them is not changed because the redistribution is carried out

[1] http://jgibblda.sourceforge.net/

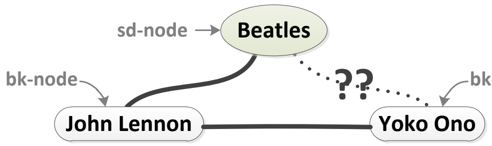

Figure 3: The edge between two bk-nodes helps in the better evaluation of relatedness between the bk-node *Yoko Ono* and the sd-node *Beatles*.

over all nodes accordingly. In our experiments, we tried different ratios and finally chose 10:1, with sd-nodes corresponding to 10 and bk-nodes to 1, which achieved the best performance.

In addition, we also modify the triple graph, the representation of a document illustrated in Section 2, by connecting every pair of bk-nodes with an edge, which is not allowed in the original model. This modification was motivated by the intuition that the relatedness between bk-nodes also contributes to the better evaluation of relevance to the source document, because the bk-nodes can serve as the intermediate nodes during the iterative propagation over the entire graph. Figure 3 shows an example, where the bk-node *John Lennon* is close to both the sd-node *Beatles* and to another bk-node *Yoko Ono*, so the relatedness between two bk-nodes *John Lennon* and *Yoko Ono* helps in better evaluation of the relatedness between the bk-node *Yoko Ono* and the sd-node *Beatles*.

We also modify the definition of $p(i,j)$, the probability of two nodes t_i and t_j propagating to each other. Zhang et al. (2014) compute this probability according to Formula 2, which highlights the number of neighbors, but weakens the relatedness between nodes, due to the normalization. For instance, if a node t_x has only one neighbor t_y, no matter how low their relatedness is, their $p(x,y)$ will still be equal to 1 in the original model, while another node with two equally but closely related neighbors will only get a probability of 0.5 for each neighbor. We modify this setup by removing the normalization process and computing $p(i,j)$ as the relatedness between t_i and t_j directly, which is evaluated according to Formula 1 .

4 Encoding background knowledge into document classification

In this part, we demonstrate that the introduction of relevant knowledge could be helpful to real NLP applications. In particular, we choose the *document classification* task as a demonstration, which aims to classify documents into predefined categories automatically (Sebastiani, 2002). We choose this task for two reasons: (1) This task has witnessed a booming interest in the last 20 years, due to the increased availability of documents in digital form and the ensuing need to organize them, so it is important in both research and application. (2) The state-of-the-art performance of this task is achieved by a series of topic model–based methods, which rely on the same model as we do, but make use of source document information only. However, there is always some omitted information and relevant knowledge, which cannot be captured from the source document. Intuitively, the recovery of this information will be helpful. If we can improve the performance by introducing extra background knowledge into existing framework of document classification, we can inference naturally that the improvement benefits from the introduction of this knowledge.

Traditional methods primarily use topic models to represent a document as a topic vector. Then a *SVM* classifier takes this vector as input and outputs the class of the document. In this work, we propose a new framework for document classification to incorporate extra knowledge. Given a document to be classified, we select the top *N* most-relevant triples of background knowledge with our model introduced in Section 3, all of which are represented as vectors of $\vec{v}_t = (p_{tz_1}, p_{tz_2}, \ldots, p_{tz_k})$. Then we combine these N triples as a new vector $\vec{v}_t^{\prime}$, which is then incorporated into the original framework of document classification. Another *SVM* classifier takes $\vec{v}_t^{\prime}$, together with the original features extracted from the source document, as input and outputs the category of the source document. To combine N triples as one, we employ an intuitive method by computing the average of N corresponding vectors in every dimension.

One possible problem is how to decide *N*, the number of triples to be introduced. We first introduce a fixed amount of triples for every document. Moreover, we also select the triples according to their relevance weight to the source document (see Section 3.2) by setting a threshold of relevance weight first and selecting the triples whose weights are higher than the threshold. We further discuss the impact of different thresholds in Section 5.2.

5 Experiments

To evaluate our model, we conduct two series of experiments: (1) We first treat this task as a ranking problem, which takes a document as input and outputs the ranked triples of background knowledge, and evaluate the ranking performance by computing the scores of *MAP* and *P@N*. (2) We also conduct a task-based evaluation, where document classification (see Section 4) is chosen as a demonstration, by enriching the background knowledge to the original framework as additional features and performing a direct comparison.

5.1 Evaluation as a ranking problem

Data preparation The data is composed of two parts: source documents and background knowledge. For source documents, we use a publicly available Chinese corpus which consists of 17,199 documents and 13,719,428 tokens extracted from Internet news[2] including 9 topics: *Finance, IT, Health, Sports, Travel, Education, Jobs, Art, Military*. We then randomly but equally select 600 articles as the set of source documents from 9 topics without data bias. We use all the other 16,599 documents of the same corpus as the source of background knowledge, and then introduce a well-known Chinese open source tool (Che et al., 2010) to extract the triples of background knowledge from the raw text automatically. So the background knowledge also distributes evenly across the same 9 topics. We use the same tool to extract the triples of source documents too.

Baseline systems As Zhang et al. (2014) argued, it is difficult to use the methods in traditional ranking tasks, such as information retrieval (Manning et al., 2008) and entity linking (Han et al., 2011; Sen, 2012), as baselines in this task, because our model takes triples as basic input and thus lacks some crucial information such as link structure. For better comparison, we implement three methods as baselines, which have been proved effective in relevance evaluation: (1) *Vector Space Model* (VSM), (2) *Word Embedding* (WE), and (3) *Latent Dirichlet Allocation* (LDA). Note that our model captures the distributional semantics of triples with LDA, while WE serves as a baseline only, where the word embeddings are acquired over the same corpus mentioned previously with the publicly available tool *word2vec*[3].

Here we use t_i, D, and w_i to denote a triple of background knowledge, a source document, and the relevance of t_i to D. For *VSM*, we represent both t_i and D with a *tf-idf* scheme first (Salton and McGill, 1986) and compute w_i as their cosine-similarity. For *WE*, we first convert both t_i and the triples extracted from D into real-valued vectors with WE and then compute w_i by accumulating all the cosine-similarities between t_i and every triple from D. For *LDA*, we represent t_i as a vector with our model introduced in Section 3.1 and get the vector of D directly with LDA. Then we evaluate their relevance of t_i to D by computing the cosine-similarity of two corresponding vectors.

Moreover, to determine whether our modified iterative propagation is helpful or not, we also compare our full model (*Ours*) against a simplified version without *iterative propagation* (*Ours-S*). In *Ours-S*, we represent both t_i and the triples extracted from D as real-valued vectors with our model introduced in Section 3.1. Then we compute w_i by accumulating all the cosine-similarities between t_i and the triples extracted from D. For all the baselines, we rank the triples of background knowledge according to w_i, their relevance to D.

Experimental setup Previous research relies on manual annotation to evaluate the ranking performance (Zhang et al., 2014), which costs a lot, and in which it is difficult to get high consistency. In this paper, we carry out an automatic evaluation. The corpus we used consists of 9 different classes, from which we extract triples of background knowledge. So correspondingly, there will be 9 sets of triples too. Then we randomly select 200 triples from every class and mix $200 \times 9 = 1800$ triples together as S, the set of triples of background knowledge. For every document D to be enriched, our model selects the top N most-relevant triples from S and returns them to D as enrichments. We treat a triple t_i selected by our model as positive only if t_i is extracted from the same class as D. We evaluate the performance of our model with two well-known criteria in ranking problem: *MAP* and *P@N* (Voorhees et al., 2005). Statistically significant differences of performance are determined using the two-tailed paired t-test computed at a 95% confidence level based on the average performance per source document.

Model	MAP_5	P@5	MAP_10	P@10
VSM	0.4968	0.3435	0.4752	0.3841
WE	0.4356	0.3354	0.4624	0.3841
LDA	0.6134	0.4775	0.6071	0.5295
Ours-S	0.5325	0.3762	0.5012	0.4054
Ours	**0.6494**	**0.5597**	**0.6338**	**0.5502**

Table 1: The performance evaluated as a ranking task. Here *Ours* corresponds to our full model, while *Ours-S* is a simplified version of our model without *iterative propagation* (see Section 3.2).

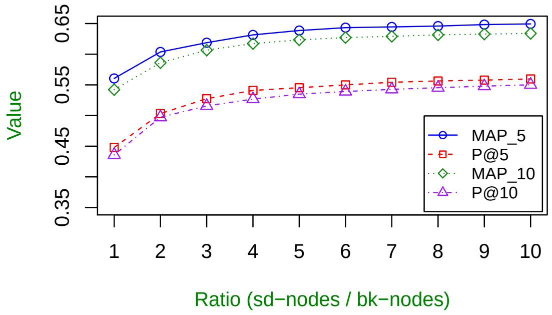

Figure 4: The performance of our model with different ratios between sd-nodes and bk-nodes.

Results The performance of multiple models is shown in Table 1. Overall, our full model *Ours* outperforms all the baseline systems significantly in every metric. When evaluating the top 10 triples with the highest relevance weight, our framework outperforms the best baseline *LDA* by 4.4% in *MAP* and by 3.91% in *P@N*. When evaluating the top 5 triples, our framework performs even better and significantly outperforms the best baseline by 5.87% in *MAP* and by 17.21% in *P@N*.

To analyze the results further, *Ours-S*, the simplified version of our model without *iterative propagation*, outperforms two strong baselines *VSM* and *WE*, which indicates the effectiveness of encoding distributional semantics. However, the performance of this simplified model is not as good as that of *LDA*, because *Ours-S* evaluates the relevance with simple accumulation, which fails to capture the relatedness between multiple triples from the source document. We tackle this problem by incorporating the modified iterative propagation over the entire triple graph into *Ours*, which achieves the best performance. One possible problem is why *WE* has a poor performance, the reason of which lies in the setup of our evaluation, where we label positive and negative instances according to the class information of triples and documents. This is better fit for topic model–based methods.

Discussion We further analyze the impact of the three modifications we made to the original model (see Section 3.2). We first focus on the impact of decreasing the relevance weight of bk-nodes and increasing that of sd-nodes after every iteration. As mentioned previously, we change their relevance weight according to a fixed ratio, which is important to the performance. Figure 4 shows the performance of models with different ratios. With any increase of the ratio, our model improves its performance in every metric, which shows the effectiveness of this setup. The performance remains stable from the value of 10:1, which is thus chosen as the final value in our experiments. We then turn to the other two modifications about the edges between bk-nodes and the setup of propagation probability. Table 2 shows the performance of our full model and the simplified models without these two modifications. With the edges between bk-nodes, our model improves the performance by 1.48% in *MAP_5* and by 1.82% in *P@5*. With the modified iterative propagation, we achieve a even greater improvement of 13.99% in *MAP_5* and 24.27% in *P@5*. All these improvements are statistically significant, which indicates the effectiveness of these modifications to the original model.

Model	MAP_5	P@5	MAP_10	P@10

Full−p	0.5697	0.4504	0.5485	0.4409

Table 2: The performance of our full model (*Full*) and two simplified models without modifications: (1) without edges between bk-nodes (*Full−bb*), (2) without the newly proposed definition of propagation probability between nodes (*Full−p*).

5.2 Task-based evaluation

Data preparation To carry out the task-based evaluation, we use the same Chinese corpus as that in previous experiments, which consists of 17,199 documents extracted from Internet news in 9 topics. We also use the same tool (Che et al., 2010) to extract triples of both source document and background knowledge. For every document *D* to be classified, we first use our model to get the top N most-relevant triples to *D*, and then use them as extra features for the original model. We conduct a direct comparison between the models with and

Model	P	R	F
VSM+one-hot	0.8214	0.8146	0.8168
VSM+tf-idf	0.8381	0.8333	0.8336
LDA+SVM	0.8512	0.8422	0.8436
LDA+SVM+Ours-S	0.8584	0.8489	0.8501
LDA+SVM+Ours	**0.8748**	**0.8689**	**0.8691**

Table 3: The performance of document classification with (*LDA+SVM+Ours-S*, *LDA+SVM+Ours*) and without (*others*) background knowledge.

without background knowledge to evaluate the impact of introducing background knowledge.

Baseline systems We first illustrate two baselines without background knowledge based on VSM and LDA. For VSM, the test document D is represented as a bag of words, where the word distribution over candidate topics is trained on the same corpus mentioned previously. Then we evaluate the similarity between D and a candidate topic with cosine-similarity directly, where the topic with the highest similarity will be chosen as the final class. We use two setups: (1) *VSM-one-hot* represents a word as 1 if it appears in a document or topic, or 0 if not. (2) *VSM-tf-idf* represents a word as the value of tf-idf. For LDA, we re-implement the state-of-the-art system as another baseline, which represents D as a topic vector $\vec{v}_d$ in the parameter estimation step, and then introduces a SVM classifier to take $\vec{v}_d$ as input and decide the final class in the inference step.

We also evaluate the impact of knowledge quality by proposing two different models to introduce background knowledge: our full model introduced in Section 3 (*Ours*), and a simplified version of our model without iterative propagation (*Ours-S*). They have different performances on introducing background knowledge as shown in previous experiments (see Section 5.1). We then conduct a direct comparison between the document classification models with these conditions, whose differing performances demonstrates the impact of different qualities of background knowledge on this task.

Results Table 3 shows the results. We use P, R, F to evaluate the performance, which are computed as the micro-average over 9 topics. Both models with background knowledge (*LDA+SVM+Ours-S*, *LDA+SVM+Ours*) outperform systems without knowledge, which shows that the introduction of background knowledge helps in better classification of documents. The system with the simplified version of our model without iterative propagation (*LDA+SVM+Ours-S*) achieves a F-value of 0.8501, which outperforms the other baselines without knowledge too. Moreover, the system with our full model (*LDA+SVM+Ours*) achieves the best performance, a F-value of 0.8691, and outperforms the best baseline *LDA+SVM* significantly. This shows that introducing better quality of background knowledge is helpful to the better classification of documents. Statistical significance is also verified using the two-tailed paired t-test computed at a 95% confidence level based on the results of classification over the test set.

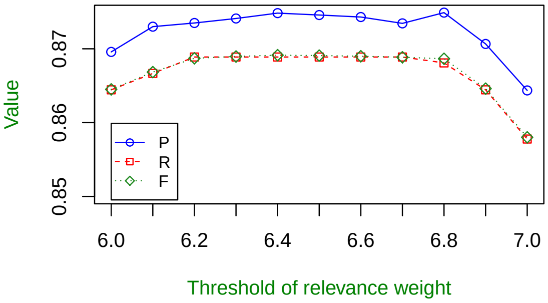

Figure 5: The performance of document classification models with different thresholds. The knowledge whose relevance weight to the source document exceeds the threshold will be introduced as background knowledge.

Discussion One important question here is how much background knowledge to include. As mentioned in Section 4, we have tried two different solutions: (1) introducing a fixed amount of background knowledge for every document, and (2) setting a threshold and selecting knowledge whose relevance weight exceeds the threshold. The results are shown in Table 4, where the systems with threshold outperform that with fixed amount, which shows that the threshold helps in better introduction of background knowledge.

Model	P	R	F
Ours-S+Top5	0.8522	0.8444	0.8456
Ours-S+ThreD	**0.8584**	**0.8489**	**0.8501**
Ours+Top5	0.8769	0.8667	0.8677
Ours+ThreD	**0.8748**	**0.8689**	**0.8691**

Table 4: The performance of document classification with the full model (*Ours*) and the simplified model (*Ours-S*) to introduce knowledge.

We also evaluate the impact of different thresholds as shown in Figure 5. The performance keeps improving as the threshold increases up to 6.4 and becomes steady from 6.4 to 6.7, while it begins to decline sharply from 6.7. This is reasonable because at the beginning, as the threshold increases, we recall more background knowledge and provide more information. However, with the further increase of the threshold, we introduce more noise, which decreases the performance. In our experiments, we choose 6.4 as the final threshold.

6 Conclusion and Future Work

This study encodes distributional semantics into the triple-based background knowledge ranking model (Zhang et al., 2014) for better document enrichment. We first use LDA to represent every triple as a real-valued vector, which is used to evaluate the relatedness between triples, and then propose a modified iterative propagation model to rank all the triples of background knowledge. For evaluation, we conduct two series of experiments: (1) evaluation as ranking problem, and (2) task-based evaluation, especially for document classification. In the first set of experiments, our model outperforms multiple strong baselines based on VSM, LDA, and WE. In the second set of experiments, our full model with background knowledge outperforms the state-of-the-art systems significantly. Moreover, we also explore the impact of knowledge quality and show its importance.

In our future work, we wish to explore a better way to encode distributional semantics by proposing a modified LDA for better triples representation. In addition, we also want to explore the effect of introducing background knowledge in conjunction with other NLP tasks, especially with discourse parsing (Marcu, 2000; Pitler et al., 2009).

Abstract

We characterize a class of indirect answers to yes/no questions, *alternative answers*, where information is given that is not directly asked about, but which might nonetheless address the underlying motivation for the question. We develop a model rooted in game theory that generates these answers via *strategic reasoning* about possible unobserved domain-level user requirements. We implement the model within an interactive question answering system simulating real estate dialogue. The system learns a prior probability distribution over possible user requirements by analyzing training dialogues, which it uses to make strategic decisions about answer selection. The system generates pragmatically natural and interpretable answers which make for more efficient interactions compared to a baseline.

1 Introduction

In natural language dialogue, questions are often answered indirectly. This is particularly apparent for yes/no questions, where a wide range of responses beyond literal "yes" and "no" answers is available. Sometimes indirect answers serve to anticipate the next step of the hearer's *plan*, as in (1) (Allen and Perrault, 1980), where the literal answer is entailed by the supplied answer, and sometimes indirect answers leave it to the hearer to infer the literal answer from common contextual assumptions, as in (2) (de Marneffe et al., 2009).

(1) Q: Has the train to Windsor left yet?
A: It's leaving soon from gate 7.

(2) Q: Is Sue at work?
A: She's sick with the flu.

But other times there is no semantic link between the question and the supplied answer. Rather, the answer must be interpreted in light of the task-specific goals of the interlocutors. Consider (3) in a context where a customer is posing questions to a real estate agent with the aim of renting an apartment.

(3) Q: Does the apartment have a garden?
A: Well, it has a large balcony.

Whether there is a balcony has no logical bearing on whether there is a garden. Intuitively, the realtor is inferring that the customer's question might have been motivated by a more general requirement (perhaps the customer wants a place to grow flowers) and supplying an alternative attribute to satisfy that requirement. In this case the answerer must reason about which attributes of an apartment might satisfy a customer who would ask about a garden. Note that multiple motivating requirements are possible (perhaps the customer just wants to relax outside), such that the answerer might just as easily have said, "It has a large balcony, and there is a park close by." In either case, the hearer can infer from the lack of a direct answer that the apartment must not have a garden, because if it did, to say so would have been more obviously helpful.

This paper focuses on this class of answers, which we call *alternative answers*. We characterize these as indirect answers to yes/no questions that offer attributes of an object under discussion which might satisfy an unobserved domain-level *requirement* of the questioner. We conceive of a requirement as a set of *satisfying conditions*, such that a particular domain-related need would be met by any one member of the set. For example, in the context of (3) we can encode a possible customer requirement of a place to grow flowers in an apartment, $\text{FLOWERS} = \{\text{GARDEN}, \text{BALCONY}\}$, such that *either* GARDEN *or* BALCONY would suffice to satisfy the requirement.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 534–542,

In order to generate alternative answers automatically, we must first solve two problems: (i) how does one learn and represent a space of likely user requirements?, and (ii) how does one use such a space to select indirect answers? To do this in a natural, pragmatically interpretable way, we must not only derive answers like in (3), but crucially, also rule out infelicitous responses like the following, where a logically possible alternative leads to incoherence due to the low probability of an appropriate requirement like {GARDEN, BASEMENT}. (In other words, wanting a garden has little effect on the probability of wanting a basement.)

(4) Q: Does the apartment have a garden?
A: #Well, it has a large basement.

To solve these problems, we propose an approach rooted in decision-theoretic and game-theoretic analyses of indirectness in natural language (van Rooij, 2003; Benz and van Rooij, 2007; Benz et al., 2011; Stevens et al., 2014) whereby a system uses *strategic reasoning* to derive an optimal response to a yes/no question given certain domain assumptions. The model operates by assuming that both the questioner and the answerer are *rational*, i.e. that both participants want to further their own goals, and will behave so as to maximize the probability of success at doing so.

One appeal of the strategic approach is its relative simplicity: the model utilizes a learned probability distribution over possible domain-level requirements of the questioner and applies simple probabilistic reasoning to feed content selection during online answer generation. Unlike plan inference approaches, we do not need to represent any complex taxonomies of stimulus conditions (Green and Carberry, 1994) or coherence relations (Green and Carberry, 1999; Asher and Lascarides, 2003).

By implementing the strategic reasoning model within a simple interactive question answering system (Konstantinova and Orasan, 2012), simulating real estate dialogues with exchanges like in (3), we are able to evaluate the current approach quantitatively in terms of dialogue efficiency, perceived coherence of the supplied answers, and ability of users to draw natural pragmatic inferences. We conclude that strategic reasoning provides a promising framework for developing answer generation methods by starting with principled theoretical analyses of human dialogue.

The following section presents the model, including a concrete content selection algorithm used for producing answers to questions, and then walks through a simple illustrative example. Section 3 describes our implementation, addresses the problem of learning requirement probabilities, and presents the results of our evaluation, providing quantitative support for our approach. Section 4 concludes with a general summary.

2 Model

2.1 Overview

We derive our model beginning with a simple description of the discourse situation. In our case, this is an exchange of questions and answers where a *user* poses questions to be answered by an *expert* who has access to a *database* of information that the user wants. The expert has no advance knowledge of the database, and thus must *look up* information as needed. Each user question is motivated by a *requirement*, conceived of as a (possibly singleton) set of database attributes (restricted for current purposes to boolean attributes), any one of which satisfies a user need (e.g. $\{\text{GARDEN}, \text{BALCONY}\}$ in the previous section). Only the user has direct access to her own requirements, and only the expert can query the database to inform the user whether her requirements can be satisfied. For current purposes we assume that each question and answer in the dialogue pertains to a specific object o from the database which is designated as the *object under discussion*. This way we can represent answers and question denotations with attributes, like GARDEN, where the queried/supplied attribute is assumed to predicate over o. In these terms, the expert can either ASSERT an attribute (if it holds of o) or DENY an attribute (if it does not hold of o) in response to a user query.

Now we describe the goals of the interlocutors. The user wants her requirements to be satisfied, and will not accept an object until she is sure this is the case. If it is clear that an object cannot satisfy one or more requirements, the user will ask to discuss a different object from the database. We can thus characterize the set of possible user responses as follows: the user may ACCEPT the object as one that meets all requirements, the user may REJECT the object and ask to see something else, or the user may FOLLOW UP, continuing to pose questions about the current object. The user's goal, then, is ultimately to accept an object that in fact satisfies her requirements, and to reject any object that does not.

The expert's goal is to help the user find an optimal object as efficiently as possible. Given this goal, the expert does better to provide alternative attributes (like BALCONY for GARDEN in (3)) in place of simple "no" answers only when those attributes are relevant to the user's underlying requirements. To use some economic terminology, we can define the *benefit* (B) of looking up a potential alternative attribute a in the database as a binary function indicating whether a is relevant to (i.e. a member of) the user requirement ρ which motivated the user's question. For example, in (3), if the user's question is motivated by requirement {GARDEN, BALCONY}, then the benefit of looking up whether there is a balcony is 1, because if that attribute turns out to hold of o, then the customer's requirement is satisfied. If, on the other hand, the questioner has requirement {GARDEN}, then the benefit of looking up BALCONY is 0, because this attribute cannot satisfy this requirement.

$$B(a|\rho) = 1 \text{ if } a \in \rho \text{ and } 0 \text{ otherwise} \quad (1)$$

Regardless of benefit, the expert incurs a *cost* by looking up information. To fully specify what cost means in this context, first assume a small, fixed effort cost associated with looking up an attribute. Further assume a larger cost incurred when the user has to ask a follow-up question to find out whether a requirement is satisfied. What really matters are not the raw cost amounts, which may be very small, but rather the *relative cost* of looking up an attribute compared to that of receiving a follow-up. We can represent the ratio of look-up cost to follow-up cost as a constant κ, which encodes the reluctance of the expert to look up new information. Intuitively, if κ is close to 1 (i.e. if follow-ups are not much more costly than simple look-ups), the expert should give mostly literal answers, and if κ is close to 0, (i.e. if relative follow-up cost is very high), the expert should look up all potentially beneficial attributes. With this, let the *utility* (U) of looking up a be the benefit of looking up a minus the relative cost.

$$U(a|\rho) = B(a|\rho) - \kappa \quad (2)$$

The expert is utility-maximizing under game-theoretic assumptions, and (assuming a baseline utility of zero for doing nothing) should aim to look up attributes for which U is positive, i.e. for which benefit outweighs cost. But the expert has a problem: ρ, on which U depends, is known only to the user. Therefore, the best the expert can do is to reason probabilistically, based on the user's question, to maximize *expected utility*, or the weighted average of $U(a|\rho)$ for all possible values of ρ. The expected utility of looking up an attribute a can be written as the *expected benefit* of a—the weighted average of $B(a|\rho)$ for all ρ—minus the relative cost. Let REQS be the set of all possible user requirements and let q be the user's question.

$$EU(a|q, \text{REQS}) = EB(a|q, \text{REQS}) - \kappa \quad (3)$$

$$EB(a|q, \text{REQS}) = \sum_{\rho \in \text{REQS}} P(\rho|q) \times B(a|\rho) \quad (4)$$

The probability of a user requirement $P(\rho|q)$ is calculated via Bayes' rule, assuming that users will choose their questions randomly from the set of questions whose denotations are in their requirement set. This yields the following.

$$P(\rho|q) = \frac{P(q|\rho) \times P(\rho)}{\sum_{\rho' \in \text{REQS}} P(q|\rho') \times P(\rho')} \quad (5)$$

$$P(q|\rho) = \frac{1}{|\rho|} \text{ if } [\![q]\!] \in \rho \text{ and } 0 \text{ otherwise} \quad (6)$$

The prior probability of a user requirement, $P(\rho)$, is given as input to the model. We will see in the next section that it is possible to learn a prior probability distribution from training dialogues.

We have now fully characterized the expected benefit (EB) of looking up an attribute in the database. As per Eq.3, the expert should only bother looking up an attribute if EB is greater than the relative cost κ, since that is when EU is positive. The final step is to give the expert a sensible way to iteratively look up attributes to potentially produce multiple alternatives. To this end, we first point out that if an alternative has been found which satisfies a certain requirement, then it no longer adds any benefit to consider that requirement when selecting further alternatives. For example, in the context of example (3), when the realtor queries the database to find the apartment has a balcony, she no longer needs to consider the probability of a requirement {BALCONY, GARDEN} when considering additional attributes, since that is already satisfied. Given this consideration, the order in which database attributes are looked up can make a difference to the outcome. So, we need a consistent and principled criterion for determining the order in which to look up attributes. The most efficient method is to start with the attribute with the highest possible EB value and then iteratively move down to the next best attribute until EB is less than or equal to cost.

Note that the attribute that was asked about will always have an EB value of 1. Consider again the QA exchange in (3). Recall that the expert assumes that the user's query is relevant to an underlying requirement ρ. This means that ρ must contain the attribute GARDEN. Therefore, by definition, supplying GARDEN will always yield positive benefit. We can use this fact to explain how alternative answers are interpreted by the user. The user knows that the most beneficial attribute to look up (in terms of EB) is the one asked about. If that attribute is not included in the answer, the user is safe to assume that it does not hold of the object under discussion. By reasoning about the expert's reasoning, the user can derive the implicature that the literal answer to her question is "no". In fact, this is what licenses the expert to leave the negation of the garden attribute out of the answer: the expert knows that the user knows that the expert would have included it if it were true. This type of "I know that you know" reasoning is characteristic of game-theoretic analysis.[1]

2.2 Algorithm and example

Our algorithm for generating alternative answers (Algorithm 1), which simulates strategic reasoning by the expert in our dialogue situation, is couched in a simple information state update (ISU) framework (Larsson and Traum, 2000; Traum and Larsson, 2003), whereby the answerer keeps track of the current object under discussion (o) as well as a history of attributes looked up for o (HIST$_o$). The output of the algorithm takes the form of a dialogue move, either an assertion (or set of assertions) or denial that an attribute holds of o. These dialogue moves can then be translated into natural language with simple sentence templates. The answerer uses HIST$_o$ to make sure redundant alternatives aren't given across QA exchanges. If all possible answers are redundant, the answerer falls back on a direct yes/no response.

Requirement set	$P(\rho)$	$P(q\|\rho)$	$P(\rho\|q)$
ρ_G ={GARDEN}	0.5	1	0.67
ρ_F ={GARDEN, BALCONY}	0.25	0.5	0.17
ρ_P ={GARDEN, PARK}	0.2	0.5	0.13
ρ_S ={GARDEN, BASEMENT}	0.05	0.5	0.03

Table 1: A toy example of a customer requirement space with probabilities for q = 'Does the apartment have a garden?'

To illustrate how the algorithm works, consider a simple toy example. Table 1 gives a hypothetical space of possible requirements along with a distribution of priors, likelihoods and Bayesian posteriors. We imagine that a customer might want a garden (ρ_G), or more generally a place to grow flowers (ρ_F), a place for their child to play outside (ρ_P), or, in rare cases, either a garden or a basement to use as storage space (ρ_S). The rather odd nature of ρ_S is reflected in its low prior. Consider a variant of (3) where HIST$_o$ is empty, and where DB$_o$ contains BALCONY, PARK and BASEMENT.

(5) Q: Does the apartment have a garden?
A: It has a balcony, and there is a park very close by.

To start, let REQS contain the requirements in Table 1, and let $\kappa = 0.1$. The algorithm derives the answer as follows. First, the algorithm looks up whether GARDEN holds of o. It does not hold, so GARDEN is not added to the answer; it is only added to the history of looked up attributes.

a = GARDEN; EB(GARDEN) = 1;
HIST$_o$ = {GARDEN}

Then, the system finds the next best attribute, BALCONY, which does hold of o, appends it to the answer as well as the history, and removes the relevant requirement from consideration.

a = BALCONY; EB(BALCONY) = 0.17;
HIST$_o$ = {GARDEN, BALCONY};
ANSWER = {BALCONY};
REQS = $\{\rho_G, \rho_P, \rho_S\}$

The attribute PARK is similarly added.

a = PARK; EB(PARK) = 0.13;
HIST$_o$ = {GARDEN, BALCONY, PARK};
ANSWER = {BALCONY, PARK};
REQS = $\{\rho_G, \rho_S\}$

The attribute BASEMENT is next in line. However, its EB value is below the threshold of 0.1 due

[1] It can be shown that the answer selection algorithm presented in this section, combined with a simple user interpretation model, constitutes a *perfect Bayesian equilibrium* (Harsanyi, 1968; Fudenberg and Tirole, 1991) in a signaling game (Lewis, 1969) with private hearer types which formally describes this kind of dialogue.

Algorithm 1 An algorithm for generating alternative answers

```
Input: A set of attributes $\Phi$, an object under discussion $o$, a database $\text{DB}_o$ of attributes which hold of $o$, a history $\text{HIST}_o$ of attributes that have been looked up in the database, a set of possible user requirements $\text{REQS}$, a prior probability distribution over $\text{REQS}$, a user-supplied question $q$ with denotation $[\![q]\!]$ and a relative cost threshold $\kappa \in (0, 1)$
Initialize: $\text{ANSWER} = \{\}$; $\text{LOOKUP} = \text{TRUE}$
while $\text{LOOKUP}$ do
    $\Phi' = (\Phi \setminus \text{HIST}_o) \cup \{[\![q]\!]\}$    ▷ Only consider alternatives once per object per dialogue.
    $a = \arg\max_{\phi \in \Phi'} \text{EB}(\phi|q, \text{REQS})$    ▷ Find the best candidate answer.
    if $\text{EB}(a|q, \text{REQS}) > \kappa$ then    ▷ Check whether expected benefit outweighs cost.
        $\text{HIST}_o = \text{HIST}_o \cup \{a\}$    ▷ Log which attribute has been looked up.
        if $a \in \text{DB}_o$ then
            $\text{ANSWER} = \text{ANSWER} \cup \{a\}$    ▷ Add to answer if attribute holds.
            $\text{REQS} = \text{REQS} \setminus \{\rho \in \text{REQS} \mid \rho \cap \text{ANSWER} \neq \emptyset\}$
                ▷ Don't consider requirements that are already satisfied.
        end if
    else
        $\text{LOOKUP} = \text{FALSE}$    ▷ Stop querying the database when there are no promising candidates left.
    end if
end while
if $\text{ANSWER} \neq \emptyset$ then $\text{ASSERT}(\text{ANSWER})$,
else $\text{DENY}([\![q]\!])$
end if
```

to its low prior probability, and thus the iteration stops there, and BASEMENT is never looked up.

$a = \text{BASEMENT}$; $EB(\text{BASEMENT}) = 0.03$;
$EB < \kappa$; exit loop

3 Implementation and evaluation

3.1 Setup

A simple interactive question answering system was built using a modified version of the PyTrindiKit toolkit[2] with a database back end implemented using an adapted version of PyKE, a Horn logic theorem prover.[3] The system was set up to emulate the behavior of a real estate agent answering customers' yes/no questions about a range of attributes pertaining to individual apartments. A set of 12 attributes was chosen for the current evaluation experiment. The system generates answers by first selecting a discourse move (i.e. assertion or denial of an attribute) and then translating the move into natural language with simple sentence templates like, "It has a(n) X" or "There is a(n) X nearby". When answers are indirect (i.e. not asserting or denying the attribute asked about), the system begins its reply with the discourse connective "well" as in example (3).[4]

Subjects interacted with our system by means of an online text-based interface accessible remotely through a web browser. At the outset of the experiment, subjects were told to behave as if they were finding an apartment for a hypothetical friend, and given a list of requirements for that friend. The task required them to identify which from among a sequence of presented apartments would satisfy the given set of requirements. One out of four lists, each containing three requirements (one of which was a singleton), was assigned to subjects at random. The requirements were constructed by the researchers to be plausible desiderata for users looking for a place to rent or buy (e.g. connection to public transit, which could be satisfied either by a nearby bus stop, or by a nearby train station).

The apartments presented by the system were individually generated for each experiment such that there was an apartment satisfying one attribute for each possible combination of the three requirements issued to subjects, plus two additional apartments that each satisfied two of the conditions ($2^3 + 2 = 10$ apartments overall). Attributes outside a subject's requirement sets were added at random to assess the effect of "unhelpful" alternative answers.

Subject interacted with one of two answer generation models: a *literal* model, which only produced direct yes/no answers, and the *strategic*

[2] `https://code.google.com/p/py-trindikit`

[3] `http://pyke.sourceforge.net/`

[4] Early feedback indicated that alternative answers were more natural when preceded by such a discourse connective. To assess this effect, we ran a separate evaluation experiment with an earlier version of the system that produced alternative answers without "well". Dialogue lengths and coherence scores were not very different from what is reported in this section; however, in contrast with the current evaluation, we found a large effect of model type (a 69% decrease for strategic vs. literal) on whether the subjects successfully completed the task (z=-2.19, p=0.03). This is consistent with the early feedback.

model as outlined above. Crucially, in both conditions, the sequence in which objects were presented was fixed so that the last apartment offered would be the sole object satisfying all of the desired criteria. Also, we set the strategic model's κ parameter high enough ($^1/_7$) that only single-attribute answers were ever given. These two properties of the task, taken together, allow us to obtain an apples-to-apples comparison of the models with respect to average dialogue length. If subjects failed to accept the optimal solution, the interaction was terminated. After completing interaction with our system, subjects were asked to complete a short survey designed to get at the perceived coherence of the system's answers. Subjects were asked to rate, on a seven-point Likert scale, the relevance of the system's answers to the questions asked, overall helpfulness, the extent to which questions seemed to be left open, and the extent to which the system seemed evasive.

We predict that the strategic system will improve overall efficiency of dialogue over that of the literal system by (i) offering helpful alternatives to satisfy the customer's needs, and (ii) allowing customers to infer implicit "no" answers from alternative answers, leading to rejections of sub-optimal apartments. If, contrary to our hypothesis, subjects fail to draw inferences/implicatures from alternative answers, then we expect unhelpful alternatives (i.e. alternatives not in the user's requirement set) to prompt repeated questions and/or failures to complete the task.

With respect to the questionnaire items, the literal system is predicted to be judged maximally coherent, since only straightforward yes/no answers are offered. The question is whether the pragmatic system also allows for coherent dialogue. If subjects judge alternative answers to be incoherent, then we expect any difference in average Likert scale ratings between strategic and literal system to reflect the proportion of alternative answers that are given.

3.2 Learning prior probabilities

Before presenting our results, we explain how prior probabilities can be learned within this framework. One of the assumptions of the strategic reasoning model is that users ask questions that are motivated by specific requirements. Moreover, we should assume that users employ a reasonable questioning strategy for finding out whether requirements hold, which is tailored to the system they are interacting with. For example, if a user interacts with a system that only produces literal yes/no answers, the user should take all answers at face value, not drawing any pragmatic inferences. In such a scenario, we expect the user's questioning strategy to be roughly as follows: for $a_1, a_2, \cdots, a_n$ in requirement ρ, ask about a_1, then if a_1 is asserted, accept (or move on to the next requirement if there are multiple requirements), and if not, ask about a_2; if a_2 is asserted, accept, and if not, ask about a_3, and so on, until a_n is asked about. If a_n is denied, then reject the object under discussion. If you need a place to grow flowers, ask if there is a balcony or garden, then, if the answer is no, ask about the other attribute. If no "yes" answers are given, reject.

S:	An apartment in the north of town might suit you. I have an additional offer for you there.
U:	Does the apartment have a garden?
S:	The apartment does not have a garden.
U:	Does the apartment have a balcony?
S:	The apartment does not have a balcony.
U:	I'd like to see something else

Figure 1: An example of the negation-rejection sequence $\langle \textsc{garden}, \textsc{balcony} \rangle$

Such a strategy predicts that potential user requirements should be able to be gleaned from dialogues with a literal system by analyzing *negation-rejection sequences* (NRSs). A negation-rejection sequence is a maximal observed sequence of questions which all receive "no" answers, without any intervening "yes" answers or any other intervening dialogue moves, such that at the end of that sequence of questions, the user chooses to reject the current object under discussion. Such a sequence is illustrated in Fig.1. By hypothesis, the NRS $\langle \textsc{garden}, \textsc{balcony} \rangle$ indicates a possible user requirement $\{\textsc{garden}, \textsc{balcony}\}$.

By considering NRSs, the system can learn from training data a reasonable prior probability distribution over possible customer requirements. This obviates the need to pre-supply the system with complex world knowledge. If customer requirements can in principle be learned, then the strategic approach could be expanded to dialogue situations where the distribution of user requirements could not sensibly be pre-supplied. While the system in its current form is not guaranteed to scale up in this way, its success here provides us with a promising proof of concept.

Using the dialogues with the literal system as training data, we were able to gather frequencies of observed negation-rejection sequences. By transforming the sequences into unordered sets and then normalizing the frequencies of those sets, we obtained a prior probability distribution over possible customer requirements. In the training dialogues, subjects were given the same lists of requirements as was given for the evaluation of the strategic model. If successful, the system should use the yes/no dialogue data to learn high probabilities for requirements which customers actually had, and low probabilities for any others, allowing us to evaluate the system without giving it any prior clues as to which customer requirements were assigned.

Because we know in advance which requirements the subjects wanted to fulfill, we have a gold standard against which we can compare the question-alternative answer pairs that different variants of the model are able to produce. For example, we know that if a subject asked whether the apartment had a balcony and received an answer about a nearby café, that answer could not have been beneficial, since no one was assigned the requirement {CAFÉ, BALCONY}.

Table 2 compares three variant models: (i) the system we use in our evaluation, which sets prior probabilities proportional to NRS frequency, (ii) a system with flat priors, where probability is zero if NRS frequency is zero, but where all observed NRSs are taken to correspond to equiprobable requirements, and finally (iii) a baseline which does not utilize an EB threshold, but rather simply randomly selects alternatives which were observed at least once in an NRS with the queried attribute. These models are compared by the maximum benefit of their possible outputs using best-case values for κ. We see that there is a good match between the answers given by the strategic model with learned priors and the actual requirements that users were told to fulfill.

Though it remains to be seen whether this would scale up to more complex requirement spaces, this result suggests that NRSs can in fact be indicative of disjunctive requirement sets, and can indeed be useful in learning what possible alternatives might be. For purposes of our evaluation, we will see that the method was successful.

Model	Precision	Recall	F1
Frequency-based	1	0.92	0.96
Flat	0.88	0.92	0.90
Baseline	0.23	1	0.37

Table 2: Comparison of best-case output with respect to potential benefit of alternative answer types to subjects. Precision = hits / hits+misses, and Recall = hits / possible hits. A “hit” is a QA pair which is a possible output of the model, such that A could be a beneficial answer to a customer asking Q, and a “miss” is such a QA pair such that A is irrelevant to Q.

3.3 Evaluation results

We obtained data from a total of 115 subjects via Amazon Mechanical Turk; 65 subjects interacted with the literal comparison model, and 50 subjects interacted with the strategic model. We excluded a total of 13 outliers across both conditions who asked too few or too many questions (1.5 interquartile ranges below the 1st or above the 3rd quartile). These subjects either quit the task early or simply asked all available questions even for apartments that were obviously not a good fit for their requirements. Two subjects were excluded for not filling out the post-experiment questionnaire. This left 100 subjects (59 literal/41 strategic), of which 86 (49/37) successfully completed the task, accepting the object which met all assigned requirements. There was no statistically significant difference between the literal and strategic models with respect to task success.

We first compare the literal and strategic models with regard to dialogue length, looking only at the subjects who successfully completed the task. Due to the highly structured nature of the experiment it was always the case that a successful dialogue consisted of 10 apartment proposals, some number of QA pairs, where each question was given a single answer, 9 rejections and, finally, one acceptance. This allows us to use the number of questions asked as a proxy for dialogue length. Figure 2 shows the comparison. The strategic model yields 27.4 questions on average, more than four fewer than the literal model’s 31.6. Standard statistical tests show the effect to be highly significant, with a one-way ANOVA yielding F=16.2, p = 0.0001, and a mixed effects regression model with a random slope for item (the items in this case being the set of requirements assigned to the sub-

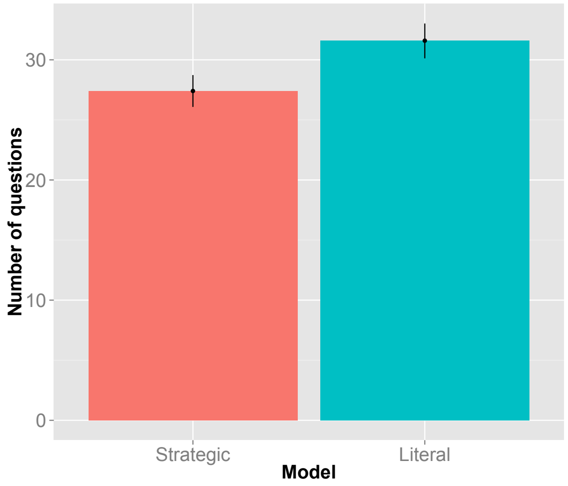

Figure 2: Avg. number of QA pairs by model

S:	How about an apartment in the east of the city? I have an offer for you there.
U:	Does the apartment have a café nearby?
S:	Well, there is a restaurant nearby.
U:	I'd like to see something else

Figure 3: A QA exchange from a dialogue where the user was instructed to find an apartment with a café nearby

ject) yielding t=4, p=0.0001.

We now ask whether the observed effect is due only to the presence of helpful alternatives which preclude the need for follow-up questions, or whether the ability of users to draw pragmatic inferences from *unhelpful* alternatives (i.e. alternatives that don't actually satisfy the user's requirement) also contributes to dialogue efficiency. Figure 3, taken from a real dialogue with our system, illustrates such an inference. The subject specifically wants a café nearby, and infers from the alternative answer that this requirement cannot be satisfied, and therefore rejects. The subject could have asked the question again to get a direct answer, which would have had a negative effect on dialogue efficiency, but this did not happen. We want to know if subjects' aggregate behavior reflects this example.

First, take the null hypothesis to be that subjects do *not* reliably draw such negative implicatures. In that case we would expect a certain proportion of questions to be repeated. Subjects are allowed to ask questions multiple times, and alternatives are never presented twice, such that repeating questions will ultimately lead to a direct yes/no answer. We do see some instances of this behavior in the dialogues. If this is indicative of an overall difficulty in drawing pragmatic inferences from an online dialogue system, then we expect the number of such repetitions to reflect the number of unhelpful alternatives that are offered. Instead, we find that when we plot a linear regression of repeated questions vs. unhelpful alternatives, we get a flat line with no observable correlation (Fig.4). Moreover, we also find no effect of unhelpful alternatives on whether the task was successfully completed. This suggests that the correct inferences are being drawn, as in Fig.3.

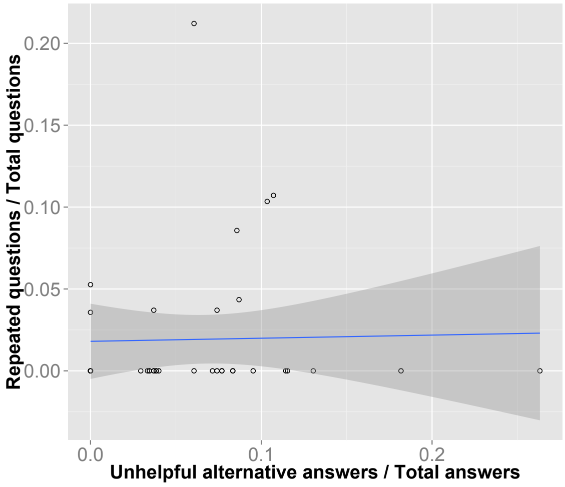

Figure 4: Proportion unhelpful alternatives vs. proportion repeated questions

We now look at the perceived coherence of the dialogues as assessed by our post-experiment questionnaire. We obtain a composite *coherence score* from all coherence-related items on the seven point Likert scale by summing all per-item scores for each subject and normalizing them to a unit interval, where 1 signifies the upper bound of perceived coherence. Although there is a difference in mean coherence score between the strategic and literal models, with the strategic model exhibiting 88% perceived coherence and the literal model 93%, the difference is not statistically significant. Moreover, we can rule out the possibility that the strategic model is judged to be coherent only when the number of alternative answers is low. To rule this out, we calculate the expected coherence score under the null hypothesis that coherence is directly proportional to the proportion of literal answers. Taking the literal model's average score of 0.93 as a ceiling, we multiply this by the proportion of literal answers to obtain a null hypothesis expected score of about 0.75 for the strategic model. This null hypothesis is disconfirmed (F=12.5, t=30.6, p<0.01). The strategic model is judged, by the criteria assessed by our post-experiment questionnaire, to be pragmatically coherent independently of the rate of indirect answers given.

4 Conclusion

We have characterized the class of alternative answers to yes/no questions and proposed a content selection model for generating these answers in dialogue. The model is based on strategic reasoning about unobserved user requirements, and is based on work in game-theoretic pragmatics (Benz and van Rooij, 2007; Stevens et al., 2014). The model was implemented as an answer selection algorithm within an interactive question answering system in a real estate domain. We have presented an evaluation of this system against a baseline which produces only literal answers. The results show that the strategic reasoning approach leads to efficient dialogues, allows pragmatic inferences to be drawn, and does not dramatically reduce the overall perceived coherence or naturalness of the produced answers. Although the strategic model requires a form of world knowledge—knowledge of possible user requirements and their probabilities—we have shown that there is a simple method, the analysis of negation-rejection sequences in yes/no QA exchanges, that can be used to learn this knowledge with positive results. Further research is required to address issues of scalability and generalizability, but the current model represents a promising step in the direction of pragmatically competent dialogue systems with solid basis in formal pragmatic theory.

Modeling Argument Strength in Student Essays

Isaac Persing and **Vincent Ng**

Abstract

While recent years have seen a surge of interest in automated essay grading, including work on grading essays with respect to particular dimensions such as prompt adherence, coherence, and technical quality, there has been relatively little work on grading the essay dimension of argument strength, which is arguably the most important aspect of argumentative essays. We introduce a new corpus of argumentative student essays annotated with argument strength scores and propose a supervised, feature-rich approach to automatically scoring the essays along this dimension. Our approach significantly outperforms a baseline that relies solely on heuristically applied sentence argument function labels by up to 16.1%.

1 Introduction

Automated essay scoring, the task of employing computer technology to evaluate and score written text, is one of the most important educational applications of natural language processing (NLP) (see Shermis and Burstein (2003) and Shermis et al. (2010) for an overview of the state of the art in this task). A major weakness of many existing scoring engines such as the Intelligent Essay Assessor$^{\text{TM}}$(Landauer et al., 2003) is that they adopt a holistic scoring scheme, which summarizes the quality of an essay with a single score and thus provides very limited feedback to the writer. In particular, it is not clear which dimension of an essay (e.g., style, coherence, relevance) a score should be attributed to. Recent work addresses this problem by scoring a particular dimension of essay quality such as coherence (Miltsakaki and Kukich, 2004), technical errors, relevance to prompt (Higgins et al., 2004; Persing and Ng, 2014), organization (Persing et al., 2010), and thesis clarity (Persing and Ng, 2013). Essay grading software that provides feedback along multiple dimensions of essay quality such as E-*rater*/Criterion (Attali and Burstein, 2006) has also begun to emerge.

Our goal in this paper is to develop a computational model for scoring the essay dimension of *argument strength*, which is arguably the most important aspect of argumentative essays. Argument strength refers to the strength of the argument an essay makes for its thesis. An essay with a high argument strength score presents a strong argument for its thesis and would convince most readers. While there has been work on *designing* argument schemes (e.g., Burstein et al. (2003), Song et al. (2014), Stab and Gurevych (2014a)) for *annotating* arguments manually (e.g., Song et al. (2014), Stab and Gurevych (2014b)) and automatically (e.g., Falakmasir et al. (2014), Song et al. (2014)) in student essays, little work has been done on scoring the argument strength of student essays. It is worth mentioning that some work has investigated the use of automatically determined argument labels for heuristic (Ong et al., 2014) and learning-based (Song et al., 2014) essay scoring, but their focus is *holistic* essay scoring, not argument strength essay scoring.

In sum, our contributions in this paper are twofold. First, we develop a scoring model for the argument strength dimension on student essays using a *feature-rich* approach. Second, in order to stimulate further research on this task, we make our data set consisting of argument strength annotations of 1000 essays publicly available. Since progress in argument strength modeling is hindered in part by the lack of a publicly annotated corpus, we believe that our data set will be a valuable resource to the NLP community.

2 Corpus Information

We use as our corpus the 4.5 million word International Corpus of Learner English (ICLE) (Granger

In his novel *Animal Farm*, George Orwell wrote "All men are equal but some are more equal than others." How true is this today?	10	64

Table 1: Some examples of writing topics.

et al., 2009), which consists of more than 6000 essays on a variety of different topics written by university undergraduates from 16 countries and 16 native languages who are learners of English as a Foreign Language. 91% of the ICLE texts are written in response to prompts that trigger argumentative essays. We select 10 such prompts, and from the subset of argumentative essays written in response to them, we select 1000 essays to annotate for training and testing of our essay argument strength scoring system. Table 1 shows three of the 10 topics selected for annotation. Fifteen native languages are represented in the set of annotated essays.

3 Corpus Annotation

We ask human annotators to score each of the 1000 argumentative essays along the argument strength dimension. Our annotators were selected from over 30 applicants who were familiarized with the scoring rubric and given sample essays to score. The six who were most consistent with the expected scores were given additional essays to annotate. Annotators evaluated the argument strength of each essay using a numerical score from one to four at half-point increments (see Table 2 for a description of each score).[1] This contrasts with previous work on essay scoring, where the corpus is annotated with a binary decision (i.e., *good* or *bad*) for a given scoring dimension (e.g., Higgins et al. (2004)). Hence, our annotation scheme not only provides a finer-grained distinction of argument strength (which can be important in practice), but also makes the prediction task more challenging.

Score	Description of Argument Strength
4	essay makes a **strong argument** for its thesis and would convince most readers
3	essay makes a **decent argument** for its thesis and could convince some readers
2	essay makes a **weak argument** for its thesis or sometimes even **argues against it**
1	essay **does not make an argument** or it is often **unclear what the argument is**

Table 2: Descriptions of the meaning of scores.

To ensure consistency in annotation, we randomly select 846 essays to have graded by multiple annotators. Though annotators exactly agree on the argument strength score of an essay only 26% of the time, the scores they apply fall within 0.5 points in 67% of essays and within 1.0 point in 89% of essays. For the sake of our experiments, whenever the two annotators disagree on an essay's argument strength score, we assign the essay the average the two scores rounded down to the nearest half point. Table 3 shows the number of essays that receive each of the seven scores for argument strength.

score	1.0	1.5	2.0	2.5	3.0	3.5	4.0
essays	2	21	116	342	372	132	15

Table 3: Distribution of argument strength scores.

4 Score Prediction

We cast the task of predicting an essay's argument strength score as a regression problem. Using regression captures the fact that some pairs of scores are more similar than others (e.g., an essay with an argument strength score of 2.5 is more similar to an essay with a score of 3.0 than it is to one with a score of 1.0). A classification system, by contrast, may sometimes believe that the scores 1.0 and 4.0 are most likely for a particular essay, even though these scores are at opposite ends of the score range. In the rest of this section, we describe how we train and apply our regressor.

Training the regressor. Each essay in the training set is represented as an instance whose label is the essay's gold score (one of the values shown in Table 3), with a set of baseline features (Section 5) and up to seven other feature types we propose (Section 6). After creating training instances, we train a linear regressor with regularization parameter c for scoring test essays using the linear SVM regressor implemented in the LIBSVM software package (Chang and Lin, 2001). All SVM-specific learning parameters are set to their default

[1] See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for the complete list of argument strength annotations.

values except c, which we tune to maximize performance on held-out validation data.[2]

Applying the regressor. After training the regressor, we use it to score the test set essays. Test instances are created in the same way as the training instances. The regressor may assign an essay any score in the range of 1.0−4.0.

5 Baseline Systems

In this section, we describe two baseline systems for predicting essays' argument strength scores.

5.1 Baseline 1: Most Frequent Baseline

Since there is no existing system specifically for scoring argument strength, we begin by designing a simple baseline. When examining the score distribution shown in Table 3, we notice that, while there exist at least a few essays having each of the seven possible scores, the essays are most densely clustered around scores 2.5 and 3.0. A system that always predicts one of these two scores will very frequently be right. For this reason, we develop a *most frequent* baseline. Given a training set, Baseline 1 counts the number of essays assigned to each of the seven scores. From these counts, it determines which score is most frequent and assigns this most frequent score to each test essay.

5.2 Baseline 2: Learning-based Ong et al.

Our second baseline is a learning-based version of Ong et al.'s (2014) system. Recall from the introduction that Ong et al. presented a rule-based approach to predict the holistic score of an argumentative essay. Their approach was composed of two steps. First, they constructed eight heuristic rules for automatically labeling each of the sentences in their corpus with exactly one of the following argument labels: OPPOSES, SUPPORTS, CITATION, CLAIM, HYPOTHESIS, CURRENT STUDY, or NONE. After that, they employed these sentence labels to construct five heuristic rules to holistically score a student essay.

We create Baseline 2 as follows, employing the methods described in Section 4 for training, parameter tuning, and testing. We employ Ong et al.'s method to tag each sentence of our essays with an argument label, but modify their method to accommodate differences between their and our corpus. In particular, our more informal corpus does not contain CURRENT STUDY or CITATION sentences, so we removed portions of rules that attempt to identify these labels (e.g. portions of rules that search for a four-digit number, as would appear as the year in a citation). Our resulting rule set is shown in Table 4. If more than one of these rules applies to a sentence, we tag it with the label from the earliest rule that applies.

#	Rule
1	Sentences that begin with a comparison discourse connective or contain any string prefixes from "conflict" or "oppose" are tagged OPPOSES.
2	Sentences that begin with a contingency connective are tagged SUPPORTS.
3	Sentences containing any string prefixes from "suggest", "evidence", "shows", "Essentially", or "indicate" are tagged CLAIM.
4	Sentences in the first, second, or last paragraph that contain string prefixes from "hypothes", or "predict", but do not contain string prefixes from "conflict" or "oppose" are tagged HYPOTHESIS.
5	Sentences containing the word "should" that contain no contingency connectives or string prefixes from "conflict" or "oppose" are also tagged HYPOTHESIS.
6	If the previous sentence was tagged hypothesis and this sentence begins with an expansion connective, it is also tagged HYPOTHESIS.
7	Do not apply a label to this sentence.

Table 4: Sentence labeling rules.

After labeling all the sentences in our corpus, we then convert three of their five heuristic scoring rules into features for training a regressor.[3] The resulting three features describe (1) whether an essay contains at least one sentence labeled HYPOTHESIS, (2) whether it contains at least one sentence labeled OPPOSES, and (3) the sum of CLAIM sentences and SUPPORTS sentences divided by the number of paragraphs in the essay. If the value of the last feature exceeds 1, we instead assign it a value of 1. These features make sense because, for example, we would expect essays containing lots of SUPPORTS sentences to offer stronger arguments.

6 Our Approach

Our approach augments the feature set available to Baseline 2 with seven types of novel features.

1. POS N-grams (POS) Word n-grams, though commonly used as features for training text classifiers, are typically not used in automated essay

[2] For parameter tuning, we employ the following c values: 10^0 10^1, 10^2, 10^3, 10^4, 10^5, or 10^6.

[3] We do not apply the remaining two of their heuristic scoring rules because they deal solely with current studies and citations.

grading. The reason is that any list of word n-gram features automatically compiled from a given set of training essays would be contaminated with prompt-specific n-grams that may make the resulting regressor generalize less well to essays written for new prompts.

To generalize our feature set in a way that does not risk introducing prompt-dependent features, we introduce POS n-gram features. Specifically, we construct one feature from each sequence of $1-5$ part-of-speech tags appearing in our corpus. In order to obtain one of these features' values for a particular essay, we automatically label each essay with POS tags using the Stanford CoreNLP system (Manning et al., 2014), then count the number of times the POS tag sequence occurs in the essay. An example of a useful feature of this type is "CC NN ,", as it is able to capture when a student writes either "for instance," or "for example,". We normalize each essay's set of POS n-gram features to unit length.

2. Semantic Frames (SFR) While POS n-grams provide syntactic generalizations of word n-grams, FrameNet-style semantic role labels provide semantic generalizations. For each essay in our data set, we employ SEMAFOR (Das et al., 2010) to identify each semantic frame occurring in the essay as well as each frame element that participates in it. For example, a semantic frame may describe an event that occurs in a sentence, and the event's frame elements may be the people or objects that participate in the event. For a more concrete example, consider the sentence "I said that I do not believe that it is a good idea". This sentence contains a Statement frame because a statement is made in it. One of the frame elements participating in the frame is the Speaker "I". From this frame, we would extract a feature pairing the frame together with its frame element to get the feature "Statement-Speaker-I". We would expect this feature to be useful for argument strength scoring because we noticed that essays that focus excessively on the writer's personal opinions and experiences tended to receive lower argument strength scores.

As with POS n-grams, we normalize each essay's set of Semantic Frame features to unit length.

3. Transitional Phrases (TRP) We hypothesize that a more cohesive essay, being easier for a reader to follow, is more persuasive, and thus makes a stronger argument. For this reason, it would be worthwhile to introduce features that measure how cohesive an essay is. Consequently, we create features based on the 149 transitional phrases compiled by Study Guides and Strategies[4]. Study Guides and Strategies collected these transitions into lists of phrases that are useful for different tasks (e.g. a list of transitional phrases for restating points such as "in essence" or "in short"). There are 14 such lists, which we use to generalize transitional features. Particularly, we construct a feature for each of the 14 phrase type lists. For each essay, we assign the feature a value indicating the average number of transitions from the list that occur in the essay per sentence. Despite being phrase-based, transitional phrases features are designed to capture only *prompt-independent* information, which as previously mentioned is important in essay grading.

4. Coreference (COR) As mentioned in our discussion of transitional phrases, a strong argument must be cohesive so that the reader can understand what is being argued. While the transitional phrases already capture one aspect of this, they cannot capture when transitions are made via repeated mentions of the same entities in different sentences. We therefore introduce a set of 19 coreference features that capture information such as the fraction of an essay's sentences that mention entities introduced in the prompt, and the average number of total mentions per sentence.[5] Calculating these feature values, of course, requires that the text be annotated with coreference information. We automatically coreference-annotate the essays using the Stanford CoreNLP system.

5. Prompt Agreement (PRA) An essay's prompt is always either a single statement, or can be split up into multiple statements with which a writer may AGREE STRONGLY, AGREE SOMEWHAT, be NEUTRAL, DISAGREE SOMEWHAT, DISAGREE STRONGLY, NOT ADDRESS, or explicitly have NO OPINION on. We believe information regarding which of these categories a writer's opinion falls into has some bearing on the strength of her argument because, for example, a writer who explicitly mentions having no opinion has probably not made a persuasive argument.

For this reason, we annotate a subset of 830 of our ICLE essays with these agreement labels. We then train a multiclass maximum entropy classifier

[4] `http://www.studygs.net/wrtstr6.htm`

[5] See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for a complete list of coreference features.

using MALLET (McCallum, 2002) for identifying which one of these seven categories an author's opinion falls into. The feature set we use for this task includes POS n-gram and semantic frame features as described earlier in this section, lemmatized word 1-3 grams, the keyword and prompt adherence keyword features we described in Persing and Ng (2013) and Persing and Ng (2014), respectively, and a feature indicating which statement in the prompt we are attempting to classify the author's agreement level with respect to.

Our classifier's training set in this case is the subset of prompt agreement annotated essays that fall within the training set of our 1000 essay argument strength annotated data. We then apply the trained classifier to our entire 1000 essay set in order to obtain predictions from which we can then construct features for argument strength scoring. For each prediction, we construct a feature indicating which of the seven classes the classifier believes is most likely, as well as seven additional features indicating the probability the classifier associates with each of the seven classes.

We produce additional related annotations on this 830 essay set in cases when the annotated opinion was neither AGREE STRONGLY nor DISAGREE STRONGLY, as the reason the annotator chose one of the remaining five classes may sometimes offer insight into the writer's argument. The classes of reasons we annotate include cases when the writer: (1) offered CONFLICTING OPINIONS, (2) EXPLICITLY STATED an agreement level, (3) gave only a PARTIAL RESPONSE to the prompt, (4) argued a SUBTLER POINT not capturable by extreme opinions, (5) did not make it clear that the WRITER'S POSITION matched the one she argued, (6) only BRIEFLY DISCUSSED the topic, (7) CONFUSINGLY PHRASED her argument, or (8) wrote something whose RELEVANCE to the topic was not clear. We believe that knowing which reason(s) apply to an argument may be useful for argument strength scoring because, for example, the CONFLICTING OPINIONS class indicates that the author wrote a confused argument, which probably deserves a lower argument strength score.

We train eight binary maximum entropy classifiers, one for each of these reasons, using the same training data and feature set we use for agreement level prediction. We then use the trained classifiers to make predictions for these eight reasons on all 1000 essays. Finally, we generate features for our argument strength regressor from these predictions by constructing two features from each of the eight reasons. The first binary feature is turned on whenever the maximum entropy classifier believes that the reason applies (i.e., when it assigns the reason a probability of over 0.5). The second feature's value is the probability the classifier assigns for this reason.

6. Argument Component Predictions (ACP) Many of our features thus far do not result from an attempt to build a deep understanding of the structure of the arguments within our essays. To introduce such an understanding into our system, we follow Stab and Gurevych (2014a), who collected and annotated a corpus of 90 persuasive essays (not from the ICLE corpus) with the understanding that the arguments contained therein consist of three types of argument components. In one essay, these argument components typically include a MAJOR CLAIM, several lesser CLAIMs which usually support or attack the major claim, and PREMISEs which usually underpin the validity of a claim or major claim.

Stab and Gurevych (2014b) trained a system to identify these three types of argument components within their corpus given the components' boundaries. Since our corpus does not contain annotated argument components, we modify their approach in order to simultaneously identify argument components and their boundaries.

We begin by implementing a maximum entropy version of their system using MALLET for performing the argument component identification task. We feed our system the same structural and lexical features they described. We then augment the system in the following ways.

First, since our corpus is not annotated with argument component boundaries, we construct a set of low precision, high recall heuristics for identifying the locations in each sentence where an argument component's boundaries might occur. The majority of these rules depend primarily on a syntactic parse tree we automatically generated for the sentence using the Stanford CoreNLP system. Since a large majority of annotated argument components are substrings of a simple declarative clause (an S node in the parse tree), we begin by identifying each S node in the sentence's tree.

Given one of these clauses, we collect a list of left and right boundaries where an argument component may begin or end. The rules we used to

(a) Potential left boundary locations

#	Rule
1	Exactly where the S node begins.
2	After an initial explicit connective, or if the connective is immediately followed by a comma, after the comma.
3	After nth comma that is an immediate child of the S node.
4	After nth comma.

(b) Potential right boundary locations

#	Rule
5	Exactly where the S node ends, or if S ends in a punctuation, immediately before the punctuation.
6	If the S node ends in a (possibly nested) SBAR node, immediately before the nth shallowest SBAR.[6]
7	If the S node ends in a (possibly nested) PP node, immediately before the nth shallowest PP.

Table 5: Rules for extracting candidate argument component boundary locations.

find these boundaries are summarized in Table 5.

Given an S node, we use our rules to construct up to $l \times r$ argument component candidate instances to feed into our system by combining each left boundary with each right boundary that occurs after it, where l is the number of potential left boundaries our rules found, and r is the number of right boundaries they found.

The second way we augment the system is by adding a boundary rule feature type. Whenever we generate an argument component candidate instance, we augment its normal feature set with two binary features indicating which heuristic rule was used to find the candidate's left boundary, and which rule was used to find its right boundary. If two rules can be used to find the same left or right boundary position, the first rule listed in the table is the one used to create the boundary rule feature. This is why, for example, the table contains multiple rules that can find boundaries at comma locations. We would expect some types of commas (e.g., ones following an explicit connective) to be more significant than others.

A last point that requires additional explanation is that several of the rules contain the word "nth". This means that, for example, if a sentence contains multiple commas, we will generate multiple left boundary positions for it using rule 4, and the left boundary rule feature associated with each position will be different (e.g., there is a unique feature for the first comma, and for the the second comma, etc.).

The last augmentation we make to the system is that we apply a NONE label to all argument component candidates whose boundaries do not exactly match those of a gold standard argument component. While Stab and Gurevych also did this, their list of such argument component candidates consisted solely of sentences containing no argument components at all. We could not do this, however, since our corpus is not annotated with argument components and we therefore do not know which sentences these would be.

We train our system on all the instances we generated from the 90 essay corpus and apply it to label all the instances we generated in the same way from our 1000 essay ICLE corpus. As a result, we end up with a set of automatically generated argument component annotations on our 1000 essay corpus. We use these annotations to generate five additional features for our argument strength scoring SVM regressor. These features' values are the number of major claims in the essay, the number of claims in the essay, the number of premises in the essay, the fraction of paragraphs that contain either a claim or a major claim, and the fraction of paragraphs that contain at least one argument component of any kind.

7. Argument Errors (ARE) We manually identified three common problems essays might have that tend to result in weaker arguments, and thus lower argument strength scores. We heuristically construct three features, one for each of these problems, to indicate to the learner when we believe an essay has one of these problems.

It is difficult to make a reasonably strong argument in an essay that is too short. For this reason, we construct a feature that encodes whether the essay has 15 or fewer sentences, as only about 7% of our essays are this short.

In the Stab and Gurevych corpus, only about 5% of paragraphs have no claims or major claims in them. We believe that an essay that contains too many of these claim or major claim-less paragraphs may have an argument that is badly structured, as it is typical for a paragraph to contain one or two (major) claim(s). For this reason, we construct a feature that encodes whether more than half of the essay's paragraphs contain no claims or major claims, as indicated by the previously generated automatic annotations.

[6] The S node may end in an SBAR node which itself has an SBAR node as its last child, and so on. In this case, the S node could be said to end with any of these "nested" SBARS, so we use the position before each (nth) one as a right boundary.

Similarly, only 5% of the Stab and Gurevych essays contain no argument components at all. We believe that an essay that contains too many of these component-less paragraphs is likely to have taken too much space discussing issues that are not relevant to the main argument of the essay. For this reason, we construct a feature that encodes whether more than one of the essay's paragraphs contain no components, as indicated by the previously generated automatic annotations.

7 Evaluation

In this section, we evaluate our system for argument strength scoring. All the results we report are obtained via five-fold cross-validation experiments. In each experiment, we use 60% of our labeled essays for model training, another 20% for parameter tuning and feature selection, and the final 20% for testing. These correspond to the training set, held-out validation data, and test set mentioned in Section 4.

7.1 Scoring Metrics

We employ four evaluation metrics. As we will see below, $S1$, $S2$, and $S3$ are *error* metrics, so lower scores on them imply better performance. In contrast, PC is a *correlation* metric, so higher correlation implies better performance.

The simplest metric, $S1$, measures the frequency at which a system predicts the wrong score out of the seven possible scores. Hence, a system that predicts the right score only 25% of the time would receive an $S1$ score of 0.75.

The $S2$ metric measures the average distance between a system's predicted score and the actual score. This metric reflects the idea that a system that predicts scores close to the annotator-assigned scores should be preferred over a system whose predictions are further off, even if both systems estimate the correct score at the same frequency.

The $S3$ metric measures the average square of the distance between a system's score predictions and the annotator-assigned scores. The intuition behind this metric is that not only should we prefer a system whose predictions are close to the annotator scores, but we should also prefer one whose predictions are not too frequently very far away from the annotated scores. The three error metric scores are given by:

$$\frac{1}{N}\sum_{A_j \neq E'_j} 1, \quad \frac{1}{N}\sum_{j=1}^{N} |A_j - E_j|, \quad \frac{1}{N}\sum_{j=1}^{N} (A_j - E_j)^2$$

System	$S1$	$S2$	$S3$	PC
Baseline 1	.668	.428	.321	.000
Baseline 2	.652	.418	.267	.061
Our System	.618	.392	.244	.212

Table 6: Five-fold cross-validation results for argument strength scoring.

where A_j, E_j, and E'_j are the annotator assigned, system predicted, and rounded system predicted scores[7] respectively for essay j, and N is the number of essays.

The last metric, PC, computes Pearson's correlation coefficient between a system's predicted scores and the annotator-assigned scores. PC ranges from -1 to 1. A positive (negative) PC implies that the two sets of predictions are positively (negatively) correlated.

7.2 Results and Discussion

Five-fold cross-validation results on argument strength score prediction are shown in Table 6. The first two rows show our baseline systems' performances. The best baseline system (Baseline 2), which recall is a learning-based version of Ong et al.'s (2014) system, predicts the wrong score 65.2% of the time. Its predictions are off by an average of .418 points, the average squared error of its predictions is .267, and its average Pearson correlation coefficient with the gold argument strength score across the five folds is .061.

Results of our system are shown on the third row of Table 6. Rather than using all of the available features (i.e., Baseline 2's features and the novel features described in Section 6), our system uses only the feature subset selected by the backward elimination feature selection algorithm (Blum and Langley, 1997) that achieves the best performance on the validation data (see Section 7.3 for details). As we can see, our system predicts the wrong score only 61.8% of the time, predicts scores that are off by an average of .392 points, the average squared error of its predictions is .244, and its average Pearson correlation coefficient with the gold scores is .212. These numbers correspond to relative error reductions[8] of 5.2%,

[7] We round all predictions to 1.0 or 4.0 if they fall outside the 1.0−4.0 range and round $S1$ predictions to the nearest half point.

[8] These numbers are calculated $\frac{B-O}{B-P}$ where B is the baseline system's score, O is our system's score, and P is a perfect score. Perfect scores for error measures and PC are 0 and 1 respectively.

6.2%, 8.6%, and 16.1% over Baseline 2 for S1, S2, S3, and PC, respectively, the last three of which are significant improvements[9]. The magnitudes of these improvements suggest that, while our system yields improvements over the best baseline by all four measures, its greatest contribution is that its predicted scores are best-correlated with the gold standard argument strength scores.

7.3 Feature Ablation

To gain insight into how much impact each of the feature types has on our system, we perform feature ablation experiments in which we remove the feature types from our system one-by-one.

We show the results of the ablation experiments on the held-out validation data as measured by the four scoring metrics in Table 7. The top line of each subtable shows what a system that uses all available features's score would be if we removed just one of the feature types. So to see how our system performs by the PC metric if we remove only prompt agreement (PRA) features, we would look at the first row of results of Table 7(d) under the column headed by PRA. The number here tells us that the resulting system's PC score is .303. Since our system that uses all feature types obtains $S1$, $S2$, $S3$, and PC scores of .521, .366, .218, and .341 on the validation data respectively, the removal of PRA features costs the complete system .038 PC points, and thus we can infer that the inclusion of PRA features has a beneficial effect.

From row 1 of Table 7(a), we can see that removing the Baseline 2 feature set (BAS) yields a system with the best $S1$ score in the presence of the remaining feature types in this row. For this reason, we permanently remove the BAS features from the system before we generate the results on line 2. We iteratively remove the feature type that yields a system with the best performance in this way until we get to the last line, where only one feature type is used to generate each result.

Since the feature type whose removal yields the best system is always the rightmost entry in a line, the order of column headings indicates the relative importance of the feature types, with the leftmost feature types being most important to performance and the rightmost feature types being least important in the presence of the other feature types. The score corresponding to the best system is boldfaced for emphasis, indicating that all feature types appearing to its left are included in the best system.[10]

.281	.281						

Table 7: Feature ablation results. In each subtable, the first row shows how our system would perform on the validation set essays if each feature type was removed. We then remove the least important feature type, and show in the next row how the adjusted system would perform without each remaining type.

It is interesting to note that while the relative importance of different feature types does not remain exactly the same if we measure performance in different ways, we can see that some feature types tend to be more important than others in a majority of the four scoring metrics.

From these tables, it is clear that POS n-grams

[9] All significance tests are paired t-tests with $p < 0.05$.

[10] The reason the performances shown in these tables appear so much better than those shown previously is that in these tables we tune parameters and display results on the validation set in order to make it clearer why we chose to remove each feature type. In Table 6, by contrast, we tune parameters on the validation set, but display results using those parameters on the test set.

	$S1$			$S2$			$S3$			PC		
Gold	.25	.50	.75	.25	.50	.75	.25	.50	.75	.25	.50	.75

3.5	2.74	2.85	2.97	2.78	2.89	3.02	2.79	2.90	3.00	2.81	2.90	2.98
4.0	2.75	2.87	3.10	2.76	2.85	3.09	2.76	2.83	3.08	2.81	2.86	3.19

Table 8: Distribution of regressor scores for our system.

(POS), prompt agreement features (PRA), and argument component predictions (ACP) are the most generally important feature types in roughly that order. They all appear in the leftmost three positions under the tables for metrics $S2$, $S3$, and PC, the three metrics by which our system significantly outperforms Baseline 2. Furthermore, removing any of them tends to have a larger negative impact on our system than removing any of the other feature types.

Transitional phrase features (TRP) and Baseline 2 features (BAS), by contrast, are of more middling importance. While both appear in the best feature sets for the aforementioned metrics (i.e., they appear to the left of the boldfaced entry in the corresponding ablation tables), the impact of their removal is relatively less than that of POS, PRA, or ACP features.

Finally, while the remaining three feature types might at first glance seem unimportant to argument strength scoring, it is useful to note that they all appear in the best performing feature set as measured by at least one of the four scoring metrics. Indeed, semantic frame features (SFR) appear to be the most important feature type as measured by the $S1$ metric, despite being one of the least useful feature types as measured by the other performance metrics. From this we learn that when designing an argument strength scoring system, it is important to understand what the ultimate goal is, as the choice of performance metric can have a large impact on what type of system will seem ideal.

7.4 Analysis of Predicted Scores

To more closely examine the behavior of our system, in Table 8 we chart the distributions of scores it predicts for essays having each gold standard score. As an example of how to read this table, consider the number 2.60 appearing in row 2.0 in the .25 column of the $S3$ region. This means that 25% of the time, when our system with parameters tuned for optimizing $S3$ (including the $S3$ feature set as selected in Table 7(c)) is presented with a test essay having a gold standard score of 2.0, it predicts that the essay has a score less than or equal to 2.60.

From this table, we see that our system has a bias toward predicting more frequent scores as the smallest entry in the table is 2.36 and the largest entry is 3.19, and as we saw in Table 3, 71.4% of essays have gold scores in this range. Nevertheless, our system does not rely entirely on bias, as evidenced by the fact that each column in the table has a tendency for its scores to ascend as the gold standard score increases, implying that our system has some success at predicting lower scores for essays with lower gold standard argument strength scores and higher scores for essays with higher gold standard argument strength scores. The major exception to this rule is line 1.0, but this is to be expected since there are only two essays having this gold score, so the sample from which the numbers on this line are calculated is very small.

8 Conclusion

We proposed a feature-rich approach to the new problem of predicting argument strength scores on student essays. In an evaluation on 1000 argumentative essays selected from the ICLE corpus, our system significantly outperformed a baseline system that relies solely on features built from heuristically labeled sentence argument function labels by up to 16.1%. To stimulate further research on this task, we make all of our annotations publicly available.

Abstract

We study the problem of summarizing DAG-structured topic hierarchies over a given set of documents. Example applications include automatically generating Wikipedia disambiguation pages for a set of articles, and generating candidate multi-labels for preparing machine learning datasets (e.g., for text classification, functional genomics, and image classification). Unlike previous work, which focuses on clustering the set of documents using the topic hierarchy as features, we directly pose the problem as a submodular optimization problem on a topic hierarchy using the documents as features. Desirable properties of the chosen topics include document coverage, specificity, topic diversity, and topic homogeneity, each of which, we show, is naturally modeled by a submodular function. Other information, provided say by unsupervised approaches such as LDA and its variants, can also be utilized by defining a submodular function that expresses coherence between the chosen topics and this information. We use a large-margin framework to learn convex mixtures over the set of submodular components. We empirically evaluate our method on the problem of automatically generating Wikipedia disambiguation pages using human generated clusterings as ground truth. We find that our framework improves upon several baselines according to a variety of standard evaluation metrics including the Jaccard Index, F1 score and NMI, and moreover, can be scaled to extremely large scale problems.

1 Introduction

Several real world machine learning applications involve hierarchy based categorization of topics for a set of objects. Objects could be, e.g., a set of documents for text classification, a set of genes in functional genomics, or a set of images in computer vision. One can often define a natural topic hierarchy to categorize these objects. For example, in text and image classification problems, each document or image is assigned a hierarchy of labels — a baseball page is assigned the labels "baseball" and "sports." Moreover, many of these applications, naturally have an existing topic hierarchy generated on the entire set of objects (Rousu et al., 2006; Barutcuoglu et al., 2006; ling Zhang and hua Zhou, 2007; Silla and Freitas, 2011; Tsoumakas et al., 2010).

Given a DAG-structured topic hierarchy and a subset of objects, we investigate the problem of finding a subset of DAG-structured topics that are induced by that subset (of objects). This problem arises naturally in several real world applications. For example, consider the problem of identifying appropriate label sets for a collection of articles. Several existing text collection datasets such as 20 Newsgroup[1], Reuters-21578[2] work with a predefined set of topics. We observe that these topic names are highly abstract[3] for the articles categorized under them. On the other hand, techniques proposed by systems such as Wikipedia Miner (Milne, 2009) and TAGME (Ferragina and Scaiella, 2010) generate several labels for each article in the dataset that are highly specific to the article. Collating all labels from all articles to create a label

Figure 1: Topic Summarization overview. On the left, we show many documents related to Apple. In the middle, a Wikipedia category hierarchy shown as a topic DAG, links these documents at the leaf level. On the right, we show the output of our summarization process, which creates a set of summary topics (Plants, Technology, Companies, Films, Music and Places in this example) with the input documents classified under them.

set for the dataset can result in a large number of labels and become unmanageable. Our proposed techniques can summarize such large sets of labels into a smaller and more meaningful label sets using a DAG-structured topic hierarchy. This also holds for image classification problems and datasets like ImageNet (Deng et al., 2009). We use the term *summarize* to highlight the fact that the smaller label set semantically covers the larger label set. For example, the topics *Physics*, *Chemistry*, and *Mathematics* can be summarized into a topic *Science*.

A particularly important application of our work (and the one we use for our evaluations in Section 4) is the following: Given a collection of articles spanning different topics, but with similar titles, automatically generate a disambiguation page for those titles using the Wikipedia category hierarchy[4] as a topic DAG. Disambiguation pages[5] on Wikipedia are used to resolve conflicts in article titles that occur when a title is naturally associated with multiple articles on distinct topics. Each disambiguation page organizes articles into several groups, where the articles in each group pertain only to a specific topic. Disambiguations may be seen as paths in a hierarchy leading to different articles that arguably could have the same title. For example, the title *Apple*[6] can refer to a plant, a company, a film, a television show, a place, a technology, an album, a record label, and a newspaper daily. The problem then, is to organize the articles into multiple groups where each group contains articles of similar nature (topics) and has an appropriately discerned group heading. Figure 1 describes the topic summarization process for creation of the disambiguation page for "Apple".

All the above mentioned problems can be modeled as the problem of finding the most representative subset of topic nodes from a DAG-Structured topic hierarchy. We argue that many formulations of this problem are natural instances of submodular maximization, and provide a learning framework to create submodular mixtures to solve this problem. A set function $\mathrm{f}(.)$ is said to be submodular if for any element v and sets $A \subseteq B \subseteq V \setminus \{v\}$, where V represents the ground set of elements, $\mathrm{f}(A \cup \{v\}) - \mathrm{f}(A) \geq \mathrm{f}(B \cup \{v\}) - \mathrm{f}(B)$. This is called the diminishing returns property and states, informally, that adding an element to a smaller set increases the function value more than adding that element to a larger set. Submodular functions naturally model notions of coverage and diversity in applications, and therefore, a number of machine learning problems can be modeled as forms of submodular optimization (Kempe et al., 2003; Krause and Guestrin, 2005; Narasimhan and Bilmes, 2004; Iyer et al., 2013; Lin and Bilmes, 2012; Lin and Bilmes, 2010). In this paper, we investigate structured prediction methods for learn-

[6] http://en.wikipedia.org/wiki/Apple_(disambiguation)

ing weighted mixtures of submodular functions to summarize topics for a collection of objects using DAG-structured topic hierarchies. Throughout this paper we use the terms "topic" and "category" interchangeably.

1.1 Related Work

To the best of our knowledge, the specific problem we consider here is new. Previous work on identifying topics can be broadly categorized into one of the following types: a) cluster the objects and then identify names for the clusters; or b) dynamically identify topics (including hierarchical) for a set of objects. LDA (Blei et al., 2003) clusters the documents and simultaneously produces a set of topics into which the documents are clustered. In LDA, each document may be viewed as a mixture of various topics and the topic distribution is assumed to have a Dirichlet prior. LDA associates a group of high probability words to each identified topic. A name can be assigned to a topic by manually inspecting the words or using additional algorithms like (Mei et al., 2007; Maiya et al., 2013). LDA does not make use of existing topic hierarchies and correlation between topics. The Correlated Topic Model (Blei and Lafferty, 2006) induces a correlation structure between topics by using the logistic normal distribution instead of the Dirichlet. Another extension is the hierarchical LDA (Blei et al., 2004), where topics are joined together in a hierarchy by using the nested Chinese restaurant process. Nonparametric extensions of LDA include the Hierarchical Dirichlet Process (Teh et al., 2006) mixture model, which allows the number of topics to be unbounded and learnt from data and the Nested Chinese Restaurant Process which allows topics to be arranged in a hierarchy whose structure is learnt from data. In each of these approaches, unlike our proposed approach, an existing topic hierarchy is not used, nor is any additional object-topic information leveraged.

The pachinko allocation model (PAM)(Li and McCallum, 2006) captures arbitrary, nested, and possibly sparse correlations between topics using a DAG. The leaves of the DAG represent individual words in the vocabulary, while each interior node represents a correlation among its children, which may be words or other interior nodes (topics). PAM learns the probability distributions of words in a topic, subtopics in a topic, and topics in a document. We cannot, however, generate a subset of topics from a large existing topic DAG that can act as summary topics, using PAM.

HSLDA (Perotte et al., 2011) introduces a hierarchically supervised LDA model to infer hierarchical labels for a document. It assumes an existing label hierarchy in the form of a tree. The model infers one or more labels such that, if a label l is inferred as relevant to a document, then all the labels from l to the root of the tree are also inferred as relevant to the document. Our approach differs from HSLDA since: (1) we use the label hierarchy to infer a set of labels for a *group* of documents; (2) we do not enforce the label hierarchy to be a tree as it can be a DAG; and (3) generalizing HSLDA to use a DAG structured hierarchy and infer labels for a *group* of documents (e.g., combining into one big document) also may not help in solving our problem. HSLDA will apply *all* the relevant labels to the documents as per the classifier that it learns for every label. Moreover, the "root" label is always applied and it is very likely that many labels near the top level of the label hierarchy are also classified as relevant to the group of documents.

Wei and James (Bi and Kwok, 2011) present a hierarchical multi-label classification algorithm that can be used on both tree and DAG structured hierarchies. They formulate a search for the optimal consistent multi-label as the finding of the best subgraph in a tree/DAG. In our approach, we assume, individual documents are already associated with one or more topics and we find a consistent label set for a group of documents using the DAG structured topic hierarchy.

Medelyan et al. (Medelyan et al., 2008) and Ferragina et al. (Ferragina and Scaiella, 2010) detect topics for a document using Wikipedia article names and category names as the topic vocabulary. These systems are able to extract signals from a text document and identify Wikipedia articles and/or categories that optimally match the document and assign those article/category names as topics for the document. When run on a large collection of documents, these approaches generate enormous numbers of topics, a problem our proposed approach addresses.

1.2 Our Contributions

While most prior work discussed above focuses on the underlying set of documents, (*e.g.*, by clustering documents), we focus directly on the topics. In particular, we formulate the problem as subset selection on the set of topics within a DAG while simultaneously considering the documents to be categorized. Our method can scale to the colossal size of the DAG (1 million topics and 3 million correlation links between topics in Wikipedia). Moreover, our approach can naturally incorporate outputs from many of the aforementioned algorithms. Our approach is based on submodular maximization and mixture learning, which has been successfully used in applications such as document summarization (Lin, 2012) and image summarization (Tschiatschek et al., 2014), but has never been applied to topic identification tasks or, more generally, DAG summarization.

We introduce a family of submodular functions to identify an appropriate set of topics from a DAG structured hierarchy of topics for a group of documents. We characterize this topic appropriateness through a set of desirable properties such as coverage, diversity, specificity, clarity, and relevance. Each of the submodular function components we consider are monotone, thereby ensuring a near optimal performance obtainable via a simple greedy algorithm for optimization.[7]. We also show how our technique naturally embodies outputs of other algorithms such as LDA, clustering, and classifications. Finally, we utilize a large margin formulation for learning mixtures of these submodular functions, and show how we can optimally learn them from training data.

Our approach demonstrates how to utilize the features collectively in the document space and the topic space to infer a set of topics. From an empirical perspective, we introduce and evaluate our approach on a dataset of around 8000 disambiguations that was extracted from Wikipedia and subsequently cleaned using the methods described in the experimentation section. We show that our learning framework outperforms many of the baselines, and is practical enough to be used on large corpora.

2 Problem Formulation

Let $G\,(V, E)$ be the DAG structured topic hierarchy with V topics. These topics are observed to have a parent child (*isa*) relationship forming a DAG. Let D be the set of documents that are associated with one or more of these topics. The middle portion of Figure 1 depicts a topic hierarchy with associated documents. The association links between the documents and topics can be hard or soft. In case of a hard link, a document is attached to a set of topics. Examples include multi-labeled documents. In case of a soft link, a document is associated with a topic with some degree of confidence (or probability). Furthermore, if a document is attached to a topic t, we assume that all the ancestor topics of t are also relevant for that document. This assumption has been employed in earlier works (Blei et al., 2004; Bi and Kwok, 2011; Rousu et al., 2006) as well. Given a budget of K, our objective is to choose a set of K topics from V, which best describe the documents in D. The notion of best describing topics is characterized through a set of desirable properties - coverage, diversity, specificity, clarity, relevance and fidelity - that K topics have to satisfy. The submodular functions that we introduce in the next section ensure these properties are satisfied. Formally, we solve the following discrete optimization problem:

$$S^* \in \underset{S \subseteq V : |S| \leq K}{\operatorname{argmax}} \sum_i w_i f_i(S) \tag{1}$$

where, f_i are monotone submodular mixture components and $w_i \geq 0$ are the weights associated with those mixture components. Set S^* is the summary topics scored best.

It is easy to find massive (i.e., size in the order of million) DAG structured topic hierarchies in practice. Wikipedia's category hierarchy consists of more than 1M categories (topics) arranged hierarchically. In fact, they form a cyclic graph (Zesch and Gurevych, 2007). However, we can convert it to a DAG by eliminating the cycles as described in the supplementary material. YAGO (Suchanek et al., 2007) and Freebase (Bollacker et al., 2008) are other instances of massive topic hierarchies. The association of the documents with the existing topic hierarchy is also well studied. Systems such as WikipediaMiner (Milne, 2009), TAGME (Ferragina and Scaiella, 2010) and several annotation systems such as (Dill et al., 2003; Mihalcea and Csomai, 2007; Bunescu and Pasca, 2006) attach topics from Wikipedia (and other catalogs) to the documents by establishing the hard or soft links mentioned above.

Our goal is the following: Given a (ground set) collection V of topics organized in a pre-existing hierarchical DAG structure, and a collection D of documents, chose a size $K \in \mathbb{Z}_+$ representative subset of topics. Our approach is distinct from earlier work (e.g., (Kanungo et al., 2002; Blei et al., 2003)) where typically only a set of documents is classified and categorized in some way. We next provide a few definitions needed later in the paper.

Definition 1: Transitive Cover Γ**):** A topic t is said to cover a set of documents $\Gamma(t)$, called the transitive cover of the topic t, if for all documents $i \in \Gamma(t)$, either i is associated directly with topic t or with any of the descendant topics of t in the topic DAG. A natural extension of this definition to a set of topics T is defined as $\Gamma(T) = \cup_{t \in T} \Gamma(t)$.

[7] A simple greedy algorithm (Nemhauser et al., 1978) obtains a $1 - 1/e$ approximation guarantee for monotone submodular function maximization

Definition 2: Truncated Transitive Cover (Γ^α)**:** This is a transitive cover of topic t, but with the limitation that the path length between a document and the topic t is not more than α. Hence, $|\Gamma^\alpha(t)| \leq |\Gamma(t)|$.

While our problem is closely related to clustering approaches, which consider the set of documents directly, there are some crucial differences. In particular, we focus on producing a clustering of documents where clusters are encouraged to honor a pre-defined DAG structured topic hierarchy. Existing agglomerative clustering algorithms focusing on the coverage of documents may not produce the desired clustering. To understand this, consider six documents d1, d2 . . . d6 to be grouped into three clusters. There may be multiple ways to do this depending upon multiple aggregation paths present in the topic DAG: ((d1, d2), (d3, d4), (d5, d6)) or ((d1, d2, d3), (d4, d5), (d6)) or ((d1, d2, d3, d4), (d5), (d6)) or something else. Hence, we need more stringent measures to prefer one clustering over the others. Our work addresses this with a variety of quality criteria (coverage, diversity, specificity, clarity, relevance and fidelity, which are explained later in this paper) that are organically derived from well established submodular functions. And, most importantly, we learn the right mixture of these qualities to be enforced from the data itself. Furthermore, our approach also generalizes these clustering approaches, since one of the components in our mixture of submodular functions is defined via these unsupervised approaches, and maps a given clustering to a set of topics in the hierarchy.

3 Submodular Components and Learning

Summarization is the task of extracting information from a source that is both small in size but still representative. Our problem is different from traditional summarization tasks since we have an underlying DAG as a topic hierarchy that we wish to summarize in response to a subset of documents. Thus, a critical part of our problem is to take the graph structure into account while creating the summaries. Below, we identify properties we wish our summaries to posses.

Coverage: A summary set of topics should cover most of the documents. A document is said to be covered by a topic if there exists a path from the topic, going through intermediary descendant topics, to the document, i.e., the document is within the transitive cover of the topic.

Diversity: Summaries should be as diverse as possible, i.e., each summary topic should cover a unique set of documents. When a document is covered by more than one topic, that document is redundantly covered, e.g., "Finance" and "Banking" would be unlikely members of the same summary.

Summary qualities also involve "quality" notions, including:

Specificity/Clarity/Relevance/Coherence: These quality measures help us choose a set of topics that are neither too abstract nor overly specific. They ensure that the topics are clear and relevant to the documents that they represent. When additional information such as clustering (from LDA or other sources) and tagging (manual) documents is available, these quality criteria encourage the chosen topics to show resemblance (coherence) to those clustering/tagging in terms of transitive cover of documents they produce.

In the below, we define a variety of submodular functions that capture the above properties, and we then describe a large margin learning framework for learning convex mixtures of such components.

3.1 Submodular Components

3.1.1 Coverage Based Functions

Coverage components capture "coverage" of a set of documents.

Weighted Set Cover Function: Given a set of categories, $S \subseteq V$, define $\Gamma(S)$ as the set of documents covered — for each topic $s \in S$, $\Gamma(s) \subseteq D$ represents the documents covered by topic s and $\Gamma(S) = \cup_{s \in S}\Gamma(s)$. The weighted set cover function, defined as $f(S) = \sum_{d \in \Gamma(S)} w_d = w(\Gamma(S))$, assigns weights to the documents based on their relative importance (e.g., in Wikipedia disambiguation, the different documents could be ranked based on their priority).

Feature-based Functions: This class of function represents coverage in feature space. Given a set of categories $S \subseteq V$, and a set of features U, define $m_u(S)$ as the score associated with the set of categories S for feature $u \in U$. The feature set could represent, for example, the documents, in which case $m_u(S)$ represents the number of times document u is covered by the set S. U could also represent more complicated features. For example, in the context of Wikipedia disambiguation, U could represent TFIDF features over the documents. Feature based are then defined as $f(S) = \sum_{u \in U} \psi(m_u(S))$, where ψ is a concave (e.g., the square root) function. This function class has been successfully used in several applications (Kirchhoff and Bilmes, 2014; Wei et al., 2014a; Wei et al., 2014b).

3.1.2 Similarity based Functions

Similarity functions are defined through a similarity matrix $\mathbf{S} = \{s_{ij}\}_{i,j \in V}$. Given categories $i, j \in V$, similarity s_{ij} in our case can be defined as $s_{ij} = |\Gamma(i) \cap \Gamma(j)|$, i.e the number of documents commonly covered by both i and j.

Facility Location: The facility location function, defined as $f(S) = \sum_{i \in V} \max_{j \in S} s_{ij}$, is a natural model for k-medoids and exemplar based clustering, and has been used in several summarization problems (Tschiatschek et al., 2014; Wei et al., 2014a).

Penalty based diversity: A similarity matrix may be used to express a form of coverage of a set S but that is then penalized with a redundancy term, as in the following difference: $f(S) = \sum_{i \in V, j \in S} s_{ij} - \lambda \sum_{i \in S} \sum_{j \in S,} s_{i,j}$ (Lin and Bilmes, 2011)). Here $\lambda \in [0, 1]$. This function is submodular, but is not in general monotone, and has been used in document summarization (Lin and Bilmes, 2011), as a dispersion function (Borodin et al., 2012), and in image summarization (Tschiatschek et al., 2014).

3.1.3 Quality Control (QC) Functions

QC functions ensure a quality criteria is met by a set S of topics. We define the quality score of the set S as $F_q(S) = \sum_{s \in S} f_q(s)$, where $f_q(s)$ is the quality score of topic s for quality q. Therefore, $F_q(S)$ is a modular function in S. We investigate three types of quality control functions: Topic Specificity, Topic Clarity, and Topic Relevance.

Topic Specificity: The farther a topic is from the root of the DAG, the more specific it becomes. Topics higher up in the hierarchy are abstract and less specific. We therefore prefer topics low in the DAG, but lower topics also have less coverage. We define $f_{\text{specificity}}(s) = s_h$ where s_h is the height of topic s in the DAG. The root topic has height zero and the "height" increases as we move down the DAG in Figure 1.

Topic Clarity: Topic clarity is the fraction of descendant topics that cover one or more documents. If a topic has many descendant topics that do not cover any documents, it has less clarity. Formally, $f_{\text{clarity}}(s) = \frac{\sum_{t \in \text{descendants}(s)} [\![\Gamma(t) > 0]\!]}{|\text{descendants}(s)|}$, where $[\![\centerdot]\!]$ is the indicator function.

Topic Relevance: A topic is considered to be better related to a document if the number of hops needed to reach the document from that topic is lower. Given any set $A \subseteq D$ of document, and any topic $s \in V$, we can define $f_{\text{relevance}}(s|A) = \operatorname{argmin}_{\alpha}\{\alpha : A \subseteq \Gamma^{\alpha}(s)\}$.

QC Functions As Barrier Modular Mixtures: We introduce a modular function for every QC function as follows

$$f^{\alpha}_{\text{specificity}}(s) = \begin{cases} 1 & \text{if the height of topic } s \text{ is at least } \alpha \\ 0 & \text{otherwise} \end{cases}$$

for every possible value of α. This creates a submodular mixture with as many components as the number of possible values of α. In our experiments with Wikipedia, we had α varying from 1 to 120 stepping by 1, adding 120 modular mixture components. Similarly, we define,

$$f^{\beta}_{\text{clarity}}(s) = \begin{cases} 1 & \text{if the clarity of topic } s \text{ is at least } \beta \\ 0 & \text{otherwise} \end{cases}$$

for every possible (discretized to make it countably finite) value of β. And,

$f^{\gamma}_{\text{relevance}}(s) = f_{\text{cov}}(s|\Gamma^{\gamma}(s))$, where $f_{\text{cov}}(\centerdot)$ is the coverage submodular function and $s|X$ indicates coverage of a topic s over a set of documents X. All these functions (modular and submodular terms) are added as mixture components in our learning framework to learn suitable weights for them. We then use these weights in our inference procedure to obtain a subset of topics as described in 3.2. We show from our experiments that this approach performs better than all other approaches and baselines.

3.1.4 Fidelity Functions

A function representing the fidelity of a set S to another reference set R is one that gets a large value when the set S represents the set R. Such a function scores inferred topics high when it resembles a reference set of topics and/or item clusters. The reference set in this case can be produced from other algorithms such as k-means, LDA and its variants or from a manually tagged corpus. Next we describe one such fidelity function.

Topic Coherence: This function scores a set of topics S high when the transitive cover (Definition 1) produced by the topics in S resembles the clusters of documents produced by an external source (k-means, LDA or manual). Given an external source that clusters the documents, producing T clusters $L_1, L_2, ..., L_T$ (for T topics), topic coherence is defined as: $f(S) = \sum_{t \in T} \max_{k \in S} w_{k,t}$ where $w_{k,t} = \text{harmonic\_mean}(w^p_{k,t}, w^r_{k,t})$ and $w^p_{k,t} = \frac{|\Gamma(k) \cap L_t|}{|\Gamma(k)|}$ and $w^r_{k,t} = \frac{|\Gamma(k) \cap L_t|}{|L_t|}$. Note that, $w^p_{k,t} \geq 0$ and $w^r_{k,t} \geq 0$ are the precision on recall of the resemblance and $w_{k,t}$ is the F1 measure. If the transitive cover of topics in S resembles the reference clusters L_t exactly, we attain maximum coherence (or fidelity). As the resemblance diminishes, the score decreases. The above function $f(S)$ is monotone submodular.

3.1.5 Mixture of Submodular Components:

Given the different classes of submodular functions above, we construct our submodular scoring functions $F_w(\cdot)$ as a convex combinations of these different submodular functions $f_1, f_2, \ldots, f_m$, above. In other words,

$$F_w(S) = \sum_{i=1}^{m} w_i f_i(S), \tag{2}$$

where $w = (w_1, \ldots, w_m)$, $w_i \geq 0, \sum_i w_i = 1$. The components f_i are submodular and assumed to be normalized: i.e., $f_i(\emptyset) = 0$, and $f_i(V) = 1$ for monotone functions and $\max_{A \subseteq V} f_i(A) \leq 1$ for non-monotone functions. A simple way to normalize a monotone submodular function is to define the component as $f_i(S)/f_i(V)$. This ensures that the components are *compatible* with each other. Obviously, the merit of the scoring function $F_w(\cdot)$ depends on the selection of the components.

3.2 Large Margin Learning

We optimize the weights w of the scoring function $F_w(\cdot)$ in a large-margin structured prediction framework. In this setting, we assume we have training data in the form of pairs of a set of documents, and a human generated summary as a set of topics. For example, in the case of Wikipedia disambiguation, we use the human generated disambiguation pages as the ground truth summary. We represent the set of ground-truth summaries as $\mathcal{S} = \{S_1, S_2, \cdots, S_N\}$. In large margin training, the weights are optimized such that ground-truth summaries $\mathcal{S}$ are separated from competitor summaries by a loss-dependent margin:

$$F_w(S) \geq F_w(S') + \mathcal{L}(S'), \quad \forall S \in \mathcal{S}, S' \in \mathcal{Y} \setminus \mathcal{S}, \tag{3}$$

where $\mathcal{L}(\cdot)$ is the loss function, and where $\mathcal{Y}$ is a structured output space (for example $\mathcal{Y}$ is the set of summaries that satisfy a certain budget B, i.e., $\mathcal{Y} = \{S' \subseteq V : |S'| \leq B\}$). We assume the loss to be normalized, $0 \leq \mathcal{L}(S') \leq 1, \forall S' \subseteq V$, to ensure that mixture and loss are calibrated. Equation (3) can be stated as $F_w(S) \geq \max_{S' \in \mathcal{Y}} [F_w(S') + \mathcal{L}(S')], \forall S \in \mathcal{S}$ which is called *loss-augmented inference*. We introduce slack variables and minimize the regularized sum of slacks (Lin and Bilmes, 2012):

$$\min_{w \geq 0, \|w\|_1 = 1} \sum_{S \in \mathcal{S}} \left[\max_{S' \in \mathcal{Y}} [F_w(S') + \mathcal{L}(S')] - F_w(S) \right] + \frac{\lambda}{2} \|w\|_2^2, \tag{4}$$

where the non-negative orthant constraint, $w \geq 0$, ensures that the final mixture is submodular. Note a 2-norm regularizer is used on top of a 1-norm constraint $\|w\|_1 = 1$ which we interpret as a prior to encourage higher entropy, and thus more diverse mixture distributions. Tractability depends on the choice of the loss function. The parameters w are learnt using stochastic gradient descent as in (Tschiatschek et al., 2014).

3.3 Loss Functions

A natural choice of loss functions for our case can be derived from cluster evaluation metrics. Every inferred topic s induces a subset of documents, namely the transitive cover $\Gamma(s)$ of s. We compare these clusters with the clusters induced from the true topics in the training set and compute the loss.

In this paper, we use the Jaccard Index (JI) as a loss function. Let S be the inferred topics and T be the true topics. The Jaccard loss is defined as $\mathcal{L}_{\text{jaccard}}(S, T) = 1 - \frac{1}{k} \sum_{s \in S} \max_{t \in T} \frac{|\Gamma(s) \cap \Gamma(t)|}{|\Gamma(s) \cup \Gamma(t)|}$, where $k = |S| = |T|$ is the number of topics. When the clustering produced by the inferred and the true topics are similar, Jaccard loss is 0. When they are completely dissimilar, the loss is maximum, i.e., 1. Jaccard loss is a modular function.

3.4 Inference Algorithm: Greedy

Having learnt the weights for the mixture components, the resulting function $F_w(S) = \sum_{i=1}^{m} w_i f_i(S)$ is a submodular function. In the case when the individual components are themselves monotone (all our functions in fact are), $F_w(S)$ can be optimized by the accelerated greedy algorithm (Minoux, 1978). Thanks to submodularity, we can obtain near optimal solutions very efficiently. In case the functions are all monotone submodular, we can guarantee that the solution is within $1 - 1/e$ factor from the optimal solution.

4 Experimental Results

To validate our approach, we make use of Wikipedia category structure as a topic DAG and apply our technique to the task of automatic generation of Wikipedia disambiguation pages. We pre-processed the category graph to eliminate the cycles in order to make it a DAG. Each Wikipedia disambiguation page is manually created by Wikipedia editors by grouping a collection of Wikipedia articles into several groups. Each group is then assigned a name, which serves as a topic for the group. Typically, a disambiguation page segregates around 20-30 articles into 5-6 groups. Our goal is to measure how accurately we can recreate the groups for a disambiguation page and label them, given only the collection of articles mentioned in that disambiguation page (when actual groupings and labels are hidden).

4.1 Datasets

We parsed the contents of Wikipedia disambiguation pages and extracted disambiguation page names, article groups and group names. We collected about 8000 disambiguation pages that had at least four groups on them. Wikipedia category structure is used as the topic DAG. We eliminated few administrative categories such as “Hidden Categories”, “Articles needing cleanup”, and the like. The final DAG had about 1M topics and 3M links.

4.2 Evaluation Metrics

Every group of articles on the Wikipedia disambiguation page is assigned a name by the editors. Unfortunately, these names may not correspond to the Wikipedia category (topic) names. For example, one of the groups on the “Matrix” disambiguation page has a name “Business and government” and there is no Wikipedia category by that name. However, the group names generated by our (and baseline) method are from the Wikipedia categories (which forms our topic DAG). In addition, there can be multiple relevant names for a group. For example, a group on a disambiguation page may be called “Calculus”, but an algorithm may rightly generate “Vector Calculus”. Hence we cannot evaluate the accuracy of an algorithm just by matching the generated group names to those on the disambiguation page. To alleviate this problem, we adopt cluster-based evaluation metrics. We treat every group of articles generated by an algorithm under a topic for a disambiguation page as a cluster of articles. These are considered as *inferred* clusters for a disambiguation page. We compare them against the actual grouping of articles on the Wikipedia disambiguation page by treating those groups as *true* clusters. We can now adopt Jaccard Index, F1-measure, and NMI (Normalized Mutual Information) based cluster evaluation metrics described in (Manning et al., 2008). For each disambiguation page in the test set, we compute every metric score and then average it over all the disambiguation pages.

4.3 Methods Compared

We validated our approach by comparing against several baselines described below. We also compared two variations of our approach as described next. For each of these cases (baselines and two variations) we generated and compared the metrics (Jaccard Index, F1-measure and NMI) as described in the previous section.

KM$_{\text{docs}}$: K-Means algorithm run on articles as TF-IDF vectors of words. The number of clusters K is set to the number of true clusters on the Wikipedia disambiguation page.

KMed$_{\text{docs}}$: K-Medoids algorithm with articles as TF-IDF vectors of words. The number of clusters are set as in KM$_{\text{docs}}$.

KMed$_{\text{topics}}$: K-Medoids run on topics as TF-IDF vectors of words. The words for each topic is taken from the articles that are in the transitive cover of the topic.

LDA$_{\text{docs}}$: LDA algorithm with the number of topics set to the number of true clusters on the Wikipedia disambiguation page. Each article is then grouped under the highest probability topic.

SMML$_{\text{cov}}$: This is the submodular mixture learning case explained in section 3.1.5. Here we consider a mixture of all the submodular functions governing coverage, diversity, fidelity and QC functions. However, we exclude the similarity based functions described in section 3.1.2. Coverage based functions have a time complexity of $O(n)$ whereas similarity based functions are $O\left(n^2\right)$. By excluding similarity based functions, we can compare the quality of the results with and without $O(n^2)$ functions. We learn the mixture weights from the training set and use them during inference on the test set to subset K topics through the submodular maximization (Equation 1).

SMML$_{\text{cov+sim}}$: This case is similar to SMML$_{\text{cov}}$ except that, we include similarity based submodular mixture components. This makes the inference time complexity $O\left(n^2\right)$.

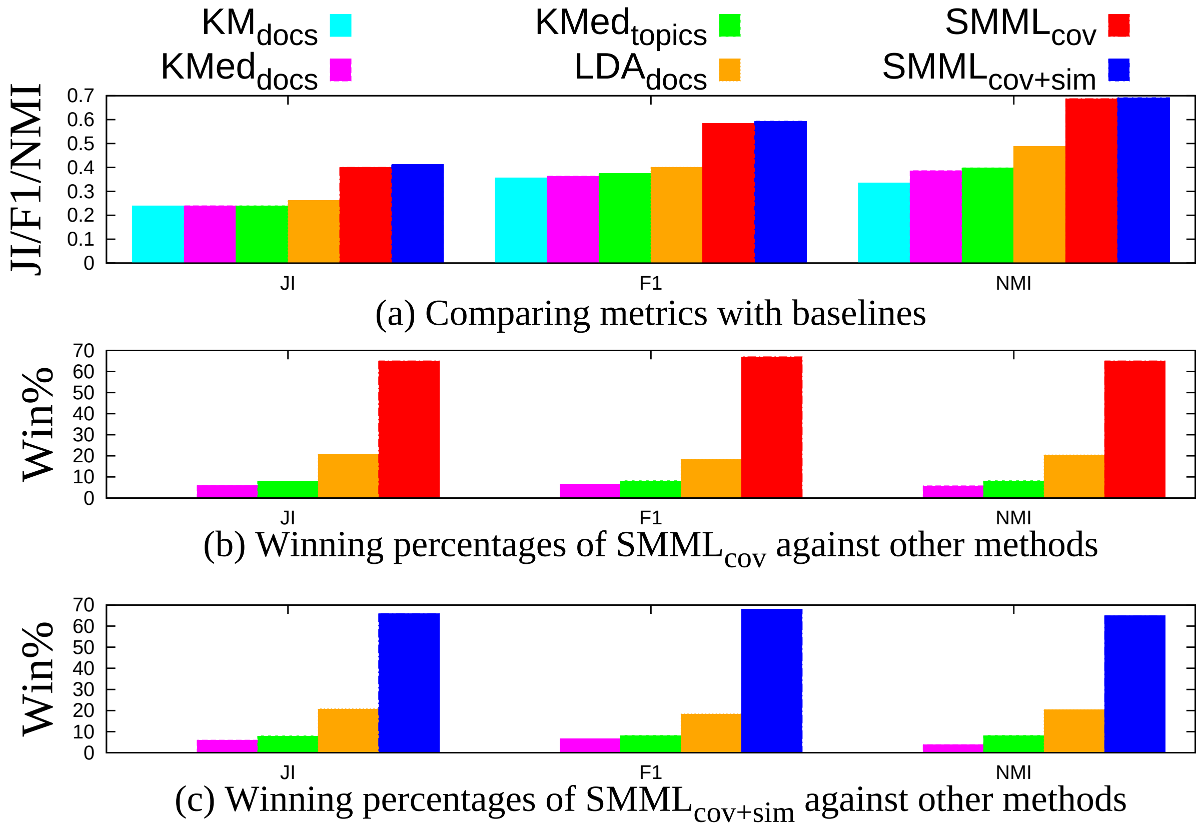
We do not compare against HSLDA, PAM and few other techniques cited in the related work sections because they do not produce a subset of K summary topics — these are not directly comparable with our work.

4.4 Evaluation Results

We show that the submodular mixture learning and maximization approaches, i.e., SMML$_{\text{cov}}$ and SMML$_{\text{cov+sim}}$ outperform other approaches in various metrics. In all these experiments, we performed 5 fold cross validation to learn the parameters from 80% of the disambiguation pages and evaluated on the rest of the 20%, in each fold.

In Figure 2a we summarize the results of the comparison of the methods mentioned above on Jaccard Index, F1 measure and NMI. Our proposed techniques SMML$_{\text{cov}}$ and SMML$_{\text{cov+sim}}$ outperform other techniques consistently.

In Figures 2b and 2c we measure the number of test instances (i.e., disambiguation queries) in which each of the algorithms dominate (win) in evaluation metrics. In 60% of the disambiguation queries, SMML$_{\text{cov}}$ and SMML$_{\text{cov+sim}}$ approaches



(a) Comparing metrics with baselines

(b) Winning percentages of SMML$_{cov}$ against other methods

(c) Winning percentages of SMML$_{cov+sim}$ against other methods

Figure 2: Comparison of techniques

produce higher JI, F1 and NMI than all other methods. This indicates that the clusters of articles produced by our technique resembles the clusters of articles present on the disambiguation page better than other techniques.

From Figures 2b and 2c it is clear that $O(n)$ time complexity based submodular mixture functions (SMML$_{cov}$) perform on par with $O(n^2)$ based functions (SMML$_{cov+sim}$), but at a greatly reduced execution time, demonstrating the sufficiency of $O(n)$ functions for our task. On the average, for each disambiguation query, SMML$_{cov}$ took around 40 seconds (over 1M topics and 3M edges DAG) to infer the topics, whereas SMML$_{cov+sim}$ took around 35 minutes. Both these experiments were carried on a machine with 32 GB RAM, Eight-Core AMD Opteron(tm) Processor 2427.

5 Conclusions

We investigated a problem of summarizing topics over a massive topic DAG such that the summary set of topics produced represents the objects in the collection. This representation is characterized through various classes of submodular (and monotone) functions that captured coverage, similarity, diversity, specificity, clarity, relevance and fidelity of the topics. Currently we assume that the number of topics K is given as an input to our algorithm. It would be an interesting future problem to estimate the value of K automatically in our setting. As future work, we also plan to extend our techniques to produce a hierarchical summary of topics and scale it across heterogeneous collection of objects (from different domains) to bring all of them under the same topic DAG and investigate interesting cases thereon.

Abstract

We study the problem of explaining relationships between pairs of knowledge graph entities with human-readable descriptions. Our method extracts and enriches sentences that refer to an entity pair from a corpus and ranks the sentences according to how well they describe the relationship between the entities. We model this task as a learning to rank problem for sentences and employ a rich set of features. When evaluated on a large set of manually annotated sentences, we find that our method significantly improves over state-of-the-art baseline models.

1 Introduction

Knowledge graphs are a powerful tool for supporting a large spectrum of search applications including ranking, recommendation, exploratory search, and web search (Dong et al., 2014). A knowledge graph aggregates information around entities across multiple content sources and links these entities together, while at the same time providing entity-specific properties (such as age or employer) and types (such as actor or movie).

Although there is a growing interest in automatically constructing knowledge graphs, e.g., from unstructured web data (Weston et al., 2013; Craven et al., 2000; Fan et al., 2012), the problem of providing evidence on why two entities are related in a knowledge graph remains largely unaddressed. Extracting and presenting evidence for linking two entities, however, is an important aspect of knowledge graphs, as it can enforce trust between the user and a search engine, which in turn can improve long-term user engagement, e.g., in the context of related entity recommendation (Blanco et al., 2013). Although knowledge graphs exist that provide this functionality to a certain degree (e.g., when hovering over Google's suggested entities, see Figure 1), to the best of our knowledge there is no previously published research on methods for entity relationship explanation.

Figure 1: Part of Google's search result page for the query "barack obama". When hovering over the related entity "Michelle Obama", an explanation of the relationship between her and "Barack Obama" is shown.

In this paper we propose a method for explaining the relationship between two entities, which we evaluate on a newly constructed annotated dataset that we make publicly available. In particular, we consider the task of explaining relationships between pairs of Wikipedia entities. We aim to infer a human-readable description for an entity pair given a relationship between the two entities. Since Wikipedia does not explicitly define relationships between entities we use a knowledge graph to obtain these relations. We cast our task as a sentence ranking problem: we automatically extract sentences from a corpus and rank

them according to how well they describe a given relationship between a pair of entities. For ranking purposes, we extract a rich set of features and use learning to rank to effectively combine them. Our feature set includes both traditional information retrieval and natural language processing features that we augment with entity-dependent features. These features leverage information from the structure of the knowledge graph. On top of this, we use features that capture the presence in a sentence of the relationship of interest. For our evaluation we focus on "people" entities and we use a large, manually annotated dataset of sentences.

The research questions we address are the following. First, we ask what the effectiveness of state-of-the-art sentence retrieval models is for explaining a relationship between two entities (RQ1). Second, we consider whether we can improve over sentence retrieval models by casting the task in a learning to rank framework (RQ2). Third, we examine whether we can further improve performance by using relationship-dependent models instead of a relationship-independent one (RQ3). We complement these research questions with an error and feature analysis.

Our main contributions are a robust and effective method for explaining entity relationships, detailed insights into the performance of our method and features, and a manually annotated dataset.

2 Related Work

We combine ideas from sentence retrieval, learning to rank, and question answering to address the task of explaining relationships between entities.

Previous work that is closest to the task we address in this paper is that of Blanco and Zaragoza (2010) and Fang et al. (2011). First, Blanco and Zaragoza (2010) focus on finding and ranking sentences that explain the relationship between an entity and a query. Our work is different in that we want to explain the relationship between two entities, rather than a query. Fang et al. (2011) explore the generation of a ranked list of knowledge base relationships for an entity pair. Instead, we try to select sentences that describe a particular relationship, assuming that this is given.

Our approach builds on sentence retrieval, where one retrieves sentences rather than documents that answer an information need. Document retrieval models such as tf-idf, BM25, and language modeling (Baeza-Yates et al., 1999) have been extended to tackle sentence retrieval. Three of the most successful sentence retrieval methods are TFISF (Allan et al., 2003), which is a variant of the vector space model with tf-idf weighting, language modeling with local context (Murdock, 2006; Fernández et al., 2011), and a recursive version of TFISF that accounts for local context (Doko et al., 2013). TFISF is very competitive compared to document retrieval models tuned specifically for sentence retrieval (e.g., BM25 and language modeling (Losada, 2008)) and we therefore include it as a baseline.

Sentences that are suitable for explaining relationships can have attributes that are important for ranking but cannot be captured by term-based retrieval models. One way to combine a wide range of ranking features is learning to rank (LTR). Recent years have witnessed a rapid increase in the work on learning to rank, and it has proven to be a very successful method for combining large numbers of ranking features, for web search, but also other information retrieval applications (Burges et al., 2011; Surdeanu et al., 2011; Agarwal et al., 2012). We use learning to rank and represent each sentence with a set of features that aim to capture different dimensions of the sentence.

Question answering (QA) is the task of providing direct and concise answers to questions formed in natural language (Hirschman and Gaizauskas, 2001). QA can be regarded as a similar task to ours, assuming that the combination of entity pair and relationship form the "question" and that the "answer" is the sentence describing the relationship of interest. Even though we do not follow the QA paradigm in this paper, some of the features we use are inspired by QA systems. In addition, we employ learning to rank to combine the devised features, which has recently been successfully applied for QA (Surdeanu et al., 2011; Agarwal et al., 2012).

3 Problem Statement

We address the problem of explaining relationships between pairs of entities in a knowledge graph. We operationalize the problem as a problem of ranking sentences from documents in a corpus that is related to the knowledge graph. More specifically, given two entities e_i and e_j that form an entity pair $\langle e_i, e_j \rangle$, and a relation r between them, the task is to extract a set of candidate sentences $S_{ij} = \{s_{ij_1}, \ldots, s_{ij_k}\}$ that refer to $\langle e_i, e_j \rangle$ and to impose a ranking on the sentences in S_{ij}. The relation r has the general form $\langle type(e_i), terms(r), type(e_j) \rangle$, where $type(e)$ is the type of the entity e (e.g., `Person` or `Actor`) and $terms(r)$ are the terms of the relation (e.g., `CoCastsWith` or `IsSpouseOf`).

We are left with two specific tasks: (1) extracting candidate sentences S_{ij}, and (2) ranking S_{ij}, where the goal is to have sentences that provide a perfect explanation of the relationship at the top position of the ranking. The next section describes our methods for both tasks.

4 Explaining Entity Relationships

We follow a two-step approach for automatically explaining relationships between entity pairs. First, in Section 4.1, we extract and enrich sentences that refer to an entity pair $\langle e_i, e_j \rangle$ from a corpus in order to construct a set of candidate sentences. Second, in Section 4.2, we extract a rich set of features describing the entities' relationship r and use supervised machine learning in order to rank the sentences in S_{ij} according to how well they describe the relationship r.

4.1 Extracting candidate sentences

To create a set of candidate sentences for a given entity pair and relationship, we require a corpus of documents that is pertinent to the entities at hand. Although any kind of document collection can be used, we focus on Wikipedia in this paper, as it provides good coverage for the majority of entities in our knowledge graph.

First, we extract surface forms for the given entities: the title of the entity's Wikipedia article (e.g., "Barack Obama"), the titles of all redirect pages linking to that article (e.g., "Obama"), and all anchor text associated with hyperlinks to the article within Wikipedia (e.g., "president obama"). We then split all Wikipedia articles into sentences and consider a sentence as a candidate if (i) the sentence is part of either entities' Wikipedia article and contains a surface form of, or a link to, the other entity; or (ii) the sentence contains surface forms of, or links to, both entities in the entity pair.

Next, we apply two sentence enrichment steps for (i) making sentences self-contained and readable outside the context of the source document and (ii) linking the sentences to entities. For (i), we replace pronouns in candidate sentences with the title of the entity. We apply a simple heuristic for the people entities, inspired by (Wu and Weld, 2010):[1] we count the frequency of the terms "he" and "she" in the article for determining the gender of the entity, and we replace the first appearance of "he" or "she" in each sentence with the entity's title. We skip this step if any surface form of the entity occurs in the sentence.

For (ii), we apply entity linking to provide links from the sentence to additional entities (Milne and Witten, 2008). This need arises from the fact that not every sentence in an article contains explicit links to the entities it mentions, as Wikipedia guidelines only allow one link to another article in the article's text.[2] The algorithm takes a sentence as input and iterates over n-grams that are not yet linked to an entity. If an n-gram matches a surface form of an entity, we establish a link between the n-gram and the entity. We restrict our search space to entities that are linked from within the source article of the sentence and from within articles to which the source article links. This way, our entity linking method achieves high precision as almost no disambiguation is necessary.

As an example, consider the sentence "He gave critically acclaimed performances in the crime thriller Seven..." on the Wikipedia page for Brad Pitt. After applying our enrichment steps, we obtain "`Brad_Pitt` gave critically acclaimed performances in the crime thriller `Seven...`", making the sentence human readable and link to the entities `Brad_Pitt` and `Seven_(1995_film)`.

4.2 Ranking sentences

After extracting candidate sentences, we rank them by how well they describe the relationship of interest r between entities e_i and e_j. There are many signals beyond simple term statistics that can indicate relevance. Automatically constructing a ranking model using supervised machine learning techniques is therefore an obvious choice. For ranking we use learning to rank (LTR) and represent each sentence with a rich set of features. Table 1 lists the features we use. Below we provide

[1] We experimented with the Stanford co-reference resolution system (Lee et al., 2011) and Apache OpenNLP and found that they were not able to consistently achieve the level of effectiveness that we require.

#	Name	Gloss
Text features		
1	Sentence length	Length of s in words
2	Sum of *idf*	Sum of IDF of terms of s in Wikipedia
3	Average *idf*	Average IDF of terms of s in Wikipedia
4	Sentence density	Lexical density of s, see Equation 1 (Lee et al., 2001)
5–8	POS fractions	Fraction of verbs, nouns, adjectives, others in s (Mintz et al., 2009)
Entity features		
9	#entities	Total number of entities in s
10	Link to e_i	Whether s contains a link to the entity e_i
11	Link to e_j	Whether s contains a link to the entity e_j
12	Links to e_i and e_j	Whether s contains links to both entities e_i and e_j
13	Entity first	Is e_i or e_j the first entity in the sentence?
14	Spread of e_i, e_j	Distance between the last match of e_i and e_j in s (Blanco and Zaragoza, 2010)
15–22	POS fractions left/right	Fraction of verbs, nouns, adjectives, others to the left/right window of e_i and e_j in s (Mintz et al., 2009)
23–25	#entities left/right/between	Number of entities to the left/right or between entities e_i and e_j in s
26	common links e_i, e_j	Whether s contains any common link of e_i and e_j
27	#common links	The number of common links of e_i and e_j in s
28	Score common links e_i, e_j	Sum of the scores of the common links of e_i and e_j in s
29–30	#common links prev/next	The number of common links of e_i and e_j in previous/next sentence of s
Relationship features		
31	Match $\mathit{terms}(r)$?	Whether s contains any term in $\mathit{terms}(r)$
32	Match $\mathit{wordnet}(r)$?	Whether s contains any phrase in $\mathit{wordnet}(r)$
33	Match $\mathit{word2vec}(r)$?	Whether s contains any phrase in $\mathit{word2vec}(r)$
34–36	or's	Boolean OR of feature 31 and one or both of features 32 and 33
37–38	or(31, 32, 33) prev/next	Boolean OR of features 31, 32, 33 for the previous/next sentence of s
39	Average $\mathit{word2vec}(r)$	Average cosine similarity of phrases in $\mathit{word2vec}(r)$ that are matched in s
40	Maximum $\mathit{word2vec}(r)$	Maximum cosine similarity of phrases in $\mathit{word2vec}(r)$ that are matched in s
41	Sum $\mathit{word2vec}(r)$	Sum of cosine similarity of phrases in $\mathit{word2vec}(r)$ that are matched in s
42	Score LC	Lucene score of s with $\mathit{titles}(e_i, e_j)$, $\mathit{terms}(r)$, $\mathit{wordnet}(r)$, $\mathit{word2vec}(r)$ as query
43	Score R-TFISF	R-TFISF score of s with queries constructed as above
Source features		
44	Sentence position	Position of s in document from which it originates
45	From e_i or e_j?	Does s originate from the Wikipedia article of e_i or e_j?
46	#(e_i or e_j)	Number of occurrences of e_i or e_j in document from which s originates, inspired by document smoothing for sentence retrieval (Murdock and Croft, 2005)

Table 1: Features used for sentence ranking.

a brief description of the more complex ones.

Text features This feature type regards the importance of the sentence s at the term level. We compute the density of s (feature 4) as:

$$density(s) = \frac{1}{K\cdot(K+1)}\sum_{j=1}^{n}\frac{idf(t_j)\cdot idf(t_{j+1})}{distance(t_j,t_{j+1})^2}, \qquad (1)$$

where K is the number of keyword terms in s and $distance(t_j, t_{j+1})$ is the number of non-keyword terms between keyword terms t_j and t_{j+1}. We treat stop words and numbers in s as non-keywords and the remaining terms as keywords. Features 5–8 capture the distribution of part-of-speech tags in the sentence.

Entity features These features partly build on (Tsagkias et al., 2011; Meij et al., 2012) and describe the entities and are dependent on the knowledge graph. Whether e_i or e_j is the first appearing entity in a sentence might be an indicator of importance (feature 13). The spread of e_i and e_j in the sentence (feature 14) might be an indicator of their centrality in the sentence (Blanco and Zaragoza, 2010). Features 15–22 capture the distribution of part-of-speech tags in the sentence in a window of four words around e_i or e_j in s (Mintz et al., 2009), complemented by the number of entities between, to the left of, and to the right of the entity pair (features 23–25).

We assume that two articles that have many common articles that point to them are strongly related (Witten and Milne, 2008). We hypothesize that, if a sentence contains common inlinks from e_i and e_j, the sentence might contain important information about their relationship. Hence, we add whether the sentence contains a common link (feature 26) and the number of common links (feature 27) as features. We score a common link l between e_i and e_j using:

$$score(l, e_i, e_j) = sim(l, e_i) \cdot sim(l, e_j), \quad (2)$$

where $sim(\cdot, \cdot)$ is defined as the similarity between two Wikipedia articles, computed using a variant of Normalized Google Distance (Witten and Milne, 2008). Feature 28 then measures the sum of the scores of the common links.

Previous research shows that using surrounding sentences is beneficial for sentence retrieval (Doko et al., 2013). We therefore consider the number of common links in the previous and next sentence (features 29–30).

Relationship features Feature 31 indicates whether any of the relationship-specific terms occurs in the sentence. Only matching the terms in the relationship may have low coverage since terms such as "spouse" may have many synonyms and/or highly related terms, e.g., "husband" or "married". Therefore, we use WordNet to find synonym phrases of r (feature 32); we refer to this method as $wordnet(r)$.

Alternatively, we use word embeddings to find such similar phrases (Mikolov et al., 2013). Such embeddings take a text corpus as input and learn vector representations of words and phrases consisting of real numbers. Given the set V_r consisting of the vector representations of all the relationship terms and the set V which consists of the vector representations of all the candidate phrases in the data, we calculate the distance between a candidate phrase represented by a vector $\mathbf{v}_i \in V$ and the vectors in V_r as:

$$distance(\mathbf{v}_i, V) = \cos\left(\mathbf{v}_i, \sum_{\mathbf{v}_j \in V_r} \mathbf{v}_j\right), \quad (3)$$

where $\sum_{\mathbf{v}_j \in V_r} \mathbf{v}_j$ is the element-wise sum of the vectors in V_r and the distance between two vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ is measured using cosine similarity. The candidate phrases in V are then ranked using Equation 3 and the top-m phrases are selected, resulting in features 33, 39, 40, and 41; we refer to the ranked set of phrases that are selected using this procedure as $word2vec(r)$.

In addition, we employ state-of-the-art retrieval functions and include the scores for queries that are constructed using the entities e_i and e_j, the relation r, $wordnet(r)$, and $word2vec(r)$. We use the titles of the entity articles $titles(e)$ to represent the entities in the query and two ranking functions, Recursive TFISF (R-TFISF) and LC,[3] (features 42–43). TFISF is a sentence retrieval model that determines the level of relevance of a sentence s given a query q as:

$$R(s, q) = \sum_{t \in q} \log(tf_{t,q} + 1) \cdot \log(tf_{t,s} + 1) \cdot \log\left(\frac{n+1}{0.5 + sf_t}\right), \quad (4)$$

where $tf_{t,q}$ and $tf_{t,s}$ are the number of occurrences of term t in the query q and the sentence s respectively, sf_t is the number of sentences in which t appears, and n is the number of sentences in the collection. R-TFISF is an improved extension of the TFISF method (Doko et al., 2013), which incorporates context from neighboring sentences in the ranking function:

$$R_c(s, q) = (1 - \mu)R(s, q) + \mu[R_c(s_{prev}(s), q) + R_c(s_{next}(s), q)], \quad (5)$$

where μ is a free parameter and $s_{prev}(s)$ and $s_{next}(s)$ indicate functions to retrieve the previous and next sentence, respectively. We use a maximum of three recursive calls.

Source features Here, we refer to features that are dependent on the source document of the sentences. We have three such features.

5 Experimental setup

In this section we describe the dataset, manual annotations, learning to rank algorithm, and evaluation metrics that we use to answer our research questions.

5.1 Dataset

We draw entities and their relationships from a proprietary knowledge graph that is created from Wikipedia, Freebase, IMDB, and other sources, and that is used by the Yahoo web search engine. We focus on "people" entities and relationships between them.[4] For our experiments we need to select a manageable set of entities, which we obtain as follows. We consider a year of query logs

[3] In preliminary experiments R-TFISF and LC were the best performing among a pool of sentence retrieval methods.

[4] Note that, except for the co-reference resolution step described in Section 4.1, our method does not depend on this restriction.

from a large commercial search engine, count the number of times a user clicks on a Wikipedia article of an entity in the results page and perform stratified sampling of entities according to this distribution. As we are bounded by limited resources for our manual assessments, we sample 1 476 entity pairs that together with nine unique relationship types form our experimental dataset.

We use an English Wikipedia dump dated July 8, 2013, containing approximately 4M articles, of which 50 638 belong to "people" entities that are also in our knowledge graph. We extract sentences using the approach described in Section 4.1, resulting in 36 823 candidate sentences for our entities. On average we have 24.94 sentences per entity pair (maximum 423 and minimum 0). Because of the large variance, it is not feasible to obtain exhaustive annotations for all sentences. We rank the sentences using R-TFISF and keep the top-10 sentences per entity pair for annotation. This results in a total of 5 689 sentences.

Five human annotators provided relevance judgments, manually judging sentences based on how well they describe the relationship for an entity pair, for which we use a five-level graded relevance scale (perfect, excellent, good, fair, bad).[5] Of all relevance grades 8.1% is perfect, 15.69% excellent, 19.98% good, 8.05% fair, and 48.15% bad. Out of 1 476 entity pairs, 1 093 have at least one sentence annotated as fair. As is common in information retrieval evaluation, we discard entity pairs that have only "bad" sentences. We examine the difficulty of the task for human annotators by measuring inter-annotator agreement on a subset of 105 sentences that are judged by 3 annotators. Fleiss' kappa is k = 0.449, which is considered to be moderate agreement.

5.2 Machine learning

For ranking sentences we use a Random Forest (RF) classifier (Breiman, 2001).[6] We set the number of iterations to 300 and the sampling rate to 0.3. Experiments with varying these two parameters did not show any significant differences. We also tried several feature normalization methods, none of them being able to significantly outperform the runs without feature normalization.

Baseline	NDCG@1	NDCG@10	ERR@1	ERR@10
B1	0.7508	0.8961	0.3577	0.4531
B2	0.7511	0.8958	0.3584	0.4530
B3	0.7595	0.8997	0.3696	0.4600
B4	0.7767	0.9070	0.3774	0.4672
B5	**0.7801**	**0.9093**	**0.3787**	**0.4682**

Table 2: Results for five baseline variants. See text for their description and significant differences.

We obtain POS tags using the Stanford part-of-speech tagger and filter out a standard list of 33 English stopwords. For the word embeddings we use *word2vec* and train our model on all text in Wikipedia using negative sampling and the continuous bag of words architecture. We set the size of the phrase vectors to 500 and m = 30.

5.3 Evaluation metrics

We employ two main evaluation metrics in our experiments, NDCG (Järvelin and Kekäläinen, 2002) and ERR (Chapelle et al., 2009). The former measures the total accumulated gain from the top of the ranking that is discounted at lower ranks and is normalized by the ideal cumulative gain. The latter models user behavior and measures the expected reciprocal rank at which a user will stop her search. We consider these ranking-based graded evaluation metrics at two cut-off points: position 1, corresponding to showing a single sentence to a user, and 10, which accounts for users who might look at more results. We report on NDCG@1, NDCG@10, ERR@1, ERR@10, and Exc@1, which indicates whether we have an "excellent" or "perfect" sentence at the top of the ranking. Likewise, Per@1 indicates whether we have a "perfect" sentence at the top of the ranking (not all entity pairs have an excellent or a perfect sentence).

We perform 5-fold cross validation and test for statistical significance using a paired two-tailed t-test. We depict a significant difference in performance for p < 0.01 with ▲ (gain) and ▼ (loss) and for p < 0.05 with △ (gain) and ▽ (loss). Boldface indicates the best score for a metric.

6 Results and Analysis

We compare the performance of typical document retrieval models and state-of-the-art sentence retrieval models in order to answer RQ1. We consider five sentence retrieval models: Lucene ranking (LC), language modeling with Dirichlet

[5] `https://github.com/nickvosk/acl2015-dataset-learning-to-explain-entity-relationships`

[6] In preliminary experiments, we contrasted RF with gradient boosted regression trees and LambdaMART and found that RF consistently outperformed other methods.

Has one	# pairs	# sentences	Method	NDCG@1	NDCG@10	ERR@1	ERR@10	Exc@1	Per@1

Table 3: Results for the best baseline (B5) and the learning to rank method (LTR).

smoothing (LM), BM25, TFISF, and Recursive TF-ISF (R-TFISF). We follow related work and set μ = 0.1 for R-TFISF, k = 1 and b = 0 for BM25 and μ = 250 for LM (Fernández et al., 2011).

In our experiments, a query q is constructed using various combinations of surface forms of the two entities e_i and e_j and the relationship r. Each entity in the entity pair can be represented by its title, the titles of any redirect pages pointing to the entity's article, the n-grams used as anchors in Wikipedia to link to the article of the entity, or the union of them all. The relationship r can be represented by the terms in the relationship, synonyms in $wordnet(r)$, or by phrases in $word2vec(r)$.

First, we fix the way we represent r. Baseline B1 does not include any representation of r in the query. B2 includes the relationship terms of r, while B3 includes the relationship terms of r and the synonyms in $wordnet(r)$. B4 includes the terms of r and the phrases in $word2vec(r)$, and B5 includes the relationship terms of r, the synonyms in $wordnet(r)$ and the phrases in $word2vec(r)$. Combining these variations with the entity representations, we find that all combinations that use the titles as representation and R-TFISF as the retrieval function outperform all other combinations.[7] This can be explained by the fact that titles are least ambiguous, thus reducing the possibility of accidentally referring to other entities. BM25 and LC perform almost as well as R-TFISF, with only insignificant differences in performance.

Table 2 shows the best performing combination of each baseline, i.e., varying the representation of r and using titles and R-TFISF. B4 and B5 are the best performing baselines, suggesting that $word2vec(r)$ and $wordnet(r)$ are beneficial. B5 significantly outperforms all baselines except B4.

We also experiment with a supervised combination of the baseline rankers using LTR. Here, we consider each baseline ranker as a separate feature and train a ranking model. The trained model is not able to outperform the best individual baseline, however.

6.1 Learning to rank sentences

Next, we provide the results of our method using the features described in Section 4.2, exploring whether our learning to rank (LTR) approach improves over sentence retrieval models (RQ2). We compare an LTR model using Table 1's features against the best baseline (B5). Table 3 shows the results. Each group in the table contains the results for the entity pairs that have at least one candidate sentence of that relevance grade for B5 and LTR.

We find that LTR significantly outperforms B5 by a large margin. The absolute performance difference between LTR and B5 becomes larger for all metrics as we move from "fair" to "perfect," which shows that LTR is more robust than the baseline for entity pairs that have at least one high quality candidate sentence. LTR ranks the best possible sentence at the top of the ranking for ~83% of the cases for entity pairs that contain an "excellent" sentence and for ~72% of the cases for entity pairs that contain a "perfect" sentence.

Note that, as indicated in Section 5.1, we discard entity pairs that have only "bad" sentences in our experiments. For the sake of completeness, we report on the results for all entity pairs in our dataset—including those without any relevant sentences—in Table 4.

6.2 Relationship-dependent models

Relevant sentences may have different properties for different relationship types. For example, a sentence describing two entities being partners would have a different form than one describing that two entities costar in a movie. A similar

[7] We omit a full table of results due to space constraints.

Has one	# pairs	# sentences	Method	NDCG@1	NDCG@10	ERR@1	ERR@10	Exc@1	Per@1

Average results over all data	1 093	4 435	**0.8661**	**0.9395**	**0.4615**	**0.5287**
LTR (Table 3; fair)			0.8489	0.9375	0.4242	0.4980

Table 5: Results for relationship-dependent models. Similar relationships are grouped together.

idea was investigated in the context of QA for associating question and answer types (Yao et al., 2013). To answer (RQ3) we examine whether learning a relationship-dependent model improves over learning a single model for all types. We split our dataset per relationship type and train a model per type using 5-fold cross-validation within each. Table 5 shows the results.[8] Our method is robust across different relationships in terms of NDCG. However, we observe some variation in ERR as this metric is more sensitive to the distribution of relevant items than NDCG—the distribution over relevance grades varies per relationship type. For example, it is much more likely to find candidate sentences that have a high relevance grade for $\langle \mathit{Person}, \mathit{isSpouseOf}, \mathit{Person}\rangle$ than for $\langle \mathit{Athlete}, \mathit{PlaysSameSportTeamAs}, \mathit{Athlete}\rangle$ in our dataset. We plan to address this issue by exploring other corpora in the future.

The second-to-last row in Table 5 shows the averaged results over the different relationship types, which is a significant improvement over LTR at $p < 0.01$ for all metrics. This method ranks the best possible sentence at the top of the ranking for ~85% of the cases for entity pairs that contain an "excellent" sentence (~2% absolute improvement over LTR) and for ~75% of the cases for entity pairs that contain a "perfect" sentence (~3% absolute improvement over LTR).

6.3 Feature type analysis

Next, we analyze the impact of the feature types. Table 6 shows how performance varies when removing one feature type at a time from the full feature set. Relationship type features are the most important, although entity type features are important as well. This indicates that introducing features based on entities identified in the sentences and the relationship is beneficial for this task. Furthermore, the limited dependency on the source feature type indicates that our method might be able to generalize in other domains. Finally, text type features do contribute to retrieval effectiveness, although not significantly. Note that calculating the sentence features is straightforward, as none of our features requires heavy linguistic analysis.

Features	NDCG@1	NDCG@10	ERR@1	ERR@10
All	**0.8661**	**0.9395**	**0.4615**	**0.5287**
All∖text	0.8620	0.9372	0.4606	0.5274
All∖source	0.8598	0.9372	0.4582	0.5261
All∖entity	0.8421▽	0.9282▼	0.4497	0.5202▽
All∖relation	0.8183▼	0.9201▼	0.4352▼	0.5112▼

Table 6: Results using relationship-dependent models, removing individual feature types.

6.4 Error analysis

When looking at errors made by the system, we find that some are due to the fact that entity pairs might have more than one relationship (e.g., ac-

[8] We omit Exc@1 and Per@1 due to space constraints.

tors that costar in movies also being partners) but the selected sentence covers only one of the relationships.[9] For example, Liza Minnelli is the daughter of Judy Garland, but they have also costarred in a movie, which is the relationship of interest. The model ranks the sentence "Liza Minnelli is the daughter of singer and actress Judy Garland…" at the top, while the most relevant sentence is: "Judy Garland performed at the London Palladium with her then 18-year-old daughter Liza Minnelli in November 1964."

Sentences that contain the relationship in which we are interested, but for which this cannot be directly inferred, are another source of error. Consider, for example, the following sentence, which explains director Christopher Nolan directed actor Christian Bale: "Jackman starred in the 2006 film The Prestige, directed by Christopher Nolan and costarring Christian Bale, Michael Caine, and Scarlett Johansson". Even though the sentence contains the relationship of interest, it focuses on actor Hugh Jackman. The sentence "In 2004, after completing filming for The Machinist, Bale won the coveted role of Batman and his alter ego Bruce Wayne in Christopher Nolan's Batman Begins…", in contrast, refers to the two entities and the relationship of interest directly, resulting in a higher relevance grade. Our method, however, ranks the first sentence on top, as it contains more phrases that refer to the relationship.

7 Conclusions and Future Work

We have presented a method for explaining relationships between knowledge graph entities with human-readable descriptions. We first extract and enrich sentences that refer to an entity pair and then rank the sentences according to how well they describe the relationship. For ranking, we use learning to rank with a diverse set of features. Evaluation on a manually annotated dataset of "people" entities shows that our method significantly outperforms state-of-the-art sentence retrieval models for this task. Experimental results also show that using relationship-dependent models is beneficial.

In future work we aim to evaluate how our method performs on entities and relationships of any type and popularity, including tail entities and miscellaneous relationships. We also want to investigate moving beyond Wikipedia and extract candidate sentences from documents that are not related to the knowledge graph, such as web pages or news articles. Employing such documents also implies an investigation into more advanced coreference resolution methods.

Our analysis showed that sentences may cover different relationships between entities or different aspects of a single relationship—we aim to account for such cases in follow-up work. Furthermore, sentences may contain unnecessary information for explaining the relation of interest between two entities. Especially when we want to show the obtained results to end users, we may need to apply further processing of the sentences to improve their quality and readability. We would like to explore sentence compression techniques to address this. Finally, relationships between entities have an inherit temporal nature and we aim to explore ways to explain entity relationships and their changes over time.

Abstract

An event chronicle provides people with an easy and fast access to learn the past. In this paper, we propose the first novel approach to automatically generate a topically relevant event chronicle during a certain period given a reference chronicle during another period. Our approach consists of two core components – a time-aware hierarchical Bayesian model for event detection, and a learning-to-rank model to select the salient events to construct the final chronicle. Experimental results demonstrate our approach is promising to tackle this new problem.

1 Introduction

Human civilization has developed for thousands of years. During the long period, history witnessed the changes of societies and dynasties, the revolution of science and technology, as well as the emergency of celebrities, which are great wealth for later generations. Even nowadays, people usually look back through history either for their work or interests. Among various ways to learn history, many people prefer reading an event chronicle summarizing important events in the past, which saves much time and efforts.

The left part of Figure 1 shows a disaster event chronicle from Infoplease[1], by which people can easily learn important disaster events in 2009. Unfortunately, almost all the available event chronicles are created and edited manually, which requires editors to learn everything that happened in the past. Even if an editor tries her best to generate an event chronicle, she still cannot guarantee that all the important events are included. Moreover, when new events happen in the future, she needs to update the chronicle in time, which is laborious. For example, the event chronicle of 2010 in Wikipedia[2] has been edited 8,488 times by 3,211 distinct editors since this page was created. In addition, event chronicles can vary according to topic preferences. Some event chronicles are mainly about disasters while others may focus more on sports. For people interested in sports, the event chronicle in Figure 1 is undesirable. Due to the diversity of event chronicles, it is common that an event chronicle regarding a specific topic for some certain period is unavailable. If editing an event chronicle can be done by computers, people can have an overview of any period according to their interests and do not have to wait for human editing, which will largely speed up knowledge acquisition and popularization.

Based on this motivation, we propose a new task of automatic event chronicle generation, whose goal is to generate a topically relevant event chronicle for some period based on a reference chronicle of another period. For example, if an disaster event chronicle during 2009 is available, we can use it to generate a disaster chronicle during 2010 from a news collection, as shown in Figure 1.

To achieve this goal, we need to know what events happened during the target period, whether these events are topically relevant to the chronicle, and whether they are important enough to be included, since an event chronicle has only a limited number of entries. To tackle these challenges, we propose an approach consisting of two core components – an event detection component based on a novel time-aware hierarchical Bayesian model and a learning-to-rank component to select the salient events to construct the final chronicle. Our event detection model can not only learn topic preferences of the reference chronicle and measure topical relevance of an event to the chronicle

Input: an event chronicle about disasters during 2009

20090109: At least 20 are killed and thousands more are left homeless after a 6.2 magnitude earthquake strikes the verdant mountains of northern Costa Rica, setting off landslides.

20090112: More than 200 people are missing and feared dead when a 250-passenger ferry sinks off the coast of the Indonesian island of Sulawesi during a storm.

20090124: At least 15 people die and more than one million homes are left without power when winds of more than 100 mph swept across France and Spain during the most severe storm to hit the region since 1999.

20090126: An avalanche slams into a group of 17 Turkish hikers on Mount Zigana, dragging them more than 1,640 ft and killing 10 of them.

...

Output: an event chronicle about disasters during 2010

20100112: The beleaguered country of Haiti is dealt a catastrophic blow when a magnitude 7.0 earthquake strikes 10 miles southwest of Port-au-Prince, the country's capital.

20100227: An 8.8 magnitude earthquake rocks Chile. Fatalities are relatively low, with some 750 people killed in the devastation.

20100404: A 7.2 earthquake, centered in Mexico but felt for miles, shakes California and kills two.

20100405: An explosion in a West Virginia coal mine kills at least 25 people and leaves 4 unaccounted for.

20100410: The President of Poland, Lech Kaczynski, and his wife are among the 96 people on board a flight from Poland to Smolensk, Russia that crashed while attempting to land in thick fog.

...

Figure 1: Example for automatic generation of a topically relevant event chronicle.

but also can effectively distinguish similar events by taking into account time information and event-specific details. Experimental results show our approach significantly outperforms baseline methods and that is promising to tackle this new problem.

The major novel contributions of this paper are:

- We propose a new task automatic generation of a topically relevant event chronicle, which is meaningful and has never been studied to the best of our knowledge.
- We design a general approach to tackle this new problem, which is language-independent, domain-independent and scalable to any arbitrary topics.
- We design a novel event detection model. It outperforms the state-of-the-art event detection model for generating topically relevant event chronicles.

2 Terminology and Task Overview

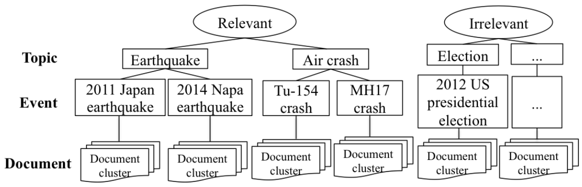

Figure 2: An example of relevance-topic-event hierarchical structure for a disaster event chronicle.

As shown in Figure 1, *an event (entry)* in an event chronicle corresponds to a specific occurrence in the real world, whose granularity depends on the chronicle. For a sports chronicle, an event entry may be a match in 2010 World Cup, while for a comprehensive chronicle, the World Cup is regarded as one event. In general, an event can be represented by a cluster of documents related to it. *The topic* of an event can be considered as the event class. For example, we can call the topic of MH17 crash as air crash (fine-grained) or disaster (coarse-grained). The relation between topic and event is shown through the example in Figure 2.

An event chronicle is a set of important events occurring in the past. Event chronicles vary according to topic preferences. For the disaster chronicle shown in Figure 1, earthquakes and air crashes are relevant topics while election is not. Hence, we can use a hierarchical structure to organize documents in a corpus, as Figure 2 shows.

Formally, we define an event chronicle $\mathbb{E} = \{e_1, e_2, ..., e_n\}$ where e_i is an event entry in $\mathbb{E}$ and it can be represented by a tuple $e_i = \langle D_{e_i}, t_{e_i}, z_{e_i}\rangle$. D_{e_i} denotes the set of documents about e_i, t_{e_i} is e_i's time and z_{e_i} is e_i's topic. Specially, we use Λ to denote the time period (interval) covered by $\mathbb{E}$, and θ to denote the topic distribution of $\mathbb{E}$, which reflects $\mathbb{E}$'s topic preferences.

As shown in Figure 1, the goal of our task is to generate an (target) event chronicle $\mathbb{E}_T$ during Λ_T based on a reference chronicle $\mathbb{E}_R$ during Λ_R. The topic distributions of $\mathbb{E}_T$ and $\mathbb{E}_R$ (i.e., θ_T and θ_R) should be consistent.

3 Event Detection

3.1 Challenges of Event Detection

(d_1) A magnitude-6.1 earthquake in southern China's Yunnan province destroyed thousands of home on Sunday, killing at least 367 people. (Aug 2014)

(d_2) A massive earthquake devastated Sichuan province in southwest China, leaving five million people homeless and taking some 87,000 lives. (May 2008)

(d_3) A 3.4-magnitude earthquake occurred in and around the city of Napa, California on Sunday, killing one person and injuring about 200. (Aug 2014)

Figure 3: Documents that are lexically similar but refer to different events. The underlined words are event-specific words.

For our task, the first step is to detect topically relevant events from a corpus. A good event detection model should be able to

(1) measure the topical relevance of a detected event to the reference chronicle.

(2) consider document time information.

(3) look into a document's event-specific details.

The first requirement is to identify topically relevant events since we want to generate a topically relevant chronicle. The second and third requirements are for effectively distinguishing events, especially similar events like the example in Figure 3. To distinguish the similar events, we must consider document time information (for distinguishing events in d_1 and d_2) and look into the document's event-specific details (the underlined words in Figure 3) (for distinguishing events in d_1 and d_3).

3.2 TaHBM: A Time-aware Hierarchical Bayesian Model

To tackle all the above challenges mentioned in Section 3.1, which cannot be tackled by conventional detection methods (e.g., agglomerative clustering), we propose a **T**ime-**a**ware **H**ierarchical **B**ayesian **M**odel (TaHBM) for detecting events.

Model Overview

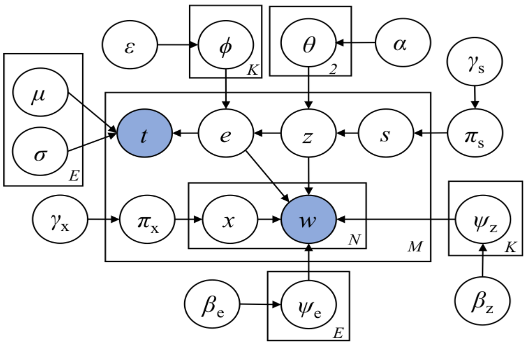

Figure 4: The plate diagram of TaHBM. The shaded nodes are observable nodes.

The plate diagram and generative story of TaHBM are depicted in Figure 4 and Figure 5 respectively. For a corpus with M documents, TaHBM assumes each document has three labels – s, z, and e. s is a binary variable indicating a document's topical relevance to the reference event chronicle, whose distribution is a Bernoulli distribution π_s drawn from a Beta distribution with symmetric hyperparameter γ_s. s=1 indicates the document is topically relevant to the chronicle while s=0 means not. z is a document's topic label drawn from a K-dimensional multinomial distribution θ, and e is a document's event label drawn from an E-dimensional multinomial distribution ϕ. θ and ϕ are drawn from Dirichlet distributions with symmetric hyperparameter α and ε respectively. For an event e', it can be represented by a set of documents whose event label is e'.

```
Draw $\pi_\text{s} \sim Beta(\gamma_\text{s})$
For each $s \in \{0,1\}$: draw $\theta^{(s)} \sim Dir(\alpha)$
For each $z = 1,2,3,...,K$: draw $\phi^{(z)} \sim Dir(\varepsilon)$, $\psi_\text{z}^{(z)} \sim Dir(\beta_\text{z})$
For each $e = 1,2,3,...,E$: draw $\psi_\text{e}^{(e)} \sim Dir(\beta_\text{e})$
For each document $m = 1,2,3,...,M$:
    Draw $s \sim Bernoulli(\pi_\text{s})$
    Draw $z \sim Multi(\theta^{(s)})$
    Draw $e \sim Multi(\phi^{(z)})$
    Draw $t' \sim Gaussian(\mu_e, \sigma_e), t \leftarrow \lfloor t' \rfloor$
    Draw $\pi_\text{x} \sim Beta(\gamma_\text{x})$
    For each word $w$ in document $m$:
        Draw $x \sim Bernoulli(\pi_\text{x})$
        If $x = 0$: draw $w \sim \psi_\text{z}^{(z)}$
        Else: draw $w \sim \psi_\text{e}^{(e)}$
```

Figure 5: The generative story of TaHBM

In TaHBM, the relations among s, z and e are similar to the hierarchical structure in Figure 2. Based on the dependencies among s, z and e, we can compute the topical relevance of an event to the reference chronicle by Eq (1) where $P(e|z)$, $P(e)$, $P(s)$ and $P(z|s)$ can be estimated using Bayesian inference (some details of estimation of $P(s)$ and $P(s|z)$ will be discussed in Section 3.3) and thus we solve the first challenge in Section 3.1 (i.e., topical relevance measure problem).

$$P(s|e) = \frac{P(s) \times P(z|s) \times P(e|z)}{P(e)} \tag{1}$$

Now, we introduce how to tackle the second challenge – how to take into account a document's time information for distinguishing events. In TaHBM, we introduce t, document timestamps. We assume $t = \lfloor t' \rfloor$ where t' is drawn from a Gaussian distribution with mean μ and variance σ^2. Each event e corresponds to a specific Gaussian distribution which serves as a temporal constraint for e. A Gaussian distribution has only one peak around where the probability is concentrated. Its value trends to zero if a point lies far away from the mean. For this reason, a Gaussian distribution is suitable to describe an event's temporal distribution whose probability usually concentrates around the event's burst time and it will be close to zero if time lies far from the burst time. Figure 6 shows the temporal distribution of *the July 2009 Urumqi riots*[3]. The probability of this event concentrates around the 7th day. If we use a Gaussian distribution (the dashed curve in Figure 6) to constrain this event's time scope, the documents whose timestamps are beyond this scope are unlikely to be grouped into this event's cluster.

Now that the problems of topical relevance measure and temporal constraints have been solved, we discuss how to identify event-specific details of a document for distinguishing events. By analyzing the documents shown in Figure 3, we find that general words (e.g., *earthquake, kill, injury, devastate*) indicate the document's topic while words about event-specific details (e.g., *Napa, California, 3.4-magnitude*) are helpful to determine what events the document talks about. Assuming a person is asked to analyze what event a document discusses, it would be a natural way to first determine topic of the document based its general words, and then determine what event it talks about given its topic, timestamp and event-specific details, which is exactly the way our TaHBM works.

For simplicity, we call the general words as **topic words** and call the words describing event-specific information as **event words**. Inspired by the idea of Chemudugunta et al. (2007), given the different roles these two kinds of words play, we assume words in a document are generated by two distributions: topic words are generated by a topic word distribution ψ_{z} while event words are generated by an event word distribution ψ_{e}. ψ_{z} and ψ_{e} are $|V|$-dimensional multinomial distributions drawn from Dirichlet distributions with symmetric hyperparameter β_{z} and β_{e} respectively, where $|V|$ denotes the size of vocabulary V. A binary indicator x, which is generated by a Bernoulli distribution π_{x} drawn from a Beta distribution with symmetric hyperparameter γ_{x}, determines whether a word is generated by ψ_{z} or ψ_{e}. Specifically, if $x = 0$, a word is drawn from ψ_{z}; otherwise the word is drawn from ψ_{e}. Since ψ_{z} is shared by all events of one topic, it can be seen as a background word distribution which captures general aspects. In contrast, ψ_{e} tends to describe the event-specific aspects. In this way, we can model a document's general and specific aspects and use the information to better distinguish similar events[4].

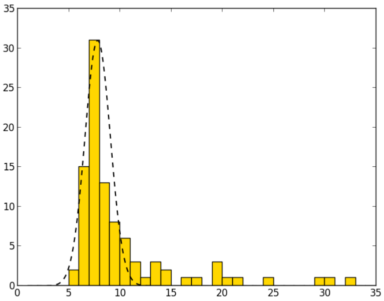

Figure 6: The temporal distribution of documents about the Urumqi riots, which can be described by a Gaussian distribution (the dashed curve). The horizontal axis is time (day) and the vertical axis is the number of documents about this event.

Model Inference

Like most Bayesian models, we use collapsed Gibbs sampling for model inference in TaHBM. For a document m, we present the conditional probability of its latent variables s, z and x for sampling:

$$P(s_m|\vec{s}_{\neg m}, \vec{z}, \gamma_{\mathrm{s}}, \alpha) = \frac{c_s + \gamma_{\mathrm{s}}}{\sum_s (c_s + \gamma_{\mathrm{s}})} \times \frac{c_{s,z_m} + \alpha}{\sum_z (c_{s,z} + \alpha)} \quad (2)$$

$$\begin{aligned} &P(z_m|\vec{z}_{\neg m}, \vec{e}, \vec{s}, \vec{w}_m, \vec{x}_m, \alpha, \varepsilon, \beta_{\mathrm{z}}) \\ &= \frac{c_{s_m,z} + \alpha}{\sum_z (c_{s_m,z} + \alpha)} \times \frac{c_{z,e_m} + \varepsilon}{\sum_e (c_{z,e} + \varepsilon)} \\ &\times \prod_{n=1}^{N_m} \Big(\frac{c_{z,w_{m,n}} + \sum_{i=1}^{n-1} \mathbf{1}(w_{m,i} = w_{m,n}) + \beta_{\mathrm{z}}}{\sum_{w \in V}(c_{z,w} + \beta_{\mathrm{z}}) + n - 1}\Big)^{(1-x_{m,n})} \end{aligned} \quad (3)$$

$$\begin{aligned} &P(x_{m,n}|\vec{w}_m, \vec{x}_{\neg m,n}, z_m, e_m, \gamma_{\mathrm{x}}) \\ &= \frac{c_{m,x} + \gamma_{\mathrm{x}}}{N_m + 2\gamma_{\mathrm{x}}} \times \Big(\frac{c_{z_m,w_{m,n}} + \beta_{\mathrm{z}}}{\sum_{w \in V}(c_{z_m,w} + \beta_{\mathrm{z}})}\Big)^{(1-x)} \\ &\times \Big(\frac{c_{e_m,w_{m,n}} + \beta_{\mathrm{e}}}{\sum_{w \in V}(c_{e_m,w} + \beta_{\mathrm{e}})}\Big)^{x} \end{aligned} \quad (4)$$

where V denotes the vocabulary, $w_{m,n}$ is the n^{th} word in a document m, c_s is the count of documents with topic relevance label s, $c_{s,z}$ is the count

[3] http://en.wikipedia.org/wiki/July_2009_Urumqi_riots

[4] TaHBM is language-independent, which can identify event words without name tagging. But if name tagging results are available, we can also exploit them (e.g., we can fix x of a named entity specific to an event to 1 during inference.).

of documents with topic relevance label s and topic label z, $c_{z,w}$ is the count of word w whose document's topic label is z, $c_{m,x}$ is the count of words with binary indicator label x in m and $\mathbf{1}(\cdot)$ is an indicator function.

Specially, for variable e which is dependent on the Gaussian distribution, its conditional probability for sampling is computed as Eq (5):

$$
\begin{aligned}
&P(e_m|\vec{e}_{\neg m}, \vec{z}, \vec{w}_m, \vec{x}_m, t_m, \varepsilon, \beta_{\mathrm{e}}, \mu_e, \sigma_e) \\
&= \frac{c_{z_m,e} + \varepsilon}{\sum_e (c_{z_m,e} + \varepsilon)} \times \int_{t_m}^{t_m+1} p_G(t_m; \mu_e, \sigma'_e) \\
&\times \prod_{n=1}^{N_m} \left(\frac{c_{e,w_{m,n}} + \sum_{i=1}^{n-1} \mathbf{1}(w_{m,i} = w_{m,n}) + \beta_{\mathrm{e}}}{\sum_{w \in V} (c_{e,w} + \beta_{\mathrm{e}}) + n - 1}\right)^{x_{m,n}}
\end{aligned}
\tag{5}
$$

where $p_G(x; \mu, \sigma)$ is a Gaussian probability mass function with parameter μ and σ.

The function $p_G(\cdot)$ can be seen as the temporal distribution of an event, as discussed before. In this sense, the temporal distribution of the whole corpus can be considered as a mixture of Gaussian distributions of events. As a natural way to estimate parameters of mixture of Gaussians, we use EM algorithm (Bilmes, 1998). In fact, Eq (5) can be seen as the E-step. The M-step of EM updates μ and σ as follows:

$$
\mu_e = \frac{\sum_{d \in D_e} t_d}{|D_e|}, \sigma_e = \sqrt{\frac{\sum_{d \in D_e} (t_d - \mu_e)^2}{|D_e|}} \tag{6}
$$

where t_d is document d's timestamp and D_e is the set of documents with event label e.

Specially, for sampling e we use σ'_e defined as $\sigma'_e = \sigma_e + \tau$ (τ is a small number for smoothing[5]) because when σ is very small (e.g., $\sigma = 0$), an event's temporal scope will be strictly constrained. Using σ'_e can help the model overcome this "trap" for better parameter estimation.

Above all, the model inference and parameter estimation procedure can be summarized by algorithm 1.

3.3 Learn Topic Preferences of the Event Chronicle

A prerequisite to use Eq (1) to compute an event's topical relevance to an event chronicle is that we know $P(s)$ and $P(z|s)$ which reflects topic preferences of the event chronicle. Nonetheless, $P(s)$ and $P(z|s)$ vary according to different event chronicles. Hence, we cannot directly estimate them in an unsupervised manner; instead, we provide TaHBM some "supervision". As we mentioned in section 3.2, the variable s indicates a document's topical relevance to the event chronicle. For some documents, s label can be easily derived with high accuracy so that we can exploit the information to learn the topic preferences.

Algorithm 1 Model inference for TaHBM

```
Initialize parameters in TaHBM;
for each $iteration$ do
    for each document $d$ in the corpus do
        sample $s$ according to Eq (2)
        sample $z$ according to Eq (3)
        sample $e$ according to Eq (5)
        for each word $w$ in $d$ do
            sample $x$ according to Eq (4)
        end for
    end for
    for each event $e$ do
        update $\mu_e, \sigma_e$ according to Eq (6)
    end for
end for
```

To obtain the labeled data, we use the description of each event entry in the reference chronicle $\mathbb{E}_R$ during period Λ_R as a query to retrieve relevant documents in the corpus using Lucene (Jakarta, 2004) which is an information retrieval software library. We define $\mathscr{R}$ as the set of documents in hits of any event entry in the reference chronicle returned by Lucene:

$$
\mathscr{R} = \cup_{e \in \mathbb{E}_R} Hit(e)
$$

where $Hit(e)$ is the complete hit list of event e returned by Lucene. For document d with timestamp t_d, if $d \notin \mathscr{R}$ and $t_d \in \Lambda_R$, then d is considered irrelevant to the event chronicle and thus it would be labeled as a negative example.

To generate positive examples, we use a strict criterion since we cannot guarantee that all the documents in $\mathscr{R}$ are actually relevant. To precisely generate positive examples, a document d is labeled as positive only if it satisfies the **positive condition** which is defined as follows:

$$
\exists_{e \in \mathbb{E}_R} 0 \leq t_d - t_e \leq 10 \wedge sim(d, e) \geq 0.4
$$

where t_e is time[6] of event e, provided by the reference chronicle. $sim(d, e)$ is Lucene's score of d given query e. According to the positive condition, a positive document example must be lexi-

[5] τ is set to 0.5 in our experiments.

[6] The time unit of t_d and t_e is one day.

cally similar to some event in the reference chronicle and its timestamp is close to the event's time.

As a result, we can use the labeled data to learn topic preferences of the event chronicle. For the labeled documents, s is fixed during model inference. In contrast, for documents that are not labeled, s is sampled by Eq (2). In this manner, TaHBM can learn topic preferences (i.e., $P(z|s)$) without any manually labeled data and thus can measure the topical relevance between an event and the reference chronicle.

4 Event Ranking

Generating an event chronicle is beyond event detection because we cannot use all detected events to generate the chronicle with a limited number of entries. We propose to use learning-to-rank techniques to select the most salient events to generate the final chronicle since we believe the reference event chronicle can teach us the principles of selecting salient events. Specifically, we use SVM-Rank (Joachims, 2006).

4.1 Training and Test Set Generation

The event detection component returns many document clusters, each of which represents an event. As Section 3.2 shows, each event has a Gaussian distribution whose mean indicates its burst time in TaHBM. We use the events whose burst time is during the reference chronicle's period as training examples and treat those during the target chronicle's period as test examples. Formally, the training set and test set are defined as follows:

$$Train = \{e|\mu_e \in \Lambda_R\}, Test = \{e|\mu_e \in \Lambda_T\}$$

In the training set, events containing at least one positive document (i.e. relevant to the event chronicle) in Section 3.3 are labeled as high rank priority while those without positive documents are labeled as low priority.

4.2 Features

We use the following features to train the ranking model, all of which can be provided by TaHBM.

- $P(s = 1|e)$: the probability that an event e is topically relevant to the reference chronicle.
- $P(e|z)$: the probability reflects an event's impact given its topic.
- σ_e: the parameter of an event e's Gaussian distribution. It determines the 'bandwidth' of the Gaussian distribution and thus can be considered as the time span of e.
- $|D_e|$: the number of documents related to event e, reflecting the impact of e.
- $\frac{|D_e|}{\sigma_e}$: For an event with a long time span (e.g., Premier League), the number of relevant documents is large but its impact may not be profound. Hence, we use $\frac{|D_e|}{\sigma_e}$ to normalize $|D_e|$, which may better reflect the impact of e.

5 Experiments

5.1 Experiment Setting

Data: We use various event chronicles during 2009 as references to generate their counterparts during 2010. Specifically, we collected disaster, sports, war, politics and comprehensive chronicles during 2009 from mapreport[7], infoplease and Wikipedia[8]. To generate chronicles during 2010, we use 2009-2010 APW and Xinhua news in English Gigaword (Graff et al., 2003) and remove documents whose titles and first paragraphs do not include any burst words. We detect burst words using Kleinberg algorithm (Kleinberg, 2003), which is a 2-state finite automaton model and widely used to detect bursts. In total, there are 140,557 documents in the corpus.

Preprocessing: We remove stopwords and use Stanford CoreNLP (Manning et al., 2014) to do lemmatization.

Parameter setting: For TaHBM, we empirically set $\alpha = 0.05$, $\beta_{\text{z}} = 0.005$, $\beta_{\text{e}} = 0.0001$, $\gamma_{\text{s}} = 0.05$, $\gamma_{\text{x}} = 0.5$, $\varepsilon = 0.01$, the number of topics $K = 50$, and the number of events $E = 5000$. We run Gibbs sampler for 2000 iterations with burn-in period of 500 for inference. For event ranking, we set regularization parameter of SVMRank $c = 0.1$.

Chronicle display: We use a heuristic way to generate the description of each event. Since the first paragraph of a news article is usually a good summary of the article and the earliest document in a cluster usually explicitly describes the event, for an event represented by a document cluster, we choose the first paragraph of the earliest document written in 2010 in the cluster to generate the event's description. The earliest document's timestamp is considered as the event's time.

[7] http://www.mapreport.com

[8] http://en.wikipedia.org/wiki/2009

5.2 Evaluation Methods and Baselines

Since there is no existing evaluation metric for the new task, we design a method for evaluation.

Although there are manually edited event chronicles on the web, which may serve as references for evaluation, they are often incomplete. For example, the 2010 politics event chronicle on Wikipedia has only two event entries. Hence, we first pool all event entries of existing chronicles on the web and chronicles generated by approaches evaluated in this paper and then have 3 human assessors judge each event entry for generating a ground truth based on its topical relevance, impact and description according to the standard of the reference chronicles. An event entry will be included in the ground-truth only if it is selected as a candidate by at least two human judges. On average, the existing event chronicles on the web cover 50.3% of event entries in the ground-truth.

Given the ground truth, we can use $Precision@k$ to evaluate an event chronicle's quality.

$$Precision@k = |\mathbb{E}_G \cap \mathbb{E}_{topk}|/k$$

where $\mathbb{E}_G$ and $\mathbb{E}_{topk}$ are ground-truth chronicle and the chronicle with top k entries generated by an approach respectively. If there are multiple event entries corresponding to one event in the ground-truth, only one is counted.

For comparison, we choose several baseline approaches. Note that event detection models except TaHBM do not provide features used in learning-to-rank model. For these detection models, we use a criterion that considers both relevance and importance to rank events:

$$rankscore_{basic}(e) = \sum_{d \in D_e} max_{e' \in \mathbb{E}_R} sim(d, e')$$

where $\mathbb{E}_R$ is the reference chronicle and $sim(d, e')$ is Lucene's score of document d given query e'. We call this ranking criterion as **basic criterion**.

- Random: We randomly select k documents to generate the chronicle.
- NB+basic: Since TaHBM is essentially an extension of NB, we use Naive Bayes (NB) to detect events and basic ranking criterion to rank events.
- B-HAC+basic: We use hierarchical agglomerative clustering (HAC) based on BurstVSM schema (Zhao et al., 2012) to detect events, which is the state-of-the-art event detection method for general domains.
- TaHBM+basic: we use this baseline to verify the effectiveness of learning-to-rank.

As TaHBM, the number of clusters in NB is set to 5000 for comparison. For B-HAC, we adopt the same setting with (Zhao et al., 2012).

5.3 Experiment Results

Using the evaluation method introduced above, we can conduct a quantitative evaluation for event chronicle generation approaches[9].

Table 1 shows the overall performance. Our approach outperforms the baselines for all chronicles. TaHBM beats other detection models for chronicle generation owing to its ability of incorporating the temporal information and identification of event-specific details of a document. Moreover, learning-to-ranking is proven more effective to rank events than the basic ranking criterion.

Among these 5 chronicles, almost all approaches perform best on disaster event chronicle while worst on sports event chronicle. We analyzed the results and found that many event entries in the sports event chronicle are about the opening match, or the first-round match of a tournament due to the display method described in Section 5.1. According to the reference sport event chronicle, however, only matches after quarterfinals in a tournament are qualified to be event entries. In other words, a sports chronicle should provide information about the results of semi-final and final, and the champion of the tournament instead of the first-round match's result, which accounts for the poor performance. In contrast, the earliest document about a disaster event always directly describes the disaster event while the following reports usually concern responses to the event such as humanitarian aids and condolence from the world leaders. The patterns of reporting war events are similar to those of disasters, thus the quality of war chronicle is also good. Politics is somewhat complex because some political events (e.g., election) are arranged in advance while others (e.g., government shutdown) are unexpected. It is notable that for generating comprehensive event chronicles, learning-to-rank does

[9] Due to the space limitation, we display chronicles generated by our approach in the supplementary notes.

	sports		politics		disaster		war		comprehensive

Table 1: Performance of event chronicle generation.

	Topically Irrelevant	Trivial Events	Indirect Description	Redundant Entries
disaster	31.91%	17.02%	44.68%	6.38%
sports	38.82%	55.29%	3.52%	2.35%
comp	-	67.16%	31.34%	1.49%

Table 2: Proportion of errors in disaster, sports and comprehensive event chronicles.

not show significant improvement. A possible reason is that a comprehensive event chronicle does not care the topical relevance of a event. In other words, its ranking problem is simpler so that the learning-to-rank does not improve the basic ranking criterion much.

Moreover, we analyze the incorrect entries in the chronicles generated by our approaches. In general, there are four types of errors.

Topically irrelevant: the topic of an event entry is irrelevant to the event chronicle.

Minor events: the event is not important enough to be included. For example, "*20100828: Lebanon beat Canada 81-71 in the opening round of the basketball world championships*" is a minor event in the sports chronicle because it is about an opening-round match and not important enough.

Indirect description: the entry does not describe a major event directly. For instance, "*20100114: Turkey expressed sorrow over the Haiti earthquake*" is an incorrect entry in the disaster chronicle though it mentions the Haiti earthquake.

Redundant entries: multiple event entries describe the same event.

We analyze the errors of the disaster, sports and comprehensive event chronicle since they are representative, as shown in Table 2.

Topical irrelevance is a major error source for both disaster and sports event chronicles. This problem mainly arises from incorrect identification of topically relevant events during detection. Moreover, disaster and sports chronicles have their own more serious problems. Disaster event chronicles suffer from the indirect description problem since there are many responses (e.g., humanitarian aids) to a disaster. These responses are topically relevant and contain many documents, and thus appear in the top list. One possible solution might be to increase the event granularity by adjusting parameters of the detection model so that the documents describing a major event and those discussing in response to this event can be grouped into one cluster (i.e., one event). In contrast, the sports event chronicle's biggest problem is on minor events, as mentioned before. Like the sports chronicle, the comprehensive event chronicle also has many minor event entries but its main problem results from its strict criterion. Since comprehensive chronicles can include events of any topic, only extremely important events can be included. For example, "*Netherlands beat Uruguay to reach final in the World Cup 2010*" may be a correct event entry in sports chronicles but it is not a good entry in comprehensive chronicles. Compared with comprehensive event chronicles, events in other chronicles tend to describe more details. For example, a sports chronicle may regard each match in the World Cup as an event while comprehensive chronicles consider the World Cup as one event, which requires us to adapt event granularity for different chronicles.

Also, we evaluate the time of event entries in these five event chronicles because event's happening time is not always equal to the timestamp of the document creation time (UzZaman et al., 2012; Ge et al., 2013). We collect existing manually edited 2010 chronicles on the web and use their event time as gold standard. We define a metric to evaluate if the event entry's time in our chronicle is accurate:

$$diff = \sum_{e \in \mathbb{E} \cap \mathbb{E}^*} |(t_e - t_e^*)| / |\mathbb{E} \cap \mathbb{E}^*|$$

where $\mathbb{E}$ and $\mathbb{E}^*$ are our chronicle and the manually edited event chronicle respectively. t_e is e's time labeled by our method and t_e^* is e's correct time. Note that for multiple entries referring the same event in event chronicles, the earliest entry's time is used as the event's time to compute *diff*.

sports	**politics**	**disaster**	**war**	**comprehensive**
0.800	3.363	1.042	1.610	2.467

Table 3: Difference between an event's actual time and the time in our chronicles. Time unit is a day.

Table 3 shows the performance of our approach in labeling event time. For disaster, sports and war, the accuracy is desirable since important events about these topics are usually reported in time. In contrast, the accuracy of political event time is the lowest. The reason is that some political events may be confidential and thus they are not reported as soon as they happen; on the other hand, some political events (e.g., a summit) are reported several days before the events happen. The comprehensive event chronicle includes many political events, which results in a lower accuracy.

6 Related Work

To the best of our knowledge, there was no previous end-to-end topically relevant event chronicle generation work but there are some related tasks.

Event detection, sometimes called topic detection (Allan, 2002), is an important part of our approach. Yang et al. (1998) used clustering techniques for event detection on news. He et al. (2007) and Zhao et al. (2012) designed burst feature representations for detecting bursty events. Compared with our TaHBM, these methods lack the ability of distinguishing similar events.

Similar to event detection, event extraction focuses on finding events from documents. Most work regarding event extraction (Grishman et al., 2005; Ahn, 2006; Ji and Grishman, 2008; Chen and Ji, 2009; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2012; Chen and Ng, 2012; Li et al., 2013) was developed under Automatic Content Extraction (ACE) program. The task only defines 33 event types and events are in much finer grain than those in our task. Moreover, there was work (Verhagen et al., 2005; Chambers and Jurafsky, 2008; Bethard, 2013; Chambers, 2013; Chambers et al., 2014) about temporal event extraction and tracking. Like ACE, the granularity of events in this task is too fine to be suitable for our task.

Also, timeline generation is related to our work. Most previous work focused on generating a timeline for a document (Do et al., 2012), a centroid entity (Ji et al., 2009) or one major event (Hu et al., 2011; Yan et al., 2011; Lin et al., 2012; Li and Li, 2013). In addition, Li and Cardie (2014) generated timelines for users in microblogs. The most related work to ours is Swan and Allan (2000). They used a timeline to show bursty events along the time, which can be seen as an early form of event chronicles. Different from their work, we generate a topically relevant event chronicle based on a reference event chronicle.

7 Conclusions and Future Work

In this paper, we propose a novel task – automatic generation of topically relevant event chronicles. It can serve as a new framework to combine the merits of Information Retrieval, Information Extraction and Summarization techniques, to rapidly extract and rank salient events. This framework is also able to rapidly and accurately capture a user's interest and needs based on the reference chronicle (instead of keywords as in Information Retrieval or event templates as in Guided Summarization) which can reflect diverse levels of granularity.

As a preliminary study of this new challenge, this paper focuses on event detection and ranking. There are still many challenges for generating high-quality event chronicles. In the future, we plan to investigate automatically adapting an event's granularity and learn the principle of summarizing the event according to the reference event chronicle. Moreover, we plan to study the generation of entity-driven event chronicles, leveraging more fine-grained entity and event extraction approaches.

Abstract

People create morphs, a special type of fake alternative names, to achieve certain communication goals such as expressing strong sentiment or evading censors. For example, "*Black Mamba*", the name for a highly venomous snake, is a morph that *Kobe Bryant* created for himself due to his agility and aggressiveness in playing basketball games. This paper presents the first end-to-end context-aware entity morph decoding system that can automatically identify, disambiguate, verify morph mentions based on specific contexts, and resolve them to target entities. Our approach is based on an absolute "*cold-start*" - it does not require any candidate morph or target entity lists as input, nor any manually constructed morph-target pairs for training. We design a semi-supervised collective inference framework for morph mention extraction, and compare various deep learning based approaches for morph resolution. Our approach achieved significant improvement over the state-of-the-art method (Huang et al., 2013), which used a large amount of training data. [1]

1 Introduction

Morphs (Huang et al., 2013; Zhang et al., 2014) refer to the fake alternative names created by social media users to entertain readers or evade censors. For example, during the World Cup in 2014, a morph "*Su-tooth*" was created to refer to the Uruguay striker "*Luis Suarez*" for his habit of biting other players. Automatically decoding human-generated morphs in text is critical for downstream deep language understanding tasks such as entity linking and event argument extraction.

However, even for human, it is difficult to decode many morphs without certain historical, cultural, or political background knowledge (Zhang et al., 2014). For example, "*The Hutt*" can be used to refer to a fictional alien entity in the *Star Wars* universe ("*The Hutt stayed and established himself as ruler of Nam Chorios*"), or the governor of New Jersey, *Chris Christie* ("*The Hutt announced a bid for a seat in the New Jersey General Assembly*"). Huang et al. (2013) did a pioneering pilot study on morph resolution, but their approach assumed the entity morphs were already extracted and used a large amount of labeled data. In fact, they resolved morphs on corpus-level instead of mention-level and thus their approach was context-independent. A practical morph decoder, as depicted in Figure 1, consists of two problems: (1) Morph Extraction: given a corpus, extract morph mentions; and (2). Morph Resolution: For each morph mention, figure out the entity that it refers to.

In this paper, we aim to solve the fundamental research problem of end-to-end morph decoding and propose a series of novel solutions to tackle the following challenges.

Challenge 1: Large-scope candidates

Only a very small percentage of terms can be used as morphs, which should be interesting and fun. As we annotate a sample of $4,668$ Chinese weibo tweets, only 450 out of $19,704$ unique terms are morphs. To extract morph mentions, we propose a

Figure 1: An Illustration of Morph Decoding Task.

two-step approach to first identify individual mention candidates to narrow down the search scope, and then verify whether they refer to morphed entities instead of their original meanings.

Challenge 2: Ambiguity, Implicitness, Informality

Compared to regular entities, many morphs contain informal terms with hidden information. For example, "不厚 *(not thick)*" is used to refer to "薄熙来 *(Bo Xilai)*" whose last name "薄 *(Bo)*" means "thin". Therefore we attempt to model the rich contexts with careful considerations for morph characteristics both globally (e.g., language models learned from a large amount of data) and locally (e.g. phonetic anomaly analysis) to extract morph mentions.

For morph resolution, the main challenge lies in that the surface forms of morphs usually appear quite different from their target entity names. Based on the distributional hypothesis (Harris, 1954) which states that words that often occur in similar contexts tend to have similar meanings, we propose to use deep learning techniques to capture and compare the deep semantic representations of a morph and its candidate target entities based on their contextual clues. For example, the morph "平西王*(Conquer West King)*" and its target entity "薄熙来 *(Bo Xilai)*" share similar implicit contextual representations such as "重庆*(Chongqing)*" (Bo was the governor of Chongqing) and "倒台 *(fall from power)*".

Challenge 3: Lack of labeled data

To the best of our knowledge, no sufficient mention-level morph annotations exist for training an end-to-end decoder. Manual morph annotations require native speakers who have certain cultural background (Zhang et al., 2014). In this paper we focus on exploring novel approaches to save annotation cost in each step. For morph extraction, based on the observation that morphs tend to share similar characteristics and appear together, we propose a semi-supervised collective inference approach to extract morph mentions from multiple tweets simultaneously. Deep learning techniques have been successfully used to model word representation in an unsupervised fashion. For morph resolution, we make use of a large amount of unlabeled data to learn the semantic representations of morphs and target entities based on the unsupervised continuous bag-of-words method (Mikolov et al., 2013b).

2 Problem Formulation

Following the recent work on morphs (Huang et al., 2013; Zhang et al., 2014), we use Chinese Weibo tweets for experiments. Our goal is to develop an end-to-end system that automatically extract morph mentions and resolve them to their target entities. Given a corpus of tweets $D = \{d_1, d_2, ..., d_{|D|}\}$, we define a candidate *morph* m_i as a unique term t_j in T, where $T = \{t_1, t_2, ..., t_{|T|}\}$ is the set of unique terms in D. To extract T, we first apply several well-developed Natural Language Processing tools, including Stanford Chinese word segmenter (Chang et al., 2008), Stanford part-of-speech tagger (Toutanova et al., 2003) and Chinese lexical analyzer ICTCLAS (Zhang et al., 2003), to process the tweets and identify noun phrases. Then we define a *morph mention* m_i^p of m_i as the p-th occurrence of m_i in a specific document d_j. Note that a mention with the same surface form as m_i but referring to its original entity is not considered as a morph mention. For instance, the "平西王 *(Conquer West King)*" in d_1 and d_3 in Figure 1 are morph mentions since they refer to the modern politician "薄熙来 *(Bo Xilai)*", while the one in d_4 is not a morph mention since it refers to the original entity, who was king "吴三桂 *(Wu Sangui)*".

For each morph mention, we discover a list of target candidates $E = \{e_1, e_2, ..., e_{|E|}\}$ from Chinese web data for morph mention resolution. We design an end-to-end morph decoder which consists of the following procedure:

- ***Morph Mention Extraction***
  - ***Potential Morph Discovery***: This first step aims to obtain a set of potential entity-level morphs $M = \{m_1, m_2, ...\} (M \subseteq T)$. Then, we only verify and resolve the mentions of these potential morphs, instead of all the terms in T in a large corpus.
  - ***Morph Mention Verification***: In this step, we aim to verify whether each mention m_i^p of the potential morph $m_i (m_i \in M)$ from a specific context d_j is a morph mention or not.
- ***Morph Mention Resolution***: The final step is to resolve each morph mention m_i^p to its target entity (e.g., "薄熙来 *(Bo Xilai)*" for the morph mention "平西王 *(Conquer West King)*" in d_1 in Figure 1).

3 Morph Mention Extraction

3.1 Why Traditional Entity Mention Extraction doesn't Work

In order to automatically extract morph mentions from any given documents, our first reflection is to formulate the task as a sequence labeling problem, just like labeling regular entity mentions. We adopted the commonly used conditional random fields (CRFs) (Lafferty et al., 2001) and got only 6% F-score. Many morphs are not presented as regular entity mentions. For example, the morph "天线 *(Antenna)*" refers to "温家宝 *(Wen Jiabao)*" because it shares one character "宝 *(baby)*" with the famous children's television series "天线宝宝 *(Teletubbies)*". Even when they are presented as regular entity mentions, they must refer to new target entities which are different from the regular ones. So we propose the following novel two-step solution.

3.2 Potential Morph Discovery

We first introduce the first step of our approach – potential morph discovery, which aims to narrow down the scope of morph candidates without losing recall. This step takes advantage of the common characteristics shared among morphs and identifies the potential morphs using a supervised method, since it is relatively easy to collect a certain number of corpus-level morphs as training data compared to labeling morph mentions. Through formulating this task as a binary classification problem, we adopt the Support Vector Machines (SVMs) (Cortes and Vapnik, 1995) as the learning model. We propose the following four categories of features.

Basic: (i) character unigram, bigram, trigram, and surface form; (ii) part-of-speech tags; (iii) the number of characters; (iv) whether some characters are identical. These basic features will help identify several common characteristics of morph candidates (e.g., they are very likely to be nouns, and very unlikely to contain single characters).

Dictionary: Many morphs are non-regular names derived from proper names while retaining some characteristics. For example, the morphs "薄督 *(Governor Bo)*" and "吃省 *(Gourmand Province)*" are derived from their target entity names "薄熙来 *(Bo Xilai)*" and "广东省 *(Guandong Province)*", respectively. Therefore, we adopt a dictionary of proper names (Li et al., 2012) and propose the following features: (i) Whether a term occurs in the dictionary. (ii) Whether a term starts with a commonly used last name, and includes uncommonly used characters as its first name. (iii) Whether a term ends with a geopolitical entity or organization suffix word, but it's not in the dictionary.

Phonetic: Many morphs are created based on phonetic (Chinese pinyin in our case) modifications. For instance, the morph "饭饼饼 *(Rice Cake)*" has the same phonetic transcription as its target entity name "范冰冰 *(Fan Bingbing)*". To extract phonetic-based features, we compile a dictionary composed of ⟨phonetic transcription, term⟩ pairs from the Chinese Gigaword corpus [2]. Then for each term, we check whether it has the same phonetic transcription as any entry in the dictionary but they include different characters.

Language Modeling: Many morphs rarely appear in a general news corpus (e.g., "六步郎 *(Six Step Man)*" refers to the NBA baseketball player "勒布朗·詹姆斯 *(Lebron James)*".). Therefore, we use the character-based language models trained from Gigaword to calculate the occurrence probabilities of each term, and use n-gram probabilities ($n \in [1:5]$) as features.

3.3 Morph Mention Verification

The second step is to verify whether a mention of the discovered potential morphs is indeed used as a morph in a specific context. Based on the ob-

[2] https://catalog.ldc.upenn.edu/LDC2011T07

servation that closely related morph mentions often occur together, we propose a semi-supervised graph-based method to leverage a small set of labeled seeds, coreference and correlation relations, and a large amount of unlabeled data to perform collective inference and thus save annotation cost. According to our observation of morph mentions, we propose the following two hypotheses:

Hypothesis 1: *If two mentions are coreferential, then they both should either be morph mentions or non-morph mentions.* For instance, the morph mentions "平西王 *(Conquer West King)*" in d_1 and d_3 in Figure 1 are coreferential, they both refer to the modern politician "薄熙来 *(Bo Xilai)*".

Hypothesis 2: *Those highly correlated mentions tend to either be morph mentions or non-morph mentions.* From our annotated dataset, 49% morph mentions co-occur on tweet level. For example, "平西王*(Conquer West King)*" and "军哥*(Brother Jun)*" are used together in d_3 in Figure 1.

Based on these hypotheses, we aim to design an effective approach to compensate for the limited annotated data. Graph-based semi-supervised learning approaches (Zhu et al., 2003; Smola and Kondor, 2003; Zhou et al., 2004) have been successfully applied many NLP tasks (Niu et al., 2005; Chen et al., 2006; Huang et al., 2014). Therefore we build a mention graph to capture the semantic relatedness (weighted arcs) between potential morph mentions (nodes) and propose a semi-supervised graph-based algorithm to collectively verify a set of relevant mentions using a small amount of labeled data. We now describe the detailed algorithm as follows.

Mention Graph Construction

First, we construct a mention graph that can reflect the association between all the mentions of potential morphs. According to the above two hypotheses, *mention coreference* and *correlation* relations are the basis to build our mention graph, which is represented by a matrix.

In Chinese Weibo, their exist rich and clean social relations including *authorship*, *replying*, *retweeting*, or *user mentioning* relations. We make use of these social relations to judge the possibility of two mentions of the same potential morph being coreferential. If there exists one social relation between two mentions m_i^p and m_i^q of the morph m_i, they are usually coreferential and assigned an association score 1. We also detect coreferential relations by performing content similarity analysis. The cosine similarity is adopted with the tf-idf representation for the contexts of two mentions. Then we get a coreference matrix W^1:

$$W^1_{m_i^p, m_i^q} = \begin{cases} 1.0 & \text{if } m_i^p \text{ and } m_i^q \text{ are linked} \\ & \text{with certain social relation} \\ cos(m_i^p, m_i^q) & \text{else if } q \in kNN(p) \\ 0 & \text{Otherwise} \end{cases}$$

where m_i^p and m_i^q are two mentions from the same potential morph m_i, and kNN means that each mention is connected to its k nearest neighboring mentions.

Users tend to use morph mentions together to achieve their communication goals. To incorporate such evidence, we measure the correlation between two mentions m_i^p and m_j^q of two different potential morphs m_i and m_j as $corr(m_i^p, m_j^q) = 1.0$ if there exists a certain social relation between them. Otherwise, $corr(m_i^p, m_j^q) = 0$. Then we can obtain the correlation matrix: $W^2_{m_i^p, m_j^q} = corr(m_i^p, m_j^q)$.

To tune the balance of coreferential relation and correlation relation during learning, we first get two matrices $\hat{W}^1$ and $\hat{W}^2$ by row-normalizing W^1 and W_2, respectively. Then we obtain the final mention matrix W with a linear combination of $\hat{W}^1$ and $\hat{W}^2$: $W = \alpha\hat{W}^1 + (1-\alpha)\hat{W}^2$, where α is the coefficient between 0 and 1 [3].

Graph-based Semi-supervised Learning

Intuitively, if two mentions are strongly connected, they tend to hold the same label. The label of 1 indicates a mention is a morph mention, and 0 means a non-morph mention. We use $Y = \begin{bmatrix} Y_l & Y_u \end{bmatrix}^T$ to denote the label vector of all mentions, where the first l nodes are verified mentions labeled as 1 or 0, and the remaining u nodes need to be verified and initialized with the label 0.5. Our final goal is to obtain the final label vector Y_u by incorporating evidence from initial labels and the mention graph.

Following the graph-based semi-supervised learning algorithm (Zhu et al., 2003), the mention verification problem is formulated to optimize the objective function $\mathcal{Q}(\mathcal{Y}) = \mu \sum_{i=1}^{l}(y_i - y_i^0)^2 + \frac{1}{2}\sum_{i,j} W_{ij}(y_i - y_j)^2$ where y_i^0 denotes the initial

[3] α is set to 0.8 in this paper, optimized from the development set.

label, and μ is a regularization parameter that controls the trade-off between initial labels and the consistency of labels on the mention graph. Zhu et al. (2003) has proven that this formula has both closed-form and iterative solutions.

4 Morph Mention Resolution

The final step is to resolve the extracted morph mentions to their target entities.

4.1 Candidate Target Identification

We start from identifying a list of target candidates for each morph mention from the comparable corpora including Sina Weibo, Chinese News and English Twitter. After preprocessing the corpora using word segmentation, noun phrase chunking and name tagging, the name entity list is still too large and too noisy for candidate ranking. To clean the name entity list, we adopt the temporal Distribution Assumption proposed in our recent work (Huang et al., 2013). It assumes that a morph m and its real target e should have similar temporal distributions in terms of their occurrences. Following the same heuristic we assume that an entity is a valid candidate for a morph if and only if the candidate appears fewer than seven days after the morph's appearance.

4.2 Candidate Target Ranking

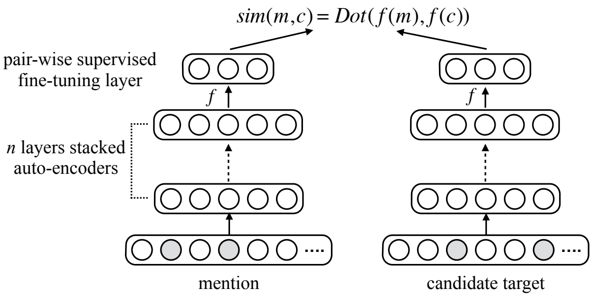
Motivations of Using Deep Learning

Compared to regular entity linking tasks (Ji et al., 2010; Ji et al., 2011; Ji et al., 2014), the major challenge of ranking a morph's candidate target entities lies in that the surface features such as the orthographic similarity between morph and target candidates have been proven inadequate (Huang et al., 2013). Therefore, it is crucial to capture the semantics of both mentions and target candidates. For instance, in order to correctly resolve "平西王 *(Conquer West King)*" from d_1 and d_3 in Figure 1 to the modern politician "薄熙来*(Bo Xilai)*" instead of the ancient king "吴三桂 *(Wu Sangui)*", it is important to model the surrounding contextual information effectively to capture important information (e.g., "重庆 *(Chongqing)*", "倒台 *(fall from power)*", and "唱红歌 *(sing red songs)*") to represent the mentions and target entity candidates. Inspired by the recent success achieved by deep learning based techniques on learning semantic representations for various NLP tasks (e.g., (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013b; He et al., 2013)), we design and compare the following two approaches to employ hierarchical architectures with multiple hidden layers to extract useful features and map morphs and target entities into a latent semantic space.

Pairwise Cross-genre Supervised Learning

Ideally, we hope to obtain a large amount of coreferential entity mention pairs for training. A natural knowledge resource is Wikipedia which includes anchor links. We compose an anchor's surface string and the title of the entity it's linked to as a positive training pair. Then we randomly sample negative training instances from those pairs that don't share any links.

Our approach consists of the following steps: (1) generating high quality embedding for each training instance; (2) pre-training with the stacked denoising auto-encoder (Bengio et al., 2003) for feature dimension reduction; and (3) supervised fine-tuning to optimize the neural networks towards a similarity measure (e.g., dot product). Figure 2 depicts the overall architecture of this approach.



$sim(m,c) = Dot(f(m), f(c))$
pair-wise supervised fine-tuning layer
f
f
n layers stacked auto-encoders
mention
candidate target

Figure 2: Overall Architecture of Pairwise Cross-genre Supervised Learning

However, morph resolution is significantly different from the traditional entity linking task since the latter mainly focuses on formal and explicit entities (e.g., "薄熙来 *(Bo Xilai)*") which tend to have stable referents in Wikipedia. In contrast, morphs tend to be informal, implicit and have newly emergent meanings which evolve over time. In fact, these morph mentions rarely appear in Wikipedia. For example, almost all "平西王 *(Conquer West King)*" mentions in Wikipedia refer to the ancient king instead of the modern politician "薄熙来 *(Bo Xilai)*". In addition, the contextual words in Wikipedia used to describe entities are quite different from those in social media. For example, to describe a death event, Wikipedia usually uses a formal expression "去世 (pass away)" while an informal expression "挂了 (hang up)" is used more often in tweets. Therefore this approach suffers from the knowledge discrepancy between these two genres.

Within-genre Unsupervised Learning

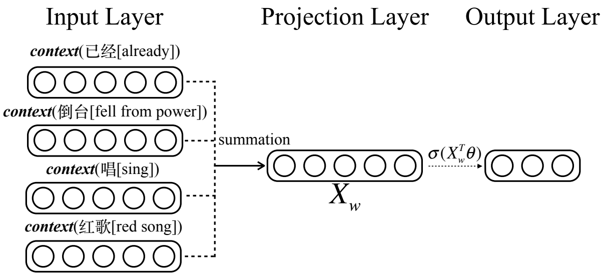


Figure 3: Continuous Bag-of-Words Architecture

To address the above challenge, we propose the second approach to learn semantic embeddings of both morph mentions and entities directly from tweets. Also we prefer unsupervised learning methods due to the lack of training data. Following (Mikolov et al., 2013a), we develop a continuous bag-of-words (CBOW) model that can effectively model the surrounding contextual information. CBOW is discriminatively trained by maximizing the conditional probability of a term w_i given its contexts $c(w_i) = \{w_{i-n}, ..., w_{i-1}, w_{i+1}, ..., w_{i+n}\}$, where n is the contextual window size, and w_i is a term obtained using the preprocessing step introduced in Section 2 [4]. The architecture of CBOW is depicted in Figure 3. We obtain a vector X_{w_i} through the projection layer by summing up the embedding vectors of all terms in $c(w_i)$, and then use the sigmoid activation function to obtain the final embedding of w_i in $c(w_i)$ in the output layer.

Formally, the objective function of CBOW can be formulated as $\mathcal{L}(\theta) = \sum_{w_i \in W} \sum_{w_j \in W} \log p(w_j|c(w_i))$, where W is the set of unique terms obtained from the whole training corpus. $p(w_j|c(w_i))$ is the conditional likelihood of w_j given the context $c(w_i)$ and it is formulated as follows:

$$\begin{aligned} p(w_j|c(w_i)) &= [\sigma(X_{w_i}^T \theta^{w_j})]^{L^{w_i}(w_j)} \times \\ &\quad [1 - \sigma(X_{w_i}^T \theta^{w_j})]^{1-L^{w_i}(w_j)}, \end{aligned}$$

Data	Training	Development	Testing
# Tweets	1,500	500	2,688
# Unique Terms	10,098	4, 848	15,108
# Morphs	250	110	341
# Morph Mentions	1,342	487	2,469

Table 1: Data Statistics

where $L^{w_i}(w_j) = \begin{cases} 1, & w_i = w_j \\ 0, & Otherwise \end{cases}$, σ is the sigmoid activation function, and θ^{w_i} is the embeddings of w_i to be learned with back-propagation during training.

5 Experiments

5.1 Data

We retrieved 1,553,347 tweets from Chinese Sina Weibo from May 1 to June 30, 2013 and 66, 559 web documents from the embedded URLs in tweets for experiments. We then randomly sampled $4,688$ non-redundant tweets and asked two Chinese native speakers to manually annotate morph mentions in these tweets. The annotated dataset is randomly split into training, development, and testing sets, with detailed statistics shown in Table 1 [5]. We used 225 positive instances and 225 negative instances to train the model in the first step of potential morph discovery.

We collected a Chinese Wikipedia dump of October 9th, 2014, which contains 2,539,355 pages. We pulled out person, organization and geo-political pages based on entity type matching with DBpedia [6]. We also filter out the pages with fewer than 300 words. For training the model, we use 60,000 mention-target pairs along with one negative sample randomly generated for each pair, among which, 20% pairs are reserved for parameter tuning.

5.2 Overall: End-to-End Decoding

In this subsection, we first study the end-to-end decoding performance of our best system, and compare it with the state-of-the-art supervised learning-to-rank approach proposed by (Huang et al., 2013) based on information networks construction and traverse with meta-paths. We use the 225 extracted morphs as input to feed (Huang et al., 2013) system. The experiment setting, implementation and evaluation process are similar to (Huang et al., 2013).

[4] Each w_i is not limited to noun phrases we consider as candidate morphs.

[5] We will make all of these annotations and other resources available for research purposes if this paper gets accepted.

[6] http://dbpedia.org

The overall performance of our approach using within-genre learning for resolution is shown in Table 2. We can see that our system achieves significantly better performance (95.0% confidence level by the Wilcoxon Matched-Pairs Signed-Ranks Test) than the approach proposed by (Huang et al., 2013). We found that (Huang et al., 2013) failed to resolve many unpopular morphs (e.g., "小马 *(Little Ma)*" is a morph referring to Ma Yingjiu, and it only appeared once in the data), because it heavily relies on aggregating contextual and temporal information from multiple instances of each morph. In contrast, our unsupervised resolution approach only leverages the pre-trained word embeddings to capture the semantics of morph mentions and entities.

Model	Precision	Recall	F_1
Huang et al., 2013	40.2	33.3	36.4
Our Approach	**41.1**	**35.9**	**38.3**

Table 2: End-to-End Morph Decoding (%)

5.3 Diagnosis: Morph Mention Extraction

The first step discovered 888 potential morphs (80.1% of all morphs, 5.9% of all terms), which indicates that this step successfully narrowed down the scope of candidate morphs.

Method	Precision	Recall	F_1
Naive	58.0	83.1	68.3
SVMs	61.3	80.7	69.7
Our Approach	88.2	77.2	**82.3**

Table 3: Morph Mention Verification (%)

Now we evaluate the performance of morph mention verification. We compare our approach with two baseline methods: (i) *Naive*, which considers all mentions as morph mentions; (ii) *SVMs*, a fully supervised model using Support Vector Machines (Cortes and Vapnik, 1995) based on unigrams and bigrams features. Table 3 shows the results. We can see that our approach achieves significantly better performance than the baseline approaches. In particular it can verify the mentions of newly emergent morphs. For instance, "棒棒棒 *(Good Good Good)*" is mistakenly identified by the first step as a potential morph, but the second step correctly filters it out.

5.4 Diagnosis: Morph Mention Resolution

The target candidate identification step successfully filters 86% irrelevant entities with high precision (98.5% of morphs retain their target entitis). For candidate ranking, we compare with several baseline approaches as follows:

- ***BOW***: We compute cosine similarity over bag-of-words vectors with tf-idf values to measure the context similarity between a mention and its candidates.
- ***Pair-wise Cross-genre Supervised Learning***: We first construct a vocabulary by choosing the top 100,000 frequent terms. Then we randomly sample 48,000 instances for training and 12,000 instances for development. At the pre-training step, we set the number of hidden layers as 3, the size of each hidden layer as 1000, the masking noise probability for the first layer as 0.7, and a Gaussian noise with standard deviation of 0.1 for higher layers. The learning rate is set to be 0.01. At the fine-tuning stage, we add a 200 units layer on top of auto-encoders and optimize the neural network models based on the training data.
- ***Within-genre Unsupervised Learning***: We directly train morph mention and entity embeddings from the large-scale tweets and web documents that we collect. We set the window size as 10 and the vector dimension as 800 based on the development set.

The overall performance of various resolution approaches using perfect morph mentions is shown in Figure 4. We can clearly see that our second within-genre learning approach achieves the best performance. Figure 5 demonstrates the differences between our two deep learning based methods. When learning semantic embeddings directly from Wikipedia, we can see that the top 10 closest entities of the mention "平西王*(Conquer West King)*" are all related to the ancient king "吴三桂*(Wu Sangui)*". Therefore this method is only able to capture the original meanings of morphs. In contrast, when we learn embeddings directly from tweets, most of the closest entities are relevant to its target entity "薄熙来 *(Bo Xilai)*".

6 Related Work

The first morph decoding work (Huang et al., 2013) assumed morph mentions are already discovered and didn't take contexts into account. To the best of our knowledge, this is the first work on context-aware end-to-end morph decoding.

Morph decoding is related to several traditional

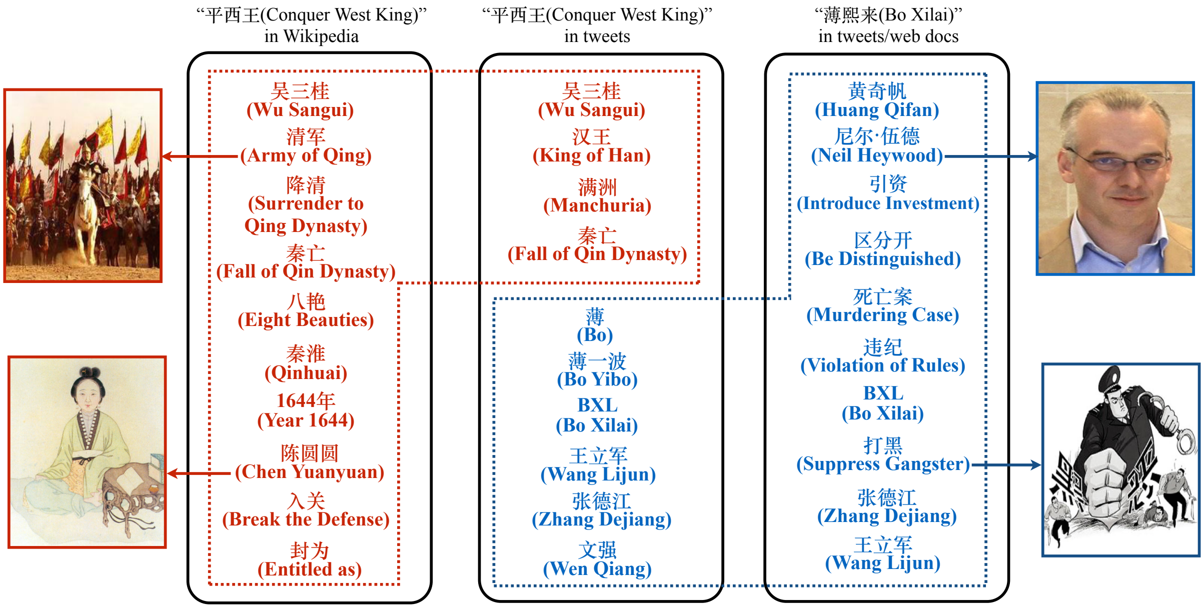

Figure 5: Top 10 closest entities to morph and target in different genres

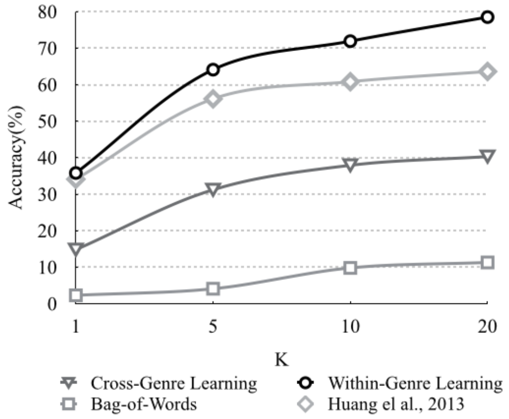

Figure 4: Resolution Acc@K for Perfect Morph Mentions

NLP tasks: entity mention extraction (e.g., (Zitouni and Florian, 2008; Ohta et al., 2012; Li and Ji, 2014)), metaphor detection (e.g., (Wang et al., 2006; Tsvetkov, 2013; Heintz et al., 2013)), word sense disambiguation (WSD) (e.g., (Yarowsky, 1995; Mihalcea, 2007; Navigli, 2009)), and entity linking (EL) (e.g., (Mihalcea and Csomai, 2007; Ji et al., 2010; Ji et al., 2011; Ji et al., 2014). However, none of these previous techniques can be applied directly to tackle this problem. As mentioned in section 3.1, entity morphs are fundamentally different from regular entity mentions. Our task is also different from metaphor detection because morphs cover a much wider range of semantic categories and can include either abstractive or concrete information. Some common features for detecting metaphors (e.g. (Tsvetkov, 2013)) are not effective for morph extraction: (1). Semantic categories. Metaphors usually fall into certain semantic categories such as noun.animal and noun.cognition. (2). Degree of abstractness. If the subject or an object of a concrete verb is abstract then the verb is likely to be a metaphor. In contrast, morphs can be very abstract (e.g., “函数 *(Function)*” refers to “杨幂 *(Yang Mi)*” because her first name “幂 *(Mi)*” means the Power Function) or very concrete (e.g., “薄督 *(Governor Bo)*” refers to “薄熙来 *(Bo Xilai)*”). In contrast to traditional WSD where the senses of a word are usually quite stable, the “sense” (target entity) of a morph may be newly emergent or evolve over time rapidly. The same morph can also have multiple senses. The EL task focuses more on explicit and formal entities (e.g., named entities), while morphs tend to be informal and convey implicit information.

Morph mention detection is also related to malware detection (e.g., (Firdausi et al., 2010; Chandola et al., 2009; Firdausi et al., 2010; Christodorescu and Jha, 2003)) which discovers abnormal behavior in code and malicious software. In contrast our task tackles anomaly texts in semantic context.

Deep learning-based approaches have been demonstrated to be effective in disambiguation related tasks such as WSD (Bordes et al., 2012), entity linking (He et al., 2013) and question linking (Yih et al., 2014; Bordes et al., 2014; Yang et al., 2014). In this paper we proved that it’s crucial to keep the genres consistent between learning embeddings and applying embeddings.

7 Conclusions and Future Work

This paper describes the first work of context-aware end-to-end morph decoding. By conducting deep analysis to identity the common characteristics of morphs and the unique challenges of this task, we leverage a large amount of unlabeled data and the coreferential and correlation relations to perform collective inference to extract morph mentions. Then we explore deep learning-based techniques to capture the semantics of morph mentions and entities and resolve morph mentions on the fly. Our future work includes exploiting the profiles of target entities as feedback to refine the results of morph mention extraction. We will also extend the framework for event morph decoding.

Abstract

In this paper, we present a novel approach to joint word sense disambiguation (WSD) and entity linking (EL) that combines a set of complementary objectives in an extensible multi-objective formalism. During disambiguation the system performs continuous optimization to find optimal probability distributions over candidate senses. The performance of our system on nominal WSD as well as EL improves state-of-the-art results on several corpora. These improvements demonstrate the importance of combining complementary objectives in a joint model for robust disambiguation.

1 Introduction

The task of automatically assigning the correct meaning to a given word or entity mention in a document is called word sense disambiguation (WSD) (Navigli, 2009) or entity linking (EL) (Bunescu and Pasca, 2006), respectively. Successful disambiguation requires not only an understanding of the topic or domain a document is dealing with, but also a deep analysis of how an individual word is used within its local context. For example, the meanings of the word "newspaper", as in the company or the physical product, often cannot be distinguished by the global topic of the document it was mentioned in, but by recognizing which type of meaning fits best into the local context of its mention. On the other hand, for an ambiguous entity mention such as a person name, e.g., "Michael Jordan", it is important to recognize the domain or topic of the wider context to distinguish, e.g., between the basketball player and the machine learning expert.

The combination of the two most commonly employed reference knowledge bases for WSD and EL, WordNet (Fellbaum, 1998) and Wikipedia, in BabelNet (Navigli and Ponzetto, 2012), has enabled a new line of research towards the joint disambiguation of words and named entities. *Babelfy* (Moro et al., 2014) has shown the potential of combining these two tasks in a purely knowledge-driven approach that jointly finds connections between potential word senses on a global, document level. On the other hand, typical supervised methods (Zhong and Ng, 2010) trained on sense-annotated datasets are usually quite successful in dealing with individual words in their local context on a sentence level. Hoffart et al. (2011) recognize the importance of combining both local and global context for robust disambiguation. However, their approach is limited to EL and optimization is performed in a discrete setting.

We present a system that combines disambiguation objectives for both global and local contexts into a single multi-objective function. The resulting system is flexible and easily extensible with complementary objectives. In contrast to prior work (Hoffart et al., 2011; Moro et al., 2014) we model the problem in a continuous setting based on probability distributions over candidate meanings instead of a binary treatment of candidate meanings during disambiguation. Our approach combines knowledge from various sources in one robust model. The system uses lexical and encyclopedic knowledge for the joint disambiguation of words and named entities, and exploits local context information of a mention to infer the type of its meaning. We integrate prior statistics from surface strings to candidate meanings in a "natural" way as starting probability distributions for each mention.

The contributions of our work are the following:

- a model for joint nominal WSD and EL that outperforms previous state-of-the-art systems on both tasks
- an extensible framework for multi-objective

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 596–605,
Beijing, China, July 26-31, 2015.

disambiguation
- an extensive evaluation of the approach on multiple standard WSD and EL datasets
- the first work that employs continuous optimization techniques for disambiguation (to our knowledge)
- publicly available code, resources and models at `https://bitbucket.org/dfki-lt-re-group/mood`

2 Approach

Our system detects mentions in texts and disambiguates their meaning to one of the candidate senses extracted from a reference knowledge base. The integral parts of the system, namely *mention detection*, *candidate search* and *disambiguation* are described in detail in this section. The model requires a tokenized, lemmatized and POS-tagged document as input; the output are sense-annotated mentions.

2.1 Knowledge Source

We employ BabelNet 2.5.1 as our reference knowledge base (KB). BabelNet is a multilingual semantic graph of concepts and named entities that are represented by synonym sets, called *Babel synsets*. It is composed of lexical and encyclopedic resources, such as WordNet and Wikipedia. Babel synsets comprise several Babel senses, each of which corresponds to a sense in another knowledge base. For example the Babel synset of “Neil Armstrong” contains multiple senses including for example “armstrong#n#1” (WordNet), “Neil_Armstrong” (Wikipedia). All synsets are interlinked by conceptual-semantic and lexical relations from WordNet and semantic relations extracted from links between Wikipedia pages.

2.2 Mention Extraction & Entity Detection

We define a mention to be a sequence of tokens in a given document. The system extracts mentions for all content words (nouns, verbs, adjectives, adverbs) and multi-token units of up to 7 tokens that contain at least one noun. In addition, we apply a NER-tagger to identify named entity (NE) mentions. Our approach distinguishes NEs from common nouns because there are many common nouns also referring to NEs, making disambiguation unnecessarily complicated. For example, the word “moon” might refer to songs, films, video games, etc., but we should only consider these meanings if the occurrence suggests that it is used as a NE.

2.3 Candidate Search

After potential mentions are extracted, the system tries to identify their candidate meanings, i.e., the appropriate synsets. Mentions without any candidates are discarded. There are various resources one can exploit to map surface strings to candidate meanings. However, existing methods or resources especially for NEs are either missing many important mappings[1] or contain many noisy mappings[2]. Therefore, we created a candidate mapping strategy that tries to avoid noisy mappings while including all potentially correct candidates. Our approach employs several heuristics that aim to avoid noise. Their union yields an almost complete mapping that includes the correct candidate meaning for 97-100% of the examples in the test datasets. Candidate mentions are mapped to synsets based on similarity of their surface strings or lemmas. If the surface string or lemma of a mention matches the lemma of a synonym in a synset that has the same part of speech, the synset will be considered as a candidate meaning. We allow partial matches for BabelNet synonyms derived from Wikipedia titles or redirections. However, partial matching is restricted to synsets that belong either to the semantic category “Place” or “Agent”. We make use of the semantic category information provided by the DBpedia ontology[3]. A partial match allows the surface string of a mention to differ by up to 3 tokens from the Wikipedia title (excluding everything in parentheses) if the partial string occurred at least once as an anchor for the corresponding Wikipedia page. E.g., for the Wikipedia title Armstrong_School_District_(Pennsylvania), the following surface strings would be considered matches: “Armstrong School District (Pennsylvania)”, “Armstrong School District”, “Armstrong”, but not “School” or “District”, since they were never used as an anchor. If there is no match we try the same procedure applied to the lowercase forms of the surface string or the lemma. For persons we allow matches to all partial names, e.g., only first name, first and middle name, last name, etc.

In addition to the aforementioned candidate extraction we also match surface strings to candidate entities mentioned on their respective disambigua-

[1] e.g., using only the synonyms of a synset

[2] e.g., partial matches for all synonyms of a synset

[3] `http://wiki.dbpedia.org/Ontology`

tion pages in Wikipedia[4]. For cases where adjectives should be disambiguated as nouns, e.g., “English” as a country to “England”, we allow candidate mappings through the *pertainment* relation from WordNet. Finally, frequently annotated surface strings in Wikipedia are matched to their corresponding entities, where we stipulate “frequently” to mean that the surface string occurs at least 100 times as anchor in Wikipedia and the entity was either at least 100 times annotated by this surface string or it was annotated above average.

The distinction between nouns and NEs imposes certain restrictions on the set of potential candidates. Candidate synsets for nouns are noun synsets considered as “Concepts” in BabelNet (as opposed to “Named Entities”) in addition to all synsets of WordNet senses. On the other hand, candidate synsets for NEs comprise all nominal Babel synsets. Thus, the range of candidate sets for NEs properly contains the one for nouns. We include all nominal synsets as potential candidates for NEs because the distinction of NEs and simple concepts is not always clear in BabelNet. For example the synset for “UN” (United Nations) is considered a concept whereas it could also be considered a NE. Finally, if there is no candidate for a potential nominal mention, we try to find NE candidates for it before discarding it.

2.4 Multi-Objective Disambiguation

We formulate the disambiguation as a continuous, multi-objective optimization problem. Individual objectives model different aspects of the disambiguation problem. Maximizing these objectives means assigning high probabilities to candidate senses that contribute most to the combined objective. After maximization, we select the candidate meaning with the highest probability as the disambiguated sense. Our model is illustrated in Figure 1.

Given a set of objectives $\mathfrak{O}$ the overall objective function $\mathbf{O}$ is defined as the sum of all normalized objectives $O \in \mathfrak{O}$ given a set of mentions M:

$$\mathbf{O}(M) = \sum_{O \in \mathfrak{O}} \frac{|M_O|}{|M|} \cdot \frac{O(M)}{O_{max}(M) - O_{min}(M)}. \tag{1}$$

The continuous approach has several advantages over a discrete setting. First, we can exploit well established continuous optimization algorithms, such as conjugate gradient or LBFGS. Second, by optimizing upon probability distributions we are optimizing the actually desired result, in contrast to densest sub-graph algorithms where normalized confidence scores are calculated afterwards, e.g., Moro et al. (2014). Third, discrete optimization usually works on a single candidate per iteration whereas in a continuous setting, probabilities are adjusted for each candidate, which is computationally advantageous for highly ambiguous documents.

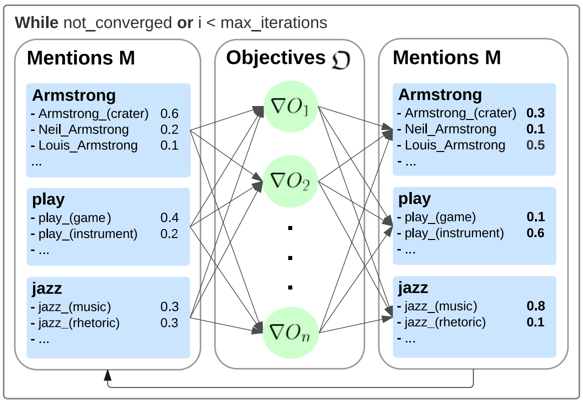

Figure 1: Illustration of our multi-objective approach to WSD & EL for the example sentence: *Armstrong plays jazz.* Mentions are disambiguated by iteratively updating probability distributions over their candidate senses with respect to the given objective gradients ∇O_i.

We normalize each objective using the difference of its maximum and minimum value for a given document, which makes the weighting of the objectives different for each document. The maximum/minimum values can be calculated analytically or, if this is not possible, by running the optimization algorithm with only the given objective for an approximate estimate for the maximum and with its negated form for an approximate minimum. Normalization is important for optimization because it ensures that the individual gradients have similar norms on average for each objective. Without normalization, optimization is biased towards objectives with large gradients.

Given that one of the objectives can be applied to only a fraction of all mentions (e.g., only nominal mentions), we scale each objective by the fraction of mentions it is applied to.

Note that our formulation could easily be extended to using additional coefficients for each ob-

[4] provided by DBpedia at `http://wiki.dbpedia.org/Downloads2014`

jective. However, these hyper-parameters would have to be estimated on development data and therefore, this method could hurt generalization.

Prior Another advantage of working with probability distributions over candidates is the easy integration of prior information. For example, the word "Paris" without further context has a strong prior on its meaning as a city instead of a person. Our approach utilizes prior information in form of frequency statistics over candidate synsets for a mention's surface string. These priors are derived from annotation frequencies provided by WordNet and Wikipedia. We make use of occurrence frequencies extracted by DBpedia Spotlight (Daiber et al., 2013) for synsets containing Wikipedia senses in case of NE disambiguation. For nominal WSD, we employ frequency statistics from WordNet for synsets containing WordNet senses. Laplace-smoothing is applied to all prior frequencies. The priors serve as initialization for the probability distributions over candidate synsets. Note that we use priors "naturally", i.e., as actual priors for initialization only and not during disambiguation itself. They should not be applied during disambiguation because these priors can be very strong and are not domain independent. However, they provide a good initialization which is important for successful continuous optimization.

3 Disambiguation Objectives

3.1 Coherence Objective

Jointly disambiguating all mentions within a document has been shown to have a large impact on disambiguation quality, especially for named entities (Kulkarni et al., 2009). It requires a measurement of semantic relatedness between concepts that can for example be extracted from a semantic network like BabelNet. However, semantic networks usually suffer from data sparsity where important links between concepts might be missing. To deal with this issue, we adopt the idea of using *semantic signatures* from Moro et al. (2014). Following their approach, we create *semantic signatures* for concepts and named entities by running a random walk with restart (RWR) in the semantic network. We count the times a vertex is visited during RWR and define all frequently visited vertices to be the *semantic signature* (i.e., a set of highly related vertices) of the starting concept or named entity vertex.

Our coherence objective aims at maximizing the semantic relatedness among selected candidate senses based on their semantic signatures S_c. We define the continuous objective using probability distributions $p_m(c)$ over the candidate set C_m of each mention $m \in M$ in a document as follows:

$$O_{\text{coh}}(M) = \sum_{\substack{m \in M \\ c \in C_m}} \sum_{\substack{m' \in M \\ m' \neq m \\ c' \in C_{m'}}} s(m, c, m', c')$$

$$s(m, c, m', c') = p_m(c) \cdot p_{m'}(c') \cdot \mathbb{1}((c, c') \in S)$$

$$p_m(c) = \frac{e^{w_{m,c}}}{\sum_{c' \in C_m} e^{w_{m,c'}}} \quad , \qquad (2)$$

where $\mathbb{1}$ denotes the indicator function and $p_m(c)$ is a softmax function. The only free, optimizable parameters are the softmax weights $\mathbf{w_m}$. This objective includes all mentions, i.e., $M_{O_{\text{coh}}} = M$. It can be interpreted as finding the densest subgraph where vertices correspond to mention-candidate pairs and edges to semantic signatures between candidate synsets. However, in contrast to a discrete setup, each vertex is now weighted by its probability and therefore each edge is weighted by the product of its adjacent vertex probabilities.

3.2 Type Objective

One of the biggest problems for supervised approaches to WSD is the limited size and synset coverage of available training datasets such as SemCor (Miller et al., 1993). One way to circumvent this problem is to use a coarser set of semantic classes that groups synsets together. Previous studies on using semantic classes for disambiguation showed promising results (Izquierdo-Beviá et al., 2006). For example, WordNet provides a mapping, called lexnames, of synsets into 45 types, which is based on the syntactic categories of synsets and their logical groupings[5]. In WordNet 13.5% of all nouns are ambiguous with an average ambiguity of 2.79 synsets per lemma. Given a noun and a type (lexname), the percentage of ambiguous nouns drops to 7.1% for which the average ambiguity drops to 2.33. This indicates that exploiting type classification for disambiguation can be very useful.

Similarly, for EL it is important to recognize the type of an entity mention in a local context.

[5] `http://wordnet.princeton.edu/man/lexnames.5WN.html`

For example, in the phrase "London beats Manchester" it is very likely that the two city names refer to sports clubs and not to the cities. We utilize an existing mapping from Wikipedia pages to types from the DBpedia ontology, restricting the set of target types to the following: "Activity", "Organisation", "Person", "Event", "Place" and "Misc" for the rest.

We train a multi-class logistic regression model for each set of types that calculates probability distributions $q_m(t)$ over WN- or DBpedia-types t given a noun- or a NE-mention m, respectively. The features used as input to the model are the following:

- word embedding of mention's surface string
- sum of word embeddings of all sentence words excluding stopwords
- word embedding of the dependency parse parent
- collocations of surrounding words as in Zhong et al. (2010)
- POS tags with up to 3 tokens distance to m
- possible types of candidate synsets

We employed pre-trained word embeddings from Mikolov et al. (2013) instead of the words themselves to increase generalization.

Type classification is included as an objective in the model as defined in equation 3. It puts type specific weights derived from type classification on candidate synsets, enforcing candidates of fitting type to have higher probabilities. The objective is only applied to noun, NE and verb mentions, i.e., $M_{O_{\text{typ}}} = M_n \cup M_{NE} \cup M_v$.

$$O_{\text{typ}}(M) = \sum_{m \in M_{O_{\text{typ}}}} \sum_{c \in C_m} q_m(t_c) \cdot p_m(c) \qquad (3)$$

3.3 Regularization Objective

Because candidate priors for NE mentions can be very high, we add an additional L2-regularization objective for NE mentions:

$$O_{L2}(M) = -\frac{\lambda}{2} \sum_{m \in M_{NE}} \|\mathbf{w_m}\|_2^2 \qquad (4)$$

The regularization objective is integrated in the overall objective function as it is, i.e., it is not normalized.

Dataset	|D|	|M|	KB

4 Experiments

4.1 Datasets

We evaluated our approach on 7 different datasets, comprising 3 WSD datasets annotated with WordNet senses, 2 datasets annotated with Wikipedia articles for EL and 2 more recent datasets annotated with Babel synsets. Table 1 contains a list of all datasets.

Besides these test datasets we used SemCor (Miller et al., 1993) as training data for WSD and the training part of the AIDA CoNLL dataset for EL.

4.2 Setup

For the creation of semantic signatures we choose the same parameter set as defined by Moro et al. (2014). We run the random walk with a restart probability of 0.85 for a total of 1 million steps for each vertex in the semantic graph and keep vertices visited at least 100 times as semantic signatures.

The L2-regularization objective for named entities is employed with $\lambda = 0.001$, which we found to perform best on the training part of the AIDA-CoNLL dataset.

We trained the multi-class logistic regression model for WN-type classification on SemCor and for DBpedia-type classification on the training part of the AIDA-CoNLL dataset using LBFGS and L2-Regularization with $\lambda = 0.01$ until convergence.

Our system optimizes the combined multi-objective function using Conjugate Gradient

System	KB	Description

(Hestenes and Stiefel, 1952) with up to a maximum of 1000 iterations per document.

We utilized existing implementations from FACTORIE version 1.1 (McCallum et al., 2009) for logistic regression, NER tagging and Conjugate Gradient optimization. For NER tagging we used a pre-trained stacked linear-chain CRF (Lafferty et al., 2001).

4.3 Systems

We compare our approach to state-of-the-art results on all datasets and a most frequent sense (MFS) baseline. The MFS baseline selects the candidate with the highest prior as described in section 2.4. Table 2 contains a list of all systems we compared against. We use *Babelfy* as our main baseline, because of its state-of-the-art performance on all datasets and because it also employed BabelNet as its sense inventory. Note that Babelfy achieved its results with different setups for WSD and EL, in contrast to our model, which uses the same setup for both tasks.

4.4 General Results

We report the performance of all systems in terms of F1-score. To ensure fairness we restricted the candidate sets of the target mentions in each dataset to candidates of their respective reference KB. Note that our candidate mapping strategy ensures for all datasets a $97\% - 100\%$ chance that the target synset is within a mention's candidate set.

This section presents results on the evaluation datasets divided by their respective target KBs: WordNet, Wikipedia and BabelNet.

Table 4: Results for NEs on Wikipedia annotated datasets.

WordNet Table 3 shows the results on three datasets for the disambiguation of nouns to WordNet. Our approach exhibits state-of-the-art results outperforming all other systems on two of the three datasets. The model performs slightly worse on the Senseval 3 dataset because of one document in particular where the F1 score is very low compared to the MFS baseline. On the other three documents, however, it performs as good or even better. In general, results from the literature are always worse than the MFS baseline on this dataset. A strong improvement can be seen on the SemEval 2013 Task 12 dataset (Sem13), which is also the largest dataset. Our system achieves an improvement of nearly 7% F1 over the best other system, which translates to an error reduction of roughly 20% given that every word mention gets annotated. Besides the results presented in Table 3, we also evaluated the system on the SemEval 2007 Task 7 dataset for coarse grained WSD, where it achieved 85.5% F1 compared to the best previously reported result of 85.5% F1 from Ponzetto et al. (2010) and Babelfy with 84.6%.

Wikipedia The performance on entity linking was evaluated against state-of-the-art systems on two different datasets. The results in Table 4 demonstrate that our model can compete with the best existing models, showing superior results especially on the large AIDA CoNLL[6] test dataset comprising 216 news texts, where we achieve an error reduction of about 16%, resulting in a new state-of-the-art of 85.1% F1. On the other hand, our system is slightly worse on the KORE dataset compared to Babelfy (6 errors more in total), which might be due to the strong priors and

[6] the largest, freely available dataset for EL.

$O_{coh} + O_{L2}$	68.1	69.6	82.7
$O_{coh} + O_{typ} + O_{L2}$	**71.5**	**75.4**	**85.1**

Table 6: Detailed results for nouns and NEs on BabelNet annotated datasets and AIDA CoNLL.

the small context. However, the dataset is rather small, containing only 50 sentences, and has been artificially tailored to the use of highly ambiguous entity mentions. For example, persons are most of the time only mentioned by their first names. It is an interesting dataset because it requires the system to employ a lot of background knowledge about mentioned entities.

BabelNet Table 5 shows the results on the 2 existing BabelNet annotated datasets. To our knowledge, our system shows the best performance on both datasets in the literature. An interesting observation is that the F1 score on SemEval 2013 with BabelNet as target KB is lower compared to WordNet as target KB. The reason is that ambiguity rises for nominal mentions by including concepts from Wikipedia that do not exist in WordNet. For example, the Wikipedia concept "formal language" becomes a candidate for the surface string "language".

4.5 Detailed Results

We also experimented with different objective combinations, namely "type only" (O_{typ}), "coherence only" ($O_{coh} + O_{L2}$) and "all" ($O_{coh} + O_{typ} + O_{L2}$), to evaluate the impact of the different objectives. Table 6 shows results of employing individual configurations compared to the MFS baseline.

Results for only using coherence or type exhibit varying performance on the datasets, but still consistently exceed the strong MFS baseline. Combining both objectives always yields better results compared to all other configurations. This finding is important because it proves that the objectives proposed in this work are indeed complementary, and thus demonstrates the significance of combining complementary approaches in one robust framework such as ours.

An additional observation was that DBpedia-type classification slightly overfitted on the AIDA CoNLL training part. When removing DBpedia-type classification from the type objective, results increased marginally on some datasets except for the AIDA CoNLL dataset, where results decreased by roughly 3% F1. The improvements of using DBpedia-type classification are mainly due to the fact that the classifier is able to correctly classify names of places in tables consisting of sports scores not to the "Place" type but to the "Organization" type. Note that the AIDA CoNLL dataset (train and test) contains many of those tables. This shows that including supervised objectives into the system helps when data is available for the domain.

4.6 Generalization

We evaluated the ability of our system to generalize to different domains based on the SemEval 2015 Task 13 dataset. It includes documents from the bio-medical, the math&computer and general domains. Our approach performs particularly well on the bio-medical domain with 86.3% F1 (MFS: 77.3%). Results on the math&computer domain (58.8% F1, MFS: 57.0%), however, reveal that performance still strongly depends on the document topic. This indicates that either the employed resources do not cover this domain as well as others, or that it is generally more difficult to disambiguate. Another potential explanation is that enforcing only pairwise coherence does not take the hidden concepts *computer* and *maths* into account, which connect all concepts, but are never actually mentioned. An interesting point for future research might be the introduction of an additional objective or the extension of the coherence objective to allow indirect connections between candidate meanings through shared topics or categories.

Besides these very specific findings, the model's ability to generalize is strongly supported by its good results across all datasets, covering a variety of different topics.

5 Related Work

WSD Approaches to WSD can be distinguished by the kind of resource exploited. The two main resources for WSD are sense annotated datasets and knowledge bases. Typical supervised approaches like IMS (Zhong and Ng, 2010) train classifiers that learn from existing, annotated examples. They suffer from the sparsity of sense annotated datasets that is due to the data acquisition bottleneck (Pilehvar and Navigli, 2014). There have been approaches to overcome this issue through the automatic generation of such resources based on bootstrapping (Pham et al., 2005), sentences containing unambiguous relatives of senses (Martinez et al., 2008) or exploiting Wikipedia (Shen et al., 2013). On the other hand, knowledge-based approaches achieve good performances rivaling state-of-the-art supervised systems (Ponzetto and Navigli, 2010) by using existing structured knowledge (Lesk, 1986; Agirre et al., 2014), or take advantage of the structure of a given semantic network through connectivity or centrality measures (Tsatsaronis et al., 2007; Navigli and Lapata, 2010). Such systems benefit from the availability of numerous KBs for a variety of domains. We believe that both knowledge-based approaches and supervised methods have unique, complementary abilities that need to be combined for sophisticated disambiguation.

EL Typical EL systems employ supervised machine learning algorithms to classify or rank candidate entities (Bunescu and Pasca, 2006; Milne and Witten, 2008; Zhang et al., 2010). Common features include popularity metrics based on Wikipedia's graph structure or on name mention frequency (Dredze et al., 2010; Han and Zhao, 2009), similarity metrics exploring Wikipedia's concept relations (Han and Zhao, 2009), and string similarity features. Mihalcea and Csomai (2007) disambiguate each mention independently given its sentence level context only. In contrast, Cucerzan (2007) and Kulkarni et al. (Kulkarni et al., 2009) recognize the interdependence between entities in a wider context. The most similar work to ours is that of Hoffart et al. (2011) which was the first that combined local and global context measures in one robust model. However, objectives and the disambiguation algorithm differ from our work. They represent the disambiguation task as a densest subgraph problem where the least connected entity is eliminated in each iteration. The discrete treatment of candidate entities can be problematic especially at the beginning of disambiguation where it is biased towards mentions with many candidates.

Babelfy (Moro et al., 2014) is a knowledge-based approach for joint WSD and EL that also uses a greedy densest subgraph algorithm for disambiguation. It employs a single coherence model based on semantic signatures similar to our coherence objective. The system's very good performance indicates that the semantic signatures provide a powerful resource for joint disambiguation. However, because we believe it is not sufficient to only enforce semantic agreement among nouns and entities, our approach includes an objective that also focuses on the local context of mentions, making it more robust.

6 Conclusions & Future Work

We have presented a novel approach for the joint disambiguation of nouns and named entities based on an extensible framework. Our system employs continuous optimization on a multi-objective function during disambiguation. The integration of complementary objectives into our formalism demonstrates that robust disambiguation can be achieved by considering both the local and the global context of a mention. Our model outperforms previous state-of-the-art systems for nominal WSD and for EL. It is the first system that achieves such results on various WSD and EL datasets using a single setup.

In future work, new objectives should be integrated into the framework and existing objectives could be enhanced. For example, it would be interesting to express semantic relatedness continuously rather than in a binary setting for the coherence objective. Additionally, using the entire model during training could ensure better compatibility between the different objectives. At the moment, the model itself is composed of different pre-trained models that are only combined during disambiguation.

Abstract

Extracted keyphrases can enhance numerous applications ranging from search to tracking the evolution of scientific discourse. We present SCHBASE, a hierarchical database of keyphrases extracted from large collections of scientific literature. SCHBASE relies on a tendency of scientists to generate new abbreviations that "extend" existing forms as a form of signaling novelty. We demonstrate how these keyphrases/concepts can be extracted, and their viability as a database in relation to existing collections. We further show how keyphrases can be placed into a semantically-meaningful "phylogenetic" structure and describe key features of this structure. The complete SCHBASE dataset is available at: http://cond.org/schbase.html.

1 Introduction

Due to the immense practical value to Information Retrieval and other text mining applications, keyphrase extraction has become an extremely popular topic of research. Extracted keyphrases, specifically those derived from scientific literature, support search tasks (Anick, 2003), classification and tagging (Medelyan et al., 2009), information extraction (Wu and Weld, 2008), and higher-level analysis such as the tracking of influence and dynamics of information propagation (Shi et al., 2010; Ohniwa et al., 2010). In our own work we use the extracted hierarchies to predict scientific emergence based on how rapidly new variants emerge. Keyphrases themselves capture a diverse set of scientific language (e.g., methods, techniques, materials, phenomena, processes, diseases, devices).

Keyphrases, and their uses, have been studied extensively (Gil-Leiva and Alonso-Arroyo, 2007). However, automated keyphrase *extraction* work has often focused on large-scale statistical techniques and ignored the scientific communication literature. This literature points to the complex ways in which keyphrases are created in light of competing demands: expressiveness, findability, succinct writing, signaling novelty, signaling community membership, and so on (Hartley and Kostoff, 2003; Ibrahim, 1989; Grange and Bloom, 2000; Gil-Leiva and Alonso-Arroyo, 2007). Furthermore, the tendency to extract keyphrases through statistical mechanisms often leads to flat keyphrase spaces that make analysis of evolution and emergence difficult.

Our contention, and the main motivation behind our work, is that we can do better by leveraging explicit mechanisms adopted by authors in keyphrase generation. Specifically, we focus on a tendency to expand keyphrases by adding terms, coupled with a pressure to abbreviate to retain succinctness. As we argue below, scientific communication has evolved the use of abbreviations to deal with various constraints. Abbreviations, and acronyms specifically, are relatively new in many scientific domains (Grange and Bloom, 2000; Fandrych, 2008) but are now ubiquitous (Ibrahim, 1989; Cheng, 2010).

Keyphrase selection is often motivated by increasing article findability within a domain (thereby increasing citation). This strategy leads to keyphrase reuse. A competing pressure, however, is to signal novelty in an author's work which is often done by creating new terminology (e.g., creating a "brand" around a system or idea). For

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 606–615,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

example, a machine learning expert working on a new type of Support Vector Machine will want their article found when someone searches for "Support Vector Machine," but will also want to add their own unique brand. In response, they will often augment the original keyphrase (e.g., "Least-Squares Support Vector Machine") rather than inventing a completely new one. Unfortunately, continuous expansion will soon render a paper unreadable (e.g., one of many extensions to *Polymerase Chain Reaction* is *Standard Curve Quantitative Competitive Reverse Transcription Polymerase Chain Reaction*). Thus emerges a second strategy: abbreviation.

Our assertion is that abbreviations are a key mechanism for resolving competing demands. Authors can simultaneously expand keyphrases, thus maintaining both findability and novelty, while at the same time addressing the need to be succinct and non-repetitive. Of interest to us is the phenomena that if a new keyphrase expands an existing keyphrase that has an established abbreviation, the new keyphrase will also be abbreviated (e.g., LS-SVM and SVM). This tendency allows us to construct hierarchies of evolved keyphrases (rather than assuming a flat keyphrase space) which can be leveraged to identify emergence, keyphrase "mash-ups," and perform other high level analysis. As we demonstrate below, edges represent the rough semantic of EXTENDS or ISSUBTYPEOF. So if keyphrase *A* is connected to *B*, we can say *A* is a subtype of *B* (e.g., *A* is "Least-Squares Support Vector Machine" and *B* is "Support Vector Machine").

In this paper we introduce SCHBASE, a hierarchical database of keyphrases. We demonstrate how we can simply, but effectively, extract keyphrases by mining abbreviations from scientific literature and composing those keyphrases into semantically-meaningful hierarchies. We further show that abbreviations are a viable mechanism for building a domain-specific keyphrase database by comparing our extracted keyphrases to a number of author-defined and automatically-created keyphrase corpora. Finally, we illustrate how authors build upon each others' terminology over time to create new keyphrases.[1]

2 Related Work

Initial work in keyphrase extraction utilized heuristics that were based on the understood structure of scientific documents (Edmundson, 1969). As more data became available, it was possible to move away from heuristic cues and to leverage statistical techniques (Paice and Jones, 1993; Turney, 2000; Frank et al., 1999) that could identify keyphrases within, and between, documents. The guiding model in this approach is that phrases that appear as statistical "anomalies" (by some measure) are effective for summarizing a document or corpus. This style of keyphrase extraction represents much of the current state-of-the-art (Kim et al., 2010). Specific extensions in this space involve the use of network structures (Mihalcea and Tarau, 2004; Litvak and Last, 2008; Das Gollapalli and Caragea, 2014), part-of-speech features (Barker and Cornacchia, 2000; Hulth, 2003), or more sophisticated metrics (Tomokiyo and Hurst, 2003).

However, as we note above, these statistical approaches largely ignore the underlying tensions in scientific communication that lead to the creation of new keyphrases and how they are signaled to others. The result is that these techniques often find statistically "anomalous" phrases which often are not valid scientific concepts (but are simply uncommon phrasing), are unstructured and disconnected, and inflexible to size variance (as in the case of fixed length n-grams), and fail to capture extremely rare terminology.

The idea that abbreviations may be useful for keyphrase extraction has been partially realized. Nguyen et al., (2007) found that they could produce better keyphrases by extending existing models (Frank et al., 1999) to include an acronym indicator as a feature. That is, if a candidate phrase had an associated parenthetical acronym associated with it in the text a binary feature would be set. This approach has been implemented by others (Bordea and Buitelaar, 2010). We propose to expand on this idea by implementing a simple, but effective, solution by performing abbreviation extraction to build a hierarchical keyphrase database – a form of open-information extraction (Etzioni et al., 2008) on large scientific corpora.

3 Keyphrases and Hierarchies

Our high level strategy for finding an initial set of keyphrases is to mine a corpus for abbrevia-

[1] Full database available at: http://cond.org/schbase.html

tion expansions. This is a simple strategy, but as we show below, highly effective. Though the idea that abbreviations and keyphrases are linked fits within our understanding of scientific writing, we confirmed our intuition through a small experiment. Specifically, we looked at the 85 unique keyphrases (in this case, article titles) listed in the Wikipedia entry for *List of Machine Learning Concepts* (Wikipedia, 2014). These ranged from well known terms (e.g., *Support Vector Machines* and *Autoencoders*) to less known (e.g., *Information fuzzy networks*). In *all* 85 cases we were able to find an abbreviation on the Web (using Google) alongside the expansion (e.g., searching for the phrases *“Support Vector Machines (SVMs)”* or *“Information Fuzzy Networks (IFN)”*). Though there may be bias in the use of abbreviations in the Machine Learning literature, our experience has been that this holds in other domains as well. When a scientific keyphrase is used often enough, someone, somewhere, will have abbreviated it.

3.1 Abbreviation Extraction

To find all abbreviation expansions we use the unsupervised SaRAD algorithm (Adar, 2004). This algorithm is simple to implement, does not require extremely large amounts of data, works for both acronyms and more general abbreviations, and has been demonstrated as effective in various contexts (Adar, 2004; Schwartz and Hearst, 2003). However, our solution does not depend on a specific implementation, only that we are able to accurately identify abbreviation expansions.

Adar (2004) presents the full details for the algorithm, but for completeness we present the high level details. The algorithm progresses by identifying abbreviations inside of parentheses (defined as single words with at least one capital letter). The algorithm then extracts a “window” of text preceding the parenthesis, up to n words long (where n is the character length of the abbreviation plus padding). This window does not cross sentence boundaries. Within the window all possible “explanations” of the abbreviation are derived.

An explanation consists of a continuous subsequence of words that contain all the characters of the original abbreviation *in order*. For example, the window “determine the geographical distribution of ribonucleic acid” preceding the abbreviation “RNA” includes the explanations: “dete*r*mi*n*e the geogr*a*phical,” “g*r*aphical distributio*n* of ribonucleic *a*cid” and “*r*ibo*n*ucleic *a*cid” (matching characters in italics). In the example above there are ten explanations (five unique). Each explanation is scored heuristically: 1 point for each abbreviation character at the start of a word; 1 point subtracted for every word between the explanation and the parenthesis; 1 point bonus if the explanation is adjacent to the parenthesis; 1 point subtracted for each extra word beyond the abbreviation length. For the explanations above, the scores are -4, 0, and 3 respectively. The highest scoring match (we require a minimum of 1 point) is returned as the mostly likely expansion.

In practice, pairs of extracted abbreviations/expansions are pulled from a large textual corpus. This both allows us to identify variants of expansions (e.g., different pluralization, spelling, hyphenation, etc.) as well as finding more plausible expansions (those that are repeated multiple times in a corpus). Thus, each expansion/abbreviation pair has an associated count which can be used to threshold and filter for increased quality. To discard units of measurement, single letter abbreviations and single word expansions are removed. We return to this decision later, but our experience is also that single word keyphrases are rare. Additionally, expansions containing brackets are not considered as they usually represent mathematical formulae.

3.1.1 The ABBREVCORPUS

In our experiments we utilize the ACM Digital Library (ACMDL) as our main corpus. Though the ACMDL is more limited than other collections, it has a number of desirable properties: spanning nearly the entire history (1954-2011) of a domain (Computer Science) with full-text and clean metadata. The corpus itself contains both journal and conference articles (77k and 197k, respectively).

In addition to the filtering rules described above, we manually constructed a set of filter terms to remove publication venues, agencies, and other institutions: ‘university’, ‘conference’, ‘symposium’, ‘journal’, ‘foundation’, ‘consortium’, ‘agency’, ‘institute’ and ‘school’ are discarded. We further normalize our keyphrases by lowercasing, removing hyphens, and using the Snowball stemmer (Porter, 2001) to merge plural variants. After stemming and normalizing, we found a total of 155,957 unique abbreviation expansions. Among these, 48,890 expansions occur more than once, 25,107 expansions thrice or more and 16,916 expansions four or more times. We refer to this collection as the AbbrevCorpus.

For each keyphrase we search within the full-text corpus to identify set of documents containing the keyphrase. This allowed us to find both the earliest mention of the keyphrase (the expansion, not the abbreviation) as well as overall popularity of keyphrases. We do not argue that abbreviations are the norm in the introduction of new keyphrases and may, in fact, only happen much later when the domain is familiar enough with the phrase.

To find the expansions in the full-text we utilize a modified suffix-tree that greedily finds the longest-matching phrase and avoids "double-counting". For example, if the text contains the phrase, "...we utilize a Least-Squares Support Vector Machine for ..." it will match against *Least-Squares Support Vector Machine* but not *Least Squares*, *Support Vector Machines*, or *Support Vector* (also keyphrases in our collection). The distribution of keyphrase frequency is a power-law (many keyphrases appearing once with a long tail) with exponent (α) of 2.17 (fit using Clauset et al., (2009)).

3.2 Building Keyphrase Hierarchies

We employ a very simple method of text containment to build keyphrase hierarchies from AbbrevCorpus. If a keyphrase A is a *substring* of keyphrase B, A is said to be contained by B ($B \rightarrow A$). If a third keyphrase, C, *contains* B and is *contained* by A, the containment link between A and B is dropped and two new ones ($A \rightarrow C$ and $C \rightarrow B$) are added. For example for the keyphrases, *circuit switching*, *optical circuit switching* and *dynamic optical circuit switching*, there are links from *optical circuit switching* to *circuit switching*, and *dynamic optical circuit switching* to *optical circuit switching*, but there is no link from *dynamic optical circuit switching* to *circuit switching*. The hierarchies formed in this manner are mostly trees, but in rare cases a keyphrase can have links to multiple branches. Example hierarchies are displayed in Figure 1.

For efficiency we sort all keyphrases by length (from largest to shortest) and iterate over each one, testing for containment in all previously "seen" keyphrases. This is computationally intensive, $O(n^2)$, but can be parallelized.

A potential issue with string containment is that negating prefixes can also appear (e.g., *non-monotonic reasoning* and *monotonic reasoning*). Our algorithm uses a dictionary of negations and can annotate the results. However, in practice we find that only .6% of our data has a leading negating-prefix ("internal" negating prefixes can also be caught in this way, but are similarly rare). It is an application-specific question if we want to consider such pairs as "siblings" or "parent-child" (with both supported).

4 Overlap with Keyphrase Corpora

To test our newly-constructed keyphrase database we generate a mixture of human- and machine-built datasets to compare. Our goal is to characterize both the intersection (keyphrases appearing in our corpus as well as the external datasets) as well as those keyphrases uniquely captured by each dataset.

4.1 ACM Author keyphrases (ACMCorpus)

The metadata for articles in ACM corpus contain author-provided keyphrases. In the corpus described above, we found 145,373 unique author-provided keyphrases after stemming and normalization. We discard 16,418 single-word keywords and those that do not appear in the full-text of any document. We retain 116,246 keyphrases which we refer to as the ACMCorpus.

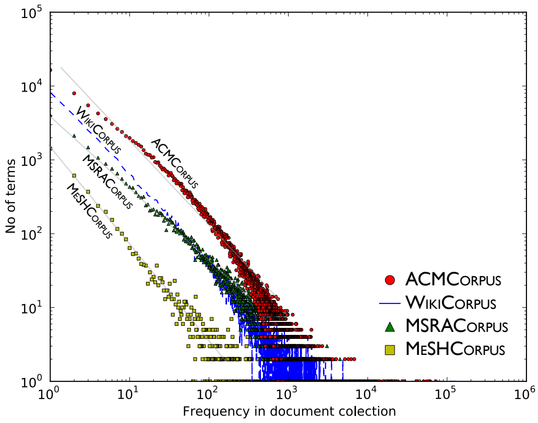

Figure 2: Keyphrase counts for the ACMCorpus (powerlaw $\alpha = 2.36$), WikiCorpus (2.49), MSRACorpus (2.55) and MeSHCorpus (2.7) within the ACM full-text.

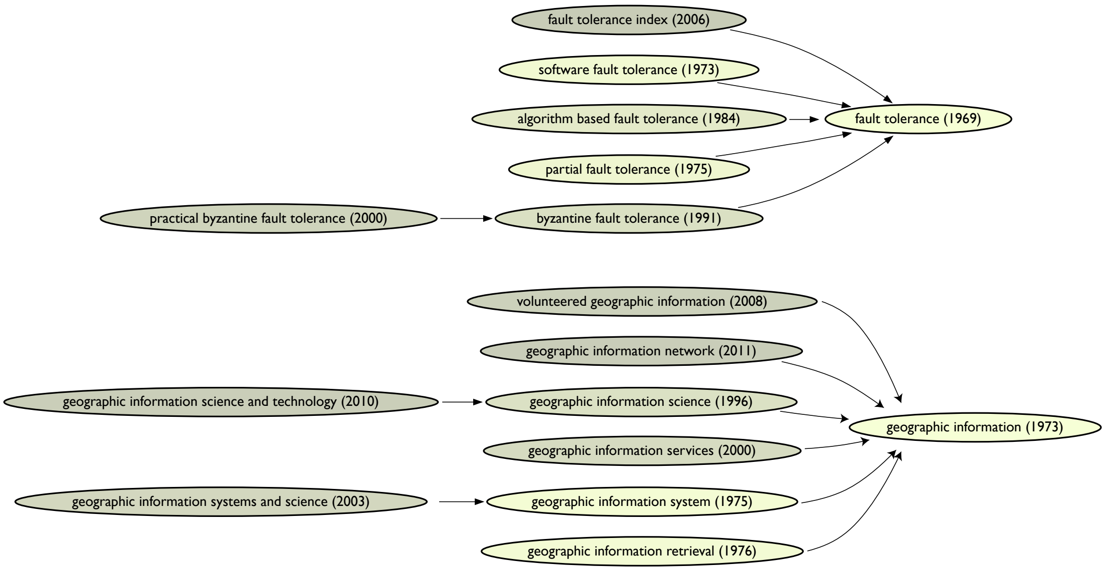
4.2 Microsoft Academic (MSRACorpus)

Our second keyphrase dataset comes from the Microsoft Academic (MSRA) search corpus (Microsoft, 2015). While particularly focused on



fault tolerance index (2006)
software fault tolerance (1973)
algorithm based fault tolerance (1984)
fault tolerance (1969)
partial fault tolerance (1975)
practical byzantine fault tolerance (2000)
byzantine fault tolerance (1991)
volunteered geographic information (2008)
geographic information network (2011)
geographic information science and technology (2010)
geographic information science (1996)
geographic information (1973)
geographic information services (2000)
geographic information systems and science (2003)
geographic information system (1975)
geographic information retrieval (1976)

Figure 1: Keyphrase hierarchy for *Fault Tolerance* (top) and *Geographic Information* (Bottom). Colors encode earliest appearance (brighter green is earlier)

Computer Science, this collection contains articles and keyphrases from over a dozen domains[2]. MSRA provides a list of keyphrases with unique IDs and different stemming variations of each keyphrase. There are a total of 46,978 (without counting stemming variations) of which 30,477 keyphrases occur in ACM full-text corpus after stemming and normalization (64% coverage).

4.3 MeSH (MESHCORPUS)

Medical Subject Headings (MeSH) (Lipscomb, 2000) is set of subject headings or descriptors in the life sciences domain. For the purpose of our work, we use the 27,149 keyphrases from the 2014 MeSH dataset. Similar to the other keyphrase lists we only use stemmed and normalized multi-word keywords that occur in in the ACM full-text corpus, which is 4,363 in case of MeSH.

4.4 Wikipedia (WIKICORPUS)

Scientific article headings in Wikipedia can often be used as a proxy for keyphrases. To collect relevant titles, we find Wikipedia articles that exactly match (in title name) existing MeSH and MSRA keyphrases. For these "seed" articles, we compile their categories and mark all the articles in these categories as potentially "relevant." However, as this also captures scientist names (e.g., a researcher's page may be placed under the "Computer Science" category), research institutes and other non-keyphrase matches, we use the page's infobox as a further filter. Pages containing "person," "place," infoboxes, in "book," "video game," "TV show" or other related "media" category, and those with geographical coordinates are removed. After applying these filters, we obtain 110,102 unique article titles (after stemming) which we treat as keyphrases. Of these, 39,974 occur in the ACM full-text corpus.

4.5 Results

The total overlap for ACMCORPUS, MESHCORPUS, MSRACORPUS and WIKICORPUS are 14.12%, 12.28%, 32.33% and 17.41% respectively. While these numbers seem low, it is worth noting that many of these terms only appear *once* in the ACM full-text corpus (see Figure 2).

Figure 3 illustrates the relationship between the number of times a keyphrase appears in the full-text and the probability that it will appear in ABBREVCORPUS. In all cases, the more often a keyphrase appears in the corpus, the more likely it is to have an abbreviation. If we qualitatively examine popular phrases that do not appear in ABBREVCORPUS we find mathematical forms (e.g., *of-the-form*, *well-defined* or *a priori*), and nouns/entities that are largely unrelated to scientific keyphrases (e.g., *New Jersey*, *Government Agency*, and *Private Sector*). More importantly,

[2] We know these keyphrases are algorithmically derived, but the details are not disclosed.

the majority of phrases that are never abbreviated are simply not Computer Science keyphrases (we return to this in Section 4.6).

We were somewhat surprised by the poor overlap of the ACMCorpus, even for terms that were very common in the full-text. We found that the cause was a large set of “bad” keyphrases. Specifically, 69.3k (69.5%) of author-defined keyphrases (occurring in ACMCorpus *but not* in AbbrevCorpus) are used as a keyword in only one paper. However, they appear more than once in the full-text – often many times. For example, one author (and only one) used *if and only if* as a keyphrase, which matched a great many articles. The result is that there is little correlation between the number of times a keyphrase appears in the full-text and how many times it used explicitly as a keyphrase in the document metadata. Because these will never be found as an abbreviation, they “pull” the mean probability down.

Instead of counting the number of times a keyphrase occurs in the full-text we generate a frequency count based on the number of times authors explicitly use it in the metadata. This new curve, labeled as ACMCorpus (key) in Figure 3 displays a very different tendency, with a rapid upward slope that peaks at 100% for frequently-occurring keyphrases. Notably, only 16k (16%) keyphrases appear once in full-text but are never abbreviated (far fewer than the 69.5% above).

It is worth briefly considering those terms that appear in AbbrevCorpus and not in the other keyphrases lists. We find roughly 17.6k, 24.7k, 19.4k, and 21.4k terms that appear in AbbrevCorpus (with a threshold of 2 to eliminate “noisy” expansions), but not in ACMCorpus, MeSHCorpus, MSRACorpus, and WikiCorpus respectively. As MeSH keyphrases tend to be focused on the biological keyphrases this is perhaps unsurprising but the high numbers for the author-provided ACM keyphrases is unexpected. We find that some of the keyphrases that are in AbbrevCorpus but not in ACMCorpus are highly specific (e.g., *Multi-object Evolutionary Algorithm Based on Decomposition* or *Stochastic Variable Graph Model*). However, many are also extremely generic terms that one *would* expect to find in a computer science corpus: *Run-Time Error Detection*, *Parallel Execution Tree*, and *Little Endian*. Our hypothesis is that these are often not the focus of a paper and are unlikely to be selected by the author. We believe this provides further evidence of the viability of the abbreviation approach to generating good keyphrase lists.

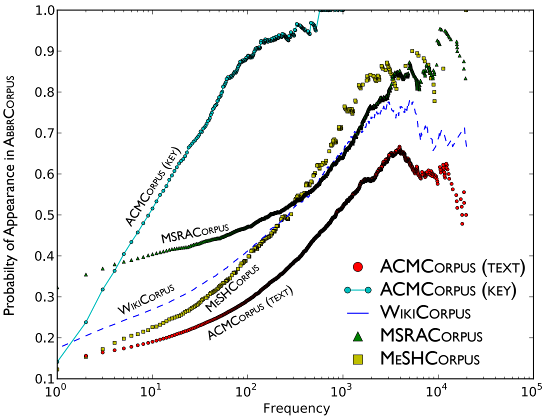


Figure 3: The probability of inclusion of keyphrases in AbbrevCorpus based on frequency of appearance in full text or, in the case if ACMCorpus (key), frequency of use as a keyword. At frequency x, the y value represents probability of appearence in AbbrevCorpus if we only consider terms that appear at least x times in the other corpus.

4.6 Domain keyphrases

When looking at keyphrases that appear in MeshCorpus but not in the AbbrevCorpus we find that many phrases do, in fact, appear in the full text but are never abbreviated. For example, *Color Perception* and *Blood Cell* both appear in ACM articles but are not abbreviated. Our hypothesis—which is motivated by the tendency of scientists to abbreviate terms that are deeply familiar to their community (Grange and Bloom, 2000)—is that terms that are possibly distant from the core domain focus tend not to be abbreviated. This is supported by the fact that these terms *are* abbreviated in other collections (e.g., one can find CP as an abbreviation for Color Perception in psychology and cognition work and BC, for Blood Cell, in medical and biological journals). Additional evidence is apparent in Figure 3 which shows that ACMCorpus keyphrases are more likely to be abbreviated (with far fewer repeats necessary). MSRACorpus, which contains many Computer Science articles, also has higher probabilities (though not nearly matching the ACM).

To test this systematically, we calculated semantic similarity between each keyphrase in the *WikiCorpus* dataset to "computer science." Specifically, we utilize Explicit Semantic Analysis (Gabrilovich and Markovitch, 2009) to calculate similarity. In this method, every segment of text is represented in a very high dimensional space in terms of keyphrases (based on Wikipedia categories). The similarity score for each term is between 0 (unrelated) and 1 (very similar).

Figure 4 demonstrates that with increasing similarity, the likelihood of abbreviation increases. From this, one may infer that to generate a domain-specific database that excludes unrelated keyphrases, the abbreviation-derived corpus is highly appropriate. Conversely, to get coverage of keyphrases from all scientific domains it is insufficient to mine for abbreviations in one specific domain's text. Even though a keyphrase may appear in the full-text it will simply never be abbreviated.

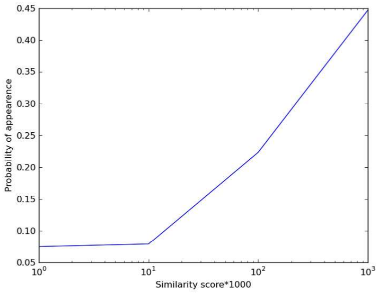

Figure 4: Probability of a keyphrase appearing in ABBREVCORPUS (y-axis) based on semantic similarity of the keyphrase to "Computer Science" (x-axis, binned exponentially for readability).

4.7 Keyphrase Hierarchies

Our hierarchy generation process (see Section 3.2) generated 1716 hierarchies accounting for 8661 unique keyphrases. Most of the hierarchies (1002 or 58%) only contained two nodes (a root and one child). The degree distribution, aggregated across all hierarchies, is again power-law ($\alpha = 2.895$). Hierarchy sizes are power-law distributed ($\alpha = 2.807$) and an average "diameter" (max height) of 1.135. The hierarchies contain a giant component with 2302 nodes and 2436 edges.

While most of our hierarchies are trees, keyphrases can connect to two independent branches. For example, *Least-Squares Support Vector Machines (LS-SVMs)* appears in both the *Least Squares* and *Support Vector* hierarchies. In total, 649 keyphrases appear in multiple hierarchies, the majority appearing 2. Only 17 keyphrases appear in 3 hierarchies. For example, the particularly long *Single Instruction Multiple Thread Evolution Strategy Pattern Search* appears in the *Evolution(ary) Strategy*, *Pattern Search*, and *Single-Instruction-Multiple-Thread* hierarchies. These collisions are interesting in that they reflect a mash-ups of different concepts, and by extension, different sub-disciplines or techniques. In some situations, where there is an overlap in many sub-keyphrases, this may indicate that two root keyphrases are in fact equivalent or highly related (e.g., *likelihood ratio* and *log likelihood*). We do not currently handle such ambiguity in SCHBASE.

To test the semantic interpretation of edges as EXTENDS/ISSUBTYPEOF we randomly sampled 200 edges and manually checked these. We found that in 92% (184) this interpretation was correct. The remaining 16 were largely an artifact of normalization errors rather than a wrong "type" (e.g., "session identifier" and "session id" where clearly a more accurate interpretation is ISEXPANSIONOF). We believe it is fair to say that the hierarchies we construct are the "skeleton" of a full EXTENDS hierarchy but one that is nonetheless fairly encompassing. Our qualitative analysis is that most keyphrases that share a type also share a root keyphrase (e.g., "classifier").

It is interesting to consider if edges which are derived by "containment" reflect a temporal pattern. That is, if keyphrase A EXTENDS B, does the first mention of A in the literature happen after B? We find that this is almost always the case. Among the 7136 edges generated by our algorithm only 165 (2.3%) are "reversed." Qualitatively, we find that these instances appear either due to missing data (the parent keyphrase first appeared outside the ACM) or publication ordering (in some cases the difference in first-appearance is only a year). In most situations the date is only 1-2 years apart. This high degree of consistency lends further support to the tendency of scientists to expand upon keyphrases over time.

Figure 5 depicts the mean change in length of "children" in keyphrase hierarchies. The numbers depicted are relative change. Thus, at year "0", the year the root keyphrase is introduced, there is no relative increase. Within 1 year, new children of that root are 50% larger in character length and after that children continue to "grow" as authors add additional keyphrases. A particularly obvious example of this is the branch for *Petri Net (PN)* which was extended as *Queueing Petri Net (QPN)* and then *Hierarchically Combined Queueing Petri Nets (HCQPN)* and finally *Extended Hierarchically Combined Queueing Petri Nets (EHCQPN)*. Notably, this may have implications to other extractors that assume fixed-sized entities over the history of the collection.

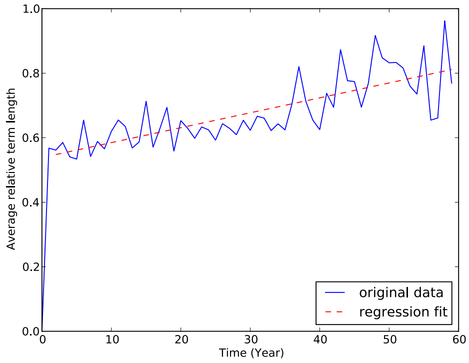

Figure 5: Average increase in character length of sub-keyphrases over time

5 Discussion and Future Work

Our decision to eliminate single-word keyphrases from consideration is an explicit one. Of the 145k keyphrases in the original ACMCorpus (pre-filtering), 16,418 (11.29%) were single-word keyphrases. Our experience with the ACM author-defined keyphrases is that such terms are too generic to be useful as "scientific" keyphrases. For example, In all the ACM proceedings, the top-5 most common single-word keyphrases are *security*, *visualization*, *evaluation*, *design*, and *privacy*. Even in specific sub-domains, such as recommender systems (Proceedings of Recsys), the most popular single-word keyphrases are *personalization*, *recommendation*, *evaluation*, and *trust*. Contrast these to the most popular multi-word terms: *recommender system(s)*, *collaborative filtering*, *matrix factorization*, and *social network(s)*.

Notably, in the MSRA corpus, which is algorithmically filtered, only .46% (226 keyphrases) were single word. MeSH, in contrast, has a full 37% of keyphrases as single-term. In most situations these reflect chemical names (e.g., 382 single-word enzymes) or biological structures. In such a domain, and if these keyphrases are desirable, it may be advisable to retain single-word abbreviations. While it may seem surprising, even single words are often abbreviated (e.g., *Transaldolase* is "T" and *Ultrafiltration* is "U" or "U/F").

A second key observation is that while the ACM full-text corpus is large, it is by no means "big." We selected to use it because it controlled and "clean." However, we have also run our algorithms on the MSRA Corpus (which contains only abstracts) and CiteSeer (which contains full-text). Because the corpora contain more text we find significantly higher overlap with the different keyphrase corpora. However, this comes at the cost of not being able to isolate the domain-specific keyphrases. To put it differently, the broader full-text collections enable to us generate a more fleshed out keyphrase hierarchies that tracks keyphrases across all domains but which may not be appropriate for certain workloads.

Finally, it is worth considering the possibility of building hierarchies (and connecting them) by relations other than "containment." We have begun to utilize metrics such as co-occurrence of keyphrases (e.g., PMI) as well as higher level citation and co-citation structure in the corpora. Thus, we are able to connect terms that are highly related but are textually dissimilar. When experimenting with PMI, for example, we have found a diverse set of edge types including isUsedFor (e.g., "n-gram language model" and "machine translation") or isUsedIn (e.g., "Expectation Maximization" and "Baum-Welch" or "euclidean algorithm" and "k-means"). By necessity, edges generated by this technique require an additional classification.

6 Summary

We have introduced SCHBase, a simple, robust, and highly effective system and database of scientific concepts/keyphrases. By leveraging the incentive structure of scientists to expand existing ideas while simultaneously signaling novelty we are able to construct semantically-meaningful hierarchies of related keyphrases. The further tendency by authors to succinctly describe new keyphrases results in a general habit of utilizing abbreviations. We have demonstrated a mechanism to identify these keyphrases by extracting abbreviation expansions and have shown that these keyphrases cover the bulk of "useful" keyphrases within the domain of the corpus. We believe that SCHBase will enable a number of applications ranging from search, categorization, and analysis of scientific communication patterns.

Abstract

Aspect extraction and sentiment analysis of reviews are both important tasks in opinion mining. We propose a novel sentiment and aspect extraction model based on Restricted Boltzmann Machines to jointly address these two tasks in an unsupervised setting. This model reflects the generation process of reviews by introducing a heterogeneous structure into the hidden layer and incorporating informative priors. Experiments show that our model outperforms previous state-of-the-art methods.

1 Introduction

Nowadays, it is commonplace for people to express their opinion about various sorts of entities, e.g., products or services, on the Internet, especially in the course of e-commerce activities. Analyzing online reviews not only helps customers obtain useful product information, but also provide companies with feedback to enhance their products or service quality. Aspect-based opinion mining enables people to consider much more fine-grained analyses of vast quantities of online reviews, perhaps from numerous different merchant sites. Thus, automatic identification of aspects of entities and relevant sentiment polarities in Big Data is a significant and urgent task (Liu, 2012; Pang and Lee, 2008; Popescu and Etzioni, 2005).

Identifying aspect and analyzing sentiment words from reviews has the ultimate goal of discerning people's opinions, attitudes, emotions, etc. towards entities such as products, services, organizations, individuals, events, etc. In this context, *aspect-based opinion mining*, also known as *feature-based opinion mining*, aims at extracting and summarizing particular salient aspects of entities and determining relevant sentiment polarities from reviews (Hu and Liu, 2004). Consider reviews of computers, for example. A given computer's components (e.g., *hard disk*, *screen*) and attributes (e.g., *volume*, *size*) are viewed as aspects to be extracted from the reviews, while sentiment polarity classification consists in judging whether an opinionated review expresses an overall positive or negative opinion.

Regarding aspect identification, previous methods can be divided into three main categories: rule-based, supervised, and topic model-based methods. For instance, association rule-based methods (Hu and Liu, 2004; Liu et al., 1998) tend to focus on extracting product feature words and opinion words but neglect connecting product features at the aspect level. Existing rule-based methods typically are not able to group the extracted aspect terms into categories. Supervised (Jin et al., 2009; Choi and Cardie, 2010) and semi-supervised learning methods (Zagibalov and Carroll, 2008; Mukherjee and Liu, 2012) were introduced to resolve certain aspect identification problems. However, supervised training requires hand-labeled training data and has trouble coping with domain adaptation scenarios.

Hence, unsupervised methods are often adopted to avoid this sort of dependency on labeled data. Latent Dirichlet Allocation, or LDA for short, (Blei et al., 2003) performs well in automatically extracting aspects and grouping corresponding representative words into categories. Thus, a number of LDA-based aspect identification approaches have been proposed in recent years (Brody and Elhadad, 2010; Titov and McDonald, 2008; Zhao et al., 2010). Still, these methods have several important drawbacks. First, inaccurate approximations of the distribution over topics may reduce the computational accuracy. Second, mixture models are unable to exploit the co-occurrence of topics to yield high probability predictions for words that are sharper than the distributions predicted by in-

dividual topics (Hinton and Salakhutdinov, 2009).

To overcome the weaknesses of existing methods and pursue the promising direction of jointly learning aspect and sentiment, we present the novel Sentiment-Aspect Extraction RBM (SERBM) model to simultaneously extract aspects of entities and relevant sentiment-bearing words. This two-layer structure model is inspired by conventional Restricted Boltzmann machines (RBMs). In previous work, RBMs with shared parameters (RSMs) have achieved great success in capturing distributed semantic representations from text (Hinton and Salakhutdinov, 2009).

Aiming to make the most of their ability to model latent topics while also accounting for the structured nature of aspect opinion mining, we propose replacing the standard hidden layers of RBMs with a novel heterogeneous structure. Three different types of hidden units are used to represent aspects, sentiments, and background words, respectively. This modification better reflects the generative process for reviews, in which review words are generated not only from the aspect distribution but also affected by sentiment information. Furthermore, we blend background knowledge into this model using priors and regularization to help it acquire more accurate feature representations. After m-step Contrastive Divergence for parameter estimation, we can capture the required data distribution and easily compute the posterior distribution over latent aspects and sentiments from reviews. In this way, aspects and sentiments are jointly extracted from reviews, with limited computational effort. This model is hence a promising alternative to more complex LDA-based models presented previously. Overall, our main contributions are as follows:

1. Compared with previous LDA-based methods, our model avoids inaccurate approximations and captures latent aspects and sentiment both adequately and efficiently.

2. Our model exploits RBMs' advantage in properly modeling distributed semantic representations from text, but also introduces heterogeneous structure into the hidden layer to reflect the generative process for online reviews. It also uses a form of regularization to incorporate prior knowledge into the model. Due these modifications, our model is very well-suited for solving aspect-based opinion mining tasks.

3. The optimal weight matrix of this RBM model can exactly reflect individual word features toward aspects and sentiment, which is hard to achieve with LDA-based models due to the mixture model sharing mechanism.

4. Last but not the least, this RBM model is capable of jointly modeling aspect and sentiment information together.

2 Related Work

We summarize prior state-of-the-art models for aspect extraction. In their seminal work, Hu and Liu (2004) propose the idea of applying classical information extraction to distinguish different aspects in online reviews. Methods following their approach exploit frequent noun words and dependency relations to extract product features without supervision (Zhuang et al., 2006; Liu et al., 2005; Somasundaran and Wiebe, 2009). These methods work well when the aspect is strongly associated with a single noun, but obtain less satisfactory results when the aspect emerges from a combination of low frequency items. Additionally, rule-based methods have a common shortcoming in failing to group extracted aspect terms into categories.

Supervised learning methods (Jin et al., 2009; Choi and Cardie, 2010; Jakob and Gurevych, 2010; Kobayashi et al., 2007) such as Hidden Markov Models, one-class SVMs, and Conditional Random Fields have been widely used in aspect information extraction. These supervised approaches for aspect identification are generally based on standard sequence labeling techniques. The downside of supervised learning is its requirement of large amounts of hand-labeled training data to provide enough information for aspect and opinion identification.

Subsequent studies have proposed unsupervised learning methods, especially LDA-based topic modeling, to classify aspects of comments. Specific variants include the Multi-Grain LDA model (Titov and McDonald, 2008) to capture local rateable aspects, the two-step approach to detect aspect-specific opinion words (Brody and Elhadad, 2010), the joint sentiment/topic model (JST) by Lin and He (2009), the topic-sentiment mixture model with domain adaption (Mei et al., 2007), which treats sentiment as different topics, and MaxEnt-LDA (Zhao et al., 2010), which integrates a maximum entropy approach into LDA.

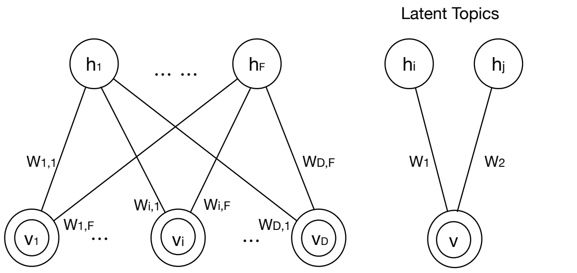

Figure 1: RBM Schema

However, these LDA-based methods can only adopt inaccurate approximations for the posterior distribution over topics rather than exact inference. Additionally, as a mixture model, LDA suffers from the drawbacks mentioned in Section 1 that are common to all mixture models.

3 Model

In order to improve over previous work, we first introduce a basic RBM-based model and then describe our modified full model.

3.1 Basic RBM-based Model

Restricted Boltzmann Machines can be used for topic modeling by relying on the structure shown in Figure 1. As shown on the left side of the figure, this model is a two-layer neural network composed of one visible layer and one hidden layer. The visible layer consists of a softmax over discrete visible units for words in the text, while the hidden layer captures its topics. More precisely, the visible layer is represented as a $K \times D$ matrix $\mathbf{v}$, where K is the dictionary size, and D is the document length. Here, if visible unit i in $\mathbf{v}$ takes the k-th value, we set $v_i^k = 1$. The hidden layer can be expressed as $h \in \{0, 1\}^F$, where F is the number of hidden layer nodes, corresponding to topics. The right side of Figure 1 is another way of viewing the network, with a single multinomial visible unit (Hinton and Salakhutdinov, 2009).

The energy function of the model can be defined as

$$\begin{aligned} E(\mathbf{v}, h) = &-\sum_{i=1}^{D}\sum_{j=1}^{F}\sum_{k=1}^{K} W_{ij}^k h_j v_i^k \\ &-\sum_{i=1}^{D}\sum_{k=1}^{K} v_i^k b_i^k - \sum_{j=1}^{F} h_j a_j, \end{aligned} \tag{1}$$

where W_{ij}^k specifies the connection weight from the i-th visible node of value k to the j-th hidden node, b_i^k corresponds to a bias of v_i^k, and a_j corresponds to a bias of h_j.

The probability of the input layer $\mathbf{v}$ is defined as

$$P(\mathbf{v}) = \frac{1}{Z}\sum_h \exp(-E(\mathbf{v}, h)), \tag{2}$$

where Z is the partition function to normalize the probability.

The conditional probabilities from the hidden to the visible layer and from the visible to the hidden one are given in terms of a softmax and logistic function, respectively, i.e.

$$\begin{aligned} P(\ v_i^k = 1 \mid\ h) &= \frac{\exp\left(b_i^k + \sum_{j=1}^{F} h_j W_{ij}^k\right)}{\sum_{q=1}^{K} \exp\left(b_i^q + \sum_{j=1}^{F} h_j W_{ij}^q\right)}, \\ P(\ h_j = 1 \mid\ \mathbf{v}) &= \sigma\left(a_j + \sum_{i=1}^{D}\sum_{k=1}^{K} v_i^k W_{ij}^k\right), \end{aligned} \tag{3}$$

where $\sigma(x) = 1/(1 + \exp(-x))$ is the logistic function.

3.2 Our Sentiment-Aspect Extraction model

While the basic RBM-based method provides a simple model of latent topics, real online reviews require a more fine-grained model, as they consist of opinion aspects and sentiment information. Therefore, aspect identification is a different task from regular topic modeling and the basic RBM-based model may not perform well in aspect extraction for reviews.

To make the most of the ability of the basic RBM-based model in extracting latent topics, and obtain an effective method that is well-suited to solve aspect identification tasks, we present our novel Sentiment-Aspect Extraction RBM model.

3.2.1 Generative Perspective

From a generative perspective, product reviews can be regarded as follows. Every word in a review text may describe a specific aspect (e.g. “expensive” for the *price* aspect), or an opinion (e.g. “amazing” for a positive sentiment and “terrible” for a negative one), or some irrelevant background information (e.g. “Sunday”). In a generative model, a word may be generated from a latent aspect variable, a sentiment variable, or a background variable. Also, there may exist certain relations between such latent variables.

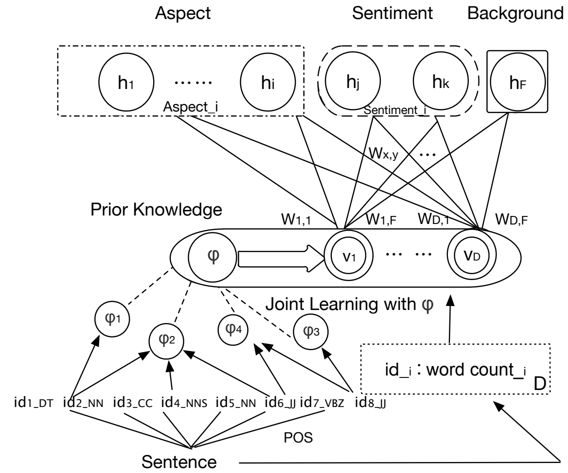

Figure 2: Sentiment-Aspect Extraction Model

3.2.2 Structure

To simulate this generative process for reviews, we adapt the standard RBM structure to reflect the aspect-sentiment identification task.

Undirected Model. Our Sentiment-Aspect Extraction model structure is illustrated in Figure 2.

Compared to standard RBMs, a crucial difference is that hidden units now have a heterogeneous structure instead of being homogeneous as in the standard basic RBM model. In particular, we rely on three types of hidden units, representing aspect, sentiment, and background, respectively. The first two types are self-explanatory, while the background units are intended to reflect the kind of words that do not contribute much to the aspect or sentiment information of review documents. Since the output of the hidden units is a re-encoding of the information in the visible layer, we obtain a deeper representation and a more precise expression of information in the input reviews. Thus, this approach enables the model to learn multi-faceted information with a simple yet expressive structure.

To formalize this, we denote $\widehat{v}^k = \sum_{i=1}^{D} v_i^k$ as the count for the k-th word, where D is the document length. The energy function can then be defined as follows:

$$\begin{aligned} E(\mathbf{v}, h) = &-\sum_{j=1}^{F}\sum_{k=1}^{K} W_j^k h_j \widehat{v}^k \\ &-\sum_{k=1}^{K} \widehat{v}^k b^k - \sum_{j=1}^{F} h_j a_j, \end{aligned} \quad (4)$$

where W_j^k denotes the weight between the k-th visible unit and the j-th hidden unit.

The conditional probability from visible to hidden unit can be expressed as:

$$P(h_j = 1|\mathbf{v}) = \sigma(a_j + \sum_{k=1}^{K} \widehat{v}^k W_j^k). \quad (5)$$

In an RBM, every hidden unit can be activated or restrained by visible units. Thus, every visible unit has a potential contribution towards the activation of a given hidden unit. The probability of whether a given visible unit affects a specific hidden unit is described as follows (cf. appendix for details):

$$\begin{aligned} P(h_j = 1 \mid \widehat{v}^k) =& P(h_j = 1 \mid h_{-j}, \widehat{v}^k) \\ =& \sigma(a_j + W_j^k \widehat{v}^k). \end{aligned} \quad (6)$$

Under this architecture, this equation can be explained as the conditional probability from visible unit k to hidden unit j (softmax of words to aspect or sentiment). According to Eq. 6, the conditional probability for the k-th word feature towards the j-th aspect or sentiment $p(h_j = 1 \mid v_k)$ is a monotone function of W_j^k , the (k, j)-th entry of the optimal weight matrix. Thus, the optimal weight matrix of this RBM model can directly reflect individual word features toward aspects and sentiment.

Informative Priors. To improve the ability of the model to extract aspects and identify sentiments, we capture priors for words in reviews and incorporate this information into the learning process of our Sentiment-Aspect Extraction model. We regularize our model based on these priors to constrain the aspect modeling and improve its accuracy. Figure 3 provides an example of how such priors can be applied to a sentence, with ϕ_i representing the prior knowledge.

Research has found that most aspect words are nouns (or noun phrases), and sentiment is often expressed with adjectives. This additional information has been utilized in previous work on aspect extraction (Hu and Liu, 2004; Benamara et al., 2007; Pang et al., 2002). Inspired by this, we first rely on Part of Speech (POS) Tagging to identify nouns and adjectives. For all noun words, we first calculate their term frequency (TF) in the review corpus, and then compute their inverse document frequency (IDF) from an external Google n-gram corpus[1]. Finally, we rank their TF$*$IDF

Figure 3: Prior Feature Extraction

values and assign them an aspect prior probability p_{A,v_k}, indicating their general probability of being an aspect word. This TF-IDF approach is motivated by the following intuitions: the most frequently mentioned candidates in reviews have the highest probability of being an opinion target and false target words are non-domain specific and frequently appear in a general text corpus (Liu et al., 2012; Liu et al., 2013). For all adjective words, if the words are also included in the online sentiment resource SentiWordNet[2], we assign prior probability p_{s,v_k} to suggest that these words are generally recognized as sentiment words.

Apart from these general priors, we obtain a small amount of fine-grained information as another type of prior knowledge. This fine-grained prior knowledge serves to indicate the probability of a known aspect word belonging to a specific aspect, denoted as p_{A_j,v_k} and an identified sentiment word bearing positive or negative sentiment, denoted as p_{S_j,v_k}. For instance, "salad" is always considered as a general word that belongs to the specific aspect *food*, and "great" is generally considered a *positive* sentiment word.

To extract p_{A_j,v_k}, we apply regular LDA on the review dataset. Since the resulting topic clusters are unlabeled, we manually assign top k words from the topics to the target aspects. We thus obtain fine-grained prior probabilities to suggest these words as belonging to specific aspects. To obtain p_{S_j,v_k}, we rely on SentiWordNet and sum up the probabilities of an identified sentiment word being positive or negative sentiment-bearing, respectively. Then we adopt the corresponding percentage value as a fine-grained specific sentiment prior.

It is worthwhile to mention that the priors are not a compulsory component. However, the procedure for obtaining priors is generic and can easily be applied to any given dataset. Furthermore, we only obtain such fine-grained prior knowledge for a small amount of words in review sentences and rely on the capability of model itself to deal with the remaining words.

3.2.3 Objective Function

We now construct an objective function for our SERBM model that includes regularization based on the priors defined above in Section 3.2.2. Suppose that the training set is $S = \mathbf{v}^1, \mathbf{v}^2, \ldots, \mathbf{v}^{n_s}$, where n_s is the number of training objects. Each element has the form $\mathbf{v}^i = (v_1^i, v_2^i, \ldots, v_K^i)^D$, where $i = 1, 2, \ldots, n_s$, and these data points are assumed to be independent and identically distributed.

We define the following novel log-likelihood function $\ln L_S$, with four forms of regularization corresponding to the four kinds of priors:

$$\begin{aligned}\ln L_S = \ln \prod_{i=1}^{n_s} P(\mathbf{v}^i) - \sum_{i=1}^{n_s} \Bigg[\\ \lambda_1 \ln \prod_{j=1}^{F_1-1} \prod_{k \in R_1} \left[P(h_j = 1 \mid \widehat{v}^k) - p_{A_j,v_k} \right]^2 \\ + \lambda_2 \ln \prod_{k \in R_2} \left[\sum_{j=1}^{F_1} P(h_j = 1 \mid \widehat{v}^k) - p_{A,v_k} \right]^2 \\ + \lambda_3 \ln \prod_{j=F_2}^{F_2+1} \prod_{k \in R_3} \left[P(h_j = 1 \mid \widehat{v}^k) - p_{S_j,v_k} \right]^2 \\ + \lambda_4 \ln \prod_{k \in R_4} \left[\sum_{j=F_2}^{F_2+1} P(h_j = 1 \mid \widehat{v}^k) - p_{S,v_k} \right]^2 \Bigg]\end{aligned} \tag{7}$$

Here, $P(h_j = 1 \mid \widehat{v}^k)$ stands for the probability of a given input word belonging to a specific hidden unit. We assume all $\lambda_i > 0$ for $i = 1 \ldots 4$, while F_1 and F_2 are integers for the offsets within the hidden layer. Units up to index F_1 capture aspects, with the last one reserved for miscellaneous *Other Aspects*, while units from F_2 capture the sentiment (with $F_1 = F_2 + 1 < F$ for convenience).

Our goal will be to maximize the log-likelihood $\ln L_S$ in order to adequately model the data, in accordance with the regularization.

3.2.4 Training

We use Stochastic Gradient Descent (SGD) to find suitable parameters that maximize the objective function. Given a single training instance $\mathbf{v}$ from

[2] http://sentiwordnet.isti.cnr.it

the training set S, we obtain

$$\begin{aligned}\frac{\partial \ln L}{\partial \theta} &= \frac{\partial \ln P(\mathbf{v})}{\partial \theta} \\ &- \lambda_1 \sum_{j=1}^{F_1-1} \sum_{k \in R_1} \frac{\partial \ln \left[P(h_j = 1 \mid \widehat{v}^k) - p_{A_j, v_k} \right]^2}{\partial \theta} \\ &- \lambda_2 \sum_{k \in R_2} \frac{\partial \ln \left[\sum_{j=1}^{F_1} P(h_j = 1 \mid \widehat{v}^k) - p_{A, v_k} \right]^2}{\partial \theta} \\ &- \lambda_3 \sum_{j=F_2}^{F_2+1} \sum_{k \in R_3} \frac{\partial \ln \left[P(h_j = 1 \mid \widehat{v}^k) - p_{S_j, v_k} \right]^2}{\partial \theta} \\ &- \lambda_4 \sum_{k \in R_4} \frac{\partial \ln \left[\sum_{j=F_2}^{F_2+1} P(h_j = 1 \mid \widehat{v}^k) - p_{S, v_k} \right]^2}{\partial \theta}\end{aligned} \tag{8}$$

where $\theta = \{W, a_j, b_i\}$ stands for the parameters. Given N documents $\{\mathbf{v}^n\}_{n=1}^N$, the first term in the log-likelihood function with respect to W is:

$$\frac{1}{N} \sum_{n=1}^{N} \frac{\partial \ln P(\mathbf{v}^n)}{\partial W_j^k} = E_{D_1}[\hat{v}^k h_j] - E_{D_2}[\hat{v}^k h_j]. \tag{9}$$

Here, $D_1[\cdot]$ and $D_2[\cdot]$ represent the expectation with respect to the data distribution and the distribution obtained by this model, respectively. We use Contrastive Divergence (CD) to approximate $E_{D_2}[\hat{v}^k h_j]$ (Hinton and Salakhutdinov, 2009). Due to the m steps of transfer between input and hidden layers in a CD-m run of the algorithm, the two types of hidden units, aspect and sentiment, will jointly affect input reviews together with the connection matrix between the two layers.

Finally, we consider the partial derivative of the entire log-likelihood function with respect to the parameter W. Denoting $\ln \frac{\partial L}{\partial W}$ as ∇W, in each step we update ∇W_j^k by adding

$$\begin{aligned}&\lambda \left[P(h_j = 1 | \mathbf{v}^{(0)}) v_k^{(0)} - P(h_j = 1 | \mathbf{v}^{(\mathrm{cdm})}) v_k^{(\mathrm{cdm})} \right] \\ &- \lambda_1 \sum_{j=1}^{F_1-1} \sum_{k \in R_1} \frac{2 G_j \widehat{v}^k}{(1+G_j)^2 (\frac{1}{1+G_j} - p_{A_j, v_k})} \\ &- \lambda_2 \sum_{k \in R_2} \frac{2 \widehat{v}^k}{\sum_{j=1}^{F_1} \frac{1}{(1+G_j)} - p_{A, v_k}} \sum_{j=1}^{F_1} \frac{G_j}{(1+G_j)^2} \\ &- \lambda_3 \sum_{j=F_2}^{F_2+1} \sum_{k \in R_3} \frac{2 G_j \widehat{v}^k}{(1+G_j)^2 (\frac{1}{1+G_j} - p_{S_j, v_k})} \\ &- \lambda_4 \sum_{k \in R_4} \frac{2 \widehat{v}^k}{\sum_{j=F_2}^{F_2+1} \frac{1}{(1+G_j)} - p_{S, v_k}} \sum_{j=F_2}^{F_2+1} \frac{G_j}{(1+G_j)^2},\end{aligned}$$

where G_j=$e^{-(a_j + W_j^k \widehat{v}^k)}$ for convenience, and $v^{(\mathrm{cdm})}$ is the result from the CD-m steps.

4 Experiments

We present a series of experiments to evaluate our model's performance on the aspect identification and sentiment classification tasks.

4.1 Data

For this evaluation, we rely on a restaurant review dataset widely adopted by previous work (Ganu et al., 2009; Brody and Elhadad, 2010; Zhao et al., 2010), which contains 1,644,923 tokens and 52,574 documents in total. Documents in this dataset are annotated with one or more labels from a gold standard label set $S = \{$*Food*, *Staff*, *Ambience*, *Price*, *Anecdote*, *Miscellaneous*$\}$. Following the previous studies, we select reviews with less than 50 sentences and remove stop words. The Stanford POS Tagger[3] is used to distinguish noun and adjective words from each other.

We later also rely on the Polarity dataset v2.0[4] to conduct an additional experiment on sentiment classification in order to better assess the model's overall performance. This dataset focuses on movie reviews and consists of 1000 positive review documents and 1000 negative ones. It has also been used in the experiments by Lin & He (2009), among others.

4.2 Aspect Identification

We first apply our novel model to identify aspects from documents in the restaurant review dataset.

4.2.1 Experimental Setup

For the experimental setup, we use ten hidden units in our Sentiment-Aspect Extraction RBM (SERBM), where units 0–6 capture aspects, units 7–8 capture sentiment information, and unit 9 stores background information. In particular, we fix hidden units 0–6 to represent the target aspects *Food*, *Staff*, *Ambience*, *Price*, *Ambience*, *Miscellaneous*, and *Other Aspects*, respectively. Units 7–8 represent *positive* and *negative* sentiment, respectively. The remaining hidden unit is intended to capture irrelevant background information.

Note that the structure of our model needs no modifications for new reviews. There are two cases for datasets from a new domain. If the new

[3] http://nlp.stanford.edu/software/tagger.shtml

Method	RBM	RSM	SERBM
PPL	49.73	39.19	21.18

Table 1: Results in terms of perplexity

dataset has a gold standard label set, then we assign one hidden unit to represent each label in the gold standard set. If not, our model only obtains the priors p_{A,v_k} and p_{S,v_k}, and the aspect set can be inferred as in the work of Zhao et al. (2010).

For evaluation, following previous work, the annotated data is fed into our unsupervised model, without any of the corresponding labels. The model is then evaluated in terms of how well its prediction matches the true labels. As for hyperparameter optimization, we use the perplexity scores as defined in Eq. 10 to find the optimal hyperparameters.

As a baseline, we also re-implement standard RBMs and the RSM model (Hinton and Salakhutdinov, 2009) to process this same restaurant review dataset and identify aspects for every document in this dataset under the same experimental conditions. We recall that RSM is a similar undirected graphical model that models topics from raw text.

Last but not the least, we conduct additional comparative experiments, including with LocLDA (Brody and Elhadad, 2010), MaxEnt-LDA (Zhao et al., 2010) and the SAS model (Mukherjee and Liu, 2012) to extract aspects for this restaurant review dataset under the same experimental conditions. In the following, we use the abbreviated name MELDA to stand for the MaxEnt LDA method.

4.2.2 Evaluation

Brody and Elhadad (2010) and Zhao et al. (2010) utilize three aspects to perform a quantitative evaluation and only use sentences with a single label for evaluation to avoid ambiguity. The three major aspects chosen from the gold standard labels are $\mathcal{S} = \{\textit{Food, Staff, Ambience}\}$. The evaluation criterion essentially is to judge how well the prediction matches the true label, resulting in Precision, Recall, and F_1 scores. Besides these, we consider perplexity (PPL) as another evaluation metric to analyze the aspect identification quality. The average test perplexity PPL over words is defined as:

$$\exp\left(-\frac{1}{N}\sum_{n=1}^{N}\frac{1}{D_n}\log P(v_n)\right), \qquad (10)$$

Aspect	Method	Precision	Recall	F_1
food	RBM	0.753	0.680	0.715
	RSM	0.718	0.736	0.727
	LocLDA	**0.898**	0.648	0.753
	MELDA	0.874	0.787	0.828
	SAS	0.867	0.772	0.817
	SERBM	0.891	**0.854**	**0.872**
staff	RBM	0.436	0.567	0.493
	RSM	0.430	0.310	0.360
	LocLDA	0.804	**0.585**	0.677
	MELDA	0.779	0.540	0.638
	SAS	0.774	0.556	0.647
	SERBM	**0.819**	0.582	**0.680**
ambi-ence	RBM	0.489	0.439	0.463
	RSM	0.498	0.441	0.468
	LocLDA	0.603	**0.677**	0.638
	MELDA	0.773	0.588	0.668
	SAS	0.780	0.542	0.640
	SERBM	**0.805**	0.592	**0.682**

Table 2: Aspect identification results in terms of precision, recall, and F_1 scores on the restaurant reviews dataset

where N is the number of documents, D_n represents the word number, and v_n stands for the word-count of document n.

Average perplexity results are reported in Table 1, while Precision, Recall, and F_1 evaluation results for aspect identification are given in Table 2. Some LDA-based methods require manual mappings for evaluation, which causes difficulties in obtaining a fair PPL result, so a few methods are only considered in Table 2.

To illustrate the differences, in Table 3, we list representative words for aspects identified by various models and highlight words without an obvious association or words that are rather unspecific in bold.

4.2.3 Discussion

Considering the results from Table 1 and the RBM, RSM, and SERBM-related results from Table 2, we find that the RSM performs better than the regular RBM model on this aspect identification task. However, the average test perplexity is greatly reduced even further by the SERBM method, resulting in a relative improvement by 45.96% over the RSM model. Thus, despite the elaborate modification, our SERBM inherits RBMs' ability in modeling latent topics, but significantly outperforms other RBM family models

Table 3: Aspects and representative words

on the aspect identification task.

In Table 2, we also observe that SERBM achieves a higher accuracy compared with other state-of-the-art aspect identification methods. More specifically, it is evident that our SERBM model outperforms previous methods' F_1 scores. Compared with MELDA, the F_1 scores for the SERBM lead to relative improvements of 5.31%, 6.58%, and 2.10%, respectively, for the *Food*, *Staff*, and *Ambience* aspects. Compared with SAS, the F_1 scores yield relative improvements by 6.73%, 5.10%, and 6.56%, respectively, on those same aspects. As for Precision and Recall, the SERBM also achieves a competitive performance compared with other methods in aspect identification.

Finally, we conclude from Table 3 that the SERBM method has the capability of extracting word with obvious aspect-specific features and makes less errors compared with other models.

4.3 Sentiment Classification

We additionally conduct two experiments to evaluate the model's performance on sentiment classification.

4.3.1 Comparison with SentiWordNet

We assign a sentiment score to every document in the restaurant review dataset based on the output of SERBM's sentiment-type hidden units. To analyze SERBM's performance in sentiment classification, we compare these results with SentiWordNet[5], a well-known sentiment lexicon. For this SentiWordNet baseline, we consult the resource to obtain a sentiment label for every word and aggregate these to judge the sentiment information of an entire review document in terms of the sum of word-specific scores. Table 4 provides a comparison between SERBM and SentiWordNet, with Accuracy as the evaluation metric.

We observe in Table 4 that the sentiment

[5] http://sentiwordnet.isti.cnr.it

Method	SentiWordNet	SERBM
Accuracy	0.703	**0.788**

Table 4: Accuracy for SERBM and SentiWordNet

classification accuracy on the restaurant review dataset sees a relative improvement by 12.1% with SERBM over the SentiWordNet baseline.

4.3.2 Comparison with JST

We additionally utilize the Polarity dataset v2.0 to conduct an additional sentiment classification experiment in order to assess SERBM's performance more thoroughly. We compare SERBM with the advanced joint sentiment/topic model (JST) by Lin & He (2009). For the JST and the Trying-JST methods only, we use the filtered subjectivity lexicon (subjective MR) as prior information, containing 374 positive and 675 negative entries, which is the same experimental setting as in Lin & He (2009). For SERBM, we use the same general setup as before except for the fact that aspect-specific priors are not used here.

Table 5 provides the sentiment classification accuracies on both the overall dataset and on the subsets for each polarity, where pos. and neg. refer to the positive and negative reviews in the dataset, respectively.

Method	overall	pos.	neg.
JST(%)	84.6	96.2	73
Trying-JST(%)	82	89.2	74.8
SERBM(%)	**89.1**	**92.0**	**86.2**

Table 5: Accuracy for SERBM and JST

In Table 5, we observe that SERBM outperforms JST both in terms of the overall accuracy and for the positive/negative-specific subsets. SERBM yields a relative improvement in the overall accuracy by 5.31% over JST and by 8.66% over Trying-JST.

5 Conclusion

In this paper, we have proposed the novel Sentiment-Aspect Extraction RBM (SERBM) model to jointly extract review aspects and sentiment polarities in an unsupervised setting. Our approach modifies the standard RBM model by introducing a heterogeneous structure into the hidden layer and incorporating informative priors into the model. Our experimental results show that this model can outperform LDA-based methods.

Hence, our work opens up the avenue of utilizing RBM-based undirected graphical models to solve aspect extraction and sentiment classification tasks as well as other unsupervised tasks with similar structure.

Appendix

The joint probability distribution is defined as

$$p_\theta(\mathbf{v}, h) = \frac{1}{Z_\theta} e^{E_\theta(\mathbf{v},h)}, \tag{11}$$

where Z_θ is the partition function. In conjunction with Eq. 1, we obtain

$$E_\theta(\widehat{v}_k, h) = -b_i\widehat{v}^k - \sum_{j=1}^{F} a_j h_j - \sum_{j=1}^{F} h_j W_j^k \widehat{v}^k \tag{12}$$

Then, we can obtain the derivation in Eq. 6.

$$\begin{aligned}
&P(h_j = 1 \mid \widehat{v}^k) \\
=&P(h_j = 1 \mid h_{-j}, \widehat{v}^k) \\
=&\frac{P(h_j = 1, h_{-j}, \widehat{v}^k)}{P(h_{-j}, \widehat{v}^k)} \\
=&\frac{P(h_j = 1, h_{-j}, \widehat{v}^k)}{P(h_j = 1, h_{-j}, \widehat{v}^k) + P(h_j = 0, h_{-j}, \widehat{v}^k)} \\
=&\frac{\frac{1}{Z} e^{-E(h_j=1,h_{-j},\widehat{v}^k)}}{\frac{1}{Z} e^{-E(h_j=1,h_{-j},\widehat{v}^k)} + \frac{1}{Z} e^{-E(h_j=0,h_{-j},\widehat{v}^k)}} \\
=&\frac{e^{-E(h_j=1,h_{-j},\widehat{v}^k)}}{e^{-E(h_j=1,h_{-j},\widehat{v}^k)} + e^{-E(h_j=0,h_{-j},\widehat{v}^k)}} \\
=&\frac{1}{1 + e^{-E(h_j=0,h_{-j},\widehat{v}^k)+E(h_j=1,h_{-j},\widehat{v}^k)}} \\
=&\sigma(a_j + W_j^k \widehat{v}^k)
\end{aligned} \tag{13}$$

Abstract

Relation classification is an important semantic processing task for which state-of-the-art systems still rely on costly handcrafted features. In this work we tackle the relation classification task using a convolutional neural network that performs classification by ranking (CR-CNN). We propose a new pairwise ranking loss function that makes it easy to reduce the impact of artificial classes. We perform experiments using the the SemEval-2010 Task 8 dataset, which is designed for the task of classifying the relationship between two nominals marked in a sentence. Using CR-CNN, we outperform the state-of-the-art for this dataset and achieve a F1 of 84.1 without using any costly handcrafted features. Additionally, our experimental results show that: (1) our approach is more effective than CNN followed by a softmax classifier; (2) omitting the representation of the artificial class *Other* improves both precision and recall; and (3) using only word embeddings as input features is enough to achieve state-of-the-art results if we consider only the text between the two target nominals.

1 Introduction

Relation classification is an important Natural Language Processing (NLP) task which is normally used as an intermediate step in many complex NLP applications such as question-answering and automatic knowledge base construction. Since the last decade there has been increasing interest in applying machine learning approaches to this task (Zhang, 2004; Qian et al., 2009; Rink and Harabagiu, 2010). One reason is the availability of benchmark datasets such as the SemEval-2010 task 8 dataset (Hendrickx et al., 2010), which encodes the task of classifying the relationship between two nominals marked in a sentence. The following sentence contains an example of the *Component-Whole* relation between the nominals *"introduction"* and *"book"*.

The [introduction]$_{e_1}$ in the [book]$_{e_2}$ is a summary of what is in the text.

Some recent work on relation classification has focused on the use of deep neural networks with the aim of reducing the number of handcrafted features (Socher et al., 2012; Zeng et al., 2014; Yu et al., 2014). However, in order to achieve state-of-the-art results these approaches still use some features derived from lexical resources such as WordNet or NLP tools such as dependency parsers and named entity recognizers (NER).

In this work, we propose a new convolutional neural network (CNN), which we name Classification by Ranking CNN (CR-CNN), to tackle the relation classification task. The proposed network learns a distributed vector representation for each relation class. Given an input text segment, the network uses a convolutional layer to produce a distributed vector representation of the text and compares it to the class representations in order to produce a score for each class. We propose a new pairwise ranking loss function that makes it easy to reduce the impact of artificial classes. We perform an extensive number of experiments using the the SemEval-2010 Task 8 dataset. Using CR-CNN, and without the need for any costly handcrafted feature, we outperform the state-of-the-art for this dataset. Our experimental results are evidence that: (1) CR-CNN is more effective than CNN followed by a softmax classifier; (2) omitting the representation of the artificial class *Other* improves both precision and recall; and (3) using only word embeddings as input features is enough to achieve state-of-the-art results if we consider only the text between the two target nominals.

The remainder of the paper is structured as follows. Section 2 details the proposed neural network. In Section 3, we present details about the setup of experimental evaluation, and then describe the results in Section 4. In Section 5, we discuss previous work in deep neural networks for relation classification and for other NLP tasks. Section 6 presents our conclusions.

2 The Proposed Neural Network

Given a sentence x and two target nouns, CR-CNN computes a score for each relation class $c \in C$. For each class $c \in C$, the network learns a distributed vector representation which is encoded as a column in the class embedding matrix $W^{classes}$. As detailed in Figure 1, the only input for the network is the tokenized text string of the sentence. In the first step, CR-CNN transforms words into real-valued feature vectors. Next, a convolutional layer is used to construct a distributed vector representations of the sentence, r_x. Finally, CR-CNN computes a score for each relation class $c \in C$ by performing a dot product between $r_x^\intercal$ and $W^{classes}$.

2.1 Word Embeddings

The first layer of the network transforms words into representations that capture syntactic and semantic information about the words. Given a sentence x consisting of N words $x = \{w_1, w_2, ..., w_N\}$, every word w_n is converted into a real-valued vector r^{w_n}. Therefore, the input to the next layer is a sequence of real-valued vectors $emb_x = \{r^{w_1}, r^{w_2}, ..., r^{w_N}\}$

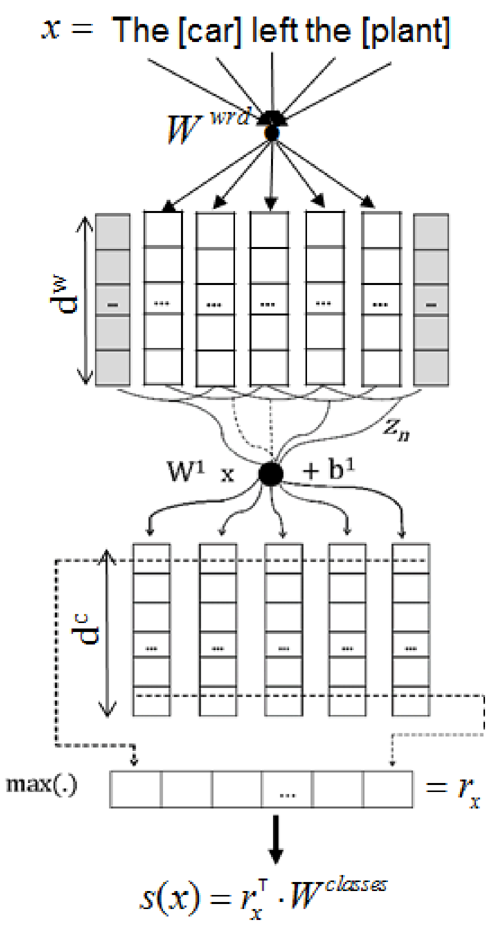
Word representations are encoded by column vectors in an embedding matrix $W^{wrd} \in \mathbb{R}^{d^w \times |V|}$, where V is a fixed-sized vocabulary. Each column $W_i^{wrd} \in \mathbb{R}^{d^w}$ corresponds to the word embedding of the i-th word in the vocabulary. We transform a word w into its word embedding r^w by using the matrix-vector product:

$$r^w = W^{wrd} v^w$$

where v^w is a vector of size $|V|$ which has value 1 at index w and zero in all other positions. The matrix W^{wrd} is a parameter to be learned, and the size of the word embedding d^w is a hyperparameter to be chosen by the user.

2.2 Word Position Embeddings

In the task of relation classification, information that is needed to determine the class of a relation between two target nouns normally comes from words which are close to the target nouns. Zeng et al. (2014) propose the use of *word position embeddings* (position features) which help the CNN by keeping track of how close words are to the target nouns. These features are similar to the position features proposed by Collobert et al. (2011) for the Semantic Role Labeling task.



x = The [car] left the [plant]
W^{wrd}
d^w
z_n
W^1 x
+ b^1
d^c
max(.)
$= r_x$
$s(x) = r_x^\intercal \cdot W^{classes}$

Figure 1: CR-CNN: a Neural Network for classifying by ranking.

In this work we also experiment with the word position embeddings (WPE) proposed by Zeng et al. (2014). The WPE is derived from the relative distances of the current word to the target $noun_1$ and $noun_2$. For instance, in the sentence shown in Figure 1, the relative distances of *left* to *car* and *plant* are -1 and 2, respectively. As in (Collobert et al., 2011), each relative distance is mapped to a vector of dimension d^{wpe}, which is initialized with random numbers. d^{wpe} is a hyperparameter of the network. Given the vectors wp_1 and wp_2 for the word w with respect to the targets $noun_1$ and $noun_2$, the position embedding of w is given by the concatenation of these two vectors, $wpe^w = [wp_1, wp_2]$.

In the experiments where word position embeddings are used, the word embedding and the word position embedding of each word are concatenated to form the input for the convolutional layer, $emb_x = \{[r^{w_1}, wpe^{w_1}], [r^{w_2}, wpe^{w_2}], ..., [r^{w_N}, wpe^{w_N}]\}$.

2.3 Sentence Representation

The next step in the NN consists in creating the distributed vector representation r_x for the input sentence x. The main challenges in this step are the sentence size variability and the fact that important information can appear at any position in the sentence. In recent work, convolutional approaches have been used to tackle these issues when creating representations for text segments of different sizes (Zeng et al., 2014; Hu et al., 2014; dos Santos and Gatti, 2014) and character-level representations of words of different sizes (dos Santos and Zadrozny, 2014). Here, we use a convolutional layer to compute distributed vector representations of the sentence. The convolutional layer first produces local features around each word in the sentence. Then, it combines these local features using a max operation to create a fixed-sized vector for the input sentence.

Given a sentence x, the convolutional layer applies a matrix-vector operation to each window of size k of successive windows in $emb_x = \{r^{w_1}, r^{w_2}, ..., r^{w_N}\}$. Let us define the vector $z_n \in \mathbb{R}^{d^w k}$ as the concatenation of a sequence of k word embeddings, centralized in the n-th word:

$$z_n = \left(r^{w_{n-(k-1)/2}}, ..., r^{w_{n+(k-1)/2}}\right)^{\intercal}$$

In order to overcome the issue of referencing words with indices outside of the sentence boundaries, we augment the sentence with a special *padding* token replicated $\frac{k-1}{2}$ times at the beginning and the end.

The convolutional layer computes the j-th element of the vector $r_x \in \mathbb{R}^{d^c}$ as follows:

$$[r_x]_j = \max_{1<n<N} \left[f\left(W^1 z_n + b^1\right)\right]_j$$

where $W^1 \in \mathbb{R}^{d^c \times d^w k}$ is the weight matrix of the convolutional layer and f is the hyperbolic tangent function. The same matrix is used to extract local features around each word window of the given sentence. The fixed-sized distributed vector representation for the sentence is obtained by using the max over all word windows. Matrix W^1 and vector b^1 are parameters to be learned. The number of convolutional units d^c, and the size of the word context window k are hyperparameters to be chosen by the user. It is important to note that d^c corresponds to the size of the sentence representation.

2.4 Class embeddings and Scoring

Given the distributed vector representation of the input sentence x, the network with parameter set θ computes the score for a class label $c \in C$ by using the dot product

$$s_\theta(x)_c = r_x^{\intercal}[W^{classes}]_c$$

where $W^{classes}$ is an embedding matrix whose columns encode the distributed vector representations of the different class labels, and $[W^{classes}]_c$ is the column vector that contains the embedding of the class c. Note that the number of dimensions in each class embedding must be equal to the size of the sentence representation, which is defined by d^c. The embedding matrix $W^{classes}$ is a parameter to be learned by the network. It is initialized by randomly sampling each value from an uniform distribution: $\mathcal{U}(-r, r)$, where $r = \sqrt{\frac{6}{|C| + d^c}}$.

2.5 Training Procedure

Our network is trained by minimizing a pairwise ranking loss function over the training set D. The input for each training round is a sentence x and two different class labels $y^+ \in C$ and $c^- \in C$, where y^+ is a correct class label for x and c^- is not. Let $s_\theta(x)_{y^+}$ and $s_\theta(x)_{c^-}$ be respectively the scores for class labels y^+ and c^- generated by the network with parameter set θ. We propose a new logistic loss function over these scores in order to train CR-CNN:

$$\begin{aligned} L = \; & log(1 + exp(\gamma(m^+ - s_\theta(x)_{y^+})) \\ & + log(1 + exp(\gamma(m^- + s_\theta(x)_{c^-})) \end{aligned} \tag{1}$$

where m^+ and m^- are margins and γ is a scaling factor that magnifies the difference between the score and the margin and helps to penalize more on the prediction errors. The first term in the right side of Equation 1 decreases as the score $s_\theta(x)_{y^+}$ increases. The second term in the right side decreases as the score $s_\theta(x)_{c^-}$ decreases. Training CR-CNN by minimizing the loss function in Equation 1 has the effect of training to give scores greater than m^+ for the correct class and (negative) scores smaller than $-m^-$ for incorrect classes. In our experiments we set γ to 2, m^+ to 2.5 and m^- to 0.5. We use $L2$ regularization by adding the term $\beta \|\theta\|^2$ to Equation 1. In our experiments we set β to 0.001. We use stochastic gradient descent (SGD) to minimize the loss function with respect to θ.

Like some other ranking approaches that only update two classes/examples at every training round (Weston et al., 2011; Gao et al., 2014), we can efficiently train the network for tasks which have a very large number of classes. This is an advantage over softmax classifiers.

On the other hand, sampling informative negative classes/examples can have a significant impact in the effectiveness of the learned model. In the case of our loss function, more informative negative classes are the ones with a score larger than $-m^-$. The number of classes in the relation classification dataset that we use in our experiments is small. Therefore, in our experiments, given a sentence x with class label y^+, the incorrect class c^- that we choose to perform a SGD step is the one with the highest score among all incorrect classes $c^- = \underset{c \,\in\, C;\; c \neq y^+}{\arg\max}\; s_\theta(x)_c$.

For tasks where the number of classes is large, we can fix a number of negative classes to be considered at each example and select the one with the largest score to perform a gradient step. This approach is similar to the one used by Weston et al. (2014) to select negative examples.

We use the backpropagation algorithm to compute gradients of the network. In our experiments, we implement the CR-CNN architecture and the backpropagation algorithm using Theano (Bergstra et al., 2010).

2.6 Special Treatment of *Artificial* Classes

In this work, we consider a class as *artificial* if it is used to group items that do not belong to any of the *actual* classes. An example of artificial class is the class *Other* in the SemEval 2010 relation classification task. In this task, the artificial class *Other* is used to indicate that the relation between two nominals does not belong to any of the nine relation classes of interest. Therefore, the class *Other* is very noisy since it groups many different types of relations that may not have much in common.

An important characteristic of CR-CNN is that it makes it easy to reduce the effect of artificial classes by omitting their embeddings. If the embedding of a class label c is omitted, it means that the embedding matrix $W^{classes}$ does not contain a column vector for c. One of the main benefits from this strategy is that the learning process focuses on the "natural" classes only. Since the embedding of the artificial class is omitted, it will not influence the prediction step, i.e., CR-CNN does not produce a score for the artificial class.

In our experiments with the SemEval-2010 relation classification task, when training with a sentence x whose class label $y = Other$, the first term in the right side of Equation 1 is set to zero. During prediction time, a relation is classified as *Other* only if all actual classes have negative scores. Otherwise, it is classified with the class which has the largest score.

3 Experimental Setup

3.1 Dataset and Evaluation Metric

We use the SemEval-2010 Task 8 dataset to perform our experiments. This dataset contains 10,717 examples annotated with 9 different relation types and an artificial relation Other, which is used to indicate that the relation in the example does not belong to any of the nine main relation types. The nine relations are *Cause-Effect, Component-Whole, Content-Container, Entity-Destination, Entity-Origin, Instrument-Agency, Member-Collection, Message-Topic* and *Product-Producer*. Each example contains a sentence marked with two nominals e_1 and e_2, and the task consists of predicting the relation between the two nominals taking into consideration the directionality. That means that the relation Cause-Effect(e1,e2) is different from the relation Cause-Effect(e2,e1), as shown in the examples below. More information about this dataset can be found in (Hendrickx et al., 2010).

The [war]$_{e_1}$ resulted in other collateral imperial [conquests]$_{e_2}$ as well. ⇒ Cause-Effect(e1,e2)

The [burst]$_{e_1}$ has been caused by water hammer [pressure]$_{e2}$. ⇒ Cause-Effect(e2,e1)

The SemEval-2010 Task 8 dataset is already partitioned into 8,000 training instances and 2,717 test instances. We score our systems by using the SemEval-2010 Task 8 official scorer, which computes the macro-averaged F1-scores for the nine actual relations (excluding Other) and takes the directionality into consideration.

3.2 Word Embeddings Initialization

The word embeddings used in our experiments are initialized by means of unsupervised pre-training. We perform pre-training using the skip-gram NN architecture (Mikolov et al., 2013) available in the `word2vec` tool. We use the December 2013 snapshot of the English Wikipedia corpus to train word embeddings with `word2vec`. We preprocess the Wikipedia text using the steps described in (dos Santos and Gatti, 2014): (1) removal of paragraphs that are not in English; (2) substitution of non-western characters for a special character; (3) tokenization of the text using the tokenizer available with the Stanford POS Tagger (Toutanova et al., 2003); (4) removal of sentences that are less than 20 characters long (including white spaces) or have less than 5 tokens. (5) lowercase all words and substitute each numerical digit by a 0. The resulting clean corpus contains about 1.75 billion tokens.

3.3 Neural Network Hyper-parameter

We use 4-fold cross-validation to tune the neural network hyperparameters. Learning rates in the range of 0.03 and 0.01 give relatively similar results. Best results are achieved using between 10 and 15 training epochs, depending on the CR-CNN configuration. In Table 1, we show the selected hyperparameter values. Additionally, we use a learning rate schedule that decreases the learning rate λ according to the training epoch t. The learning rate for epoch t, λ_t, is computed using the equation: $\lambda_t = \frac{\lambda}{t}$.

Parameter	Parameter Name	Value
d^w	Word Emb. size	400
d^{wpe}	Word Pos. Emb. size	70
d^c	Convolutinal Units	1000
k	Context Window size	3
λ	Initial Learning Rate	0.025

Table 1: CR-CNN Hyperparameters

4 Experimental Results

4.1 Word Position Embeddings and Input Text Span

In the experiments discussed in this section we assess the impact of using word position embeddings (WPE) and also propose a simpler alternative approach that is almost as effective as WPEs. The main idea behind the use of WPEs in relation classification task is to give some hint to the convolutional layer of how close a word is to the target nouns, based on the assumption that closer words have more impact than distant words.

Here we hypothesize that most of the information needed to classify the relation appear between the two target nouns. Based on this hypothesis, we perform an experiment where the input for the convolutional layer consists of the word embeddings of the word sequence $\{w_{e_1} - 1, ..., w_{e_2} + 1\}$ where e_1 and e_2 correspond to the positions of the first and the second target nouns, respectively.

In Table 2 we compare the results of different CR-CNN configurations. The first column indicates whether the full sentence was used (*Yes*) or whether the text span between the target nouns was used (*No*). The second column informs if the WPEs were used or not. It is clear that the use of WPEs is essential when the full sentence is used, since F1 jumps from 74.3 to 84.1. This effect of WPEs is reported by (Zeng et al., 2014). On the other hand, when using only the text span between the target nouns, the impact of WPE is much smaller. With this strategy, we achieve a F1 of 82.8 using only word embeddings as input, which is a result as good as the previous state-of-the-art F1 of 83.0 reported in (Yu et al., 2014) for the SemEval-2010 Task 8 dataset. This experimental result also suggests that, in this task, the CNN works better for short texts.

All experiments reported in the next sections use CR-CNN with full sentence and WPEs.

Full Sentence	Word Position	Prec.	Rec.	F1
Yes	Yes	**83.7**	**84.7**	**84.1**
No	Yes	83.3	83.9	83.5
No	No	83.4	82.3	82.8
Yes	No	78.1	71.5	74.3

Table 2: Comparison of different CR-CNN configurations.

4.2 Impact of Omitting the Embedding of the artificial class *Other*

In this experiment we assess the impact of omitting the embedding of the class *Other*. As we mentioned above, this class is very noisy since it groups many different infrequent relation types. Its embedding is difficult to define and therefore brings noise into the classification process of the natural classes. In Table 3 we present the results comparing the use and omission of embedding for the class *Other*. The two first lines of results present the official F1, which does not take into account the results for the class *Other*. We can see that by omitting the embedding of the class *Other* both precision and recall for the other classes improve, which results in an increase of 1.4 in the F1. These results suggest that the strategy we use in CR-CNN to avoid the noise of artificial classes is effective.

Use embedding of class *Other*	Class	Prec.	Rec.	F1
No	All	**83.7**	**84.7**	**84.1**
Yes	All	81.3	84.3	82.7
No	Other	52.0	48.7	50.3
Yes	Other	60.1	48.7	53.8

Table 3: Impact of not using an embedding for the artificial class Other.

In the two last lines of Table 3 we present the results for the class *Other*. We can note that while the recall for the cases classified as *Other* remains 48.7, the precision significantly decreases from 60.1 to 52.0 when the embedding of the class *Other* is not used. That means that more cases from natural classes (all) are now been classified as *Other*. However, as both the precision and the recall of the natural classes increase, the cases that are now classified as *Other* must be cases that are also wrongly classified when the embedding of the class *Other* is used.

4.3 CR-CNN versus CNN+Softmax

In this section we report experimental results comparing CR-CNN with CNN+Softmax. In order to do a fair comparison, we've implemented a CNN+Softmax and trained it with the same data, word embeddings and WPEs used in CR-CNN. Concretely, our CNN+Softmax consists in getting the output of the convolutional layer, which is the vector r_x in Figure 1, and giving it as input for a softmax classifier. We tune the parameters of CNN+Softmax by using a 4-fold cross-validation with the training set. Compared to the hyperparameter values for CR-CNN presented in Table 1, the only difference for CNN+Softmax is the number of convolutional units d^c, which is set to 400.

In Table 4 we compare the results of CR-CNN and CNN+Softmax. CR-CNN outperforms CNN+Softmax in both precision and recall, and improves the F1 by 1.6. The third line in Table 4 shows the result reported by Zeng et al. (2014) when only word embeddings and WPEs are used as input to the network (similar to our CNN+Softmax). We believe that the word embeddings employed by them is the main reason their result is much worse than that of CNN+Softmax. We use word embeddings of size 400 while they use word embeddings of size 50, which were trained using much less unlabeled data than we did.

Neural Net.	Prec.	Rec.	F1
CR-CNN	**83.7**	**84.7**	**84.1**
CNN+SoftMax	82.1	83.1	82.5
CNN+SoftMax (Zeng et al., 2014)	-	-	78.9

Table 4: Comparison of results of CR-CNN and CNN+Softmax.

4.4 Comparison with the State-of-the-art

In Table 5 we compare CR-CNN results with results recently published for the SemEval-2010 Task 8 dataset. Rink and Harabagiu (2010) present a support vector machine (SVM) classifier that is fed with a rich (traditional) feature set. It obtains an F1 of 82.2, which was the best result at SemEval-2010 Task 8. Socher et al. (2012) present results for a recursive neural network (RNN) that employs a matrix-vector representation to every node in a parse tree in order to compose the distributed vector representation for the complete sentence. Their method is named the matrix-vector recursive neural network (MVRNN) and achieves a F1 of 82.4 when POS, NER and WordNet features are used. In (Zeng et al., 2014), the authors present results for a CNN+Softmax classifier which employs lexical and sentence-level features. Their classifier achieves a F1 of 82.7 when adding a handcrafted feature based on the WordNet. Yu et al. (2014) present the Factor-based Compositional Embedding Model (FCM), which achieves a F1 of 83.0 by deriving sentence-level and substructure embeddings from word embeddings utilizing dependency trees and named entities.

As we can see in the last line of Table 5, CR-CNN using the full sentence, word embeddings and WPEs outperforms all previous reported results and reaches a new state-of-the-art F1 of 84.1. This is a remarkable result since we do not use any complicated features that depend on external lexical resources such as WordNet and NLP tools such as named entity recognizers (NERs) and dependency parsers.

We can see in Table 5 that CR-CNN[1] also achieves the best result among the systems that use word embeddings as the only input features. The closest result (80.6), which is produced by the FCM system of Yu et al. (2014), is 2.2 F1 points behind CR-CNN result (82.8).

4.5 Most Representative Trigrams for each Relation

In Table 6, for each relation type we present the five trigrams in the test set which contributed the most for scoring correctly classified examples. Remember that in CR-CNN, given a sentence x the score for the class c is computed by $s_\theta(x)_c = r_x^\intercal [W^{classes}]_c$. In order to compute the most representative trigram of a sentence x, we trace back each position in r_x to find the trigram responsible for it. For each trigram t, we compute its particular contribution for the score by summing the terms in score that use positions in r_x that trace back to t. The most *representative* trigram in x is the one with the largest contribution to the improvement of the score. In order to create the results presented in Table 6, we rank the trigrams which were selected as the most representative of any sentence in decreasing order of contribution value. If a trigram appears as the largest contributor for more than one sentence, its contribuition value becomes the sum of its contribution for each sentence.

We can see in Table 6 that for most classes, the trigrams that contributed the most to increase the score are indeed very informative regarding the relation type. As expected, different trigrams play an important role depending on the direction of the relation. For instance, the most informative trigram for *Entity-Origin(e1,e2)* is *"away from the"*, while reverse direction of the relation, *Entity-Origin(e2,e1)* or *Origin-Entity*, has *"the source of"* as the most informative trigram. These results are a step towards the extraction of meaningful knowledge from models produced by CNNs.

5 Related Work

Over the years, various approaches have been proposed for relation classification (Zhang, 2004; Qian et al., 2009; Hendrickx et al., 2010; Rink and Harabagiu, 2010). Most of them treat it as a multi-class classification problem and apply a variety of machine learning techniques to the task in order to achieve a high accuracy.

Recently, deep learning (Bengio, 2009) has become an attractive area for multiple applications, including computer vision, speech recognition and natural language processing. Among the different deep learning strategies, convolutional neural networks have been successfully applied to different NLP task such as part-of-speech tagging (dos Santos and Zadrozny, 2014), sentiment analysis (Kim, 2014; dos Santos and Gatti, 2014), question classification (Kalchbrenner et al., 2014), semantic role labeling (Collobert et al., 2011), hashtag prediction (Weston et al., 2014), sentence completion and response matching (Hu et al., 2014).

Some recent work on deep learning for relation classification include Socher et al. (2012), Zeng et al. (2014) and Yu et al. (2014). In (Socher et al., 2012), the authors tackle relation classification using a recursive neural network (RNN) that assigns a matrix-vector representation to every node in a parse tree. The representation for the complete sentence is computed bottom-up by recursively combining the words according to the syntactic structure of the parse tree Their method is named the matrix-vector recursive neural network (MVRNN).

Zeng et al. (2014) propose an approach for relation classification where sentence-level features are learned through a CNN, which has word embedding and position features as its input. In parallel, lexical features are extracted according to given nouns. Then sentence-level and lexical features are concatenated into a single vector and fed into a softmax classifier for prediction. This approach achieves state-of-the-art performance on the SemEval-2010 Task 8 dataset.

Yu et al. (2014) propose a Factor-based Com-

positional Embedding Model (FCM) by deriving sentence-level and substructure embeddings from word embeddings, utilizing dependency trees and named entities. It achieves slightly higher accuracy on the same dataset than (Zeng et al., 2014), but only when syntactic information is used.

There are two main differences between the approach proposed in this paper and the ones proposed in (Socher et al., 2012; Zeng et al., 2014; Yu et al., 2014): (1) CR-CNN uses a pair-wise ranking method, while other approaches apply multiclass classification by using the softmax function on the top of the CNN/RNN; and (2) CR-CNN employs an effective method to deal with artificial classes by omitting their embeddings, while other approaches treat all classes equally.

6 Conclusion

In this work we tackle the relation classification task using a CNN that performs classification by ranking. The main contributions of this work are: (1) the definition of a new state-of-the-art for the SemEval-2010 Task 8 dataset without using any costly handcrafted features; (2) the proposal of a new CNN for classification that uses class embeddings and a new rank loss function; (3) an effective method to deal with artificial classes by omitting their embeddings in CR-CNN; (4) the demonstration that using only the text between target nominals is almost as effective as using WPEs; and (5) a method to extract from the CR-CNN model the most representative contexts of each relation type. Although we apply CR-CNN to relation classification, this method can be used for any classification task.

Abstract

We study the application of word embeddings to generate semantic representations for the domain adaptation problem of relation extraction (RE) in the tree kernel-based method. We systematically evaluate various techniques to generate the semantic representations and demonstrate that they are effective to improve the generalization performance of a tree kernel-based relation extractor across domains (up to 7% relative improvement). In addition, we compare the tree kernel-based and the feature-based method for RE in a compatible way, on the same resources and settings, to gain insights into which kind of system is more robust to domain changes. Our results and error analysis shows that the tree kernel-based method outperforms the feature-based approach.

1 Introduction

Relation Extraction (RE) is an important aspect of information extraction that aims to discover the semantic relationships between two entity mentions appearing in the same sentence. Previous research on RE has followed either the kernel-based approach (Zelenko et al., 2003; Bunescu and Mooney, 2005; Zhao and Grishman, 2005; Zhang et al., 2006; Bunescu, 2007; Qian et al., 2008; Nguyen et al., 2009) or the feature-based approach (Kambhatla, 2004; Grishman et al., 2005; Zhou et al., 2005; Jiang and Zhai, 2007a; Chan and Roth, 2010; Sun et al., 2011). Usually, in such supervised machine learning systems, it is assumed that the training data and the data to which the RE system is applied to are sampled independently and identically from the same distribution. This assumption is often violated in reality and exemplified in the fact that the performance of the traditional RE techniques degrades significantly in such a domain mismatch case (Plank and Moschitti, 2013). To alleviate this performance loss, we need to resort to domain adaptation (DA) techniques to adapt a system trained on some *source domain* to perform well on new *target domains*. We here focus on the *unsupervised domain adaptation* (i.e., no labeled target data) and *single-system* DA (Petrov and McDonald, 2012; Plank and Moschitti, 2013), i.e., building a single system that is able to cope with different, yet related target domains.

While DA has been investigated extensively in the last decade for various natural language processing (NLP) tasks, the examination of DA for RE is only very recent. To the best of our knowledge, there have been only three studies on DA for RE (Plank and Moschitti, 2013; Nguyen and Grishman, 2014; Nguyen et al., 2014). Of these, Nguyen et al. (2014) follow the supervised DA paradigm and assume some labeled data in the target domains. In contrast, Plank and Moschitti (2013) and Nguyen and Grishman (2014) work on the unsupervised DA. In our view, unsupervised DA is more challenging, but more realistic and practical for RE as we usually do not know which target domains we need to work on in advance, thus cannot expect to possess labeled data of the target domains. Our current work therefore focuses on the single-system *unsupervised* DA. Besides, note that this setting tries to construct a single system that can work robustly with different but related domains (multiple target domains), thus being different from most previous studies on DA (Blitzer et al., 2006; Blitzer et al., 2007) which have attempted to design a specialized system for every specific target domain.

Plank and Moschitti (2013) propose to embed word clusters and latent semantic analysis (LSA) of words into tree kernels for DA of RE, while Nguyen and Grishman (2014) studies the appli-

Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

cation of word clusters and word embeddings for DA of RE on the feature-based method. Although word clusters (Brown et al., 1992) have been employed by both studies to improve the performance of relation extractors across domains, the application of word embeddings (Bengio et al., 2003; Mnih and Hinton, 2008; Turian et al., 2010) for DA of RE is only examined in the feature-based method and never explored in the tree kernel-based method so far, giving rise to the first question we want to address in this paper:

(i) Can word embeddings help the tree kernel-based methods on DA for RE and more importantly, in which way can we do it effectively?

This question is important as word embeddings are real valued vectors, while the tree kernel-based methods rely on the symbolic matches or mismatches of concrete labels in the parse trees to compute the kernels. It is unclear at the first glance how to encode word embeddings into the tree kernels effectively so that word embeddings could help to improve the generalization performance of RE. One way is to use word embeddings to compute similarities between words and embed these similarity scores into the kernel functions, e.g., by resembling the method of Plank and Moschitti (2013) that exploited LSA (in the semantic syntactic tree kernel (SSTK), cf. §2.1). We explore various methods to apply word embeddings to generate the semantic representations for DA of RE and demonstrate that semantic representations are very effective to significantly improve the portability of the relation extractors based on the tree kernels, bringing us to the second question:

(ii) Between the feature-based method in Nguyen and Grishman (2014) and the SSTK method in Plank and Moschitti (2013), which method is better for DA of RE, given the recent discovery of word embeddings for both methods?

It is worth noting that besides the approach difference, these two works employ rather different resources and settings in their evaluation, making it impossible to directly compare their performance. In particular, while Plank and Moschitti (2013) only use the path-enclosed trees induced from the constituent parse trees as the representation for relation mentions, Nguyen and Grishman (2014) include a rich set of features extracted from multiple resources such as constituent trees, dependency trees, gazetteers, semantic resources in the representation. Besides, Plank and Moschitti (2013) consider the direction of relations in their evaluation (i.e, distinguishing between relation classes and their inverses) but Nguyen and Grishman (2014) disregard this relation direction. Finally, we note that although both studies evaluate their systems on the ACE 2005 dataset, they actually have different dataset partitions. In order to overcome this limitation, we conduct an evaluation in which the two methods are directed to use the same resources and settings, and are thus compared in a *compatible* manner to achieve an insight on their effectiveness for DA of RE. In fact, the problem of incompatible comparison is unfortunately very common in the RE literature (Wang, 2008; Plank and Moschitti, 2013) and we believe there is a need to tackle this increasing confusion in this line of research. Therefore, this is actually the first attempt to compare the two methods (tree kernel-based and feature-based) on the same settings. To ease the comparison for future work and circumvent the *Zigglebottom* pitfall (Pedersen, 2008), the entire setup and package is available.[1]

2 Relation Extraction Approaches

In the following, we introduce the two relation extraction systems further examined in this study.

2.1 Tree kernel-based Method

In the tree kernel-based method (Moschitti, 2006; Moschitti, 2008; Plank and Moschitti, 2013), a relation mention (the two entity mentions and the sentence containing them) is represented by the path-enclosed tree (PET), the smallest constituency-based subtree including the two target entity mentions (Zhang et al., 2006). The syntactic tree kernel (STK) is then defined to compute the similarity between two PET trees (where target entities are marked) by counting the common sub-trees, without enumerating the whole fragment space (Moschitti, 2006; Moschitti, 2008). STK is then applied in the support vector machines (SVMs) for RE. The major limitation of STK is its inability to match two trees that share the same substructure, but involve different though semantically related terminal nodes (words). This is caused by the hard matches between words, and consequently between sequences containing them. For instance, in the following example taken from Plank and Moschitti (2013), the two fragments "*governor from Texas*" and "*head of Mary-*

[1] `https://bitbucket.org/nycphre/limo-re`

land" would not match in STK although they have very similar syntactic structures and basically convey the same relationship.

Plank and Moschitti (2013) propose to resolve this issue for STK using the semantic syntactic tree kernel (SSTK) (Bloehdorn and Moschitti, 2007) and apply it to the domain adaptation problem of RE. The two following techniques are utilized to activate the SSTK: (i) replace the part-of-speech nodes in the PET trees by the new ones labeled by the word clusters of the corresponding terminals (words); (ii) replace the binary similarity scores between words (i.e, either 1 or 0) by the similarities induced from the latent semantic analysis (LSA) of large corpus. The former generalizes the part-of-speech similarity to the semantic similarity on word clusters; the latter, on the other hand, allows soft matches between words that have the same latent semantic but differ in symbolic representation. Both techniques emphasize the invariants of word semantics in different domains, thus being helpful to alleviate the vocabulary difference across domains.

2.2 Feature-based Method

In the feature-based method (Zhou et al., 2005; Sun et al., 2011; Nguyen and Grishman, 2014), relation mentions are first transformed into rich feature vectors that capture various characteristics of the relation mentions (i.e, lexicon, syntax, semantics etc). The resulting vectors are then fed into the statistical classifiers such as Maximum Entropy (MaxEnt) to perform classification for RE.

The main reason for the performance loss of the feature-based systems on new domains is the behavioral changes of the features when domains shift. Some features might be very informative in the source domain but become less relevant in the target domains. For instance, some words, that are very indicative in the source domain might not appear in the target domains (lexical sparsity). Consequently, the models putting high weights on such words (features) in the source domain will fail to perform well on the target domains. Nguyen and Grishman (2014) address this problem for the feature-based method in DA of RE by introducing word embeddings as additional features. The rationale is based on the fact that word embeddings are low dimensional and real valued vectors, capturing latent syntactic and semantic properties of words (Bengio et al., 2003; Mnih and Hinton, 2008; Turian et al., 2010). The embeddings of symbolically different words are often close to each other if they have similar semantic and syntactic functions. This again helps to mitigate the lexical sparsity or the vocabulary difference between the domains and has proven helpful for, amongst others, the feature-based method in DA of RE.

2.3 Tree Kernel-based vs Feature-based

The feature-based method explicitly encapsulates the linguistic intuition and domain expertise for RE into the features, while the tree kernel-based method avoids the complicated feature engineering and implicitly encode the features into the computation of the tree kernels. Which method is better for DA of RE?

In order to ensure the two methods (Plank and Moschitti, 2013; Nguyen and Grishman, 2014) are compared compatibly on the same resources, we make sure the two systems have access to the same amount of information. Thus, we follow Plank and Moschitti (2013) and use the PET trees (beside word clusters and word embeddings) as the only resource the two methods can exploit.

For the feature-based method, we utilize all the features extractable from the PET trees that are standardly used in the state-of-the-art feature-based systems for DA of RE (Nguyen and Grishman, 2014). Specifically, the feature set employed in this paper (denoted by FET) includes: the lexical features, i.e., the context words, the head words, the bigrams, the number of words, the lexical path, the order of mention (Zhou et al., 2005; Sun et al., 2011); and the syntactic features, i.e., the path connecting the two mentions in PET and the unigrams, bigrams, trigrams along this path (Zhou et al., 2005; Jiang and Zhai, 2007a).

Hypothesis: Assuming identical settings and resources, we hypothesize that the tree kernel-based method is better than the feature-based method for DA of RE. This is motivated because of at least two reasons: (i) the tree kernel-based method implicitly encodes a more comprehensive feature set (involving all the sub-trees in the PETs), thus potentially captures more domain-independent features to be useful for DA of RE; (ii) the tree kernel-based method avoids the inclusion of fine-tuned and domain-specific features originated from the excessive feature engineering (i.e., hand-designing feature sets based on the linguistic intuition for specific domains) of the feature-based method.

3 Word Embeddings & Tree Kernels

In this section, we first give the intuition that guides us in designing the proposed methods. In particular, one limitation of the syntactic semantic tree kernel presented in Plank and Moschitti (2013) (§2.1) is that semantics is highly tied to syntax (the PET trees) in the kernel computation, limiting the generalization capacity of semantics to the extent of syntactic matches. If two relation mentions have different syntactic structures, the two relation mentions will not match, although they share the same semantic representation and express the same relation class. For instance, the two fragments "*Tom is the CEO of the company*" and "*the company, headed by Tom*" express the same relationship between "*Tom*" and "*company*" based on the semantics of their context words, but cannot be matched in SSTK as their syntactic structures are different. In such a case, it is desirable to have a representation of relation mentions that is grounded on the semantics of the context words and reflects the latent semantics of the whole relation mentions. This representation is expected to be general enough to be effective on different domains. Once the semantic representation of relation mentions is established, we can use it in conjunction with the traditional tree kernels to extend their coverage. The benefit is mutual as both semantics and syntax help to generalize relation mentions to improve the recall, but also constrain each other to support precision. This is the basic idea of our approach, which we compare to the previous methods.

3.1 Methods

We propose to utilize word embeddings of the context words as the principal components to obtain semantic representations for relation mentions in the tree kernel-based methods. Besides more traditional approaches to exploit word embeddings, we investigate representations that go beyond the word level and use compositionality embeddings for domain adaptation for the first time.

In general, suppose we are able to acquire an additional real-valued vector V_i from word embeddings to semantically represent a relation mention R_i (along with the PET tree T_i), leading to the new representation of $R_i = (T_i, V_i)$. The new kernel function in this case is then defined by:

$$K_{new}(R_i, R_j) = (1 - \alpha)\text{SSTK}(T_i, T_j) + \alpha K_{vec}(V_i, V_j)$$

where $K_{vec}(V_i, V_j)$ is some standard vector kernel like the polynomial kernels. α is a trade-off parameter and indicates whether the system attributes more weight to the traditional SSTK or the new semantic kernel K_{vec}.

In this work, we consider the following methods to obtain the semantic representation V_i from the word embeddings of the context words of R_i (assuming d is the dimensionality of the word embeddings):

HEAD: V_i = the concatenation of the word embeddings of the two entity mention heads of R_i. This representation is inherited from Nguyen and Grishman (2014) that only examine embeddings at the word level separately for the feature-based method without considering the compositionality embeddings of relation mentions. The dimensionality of HEAD is $2d$.

According to the principle of compositionality (Werning et al., 2006; Baroni and Zamparelli, 2010; Paperno et al., 2014), the meaning of a complex expression is determined by the meanings of its components and the rules to combine them. We study the following two compositionality embeddings for relation mentions that can be generated from the embeddings of the context words:

PHRASE: V_i = the mean of the embeddings of the words contained in the PET tree T_i of R_i. Although this composition is simple, it is in fact competitive to the more complicated methods based on recursive neural networks (Socher et al., 2012b; Blacoe and Lapata, 2012; Sterckx et al., 2014) on representing phrase semantics.

TREE: This is motivated by the training of recursive neural networks (Socher et al., 2012a) for semantic compositionality and attempts to aggregate the context words embeddings syntactically. In particular, we compute an embedding for every node in the PET tree in a bottom-up manner. The embeddings of the leaves are the embeddings of the words associated with them while the embeddings of the internal nodes are the means of the embeddings of their children nodes. We use the embeddings of the root of the PET tree to represent the relation mention in this case. Both PHRASE and TREE have d dimensions.

It is also interesting to examine combinations of these three representations (cf., Table 1).

SIM: Finally, for completeness, we experiment with a more obvious way to introduce word embeddings into tree kernels, resembling more closely the approach of Plank and Moschitti (2013). In particularly, the SIM method simply replaces the similarity scores between word pairs obtained from LSA by the cosine similarities between the word embeddings to be used in the SSTK kernel.

4 Experiments

4.1 Dataset, Resources and Parameters

We use the word clusters trained by Plank and Moschitti (2013) on the ukWaC corpus (Baroni et al., 2009) with 2 billion words, and the C&W word embeddings from Turian el al. (2010)[2] with 50 dimensions following Nguyen and Grishman (2014). In order to make the comparisons compatible, we introduce word embeddings into the tree kernel by extending the package provided by Plank and Moschitti (2013), which uses the Charniak parser to obtain the constituent trees, the SVM-light-TK for the SSTK kernel in SVM, the directional relation classes, etc. We utilize the default vector kernel in the SVM-light-TK package (`d=3`). For the feature-based method, we apply the MaxEnt classifier in the MALLET[3] package with the L2 regularizer on the hierarchical architecture for relation extraction as in Nguyen and Grishman (2014).

Following prior work, we evaluate the systems on the ACE 2005 dataset which involves 6 domains: broadcast news (bn), newswire (nw), broadcast conversation (bc), telephone conversation (cts), weblogs (wl) and usenet (un). The union of **bn** and **nw** (**news**) is used as the source domain while **bc**, **cts** and **wl** play the role of the target domains. We take half of bc as the only target development set, and use the remaining data and domains for testing. The dataset partition is exactly the same as in Plank and Moschitti (2013). As described in their paper, the target domains quite differ from the source domain in the relation distributions and vocabulary.

4.2 Word Embeddings for Tree Kernel

We investigate the effectiveness of different semantic representations (§3.1) in tree kernels by taking the PET tree as the baseline[4], and evaluate the performance of the representations when combined with the baseline on the bc development set.

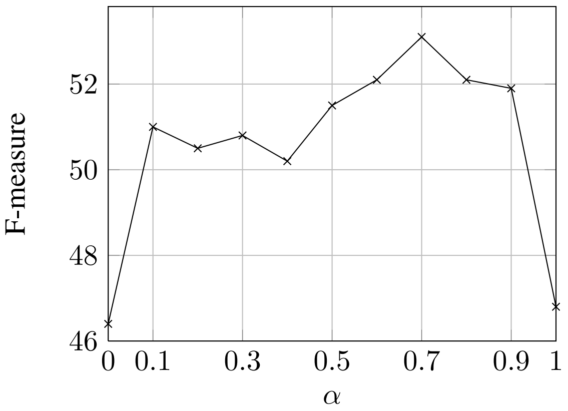

Figure 1: α vs F-measure on PET+HEAD+PHRASE

Method	P	R	F1
PET (Plank and Moschitti, 2013)	52.2	41.7	46.4
PET+SIM	39.4	37.2	38.3
PET+HEAD	60.4	44.9	51.5
PET+PHRASE	58.4	40.7	48.0
PET+TREE	59.8	42.2	49.5
PET+HEAD+PHRASE	63.2	46.2	**53.4**
PET+HEAD+TREE	61.0	45.7	52.3
PET+PHRASE+TREE	59.2	42.4	49.4
PET+HEAD+PHRASE+TREE	60.8	45.2	51.9

Table 1: Performance on the bc dev set for PET. Best combination (HEAD+PHRASE) is denoted WED in Table 2

Table 1 shows the results. The main conclusions include:

(i) The substitution of LSA similarity scores with the word embedding cosine similarities (SIM) does not help to improve the performance of the tree kernel method.

(ii) When employed independently, both the word level embeddings (HEAD) and the compositionality embeddings (PHRASE, TREE) are effective for the tree kernel-based method on DA for RE, showing a slight advantage for HEAD.

(iii) Thus, the compositionality embeddings PHRASE and TREE seem to capture different information with respect to the word level embeddings HEAD. We expect the combination of HEAD with either PHRASE or TREE to further improve performance. This is the case when adding one of them at a time. PHRASE and TREE seem to capture similar information, combining all (last row in Table 1) is not the overall best system. The best performance is achieved when the HEAD and PHRASE embeddings are utilized at

12	PET+PET_WC+PET_LSA+WED	55.0	48.8	51.7	58.5	47.3	**52.3**	52.6	38.8	44.7	42.3	38.9	**40.5**

Table 2: In-domain (first column) and out-of-domain performance (columns two to four) on ACE 2005. Systems of the rows not in gray come from Plank and Moschitti (2013) (the baselines). WED means HEAD+PHRASE.

the same time, reaching an F1 of 53.4% (compared to 46.4% of the baseline) on the development set.

The results in Table 1 are obtained using the trade-off parameter $\alpha = 0.7$. Figure 1 additionally shows the variation of the performance with changing α (for the best system on dev, i.e., for the representation PET+HEAD+PHRASE). As we can see, the performance for $\alpha > 0.5$ is in general better, suggesting a preference for the semantic representation over the syntactic representation in DA for RE. The performance reaches its peak when the suitable amounts of semantics and syntax are combined (i.e, $\alpha = 0.7$).

In the following experiments, we use the embedding combination (HEAD+PHRASE) with $\alpha = 0.7$ for the tree kernels, denoted WED.

4.3 Domain Adaptation Experiments

In this section, we examine the semantic representation for DA of RE in the tree kernel-based method. In particular, we take the systems using the PET trees, word clusters and LSA in Plank and Moschitti (2013) as the baselines and augment them with the embeddings WED = HEAD+PHRASE. We report the performance of these augmented systems in Table 2 for the two scenarios: (i) in-domain: both training and testing are performed on the source domain via 5-fold cross validation and (ii) out-of-domain: models are trained on the source domain but evaluated on the three target domains. To summarize, we find:

First, word embeddings seem to subsume word clusters in the tree kernel-based method (comparing rows 2 and 4, and except domain cts) while word embeddings and LSA actually encode different information (comparing rows 2 and 6 for the out-of-domain experiments) and their combination would be helpful for DA of RE.

Second, regarding composite kernels, given word embeddings, the addition of the baseline kernel (PET) is in general useful for the augmented kernels PET_WC and PET_LSA (comparing rows 4 and 8, rows 6 and 10) although it is less pronounced for PET_LSA.

Third and most importantly, for all the systems in Plank and Moschitti (2013) (the baselines) and for all the target domains, whether word clusters and LSA are utilized or not, we consistently witness the performance improvement of the baselines when combined with word embedding (comparing systems X and X+WED where X is some baseline system). The best out-of-domain performance is achieved when word embeddings are employed in conjunction with the composite kernels (PET+PET_WC+PET_LSA for the target domains bc and wl, and PET+PET_WC for the target domain cts). To be more concrete, the best system with word embeddings (row 12 in Table 2) significantly outperforms the best system in Plank and Moschitti (2013) with $p < 0.05$, an improvement of 3.7%, 1.1% and 2.7% on the target domains bc, cts and wl respectively, demonstrating the benefit of word embeddings for DA of RE in the tree kernel-based method.

4.4 Tree Kernel-based vs Feature-based DA of RE

This section aims to compare the tree kernel-based method in Plank and Moschitti (2013) and the feature-based method in Nguyen and Grishman (2014) for DA of RE on the same settings (i.e, same dataset partition, the same pre-processing

Table 3: Tree kernel-based in Plank and Moschitti (2013) vs feature-based in Nguyen and Grishman (2014). All the comparisons between the tree kernel-based method and the feature-based method in this table are significant with $p < 0.05$.

procedure, the same model of directional relation classes, the same PET trees for tree kernels and feature extraction, the same word clusters and the same word embeddings). We first evaluate the feature-based system with different combinations of embeddings (i.e, HEAD, PHRASE and TREE) on the bc development set. Based on the evaluation results, we then discuss the effect of the semantic representations on the feature-based system and the tree kernel-based system, and then compare the performance of the two methods when they are augmented with their best corresponding embedding combinations.

Table 4: Performance of the feature-based method (dev).

Table 4 presents the evaluation results on the bc development for the feature-based system where B is the baseline feature set consisting of FET and word clusters (WC) (Nguyen and Grishman, 2014).

The Role of Semantic Representations Considering Table 4 for the feature-based method and Table 1 for the tree kernel-based method, we see that when combined with the HEAD embeddings, the compositionality embedding TREE is more effective for the feature-based method, in contrast to the tree kernel-based method, where the PHRASE embeddings are better. This can be partly explained by the fact that the tree kernel-based method emphasizes the syntactic structure of the relation mentions, while the feature-based method exploits the sequential structure more. Consequently, the syntactic semantics of TREE are more helpful for the feature-based method, whereas the sequential semantics of PHRASE are more useful for the tree kernel-based method.

Performance Comparison The three best embedding combinations for the feature-based system in Table 4 are (listed by performance order): (HEAD), (HEAD+TREE) and (TREE), where (HEAD) is also the best word level method employed in Nguyen and Grishman (2014). In order to enable a fairer and clearer evaluation, when doing comparison, we use both the three best embedding combinations in the feature-based method and the best embedding combination (HEAD+PHRASE) in the tree kernel-based method. In the tree kernel-based method, we do not employ the LSA information as it comes in the form of similarity scores between pairs of words, and it is not clear how to encode this information into the feature-based method effectively. Finally, we utilize the composite kernel for its demonstrated effectiveness in Section 4.3.

The most important observation from the experimental results (shown in Table 3) is that over all the target domains, the tree kernel-based system is significantly better than the feature-based systems with $p < 0.05$ (assuming the same resources and settings mentioned above). In fact, there are large margins between the tree kernel-based and the feature-based methods in this case (i.e, about 3.7% for bc, 3.1% for cts and 2.3% for wl), clearly confirming the hypothesis about the advantage of the tree kernel-based method over the feature-based method on DA for RE in Section 2.3.

5 Analysis

This section analyzes the output of the systems to gain more insights into their operation.

Word Embeddings for the Tree-kernel based Method We focus on the comparison of the best model in Plank and Moschitti (2013) (row 11 in Table 2) (called P) with the same model but augmented with the embedding WED (row 12 in Tabel 2) (called P+WED). One of the most interesting insights is that the embedding WED helps to semantically generalize the phrases connecting the two target entity mentions beyond the syntactic constraints. For instance, model P fails to discover the relation between "*Chuck Hagel*" and "*Vietnam*" in the sentence (of the target domain bc): "*Sergeant Chuck Hagel was seriously wounded twice in Vietnam.*" (i.e, it returns the NONE relation as the prediction) as the substructure associated with "*seriously wounded twice*" does not appear with any relation in the source domain. Model P+WED, on the other hand, correctly predicts the PHYS (Located) relation between the two entities as the PHRASE embedding of "*Chuck Hagel was seriously wounded twice in Vietnam.*" (phrase X1) is very close to the embedding of the source domain phrase: "*Stewart faces up to 30 years in prison*" (phrase X2) (annotated with the PHYS relation between "*Stewart*" and "*prison*").

In fact, X2 is only the 9th closest phrase in the source domain of X1. The closest phrase of X1 in the source domain is X3: the phrase between "*Iraqi soldiers*" and "*herself*" in the sentence "*The Washington Post is reporting she shot several* ***Iraqi soldiers before she was captured and she was shot herself****, too.*". However, as the syntactical structure of X1 is more similar to X2's, and is remarkably different from X3 as well as the other closest phrases (ranked from 2nd to 8th), the new kernel function K_{new} would still prefer X2 due to its trade-off between syntax and semantics.

Tree Kernel-based vs Feature-based From the analysis of the systems in Table 3, we find that, among others, the tree kernel-based method improves the precision significantly via the semantic and syntactic refinement it maintains. Let us consider the following phrase of the target domain bc: "*troops have dislodged stubborn Iraqi soldiers*" (called Y1). The feature-based systems in Table 3 incorrectly predict the ORG-AFF relation (Employment or Membership) between "*Iraqi soldiers*" and "*troops*". This is mainly due to the high weights of the features linking the words "*troop*" and "*soldiers*" with the relation type ORG-AFF in the feature-based models, which is, in turn, originated from the high correlation of these words and the relation type in the training data of the source domain (domain bias). The tree kernel-based model in Table 3 successfully recognizes the NONE relation in this case. A closer examination shows that the phrase with the closest embedding to Y1 in the source domain is Y2: "*Iraqi soldiers abandoned their posts*",[5] which is annotated with the NONE relation between "*Iraqi soldiers*" and "*their posts*". As the syntactic structure of Y2 is also very similar to Y1, it is not surprising that Y1 is closest to Y2 in the new kernel function, consequently helping the tree kernel-based method work correctly in this case.

6 Related work

Word embeddings are only applied to RE recently. Socher et al. (2012b) use word embeddings as input for matrix-vector recursive neural networks in relation classification while Zeng et al. (2014), and Nguyen and Grishman (2015) employ word embeddings in the framework of convolutional neural networks for relation classification and extraction, respectively. Sterckx et al. (2014) utilize word embeddings to reduce noise of training data in distant supervision. Kuksa et al. (2010) present a string kernel for bio-relation extraction with word embeddings, and Yu et al. (2014; 2015) study the factor-based compositional embedding models. However, none of this work examines word embeddings for tree kernels as well as domain adaptation as we do.

Regarding DA, in the unsupervised DA setting, Huang and Yates (2010) attempt to learn multidimensional feature representations while Blitzer et al. (2006) introduce structural correspondence learning. Daumé (2007) proposes an easy adaptation framework (EA) while Xiao and Guo (2013) present a log-bilinear language adaptation technique in the supervised DA setting. Unfortunately, all of this work assumes some prior (in the form of either labeled or unlabeled data) on the target domains for the sequential labeling tasks, in contrast to our single-system unsupervised DA setting for relation extraction. An alternative method that is also popular to DA is instance weighting (Jiang and Zhai, 2007b). However, as shown by Plank and Moschitti (2013), instance weighting is not

[5] The full sentence is: "*After today's air strikes, Iraqi soldiers abandoned their posts and surrendered to Kurdish fighters.*".

very useful for DA of RE.

7 Conclusion

In order to improve the generalization of relation extractors, we propose to augment the semantic syntactic tree kernels with the semantic representation of relation mentions, generated from the word embeddings of the context words. The method demonstrates strong promise for the DA of RE, i.e, it significantly improves the best system of Plank and Moschitti (2013) (up to 7% relative improvement). Moreover, we perform a compatible comparison between the tree kernel-based method and the feature-based method on the same settings and resources, which suggests that the tree kernel-based method (Plank and Moschitti, 2013) is better than the feature-based method (Nguyen and Grishman, 2014) for DA of RE. An error analysis is conducted to get a deeper comprehension of the systems. Our future plan is to investigate other syntactic and semantic structures (such as dependency trees, abstract meaning representation etc) for DA of RE, as well as continue the comparison between the kernel-based method and the feature-based method when they are allowed to exploit more resources.

Abstract

In the current fast-paced world, people tend to possess limited knowledge about things from the past. For example, some young users may not know that Walkman played similar function as iPod does nowadays. In this paper, we approach the *temporal correspondence problem* in which, given an input term (e.g., *iPod*) and the target time (e.g. 1980s), the task is to find the counterpart of the query that existed in the target time. We propose an approach that transforms word contexts across time based on their neural network representations. We then experimentally demonstrate the effectiveness of our method on the New York Times Annotated Corpus.

1 Introduction

What music device 30 years ago played similar role as iPod does nowadays? Who are today's Beatles? Who was a counterpart of President Chirac in 1988? These and many other similar questions may be difficult to answer by average users (especially, by young ones). This is because people tend to possess less knowledge about the past than about the contemporary time.

In this work we propose an effective method to solve the problem of finding counterpart terms across time. In particular, for an input pair of a term (e.g., *iPod*) and the target time (e.g. 1980s), we find the corresponding term that existed in the target time (*walkman*). We consider temporal counterparts to be terms which are semantically similar, yet, which existed in different time.

Knowledge of temporal counterparts can help to alleviate the problem of terminology gap for users searching within temporal document collections such as archives. For example, given a user's query and the target time frame, a new modified query that represents the same meaning could be suggested to improve search results. Essentially, it would mean letting searchers use the knowledge they possess on the current world to perform search within unknown collections such as ones containing documents from the distant past. Furthermore, solving temporal correspondence problem can help timeline construction, temporal summarization, reference forecasting and can have applications in education.

The problem of temporal counterpart detection is however not trivial. The key difficulty comes from the change of the entire context that results in low overlap of context across time. In other words, it is difficult to find temporal counterpart terms by directly comparing context vectors across time. This fact is nicely portrayed by the Latin proverb: "omnia mutantur, nihil interit" (in English: "everything changes, nothing perishes") which indicates that there are no completely static things, yet, many things and concepts are still similar across time. Another challenge is the lack of training data. If we have had enough training pairs of input terms and their temporal counterparts, then it would have become possible to represent the task as a typical machine learning problem. However, it is difficult to collect multiple training pairs over various domains and for arbitrary time.

In view of the challenges mentioned above, we propose an approach that transforms term representations from one vector space (e.g., one derived from the present documents) to another vector space (e.g., one obtained from the past documents). Terms in both the vector spaces are represented by the distributed vector representation (Mikolov et al. 2013a; Mikolov et al. 2013c). Our method then matches the terms by comparing their relative positions in the vector spaces of different time periods alleviating the problem of low overlap between word contexts over time. It also does not require to manually prepare seed pairs of temporal counterparts. We further improve this method by automatically generating reference points that more precisely represent target terms in the form of local graphs. In result, our approach consists of finding *global* and *local* correspondence between terms over time.

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 645–655,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

To sum up, we make the following contributions in this paper: (1) we propose an efficient method to find temporal counterparts by transforming the representation of terms within different temporal spaces, (2) we then enhance the *global correspondence* method by considering also the local context of terms (*local correspondence*) and (3) we perform extensive experiments on the New York Times Annotated Corpus (Sandhaus, 2008), including the search from the present to the past and vice versa, which prove the effectiveness of our approach.

2 Global Correspondence Across Time

Let the *base time* denoted as T^B mean the time period associated with the input term and let the *target time*, T^T, mean the time period in which we want to find this term's counterparts. Typically, for users, the base time is the present time and the target time is some selected time period in the past. Note however, that we do not impose any restriction on the order and the distance of the both times. Hence, it is possible to search for present counterparts of terms that existed in the past.

In our approach we first represent all the terms in the base time and in the target time within their respective semantic vector spaces, χ^B and χ^T. Then, we construct a transformation matrix to bridge the two vector spaces. Algorithm 1 summarizes the procedures needed to compute the global transformation. We will explain it in Section 2.1 and 2.2.

```
**Algorithm 1** Overview of Global Transformation
  **Input:** query $q$, base time $T^B$ and target time $T^T$
  1. Construct word representation model for
     corpus in the base time, $D(T^B)$, and in the
     target time, $D(T^T)$. (**Section 2.1**)
  2. Construct transformation matrix $M$ between
     $D(T^B)$ and $D(T^T)$ by first collecting
     **CFTs** as training pairs and then learning $M$
     using **Eq. 1**. (**Section 2.2**)
  3. Rank the words in target time by their correspondence
     scores (**Eq. 2**)
  **Output:** ranked list of temporal counterparts
```

2.1 Vector space word representations

Distributed representation of words by neural network was first proposed by Rumelhart et al. (1986). More recently, Mikolov et al. (2013a, 2013c) introduced the *Skip-gram model* which utilizes a simplified neural network architecture for learning vector representations of words from unstructured text data. We apply this model due to its advantages: (1) it can capture precise semantic word relationships; (2) due to the simplified neural network architecture, the model can easily scale to millions of words. After applying the Skip-gram model, the documents in the base time, $D(T^B)$, are converted to a $m\times p$ matrix where n is the vocabulary size and p are the dimensions of feature vectors. Similarly, the documents in the target time, $D(T^T)$, are represented as a $n\times q$ matrix (as shown in Fig. 1).

Figure 1: Word vector representations for the base and the target time.

2.2 Transformation across vector spaces

Our goal is to compare words in the base time and the target time in order to find temporal counterparts. However, it is impossible to directly compare words in two different semantic vector spaces, as the features in both spaces have no direct correspondence between each other (as can be seen in Fig. 1). To solve this problem, we propose to train a transformation matrix in order to build the connection between different vector spaces. The key idea is that the relative positions of words in each vector space should remain more or less stable. In other words, a temporal counterpart term should have similar relative position in its own vector space as the position of the queried term in the base time space. Fig. 2 conceptually portrays this idea as the correspondence between the context of *Walkman* and the context of *iPod* (only two dimensions are shown for simplicity).

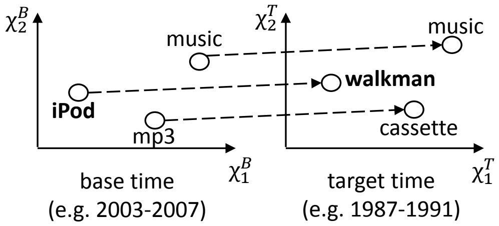

Figure 2: Conceptual view of the across-time transformation by matching similar relative geometric positions in each space.

Our task is then to train the transformation matrix to automatically "rotate" the base vector space into the target vector space. Suppose we have K pairs of temporal counterparts $\{(\omega_1, w_1),\ldots,(\omega_k, w_k,)\}$ where ω_i is a base time term and w_i is its counterpart in the target time. Then the transformation matrix $\boldsymbol{M}$ can be computed by minimizing the differences between $\boldsymbol{M}\cdot\omega_i$ and w_i as given in Eq. 1. The latter part of Eq. 1 is added as regularization to overcome the problem of overfitting. Intuitively, matrix M is obtained by making sure that the sum of Euclidean 2-norms between transformed query vectors and their counterparts is minimal on K seed query-counterpart pairs. Eq.1 is used for solving regularized least squares problem (γ equals to 0.02).

$$M = \arg\min_{M} \sum_{i=1}^{K} \left\| M \cdot \omega_i - w_i \right\|_2^2 + \gamma \left\| M \right\|_2^2 \qquad (1)$$

However, as mentioned before, the other challenge is that the training pairs are difficult to be obtained. It is non-trivial to prepare large enough training data that would also cover various domains and any possible combinations of the base and target time periods. We apply here a simple trick that performs reasonably well. We select terms that (a) have the same syntactic forms in the base and the target time periods and (b) are frequent in the both time periods. Such *Common Frequent Terms (CFT*s*)* are then used as the training data. Essentially, we assume here that very frequent terms (e.g., *man*, *women*, *water*, *dog*, *see*, *three*) change their meanings only to small extent. The reasoning is that the more frequently the word is used, the harder is to change its dominant meaning (or the longer time it takes to make the meaning shift) as the word is commonly used by many people. The phenomenon that words used more often in everyday language had evolved more slowly has been observed in several languages including English, Spanish, Russian and Greek (Pargel et al., 2007; Lieberman et al. 2007). Then, using the common frequent terms as the training pairs, we solve Eq. 1 as the least squares problem. Note that the number of *CFT*s is heuristically decided. In Sec. 5 we discuss transformation performance with regards to different numbers of *CFT*s.

After obtaining matrix $\boldsymbol{M}$, we can then transform the base time term, q, first by multiplying its vector representation with the transformation matrix $\boldsymbol{M}$, and then by calculating the cosine similarity between such transformed vector and the vectors of all the terms in the target time. We call the result of this similarity comparison the *correspondence score* between the input term q in the base time and a given term w in the target time (see Eq. 2). A term which has the highest correspondence score could be then considered as temporal counterpart of q.

$$Correspondence(q, w) = \cos(M \cdot q, w) \qquad (2)$$

3 Local Correspondence across Time

The method described above computes "global similarity" between terms across time. In result, the discovered counterparts can be similar to the query term for variety of reasons, some of which may not always lead to the best results. For instance, the global transformation finds *VCR* as the temporal counterpart of *iPod* in 1980s simply because both of them can have recording and playback functions. *Macintosh* is another term judged to be strongly corresponding to *iPod* since both are produced by *Apple*. Clearly, although *VCR* and *Macintosh* are somewhat similar to *iPod*, they are far from being its counterparts. The global transformation, as presented in the previous section, may thus fail to find correct counterparts due to neglecting fundamental relations between a query term and its context.

Inspired by these observations, we propose another method for leveraging the informative context terms of an input query term called *reference points*. They are used to help mapping the query to its correct temporal counterpart by considering the relation between the query and the reference points. We call this kind of similarity matching as *local correspondence* in contrast to *global correspondence* described in Sec. 2. In the following sub-sections, we first introduce the desired characteristics of the *reference points* and we then propose three computation methods for selecting them. Finally, we describe how to find temporal counterparts using the selected reference points. Algorithm 2 shows the process of computing the local transformation.

Algorithm 2 Overview of Local Transformation

```
Input: query $q$, base time $T^B$ and target time $T^T$
1. Construct the local graph of $q$ by detecting the reference points in the context of $q$. (Section 3.1)
2. Compute similarity of the local graph of $q$ with all the local graphs of candidate temporal counterparts in the target time. (Section 3.2)
3. Rank the candidate temporal counterparts in the target time by graph similarity score (Eq. 4).
Output: ranked list of temporal counterparts
```

3.1 Reference points detection

Reference points are terms in the query's context which help to build connection between the query and its temporal counterparts. Reference points should have at least some of the following characteristics: (a) have high relation with the query (b) be sufficiently general and (c) be independent from each other.

Note that it does not mean that the selected reference point should have exactly same surface form across time. Let us consider the previous example query *iPod* and 1980s as the target time. The term *music* could be a candidate reference point for this query. Its temporal counterpart has exactly the same syntax form in the target time (*music*). However, *mp3* could be another reference point. Even though *mp3* did not exist in 1980s, it can still be referred to storage devices at the target time such as *cassette* or *disk* helping thus to find the correct counterparts of *iPod*, that is, *walkman* and *CD player*.

Since different reference points will lead to different answers, we propose three methods for selecting the reference points. Each one considers the previously mentioned characteristics of reference points to different extent. Note that, if necessary, the choice of the references points can be left to users.

Term co-occurrence. The first approach satisfies the reference points' characteristics of being related to the query. To select reference points using this approach we rank context terms by multiplying two factors: *tf(c)* and *relatedness(q,c)*, where *tf(c)* is the frequency of a context term *c*, while *relatedness(q,c)* is the relation strength of *q* and *c* measured by the χ^2 test. The test is conducted based on the hypothesis that $P(c|q)=P(c|\bar{q})$, according to which the term *c* has the same probability of occurring in documents containing query *q* and in the documents not containing *q*. We then use the inverse of the p-value obtained from the test as *relatedness(q,c)*.

Lexico-syntactic patterns. As the second approach we propose using hypernyms of terms. This corresponds to the characteristic of reference points to be general words. General terms are preferred rather than specific or detailed ones since the former are more probable to be associated with correct temporal counterparts[1]. This is because detailed or specific terms are less likely to have corresponding terms in the target time. To detect hypernyms on the fly, we adopt the method proposed by Ohshima et al. (2010) that uses bi-directional lexico-syntactic patterns due to its high speed and the lack of requirements for using external ontologies. The latter is important since, to the best of our knowledge, there are no ready ontology resources for arbitrary periods in the past (e.g., there seems to be no Wordnet for the past).

Semantic clustering. The last method chooses reference points from clusters of context terms. The purpose of applying clustering is to avoid choosing semantically similar reference points. Clustering helps to select typical terms from different sematic clusters to provide diverse informative context.

For grouping the context terms we utilize the bisecting k-means algorithm. It is superior over k-means and the agglomerative approach (Steinbach et al., 2000) in terms of accuracy. The procedure of bisecting k-means is to, first, select a cluster to split and then to utilize the basic k-means to form two sub-clusters. These two steps are repeated until the desired number of clusters is obtained. The distance between any two terms w_1, w_2 is the inverse of cosine similarity between their vector representations.

$$Dist(w_1, w_2) = 1 - \cos(w_1, w_2) \qquad (3)$$

3.2 Local graph matching

Formulation. The local graph of query *q* is a star shaped graph, denoted as $S_q^{F_B}$, in which *q* is the internal node, and the set of reference points, $F_B = \{f_1, f_2, ..., f_u\}$, are leaf nodes where *u* is the number of reference points. Our objective is to find a local graph $S_w^{F_T}$ in the target vector space that is most similar to $S_q^{F_B}$ in the base vector space. *w* denotes here the temporal counterpart of *q* and F_T is the set of terms in the target vector space that corresponds to F_B.

Algorithm. *Step (1)*: to compare the similarity between two graphs in different vector spaces, every node (i.e. term) in $S_q^{F_B}$ is required to be transformed first to allow for comparison under the same vector space. So the transformed vector representation of *q* becomes $\boldsymbol{M}\cdot q$ and F_B is transformed to $\{\boldsymbol{M}\cdot f_1, \boldsymbol{M}\cdot f_2 ..., \boldsymbol{M}\cdot f_u\}$ (recall that $\boldsymbol{M}$ is the transformation matrix). *Step (2)*: for each node in $S_q^{F_B}$, we then choose the top *k* candidate terms with the highest correspondence score in the target space. Note that we would need to perform $k\cdot k^u$

[1] We have experimented with hyponyms and coordinate terms used as reference points and found the results are worse than when using hypernyms.

combinations of nodes (or candidate local graphs) in total, to find the best graph with the highest graph similarity. The computation time becomes then an issue as the number of comparisons grows in polynomial way with the increase in the number of candidate terms. However, we manage to reduce the number of combinations to $k{\cdot}k{\cdot}u$ by assuming the reference points be independent of each other. Then, for every selected candidate temporal counterpart, we only choose the set of corresponding terms F_T which maximizes the current graph similarity. By default we set k equal to 1000. The process is shown in Algorithm 3.

Algorithm 3 Local Graph Matching

```
Input: local graph of $q$, $S_q^{F_B}$
$W$ = top $k$ corresponding terms of $q$ (by Eq. 2)
$FF$ = {top $k$ corresponding terms of each $f$ in reference points $F_B$={ $f_0, f_1, ..., f_u$}} (by Eq. 2)
for $w$ = $W[1:k]$ do:
    sum_cos = 0  # total graph similarity score
    for $F$ = $FF[1:u]$ do:
        max_cos = 0 # current maximum similarity
        for $c$ = $F[1:k]$ do:
            find $c$ which maximizes current graph similarity
        end for
        sum_cos += max_cos
    end for
end for
sort $W$ by sum_cos of each $w$ in $W$.
Output: sorted $W$ as ranked list of temporal counterparts
```

Graph similarity computation. To compute the similarity of two star shaped graphs, we take both the *semantic* and *relational similarities* into consideration. Fig. 3 conceptually portrays this idea. Since all the computation is done under the same vector space (after transformation), the semantic meaning is represented by the absolute position of the term, that is, by its vector representation in the vector space. On the other hand, the relation is described by the difference of two term vectors. Finally, the graph similarity function $g(S_q^{F_B},S_w^{F_T})$ is defined as the combination of the *relational similarity function*, $h(S_q^{F_B},S_w^{F_T})$, and *semantic similarity function*, $z(S_q^{F_B},S_w^{F_T})$, as follows:

$$\begin{aligned} g(S_q^{F_B}, S_w^{F_T}) &= (1-\lambda)\cdot h(S_q^{F_B}, S_w^{F_T}) + \lambda\cdot z(S_q^{F_B}, S_w^{F_T}) \\ &= (1-\lambda)\cdot \sum_{f_B\in F_B,\, f_T\in F_T} \max(R_q^{f_B}\cdot R_w^{f_T}) \\ &+ \lambda\cdot\max\Big(\sum_{f_B\in F_B,\, f_T\in F_T}\cos(f_B, f_T) + \cos(q,w)\Big) \end{aligned} \tag{4}$$

where $R_q^{f_B}$ is the difference of vectors between q and f_B in F_B represented as [q-f_B]. $R_w^{f_T}$ is the difference of vectors between w and f_T in F_T, [w-f_T], where f_T is selected from k candidates corresponding terms of f_B. f_T maximizes the cosine similarity between [q- f_B] and [w- f_T]. λ is set to 0.5 by default. Intuitively, $S_q^{F_B}$ is a graph composed of query and its reference points, while $S_w^{F_T}$ is a graph containing candidate word w and its reference points. The first maximum in Eq. 4 finds for each reference point in the base time, f_B, the top-k candidate terms corresponding to f_B in the target time. Next, it finds within k such f_T that similarity between [q- f_B] and [w- f_T] is maximum (relational similarity). The second maximum in Eq. 4 is same as the first one with the exception that it computes the semantic similarity instead of the relational similarity. The two summations in Eq. 4 aggregate both the similarity scores over all the reference points.

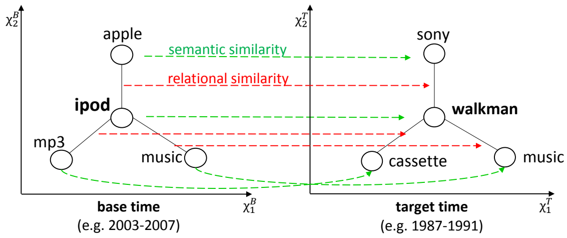

Figure 3: The concept of computing semantic and relational similarity in matching local graphs.

4 Experimental Setup

4.1 Training sets

For the experiments we use the New York Times Annotated Corpus (Sandhaus, 2008). This dataset contains over 1.8 million newspaper articles published between 1987 and 2007. We first divide it into four parts according to article publication time: [1987-1991], [1992-1996], [1997-2001] and [2002-2007]. Each time period contains then around half a million articles. We next train the model of distributed vector representation separately for each time period. The vocabulary size of the entire corpus is 360k, while the vocabulary size of each time period is around 300k.

In the experiments, we first focus on the pair of time periods separated by the longest time gap, that is, [2002, 2007] as the base time and [1987, 1991] as the target time. We also repeat the experiment using more recent target time: [1992, 1996].

q [2002,2007]	*tc* [1987,1991]	BOW (baseline)	LSI-Com (baseline)	LSI-Tran (baseline)	GT (proposed)	LT-Cooc (proposed)	LT-Lex (proposed)	LT-Clust (proposed)

Table 1: Example results where *q* is the input term and *tc* is the matching temporal counterpart. The numbers are the ranks of the correct temporal counterpart in the results ranked by each method. Since we output only the top 1000 results, ranks lower than 1000 are represented as 1000+.

4.2 Test sets

As far as we know there is no standard test bench for temporal correspondence finding. We then had to manually create test sets containing queries in the base time and their correct temporal counterparts in the target time. In this process we used external resources including the Wikipedia, a Web search engine and several historical textbooks. The test terms cover three types of entities: persons, locations and objects.

The examples of the test queries and their temporal counterparts for [1987, 1991] are shown in Table 1 where *q* denotes the input term and *tc* is the correct counterpart. Note that the expected answer is not required to be single neither exhaustive. For example, there can be many answers for the same query term, such as *letter*, *mail*, *fax*, all being commonly used counterparts in 1980s for *email*. Furthermore, as we do not care for recall in this research, we do not require all the correct counterpart terms to be found. In total, there are 95 pairs of terms (query and its counterpart) resulting from 54 input query terms for the task of mapping [2002, 2007] with [1987, 1991], and 50 term pairs created from 25 input query terms for matching [2002, 2007] and [1992, 1996].

4.3 Evaluation measures and baselines

We use the *Mean Reciprocal Rank* (*MRR*) as a main metric to evaluate the ranked search results for each method. MRR is expressed as the mean of the inverse ranks for each test where a correct result appears. It is calculated as follows:

$$MRR = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{rank_i} \tag{5}$$

where $rank_i$ is the rank of a correct counterpart at the *i-th* test. *N* is the number of query-answer pairs. MRR's values range between [0,1]. The higher the value, the more correct the method is. Besides MRR, we also report precision @1, @5, @10 and @20. They are equal to the rates of tests in which the correct counterpart term *tc* was found in the top 1, 5, 10 and 20 results, respectively.

Baselines. We prepare three baselines:

(1) ***Bag of words approach*** (***BOW***) without transformation: this method directly compares the context of the query in the base time with the context of the candidate term in the target time. We use it to examine whether the distributed vector representation and transformation are necessary.

(2) ***Latent Semantic Indexing (LSI)*** **without transformation (LSI-Com)**: we first merge the documents in the base time and the documents in the target time. Then, we train LSI (Deerwester, 1988) on such combined collection to represent each term by the same distribution of detected topics. We next search for the terms that exist in the target period and that are also semantically similar to the queried terms by comparing their vector

representations. The purpose of using LSI-Com is to check the need for the transformation over time.

(3) ***Latent Semantic Indexing*** (***LSI***) **with transformation** (**LSI-Tran**): we train two LSI models separately on the documents in the base time and the documents in the target time. Then we train the *transformation matrix* in the same way as we did for our proposed methods. Lastly, for a given input query, we compare its transformed vector representation with terms in the target time. LSI-Tran is used to investigate if LSI can be an alternative for the vector representation under our transformation scenario.

Proposed Methods. All our methods use the neural network based term representation. The first one is the method without considering the local context graph called **GT** (see Sec. 2). By testing it we want to investigate the necessity of transforming the context of the query in the target time.

We also test the three variants of the proposed approach that applies the local graph (explained in Sec. 3). The first one, **LT-Lex**, constructs the local graph by using the hypernyms of terms. **LT-Cooc** applies term co-occurrence to select the reference points. Finally, **LT-Clust** clusters the context terms by their semantic meanings and selects the most common term from each cluster.

4.4 Parameter settings

We set the parameters as follows:
(1) *num_of_dim*: we experimentally set the number of dimensions of the Skip-gram model and the number of topics of LSI to be 200.
(2) *num_of_CFTs*: we utilize the top 5% (18k words) of Common Frequent Terms to train the transformation matrix. We have tried other numbers but we found 5% to perform best (see Fig. 4).
(3) *u*: the number of reference points (same as the number of semantic clusters) is set to be 5. According to the results, we found that increasing the number of reference points does not always improve the results. The performance depends rather on whether the reference points are general enough, as too detailed ones hurt the results.

5 Experimental Results

First, we look at the results of finding temporal counterparts in [1987, 1991]. The average scores for each method are shown in Table 2. Table 1 shows detailed results for few example queries.

The main finding is that all our methods outperform the baselines when measured by MRR and by the precisions at different ranks. In the following subsections we discuss the results in detail.

5.1 Context change over time

The first observation is that the task is quite difficult as evidenced by extremely poor performance of the bag of words approach (**BOW**). The correct answers in **BOW** approach are usually found at ranks 10k-30k (recall that the vocabulary size is 360k). This suggests little overlap in the contexts of query and counterpart terms. The fact that all our methods outperform the baselines suggests that the across-time transformation is helpful.

5.2 Using local context graph

We can observe from Table 2 that, in general, using the local context graph improves the results. The best performing approach, **LT-Lex**, improves **GT** method, which uses only global similarity matching, by 24% when measured using MRR. It increases the precision at certain levels of top ranks, especially, at the top 1, where it boosts the performance by 44%. **LT-Lex** uses the hypernyms of query as reference points in the local graph. This suggests that using generalized context terms as reference points is most helpful for finding correct temporal counterparts. On the other hand, **LT-Cooc** and **LT-Clust** usually fail to improve **GT**. It may be because the term co-occurrence and semantic clustering approaches detect less general terms that tend to capture too detailed information which is then poorly related to the temporal counterpart. For example, **LT-Cooc** detects *{music, Apple, computer, digital, iTunes}* as the reference points of the query *iPod*. While *music* is shared by *iPod*'s counterpart (*walkman*) and *Apple* can be considered analogical to *Sony*, other terms (i.e., *computer, digital, iTunes*) are rather too specific and unique for *iPod*.

5.3 Using neural network model

When comparing the results of **LSI-Com** and **LSI-Tran** in Table 2, we can see that using the *transformation* does not help LSI to enhance the performance but, on the contrary, it makes the results worse.

Method	MRR	P@1	P@5	P@10	P@20
BOW	4.1E-5	0	0	0	0
LSI-Com	0.206	15.8	27.3	29.5	38.6
LSI-Tran	0.112	7.9	13.6	21.6	22.7
GT	0.298	16.8	44.2	56.8	**73.7**
LT-Cooc	0.283	18.8	35.3	50.6	62.4
LT-Lex	**0.369**	**24.2**	**49.5**	**63.2**	71.6
LT-Clust	0.285	14.7	42.1	55.1	65.2

Table 2: Results of searching from present to past (present: 2002-2007; past: 1987-1991).

Yet, as discussed above, applying the *transformation* is good idea in the case of the Neural Network Model. We believe the reason for this is because it is difficult to perform the global transformation between topics underling the dimensions of LSI, in contrast to transforming “semantic dimensions” of Neural Network Model.

5.4 Effect of the number of CFTs

Fig. 4 shows MRR results for different numbers of *Common Frequent Terms* (*CFT*s) when applying **GT** method. Note that the level of 0.10% (the first point) corresponds to using 658 stop words as seed pairs. As mentioned before, 5% of CFTs allows to obtain the best results.

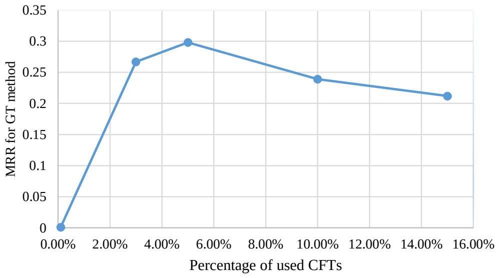

Figure 4: Results of MRR for **GT** method depending on number of used *CFT*s.

5.5 Searching from past to present

We next analyze the case of searching from the past to the present. This scenario may apply to the case of a user (perhaps, an older person) who possesses knowledge about the past term but does not know its modern counterparts.

Table 3 shows the performance. We can see that, again, all our approaches outperform all the baselines using all the measures. **LT-Lex** is the best performing approach, when measured by MRR and P@1 and P@20. **LT-Cooc** this time returns the best results at P@5 and P@10.

Method	MRR	P@1	P@5	P@10	P@20
BOW	3.4E-5	0	0	0	0
LSI-Com	0.181	13.2	19.7	28.9	35.5
LSI-Tran	0.109	5.3	17.1	21.1	23.7
GT	0.226	15.2	27.3	33.3	45.5
LT-Cooc	0.231	14.7	**30.7**	**36**	46.7
LT-Lex	**0.235**	**16.7**	28.8	31.8	**48.5**
LT-Clust	0.228	13.6	28.8	31.8	47

Table 3: Average scores of searching from past to present (present: 2002-2007; past: 1987-1991).

The objective of testing the search from the past to present is to prove our methods work in both directions. As for now, we can only conclude the performance is asymmetrical. Yet, we might speculate that, along with the increase in distance, searching from past to present could be harder due to present world becoming relatively more diverse when seen from the distant past.

5.6 Results using different time period

Finally, we perform additional experiment using another target time period [1992, 1996] to verify whether our approach is still superior on different target time. For the experiment we use the best performing baseline listed in Table 2, **LSI-Com**, and the best proposed approach, **LT-Lex**, as well as **GT**. The results are shown in Tables 4 and 5. **LT-Lex** outperforms the other baselines in both the search from the present to the past (Table 4) and from the past to the present (Table 5). Note that since the query-answers pairs for [1992, 1996] are different than ones for [1987, 1991], their results cannot be directly compared.

Method	MRR	P@1	P@5	P@10	P@20
LSI-Com	0.115	10.6	14.9	21.3	23.4
GT	0.132	8.5	27.7	40.4	53.2
LT-Lex	**0.169**	**10.6**	**34.1**	**48.9**	**55.3**

Table 4: Results of searching from present to past (present: 2002-2007; past: 1992-1996).

Method	MRR	P@1	P@5	P@10	P@20
LSI-Com	0.148	11.6	18.6	23.3	30.2
GT	0.184	11.6	23.3	30.2	44.2
LT-Lex	**0.212**	**14**	**28**	**32.6**	**44.2**

Table 5: Results of searching from past to present (present: 2002-2007; past: 1992-1996).

5.7 Confidence of Results

The approach described in this paper will always try to output some matching terms to a query in the target time period. However in some cases, no term corresponding to the one in the base time existed in the target time (e.g. when the semantic concept behind the term was not yet born or, on the contrary, it has already felt out of use). For example, junk mail may not have any equivalent in texts created around 1800s. A simple solution to this problem would be to use Eqs. 2 and 4 to serve as measures of confidence behind each result in order to decide whether the found counterparts should or not be shown to users. Note however that the scores returned by Eqs. 2 and 4 need to be first normalized according to the distance between the target time and the base time periods.

6 Related Work

Temporal changes in word meaning have been an important topic of study within historical linguistics (Aitchison, 2001; Campbell 2004; Labov, 2010; Hughes, 1988). Some researchers employed computational methods for analyzing changes in word senses over time (Mihalcea and Nastase, 2012; Kim et al., 2014; Jatowt and Duh, 2014; Kulkarni et al., 2015). For example, Mihalcea and Nastase (2012) classified words to one of three past epochs based on words' contexts. Kim et al. (2014) and Kulkarni et al. (2015) computed the degree of meaning change by applying neural networks for word representation. Jatowt and Duh (2014) used also sentiment analysis and word pair comparison for meaning change estimation. Our objective is different as we search for corresponding terms across time, and, in our case, temporal counterparts can have different syntactic forms.

Some works considered computing term similarity across time (Kalurachchi et al., 2010; Kanhabua et al. 2010; Tahmasebi et al. 2012, Berberich et al. 2009). Kalurachchi et al. (2010) proposed to discover semantically identical temporally altering concepts by applying association rule mining, assuming that the concepts referred by similar events (verbs) are semantically related. Kanhabua et al. (2010) discovered the change of terms through the comparison of temporal Wikipedia snapshots. Berberich et al. (2009) approached the problem by introducing a HMM model and measuring the across-time sematic similarity between two terms by comparing the contexts captured by co-occurrence measures. Tahmasebi et al. (2012) improved their approach by first detecting the periods of name change and then by analyzing the contexts during the change periods to find the temporal co-references of different names. There are important differences between those works and ours. First, the previous works mainly focused on detecting changes of the names of the same, single entity over time. For example, the objective was to look for the previous name of Pope Benedict (i.e. Joseph Ratzinger) or the previous name of St. Petersburg (i.e. Leningrad). Second, these approaches relied on applying the co-occurrence statistics according to the intuition that if two terms share similar contexts, then these terms are semantically similar. In our work, we do not require the context to be literally same but to have the same meaning.

Transfer Learning (Pan et al., 2010) is related to some extent to our work. It has been mainly used in tasks such as POS tagging (Blitzer et al., 2006), text classification (Blitzer et al., 2007; Ling et al., 2008; Wang et al., 2011; Xue et al., 2008), learning to rank (Cai et al., 2011; Gao et al., 2010; Wang et al., 2009) and content-based retrieval (Kato et al., 2012). The temporal correspondence problem can be also understood as a transfer learning as it is a search process that uses samples in the base time for inferring correspondent instances existing in the target time. However, the difference is that we do not only consider the structural correspondence but we also utilize the semantic similarity across time.

The idea of distance-preserving projections is also used in automatic translation (Mikolov et al., 2013b). Our research problem is however more difficult and is still unexplored. In the traditional language translation, languages usually share same concepts, while in the across-time translation concepts evolve and thus may be similar but not always same. Furthermore, the lack of training data is another key problem.

7 Conclusions and Future Work

This work approaches the problem of finding temporal counterparts as a way to build a "bridge" across different times. Knowing corresponding terms across time can have direct usage in supporting search within longitudinal document collections or be helpful for constructing evolution timelines. We first discuss the key challenge of the temporal counterpart detection – the fact that contexts of terms change, too. We then propose the global correspondence method using transformation between two vector spaces. Based on this, we then introduce more refined approach of computing the local correspondence. Through experiments we demonstrate that the local correspondence using hypernyms outperforms both the baselines and the global correspondence approach.

In the future, we plan to test our approaches over longer time spans and to design the way to automatically "explain" temporal counterparts by outputting "evidence" terms for clarifying the similarity between the counterparts.

Abstract

Identifying negative or speculative narrative fragments from fact is crucial for natural language processing (NLP) applications. Previous studies on negation and speculation identification in Chinese language suffers much from two problems: corpus scarcity and the bottleneck in fundamental Chinese information processing. To resolve these problems, this paper constructs a Chinese corpus which consists of three sub-corpora from different resources. In order to detect the negative and speculative cues, a sequence labeling model is proposed. Moreover, a bilingual cue expansion method is proposed to increase the coverage in cue detection. In addition, this paper presents a new syntactic structure-based framework to identify the linguistic scope of a cue, instead of the traditional chunking-based framework. Experimental results justify the usefulness of our Chinese corpus and the appropriateness of our syntactic structure-based framework which obtained significant improvement over the state-of-the-art on negation and speculation identification in Chinese language.

1 Introduction

Negation and speculation are ubiquitous phenomena in natural language. While negation is a grammatical category which comprises various kinds of devices to reverse the truth value of a proposition, speculation is a grammatical category which expresses the attitude of a speaker towards a statement in terms of degree of certainty, reliability, subjectivity, sources of information, and perspective (Morante and Sporleder, 2012).

Current studies on negation and speculation identification mainly focus on two tasks: 1) cue detection, which aims to detect the signal of a negative or speculative expression, and 2) scope resolution, which aims to determine the linguistic coverage of a cue in sentence, in distinguishing unreliable or uncertain information from facts. For example, (E1) and (E2) include a negative cue and a speculative cue respectively, both denoted in **boldface** with their linguistic scopes denoted in square brackets (adopted hereinafter). In sentence (E1), the negative cue “不(not)” triggers the scope of “不会追究酒店的这次管理失职(would not investigate the dereliction of hotel)”, within which the fragment “investigate the dereliction of hotel” is the part that is repudiated; While the speculative cue “有望(expected)” in sentence (E2) triggers the scope “后期仍有望反弹(is still expected to rebound in the late)”, within which the fragment “the benchmark Shanghai Composite Index will rebound in the late” is the speculative part.

(E1) *所有住客均表示[**不**会追究酒店的这次管理失职].*
(*All of guests said that they [would **not** investigate the dereliction of hotel].*)

(E2) *尽管上周五沪指盘中还受创业板的下跌所拖累,但[后期仍**有望**反弹].*
(*Although dragged down by GEM last Friday, the benchmark Shanghai Composite Index [is still **expected** to rebound in the late].*)

Negation and speculation identification is very relevant for almost all NLP applications involving text understanding which need to discriminate between factual and non-factual information. The treatment of negation and speculation in computational linguistics has been shown to be

useful for biomedical text processing (Morante et al., 2008; Chowdhury and Lavelli, 2013), information retrieval (Averbuch, 2004), sentiment analysis (Councill et al., 2010; Zhu et al., 2014), recognizing textual entailment (Snow et al., 2006), machine translation (Baker et al., 2010; Wetzel and Bond, 2012), and so forth.

The research on negation and speculation identification in English has received a noticeable boost. However, in contrast to the significant achievements concerning English, the research progress in Chinese language is quite limited. The main reason includes the following two aspects: First, the scarcity of linguistic resource seriously limits the advance of related research. To the best of our knowledge, there are no publicly available standard Chinese corpus of reasonable size annotated with negation and speculation. Second, this may be attributed to the limitations of Chinese information processing.

The contributions of this paper are as follows:

- To address the aforementioned first issue, this paper seeks to fill this gap by presenting the Chinese negation and speculation corpus which consists of three kind of sub-corpora annotated for negative and speculative cues, and their linguistic scopes. The corpus has been made publicly available for research purposes and it is freely downloadable from http://nlp.suda.edu.cn/corpus.
- For cue detection, we propose a feature-based sequence labeling model to identify cues. It is worth noting that the morpheme feature is employed to better represent the compositional semantics inside Chinese words. Moreover, for improving the low recall rate which suffers from the unknown cues, we propose a cross-lingual cue expansion strategy based on parallel corpora.
- For scope resolution, we present a new syntactic structure-based framework on dependency tree. Evaluation justifies the appropriateness and validity of this framework on Chinese scope resolution, which outperforms the chunking-based framework that widely used in mainstream scope resolution systems.

The layout of the rest paper is organized as follows. Section 2 describes related work. Section 3 provides details about annotation guidelines and also presents statistics about corpus characteristics. Section 4 describes our approach in detail. Section 5 reports and discusses our experimental results. Finally, we conclude our work and indicate some future work in Section 6.

2 Related Work

Currently, both cue detection task and scope resolution task are always modeled as a classification problem with the purpose of predicting whether a token is inside or outside the cue and its scope. Among them, feature-based and kernel-based approaches are most popular.

In the feature-based framework, Agarwal and Yu (2010) employed a conditional random fields (CRFs) model to detect speculative cues and their scopes on the BioScope corpus. The CRFs-based model achieved an F1-meature of 88% in detecting speculative cues. We train this model on our corpus as the baseline system for cue detection. Our work is different from theirs in that we employ a new feature (morpheme feature) which is particularly appropriate for Chinese.

Besides, kernel-based approaches exploit the structure of the tree that connects cue and its corresponding scope. Zou et al. (2013) developed a tree kernel-based system to resolve the scope of negation and speculation, which captures the structured information in syntactic parsing trees. To the best of our knowledge, this system is the best English scope resolution system. For this reason, we train this system on our corpus as the baseline system for scope resolution.

Compared with a fair amount of works on English negation and speculation identification, unfortunately, few works has been published on Chinese. Ji et al. (2010) developed a system to detect speculation in Chinese news texts. However, only the speculative sentences have been found out, with no more fine-grained information such as scope. The insufficient study on Chinese negation and speculation identification drives us to construct a high-quality corpus and investigate how to find an approach that is particularly appropriate for Chinese language.

3 Corpus Construction

In this section, we elaborate on the overall characteristics of the Chinese Negation and Speculation (abbr., CNeSp) corpus we constructed, including a brief description of the sources that constitute our corpus, general guidelines which illustrated with lots of examples and some special cases, and statistics on the overall results of our corpus.

3.1 Sources

To capture the heterogeneity of language use in texts, the corpus consists of three different sources and types, including scientific literature, product reviews, and financial articles.

Vincze et al. (2008) described that it is necessary to separate negative and speculative information from factual especially in science articles, because conclusions of science experiment are always described by using diversity of expressions and include hypothetical asserts or viewpoints. For this reason, we adopt the 19 articles from Chinese Journal of Computers (Vol.35(11)), an authoritative academic journal in Chinese, to construct the Scientific Literature sub-corpus.

Another part of the corpus consists of 311 articles from “股市及时雨(timely rain for stock market)” column from Sina.com in April, 2013. There are 22.3% and 40.2% sentences in the Financial Article sub-corpus containing negation and speculation respectively.

Many researches have investigated the role of negation in sentiment analysis task, as an important linguistic qualifier which leads to a change in polarity. For example, Councill et al. (2010) investigated the problem of determining the polarity of sentiment in movie reviews when negation words occur in the sentences. On the other hand, speculation is a linguistic expression that tends to correlate with subjectivity which is also crucial for sentiment analysis. Pang and Lee (2004) showed that subjectivity detection in the review domain helps to improve polarity classification. Therefore, the Product Review sub-corpus consists of 821 comments of hotel service from the website Ctrip.com.

3.2 Annotation Guidelines

The guidelines of our CNeSp corpus have partly referred to the existing Bioscope corpus guidelines (BioScope, 2008) in order to fit the needs of the Chinese language. In annotation process, negative or speculative cues and their linguistic scopes in sentence are annotated. There are several general principles below:

(G1) Cue is contained in its scope.

(G2) The minimal unit that expresses negation or speculation is annotated as a cue.

(E3) _该股极有**可能**再度出现涨停._
(_The stock is very **likely** to hit limit up._)

To G2, the modifiers such as prepositions, determiners, or adverbs are not annotated as parts of the cue. For example, in Sentence (E3), “极(very)” is only a modifier of the speculative cue “可能(likely)”, but not a constituent of the cue.

For the drawbacks of the Bioscope corpus guidelines either on itself or for Chinese language, we introduced some modifications. These main changes are summarized below:

(G3) A cue is annotated only relying on its actual semantic in context.

(E4) _大盘**不可能**再次出现高开低走._
(_It is **not possible** that the broader market opens high but slips later again._)

To G3, “不可能(not possible)” means that the author denies the possibility of the situation that “the broader market opens high but slips later again”, which contains negative meanings than speculative. Thus, the phrase “不可能(not possible)” should be labeled as a negative cue.

(G4) A scope should contain the subject which contributes to the meaning of the content being negated or speculated if possible.

(E5) _*Once again, the Disorder module does [**not** contribute positively to the prediction]._

The BioScope corpus suggests that the scope of negative adverbs usually starts with the cue and ends at the end of the phrase, clause or sentence (E5). However, in our view, the scope should contain the subject for the integrity of meaning. Following is an exceptional case.

(G5) Scope should be a continuous fragment in sentence.

(E6) _酒店有高档的配套设施,然而却[**不能**多给我们提供一个枕头]._
(_The hotel are furnished with upscale facilities, but [**cannot** offer us one more pillow]._)

Some rhetoric in Chinese language, such as parallelism or ellipsis, often gives rise to separation of some sentence constituents from others. For example, in Sentence (E6), the subject of the second clause should be “酒店(the hotel)”, which is omitted. In this situation, we only need to identify the negative or speculative part in sentence than all semantic constituents which can be completed through other NLP technologies, such as zero subject anaphora resolution or semantic role labeling.

(G6) A negative or speculative character or word may not be a cue.

(E7) _早茶的种类之多不得不赞._
(We are difficult not to give credit to the variety of morning snack.)

We have come across several cases where the presence of a negative or speculative character or word does not denote negative or speculative meaning. For example, there are lots of double negatives in Chinese language only for emphasizing than negative meanings. In Sentence (E7), obviously, the author wants to emphasis the praise of the variety of breakfast buffet by using the phrase “不得不(be difficult not to)” which does not imply a negative meaning.

The CNeSp corpus is annotated by two independent annotators who are not allowed to communicate with each other. A linguist expert resolves the differences between the two annotators and modified the guidelines when they are confronted with problematic issues, yielding the gold standard labeling of the corpus.

3.3 Statistics and Agreement Analysis

Table 1 summarizes the chief characteristics of the three sub-corpora, including Scientific Literature (Sci., for short), Financial Article (Fin.), and Product Review (Prod.). As shown in Table 1, out of the total amount of 16,841 sentences more than 20% contained negation or speculation, confirming the availability for corpus.

Item	Sci.	Fin.	Prod.
#Documents	19	311	821
#Sentences	4,630	7,213	4,998
Avg. Length of Sentences	30.4	30.7	24.1
Negation			
%Sentence	13.2	17.5	52.9
Avg. Length of Scopes	9.1	7.2	5.1
Speculation			
%Sentence	21.6	30.5	22.6
Avg. Length of Scopes	12.3	15.0	6.9

(Avg. Length: The average number of Chinese characters.)

Table 1. Statistics of corpus.

Type		Sci.	Fin.	Prod.
Negation	Cue	0.96	0.96	0.93
	Cue & Scope	0.90	0.91	0.88
Speculation	Cue	0.94	0.90	0.93
	Cue & Scope	0.93	0.85	0.89

Table 2. Inter-annotator agreement.

We measured the inter-annotator agreement of annotating cues and their linguistic scope for all of three sub-corpora between the two independent annotators in terms of Kappa (Cohen, 1960). The results are shown in Table 2. The 2nd and 4th rows of the table show the kappa value of only cue annotation for negation and speculation, respectively. The 3rd and 5th rows show the agreement rate for both cue and its full scope. The most obvious conclusions here are that the identification of speculation is more complicated than negation even for humans because of the higher ambiguity of cues and the longer average length of scopes in speculation.

4 Chinese Negation and Speculation Identification

As a pipeline task, negation and speculation identification generally consists of two basic stages, cue detection and scope resolution. The former detects whether a word or phrase implies negative or speculative meanings, while the latter determines the sequences of terms which are dominated by the corresponding cue in sentence.

In this section, we improve our cue detection system by using the morpheme features of Chinese characters and expanding the cue clusters based on bilingual parallel corpora. Then, we present a new syntactic structure-based framework for Chinese language, which regards the sub-structures of dependency tree selected by a heuristic rule as scope candidates.

4.1 Cue Detection

Most of the existing cue detection approaches are proposed from feature engineering perspective. They formulate cue detection as a classification issue, which is to classify each token in sentence as being the element of cue or not.

Feature-based sequence labeling model

At the beginning, we explore the performance of an English cue detection system, as described in Agarwal and Yu (2010), which employs a conditional random fields (abbr., CRFs) model with lexical and syntactic features. Unfortunately, the performance is very low on Chinese texts (Section 5.1). This may be attributed to the different characteristic of Chinese language, for example, no word boundaries and lack of morphologic variations. Such low performance drives us to investigate new effective features which are particularly appropriate for Chinese. We employed three kinds of features for cue detection:

1) N-gram features

For each character c_i, assuming its 5-windows characters are c_{i-2} c_{i-1} c_i c_{i+1} c_{i+2}, we adopt following features: c_{i-2}, c_{i-1}, c_i, c_{i+1}, c_{i+2}, $c_{i-1}c_i$, c_ic_{i+1}, $c_{i-2}c_{i-1}c_i$, $c_{i-1}c_ic_{i+1}$, $c_ic_{i+1}c_{i+2}$.

2) Lexical features

To achieve high performance as much as possible, we also use some useful basic features which are widely used in other NLP tasks on Chinese. The basic feature set consists of POS tag, the left/right character and its PoS tag. It is worth noting that the cue candidates in our model are characters. Thus, in order to get these features, we substitute them with corresponding features of the words which contain the characters.

3) Morpheme features

The word-formation of Chinese implies that almost all of the meanings of a word are made up by the morphemes, a minimal meaningful unit in Chinese language contained in words. This more fine-grained semantics are the compositional semantics inside Chinese words namely. We assume that the morphemes in a given cue are also likely to be contained in other cues. For example, “猜测(guess)” is a given speculative cue which consists of “猜(guess)” and “测(speculate)”, while the morpheme “猜(guess)” could be appeared in “猜想(suppose)”. In consideration of the Chinese characteristics, we use every potential character in cues to get the morpheme feature.

A Boolean feature is taken to represent the morpheme information. Specifically, the characters which appear more than once within different cues in training corpus were selected as the features. The morpheme feature is set to 1, if the character is a negative or speculative morpheme.

For the ability of capturing the local information around a cue, we choose CRFs, a conditional sequence model which represents the probability of a hidden state sequence given some observations, as classifier to label each character with a tag indicating whether it is out of a cue (O), the beginning of the cue (B) or a part of the cue except the beginning one (I). In this way, our CRFs-based cue identifier performs sequential labeling by assigning each character one of the three tags and a character assigned with tag B is concatenated with following characters with tag I to form a cue.

Cross-lingual Cue Expansion Strategy

The feature-based cue detection approach mentioned above shows that a bottleneck lies in low recall (see Table 4). This is probably due to the absence of about 12% negation cues and 17% speculation cues from the training data. It is a challenging task to identify unknown cues with the limited amount of training data. Hence, we propose a cross-lingual cue expansion strategy.

In the approach, we take use of the top 5 Chinese cues in training corpus as our “anchor set”. For each cue, we search its automatically aligned English words from a Chinese-English parallel corpus to construct an English word cluster. The parallel corpus consisting of 100,000 sentence pairs is built by using Liu's approach (Liu et al., 2014), which combines translation model with language model to select high-quality translation pairs from 16 million sentence pairs. The word alignment was obtained by running Giza++ (Och and Ney, 2003). In each cluster, we record the frequency of each unique English word. Considering the word alignment errors in cross-lingual clusters, we filter the clusters by word alignment probability which is formulated as below:

$$\begin{aligned} P_A &= \alpha P(w_E \mid w_C) + (1-\alpha) P(w_C \mid w_E) \\ &= \alpha \frac{P(w_E, w_C)}{P(w_C)} + (1-\alpha) \frac{P(w_E, w_C)}{P(w_E)} \\ &= \alpha \frac{align(w_E, w_C)}{\sum_i align(w_{Ei}, w_C)} + (1-\alpha) \frac{align(w_E, w_C)}{\sum_i align(w_{Ci}, w_E)} \end{aligned} \qquad (1)$$

where $P(w_E \mid w_C)$ is the translation probability of English word w_E conditioned on Chinese word w_C, reversely, while $P(w_C \mid w_E)$ is the translation probability of Chinese word w_C conditioned on English word w_E. $align(w_m, w_n)$ is the number of alignments of word w_m and word w_n in parallel corpus. $\sum_i align(w_{mi}, w_n)$ is the sum of the number of alignments which contain word w_n. The parameter $\alpha \in [0,1]$ is the coefficient controlling the relative contributions from the two directions of translation probability.

Then we conduct the same procedure in the other direction to construct Chinese word clusters anchored by English cues, until no new word comes about. For example, applying the above approach from the cue “可能(may)”, we obtain 59 Chinese speculative cues. All of words in the final expansion cluster are identified as cues.

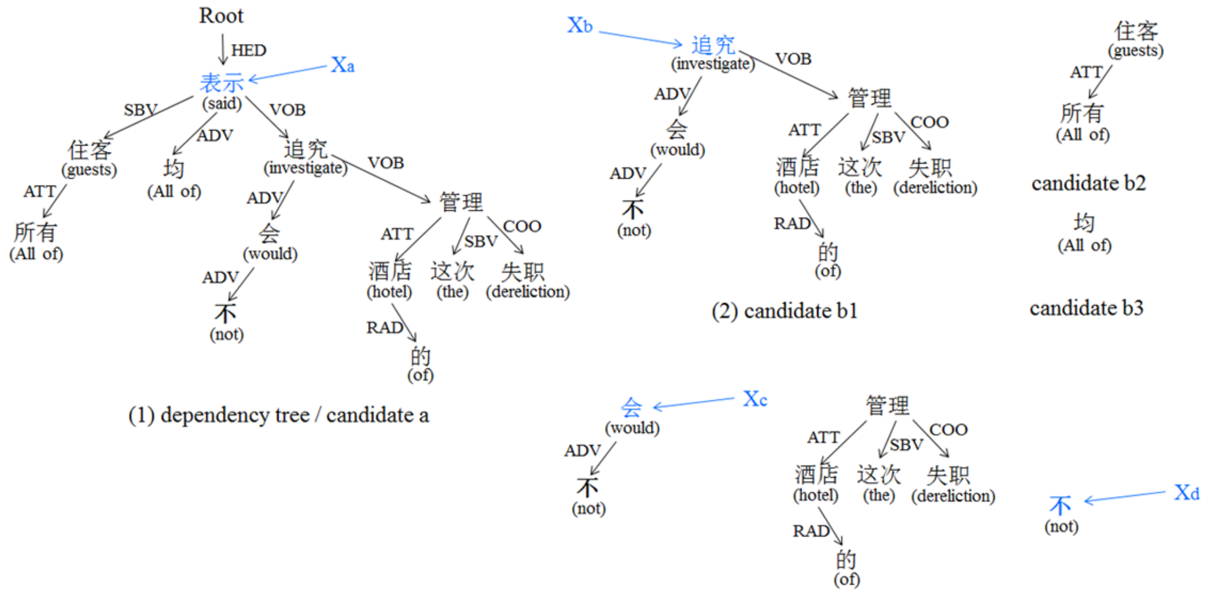
4.2 Scope Resolution

Currently, mainstream approaches formulated the scope resolution as a chunking problem, which classifies every word of a sentence as being inside or outside the scope of a cue. However, unlike in English, we found that plenty of errors occurred in Chinese scope resolution by using words as the basic identifying candidate.

In this paper we propose a new framework using the sub-structures of dependency tree as scope candidates. Specifically, given a cue, we adopt the following heuristic rule to get the scope candidates in the dependency tree.

Setting constituent X and its siblings as the root nodes of candidate structure of scope, X should be the ancestor node of cue or cue itself.

For example, in the sentence “所有住客均表示不会追究酒店的这次管理失职(All of guests said that they would not investigate the dereliction of hotel)”, the negative cue “不(not)” has four constituent Xs and seven scope candidates, as shown in Figure 1. According to the above rule, three ancestor nodes {Xa: “表示(said)”, Xb: “追究(investigate)”, and Xc: “会(would)”} correspond to three scope candidates (a, b1, and c),



(1) dependency tree / candidate a

(2) candidate b1

candidate b2

candidate b3

(3) candidate c1

candidate c2

(4) candidate d

Figure 1. Examples of a negative cue and its seven scope candidates in dependency tree.

Feature	Description	Instantiation
Cue:		
C1: Itself	Tokens of cue	不(not)
C2: PoS	PoS of cue	d(adverb)
Scope candidate:		
S1: Itself	Tokens of headword	追究(investigate)
S2: PoS	PoS of headword	v(verb)
S3: Dependency type	Dependency type of headword	VOB
S4: Dependency type of child nodes	Dependency type of child nodes of headword	ADV+VOB

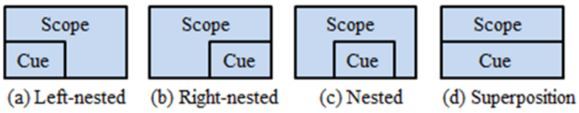
Table 3. Features and their instantiations for scope resolution.

and the cue itself is certainly a scope candidate (d). In addition, the Xb node has two siblings in dependency tree { "住客(guests)" and "均(all of)" }. Therefore, the two scope candidates corresponding to them are b2 and b3, respectively. Similarly, the sibling of the Xc node is labeled as candidate c2.

A binary classifier is applied to determine each candidate as either part of scope or not. In this paper, we employ some lexical and syntactic features about cue and candidate. Table 3 lists all of the features for scope resolution classification (with candidate b1 as the focus constituent (i.e., the scope candidate) and "不(not)" as the given cue, regarding candidate b1 in Figure 1(2)).

For clarity, we categorize the features into three groups according to their relevance with the given cue (C, in short), scope candidate (S, in short), and the relationship between cue andcandidate (R, in short). Figure 2 shows four kinds of positional features between cue and scope candidate we defined (R4).



(a) Left-nested (b) Right-nested (c) Nested (d) Superposition

Figure 2. Positional features.

Some features proposed above may not be effective in classification. Therefore, we adopt a greedy feature se-lection algorithm as described in (Jiang and Ng, 2006) to pick up positive features incrementally according to their contributions on the development data. Additionally, a cue should have one continuous block as its scope, but the scope identifier may result in discontinuous scope due to independent candidate in classification. For this reason, we employ a post-processing algorithm as described in Zhu et al. (2010) to identify the boundaries.

5 Experimentation

In this section, we evaluate our feature-based sequence labeling model and cross-lingual cue expansion strategy on cue detection, and report the experimental results to justify the appropriateness of our syntactic structure-based framework on scope resolution in Chinese language.

The performance is measured by Precision (P), Recall (R), and F1-score (F). In addition, for scope resolution, we also report the accuracy in PCS (Percentage of Correct Scopes), within which a scope is fully correct if the output of scope resolution system and the correct scope have been matched exactly.

5.1 Cue Detection

Results of the Sequence Labeling Model

Every sub-corpus is randomly divided into ten equal folds so as to perform ten-fold cross validation. Lexical features are gained by using an open-source Chinese language processing platform, LTP[1](Che et al., 2010) to perform word segmentation, POS tagging, and syntactic parsing. CRF++0.58[2] toolkit is employed as our sequence labeling model for cue detection.

Table 4 lists the performances of cue detection systems using a variety of features. It shows that the morpheme features derived from the word-formation of Chinese improve the performance for both negation and speculation cue detection systems on all kinds of sub-corpora. However, the one exception occurs in negation cue detection on the Product Review sub-corpus, in which the performance is decreased about 4.55% in precision. By error analysis, we find out the main reason is due to the pseudo cues. For example, "非常(very)" is identified by the negative morpheme "非(-un)", which is a pseudo cue.

Table 4 also shows a bottleneck of our sequence labeling model, which lies in low recall. Due to the diversity of Chinese language, many cues only appear a few times in corpus. For example, 83% (233/280) of speculative cues appear less than ten times in Financial Article sub-corpus. This data sparse problem directly leads to the low recall of cue detection.

Table 4. Contribution of features to cue detection.

Results of the Cross-lingual Cue Expansion Strategy

Before cue expansion, we select the parameter α as defined in formula (1) by optimizing the F1-measure score of on Financial Article sub-corpus. Figure 3 shows the effect on F1-measure of varying the coefficient from 0 to 1. We can see that the best performance can be obtained by selecting parameter 0.6 for negation and 0.7 for speculation. Then we apply these parameter values directly for cue expansion.

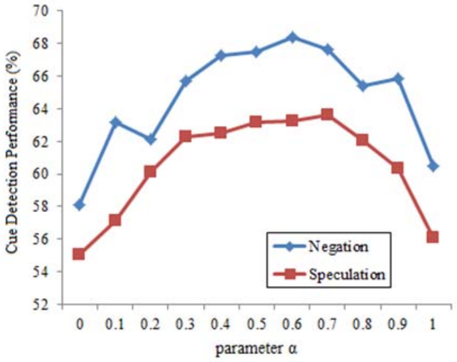

Figure 3. The effect of varying the value of parameter α on Financial Article sub-corpus.

Table 5 lists the performances of feature-based system, expansion-based system, and the combined system. A word is identified as a cue by combined system if it is identified by one of the above systems (Feat-based or Exp-based) at least.

For both negation and speculation, the cross-lingual cue expansion approach provides significant improvement over the feature-based sequence labeling model, achieving about 15-20%

[1] http://www.ltp-cloud.com
[2] https://crfpp.googlecode.com/svn/trunk/doc/index.html

better recall with little loss in precision. More importantly, the combined system obtains the best performance.

Table 5. Performance of cue detection.

5.2 Syntactic Structure-based Scope Resolution

Considering the effectiveness of different features, we divide the Financial Article sub-corpus into 5 equal parts, within which 2 parts are used for feature selection. Then, the feature selection data are divided into 5 equal parts, within which 4 parts for training and the rest for developing. On this data set, a greedy feature selection algorithm (Jiang and Ng, 2006) is adopted to pick up positive features proposed in Table 3. In addition, SVM^{Light}[3] with the default parameter is selected as our classifier.

Table 6 lists the performance of selected features. 7 features {C1, C2, S4, S5, S6, R1, R4} are selected consecutively for negation scope resolution, while 9 features {C2, S1, S3, S4, S5, R1, R2, R3, R4} are selected for speculation scope resolution. We will include those selected features in all the remaining experiments.

Type	Feature set	Sci.	Fin.	Prod.
Negation	Selected features	62.16	56.07	60.93
	All features	59.74	54.20	55.42
Speculation	Selected features	54.16	49.64	52.89
	All features	52.33	46.27	48.07

Table 6. Feature selection for scope resolution on golden cues (PCS %).

The feature selection experiments suggest that the feature C2 (POS of cue) plays a critical role for both negation and speculation scope resolution. It may be due to the fact that cues of different POS usually undertake different syntactic roles. Thus, there are different characteristics in triggering linguistic scopes. For example, an adjective cue may treat a modificatory structure as its scope, while a conjunction cue may take the two connected components as its scope.

As a pipeline task, the negation and speculation identification could be regarded as a combination of two sequential tasks: first, cue detection, and then scope resolution. Hence, we turn to a more realistic scenario in which cues are automatically recognized.

Type	Corpus	P	R	F1	PCS
Negation	Sci.	55.32	53.06	54.17	59.08
	Fin.	42.14	46.37	44.15	49.24
	Prod.	50.57	48.55	49.54	52.17
Speculation	Sci.	45.68	47.15	46.40	48.36
	Fin.	34.21	31.80	32.96	41.33
	Prod.	32.64	33.59	33.11	39.78

Table 7. Performance of scope resolution with automatic cue detection.

Table 7 lists the performance of scope resolution by using automatic cues. It shows that automatic cue detection lowers the performance by 3.08, 6.83, and 8.76 in PCS for the three sub-corpora, respectively; while it lowers the performance by 5.80, 8.31 and 13.11 in PCS for speculation scope resolution on the three sub-corpora, respectively (refer to Table 6). The main reason of performance lost is the error propagation from the automatic cue detection.

We employ a start-of-the-art chunking-based scope resolution system (described in Zou et al., (2013)) as a baseline, in which every word in sentence has been labelled as being the element of the scope or not. Table 8 compares our syntactic structure-based framework with the chunking-based framework on scope resolution. Note that all the performances are achieved on Financial Article sub-corpus by using golden cues. The results in Table 8 shows that our scope resolution system outperforms the chunking ones both on negation and speculation, improving 8.75 and 7.44 in PCS, respectively.

Type	System	PCS
Negation	Chunking-based	47.32
	Ours	56.07
Speculation	Chunking-based	42.20
	Ours	49.64

Table 8. Comparison with the chunking-based system on Financial Article sub-corpus.

6 Conclusion

In this paper we construct a Chinese corpus for negation and speculation identification, which annotates cues and their linguistic scopes. For cue detection, we present a feature-based sequence labeling model, in which the morpheme

[3] http://svmlight.joachims.org

feature is employed to better catch the composition semantics inside the Chinese words. Complementally, a cross-lingual cue expansion strategy is pro-posed to increase the coverage in cue detection. For scope resolution, we present a new syntactic structure-based framework to identify the linguistic scope of a cue. Evaluation justifies the usefulness of our Chinese corpus and the appropriateness of the syntactic structure-based framework. It also shows that our approach outperforms the state-of-the-art chunking ones on negation and speculation identification in Chinese language.

In the future we will explore more effective features to improve the negation and speculation identification in Chinese language, and focus on joint learning of the two subtasks.

Abstract

The path ranking algorithm (PRA) has been recently proposed to address relational classification and retrieval tasks at large scale. We describe Cor-PRA, an enhanced system that can model a larger space of relational rules, including longer relational rules and a class of first order rules with constants, while maintaining scalability. We describe and test faster algorithms for searching for these features. A key contribution is to leverage backward random walks to efficiently discover these types of rules. An empirical study is conducted on the tasks of graph-based knowledge base inference, and person named entity extraction from parsed text. Our results show that learning paths with constants improves performance on both tasks, and that modeling longer paths dramatically improves performance for the named entity extraction task.

1 Introduction

Structured knowledge about entities and the relationships between them can be represented as an edge-typed graph, and relational learning methods often base predictions on connectivity patterns in this graph. One such method is the Path Ranking Algorithm (PRA), a random-walk based relational learning and inference framework due to Lao and Cohen (2010b). PRA is highly scalable compared with other statistical relational learning approaches, and can therefore be applied to perform inference in large knowledge bases (KBs). Several recent works have applied PRA to link prediction in semantic KBs, as well as to learning syntactic relational patterns used in information extraction from the Web (Lao et al., 2012; Gardner et al., 2013; Gardner et al., 2014; Dong et al., 2014).

A typical relational inference problem is illustrated in Figure 1. Having relational knowledge represented as a graph, it is desired to infer additional relations of interest between entity pairs. For example, one may wish to infer whether an *AthletePlaysInLeague* relation holds between nodes *HinesWard* and *NFL*. More generally, link prediction involves queries of the form: which entities are linked to a source node s (*HinesWard*) over a relation of interest r (e.g., r is *AlthletePlaysInLeague*)?

PRA gauges the relevance of a target node t with respect to the source node s and relation r based on a set of relation paths (i.e., sequences of edge labels) that connect the node pair. Each path π_i is considered as feature, and the value of feature π_i for an instance (s, t) is the probability of reaching t from s following path π_i. A classifier is learned in this feature space, using logistic regression.

PRA's candidate paths correspond closely to a certain class of Horn clauses: for instance, the path $\pi = \langle \textit{AthletePlaysForTeam}, \textit{TeamPlaysInLeague} \rangle$, when used as a feature for the relation $r = \textit{AthletePlaysForLeague}$, corresponds to the Horn clause

$$\textit{AthletePlaysForTeam}(s, z) \wedge \textit{TeamPlaysInLeague}(z, t) \\ \rightarrow \textit{AthletePlaysForLeague}(s, t)$$

One difference between PRA's features and more traditional logical inference is that random-walk weighting means that not all inferences instantiated by a clause will be given the same weight. Another difference is that PRA is very limited in terms of expressiveness. In particular, inductive logic programming

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 666–675,
Beijing, China, July 26-31, 2015.

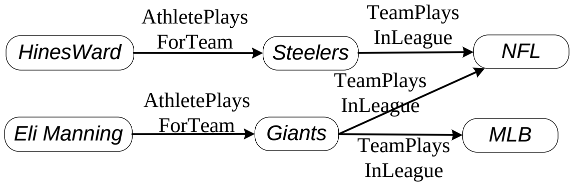

Figure 1: An example knowledge graph

(ILP) methods such as FOIL (Quinlan and Cameron-Jones, 1993) learn first-order Horn rules that may involve constants. Consider the following rules as motivating examples.

$$\begin{aligned}&\mathit{EmployeedByAgent}(s,t) \wedge \mathit{IsA}(t,\mathit{SportsTeam})\\ &\qquad\qquad \rightarrow \mathit{AthletePlaysForTeam}(s,t)\\ &t = \mathit{NFL} \rightarrow \mathit{AthletePlaysForTeam}(s,t)\end{aligned}$$

The first rule includes *SportsTeam* as a constant, corresponding to a particular graph node, which is a the semantic class (hypernym) of the target node t. The second rule simply assigns *NFL* as the target node for the *AthletePlaysForTeam* relation; if used probabilistically, this rule can serve as a prior. Neither feature can be expressed in PRA, as PRA features are restricted to edge type sequences.

We are interested in extending the range of relational rules that can be represented within the PRA framework, including rules with constants. A key challenge is that this greatly increases the space of candidate rules. Knowledge bases such as Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007), or NELL (Carlson et al., 2010a), may contain thousands of predicates and millions of concepts. The number of features involving concepts as constants (even if limited to simple structures such as the example rules above) will thus be prohibitively large. Therefore, it is necessary to search the space of candidate paths π very efficiently. More efficient candidate generation is also necessary if one attempts to use a looser bound on the length of candidate paths.

To achieve this, we propose using *backward random walks*. Given target nodes that are known to be relevant for relation r, we perform backward random walks (up to finite length ℓ) originating at these target nodes, where every graph node c reachable in this random walk process is considered as a potentially useful constant. Consequently, the relational paths that connect nodes c and t are evaluated as possible random walk features. As we will show, such paths provide informative class priors for relational classification tasks.

Concretely, this paper makes the following contributions. First, we outline and discuss a new and larger family of relational features that may be represented in terms of random walks within the PRA framework. These features represent paths with constants, expanding the expressiveness of PRA. In addition, we propose to encode bi-directional random walk probabilities as features; we will show that accounting for this sort of directionality provides useful information about graph structure.

Second, we describe the learning of this extended set of paths by means of backward walks from relevant target nodes. Importantly, the search and computation of the extended set of features is performed efficiently, maintaining high scalability of the framework. Concretely, using backward walks, one can compute random walk probabilities in a bi-directional fashion; this means that for paths of length $2M$, the time complexity of path finding is reduced from $O(|V|^{2M})$ to $O(|V|^{M})$, where $|V|$ is the number of edge types in graph.

Finally, we report experimental results for relational inference tasks in two different domains, including knowledge base link prediction and person named entity extraction from parsed text (Minkov and Cohen, 2008). It is shown that the proposed extensions allow one to effectively explore a larger feature space, significantly improving model quality over previously published results in both domains. In particular, incorporating paths with constants significantly improves model quality on both tasks. Bi-directional walk probability computation also enables the learning of longer predicate chains, and the modeling of long paths is shown to substantially improve performance on the person name extraction task. Importantly, learning and inference remain highly efficient in both these settings.

2 Related Work

ILP complexity stems from two main sources—the complexity of searching for clauses, and of evaluating them. First-order learning systems (e.g. FOIL, FOCL (Pazzani et al., 1991)) mostly rely on hill-climbing search, i.e., incrementally expanding existing patterns to explore the combinatorial model space, and are thus often vulnerable to local maxima. PRA takes another approach, generating features using efficient random graph walks, and selecting a subset of those features which pass precision and frequency thresholds. In this respect, it resembles a stochastic approach to ILP used in earlier work (Sebag and Rouveirol, 1997).The idea of sampling-based inference and induction has been further explored by later systems (Kuželka and Železný, 2008; Kuželka and Železný, 2009).

Compared with conventional ILP or relational learning systems, PRA is limited to learning from binary predicates, and applies random-walk semantics to its clauses. Using sampling strategies (Lao and Cohen, 2010a), the computation of clause probabilities can be done in time that is independent of the knowledge base size, with bounded error rate (Wang et al., 2013). Unlike in FORTE and similar systems, in PRA, sampling is also applied to the induction path-finding stage. The *relational feature construction* problem (or propositionalization) has previously been addressed in the ILP community—*e.g.*, the RSD system (Železný and Lavrač, 2006) performs explicit first-order feature construction guided by an precision heuristic function. In comparison, PRA uses precision and recall measures, which can be readily read off from random walk results.

Bi-directional search is a popular strategy in AI, and in the ILP literature. The *Aleph* algorithm (Srinivasan, 2001) combines top-down with bottom-up search of the refinement graph, an approach inherited from Progol. FORTE (Richards and Mooney, 1991) was another early ILP system which enumerated paths via a bi-directional seach. Computing backward random walks for PRA can be seen as a particular way of bi-directional search, which is also assigned a random walk probability semantics. Unlike in prior work, we will use this probability semantics directly for feature selection.

3 Background

We first review the Path Ranking Algorithm (PRA) as introduced by (Lao and Cohen, 2010b), paying special attention to its random walk feature estimation and selection components.

3.1 Path Ranking Algorithm

Given a directed graph G, with nodes N, edges E and edge types R, we assume that all edges can be traversed in both directions, and use r^{-1} to denote the reverse of edge type $r \in R$. A *path type* π is defined as a sequence of edge types $r_1 \ldots r_\ell$. Such path types may be indicative of an extended relational meaning between graph nodes that are linked over these paths; for example, the path $\langle$*AtheletePlaysForTeam*, *TeamPlaysInLeague*$\rangle$ implies the relationship "the league a certain player plays for". PRA encodes $P(s \to t; \pi_j)$, the probability of reaching target node t starting from source node s and following path π_j, as a feature that describes the semantic relation between s and t. Specifically, provided with a set of selected path types up to length ℓ, $\mathcal{P}_\ell = \{\pi_1, \ldots, \pi_m\}$, the relevancy of target nodes t with respect to the query node s and the relationship of interest is evaluated using the following scoring function

$$score(s,t) = \sum_{\pi_j \in \mathcal{P}_\ell} \theta_j P(s \to t; \pi_j), \qquad (1)$$

where θ are appropriate weights for the features, estimated in the following fashion.

Given a relation of interest r and a set of annotated node pairs $\{(s,t)\}$, for which it is known whether $r(s,t)$ holds or not, a training data set $\mathcal{D} = \{(\mathbf{x}, y)\}$ is constructed, where $\mathbf{x}$ is a vector of all the path features for the pair (s,t)—i.e., the j-th component of $\mathbf{x}$ is $P(s \to t; \pi_j)$, and y is a boolean variable indicating whether $r(s,t)$ is true. We adopt the closed-world assumption—a set of relevant target nodes G_i is specified for every example source node s_i and relation r, and all other nodes are treated as negative target nodes. A biased sampling procedure selects only a small subset of negative samples to be included in the objective function (Lao and Cohen, 2010b). The parameters θ are estimated from both positive and negative examples using a regularized logistic regression model.

3.2 PRA Features–Generation and Selection

PRA features are of the form $P(s \to t; \pi_j)$, denoting the probability of reaching target node t, originating random walk at node s and following edge type sequence π_j. These path probabilities need to be estimated for every node pair, as part of both training and inference. High scalability is achieved due to efficient path probability estimation. In addition, feature selection is applied so as to allow efficient learning and avoid overfitting.

Concretely, the probability of reaching t from s following path type π can be recursively defined as

$$P(s \to t; \pi) = \sum_z P(s \to z; \pi')P(z \to t; r), \tag{2}$$

where r is the last edge type in path π, and π' is its prefix, such that adding r to π' gives π. In the terminal case that π' is the empty path ϕ, $P(s \to z; \phi)$ is defined to be 1 if $s = z$, and 0 otherwise. The probability $P(z \to t; r)$ is defined as $1/|r(z)|$ if $r(z, t)$, and 0 otherwise, where $r(z)$ is the set of nodes linked to node z over edge type r. It has been shown that $P(s \to t; \pi)$ can be effectively estimated using random walk sampling techniques, with bounded complexity and bounded error, for all graph nodes that can be reached from s over path type π (Lao and Cohen, 2010a).

Due to the exponentially large feature space in relational domains, candidate path features are first generated using a dedicated particle filtering path-finding procedure (Lao et al., 2011), which is informed by training signals. Meaningful features are then selected using the following *goodness measures*, considering path precision and coverage:

$$precision(\pi) = \frac{1}{n}\sum_i P(s_i \to G_i; \pi), \tag{3}$$

$$coverage(\pi) = \sum_i I(P(s_i \to G_i; \pi) > 0). \tag{4}$$

where $P(s_i \to G_i; \pi) \equiv \sum_{t \in G_i} P(s_i \to t; \pi)$. The first measure prefers paths that lead to correct nodes with high average probability. The second measure reflects the number of queries for which some correct node is reached over path π. In order for a path type π to be included in the PRA model, it is required that the respective scores pass thresholds, $precision(\pi) \geq a$ and $coverage(\pi) \geq h$, where the thresholds a and h are tuned empirically using training data.

4 Cor-PRA

We will now describe the enhanced system, which we call Cor-PRA, for the Constant and Reversed Path Ranking Algorithm. Our goal is to enrich the space of relational rules that can be represented using PRA, while maintaining the scalability of this framework.

4.1 Backward random walks

We first introduce *backward* random walks, which are useful for generating and evaluating the set of proposed relational path types, including paths with constants. As discussed in Sec.4.4, the use of backward random walks also enables the modeling of long relational paths within Cor-PRA.

A key observation is that the path probability $P(s \to t; \pi)$ may be computed using forward random walks (Eq. (2)), or alternatively, it can be recursively defined in a *backward* fashion:

$$P(t \leftarrow s; \pi) = \sum_z P(t \leftarrow z; \pi'^{-1})P(z \leftarrow s; r^{-1}) \tag{5}$$

where π'^{-1} is the path that results from removing the last edge type r in π'. Here, in the terminal condition that $\pi'^{-1} = \phi$, $P(t \leftarrow z; \pi'^{-1})$ is defined to be 1 for $z = t$, and 0 otherwise. In what follows, the starting point of the random walk calculation is indicated at the left side of the arrow symbol; i.e., $P(s \to t; \pi)$ denotes the probability of reaching t from s computed using forward random walks, and $P(t \leftarrow s; \pi)$ denotes the same probability, computed in a backward fashion.

4.2 Relational paths with constants

As stated before, we wish to model relational rules that may include constants, denoting related entities or concepts. Main questions are, how can relational rules with constants be represented as path probability features? and, how can meaningful rules with constants be generated and selected efficiently?

In order to address the first question, let us assume that a set of *constant nodes* $\{c\}$, which are known to be useful with respect to relation r, has been already identified. The relationship between each constant c and target node t may be represented in terms of path probability features, $P(c \to t; \pi)$. For example, the rule *IsA*$(t,$ *SportsTeam*$)$ corresponds to a path originating at constant *SportsTeam*, and reaching target node t over a direct edge typed *IsA*$^{-1}$. Such paths, which are independent of the source node s, readily represent the semantic type, or other characteristic attributes of relevant target nodes. Similarly, a feature (c, ϕ), designating a constant and an empty path, forms a prior for the target node identity.

The remaining question is how to identify meaningful constant features. Apriori, candidate constants range over all of the graph nodes, and searching for useful paths that originate at arbitrary constants is generally intractable. Provided with labeled examples, we apply the path-finding procedure for this purpose, where rather than search for high-probability paths from source node s to target t, paths are explored in a backward fashion, initiating path search at the known relevant target nodes $t \in G_i$ per each labeled query. This process identifies candidate (c, π) tuples, which give high $P(c \leftarrow t; \pi^{-1})$ values, at bounded computation cost. As a second step, $P(c \rightarrow t; \pi)$ feature values are calculated, where useful path features are selected using the *precision* and *coverage* criteria. Further details are discussed in Section 4.4.

4.3 Bi-directional Random Walk Features

The PRA algorithm only uses features of the form $P(s \rightarrow t; \pi)$. In this study we also consider graph walk features in the inverse direction of the form $P(s \leftarrow t; \pi^{-1})$. Similarly, we consider both $P(c \rightarrow t; \pi)$ and $P(c \leftarrow t; \pi^{-1})$. While these path feature pairs represent the same logical expressions, the directional random walk probabilities may greatly differ. For example, it may be highly likely for a random walker to reach a target node representing a sports team t from node s denoting a player over a path π that describes the functional *AthletePlaysForTeam* relation, but unlikely to reach a particular player node s from the multiplayer team t via the reversed path π^{-1}.

In general, there are six types of random walk probabilities that may be modeled as relational features following the introduction of constant paths and inverse path probabilities. The random walk probabilities between s and constant nodes c, $P(s \rightarrow c; \pi)$ and $P(s \leftarrow c; \pi)$, do not directly affect the ranking of candidate target nodes, so we do not use them in this study. It is possible, however, to generate random walk features that combine these probabilities with random walks starting or ending with t through conjunction.

Algorithm 1 Cor-PRA Feature Induction[1]

```
Input training queries $\{(s_i, G_i)\}, i = 1...n$
for each query $(s, G)$ do
    1. Path exploration
    (i). Apply path-finding to generate paths $\mathcal{P}_s$ up to length $\ell$ that originate at $s_i$.
    (ii). Apply path-finding to generate paths $\mathcal{P}_t$ up to length $\ell$ that originate at every $t_i \in G_i$.
    2. Calculate random walk probabilities:
    for each $\pi_s \in \mathcal{P}_s$: do
        compute $P(s \rightarrow x; \pi_s)$ and $P(s \leftarrow x; \pi_s^{-1})$
    end for
    for each $\pi_t \in \mathcal{P}_t$: do
        compute $P(G \rightarrow x; \pi_t)$ and $P(G \leftarrow x; \pi_t^{-1})$
    end for
    3. Generate constant paths candidates:
    for each $(x \in N, \pi \in \mathcal{P}_t)$ with $P(G \rightarrow x|\pi_t) > 0$ do
        propose path feature $P(c \leftarrow t; \pi_t^{-1})$ setting $c = x$,
        and update its statistics by $coverage$ += 1.
    end for
    for each $(x \in N, \pi \in \mathcal{P}_t)$ with $P(G \leftarrow x|\pi_t^{-1}) > 0$
    do
        propose $P(c \rightarrow t; \pi_t)$ setting $c = x$ and update its
        statistics by $coverage$ += 1
    end for
    4. Generate long (concatenated) path candidates:
    for each $(x \in N, \pi_s \in \mathcal{P}_s, \pi_t \in \mathcal{P}_t)$ with $P(s \rightarrow x|\pi_s) > 0$ and $P(G \leftarrow x|\pi_t^{-1}) > 0$ do
        propose long path $P(s \rightarrow t; \pi_s.\pi_t^{-1})$ and update its
        statistics by $coverage$ += 1, and $precision$ +=
        $P(s \rightarrow x|\pi_s)P(G \leftarrow x|\pi_t^{-1})/n.$
    end for
    for each $(x \in N, \pi_s \in \mathcal{P}_s, \pi_t \in \mathcal{P}_t)$ with $P(s \leftarrow x|\pi_s^{-1}) > 0$ and $P(G \rightarrow x|\pi_t) > 0$ do
        propose long path $P(s \leftarrow t; \pi_t.\pi_s^{-1})$ and update its
        statistics by $coverage$ += 1, and $precision$ +=
        $P(s \leftarrow x|\pi_s^{-1})P(G \rightarrow x|\pi_t)/n.$
    end for
end for
```

4.4 Cor-PRA feature induction and selection

The proposed feature induction procedure is outlined in Alg. 1. Given labeled node pairs, the particle-filtering path-finding procedure is first applied to identify edge type sequences up to length ℓ that originate at either source nodes s_i or relevant target nodes t_i (step 1). Bi-directional path probabilities are then calculated over these paths, recording the terminal graph nodes x (step 2). Note that since the set of nodes x may be large, path probabilities are all computed with respect to s or t as starting points. As a result of the induction process, candidate relational paths involving constants are identified, and are associated with precision and coverage statistics (step 3). Further, long paths up to length 2ℓ are formed between the source and target nodes as the combination of paths π_s from the source side and path π_t from the target side, updating accuracy and coverage statistics for the concatenated paths $\pi_s\pi_t$

(step 4).

Following feature induction, feature selection is applied. First, random walks are performed for all the training queries, so as to obtain complete (rather than sampled) precision and coverage statistics per path. Then relational paths, which pass respective tuned thresholds are added to the model. We found, however, that applying this strategy for paths with constants often leads to over-fitting. We therefore select only the top K constant features in terms of ${F_1}^2$, where K is tuned using training examples.

Finally, at test time, random walk probabilities are calculated for the selected paths, starting from either s or c nodes per query–since the identity of relevant targets t is unknown, but rather has to be revealed.

5 Experiments

In this section, we report the results of applying Cor-PRA to the tasks of knowledge base inference and person named entity extraction from parsed text.

We performed 3-fold cross validation experiments, given datasets of labeled queries. For each query node in the evaluation set, a list of graph nodes ranked by their estimated relevancy to the query node s and relation r is generated. Ideally, relevant nodes should be ranked at the top of these lists. Since the number of correct answers is large for some queries, we report results in terms of mean average precision (MAP), a measure that reflects both precision and recall (Turpin and Scholer, 2006).

The *coverage* and *precision* thresholds of Cor-PRA were set to $h = 2$ and $a = 0.001$ in all of the experiments, following empirical tuning using a small subset of the training data. The particle filtering path-finding algorithm was applied using the parameter setting $w_g = 10^6$, so as to find useful paths with high probability and yet constrain the computational cost.

Our results are compared against the FOIL algorithm[3], which learns first-order horn clauses. In order to evaluate FOIL using MAP, its candidate beliefs are first ranked by the number of FOIL rules they match. We further report results using *Random Walks with Restart* (RWR), also known as personalized PageRank (Haveliwala, 2002), a popular random walk based graph similarity measure, that has been shown to be fairly successful for many types of tasks (e.g., (Agirre and Soroa, 2009; Moro et al., 2014)). Finally, we compare against PRA, which models relational paths in the form of edge-sequences (no constants), using only uni-directional path probabilities, $P(s \rightarrow t; \pi)$.

Table 1: MAP and training time [sec] on KB inference and NE extraction tasks. $const_i$ denotes constant paths up to length i.

	KB inference		NE extraction	
	Time	MAP	Time	MAP
RWR	25.6	0.429	7,375	0.017
FOIL	18918.1	0.358	366,558	0.167
PRA	10.2	0.477	277	0.107
CoR-PRA-*no-const*	16.7	0.479	449	0.167
CoR-PRA-$const_2$	23.3	0.524	556	0.186
CoR-PRA-$const_3$	27.1	**0.530**	643	**0.316**

All experiments were run on a machine with a 16 core Intel Xeon 2.33GHz CPU and 24Gb of memory. All methods are trained and tested with the same data splits. We report the total training time of each method, measuring the efficiency of inference and induction as a whole.

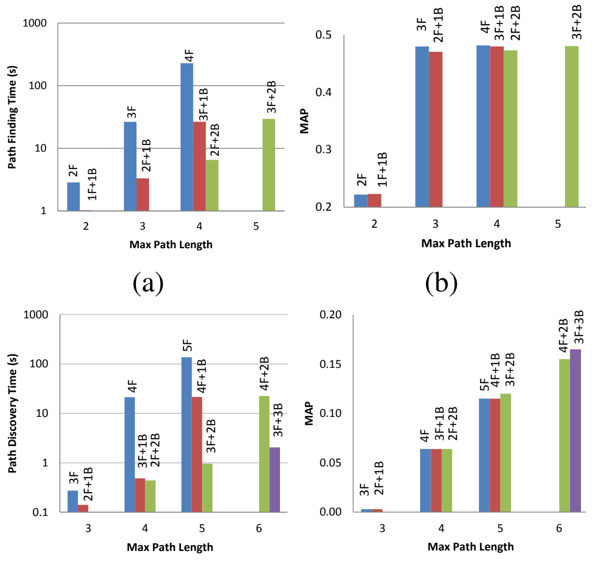
5.1 Knowledge Base Inference

We first consider relational inference in the context of NELL, a semantic knowledge base constructed by continually extracting facts from the Web (Carlson et al., 2010b). This work uses a snapshot of the NELL knowledge base graph, which consists of ~1.6M edges comprised of 353 edge types, and ~750K nodes. Following Lao et al. (2011), we test our approach on 16 link prediction tasks, targeting relations such as *Athlete-plays-in-league*, *Team-plays-in-league* and *Competes-with*.

Table 1 reports MAP results and training times for all of the evaluated methods. The maximum path length of RWR, PRA, and CoR-PRA are set to 3 since longer path lengths do not result in better MAPs. As shown, RWR performance is inferior to PRA; unlike the other approaches, RWR is merely associative and does not involve path learning. PRA is significantly faster than FOIL due to its particle filtering approach in feature induction and inference. It also results in a better MAP performance due to its ability to combine random walk features in a discriminative model.

[2] F_1 is the harmonic mean of precision and recall, where the latter is defined as $\frac{coverage}{total\_number\_targets\_in\_training\_queries}$

[3] http://www.rulequest.com/Personal/



(a) (b)

(c) (d)

Figure 2: Path finding time (a) and MAP (b) for the KB inference (top) and name extraction (bottom) tasks. A marker $iF + jB$ indicates the maximum path exploration depth i from query node s and j from target node t–so that the combined path length is up to $i + j$. No paths with constants were used.

Table 1 further displays the evaluation results of several variants of CoR-PRA. As shown, modeling features that encode random walk probabilities in both directions (CoR-PRA-*no-const*), yet no paths with constants, requires longer training times, but results in slightly better performance compared with PRA. Note that for a fixed path length, CoR-PRA has "forward" features of the form $P(s \rightarrow t; \pi)$, the probability of reaching target node t from source node s over path π (similarly to PRA), as well as backward features of the form $P(s \leftarrow t; \pi^{-1})$, the probability of reaching s from t over the backward path π^{-1}. As mentioned earlier these probabilities are not the same; for example, a player usually plays for one team, whereas a team is linked to many players.

Performance improves significantly, however, when paths with constants are further added. The table includes our results using constant paths up to length $\ell = 2$ and $\ell = 3$ (denoted as CoR-PRA-$const_\ell$). Based on tuning experiments on one fold of the data, $K = 20$ top-rated constant paths were included in the models.[4] We found that these paths provide informative class priors; example paths and their interpretation are included in Table 2.

Table 2: Example paths with constants learnt for the knowledge base inference tasks. (ϕ denotes empty paths.)

Constant path	Interpretation
r=athletePlaysInLeague	
$P(mlb \rightarrow t; \phi)$	Bias toward *MLB*.
$P(boston\_braves \rightarrow t;$ $\langle athletePlaysForTeam^{-1}$, *athletePlaysInLeague*$\rangle)$	The leagues played by *Boston Braves* university team members.
r=competesWith	
$P(google \rightarrow t; \phi)$	Bias toward *Google*.
$P(google \rightarrow t;$ $\langle competesWith, competesWith\rangle)$	Companies which compete with Google's competitors.
r=teamPlaysInLeague	
$P(ncaa \rightarrow t; \phi)$	Bias toward *NCAA*.
$P(boise\_state \rightarrow t;$ $\langle teamPlaysInLeague\rangle)$	The leagues played by *Boise State* university teams.

Figure 2(a) shows the effect of increasing the maximal path length on path finding and selection time. The leftmost (blue) bars show baseline performance of PRA, where only forward random walks are applied. It is clearly demonstrated that the time spent on path finding grows exponentially with ℓ. Due to memory limitations, we were able to execute forward-walk models only up to 4 steps. The bars denoted by $iF + jB$ show the results of combining forward walks up to length i with backward walks of up to $j = 1$ or $j = 2$ steps. Time complexity using bidirectional random walks is dominated by the longest path segment (either forward or backward)—e.g., the settings $3F$, $3F + 1B$, $3F + 2B$ have similar time complexity. Using bidirectional search, we were able to consider relational paths up to length 5. Figure 2(b) presents MAP performance, where it is shown that extending the maximal explored path length did not improve performance in this case. This result indicates that meaningful paths in this domain are mostly short. Accordingly, path length was set to 3 in the respective main experiments.

5.2 Named Entity Extraction

We further consider the task of named entity extraction from a corpus of parsed texts, following previous work by Minkov and Cohen (2008).

In this case, an entity-relation graph schema is used to represent a corpus of parsed sentences, as illustrated in Figure 3. Graph nodes denoting word mentions (in round edged boxes) are linked over edges typed with dependency relations. The

[4] MAP performance peaked at roughly $K = 20$, and gradually decayed as K increased.

parsed sentence structures are connected via nodes that denote word lemmas, where every word lemma is linked to all of its mentions in the corpus via the special edge type W. We represent part-of-speech tags as another set of graph nodes, where word mentions are connected to the relevant tag over POS edge type.

In this graph, task-specific word similarity measures can be derived based on the lexico-syntactic paths that connect word types (Minkov and Cohen, 2014). The task defined in the experiments is to retrieve a ranked list of *person names* given a small set of seeds. This task is implemented in the graph as a query, where we let the query distribution be uniform over the given seeds (and zero elsewhere). That is, our goal is to find target nodes that are related to the query nodes over the relation r =*similar-to*, or, *coordinate-term*. We apply link prediction in this case with the expected result of generating a ranked list of graph nodes, which is populated with many additional person names. The named entity extraction task we consider is somewhat similar to the one adopted by FIGER (Ling and Weld, 2012), in that a finer-grain category is being assigned to proposed named entities. Our approach follows however set expansion settings (Wang and Cohen, 2007), where the goal is to find new instances of the specified type from parsed text.

In the experiments, we use the training set portion of the MUC-6 data set (MUC, 1995), represented as a graph of 153k nodes and 748K edges. We generated 30 labeled queries, each comprised of 4 person names selected randomly from the person names mentioned in the data set. The MUC corpus is fully annotated with entity names, so that relevant target nodes (other person names) were readily sampled. Extraction performance was evaluated considering the tagged *person names*, which were not included in the query, as the correct answer set. The maximum path length of RWR, PRA, and CoR-PRA are set to 6 due to memory limitation.

Table 1 shows that PRA is much faster than RWR or FOIL on this data set, giving competitive MAP performance to FOIL. RWR is generally ineffective on this task, because similarity in this domain is represented by a relatively small set of long paths, whereas RWR express local node associations in the graph (Minkov and Cohen, 2008). Modeling inverse path probabilities improves performance substantially, and adding relational features with constants boosts performance further. The constant paths learned encode lexical features, as well as provide useful priors, mainly over different part-of-speech tags. Example constant paths that were highly weighted in the learned models and their interpretation are given in Table 3.

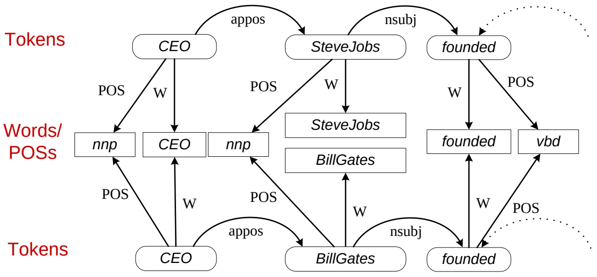


Figure 3: Part of a typed graph representing a corpus of parsed sentences.

Table 3: Highly weighted paths with constants learnt for the person name extraction task.

Constant path	Interpretation
$P(said \leftarrow t; W^{-1}, nsubj, W)$	The subjects of ‘said’ or ‘say’
$P(says \leftarrow t; W^{-1}, nsubj, W)$	are likely to be a person name.
$P(vbg \leftarrow t; POS^{-1}, nsubj, W)$	Subjects, proper nouns, and
$P(nnp \leftarrow t; POS^{-1}, W)$	nouns with apposition or
$P(nn \leftarrow t; POS^{-1}, appos^{-1}, W)$	possessive constructions, are
$P(nn \leftarrow t; POS^{-1}, poss, W)$	likely to be person names.

Figure 2(c) shows the effect of modeling long relational paths using bidirectional random walks in the language domain. Here, forward path finding was applied to paths up to length 5 due to memory limitation. The figure displays the results of exploring paths up to a total length of 6 edges, performing backward search from the target nodes of up to $j = 1, 2, 3$ steps. MAP performance (Figure 2(d)) using paths of varying lengths shows significant improvements as the path length increases. Top weighted long features include:

$P(s \rightarrow t; W^{-1}, conj\_and^{-1}, W, W^{-1}, conj\_and, W)$
$P(s \rightarrow t; W^{-1}, nn, W, W^{-1}, appos^{-1}, W)$
$P(s \rightarrow t; W^{-1}, appos, W, W^{-1}, appos^{-1}, W)$

These paths are similar to the top ranked paths found in previous work (Minkov and Cohen, 2008). In comparison, their results on this dataset using paths of up to 6 steps measured 0.09 in MAP. Our results reach roughly 0.16 in MAP due to modeling of inverse paths; and, when constant paths are incorporated, MAP reaches 0.32.

Interestingly, in this domain, FOIL generates fewer yet more complex rules, which are characterised with low recall and high precision, such as: $W(B,A) \wedge POS(B,nnp) \wedge nsubj(D,B) \wedge W(D,said) \wedge appos(B,F) \rightarrow person(A)$. Note that subsets of these rules, namely, $POS(B,nnp)$, $nsubj(D,B) \wedge W(D,said)$ and $appos(B,F)$ have been discovered by PRA as individual features assigned with high weights (Table 3). This indicates an interesting future work, where products of random walk features can be used to express their conjunctions.

6 Conclusion

We have introduced CoR-PRA, extending an existing random walk based relational learning paradigm to consider relational paths with constants, bi-directional path features, as well as long paths. Our experiments on knowledge base inference and person name extraction tasks show significant improvements over previously published results, while maintaining efficiency. An interesting future direction is to use products of these random walk features to express their conjunctions.

Abstract

In this paper we present a formal computational framework for modeling manipulation actions. The introduced formalism leads to semantics of manipulation action and has applications to both observing and understanding human manipulation actions as well as executing them with a robotic mechanism (e.g. a humanoid robot). It is based on a Combinatory Categorial Grammar. The goal of the introduced framework is to: (1) represent manipulation actions with both syntax and semantic parts, where the semantic part employs λ-calculus; (2) enable a probabilistic semantic parsing schema to learn the $lambda$-calculus representation of manipulation action from an annotated action corpus of videos; (3) use (1) and (2) to develop a system that visually observes manipulation actions and understands their meaning while it can reason beyond observations using propositional logic and axiom schemata. The experiments conducted on a public available large manipulation action dataset validate the theoretical framework and our implementation.

1 Introduction

Autonomous robots will need to learn the actions that humans perform. They will need to recognize these actions when they see them and they will need to perform these actions themselves. This requires a formal system to represent the action semantics. This representation needs to store the semantic information about the actions, be encoded in a machine readable language, and inherently be in a programmable fashion in order to enable reasoning beyond observation. A formal representation of this kind has a variety of other applications such as intelligent manufacturing, human robot collaboration, action planning and policy design, etc.

In this paper, we are concerned with manipulation actions, that is actions performed by agents (humans or robots) on objects, resulting in some physical change of the object. However most of the current AI systems require manually defined semantic rules. In this work, we propose a computational linguistics framework, which is based on probabilistic semantic parsing with Combinatory Categorial Grammar (CCG), to learn manipulation action semantics (lexicon entries) from annotations. We later show that this learned lexicon is able to make our system reason about manipulation action goals beyond just observation. Thus the intelligent system can not only imitate human movements, but also imitate action goals.

Understanding actions by observation and executing them are generally considered as dual problems for intelligent agents. The sensori-motor bridge connecting the two tasks is essential, and a great amount of attention in AI, Robotics as well as Neurophysiology has been devoted to investigating it. Experiments conducted on primates have discovered that certain neurons, the so-called mirror neurons, fire during both observation and execution of identical manipulation tasks (Rizzolatti et al., 2001; Gazzola et al., 2007). This suggests that the same process is involved in both the observation and execution of actions. From a functionalist point of view, such a process should be able to first build up a semantic structure from observations, and then the decomposition of that same structure should occur when the intelligent agent executes commands.

Additionally, studies in linguistics (Steedman, 2002) suggest that the language faculty develops in humans as a direct adaptation of a more primitive apparatus for planning goal-directed action in the world by composing affordances of tools and consequences of actions. It is this more primitive

apparatus that is our major interest in this paper. Such an apparatus is composed of a “syntax part” and a “semantic part”. In the syntax part, every linguistic element is categorized as either a function or a basic type, and is associated with a syntactic category which either identifies it as a function or a basic type. In the semantic part, a semantic translation is attached following the syntactic category explicitly.

Combinatory Categorial Grammar (CCG) introduced by (Steedman, 2000) is a theory that can be used to represent such structures with a small set of combinators such as functional application and type-raising. What do we gain though from such a formal description of action? This is similar to asking what one gains from a formal description of language as a generative system. Chomskys contribution to language research was exactly this: the formal description of language through the formulation of the Generative and Transformational Grammar (Chomsky, 1957). It revolutionized language research opening up new roads for the computational analysis of language, providing researchers with common, generative language structures and syntactic operations, on which language analysis tools were built. A grammar for action would contribute to providing a common framework of the syntax and semantics of action, so that basic tools for action understanding can be built, tools that researchers can use when developing action interpretation systems, without having to start development from scratch. The same tools can be used by robots to execute actions.

In this paper, we propose an approach for learning the semantic meaning of manipulation action through a probabilistic semantic parsing framework based on CCG theory. For example, we want to learn from an annotated training action corpus that the action “Cut” is a function which has two arguments: a subject and a patient. Also, the action consequence of “Cut” is a separation of the patient. Using formal logic representation, our system will learn the semantic representations of “Cut”:

$$Cut := (AP\backslash NP)/NP : \lambda x.\lambda y.cut(x,y) \rightarrow divided(y)$$

Here $cut(x, y)$ is a primitive function. We will further introduce the representation in Sec. 3. Since our action representation is in a common calculus form, it enables naturally further logical reasoning beyond visual observation.

The advantage of our approach is twofold: 1) Learning semantic representations from annotations helps an intelligent agent to enrich automatically its own knowledge about actions; 2) The formal logic representation of the action could be used to infer the object-wise consequence after a certain manipulation, and can also be used to plan a set of actions to reach a certain action goal. We further validate our approach on a large publicly available manipulation action dataset (MANIAC) from (Aksoy et al., 2014), achieving promising experimental results. Moreover, we believe that our work, even though it only considers the domain of manipulation actions, is also a promising example of a more closely intertwined computer vision and computational linguistics system. The diagram in Fig.1 depicts the framework of the system.

2 Related Works

Reasoning beyond appearance: The very small number of works in computer vision, which aim to reason beyond appearance models, are also related to this paper. (Xie et al., 2013) proposed that beyond state-of-the-art computer vision techniques, we could possibly infer implicit information (such as functional objects) from video, and they call them “Dark Matter” and “Dark Energy”. (Yang et al., 2013) used stochastic tracking and graph-cut based segmentation to infer manipulation consequences beyond appearance. (Joo et al., 2014) used a ranking SVM to predict the persuasive motivation (or the intention) of the photographer who captured an image. More recently, (Pirsiavash et al., 2014) seeks to infer the motivation of the person in the image by mining knowledge stored in a large corpus using natural language processing techniques. Different from these fairly general investigations about reasoning beyond appearance, our paper seeks to learn manipulation actions semantics in logic forms through CCG, and further infer hidden action consequences beyond appearance through reasoning.

Action Recognition and Understanding: Human activity recognition and understanding has been studied heavily in Computer Vision recently, and there is a large range of applications for this work in areas like human-computer interactions, biometrics, and video surveillance. Both visual recognition methods, and the non-visual description methods using motion capture systems have been used. A few good surveys of the former can be found in (Moeslund et al., 2006) and (Turaga et al., 2008). Most of the focus has been on recognizing single human actions like walking, jumping, or running etc. (Ben-Arie et al., 2002; Yilmaz and Shah, 2005). Approaches to more complex actions have employed parametric approaches, such as HMMs (Kale et al., 2004) to learn the transition between feature representations in individual frames e.g. (Saisan et al., 2001; Chaudhry et al., 2009). More recently, (Aksoy et al., 2011; Aksoy et al., 2014) proposed a semantic event chain (SEC) representation to model and learn the semantic segment-wise relationship transition from spatial-temporal video segmentation.

There also have been many syntactic approaches to human activity recognition which used the concept of context-free grammars, because such grammars provide a sound theoretical basis for modeling structured processes. Tracing back to the middle 90's, (Brand, 1996) used a grammar to recognize disassembly tasks that contain hand manipulations. (Ryoo and Aggarwal, 2006) used the context-free grammar formalism to recognize composite human activities and multi-person interactions. It is a two level hierarchical approach where the lower-levels are composed of HMMs and Bayesian Networks while the higher-level interactions are modeled by CFGs. To deal with errors from low-level processes such as tracking, stochastic grammars such as stochastic CFGs were also used (Ivanov and Bobick, 2000; Moore and Essa, 2002). More recently, (Kuehne et al., 2014) proposed to model goal-directed human activities using Hidden Markov Models and treat subactions just like words in speech. These works proved that grammar based approaches are practical in activity recognition systems, and shed insight onto human manipulation action understanding. However, as mentioned, thinking about manipulation actions solely from the viewpoint of recognition has obvious limitations. In this work we adopt principles from CFG based activity recognition systems, with extensions to a CCG grammar that accommodates not only the hierarchical structure of human activity but also action semantics representations. It enables the system to serve as the core parsing engine for both manipulation action recognition and execution.

Manipulation Action Grammar: As mentioned before, (Chomsky, 1993) suggested that a minimalist generative grammar, similar to the one of human language, also exists for action understanding and execution. The works closest related to this paper are (Pastra and Aloimonos, 2012; Summers-Stay et al., 2013; Guha et al., 2013). (Pastra and Aloimonos, 2012) first discussed a Chomskyan grammar for understanding complex actions as a theoretical concept, and (Summers-Stay et al., 2013) provided an implementation of such a grammar using as perceptual input only objects. More recently, (Yang et al., 2014) proposed a set of context-free grammar rules for manipulation action understanding, and (Yang et al., 2015) applied it on unconstrained instructional videos. However, these approaches only consider the syntactic structure of manipulation actions without coupling semantic rules using λ expressions, which limits the capability of doing reasoning and prediction.

Combinatory Categorial Grammar and Semantic Parsing: CCG based semantic parsing originally was used mainly to translate natural language sentences to their desired semantic representations as λ-calculus formulas (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007). (Mooney, 2008) presented a framework of grounded language acquisition: the interpretation of language entities into semantically informed structures in the context of perception and actuation. The concept has been applied successfully in tasks such as robot navigation (Matuszek et al., 2011), forklift operation (Tellex et al., 2014) and of human-robot interaction (Matuszek et al., 2014). In this work, instead of grounding natural language sentences directly, we ground information obtained from visual perception into semantically informed structures, specifically in the domain of manipulation actions.

3 A CCG Framework for Manipulation Actions

Before we dive into the semantic parsing of manipulation actions, a brief introduction to the Combinatory Categorial Grammar framework in Linguistics is necessary. We will only introduce related concepts and formalisms. For a complete background reading, we would like to refer readers to (Steedman, 2000). We will first give a brief introduction to CCG and then introduce a fundamental combinator, i.e., functional application. The introduction is followed by examples to show how the combinator is applied to parse actions.

3.1 Manipulation Action Semantics

The semantic expression in our representation of manipulation actions uses a typed λ-calculus language. The formal system has two basic types: entities and functions. Entities in manipulation actions are Objects or Hands, and functions are the Actions. Our $lambda$-calculus expressions are formed from the following items:

Constants: Constants can be either entities or functions. For example, *Knife* is an entity (i.e., it is of type N) and *Cucumber* is an entity too (i.e., it is of type N). *Cut* is an action function that maps entities to entities. When the event *Knife Cut Cucumber* happened, the expression *cut(Knife, Cucumber)* returns an entity of type AP, aka. Action Phrase. Constants like *divided* are status functions that map entities to truth values. The expression $divided(cucumber)$ returns a true value after the event (*Knife Cut Cucumber*) happened.

Logical connectors: The λ-calculus expression has logical connectors like conjunction ($\wedge$), disjunction ($\vee$), negation($\neg$) and implication($\rightarrow$).

For example, the expression

$$connected(tomato, cucumber)\wedge \\ divided(tomato) \wedge divided(cucumber)$$

represents the joint status that the sliced *tomato* merged with the sliced *cucumber*. It can be regarded as a simplified goal status for "making a cucumber tomato salad". The expression $\neg connected(spoon, bowl)$ represents the status after the *spoon* finished stirring the *bowl*.

$$\lambda x.cut(x, cucumber) \rightarrow divided(cucumber)$$

represents that if the *cucumber* is cut by x, then the status of the *cucumber* is divided.

λ **expressions**: $lambda$ expressions represent functions with unknown arguments. For example, $\lambda x.cut(knife, x)$ is a function from entities to entities, which is of type NP after any entities of type N that is cut by *knife*.

3.2 Combinatory Categorial Grammar

The semantic parsing formalism underlying our framework for manipulation actions is that of combinatory categorial grammar (CCG) (Steedman, 2000). A CCG specifies one or more logical forms for each element or combination of elements for manipulation actions. In our formalism, an element of Action is associated with a syntactic "category" which identifies it as functions, and specifies the type and directionality of their arguments and the type of their result. For example, action "Cut" is a function from patient object phrase (NP) on the right into predicates, and into functions from subject object phrase (NP) on the left into a sub action phrase (AP):

$$Cut := (AP\backslash NP)/NP. \tag{1}$$

As a matter of fact, the pure categorial grammar is a conext-free grammar presented in the accepting, rather than the producing direction. The expression (1) is just an accepting form for Action "Cut" following the context-free grammar. While it is now convenient to write derivations as follows, they are equivalent to conventional tree structure derivations in Figure. 3.2.

$$\begin{array}{ccc}
\text{Knife} & \text{Cut} & \text{Cucumber} \\
\hline
N & & N \\
\hline
NP & (AP\backslash NP)/NP & NP \\
\hline
 & \multicolumn{2}{c}{AP\backslash NP \quad >} \\
\hline
\multicolumn{2}{c}{AP \quad <} &
\end{array}$$

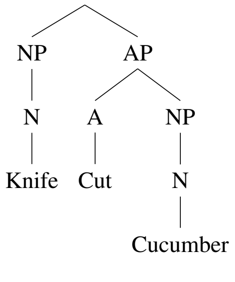

Figure 2: Example of conventional tree structure.

The semantic type is encoded in these categories, and their translation can be made explicit in an expanded notation. Basically a λ-calculus expression is attached with the syntactic category. A colon operator is used to separate syntactical and semantic expressions, and the right side of the colon is assumed to have lower precedence than the left side of the colon. Which is intuitive as any explanation of manipulation actions should first obey syntactical rules, then semantic rules. Now the basic element, Action "Cut", can be further represented by:

$$Cut := (AP\backslash NP)/NP : \lambda x.\lambda y.cut(x,y) \rightarrow divided(y).$$

$(AP\backslash NP)/NP$ denotes a phrase of type AP, which requires an element of type NP to specify what object was cut, and requires another element of type NP to further complement what effector initiates the cut action. $\lambda x.\lambda y.cut(x,y)$ is the λ-calculus representation for this function. Since the functions are closely related to the state update, $\rightarrow divided(y)$ further points out the status expression after the action was performed.

A CCG system has a set of combinatory rules which describe how adjacent syntatic categories in a string can be recursively combined. In the setting of manipulation actions, we want to point out that similar combinatory rules are also applicable. Especially the functional application rules are essential in our system.

3.3 Functional application

The functional application rules with semantics can be expressed in the following form:

$$A/B : f \quad B : g => A : f(g) \tag{2}$$

$$B : g \quad A\backslash B : f => A : f(g) \tag{3}$$

Rule. (2) says that a string with type A/B can be combined with a right-adjacent string of type B to form a new string of type A. At the same time, it also specifies how the semantics of the category A can be compositionally built out of the semantics for A/B and B. Rule. (3) is a symmetric form of Rule. (2).

In the domain of manipulation actions, following derivation is an example CCG parse. This parse shows how the system can parse an observation ("Knife Cut Cucumber") into a semantic representation ($cut(knife, cucumber) \rightarrow divided(cucumber)$) using the functional application rules.

$$\begin{array}{ccc}
\text{Knife} & \text{Cut} & \text{Cucumber} \\ \hline
N & & N \\ \hline
NP & (AP\backslash NP)/NP & NP \\
knife & \lambda x.\lambda y.cut(x,y) & cucumber \\
knife & \rightarrow divided(y) & cucumber \\ \cline{2-3}
 & \multicolumn{2}{c}{AP\backslash NP \quad >} \\
 & \multicolumn{2}{c}{\lambda x.cut(x, cucumber)} \\
 & \multicolumn{2}{c}{\rightarrow divided(cucumber)} \\ \hline
\multicolumn{3}{c}{AP \quad <} \\
\multicolumn{3}{c}{cut(knife, cucumber)} \\
\multicolumn{3}{c}{\rightarrow divided(cucumber)}
\end{array}$$

4 Learning Model and Semantic Parsing

After having defined the formalism and application rule, instead of manually writing down all the possible CCG representations for each entity, we would like to apply a learning technique to derive them from the paired training corpus. Here we adopt the learning model of (Zettlemoyer and Collins, 2005), and use it to assign weights to the semantic representation of actions. Since an action may have multiple possible syntactic and semantic representations assigned to it, we use the probabilistic model to assign weights to these representations.

4.1 Learning Approach

First we assume that complete syntactic parses of the observed action are available, and in fact a manipulation action can have several different parses. The parsing uses a probabilistic combinatorial categorial grammar framework similar to the one given by (Zettlemoyer and Collins, 2007). We assume a probabilistic categorial grammar (PCCG) based on a log linear model. M denotes a manipulation task, L denotes the semantic representation of the task, and T denotes its parse tree. The probability of a particular syntactic and semantic parse is given as:

$$P(L,T|M;\Theta) = \frac{e^{f(L,T,M)\cdot\Theta}}{\sum_{(L,T)} e^{f(L,T,M)\cdot\Theta}} \tag{4}$$

where f is a mapping of the triple (L,T,M) to feature vectors $\in R^d$, and the $\Theta \in R^d$ represents the weights to be learned. Here we use only lexical features, where each feature counts the number of times a lexical entry is used in T. Parsing a manipulation task under PCCG equates to finding L such that $P(L|M;\Theta)$ is maximized:

$$\begin{aligned} &argmax_L P(L|M;\Theta) \\ &= argmax_L \sum_T P(L,T|M;\Theta). \end{aligned} \tag{5}$$

We use dynamic programming techniques to calculate the most probable parse for the manipulation task. In this paper, the implementation from (Baral et al., 2011) is adopted, where an inverse-λ technique is used to generalize new semantic representations. The generalization of lexicon rules are essential for our system to deal with unknown actions presented during the testing phase.

5 Experiments

5.1 Manipulation Action (MANIAC) Dataset

(Aksoy et al., 2014) provides a manipulation action dataset with 8 different manipulation actions (cutting, chopping, stirring, putting, taking, hiding, uncovering, and pushing), each of which consists of 15 different versions performed by 5 different human actors[1]. There are in total 30 different objects manipulated in all demonstrations. All manipulations were recorded with the Microsoft Kinect sensor and serve as **training** data here.

The MANIAC data set contains another 20 long and complex chained manipulation sequences (e.g. "making a sandwich") which consist of a total of 103 different versions of these 8 manipulation tasks performed in different orders with novel objects under different circumstances. These serve as **testing** data for our experiments.

(Aksoy et al., 2014; Aksoy and Wörgötter, 2015) developed a semantic event chain based model free decomposition approach. It is an unsupervised probabilistic method that measures the frequency of the changes in the spatial relations embedded in event chains, in order to extract the subject and patient visual segments. It also decomposes the long chained complex testing actions into their primitive action components according to the spatio-temporal relations of the manipulator. Since the visual recognition is not the core of this work, we omit the details here and refer the interested reader to (Aksoy et al., 2014; Aksoy and Wörgötter, 2015). All these features make the MANIAC dataset a great testing bed for both the theoretical framework and the implemented system presented in this work.

5.2 Training Corpus

We first created a training corpus by annotating the 120 training clips from the MANIAC dataset, in the format of observed triplets (subject action patient) and a corresponding semantic representation of the action as well as its consequence. The semantic representations in λ-calculus format are given by human annotators after watching each action clip. A set of sample training pairs are given in Table.1 (one from each action category in the training set). Since every training clip contains one single full execution of each manipulation action considered, the training corpus thus has a total of 120 paired training samples.

Snapshot	triplet	semantic representation
	cleaver chopping carrot	$chopping(cleaver, carrot)$ $\rightarrow divided(carrot)$
	spatula cutting pepper	$cutting(spatula, pepper)$ $\rightarrow divided(pepper)$
	spoon stirring bucket	$stirring(spoon, bucket)$
	cup take_down bucket	$take\_down(cup, bucket)$ $\rightarrow \neg connected(cup, bucket)$ $\wedge moved(cup)$
	cup put_on_top bowl	$put\_on\_top(cup, bowl)$ $\rightarrow on\_top(cup, bowl)$ $\wedge moved(cup)$
	bucket hiding ball	$hiding(bucket, ball)$ $\rightarrow contained(bucket, ball)$ $\wedge moved(bucket)$
	hand pushing box	$pushing(hand, box)$ $\rightarrow moved(box)$
	box uncover apple	$uncover(box, apple)$ $\rightarrow appear(apple)$ $\wedge moved(box)$

Table 1: Example annotations from training corpus, one per manipulation action category.

We also assume the system knows that every "object" involved in the corpus is an entity of its own type, for example:

$$Knife := N : knife$$
$$Bowl := N : bowl$$
$$......$$

Additionally, we assume the syntactic form of each "action" has a main type $(AP\backslash NP)/NP$ (see Sec. 3.2). These two sets of rules form the initial seed lexicon for learning.

5.3 Learned Lexicon

We applied the learning technique mentioned in Sec. 4, and we used the NL2KR implementation from (Baral et al., 2011). The system learns and generalizes a set of lexicon entries (syntactic and semantic) for each action categories from the training corpus accompanied with a set of weights.

[1] Dataset available for download at https://fortknox.physik3.gwdg.de/cns/index.php?page=maniac-dataset.

We list the one with the largest weight for each action here respectively:

$$\begin{aligned}
Chopping :=& (AP\backslash NP)/NP : \lambda x.\lambda y.chopping(x,y)\\
&\rightarrow divided(y)\\
Cutting :=& (AP\backslash NP)/NP : \lambda x.\lambda y.cutting(x,y)\\
&\rightarrow divided(y)\\
Stirring :=& (AP\backslash NP)/NP : \lambda x.\lambda y.stirring(x,y)\\
Take\_down :=& (AP\backslash NP)/NP : \lambda x.\lambda y.take\_down(x,y)\\
&\rightarrow \neg connected(x,y) \wedge moved(x)\\
Put\_on\_top :=& (AP\backslash NP)/NP : \lambda x.\lambda y.put\_on\_top(x,y)\\
&\rightarrow on\_top(x,y) \wedge moved(x)\\
Hiding :=& (AP\backslash NP)/NP : \lambda x.\lambda y.hiding(x,y)\\
&\rightarrow contained(x,y) \wedge moved(x)\\
Pushing :=& (AP\backslash NP)/NP : \lambda x.\lambda y.pushing(x,y)\\
&\rightarrow moved(y)\\
Uncover :=& (AP\backslash NP)/NP : \lambda x.\lambda y.uncover(x,y)\\
&\rightarrow appear(y) \wedge moved(x).
\end{aligned}$$

The set of seed lexicon and the learned lexicon entries are further used to probabilistically parse the detected triplet sequences from the 20 long manipulation activities in the testing set.

5.4 Deducing Semantics

Using the decomposition technique from (Aksoy et al., 2014; Aksoy and Wörgötter, 2015), the reported system is able to detect a sequence of action triplets in the form of (Subject Action Patient) from each of the testing sequence in MANIAC dataset. Briefly speaking, the event chain representation (Aksoy et al., 2011) of the observed long manipulation activity is first scanned to estimate the main manipulator, i.e. the hand, and manipulated objects, e.g. knife, in the scene without employing any visual feature-based object recognition method. Solely based on the interactions between the hand and manipulated objects in the scene, the event chain is partitioned into chunks. These chunks are further fragmented into subunits to detect parallel action streams. Each parsed Semantic Event Chain (SEC) chunk is then compared with the model SECs in the library to decide whether the current SEC sample belongs to one of the known manipulation models or represents a novel manipulation. SEC models, stored in the library, are learned in an on-line unsupervised fashion using the semantics of manipulations derived from a given set of training data in order to create a large vocabulary of single atomic manipulations.

For the different testing sequence, the number of triplets detected ranges from two to seven. In total, we are able to collect 90 testing detections and they serve as the testing corpus. However, since many of the objects used in the testing data are not present in the training set, an object model-free approach is adopted and thus "subject" and "patient" fields are filled with segment IDs instead of a specific object name. Fig. 3 and 4 show several examples of the detected triplets accompanied with a set of key frames from the testing sequences. Nevertheless, the method we used here can 1) generalize the unknown segments into the category of object entities and 2) generalize the unknown actions (those that do not exist in the training corpus) into the category of action function. This is done by automatically generalizing the following two types of lexicon entries using the inverse-λ technique from (Baral et al., 2011):

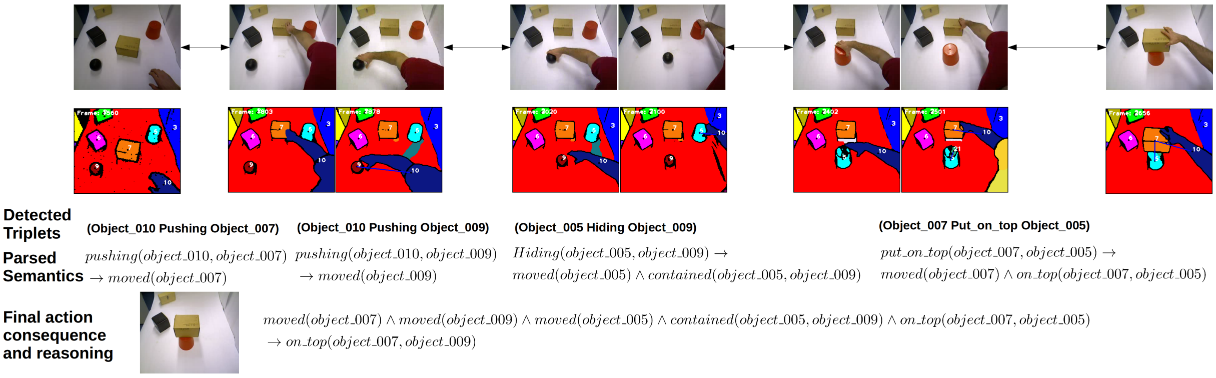
$$\begin{aligned}
Object\_[ID] :=& N : object\_[ID]\\
Unknown :=& (AP\backslash NP)/NP : \lambda x.\lambda y.unknown(x,y)
\end{aligned}$$

Among the 90 detected triplets, using the learned lexicon we are able to parse all of them into semantic representations. Here we pick the representation with the highest probability after parsing as the individual action semantic representation. The "parsed semantics" rows of Fig. 3 and 4 show several example action semantics on testing sequences. Taking the fourth sub-action from Fig. 4 as an example, the visually detected triplets based on segmentation and spatial decomposition is $(Object\_014, Chopping, Object\_011)$. After semantic parsing, the system predicts that $divided(Object\_011)$. The complete training corpus and parsed results of the testing set will be made publicly available for future research.

5.5 Reasoning Beyond Observations

As mentioned before, because of the use of λ-calculus for representing action semantics, the obtained data can naturally be used to do logical reasoning beyond observations. This by itself is a very interesting research topic and it is beyond this paper's scope. However by applying a couple of common sense Axioms on the testing data, we can provide some flavor of this idea.

Case study one: See the "final action consequence and reasoning" row of Fig. 3 for case one. Using propositional logic and axiom schema, we can represent the common sense statement ("if an object x is contained in object y, and object z is on top of object y, then object z is on top of object x") as follows:



Detected Triplets
(Object_010 Pushing Object_007)
(Object_010 Pushing Object_009)
(Object_005 Hiding Object_009)
(Object_007 Put_on_top Object_005)
Parsed Semantics
$pushing(object\_010, object\_007) \rightarrow moved(object\_007)$
$pushing(object\_010, object\_009) \rightarrow moved(object\_009)$
$Hiding(object\_005, object\_009) \rightarrow moved(object\_005) \wedge contained(object\_005, object\_009)$
$put\_on\_top(object\_007, object\_005) \rightarrow moved(object\_007) \wedge on\_top(object\_007, object\_005)$
Final action consequence and reasoning
$moved(object\_007) \wedge moved(object\_009) \wedge moved(object\_005) \wedge contained(object\_005, object\_009) \wedge on\_top(object\_007, object\_005) \rightarrow on\_top(object\_007, object\_009)$

Figure 3: System output on complex chained manipulation testing sequence one. The segmentation output and detected triplets are from (Aksoy and Wörgötter, 2015)

Final action consequence and reasoning
$moved(object\_005) \wedge moved(object\_010) \wedge moved(object\_011) \wedge \neg connceted(object\_005, object\_006) \wedge contained(object\_010, object\_005) \wedge contained(object\_011, object\_010) \wedge divided(object\_011) \wedge on\_top(object\_011, object\_012) \rightarrow divided(object\_005) \wedge divided(object\_010) \wedge on\_top(object\_005, object\_012) \wedge on\_top(object\_010, object\_012)$

Figure 4: System output on the 18th complex chained manipulation testing sequence. The segmentation output and detected triplets are from (Aksoy and Wörgötter, 2015)

.

Axiom (1): $\exists x, y, z, contained(y, x) \wedge on\_top(z, y) \rightarrow on\_top(z, x)$.

Then it is trivial to deduce an additional final action consequence in this scenario that $(on\_top(object\_007, object\_009))$. This matches the fact: the yellow box which is put on top of the red bucket is also on top of the black ball.

Case study two: See the "final action consequence and reasoning" row of Fig. 4 for a more complicated case. Using propositional logic and axiom schema, we can represent three common sense statements:

1) "if an object y is contained in object x, and object z is contained in object y, then object z is contained in object x";

2) "if an object x is contained in object y, and object y is divided, then object x is divided";

3) "if an object x is contained in object y, and object y is on top of object z, then object x is on top of object z" as follows:

Axiom (2): $\exists x, y, z, contained(y, x) \wedge contained(z, y) \rightarrow contained(z, x)$.

Axiom (3): $\exists x, y, contained(y, x) \wedge divided(y) \rightarrow divided(x)$.

Axiom (4): $\exists x, y, z, contained(y, x) \wedge on\_top(y, z) \rightarrow on\_top(x, z)$.

With these common sense Axioms, the system is able to deduce several additional final action consequences in this scenario:

$$divided(object\_005) \wedge divided(object\_010)$$
$$\wedge\ on\_top(object\_005, object\_012)$$
$$\wedge\ on\_top(object\_010, object\_012).$$

From Fig. 4, we can see that these additional consequences indeed match the facts: 1) the bread and cheese which are covered by ham are also divided, even though from observation the system only detected the ham being cut; 2) the divided bread and cheese are also on top of the plate, even though from observation the system only detected the ham being put on top of the plate.

We applied the four Axioms on the 20 testing action sequences and deduced the "hidden" consequences from observation. To evaluate our system performance quantitatively, we first annotated all the final action consequences (both obvious and "hidden" ones) from the 20 testing sequences as ground-truth facts. In total there are 122 consequences annotated. Using perception only (Aksoy and Wörgötter, 2015), due to the decomposition errors (such as the red font ones in Fig. 4) the system can detect 91 consequences correctly, yielding a 74% correct rate. After applying the four Axioms and reasoning, our system is able to detect 105 consequences correctly, yielding a 86% correct rate. Overall, this is a 15.4% of improvement.

Here we want to mention a caveat: there are definitely other common sense Axioms that we are not able to address in the current implementation. However, from the case studies presented, we can see that using the presented formal framework, our system is able to reason about manipulation action goals instead of just observing what is happening visually. This capability is essential for intelligent agents to imitate action goals from observation.

6 Conclusion and Future Work

In this paper we presented a formal computational framework for modeling manipulation actions based on a Combinatory Categorial Grammar. An empirical study on a large manipulation action dataset validates that 1) with the introduced formalism, a learning system can be devised to deduce the semantic meaning of manipulation actions in λ-schema; 2) with the learned schema and several common sense Axioms, our system is able to reason beyond just observation and deduce "hidden" action consequences, yielding a decent performance improvement.

Due to the limitation of current testing scenarios, we conducted experiments only considering a relatively small set of seed lexicon rules and logical expressions. Nevertheless, we want to mention that the presented CCG framework can also be extended to learn the formal logic representation of more complex manipulation action semantics. For example, the temporal order of manipulation actions can be modeled by considering a seed rule such as $AP\backslash AP : \lambda f.\lambda g.before(f(\cdot), g(\cdot))$, where $before(\cdot,\cdot)$ is a temporal predicate. For actions in this paper we consider seed main type $(AP\backslash NP)/NP$. For more general manipulation scenarios, based on whether the action is transitive or intransitive, the main types of action can be extended to include $AP\backslash NP$.

Moreover, the logical expressions can also be extended to include universal quantification $\forall$ and existential quantification $\exists$. Thus, manipulation action such as "knife cut every tomato" can be parsed into a representation as $\forall x.tomato(x) \wedge cut(knife, x) \rightarrow divided(x)$ (the parse is given in the following chart). Here, the concept "every" has a main type of $NP\backslash NP$ and semantic meaning of $\forall x.f(x)$. The same framework can also extended to have other combinatory rules such as **composition** and **type-raising** (Steedman, 2002). These are parts of the future work along the line of the presented work.

$$
\begin{array}{cccc}
\text{Knife} & \text{Cut} & \text{every} & \text{Tomato} \\
\hline
N & & & N \\
\hline
NP & (AP\backslash NP)/NP & NP\backslash NP & NP \\
knife & \lambda x.\lambda y.cut(x,y) & \forall x.f(x) & tomato \\
knife & \rightarrow divided(y) & \forall x.f(x) & tomato \\
\cline{3-4}
 & & \multicolumn{2}{c}{NP \quad >} \\
 & & \multicolumn{2}{c}{\forall x.tomato(x)} \\
\cline{2-4}
 & \multicolumn{3}{c}{AP\backslash NP \quad >} \\
 & \multicolumn{3}{c}{\forall y.\lambda x.tomato(y) \wedge cut(x,y) \rightarrow divided(y)} \\
\hline
\multicolumn{4}{c}{AP \quad <} \\
\multicolumn{4}{c}{\forall y.tomato(y) \wedge cut(knife,y) \rightarrow divided(y)}
\end{array}
$$

The presented computational linguistic framework enables an intelligent agent to predict and reason action goals from observation, and thus has many potential applications such as human intention prediction, robot action policy planning, human robot collaboration etc. We believe that our formalism of manipulation actions bridges computational linguistics, vision and robotics, and opens further research in Artificial Intelligence and Robotics. As the robotics industry is moving towards robots that function safely, effectively and autonomously to perform tasks in real-world unstructured environments, they will need to be able to understand the meaning of actions and acquire human-like common-sense reasoning capabilities.

Abstract

Knowledge graphs are useful resources for numerous AI applications, but they are far from completeness. Previous work such as TransE, TransH and TransR/CTransR regard a relation as translation from head entity to tail entity and the CTransR achieves state-of-the-art performance. In this paper, we propose a more fine-grained model named TransD, which is an improvement of TransR/CTransR. In TransD, we use two vectors to represent a named symbol object (entity and relation). The first one represents the meaning of a(n) entity (relation), the other one is used to construct mapping matrix dynamically. Compared with TransR/CTransR, TransD not only considers the diversity of relations, but also entities. TransD has less parameters and has no matrix-vector multiplication operations, which makes it can be applied on large scale graphs. In Experiments, we evaluate our model on two typical tasks including triplets classification and link prediction. Evaluation results show that our approach outperforms state-of-the-art methods.

1 Introduction

Knowledge Graphs such as WordNet (Miller 1995), Freebase (Bollacker et al. 2008) and Yago (Suchanek et al. 2007) have been playing a pivotal role in many AI applications, such as relation extraction(RE), question answering(Q&A), etc. They usually contain huge amounts of structured data as the form of triplets (*head entity*, *relation*, *tail entity*)(denoted as (h, r, t)), where relation models the relationship between the two entities. As most knowledge graphs have been built either collaboratively or (partly) automatically, they often suffer from incompleteness. Knowledge graph completion is to predict relations between entities based on existing triplets in a knowledge graph. In the past decade, much work based on symbol and logic has been done for knowledge graph completion, but they are neither tractable nor enough convergence for large scale knowledge graphs. Recently, a powerful approach for this task is to encode every element (entities and relations) of a knowledge graph into a low-dimensional embedding vector space. These methods do reasoning over knowledge graphs through algebraic operations (see section "Related Work").

Among these methods, TransE (Bordes et al. 2013) is simple and effective, and also achieves state-of-the-art prediction performance. It learns low-dimensional embeddings for every entity and relation in knowledge graphs. These vector embeddings are denoted by the same letter in boldface. The basic idea is that every relation is regarded as translation in the embedding space. For a golden triplet (h, r, t), the embedding $\mathbf{h}$ is close to the embedding $\mathbf{t}$ by adding the embedding $\mathbf{r}$, that is $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$. TransE is suitable for 1-to-1 relations, but has flaws when dealing with 1-to-N, N-to-1 and N-to-N relations. TransH (Wang et al. 2014) is proposed to solve these issues. TransH regards a relation as a translating operation on a relation-specific hyperplane, which is characterized by a norm vector $\mathbf{w}_r$ and a translation vector $\mathbf{d}_r$. The embeddings $\mathbf{h}$ and $\mathbf{t}$ are first projected to the hyperplane of relation r to obtain vectors $\mathbf{h}_\perp = \mathbf{h} - \mathbf{w}_r^\top \mathbf{h} \mathbf{w}_r$ and $\mathbf{t}_\perp = \mathbf{t} - \mathbf{w}_r^\top \mathbf{t} \mathbf{w}_r$, and then $\mathbf{h}_\perp + \mathbf{d}_r \approx \mathbf{t}_\perp$. Both in TransE and TransH, the embeddings of entities and relations are in the same space. However, entities and relations are different types objects, it is insufficient to model them in the same space. TransR/CTransR (Lin et al. 2015) set a mapping matrix $\mathbf{M}_r$ and a vector $\mathbf{r}$ for every relation r. In TransR, $\mathbf{h}$ and $\mathbf{t}$ are projected to the aspects that relation r focuses on through the ma-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 687–696,
Beijing, China, July 26-31, 2015.

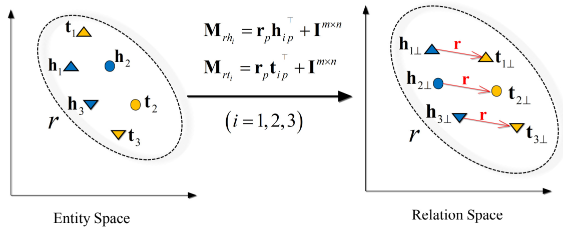

Figure 1: Simple illustration of TransD. Each shape represents an entity pair appearing in a triplet of relation r. $\mathbf{M}_{rh}$ and $\mathbf{M}_{rt}$ are mapping matrices of $\mathbf{h}$ and $\mathbf{t}$, respectively. $\mathbf{h}_{ip}$, $\mathbf{t}_{ip}(i = 1, 2, 3)$, and $\mathbf{r}_p$ are projection vectors. $\mathbf{h}_{i\perp}$ and $\mathbf{t}_{i\perp}(i = 1, 2, 3)$ are projected vectors of entities. The projected vectors satisfy $\mathbf{h}_{i\perp} + \mathbf{r} \approx \mathbf{t}_{i\perp}(i = 1, 2, 3)$.

trix $\mathbf{M}_r$ and then $\mathbf{M}_r\mathbf{h} + \mathbf{r} \approx \mathbf{M}_r\mathbf{t}$. CTransR is an extension of TransR by clustering diverse head-tail entity pairs into groups and learning distinct relation vectors for each group. TransR/CTransR has significant improvements compared with previous state-of-the-art models. However, it also has several flaws: (1) For a typical relation r, all entities share the same mapping matrix $\mathbf{M}_r$. However, the entities linked by a relation always contains various types and attributes. For example, in triplet (*friedrich_burklein, nationality, germany*), *friedrich_burklein* and *germany* are typical different types of entities. These entities should be projected in different ways; (2) The projection operation is an interactive process between an entity and a relation, it is unreasonable that the mapping matrices are determined only by relations; and (3) Matrix-vector multiplication makes it has large amount of calculation, and when relation number is large, it also has much more parameters than TransE and TransH. As the complexity, TransR/CTransR is difficult to apply on large-scale knowledge graphs.

In this paper, we propose a novel method named TransD to model knowledge graphs. Figure 1 shows the basic idea of TransD. In TransD, we define *two* vectors for each entity and relation. The first vector represents the meaning of an entity or a relation, the other one (called *projection vector*) represents the way that how to project a entity embedding into a relation vector space and it will be used to construct mapping matrices. Therefore, every entity-relation pair has an unique mapping matrix. In addition, TransD has no matrix-by-vector operations which can be replaced by vectors operations. We evaluate TransD with the task of triplets classification and link prediction. The experimental results show that our method has significant improvements compared with previous models.

Our contributions in this paper are: (1)We propose a novel model TransD, which constructs a dynamic mapping matrix for each entity-relation pair by considering the diversity of entities and relations simultaneously. It provides a flexible style to project entity representations to relation vector space; (2) Compared with TransR/CTransR, TransD has fewer parameters and has no matrix-vector multiplication. It is easy to be applied on large-scale knowledge graphs like TransE and TransH; and (3) In experiments, our approach outperforms previous models including TransE, TransH and TransR/CTransR in link prediction and triplets classification tasks.

2 Related Work

Before proceeding, we define our mathematical notations. We denote a triplet by (h, r, t) and their column vectors by bold lower case letters $\mathbf{h}, \mathbf{r}, \mathbf{t}$; matrices by bold upper case letters, such as $\mathbf{M}$; tensors by bold upper case letters with a hat, such as $\widehat{\mathbf{M}}$. Score function is represented by $f_r(\mathbf{h}, \mathbf{t})$. For a golden triplet (h, r, t) that corresponds to a true fact in real world, it always get a relatively higher score, and lower for an negative triplet. Other notations will be described in the appropriate sections.

2.1 TransE, TransH and TransR/CTransR

As mentioned in Introduction section, TransE (Bordes et al. 2013) regards the relation $\mathbf{r}$ as translation from $\mathbf{h}$ to $\mathbf{t}$ for a golden triplet (h, r, t). Hence, $(\mathbf{h}+\mathbf{r})$ is close to $(\mathbf{t})$ and the score function is

$$f_r(\mathbf{h}, \mathbf{t}) = -\|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_2^2. \qquad (1)$$

TransE is only suitable for 1-to-1 relations, there remain flaws for 1-to-N, N-to-1 and N-to-N relations.

To solve these problems, TransH (Wang et al. 2014) proposes an improved model named translation on a hyperplane. On hyperplanes of different relations, a given entity has different representations. Similar to TransE, TransH has the score function as follows:

$$f_r(\mathbf{h}, \mathbf{t}) = -\|\mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp\|_2^2. \qquad (2)$$

Model	#Parameters	# Operations (Time complexity)
Unstructured (Bordes et al. 2012; 2014)	$O(N_em)$	$O(N_t)$
SE (Bordes et al. 2011)	$O(N_em + 2N_rn^2)(m = n)$	$O(2m^2N_t)$
SME(linear) (Bordes et al. 2012; 2014)	$O(N_em + N_rn + 4mk + 4k)(m = n)$	$O(4mkN_t)$
SME (bilinear) (Bordes et al. 2012; 2014)	$O(N_em + N_rn + 4mks + 4k)(m = n)$	$O(4mksN_t)$
LFM (Jenatton et al. 2012; Sutskever et al. 2009)	$O(N_em + N_rn^2)(m = n)$	$O((m^2 + m)N_t)$
SLM (Socher et al. 2013)	$O(N_em + N_r(2k + 2nk))(m = n)$	$O((2mk + k)N_t)$
NTN (Socher et al. 2013)	$O(N_em + N_r(n^2s + 2ns + 2s))(m = n)$	$O(((m^2 + m)s + 2mk + k)N_t)$
TransE (Bordes et al. 2013)	$O(N_em + N_rn)(m = n)$	$O(N_t)$
TransH (Wang et al. 2014)	$O(N_em + 2N_rn)(m = n)$	$O(2mN_t)$
TransR (Lin et al. 2015)	$O(N_em + N_r(m + 1)n)$	$O(2mnN_t)$
CTransR (Lin et al. 2015)	$O(N_em + N_r(m + d)n)$	$O(2mnN_t)$
TransD (this paper)	$O(2N_em + 2N_rn)$	$O(2nN_t)$

Table 1: Complexity (the number of parameters and the number of multiplication operations in an epoch) of several embedding models. N_e and N_r represent the number of entities and relations, respectively. N_t represents the number of triplets in a knowledge graph. m is the dimension of entity embedding space and n is the dimension of relation embedding space. d denotes the average number of clusters of a relation. k is the number of hidden nodes of a neural network and s is the number of slice of a tensor.

In order to ensure that $\mathbf{h}_\perp$ and $\mathbf{t}_\perp$ are on the hyperplane of r, TransH restricts $\|\mathbf{w}_r\| = 1$.

Both TransE and TransH assume that entities and relations are in the same vector space. But relations and entities are different types of objects, they should not be in the same vector space. TransR/CTransR (Lin et al. 2015) is proposed based on the idea. TransR set a mapping matrix $\mathbf{M}_r$ for each relation r to map entity embedding into relation vector space. Its score function is:

$$f_r(\mathbf{h}, \mathbf{t}) = -\|\mathbf{M}_r\mathbf{h} + \mathbf{r} - \mathbf{M}_r\mathbf{t}\|_2^2. \qquad (3)$$

where $\mathbf{M}_r \in \mathbb{R}^{m \times n}$, $\mathbf{h}, \mathbf{t} \in \mathbb{R}^n$ and $\mathbf{r} \in \mathbb{R}^m$. CTransR is an extension of TransR. As head-tail entity pairs present various patterns in different relations, CTransR clusters diverse head-tail entity pairs into groups and sets a relation vector for each group.

2.2 Other Models

Unstructured. Unstructured model (Bordes et al. 2012; 2014) ignores relations, only models entities as embeddings. The score function is

$$f_r(\mathbf{h}, \mathbf{t}) = -\|\mathbf{h} - \mathbf{t}\|_2^2. \qquad (4)$$

It's a simple case of TransE. Obviously, Unstructured model can not distinguish different relations.

Structured Embedding (SE). SE model (Bordes et al. 2011) sets two separate matrices $\mathbf{M}_{rh}$ and $\mathbf{M}_{rt}$ to project head and tail entities for each relation. Its score function is defined as follows:

$$f_r(\mathbf{h}, \mathbf{t}) = -\|\mathbf{M}_{rh}\mathbf{h} - \mathbf{M}_{rt}\mathbf{t}\|_1 \qquad (5)$$

Semantic Matching Energy (SME). SME model (Bordes et al. 2012; 2014) encodes each named symbolic object (entities and relations) as a vector. Its score function is a neural network that captures correlations between entities and relations via matrix operations. Parameters of the neural network are shared by all relations. SME defines two semantic matching energy functions for optimization, a linear form

$$\mathbf{g}_\eta = \mathbf{M}_{\eta 1}\mathbf{e}_\eta + \mathbf{M}_{\eta 2}\mathbf{r} + \mathbf{b}_\eta \qquad (6)$$

and a bilinear form

$$\mathbf{g}_\eta = (\mathbf{M}_{\eta 1}\mathbf{e}_\eta) \otimes (\mathbf{M}_{\eta 2}\mathbf{r}) + \mathbf{b}_\eta \qquad (7)$$

where $\eta = \{left, right\}$, $\mathbf{e}_{left} = \mathbf{h}$, $\mathbf{e}_{right} = \mathbf{t}$ and $\otimes$ is the Hadamard product. The score function is

$$f_r(\mathbf{h}, \mathbf{t}) = \mathbf{g}_{left}{}^\top \mathbf{g}_{right} \qquad (8)$$

In (Bordes et al.2014), matrices of the bilinear form are replaced by tensors.

Latent Factor Model (LFM). LFM model (Jenatton et al. 2012; Sutskever et al. 2009) encodes each entity into a vector and sets a matrix for every relation. It defines a score function $f_r(\mathbf{h}, \mathbf{t}) = \mathbf{h}^\top\mathbf{M}_r\mathbf{t}$, which incorporates the interaction of the two entity vectors in a simple and effecitve way.

Single Layer Model (SLM). SLM model is designed as a baseline of Neural Tensor Network (Socher et al. 2013). The model constructs a nonlinear neural network to represent the score function defined as follows.

$$f_r(\mathbf{h}, \mathbf{t}) = \mathbf{u}_r^\top f(\mathbf{M}_{r1}\mathbf{h} + \mathbf{M}_{r2}\mathbf{t} + \mathbf{b}_r) \qquad (9)$$

where $\mathbf{M}_{r1}$, $\mathbf{M}_{r2}$ and $\mathbf{b}_r$ are parameters indexed by relation r, $f()$ is $tanh$ operation.

Neural Tensor Network (NTN). NTN model (Socher et al. 2013) extends SLM model by considering the second-order correlations into nonlinear neural networks. The score function is

$$f_r(\mathbf{h},\mathbf{t}) = \mathbf{u}_r^\top f(\mathbf{h}^\top \widehat{\mathbf{W}}_r \mathbf{t} + \mathbf{M}_r \begin{bmatrix} \mathbf{h} \\ \mathbf{t} \end{bmatrix} + \mathbf{b}_r) \quad (10)$$

where $\widehat{\mathbf{W}}_r$ represents a 3-way tensor, $\mathbf{M}_r$ denotes the weight matrix, $\mathbf{b}_r$ is the bias and $f()$ is $tanh$ operation. NTN is the most expressive model so far, but it has so many parameters that it is difficult to scale up to large knowledge graphs.

Table 1 lists the complexity of all the above models. The complexity (especially for time) of TransD is much less than TransR/CTransR and is similar to TransE and TransH. Therefore, TransD is effective and train faster than TransR/CTransR. Beyond these embedding models, there is other related work of modeling multi-relational data, such as matrix factorization, recommendations, etc. In experiments, we refer to the results of **RESCAL** presented in (Lin et al. 2015) and compare with it.

3 Our Method

We first define notations. Triplets are represented as $(h_i, r_i, t_i)(i = 1, 2, \ldots, n_t)$, where h_i denotes a head entity, t_i denotes a tail entity and r_i denotes a relation. Their embeddings are denoted by $\mathbf{h}_i, \mathbf{r}_i, \mathbf{t}_i(i = 1, 2, \ldots, n_t)$. We use Δ to represent golden triplets set, and use $\Delta^{'}$ to denote negative triplets set. Entities set and relations set are denoted by E and R, respectively. We use $\mathbf{I}^{m \times n}$ to denote the identity matrix of size $m \times n$.

3.1 Multiple Types of Entities and Relations

Considering the diversity of relations, CTransR segments triplets of a specific relation r into several groups and learns a vector representation for each group. However, entities also have various types. Figure 2 shows several kinds of head and tail entities of relation *location.location.partially_containedby* in FB15k. In both TransH and TransR/CTransR, all types of entities share the same mapping vectors/matrices. However, different types of entities have different attributes and functions, it is insufficient to let them share the same transform parameters of a relation. And for a given relation, similar entities should have similar mapping matrices and otherwise for dissimilar entities. Furthermore, the mapping process is a transaction between entities and relations that both have various types. Therefore, we propose a more fine-grained model TransD, which considers different types of both entities and relations, to encode knowledge graphs into embedding vectors via dynamic mapping matrices produced by projection vectors.

Figure 2: Multiple types of entities of relation *location.location.partially_containedby*.

3.2 TransD

Model In TransD, each named symbol object (entities and relations) is represented by *two* vectors. The first one captures the meaning of entity (relation), the other one is used to construct mapping matrices. For example, given a triplet (h, r, t), its vectors are $\mathbf{h}, \mathbf{h}_p, \mathbf{r}, \mathbf{r}_p, \mathbf{t}, \mathbf{t}_p$, where subscript p marks the projection vectors, $\mathbf{h}, \mathbf{h}_p, \mathbf{t}, \mathbf{t}_p \in \mathbb{R}^n$ and $\mathbf{r}$, $\mathbf{r}_p \in \mathbb{R}^m$. For each triplet (h, r, t), we set two mapping matrices $\mathbf{M}_{rh}, \mathbf{M}_{rt} \in \mathbb{R}^{m \times n}$ to project entities from entity space to relation space. They are defined as follows:

$$\mathbf{M}_{rh} = \mathbf{r}_p \mathbf{h}_p^\top + \mathbf{I}^{m \times n} \quad (11)$$

$$\mathbf{M}_{rt} = \mathbf{r}_p \mathbf{t}_p^\top + \mathbf{I}^{m \times n} \quad (12)$$

Therefore, the mapping matrices are determined by both entities and relations, and this kind of operation makes the two projection vectors interact sufficiently because each element of them can meet every entry comes from another vector. As we initialize each mapping matrix with an identity matrix, we add the $\mathbf{I}^{m \times n}$ to $\mathbf{M}_{rh}$ and $\mathbf{M}_{rh}$. With the mapping matrices, we define the projected vectors as follows:

$$\mathbf{h}_\perp = \mathbf{M}_{rh}\mathbf{h}, \quad \mathbf{t}_\perp = \mathbf{M}_{rt}\mathbf{t} \quad (13)$$

Then the score function is

$$f_r(\mathbf{h},\mathbf{t}) = -\|\mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp\|_2^2 \tag{14}$$

In experiments, we enforce constrains as $\|\mathbf{h}\|_2 \leq 1, \|\mathbf{t}\|_2 \leq 1, \|\mathbf{r}\|_2 \leq 1, \|\mathbf{h}_\perp\|_2 \leq 1$ and $\|\mathbf{t}_\perp\|_2 \leq 1$.

Training Objective We assume that there are n_t triplets in training set and denote the ith triplet by $(h_i, r_i, t_i)(i = 1, 2, \ldots, n_t)$. Each triplet has a label y_i to indicate the triplet is positive ($y_i = 1$) or negative ($y_i = 0$). Then the golden and negative triplets are denoted by $\Delta = \{(h_j, r_j, t_j) \mid y_j = 1\}$ and $\Delta' = \{(h_j, r_j, t_j) \mid y_j = 0\}$, respectively. Before training, one important trouble is that knowledge graphs only encode positive training triplets, they do not contain negative examples. Therefore, we obtain Δ from knowledge graphs and generate Δ' as follows: $\Delta' = \{(h_l, r_k, t_k) \mid h_l \neq h_k \wedge y_k = 1\} \cup \{(h_k, r_k, t_l) \mid t_l \neq t_k \wedge y_k = 1\}$. We also use two strategies "unif" and "bern" described in (Wang et al. 2014) to replace the head or tail entity.

Let us use ξ and ξ' to denote a golden triplet and a corresponding negative triplet, respectively. Then we define the following margin-based ranking loss as the objective for training:

$$L = \sum_{\xi \in \Delta} \sum_{\xi' \in \Delta'} [\gamma + f_r(\xi') - f_r(\xi)]_+ \tag{15}$$

where $[x]_+ \triangleq \max\,(0, x)$, and γ is the margin separating golden triplets and negative triplets. The process of minimizing the above objective is carried out with stochastic gradient descent (SGD). In order to speed up the convergence and avoid overfitting, we initiate the entity and relation embeddings with the results of TransE and initiate all the transfer matrices with identity matrices.

3.3 Connections with TransE, TransH and TransR/CTransR

TransE is a special case of TransD when the dimension of vectors satisfies $m = n$ and all projection vectors are set zero.

TransH is related to TransD when we set $m = n$. Under the setting, projected vectors of entities can be rewritten as follows:

$$\mathbf{h}_\perp = \mathbf{M}_{rh}\mathbf{h} = \mathbf{h} + \mathbf{h}_p^\top \mathbf{h}\mathbf{r}_p \tag{16}$$

$$\mathbf{t}_\perp = \mathbf{M}_{rt}\mathbf{t} = \mathbf{t} + \mathbf{t}_p^\top \mathbf{t}\mathbf{r}_p \tag{17}$$

Hence, when $m = n$, the difference between TransD and TransH is that projection vectors are determinded only by relations in TransH, but TransD's projection vectors are determinded by both entities and relations.

As to TransR/CTransR, TransD is an improvement of it. TransR/CTransR directly defines a mapping matrix for each relation, TransD consturcts two mapping matrices dynamically for each triplet by setting a projection vector for each entity and relation. In addition, TransD has no matrix-vector multiplication operation which can be replaced by vector operations. Without loss of generality, we assume $m \geq n$, the projected vectors can be computed as follows:

$$\mathbf{h}_\perp = \mathbf{M}_{rh}\mathbf{h} = \mathbf{h}_p^\top \mathbf{h}\mathbf{r}_p + \left[\ \mathbf{h}^\top, \mathbf{0}^\top\ \right]^\top \tag{18}$$

$$\mathbf{t}_\perp = \mathbf{M}_{rt}\mathbf{t} = \mathbf{t}_p^\top \mathbf{t}\mathbf{r}_p + \left[\ \mathbf{t}^\top, \mathbf{0}^\top\ \right]^\top \tag{19}$$

Therefore, TransD has less calculation than TransR/CTransR, which makes it train faster and can be applied on large-scale knowledge graphs.

4 Experiments and Results Analysis

We evaluate our apporach on two tasks: triplets classification and link prediction. Then we show the experiments results and some analysis of them.

4.1 Data Sets

Triplets classification and link prediction are implemented on two popular knowledge graphs: WordNet (Miller 1995) and Freebase (Bollacker et al. 2008). WordNet is a large lexical knowledge graph. Entities in WordNet are synonyms which express distinct concepts. Relations in WordNet are conceptual-semantic and lexical relations. In this paper, we use two subsets of WordNet: WN11 (Socher et al. 2013) and WN18 (Bordes et al. 2014). Freebase is a large collaborative knowledge base consists of a large number of the world facts, such as triplets (*anthony_asquith, location, london*) and (*nobuko_otowa, profession, actor*). We also use two subsets of Freebase: FB15k (Bordes et al. 2014) and FB13 (Socher et al. 2013). Table 2 lists statistics of the 4 datasets.

Dataset	#Rel	#Ent	#Train	#Valid	#Test
WN11	11	38,696	112,581	2,609	10,544
WN18	18	40,943	141,442	5,000	5,000
FB13	13	75,043	316,232	5908	23,733
FB15k	1,345	14,951	483,142	50,000	59,071

Table 2: Datesets used in the experiments.

4.2 Triplets Classification

Triplets classification aims to judge whether a given triplet (h, r, t) is correct or not, which is a binary classification task. Previous work (Socher et al. 2013; Wang et al. 2014; Lin et al. 2015) had explored this task. In this paper ,we use three datasets WN11, FB13 and FB15k to evaluate our approach. The test sets of WN11 and FB13 provided by (Socher et al. 2013) contain golden and negative triplets. As to FB15k, its test set only contains correct triplets, which requires us to construct negative triplets. In this parper, we construct negative triplets following the same setting used for FB13 (Socher et al. 2013).

For triplets classification, we set a threshold δ_r for each relation r. δ_r is obtained by maximizing the classification accuracies on the valid set. For a given triplet (h, r, t), if its score is larger than δ_r, it will be classified as positive, otherwise negative.

We compare our model with several previous embedding models presented in Related Work section. As we construct negative triplets for FB15k by ourselves, we use the codes of TransE, TransH and TransR/CTransR provied by (Lin et al. 2015) to evaluate the datasets instead of reporting the results of (Wang et al.2014; Lin et al. 2015) directly.

In this experiment, we optimize the objective with ADADELTA SGD (Zeiler 2012). We select the margin γ among {1, 2, 5, 10}, the dimension of entity vectors m and the dimension of relation vectors n among {20, 50, 80, 100}, and the mini-batch size B among {100, 200, 1000, 4800}. The best configuration obtained by valid set are:$\gamma = 1, m, n = 100, B = 1000$ and taking L_2 as dissimilarity on WN11; $\gamma = 1, m, n = 100, B = 200$ and taking L_2 as dissimilarity on FB13; $\gamma = 2, m, n = 100, B = 4800$ and taking L_1 as dissimilarity on FB15k. For all the three datasets, We traverse to training for 1000 rounds. As described in Related Work section, TransD trains much faster than TransR (On our PC, TransR needs 70 seconds and TransD merely spends 24 seconds a round on FB15k).

Data sets	WN11	FB13	FB15K
SE	53.0	75.2	-
SME(bilinear)	70.0	63.7	-
SLM	69.9	85.3	-
LFM	73.8	84.3	-
NTN	70.4	87.1	68.2
NTN(+E)	86.2	**90.0**	-
TransE(unif)	75.9	70.9	77.3
TransE(bern)	75.9	81.5	79.8
TransH(unif)	77.7	76.5	74.2
TransH(bern)	78.8	83.3	79.9
TransR(unif)	85.5	74.7	81.1
TransR(bern)	85.9	82.5	82.1
CTransR(bern)	85.7	-	84.3
TransD(unif)	85.6	85.9	86.4
TransD(bern)	**86.4**	89.1	**88.0**

Table 3: Experimental results of Triplets Classification(%). "+E" means that the results are combined with word embedding.

Table 3 shows the evaluation results of triplets classification. On WN11, we found that there are 570 entities appearing in valid and test sets but not appearing in train set, we call them "NULL Entity". In valid and test sets, there are 1680 (6.4%) triplets containing "NULL Entity". In NTN(+E), these entity embeddings can be obtained by word embedding. In TransD, however, they are only initialized randomly. Therefore, it is not fair for TransD, but we also achieve the accuracy 86.4% which is higher than that of NTN(+E) (86.2%). From Table 3, we can conclude that: (1) On WN11, TransD outperforms any other previous models including TransE, TransH and TransR/CTransR, especially NTN(+E); (2) On FB13, the classification accuracy of TransD achieves 89.1%, which is significantly higher than that of TransE, TransH and TransR/CTransR and is near to the performance of NTN(+E) (90.0%); and (3) Under most circumstances, the "bern" sampling method works better than "unif".

Figure 3 shows the prediction accuracy of different relations. On the three datasets, different relations have different prediction accuracy: some are higher and the others are lower. Here we focus on the relations which have lower accuracy. On WN11, the relation *similar_to* obtains accuracy 51%, which is near to random prediction accuracy. In the view of intuition, *similar_to* can be inferred from other information. However, the number of entity pairs linked by relation *similar_to* is only 1672, which accounts for 1.5% in all train data, and prediction of the relation needs much information about entities. Therefore, the insufficient of train data is the main cause. On FB13, the accuracies of relations *cuase_of_death* and *gender* are lower than that of other relations because they are difficult to infer from other imformation, especially *cuase_of_death*. Relation *gender* may be inferred from a person's name (Socher et al. 2013), but we learn a vector for each name, not for the words included in the names, which makes the

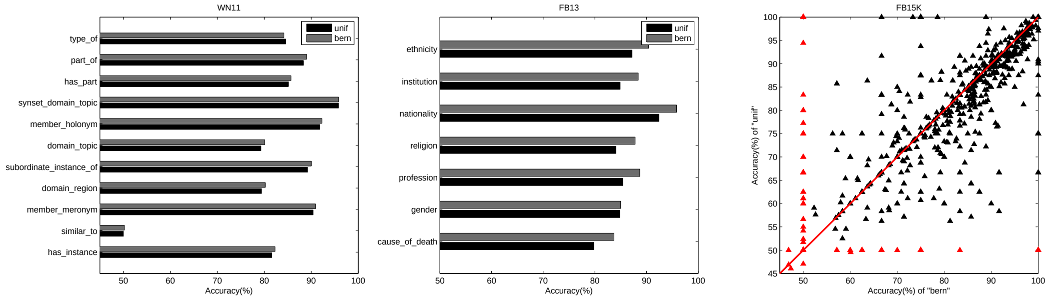

Figure 3: Classification accuracies of different relations on the three datasets. For FB15k, each triangle represent a relation, in which the red triangles represent the relations whose accuracies of "bern" or "unif" are lower than 50% and the blacks are higher than 50%. The red line represents the function $y = x$. We can see that the most relations are in the lower part of the red line.

names information useless for *gender*. On FB15k, accuracies of some relations are lower than 50%, for which some are lack of train data and some are difficult to infer. Hence, the ability of reasoning new facts based on knowledge graphs is under a certain limitation, and a complementary approach is to extract facts from plain texts.

4.3 Link Prediction

Link prediction is to predict the missing h or t for a golden triplet (h, r, t). In this task, we remove the head or tail entity and then replace it with all the entities in dictionary in turn for each triplet in test set. We first compute scores of those corrupted triplets and then rank them by descending order; the rank of the correct entity is finally stored. The task emphasizes the rank of the correct entity instead of only finding the best one entity. Similar to (Bordes et al. 2013), we report two measures as our evaluation metrics: the average rank of all correct entites (*Mean Rank*) and the proportion of correct entities ranked in top 10 (*Hits@10*). A lower *Mean Rank* and a higher *Hits@10* should be achieved by a good embedding model. We call the evaluation setting "Raw'. Noting the fact that a corrupted triplet may also exist in knowledge graphs, the corrupted triplet should be regard as a correct triplet. Hence, we should remove the corrupted triplets included in train, valid and test sets before ranking. We call this evaluation setting "Filter". In this paper, we will report evaluation results of the two settings .

In this task, we use two datasets: WN18 and FB15k. As all the data sets are the same, we refer to their experimental results in this paper. On WN18, we also use ADADELTA SGD (Zeiler 2012) for optimization. We select the margin γ among {0.1, 0.5, 1, 2}, the dimension of entity vectors m and the dimension of relation vectors n among {20, 50, 80, 100}, and the mini-batch size B among {100, 200, 1000, 1400}. The best configuration obtained by valid set are:$\gamma = 1, m, n = 50, B = 200$ and taking L_2 as dissimilarity. For both the two datasets, We traverse to training for 1000 rounds.

Experimental results on both WN18 and FB15k are shown in Table 4. From Table 4, we can conclude that: (1) TransD outperforms other baseline embedding models (TransE, TransH and TransR/CTransR), especially on sparse dataset, i.e., FB15k; (2) Compared with CTransR, TransD is a more fine-grained model which considers the multiple types of entities and relations simultaneously, and it achieves a better performance. It indicates that TransD handles complicated internal correlations of entities and relations in knowledge graphs better than CTransR; (3) The "bern" sampling trick can reduce false negative labels than "unif".

For the comparison of *Hits@10* of different kinds of relations, Table 5 shows the detailed results by mapping properties of relations[1] on FB15k. From Table 5, we can see that TransD outperforms TransE, TransH and TransR/CTransR significantly in both "unif" and "bern" settings. TransD achieves better performance than CTransR in all types of relations (1-to-1, 1-to-N, N-to-1 and N-to-N). For N-to-N relations in predicting both head and tail, our approach improves the *Hits@10* by almost 7.4% than CTransR. In particular, for

[1] Mapping properties of relations follows the same rules in (Bordes et al. 2013)

Table 5: Experimental results on FB15K by mapping properities of relations (%).

N-to-1 relations (predicting head) and 1-to-N relations (predicting tail), TransD improves the accuracy by 9.0% and 14.7% compared with previous state-of-the-art results, respectively. Therefore, the diversity of entities and relations in knowledge grahps is an important factor and the dynamic mapping matrix is suitable for modeling knowledge graphs.

5 Properties of Projection Vectors

As mentioned in Section ”Introduction”, TransD is based on the motivation that each mapping matrix is determined by entity-relation pair dynamically. These mapping matrices are constructed with projection vectors of entities and relations. Here, we analysis the properties of projection vectors. We seek the similar objects (entities and relations) for a given object (entities and relations) by projection vectors. As WN18 has the most entities (40,943 entities which contains various types of words. FB13 also has many entities, but the most are person’s names) and FB15k has the most relations (1,345 relations), we show the similarity of projection vectors on them. Table 6 and 7 show that the same category objects have similar projection vectors. The similarity of projection vectors of different types of entities and relations indicates the rationality of our method.

6 Conclusions and Future Work

We introduced a model TransD that embed knowledge graphs into continues vector space for their completion. TransD has less complexity and more flexibility than TransR/CTransR. When learning embeddings of named symbol objects (entities or relations), TransD considers the diversity of them both. Extensive experiments show that TransD outperforms TrasnE, TransH and TransR/CTransR on two tasks including triplets classification and link prediction.

As shown in Triplets Classification section, not all new facts can be deduced from the exist-

ing triplets in knowledge graphs, such as relations *gender, place of place, parents* and *children*. These relations are difficult to infer from all other information, but they are also useful resource for practical applications and incomplete, i.e. the *place of birth* attribute is missing for 71% of all people included in FreeBase (Nickel, et al. 2015). One possible way to obtain these new triplets is to extract facts from plain texts. We will seek methods to complete knowledge graphs with new triplets whose entities and relations come from plain texts.

Abstract

In this paper, we first explore the role of inter-annotator agreement statistics in grammatical error correction and conclude that they are less informative in fields where there may be more than one correct answer. We next created a dataset of 50 student essays, each corrected by 10 different annotators for all error types, and investigated how both human and GEC system scores vary when different combinations of these annotations are used as the gold standard. Upon learning that even humans are unable to score higher than 75% $F_{0.5}$, we propose a new metric based on the ratio between human and system performance. We also use this method to investigate the extent to which annotators agree on certain error categories, and find that similar results can be obtained from a smaller subset of just 10 essays.

1 Introduction

Interest in grammatical error correction (GEC) systems has grown considerably in the past few years, thanks mainly to the success of the recent Helping Our Own (HOO) (Dale and Kilgarriff, 2011; Dale et al., 2012) and Conference on Natural Language Learning (CoNLL) (Ng et al., 2013; Ng et al., 2014) shared tasks. Despite this increasing attention, however, one of the most significant challenges facing GEC today is the lack of a robust evaluation practice. In fact Chodorow et al. (2012) even go as far to say that it is sometimes "hard to draw meaningful comparisons between different approaches, even when they are evaluated on the same corpus."

One of the reasons for this is that, traditionally, system performance has only ever been evaluated against the gold standard annotations of a single native speaker (rarely, two native speakers). As such, system output is not actually scored on the basis of grammatical acceptability alone, but rather is also constrained by the idiosyncrasies of the particular annotators.

The obvious solution to this problem would be to compare systems against the gold standard annotations of multiple annotators, in an effort to dilute the effect of individual annotator bias, however creating manual annotations is often considered too time consuming and expensive. In spite of this, while other studies have instead elected to use crowdsourcing to produce multiply-corrected annotations, often concerning only a limited number of error types (Madnani et al., 2011; Pavlick et al., 2014; Tetreault et al., 2014), one of the main contributions of this paper is the provision of a dataset of 10 human expert annotations, annotated in the tradition of CoNLL-2014, that is moreover annotated for all error types.[1]

With this new dataset, we have, for the first time, been able to compare system output against the gold standard annotations of a larger group of human annotators, in a realistic grammar checking scenario, and consequently been able to quantify the extent to which additional annotators affect system performance. Additionally, we also noticed that some annotators tend to agree on certain error categories more than others and so attempt to explain this.

In light of the results, we also explore how human annotators themselves compare against the combined annotations of the remaining annotators and thus calculate an upper bound $F_{0.5}$ score for the given dataset and number of annotators; e.g., if one human versus nine other humans is only able to score a maximum of 70% $F_{0.5}$, then it is unreasonable to expect a machine to do better. For this reason, we propose a more informative method of

evaluating a system based on the ratio of that system's $F_{0.5}$ score against the equivalent human $F_{0.5}$ score.

Section 2 contains an overview of some of the latest research in both GEC and SMT that makes use of IAA statistics. Section 3 shows an example sentence from our dataset and qualitatively analyses how individual annotator bias affects their choice of corrections. Section 4 describes the data collection process and presents some preliminary results. Section 5 discusses the main quantitative results of the paper, formalizing the formulas used and introducing the more informative method of ratio scoring for GEC, while Section 6 summarizes the results from our additional experiments on category agreement and essay subsets. Section 7 concludes the paper.

2 Inter-Annotator Agreement (IAA)

Whenever we discuss multiple annotators, researchers invariably raise the issue of inter-annotator agreement (IAA), or rather the extent to which annotators agree with each other. This is because data which shows a higher level of agreement is often believed to be in some way more reliable than data which has a lower agreement score. Within GEC, agreement has often been reported in terms of Cohen's-κ (Cohen, 1960), although other agreement statistics could also be used.[2]

In the rest of this section, however, we wish to challenge the use of IAA statistics in GEC and question their value in this field. Specifically, while IAA statistics may be informative in areas where items can be classified into single, well-defined categories, such as in part-of-speech tagging, we argue that they are less well-suited to GEC and SMT, where there is often more than one correct answer. For example, two annotators may correct or translate a given sentence in two completely different yet valid ways, but IAA statistics are only able to interpret the alternative answers as disagreements.

2.1 Inter-Annotator Agreement in GEC

One important study that made use of κ as a measure of agreement between raters is by Tetrault and Chodorow (2008) (also in Tetreault et al. (2014)), who asked two native English speakers to insert a missing preposition into 200 randomly chosen, well-formed sentences from which a single preposition had been removed.

Despite the simplicity of this correction task, the authors reported κ-agreement of just 0.7, noting that in cases where the raters disagreed, their disagreements were often "licensed by context" and thus actually "acceptable alternatives". This led them to conclude that they would "expect even more disagreement when the task is preposition error detection in 'noisy' learner texts" and, by extension, imply that detection of *all* error types in 'noisy' texts would show more disagreement still.

The most important question to ask then, as a result of this study, is whether low κ-scores in 'noisy' texts are truly indicative of real disagreement, or whether, as in this preposition test, the disagreement is actually the result of multiple correct answers, and therefore not disagreement at all.

In a related study, and aware of the fact that there are often multiple ways to correct individual words in sentence, Rozovskaya and Roth (2010) instead chose to compute agreement at the sentence level. Specifically, three raters were asked simply to decide whether they thought 200 sentences were correct or not.

This time, despite operating at the more general sentence level, the authors reported κ scores of just 0.16, 0.4 and 0.23, surmising that "the low numbers reflect the difficulty of the task and the variability of the native speakers' judgments about acceptable usage." If that is the case, then true disagreement may be indistinguishable from native variability, and we should be wary of using IAA statistics as a measure of agreement or evaluation in GEC.

2.2 Inter-Annotator Agreement in SMT

In fact, the issues regarding the reliability of IAA metrics are not unique to GEC and we can also draw a parallel with the field of statistical machine translation (SMT). In the same way that there is often more than one way to correct a sentence in GEC, it is also well known that there is often more than one way to translate a sentence in SMT.

Nevertheless, while several papers have successfully discussed ways to minimize annotator bias effects in SMT (Snover et al., 2006; Madnani et al., 2008), IAA metrics such as κ still unhelpfully play a role in the field and have, for example, been reported almost every year in the Workshop on Machine Translation (WMT) conference.

[2] See Hayes and Krippendorff (2007) or Artstein and Poesio (2008) for the pros and cons of different IAA metrics.

Table 1: Table showing how each of the 10 annotators edited the same source sentence in Essay 25. The words in the source sentence that were changed are highlighted in bold.

This is in spite of the fact that the average inter-annotator κ score across all language pairs over the past five years has never been higher than 0.4 (Bojar et al., 2014).

One important paper that attempts to explain why IAA metrics score so poorly in SMT is by Lommel et al. (2014), who asked annotators to highlight and categorize sections of automatically translated text they believed to be erroneous. Their results showed that while annotators were often able to agree on the rough locations of errors, they often disagreed as to the specific boundaries of those errors: for instance, given the phrase "had go", some annotators considered just the participle "go" → "gone" to be the minimal error, while others considered the whole verbal unit, "had go" → "had gone", to be the minimal error. Similarly, the authors also noted that annotators sometimes had problems categorizing ambiguous errors which could be classified into more than one error category.

In short, while annotators already vary as to what they consider an error, these observations show that even when they do apparently agree, there is no guarantee that every annotator will define the error in exactly the same terms. This poses a problem for IAA statistics, which rely on an exact match to measure agreement.

Finally, it is also worth mentioning that a related study, by Denkowski and Lavie (2010), suggested that "annotators also have difficulty agreeing with themselves" (shown from *intra*-annotator agreement κ scores of about 0.6), and so we should be especially wary of using IAA metrics to validate datasets that may even be unreliable for a single annotator.

3 Annotator Bias

In an effort to better understand how annotators' judgments might differ, we first carried out a small-scale qualitative analysis on a handful of random sentences corrected by the 10 human annotators in our dataset. One such sentence, and all its various corrections, is shown in Table 1.

It is interesting to note that, for even as short an idiom as "To put it in the nutshell', there are still multiple alternative edits. Although 8 out of the 10 annotators elected to replace the article "the" with "a", among them, A2 and A4 also deleted "To put it" from the expression. Of the remaining 2 annotators, A3 chose to replace the idiom entirely with "In summary", while A6 made no correction at all. Although no correction appears to be unacceptable to the majority of annotators, it is also not completely ungrammatical (just idiomatically awkward) so it may be that A6 has a higher tolerance for this kind of error than the other annotators. Alternatively, there is also always the possibility that, given such a large amount of text to correct, this error was simply overlooked.

Another noteworthy difference is that annotators A1, A4, A5, and A8 all elected to change the verb “have the obligation” from active to passive, although A1 still disagreed with the others on the form of the participle. Similarly, there is also a great difference of opinion on whether “testing result” should be corrected or not, and if so, how. While half of the annotators left the phrase unchanged, A1, A6, and A10 all changed both words to “test results”. Meanwhile, somewhere in between, A5 decided to change “result” to “results”, but not “testing” to “test”, while, conversely, A9 decided to do the opposite. This would suggest that error correction of even minor phrases falls along a continuum governed by each annotator’s natural bias.

Finally, one of the most important results of this qualitative evaluation is that even though all 10 annotators edited the same sentence to a level they deemed grammatical, not one single annotator agreed with another exactly. This fact alone suggests IAA statistics are not a good way to evaluate GEC data and that a more robust agreement metric must take into account the possibility of alternative correct answers.

4 Data Collection

The raw text data in our dataset was originally produced by 25 students at the National University of Singapore (NUS) who were non-native speakers of English. They were asked to write two essays on the topics of genetic testing and social media respectively. All essays were of similar length and quality. This was important because varying the skill level of the essays is likely to further affect the natural bias of the annotators, who may then consistently over- or under-correct essays. These raw essays also formed the basis of the CoNLL-2014 test data (Ng et al., 2014). See Table 2 for some basic statistics on the resulting 50 essays.

	Total	**Average per essay**
# Paragraphs	252	5.0
# Sentences	1312	26.2
# Tokens	30144	602.9

Table 2: Statistics for the 50 unannotated essays.

The 10 annotators who annotated all 50 essays include: the 2 official annotators of CoNLL-2014, the first author of this paper, and 7 freelancers who were recruited via online recruitment website, Elance.[3] All annotators are native British English speakers, many of whom also have backgrounds in English language teaching, proofreading, and/or Linguistics.

All annotations were made using an online annotation platform, WAMP, especially designed for annotating ESL errors (Dahlmeier et al., 2013). Using this platform, annotators were asked to highlight a minimal error string in the source text, provide an appropriate correction, and then categorize their selection according to the same 28-category error framework used by CoNLL-2014. Before commencing annotation, however, each annotator was given detailed instructions on how to use the tool, along with an explanation of each of the error categories. In cases of uncertainty, annotators were also encouraged to ask questions.

As it was slightly harder to control the quality of the 7 independently recruited annotators via Elance, they were each preliminarily asked to annotate only the first two essays before being given detailed feedback on their work. The main purpose of this feedback was to make sure that they a) understood the error category framework, and b) knew how to deal with more complicated cases such as word insertions, punctuation, etc. Unless it was felt that they had overlooked an obvious error in these first two essays, the feedback did not go so far as to tell annotators what they should and should not highlight in an effort to preserve individual annotator bias.

In all, while the specific time taken to complete annotation of all 50 essays was not calculated, all annotators completed the task over a period of about 3 weeks, at a rate of about 45 minutes per essay.

4.1 Early Observations

To investigate the extent to which different annotators have different biases, we first counted the total number of edits made by each annotator and sorted them by error category (Table 3).

As can be seen, there is quite a difference between the annotator who made the most edits (A1) and the annotator who made the fewest edits (A7), with A1 making more than twice the number of edits as A7. This just goes to show how varied judgments on grammaticality can be. Incidentally, annotators A3 and A7, who are among those who made the fewest edits, were also the two official gold standard annotators in CoNLL-2014.

There is also a large difference between edits in

terms of category use, with almost half of all edits falling into the categories for article or determiner (ArtOrDet), spelling or punctuation (Mec), preposition (Prep), or word choice (Wci) errors.

5 Quantitative Analysis

In the main phase of experimentation, we first investigated how different numbers of annotators affected the performance of various systems in the context of the CoNLL-2014 shared task. To do this, we downloaded the official system output of all the participating teams[4] and then the *Max-Match* (M2) Scorer[5] (Dahlmeier and Ng, 2012), which was the official scorer of the previous CoNLL-2013 and CoNLL-2014 shared tasks.

This scorer evaluates a system at the sentence level in terms of correct edits, proposed edits, and gold edits, and uses these to calculate an F-score for each team. When more than one set of gold standard annotations is available, the scorer will calculate F-scores for each alternative gold-standard *sentence* and choose the one from whichever annotator scored the highest. As in CoNLL-2014, we calculate $F_{0.5}$, which weights precision twice as much as recall, because it is more important for a system to be accurate than to correct every possible error. See (Ng et al., 2014) for more details on how $F_{0.5}$ is calculated.

5.1 Pairwise Evaluation

In order to quantify how much the F-score can vary in a realistic grammar checking scenario when there is only one gold standard annotator, we first computed the scores for a participating system vs each annotator in a pairwise fashion. Table 4 hence shows how the top team in CoNLL-2014, CAMB (Felice et al., 2014), performed against each of the 10 human annotators individually.

While Tetrault and Chodorow (2008) and Tetreault et al. (2014) reported a difference of 10% precision and 5% recall between their two individual annotators in their simplified preposition correction task, Table 4 shows this difference can actually be as much as almost 15% precision (A1 vs A7) and 6% recall (A1 vs A3) in a more realistic full scale correction task. This equates to a differ-

ence of over 7% $F_{0.5}$ (A3 vs A7) and once again shows how varied annotator's judgments can be.

5.2 All Combinations

5.2.1 Human vs Human

Whereas previously we could only calculate $F_{0.5}$ scores on a system vs human basis, when there are two or more annotators, we can also calculate scores on a human vs human basis. In fact, as the number of annotators increases, we can also start to calculate scores against different combinations of gold standard annotations.[6]

To give an example, since we have 10 annotators, a subset of these annotators, say annotators a2–a8, could be chosen as the gold standard annotations. We could then evaluate how each of the remaining annotators (i.e., annotator a1, a9, and a10) performs against this gold standard, by computing the M2 score for annotator a1 against annotators a2–a8, annotator a9 against annotators a2–a8, and annotator a10 against annotators a2–a8. We then average these 3 M2 scores, to determine how, on average, an annotator performs when measured against gold standard annotators a2–a8.

It is worth reiterating, however, that when more than one annotator is used as the gold standard, the M2 scorer will choose whichever annotator for the given *sentence* produces the highest F-score; i.e., if a2–a8 are the gold standard and we want to compute the F-score for a9, the M2 scorer will compute a9 vs a2, a9 vs a3, ..., a9 vs a8 separately *for each sentence*, and choose the highest.

The above calculations can be formalized as Equation 1:

$$g(X) = \frac{1}{|A| - |X|} \sum_{a \in A \setminus X} f(a, X) \qquad (1)$$

where A is the set of all annotators ($|A| = 10$ in our case) and X is a non-empty and proper subset of A, denoting the set of annotators chosen to be in the gold standard. The function $f(a, X)$ is the score computed by the M2 scorer to evaluate annotator a against each set of gold standard annotators X. $g(X)$ is thus the average M2 scores for the remaining annotators against the input gold standard combination X.

So far, in our example, we have chosen annotators a2–a8 to be the gold standard. There are, however, many other different ways of choosing 7 annotators to serve as the gold standard. For example, we could have chosen { a1, a2, ..., a7 }, { a1, a3, a4, ..., a8 }, etc. In fact, there are $\binom{10}{7} = 120$ different combinations of 7 annotators. As such, we can also compute how an individual human annotator performs when measured against any combination of 7 gold standard annotators, by averaging these 120 M2 scores. The above calculation is formalized in the general case in Equation 2:

$$h_i = \frac{1}{\binom{|A|}{|X|}} \sum_{X:|X|=i} g(X) \qquad (2)$$

where $\binom{|A|}{|X|}$ is the binomial coefficient for $|A|$ choose $|X|$ and $1 \leq i < |A|$. The function $g(X)$ is defined in Equation 1.

The resulting h_i values are hence the average $F_{0.5}$ scores achieved by any human against any combination of i other humans, and so, in some ways, also represent the upper bound of human performance on the current dataset. The specific values for h_i are shown in the second column of Table 5.

5.2.2 Caveat

One caveat regarding this method is that the number of *all* possible combinations of annotators is of the order $2^{|A|}$, which quickly becomes computationally expensive for large values of $|A|$. Fortunately however, in a realistic GEC evaluation scenario, it is only the last row of Table 5 that we are most interested in, and so it is actually only necessary to calculate a much more manageable $\binom{|A|}{|A|-1}$ gold standard combinations, which is conveniently

[6] Note that by combinations of annotators, we mean simply that the M2 scorer has access to a larger number of alternative gold standard corrections; we do not attempt to merge annotations in any way.

Gold	Human (h_i)	AMU		CAMB		CUUI	
Annotators (*i*)	Avg $F_{0.5}$	Avg $F_{0.5}$	Ratio	Avg $F_{0.5}$	Ratio	Avg $F_{0.5}$	Ratio
1	45.91	24.20	52.71%	28.22	61.46%	26.76	58.29%
2	56.68	33.47	59.05%	37.77	66.64%	36.04	63.59%
3	61.83	38.35	62.03%	42.68	69.03%	40.76	65.92%
4	65.05	41.53	63.85%	45.87	70.51%	43.77	67.29%
5	67.33	43.84	65.11%	48.17	71.54%	45.94	68.23%
6	69.07	45.62	66.06%	49.93	72.29%	47.60	68.92%
7	70.45	47.06	66.80%	51.34	72.87%	48.94	69.46%
8	71.60	48.26	67.40%	52.50	73.32%	50.05	69.89%
9	72.58	49.28	67.90%	53.47	73.67%	50.99	70.25%

Table 5: Table showing average human $F_{0.5}$ scores over all combinations of $1 \leq i < 10$ gold annotators compared to the same averages for the top 3 systems in CoNLL-2014, and the ratio percentage of each team's average score versus the human average score.

equal to the total number of annotators. We only compute all combinations here in order to quantify, for the first time, how much each additional annotator affects performance.

5.2.3 System vs Human

In addition to calculating scores on a human vs human basis, we also calculated the F-scores for the top three CoNLL-2014 teams, AMU (Junczys-Dowmunt and Grundkiewicz, 2014), CAMB (Felice et al., 2014), and CUUI (Rozovskaya et al., 2014), versus all the combinations of humans (Equation 3).

$$s_i = \frac{1}{\binom{|A|}{|X|}} \sum_{X:|X|=i} f(s, X) \qquad (3)$$

Specifically, $s \in S$, where S is the set of all three shared task systems, i.e., $\{$AMU, CAMB, CUUI$\}$, and $f(s, X)$ is the same function in Equation 1 which is the score computed by the M2 scorer to evaluate system s against the set of annotators X chosen to be in the gold standard. The average $F_{0.5}$ scores for each of the team's systems versus increasing numbers of i annotators are also shown in Table 5.

We notice from these scores that, as expected, both system and human performance increases as more annotators are used in a gold standard. We do now, however, have data that quantifies exactly how much each additional annotator affects the score. This effect can be more clearly seen in Figure 1.

It is important to note, however, that even with 9 annotators, human output itself does not reach close to 100% $F_{0.5}$ and instead, the difference between the systems and the humans is about 20% $F_{0.5}$. Furthermore, the curves for humans and systems also remain roughly parallel, suggesting human corrections gain as much benefit as system corrections from larger sets of gold standard annotations.

5.3 Ratio Scoring

In light of the above observation that even humans vs humans are unable to score 100% $F_{0.5}$, it thus seems unreasonable to expect machines to do the same. As such, we propose that it is much more informative to score system output against the average performance of humans instead of against the theoretical maximum score. The ratio values for the three CoNLL-2014 teams against the human gold standards of various sizes are hence also reported in Table 5. The most important thing to note is that these figures are not only much higher than the low $F_{0.5}$ values currently reported in the literature, they are also more representative of the state of the art. For instance, it is highly significant that we can report that the top system in CoNLL-2014, CAMB, is actually able to perform 73% as reliably as a human, which suggests GEC may actually be a more viable technology than was previously thought.

6 Additional Experiments

6.1 Error Categories

As well as carrying out experiments at the system level, we also carried out similar experiments at the error category level. More specifically, we recalculated the values of Equation 1 and 2 for cases where the set of annotations consisted of only a

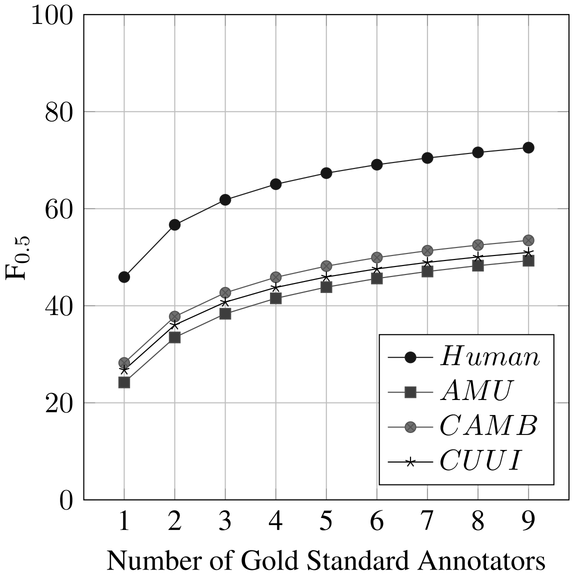

Figure 1: Graph showing how average $F_{0.5}$ scores for humans and systems increase as the number of gold standard annotators also increases (*all error types, 50 Essays*).

single specific error type. Since the participating teams in CoNLL-2014 were not asked to classify the type of errors their systems corrected, we were only able to calculate these new values using the 10 sets of human annotations.

Like Figure 1, we can see from Figure 2 that the $F_{0.5}$ performance of individual error types increases diminishingly as the number of annotators in the gold standard also increases. More importantly, however, we notice that some error types achieve much higher scores than others, which suggests some annotators agree on certain categories more than others.

In particular, noun number (Nn) and subject-verb agreement (SVA) errors achieve the highest scores, at just under 90% $F_{0.5}$, which is also not far from the 100% $F_{0.5}$ that would be achieved if we had gold standard answers for all possible alternative corrections of this type. The most likely reason for this is that, as the correction of these error types typically only involves the addition or removal of an -s suffix, i.e., a minor change in number morphology, there is very little room for annotators to disagree.

In contrast, the next highest category, article and determiner errors (ArtOrDet), has a slightly larger confusion set, $\{$the, a/an, $\epsilon\}$, which may account for the slightly lower score. Similarly, the next group of error categories, spelling and punctuation

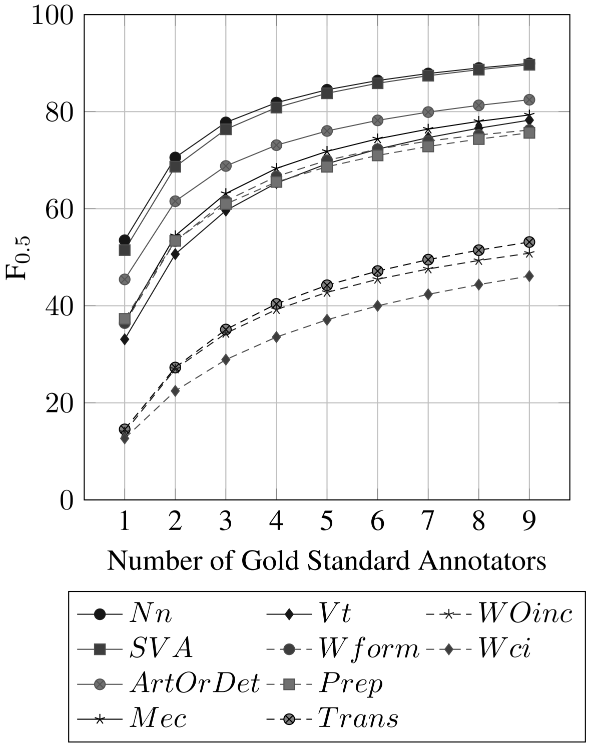

Figure 2: Graph showing how average $F_{0.5}$ scores for various error categories increase as the number of gold standard annotators also increases (*50 essays*). Calculations based on human annotations only.

(Mec), verb tense (Vt), and word form (Wform), which all often involve a similar type of edit operation to a word lemma, likewise have slightly larger confusion sets that include a larger variety of possible morphological inflections. It is likely that the next category, prepositions (Prep), also has a confusion set of a similar size.

The last three categories, conjunctions (all-types) (Trans), word order (WOinc) and word choice (Wci), are all notable because they perform significantly worse than the hitherto mentioned categories. The main reason for this is that these error types all typically have a scope much larger than most other categories in that they often involve changes at the structural or semantic level; e.g., changing an active to a passive or choosing a synonym. For this reason, there are often many more alternative ways to correct them, meaning they are also much more likely to be affected by annotator bias.

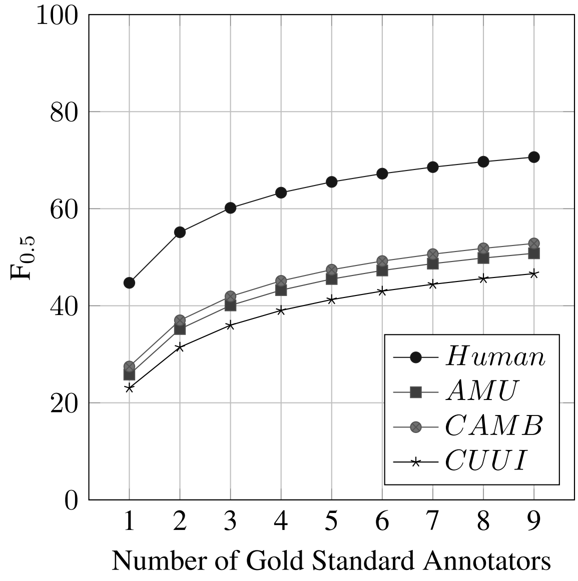

Figure 3: Graph showing how average $F_{0.5}$ scores for humans and systems increase as the number of gold standard annotators also increases (*all error types, 10 Essays*).

6.2 Essay Subsets

Now that we had empirical evidence showing how $F_{0.5}$ scores varied with the number of annotators, an additional question to ask was whether the same trends for 50 essays were also present in a smaller subset of essays. We therefore repeated the main experiment with all error types, but this time used just 10 essays (specifically, essays 1–10) in both the hypothesis and gold standard. The results are shown in Figure 3.

Compared to Figure 1, the most significant difference between these two graphs is that the ranking for AMU and CUUI has changed, although not by much in terms of $F_{0.5}$. The most likely reason for this is that the distribution of error types in the smaller subset of essays is better suited to AMU's more general SMT approach than to CUUI's more targeted classifier based approach. For instance, see Table 9 in Ng et al. (2014) to compare each team's performance on different error types in the CoNLL-2014 shared task.

In other words, while the overall relationship between the system and human scores on 10 and 50 essays remains more or less the same, researchers must be aware that smaller datasets may have more skewed error distributions, which in turn may affect system performance, dependent upon correction strategy. With a balanced test set though, it would seem feasible to carry out future evaluation research on as few as 10 essays (about 6000 words).

7 Conclusion

To summarize, we first showed that 10 individual annotators can all correct the same sentence in 10 different ways, yet also all produce valid alternatives. This implies that inter-annotator agreement statistics, which rely on exact matching, are not well-suited to grammatical error correction, because it may not be the case that annotators truly disagree, but rather that they have a bias towards a particular type of alternative answer.

We next showed that, as has long been suspected, increasing the number of annotators in the gold standard also leads to an increase in $F_{0.5}$, although at a diminishing rate. This data can be used to help researchers decide how many gold standard annotations should be used in GEC evaluation.

The main result of this paper however, is that by computing scores for human against human, we determined that it is *not* true that any human correction is able to score 100% $F_{0.5}$. Instead, we found that the human upper bound is roughly 73% $F_{0.5}$ and that the top 3 teams from CoNLL-2014 actually perform, on average, between 67-73% as reliably as this human upper bound. This result is highly significant, because it suggests GEC systems may actually be more viable than their previously low $F_{0.5}$ scores would suggest.

In addition to the above, we also found that humans tend to agree on some error categories more than others, and suggest that one of the main reasons for this concerns the size of the confusion set of the particular error type.

Finally, not only are we making the corrections by 10 annotators of all 50 essays available with this paper, we also showed that the trends found in the data are also consistent with the annotations of just 10 essays, allowing future research to be conducted on much less text.

Abstract

Our research focuses on the multilingual enhancement of ontologies that, often represented only in English, need to be translated in different languages to enable knowledge access across languages. Ontology translation is a rather different task then the classic document translation, because ontologies contain highly specific vocabulary and they lack contextual information. For these reasons, to improve automatic ontology translations, we first focus on identifying relevant unambiguous and domain-specific sentences from a large set of generic parallel corpora. Then, we leverage Linked Open Data resources, such as DBPedia, to isolate ontology-specific bilingual lexical knowledge. In both cases, we take advantage of the semantic information of the labels to select relevant bilingual data with the aim of building an ontology-specific statistical machine translation system. We evaluate our approach on the translation of a medical ontology, translating from English into German. Our experiment shows a significant improvement of around 3 BLEU points compared to a generic as well as a domain-specific translation approach.

1 Introduction

Currently, most of the semantically structured data, i.e. ontologies or taxonomies, has labels expressed in English only.[1] On the one hand, the increasing amount of ontologies offers an excellent opportunity to link this knowledge together (Gómez-Pérez et al., 2013). On the other hand, non-English users may encounter difficulties when using the ontological knowledge represented only in English. Furthermore, applications in information retrieval, question answering or knowledge management, that use monolingual ontologies are therefore limited to the language in which the ontology labels are stored. To make the ontological knowledge language-independent and accessible beyond language borders, these monolingual resources need to be transformed into multilingual knowledge bases. This multilingual enhancement can enable queries on documents beyond English, e.g. for cross-lingual business intelligence in the financial domain (O'Riain et al., 2013), providing information related to an ontology label, e.g. *other intangible assets*,[2] in Spanish, German or Italian. The main challenge involved in building multilingual knowledge bases is, however, to bridge the gap between language-specific information and the language-independent semantic content of ontologies or taxonomies (Gracia et al., 2012).

Since manual multilingual enhancement of ontologies is a very time consuming and expensive process, we engage an ontology-specific statistical machine translation (SMT) system to automatically translate the ontology labels. Due to the fact that ontology labels are usually highly domain-specific and stored only in knowledge representations (Chandrasekaran et al., 1999), the labels appear infrequent in parallel corpora, which are needed to build a domain-specific translation system with accurate translation candidates. Additionally, ambiguous labels built out of only a few words do often not express enough semantic or contextual information to guide the SMT system to translate a label into the targeted domain. This can be observed by domain-unadapted SMT systems, e.g. Google Translate, where ambiguous expressions, such as *vessel* stored in an medical ontology, are often translated into a generic do-

[1] Based on (Gracia et al., 2012), around 80% of ontology labels indexed in Watson are English.

[2] ontology label stored in FINREP - FINancial REPorting

main as *Schiff*[3] in German (meaning *ship* or *boat*), but not into the targeted medical domain as *Gefäß*. Since ontologies may change over time, keeping up with these changes can be challenging for a human translator. Having in place an SMT system adapted to an ontology can therefore be very beneficial.

In this work, we propose an approach to select the most relevant (parallel) sentences from a pool of generic sentences based on the lexical and semantic overlap with the ontology labels. The goal is to identify sentences that are domain-specific in respect of the target domain and contain as much as possible relevant words that can allow the SMT system to learn the translations of the monolingual ontology labels. For instance, with the sentence selection we aim to retain only parallel sentences where the English word *injection* is translated into the German language as *Impfung* in the medical domain, but not into *Eindüsung*, belonging to the technical domain. This selection process aims to reduce the semantic noise in the translation process, since we try to avoid learning translation candidates that do not belong to the targeted domain. Nonetheless, some of the domain-specific ontology labels may not be automatically translatable with SMT, due to the fact that the bilingual information is missing and cannot be learned from the parallel sentences. Therefore we use the information contained in the DBpedia knowledge base (Lehmann et al., 2015) to improve the translation of expressions which are not known to the SMT system. We tested our approach on the medical domain translating from English to German, showing improvements of around 3 BLEU points compared to a generic as well as a domain-specific translation model.

The remainder of this paper is organized as follows: Section 2 gives an overview of the related work done in the field of ontology translation within SMT. In Section 3, we present the methodology of parallel data selection and terminology identification to improve ontology label translation. Furthermore we show different methods of embedding domain-specific knowledge into SMT. In Experimental Setting, Section 4, we describe the ontology to be translated along the training data needed for SMT. Moreover we introduce existing approaches and give a description of metrics for automatic translation evaluation. Section 5 presents the automatic and manual evaluation of the translated labels. Finally, conclusions and future work are shown in Section 6.

2 Related Work

The task of ontology translation involves the finding of an appropriate translation for the lexical layer, i.e. labels, of the ontology. Most of the previous work tackled this problem by accessing multilingual lexical resources, e.g. EuroWordNet or IATE (Declerck et al., 2006; Cimiano et al., 2010). Their work focuses on the identification of the lexical overlap between the ontology and the multilingual resource. Since the replacement of the source and target vocabulary guarantees a high precision but a low recall, external translation services, e.g. BabelFish, SDL FreeTranslation tool or Google Translate, were used to overcome this issue (Fu et al., 2009; Espinoza et al., 2009). Additionally, ontology label disambiguation was performed by (Espinoza et al., 2009) and (McCrae et al., 2011), where the structure of the ontology along with existing multilingual ontologies was used to annotate the labels with their semantic senses. Differently to the aforementioned approaches, which rely on external knowledge or services, we focus on how to gain adequate translations using a small, but ontology-specific SMT system. We learned that using external SMT services often results in wrong translations of labels, because the external SMT services are not able to adapt to the specificity of the ontology. Avoiding existing multilingual resources, which enables a simple replacement of source and target labels, showed the possibility of improving label translations without manually generated lexical resources, since not every ontology may benefit of current multilingual resources.

Due to the specificity of the labels, previous research (Wu et al., 2008; Haddow and Koehn, 2012) showed that generic SMT systems, which merge all accessible data together, cannot be used to translate domain-specific vocabulary. To avoid unsatisfactory translations of specific vocabulary we have to provide the SMT system domain-specific bilingual knowledge, from where it can learn specific translation candidates. (Eck et al., 2004) used for the language model adaptation within SMT the information retrieval technique *tf-idf*. Similarly, (Hildebrand et al., 2005) and (Lü et al., 2007) utilized this approach to select

[3] Translation performed on 25.02.2015

relevant sentences from available parallel text to adapt translation models. The results confirmed that large amounts of generic training data cannot compensate for the requirement of domain-specific training sentences. Another approach is taken by (Moore and Lewis, 2010), where, based on source and target language models, the authors calculated the difference of the cross-entropy values for a given sentence. (Axelrod et al., 2011) extend this work using the bilingual difference of cross-entropy on in-domain and out-of-domain language models for training sentence selection for SMT. (Wuebker et al., 2014) reused the cross-entropy approach and applied it to the translation of video lectures. (Kirchhoff and Bilmes, 2014) introduce submodular optimization using complex features for parallel sentence selection. In their experiments they use the source and target side of the text to be translated, and show significant improvements over the widely used cross-entropy method. A different approach for sentence selection is shown in (Cuong and Sima'an, 2014), where the authors propose a latent domain translation model to distinguish between hidden in- and out-of-domain data. (Gascó et al., 2012) and (Bicici and Yuret, 2011) sub-sample sentence pairs whose source has most overlap with the evaluation dataset. Different from these approaches, we do not embed any specific in-domain knowledge to the generic corpus, from which sentence selection is performed. Furthermore, none of these methods explicitly exploit the ontological hierarchy for label disambiguation and are not specifically designed to deal with the characteristics of ontology labels.

As a lexical resource, Wikipedia with its rich semantic knowledge was used as a resource for bilingual term identification in the context of SMT. (Tyers and Pieanaar, 2008) extracts bilingual dictionary entries from Wikipedia to support the machine translation system. Based on exact string matching they query Wikipedia with a list of around 10,000 noun lemmas to generate the bilingual dictionary. Besides the interwiki link system, (Erdmann et al., 2009) enhance their bilingual dictionary by using redirection page titles and anchor text within Wikipedia. To cast the problem of ambiguous Wikipedia titles, (Niehues and Waibel, 2011; Arcan et al., 2014a) use the information of Wikipedia categories and the text of the articles to provide the SMT system domain-specific bilingual knowledge. This research showed that using the lexical information stored in this knowledge base improves the translation of highly domain-specific vocabulary. However, we do not rely on category annotations of Wikipedia articles, but perform domain-specific dictionary generation based on the overlap between related words from the ontology label and the abstract of a Wikipedia article.

3 Methodology

We propose an approach that uses the ontology labels to be translated to select the most relevant parallel sentences from a generic parallel corpus. Since ontology labels tend to be short (McCrae et al., 2011), we expand the label representation with its semantically related words. This expansion enables a larger semantic overlap between a label and the (parallel) sentences, which gives us more information to distinguish between related and unrelated sentences. Our approach reduces the ambiguity of expressions in the selected parallel sentences, which consequently gives more preference to translation candidates of the targeted domain. Furthermore, we access the DBpedia knowledge base to identify bilingual terminology belonging to the domain of the ontology. Once the domain-specific parallel sentences and lexical knowledge is available, we use different techniques to embed this knowledge into the SMT system. These methods are detailed in the following subsections.

3.1 Domain-Specific Parallel Sentence Selection

In order to generate the best translation system we select only sentences from the generic parallel corpus which are most relevant to the labels to be translated. The first criteria for relevance was the *n-gram overlap* between a label and a source sentence coming from the generic corpus. Therefore we calculate the cosine similarity between the n-grams extracted from a label and the n-grams of each source sentence in the generic corpus. The similarity between the label and the sentence is defined as the cosine of the angle between the two vectors. The calculated similarity score allows us to distinguish between more and less relevant sentences.

Due to the specificity of ontology labels, the *n-gram overlap* approach is not able to select useful sentences in the presence of short labels. For this reason, we improve it by extending the semantic information of labels using a technique for computing vector representations of words. The technique is based on a neural network that analyses the textual data provided as input and provides as output a list of semantically related words (Mikolov et al., 2013). Each input string is vectorized using the surrounding context and compared to other vectorized sets of words (from the training data) in a multi-dimensional vector space. For obtaining the vector representations we used a distributional semantic model trained on the Wikipedia articles,[4] containing more than 3 billion words. Word relatedness is measured through the cosine similarity between two word vectors. A score of 1 would represent a perfect word similarity; e.g. *cholera* equals *cholera*, while the medical expression *medicine* has a cosine distance of 0.678 to *cholera*. Since words, which occur in similar contexts tend to have similar meanings (Harris, 1954), this approach enables to group related words together. The output of this technique is the analysed label with a vector attached to it, e.g. for the medical label *cholera* it provides related words with its relatedness value, e.g. *typhus* (0.869), *smallpox* (0.849), *epidemic* (0.834), *dysentery* (0.808) ... In our experiments, this method is implemented by the use of Word2Vec.[5]

To additionally disambiguate short labels, the related words of the current label are combined with the related words of its direct parent in the ontology. The usage of the ontology hierarchy allows us to take advantage of the specific vocabulary of the related words in the computation of the cosine similarity. Given a label and a source sentence from the generic corpus, related words and their weights are extracted from both of them and used as entries of the vectors passed to the cosine similarity. The most similar source sentence and the label should share the largest number of related words (largest cosine similarity).

3.2 Bilingual Terminology Identification

The automatic translation of domain-specific vocabulary can be a hard task for a generic SMT system, if the bilingual knowledge is not present in the parallel dataset. To complement the previous approaches we access DBpedia[6] as a multilingual lexical resource.

We engage the idea of (Arcan et al., 2012) where the authors provide to the SMT system unambiguous terminology identified in Wikipedia to improve the translations of labels in the financial domain. To disambiguate Wikipedia entries with translations into different domains, they query the repository for analysing the n-gram overlap between the financial labels and the Wikipedia entries and store the frequency of categories which are associated with the matched entry. In a final step they extract only bilingual Wikipedia entries, which are associated with the most frequent Wikipedia categories identified in the previous step.

Since the Wikipedia entries are often associated only with a few categories, this limited vocabulary may give only a small contribution for this disambiguation of different meanings or topics of the same Wikipedia entry. For this reason, we use for each Wikipedia entry the extended abstract, which contains more information about the entry compared to the previous approach. For ambiguous Wikipedia entries, which overlap with a medical label, we therefore calculate the cosine similarity between the related words associated with the label and the lexical information of the Wikipedia abstract. Among different ambiguous entries, the cosine similarity gives more weight to the Wikipedia entry, which is closer to our preferred domain. Finally, if the Wikipedia entry has an equivalent in the target language, i.e. German, we use the bilingual information for the lexical enhancement of the SMT system.

3.3 Integration of Domain-Specific Knowledge into SMT

After the identification of domain-specific bilingual knowledge, it has to be integrated into the workflow of the SMT system. The injection of new obtained knowledge can be performed by retraining the domain-specific knowledge with the generic parallel corpus (Langlais, 2002; Ren et al., 2009; Haddow and Koehn, 2012) or by adding new entries directly to the translation system (Pinnis et al., 2012; Bouamor et al., 2012). These methods have the drawback that the bilingual domain specificity may get lost due to the usually larger generic parallel corpora. Giving more priority to domain-specific translations than generic ones, we focus on two techniques, i.e. the Fill-Up model (Bisazza et al., 2011) and the Cache-Based

[4] Wikipedia dump id enwiki-20141106

[5] `https://code.google.com/p/word2vec/`

[6] `http://wiki.dbpedia.org/Downloads2014`

Model (Bertoldi et al., 2013) approach.

The Fill-Up model has been developed to address a common scenario where a large generic background model exists, and only a small quantity of domain-specific data can be used to build a translation model. Its goal is to leverage the large coverage of the background model, while preserving the domain-specific knowledge coming from the domain-specific data. For this purpose the generic and the domain-specific translation models are merged. For those translation candidates that appear in both models, only one instance is reported in the Fill-Up model with the largest probabilities according to the translation models. To keep track of a translation candidate's provenance, a binary feature is added that gives preference to a translation candidate if it comes from the domain-specific translation model. We engage the idea of the Fill-Up model to combine the domain-specific parallel knowledge from the selected sentences with the generic (1.9M) parallel corpus.

Furthermore, for embedding bilingual lexical knowledge into the SMT system, we engage the idea of cache-based translation and language models (Bertoldi et al., 2013). The main idea behind these models is to combine a large static global model with a small, but dynamic local model. This approach has already shown its potential of injecting domain-specific knowledge into a generic SMT system (Arcan et al., 2014b). For our experiments we inject the bilingual lexical knowledge identified in DBpedia and IATE into the cache-based models. The cache-based model relies on a local translation model (CBTM) and language model (CBLM). The first is implemented as an additional table in the translation model providing one score. All entries are associated with an 'age' (initially set to 1), corresponding to the time when they were actually inserted. Each new insertion causes an ageing of the existing translation candidates and hence their re-scoring; in case of re-insertion of a phrase pair, the old value is set to the initial value. Similarly to the CBTM, the local language model is built to give preference to the provided target expressions. Each entry stored in CBLM is associated with a decaying function of the age of insertion into the model. Both models are used as additional features of the log-linear model in the SMT system.

4 Experimental Setting

In this Section, we give an overview on the dataset and the translation toolkit used in our experiment. Furthermore, we describe the existing approaches and give insights into the SMT evaluation techniques, considering the translation direction from English to German.

Evaluation Dataset For our experiments we used the International Classification of Diseases (ICD) ontology as the gold standard,[7] whereby the considered translation direction is from English to German. The ICD ontology, translated into 43 languages, is used to monitor diseases and to report the general health situation of the population in a country. This stored information also provides an overview of the national mortality rate and appearance of diseases of WHO member countries.

For our experiment we used 2000 English labels from the ICD-10 dataset, which were aligned to their German equivalents (Table 1). To identify the best set of sentences we experiment with different values of τ, which is the percentage of all the sentences that are considered relevant (domain-specific) by the sentence extraction approach. The value that allows the SMT system to achieve the best performance on the *development dataset 1* is used on the *evaluation set*, which is used for the translation evaluation of ontology labels reported in this paper. The parameters within the SMT system are optimized on the *development dataset 2*.

Statistical Machine Translation and Training Dataset For our translation task, we use the statistical translation toolkit Moses (Koehn et al., 2007), where the word alignments were built with the GIZA++ toolkit (Och and Ney, 2003). The SRILM toolkit (Stolcke, 2002) was used to build the 5-gram language model.

For a broader domain coverage of the generic training dataset necessary for the SMT system, we merged parts of JRC-Acquis 3.0[8] (Steinberger et al., 2006), Europarl v7[9] (Koehn, 2005) and OpenSubtitles2013[10] (Tiedemann, 2012), obtaining a training corpus of 1.9M sentences, con-

taining around 38M running words (Table 1).[11] The generic SMT system, trained on the concatenated 1.9 sentences, is used as a baseline, which we compare against the domain-specific models generated with different sentence selection methods. Furthermore we use the generic SMT system in combination with the smaller domain-specific models to evaluate different approaches when combining generic and domain-specific data together.

We additionally compare our results to an SMT system built on an existing domain-specific parallel dataset, i.e. EMEA[12] (Tiedemann, 2009), which holds specific medical parallel data extracted from the European Medicines Agency documents and websites.

Comparison to Existing Approaches We compare our approach on knowledge expansion for sentence selection with similar methods that distinguish between more important sentences and less important ones. First, we sort 1.9M sentences from the generic corpus based on the *perplexity* of the ontology vocabulary. The perplexity score gives a notion of how well the probability model based on the ontology vocabulary predicts a sample, which is in our case each sentence in the generic corpus.

Second, we use the method shown in (Hildebrand et al., 2005), where the authors use a method based on *tf-idf*[13] to select the most relevant sentences. This widely-used method in information retrieval tells us how important a word is to a document, whereby each sentence from the generic corpus is treated as a document.

Finally, we compare our approach with the *infrequent n-gram recovery* method, described in (Gascó et al., 2012). Their technique consists of selection of relevant sentences from the generic corpus, which contain infrequent n-grams based on their test data. They consider an n-gram as infrequent if it appears in the generic corpus less times than an infrequent threshold *t*.

Furthermore we enrich and evaluate our proposed ontology-specific SMT system with the lexical information coming from the terminological database IATE[14] (Inter-Active Terminology for Europe). IATE is the institutional terminology database of the EU and is used for the collection, dissemination and shared management of specific terminology and contains approximately 1.4 million multilingual entries.

Evaluation Metrics The automatic translation evaluation is based on the correspondence between the SMT output and reference translation (gold standard). For the automatic evaluation we used the BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014) algorithms.[15]

BLEU (Bilingual Evaluation Understudy) is calculated for individual translated segments (n-grams) by comparing them with a dataset of reference translations. Considering the shortness of the labels, we report scores based on the bi-gram overlap (BLEU-2) and the standard four-gram overlap (BLEU-4). Those scores, between 0 and 100 (perfect translation), are then averaged over the whole *evaluation dataset* to reach an estimate of the translation's overall quality.

METEOR (Metric for Evaluation of Translation with Explicit ORdering) is based on the harmonic mean of precision and recall, whereby recall is weighted higher than precision. Along with standard exact word (or phrase) matching it has additional features, i.e. stemming, paraphrasing and synonymy matching. Differently to BLEU, the metric produces good correlation with human judgement at the sentence or segment level.

[11] For reproducibility and future evaluation we take the first one-third part of each corpus.

The approximate randomization approach in MultEval (Clark et al., 2011) is used to test whether differences among system performances are statistically significant with a p-value < 0.05.

5 Evaluation of Ontology Labels

In this Section, we report the translation quality of ontology labels based on translation systems learned from different sentence selection methods. Additionally, we perform experiments training an SMT system on the combination of in- and out-domain knowledge. The final approach enhances a domain-specific translation system with lexical knowledge identified in IATE or DBpedia.

5.1 Automatic Translation Evaluation

We report the automatic evaluation based on BLEU and METEOR for the sentence selection techniques, the combination of in- and out-domain data and the lexical enhancement of SMT.

Sentence Selection Techniques As a first evaluation, we automatically compare the quality of the ICD labels translated with different SMT systems trained on specific sentences by the aforementioned selection techniques (Table 2). Due to the in-domain bilingual knowledge, the translation system trained using the EMEA dataset performs slightly better compared to the large generic baseline system. Among the different sentence selection approaches, the *infrequent n-gram recovery* method (infreq. in Table 2) outperforms the baselines and all the other techniques. This is due to the very strict criteria of selecting relevant sentences that allows the *infrequent n-gram recovery* method to identify a limited number (20,000) of highly ontology-specific bilingual sentences. The *related words* and the *n-gram overlap* models perform slightly better than the baseline, with a usage of 81,000 and 59,000 relevant sentences, and perform similarly to the in-domain EMEA translation system.

Further translation quality improvement is possible, if sentence selection methods are combined together (last four rows in Table 2). The cosine similarities of the methods are combined together, whereby new thresholds τ are computed on the *development dataset 1* and applied on the ICD *evaluation dataset*. Each combined method showed improvement compared to the stand-alone method. The best overall performance is obtained when combining the *n-gram overlap*, the semantic *related words* and *infrequent n-gram recovery* methods. With this combination, we reduce the amount of parallel sentences by 98% compared to the generic corpus and significantly outperform the baseline by 2.3 BLEU score points. These two factors confirm the capability of the combined approach of selecting only few ontology-specific bilingual sentences (30,000) that allows the SMT system to identify the correct translations in the target ontology domain. This is due to the fact that the three combined methods are quite complementary. In fact, the *n-gram overlap* method selects a relatively large amount of bilingual sentences with few words in common with the label, the *related words* approach identifies bilingual sentences in the ontology target domain, and the infrequent n-gram recovery technique selects few bilingual sentences with only specific n-grams in common with the labels balancing the effect of the n-gram overlap method.

Dataset Type	Size	BLEU-2	BLEU-4	METEOR
Generic dataset	1.9M	17.2	6.6	24.7
EMEA dataset	1.1M	18.5	7.0	25.8
(1) perplexity	89K	17.5	6.8	24.8

(5) $\wedge$ (4) $\wedge$ (3)	30K	**20.1**	**8.9***	**27.2***

Table 2: Automatic translation evaluation on the evaluation dataset of the ICD ontology (Size = amount of selected sentences from the generic parallel corpus. bold results = best performance; *statistically significant compared to baseline)

Combining In- and Out-Domain Data Considering the relatively small amount of parallel data extracted with the sentence selecting methods for the SMT community, we evaluate different approaches that combine a large generic translation model with domain-specific data. For this purpose, we use the sentences selected by the best approach ((5)$\wedge$(4)$\wedge$(3)) in the previous experiments and combine them with the generic parallel dataset. We evaluate the translation performance when *(i)* concatenating the selected domain-specific parallel dataset with the generic

Dataset Type	BLEU-2	BLEU-4	METEOR

Fill-Up Model (*iii*)	17.7	7.0	24.7
(5)∧(4)∧(3) + IATE	19.8	9.0*	27.8*
(5)∧(4)∧(3) + DBpedia$^{(1)}$	20.6	9.1*	27.3*
(5)∧(4)∧(3) + DBpedia$^{(2)}$	**21.0**	**9.6***◇	**28.2***◇

Table 3: Evaluation of the ICD ontology evaluation dataset combining domain-specific with generic parallel knowledge and lexical enhancement of SMT using IATE and DBpedia (bold results = best performance; *statistically significant compared to baseline; ◇statistically significant compared to best sentence selection model)

parallel one, *(ii)* combining the generated translation models from the selected domain-specific parallel dataset and the generic corpus and *(iii)* applying the Fill-Up model to emphasise the domain-specific data in a single translation model. The translation performance of the combination methods are shown in Table 3. It is interesting to notice that none of them benefits from the use of the additional generic parallel data showing translation performance smaller than the domain-specific model. Although all methods outperform the generic translation model, only the log-linear approach, keeping in- and out-domain translation models separated, shows significant improvement. Comparing it to the combined sentence selection technique ((5)∧(4)∧(3)) does not show any statistical significant differences between the approaches. We conclude that the generic corpus is too large compared to the selected in-domain corpus, nullifying the influence of the extracted domain-specific parallel knowledge.

Lexical enhancement for SMT Since the out-of-vocabulary problem can be only mitigated with sentence selection, we accessed lexical resources IATE and DBpedia to further improve the translations of the medical labels. Based on the word overlap between labels and entries in IATE we extracted 11,641 English lexical entries with its equivalent in German. The DBpedia$^{(1)}$ approach, which disambiguates DBpedia entries based on the (Wikipedia article) categories (Arcan et al., 2012), identified 7,911 English-German expression for the targeted domain, while the abstract based disambiguation approach, marked as DBpedia$^{(2)}$ in Table 3 identified 3,791 bilingual entries. The lexical enhanced models further improved the translations of the medical labels (last three rows in Table 3) due to the additional bilingual information from the lexical resources, which is missing in the standalone sentence selection model. Comparing the ICD *evaluation dataset* and the translations generated with the DBpedia$^{(2)}$ lexical enhanced model we observed that more than 80 labels benefit from the additional lexical knowledge, e.g. correcting the mistranslated "adrenal gland" into "Nebenniere". The lexical extraction and disambiguation of bilingual knowledge based on the abstract of the article compared to the article categories further improves the lexical choice, helping SMT systems to improve the translation of ontology labels.

5.2 Manual Evaluation of Translated Labels

Since ontologies store specific vocabulary about a domain, this vocabulary is adapted to a concrete language and culture community (Cimiano et al., 2010). In order to investigate to what extent the automatically generated translations differ from a translator's adapted point of view, we manually inspected the translations produced by the sentence selection approaches described in Section 5.1.

While analysing the English and German part of the ICD ontology gold standard we noticed significant differences in the translations of the medical labels. As a result of the language and cultural adaptation, many labels in the ICD ontology were not always translated literally, i.e. parts of a label were semantically merged, omitted or new information was added while crossing the language border. For example, the ICD label "acute kidney failure and chronic kidney disease" is stored in the German part of the ontology as "Niereninsuffizienz".[16] Although none of the translation systems can generate the compounded medical expression for German, the SMT system generated nevertheless an acceptable translation, i.e. "akutes Nierenversagen und chronischer Nierenerkrankungen".[17] A more extreme example is the English label "slipping, tripping, stumbling and falls", in the German ICD ontology represented as

[16] Niereninsuffizienz←kidney insufficiency

[17] akutes←acute, Nierenversagen←kidney failure, und←and, chronischer←chronic, Nierenerkrankungen←kidney disease

”sonstige Stürze auf gleicher Ebene”.[18] The language and cultural adaptation is very active for this example, where the whole English label is semantically merged into the word ”Stürze”, meaning ”falls”. Additionally, the German part holds more information within the label, i.e. ”auf gleicher Ebene” (en. ”at the same level”), which is not represented on the English side. Since the SMT system will always try to translate every phrase (word or word segments) into the target language, an automatic translation evaluation cannot reflect the overall SMT performance.

Further we detected a large error class caused by compounding, a common linguistic feature of German. Although the phrase ”heart diseases” with its reference translation ”Herzkrankheiten” appears frequent in the generic training dataset, the SMT system prefers to translate it word by word into ”Herz Krankheiten”. [19] Similar observations were made with ”upper arm” (German ”Oberarm”) with the SMT word to word translation ”oberen Arm”.

Finally, we analysed the impact of the semantically enriched sentence selection with *related words* coming from Word2Vec compared to the surface based sentence selection, e.g. *preplexity*, *infrequent n-gram recovery* or *n-gram overlap*. Since semantically enriched selection stored the most relevant sentences, we observed the correct translation of the label ”blood vessels” into ”Blutgefäße”. The generic and other surface based selections translated the expression individually into ”Blut Schiffe”, where ”Schiffe” refers to the more common English word ”ship”, but not to ’part of the system transporting blood throughout our body’. The last example illustrates further the semantic mismatch between the training domain and the test domain. Using the generic model, built mainly out of European laws and parliament discussions (JRC-Acquis/Europarl) the word ”head” inside the label ”injury of head” is wrongly translated into the word ”Leiter”, meaning ”leader” in the legal domain. Nevertheless, the additional semantic information prevents storing wrong parallel sentences and guides the SMT to the correct translation, i.e. ”Schädigung des Kopfes”.[20]

6 Conclusion

In this paper we presented an approach to identify the most relevant sentences from a large generic parallel corpus, giving the possibility to translate highly specific ontology labels without particular in-domain parallel data. We enhanced furthermore the translation system build on the in-domain parallel knowledge with additional lexical knowledge accessing DBpedia. With the aim to better select relevant bilingual knowledge for SMT, we extend previous sentence and lexical selection techniques with additional semantic knowledge. Our proposed ontology-specific SMT system showed a statistical significant improvement (up to 3 BLEU points) of ontology label translation over the compared translation approaches.

In future, we plan to integrate a larger diversity of surface, semantic and linguistic information for relevant sentence selection. Although the SMT system is capable of translating several words into a compound word, the small amount of the selected sentences limits this capability. To improve the ontology label translations, we therefore see the need to focus more on the German compound feature. Additionally we observed that more than 25% of the identified lexical knowledge consists of multi-word-expressions, e.g. ”fatal familial insomnia”. For this reason, our ongoing work focuses on the alignment of nested knowledge inside those expressions. To move further in this direction, we plan to focus on exploiting morphological term variations taking advantage of the alternative terms provided by DBpedia.

Automatic disambiguation of English puns

Tristan Miller and Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt
https://www.ukp.tu-darmstadt.de/

Abstract

Traditional approaches to word sense disambiguation (WSD) rest on the assumption that there exists a single, unambiguous communicative intention underlying every word in a document. However, writers sometimes intend for a word to be interpreted as simultaneously carrying multiple distinct meanings. This deliberate use of lexical ambiguity—*i.e.*, punning—is a particularly common source of humour. In this paper we describe how traditional, language-agnostic WSD approaches can be adapted to "disambiguate" puns, or rather to identify their double meanings. We evaluate several such approaches on a manually sense-annotated collection of English puns and observe performance exceeding that of some knowledge-based and supervised baselines.

1 Introduction

Word sense disambiguation, or WSD, is the task of identifying a word's meaning in context. No matter whether it is performed by a human or a machine, WSD usually rests on the assumption that there is a single unambiguous communicative intention underlying each word in the document.[1] However, there exists a class of language constructs known as *paronomasia* and *syllepsis*, or more generally as *puns*, in which homonymic (*i.e.*, coarse-grained) lexical-semantic ambiguity is a *deliberate* effect of the communication act. That is, the writer intends for a certain word or other lexical item to be interpreted as simultaneously carrying two or more separate meanings, or alternatively for it to be unclear which meaning is the intended one. There are a variety of motivations writers have for employing such constructions, and in turn for why such uses are worthy of scholarly investigation.

Perhaps surprisingly, this sort of intentional lexical ambiguity has attracted little attention in the fields of computational linguistics and natural language processing. What little research has been done is confined largely to computational mechanisms for pun generation (in the context of natural language generation for computational humour) and to computational analysis of phonological properties of puns. A fundamental problem which has not yet been as widely studied is the automatic detection and identification of intentional lexical ambiguity—that is, given a text, does it contain any lexical items which are used in a deliberately ambiguous manner, and if so, what are the intended meanings?

We consider these to be important research questions with a number of real-world applications. For instance, puns are particularly common in advertising, where they are used not only to create humour but also to induce in the audience a valenced attitude toward the target (Valitutti et al., 2008). Recognizing instances of such lexical ambiguity and understanding their affective connotations would be of benefit to systems performing sentiment analysis on persuasive texts. Wordplay is also a perennial topic of scholarship in literary criticism and analysis. To give just one example, puns are one of the most intensively studied aspects of Shakespeare's rhetoric, and laborious manual counts have shown their frequency in certain

[1] Under this assumption, lexical ambiguity arises due to there being a plurality of words with the same surface form but different meanings, and the task of the interpreter is to select correctly among them. An alternative view is that each word is a single lexical entry whose specific meaning is *underspecified* until it is activated by the context (Ludlow, 1996). In the case of *systematically polysemous* terms (*i.e.*, words that have several related senses shared in a systematic way by a group of similar words), it may not be necessary to disambiguate them at all in order to interpret the communication (Buitelaar, 2000). While there has been some research in modelling intentional lexical-semantic underspecification (Jurgens, 2014), it is intended for closely related senses such as those of systematically polysemous terms, not those of coarser-grained homonyms which are the subject of this paper.

of his plays to range from 17 to 85 instances per thousand lines (Keller, 2009). It is not hard to image how computer-assisted detection, classification, and analysis of puns could help scholars in the digital humanities. Finally, computational pun detection and understanding hold tremendous potential for machine-assisted translation. Some of the most widely disseminated and translated popular discourses—particularly television shows and movies—feature puns and other forms of wordplay as a recurrent and expected feature (Schröter, 2005). These pose particular challenges for translators, who need not only to recognize and comprehend each instance of humour-provoking ambiguity, but also to select and implement an appropriate translation strategy.[2] NLP systems could assist translators in flagging intentionally ambiguous words for special attention, and where they are not directly translatable (as is usually the case), the systems may be able to propose ambiguity-preserving alternatives which best match the original pun's double meaning.

In the present work, we discuss the adaptation of automatic word sense disambiguation techniques to intentionally ambiguous text and evaluate these adaptations in a controlled setting. We focus on humorous puns, as these are by far the most commonly encountered and more readily available in (and extractable from) existing text corpora.

The remainder of this paper is structured as follows: In the following section we give a brief introduction to puns, WSD, and related previous work on computational detection and comprehension of humour. In §3 we describe the data set produced for our experiments. In §§4 and 5 we describe how disambiguation algorithms, evaluation metrics, and baselines from traditional WSD can be adapted to the task of pun identification, and in §6 we report and discuss the performance of our adapted systems. Finally, we conclude in §7 with a review of our research contributions and an outline of our plans for future work.

2 Background

2.1 Puns

Punning is a form of wordplay where a word is used in such a way as to evoke several independent meanings simultaneously. Humorous and non-humorous puns have been the subject of extensive study in the humanities and social sciences, which has led to insights into the nature of language-based humour and wordplay, including their role in commerce, entertainment, and health care; how they are processed in the brain; and how they vary over time and across cultures (Monnot, 1982; Culler, 1988; Lagerwerf, 2002; Bell et al., 2011; Bekinschtein et al., 2011). Study of literary puns imparts a greater understanding of the cultural or historical context in which the literature was produced, which is often necessary to properly interpret and translate it (Delabastita, 1997).

Puns can be classified in various ways (Attardo, 1994), though from the point of view of our particular natural language processing application the most important distinction is between homographic and homophonic puns. A *homographic* pun exploits distinct meanings of the same written word, and a *homophonic* pun exploits distinct meanings of the same spoken word. Puns can be homographic, homophonic, both, or neither, as the following examples illustrate:

(1) A lumberjack's world revolves on its axes.

(2) She fell through the window but felt no pane.

(3) A political prisoner is one who stands behind her convictions.

(4) The sign at the nudist camp read, "Clothed until April."

In (1), the pun on *axes* is homographic but not homophonic, since the two meanings ("more than one axe" and "more than one axis") share the same spelling but have different pronunciations. In (2), the pun on *pane* ("sheet of glass") is homophonic but not homographic, since the word for the secondary meaning ("feeling of injury") is properly spelled *pain* but pronounced the same. The pun on *convictions* ("strongly held beliefs" and "findings of criminal guilt") in (3) is both homographic and homophonic. Finally, the pun on *clothed* in (4) is neither homographic nor homophonic, since the word for the secondary meaning, *closed*, differs in both spelling and pronunciation. Such puns are commonly known as *imperfect* puns.

Other characteristics of puns important for our work include whether they involve compounds, multiword expressions, or proper names, and whether the pun's multiple meanings involve mul-

[2] The problem is compounded in audio-visual media such as films; often one or both of the pun's meanings appears in the visual channel, and thus cannot be freely substituted.

tiple parts of speech. We elaborate on the significance of these characteristics in the next section.

2.2 Word sense disambiguation

Word sense disambiguation (WSD) is the task of determining which sense of a polysemous term is the one intended when that term is used in a given communicative act. Besides the target term itself, a WSD system generally requires two inputs: the *context* (*i.e.*, the running text containing the target), and a *sense inventory* which specifies all possible senses of the target.

Approaches to WSD can be categorized according to the type of knowledge sources used to help discriminate senses. *Knowledge-based* approaches restrict themselves to using pre-existing lexical-semantic resources (LSRs), or such additional information as can be automatically extracted or mined from raw text corpora. *Supervised* approaches, on the other hand, use manually sense-annotated corpora as training data for a machine learning system, or as seed data for a bootstrapping process. Supervised WSD systems generally outperform their knowledge-based counterparts, though this comes at the considerable expense of having human annotators manually disambiguate hundreds or thousands of example sentences. Moreover, supervised approaches tend to be such that they can disambiguate only those words for which they have seen sufficient training examples to cover all senses. That is, most of them cannot disambiguate words which do not occur in the training data, nor can they select the correct sense of a known word if that sense was never observed in the training data.

Regardless of the approach, all WSD systems work by extracting contextual information for the target word and comparing it against the sense information stored for that word. A seminal knowledge-based example is the Lesk algorithm (Lesk, 1986) which disambiguates a pair of target terms in context by comparing their respective dictionary definitions and selecting the two with the greatest number of words in common. Though simple, the Lesk algorithm performs surprisingly well, and has frequently served as the basis of more sophisticated approaches. In recent years, Lesk variants in which the contexts and definitions are supplemented with entries from a distributional thesaurus (Lin, 1998) have achieved state-of-the-art performance for knowledge-based systems on standard data sets (Miller et al., 2012; Basile et al., 2014).

In traditional word sense disambiguation, the part of speech and lemma of the target word are usually known *a priori*, or can be determined with high accuracy using off-the-shelf natural language processing tools. The pool of candidate senses can therefore be restricted to those whose lexicalizations exactly match the target lemma and part of speech. No such help is available for puns, at least not in the general case. Take the following two examples:

(5) Tom moped.

(6) “I want a scooter,” Tom moped.

In the first of these sentences, the word *moped* is unambiguously a verb with the lemma *mope*, and would be correctly recognized as such by any automatic lemmatizer and part-of-speech tagger. The *moped* of the second example is a pun, one of whose meanings is the same inflected form of the verb *mope* (“to sulk”) and the other of which is the noun *moped* (“motorized scooter”). For such cases an automated pun identifier would therefore need to account for all possible lemmas for all possible parts of speech of the target word. The situation becomes even more onerous for heterographic and imperfect puns, which may require the use of pronunciation dictionaries, and application of phonological theories of punning, in order to recover the lemmas (Hempelmann, 2003).

As our research interests are in lexical semantics rather than phonology, we focus on puns which are homographic and monolexemic. This allows us to investigate the problem of pun identification in as controlled a setting as possible.

2.3 Previous work

2.3.1 Computational humour

There is some previous research on computational detection and comprehension of humour, though by and large it is not concerned specifically with puns; those studies which do analyze puns tend to have a phonological or syntactic rather than semantic bent. In this subsection we briefly review some prior work which is relevant to ours.

Yokogawa (2002) describes a system for detecting the presence of puns in Japanese text. However, this work is concerned only with puns which are both imperfect and ungrammatical, relying on syntactic cues rather than the lexical-semantic information we propose to use. Taylor and Mazlack (2004) describe an *n*-gram–based approach for recognizing when imperfect puns are used for humorous effect in a certain narrow class of English knock-knock jokes. Their focus on imperfect puns and their use of a fixed syntactic context makes their approach largely inapplicable to perfect puns in running text. Mihalcea and Strapparava (2005) treat humour recognition as a classification task, employing various machine learning techniques on humour-specific stylistic features such as alliteration and antonymy. Of particular interest is their follow-up analysis (Mihalcea and Strapparava, 2006), where they specifically point to their system's failure to resolve lexical-semantic ambiguity as a stumbling block to better accuracy, and speculate that deeper semantic analysis of the text, such as via word sense disambiguation or domain disambiguation, could aid in the detection of humorous incongruity and opposition.

The previous work which is perhaps most relevant to ours is that of Mihalcea et al. (2010). They build a data set consisting of 150 joke set-ups, each of which is followed by four possible "punchlines", only one of which is actually humorous (but not necessarily due to a pun). They then compare the set-ups against the punchlines using various models of incongruity detection, including many exploiting knowledge-based semantic relatedness such as Lesk. The Lesk model had an accuracy of 56%, which is lower than that of a naïve polysemy model which simply selects the punchline with the highest mean polysemy (66%) and even of a random-choice baseline (62%). However, it should be stressed here that the Lesk model did not directly account for the possibility that any given word might be ambiguous. Rather, for every word in the setup, the Lesk measure was used to select a word in the punchline such that the lexical overlap between each *one* of their possible definitions was maximized. The overlap scores for all word pairs were then averaged, and the punchline with the lowest average score selected as the most humorous.

2.3.2 Corpora

There are a number of English-language corpora of intentional lexical ambiguity which have been used in past work, usually in linguistics or the social sciences. In their work on computer-generated humour, Lessard et al. (2002) use a corpus of 374 "Tom Swifty" puns taken from the Internet, plus a well-balanced corpus of 50 humorous and non-humorous lexical ambiguities generated programmatically (Venour, 1999). Hong and Ong (2009) also study humour in natural language generation, using a smaller data set of 27 punning riddles derived from a mix of natural and artificial sources. In their study of wordplay in religious advertising, Bell et al. (2011) compile a corpus of 373 puns taken from church marquees and literature, and compare it against a general corpus of 1515 puns drawn from Internet websites and a specialized dictionary. Zwicky and Zwicky (1986) conduct a phonological analysis on a corpus of several thousand puns, some of which they collected themselves from advertisements and catalogues, and the remainder of which were taken from previously published collections. Two studies on cognitive strategies used by second language learners (Kaplan and Lucas, 2001; Lucas, 2004) used a data set of 58 jokes compiled from newspaper comics, 32 of which rely on lexical ambiguity. Bucaria (2004) conducts a linguistic analysis of a set of 135 humorous newspaper headlines, about half of which exploit lexical ambiguity.

Such data sets—particularly the larger ones—provided us good evidence that intentionally lexical ambiguous exemplars exist in sufficient numbers to make a rigorous evaluation of our task feasible. Unfortunately, none of the above-mentioned corpora have been published in full, and moreover many of them contain (sometimes exclusively) the sort of imperfect or otherwise heterographic puns which we mean to exclude from consideration. This has motivated us to produce our own corpus of puns, the construction and analysis of which is described in the following section.

3 Data set

As in traditional WSD, a prerequisite for our research is a corpus of examples, where one or more human annotators have already identified the ambiguous words and marked up their various meanings with reference to a given sense inventory. Such a corpus is sufficient for evaluating what we term *pun identification* or *pun disambiguation*—that is, identifying the senses of a term known *a priori* to be a pun.

3.1 Construction

Though several prior studies have produced corpora of puns, none of them are systematically sense-annotated. We therefore compiled our own corpus by pooling together some of the aforementioned corpora, the user-submitted puns from the Pun of the Day website,[3] and private collections provided to us by some professional humorists. This raw collection of 7750 one-liners was then filtered by trained human annotators to those instances meeting the following four criteria:

One pun per instance: Of all the lexical units in the instance, one and only one may be a pun. (This criterion simplifies the task detecting the presence and location of puns in a text, a classification task which we intend to investigate in future work.)

One content word per pun: The lexical unit that forms the pun must consist of, or contain, only a single content word (*i.e.*, a noun, verb, adjective, or adverb), excepting adverbial particles of phrasal verbs. This criterion is important because, in our observations, it is often only one word which carries ambiguity in puns on compounds and multi-word expressions. Accepting lexical units containing more than one content word would have required our annotators to laboriously partition the pun into (possibly overlapping) sense-bearing units and to assign sense sets to each of them, inflating the complexity of the annotation task to unacceptable levels.

Two meanings per pun: The pun must have exactly two distinct meanings. Though many sources state that puns have only two senses (Redfern, 1984; Attardo, 1994), our annotators identified a handful of corpus examples where the pun could plausibly be analyzed as carrying three distinct meanings. To simplify our manual annotation procedure and our evaluation metrics we excluded these rare outliers.

Weak homography: The lexical units corresponding to the two distinct meanings must be spelled exactly the same way, except that particles and inflections may be disregarded. This somewhat softer definition of homography allows us to admit a good many morphologically interesting cases which were nonetheless readily recognized by our human annotators.

The filtering reduced the number of instances to 1652, whose puns two human judges annotated with sense keys from WordNet 3.1 (Fellbaum, 1998). Using an online annotation tool specially constructed for this study, the annotators applied two sets of sense keys to each instance, one for each of the two meanings of the pun. For cases where the distinction between WordNet's fine-grained senses was irrelevant, the annotators had the option of labelling the meaning with more than one sense key. Annotators also had the option of marking a meaning as unassignable if WordNet had no corresponding sense key. Further details of our annotation tool and its use can be found in Miller and Turković (2015).

3.2 Analysis

Our judges agreed on which word was the pun in 1634 out of 1652 cases, a raw agreement of 98.91%. For the agreed cases, we used DKPro Agreement (Meyer et al., 2014) to compute Krippendorff's α (Krippendorff, 1980) for the sense annotations. This is a chance-correcting metric of inter-annotator agreement ranging in $(-1,1]$, where 1 indicates perfect agreement, -1 perfect disagreement, and 0 the expected score for random labelling. Our distance metric for α is a straightforward adaptation of the MASI set comparison metric (Passonneau, 2006). Whereas standard MASI, $d_M(A,B)$, compares two annotation sets A and B, our annotations take the form of unordered *pairs* of sets $\{A_1,A_2\}$ and $\{B_1,B_2\}$. We therefore find the mapping between elements of the two pairs that gives the lowest total distance, and halve it: $d_{M'}(\{A_1,A_2\},\{B_1,B_2\}) = \frac{1}{2}\min(d_M(A_1,B_1) + d_M(A_2,B_2), d_M(A_1,B_2) + d_M(A_2,B_1))$. With this method we observe a Krippendorff's α of 0.777; this is only slightly below the 0.8 threshold recommended by Krippendorff, and far higher than what has been reported in other sense annotation studies (Passonneau et al., 2006; Jurgens and Klapaftis, 2013).

Where possible, we resolved sense annotation disagreements automatically by taking the intersection of corresponding sense sets. Where the annotators' sense sets were disjoint or contradictory (including the cases where the annotators disagreed on the pun word), we had a human adjudicator attempt to resolve the disagreement in favour of one annotator or the other. This left us with 1607 instances,[4] of which we retained only the 1298 that had successful (*i.e.*, not marked as unassignable)

[3] `http://www.punoftheday.com/`

[4] Pending clearance of the distribution rights, we will make some or all of our annotated data set available on our website at `https://www.ukp.tu-darmstadt.de/data/`.

annotations for the present study. The contexts in this data set range in length from 3 to 44 words, with an average length of 11.9. The 2596 meanings carry sense key annotations corresponding to anywhere from one to seven WordNet synsets, with an average of 1.08. As expected, then, WordNet's sense granularity proved to be somewhat finer than necessary to characterize the meanings in the data set, though only marginally so.

Of the 2596 individual meanings, 1303 (50.2%) were annotated with noun senses only, 877 (33.8%) with verb senses only, 340 (13.1%) with adjective senses only, and 41 (1.6%) with adverb senses only. Only 35 individual meanings (1.3%) carry sense annotations corresponding to multiple parts of speech. However, for 297 (22.9%) of our puns, the two meanings had different parts of speech. Similarly, sense annotations for each individual meaning correspond to anywhere from one to four different lemmas, with a mean of 1.25. These observations confirm the concerns we raised in §2.2 that pun disambiguators, unlike traditional WSD systems, cannot always rely on the output of a lemmatizer or part-of-speech tagger to narrow down the list of sense candidates.

4 Pun disambiguation

It has long been observed that gloss overlap–based WSD systems, such as those based on the Lesk algorithm, fail to distinguish between candidate senses when their definitions have a similar overlap with the target word's context. In some cases this is because the overlap is negligible or nonexistent; this is known as the *lexical gap* problem, and various solutions to it are discussed in (*inter alia*) Miller et al. (2012). In other cases, the indecision arises because the definitions provided by the sense inventory are too fine-grained; this problem has been addressed, with varying degrees of success, through sense clustering or coarsening techniques (a short but reasonably comprehensive survey of which appears in Matuschek et al. (2014)). A third condition under which senses cannot be discriminated is when the target word is used in an underspecified or intentionally ambiguous manner. We hold that for this third scenario a disambiguator's inability to discriminate senses should not be seen as a failure condition, but rather as a limitation of the WSD task as traditionally defined. By reframing the task so as to permit the assignment of multiple senses (or groups of senses), we can allow disambiguation systems to sense-annotate intentionally ambiguous constructions such as puns.

Many approaches to WSD, including Lesk-like algorithms, involve computing some score for all possible senses of a target word, and then selecting the single highest-scoring one as the "correct" sense. The most straightforward modification of these techniques to pun disambiguation, then, is to have the systems select the *two* top-scoring senses, one for each meaning of the pun. Accordingly we applied this modification to the following knowledge-based WSD algorithms:

Simplified Lesk (Kilgarriff and Rosenzweig, 2000) disambiguates a target word by examining the definitions[5] for each of its candidate senses and selecting the single sense—or in our case, the two senses—which have the greatest number of words in common with the context. As we previously demonstrated that puns often transcend part of speech, our pool of candidate senses is constructed as follows: we apply a morphological analyzer to recover all possible lemmas of the target word without respect to part of speech, and for each lemma we add all its senses to the pool.

Simplified extended Lesk (Ponzetto and Navigli, 2010) is similar to simplified Lesk, except that the definition for each sense is concatenated with those of neighbouring senses in WordNet's semantic network.

Simplified lexically expanded Lesk (Miller et al., 2012) is also based on simplified Lesk, with the extension that every word in the context and sense definitions is expanded with up to 100 entries from a large distributional thesaurus.

The above algorithms fail to make a sense assignment when more than two senses are tied for the highest lexical overlap, or when there is a single highest-scoring sense but multiple senses are tied for the second-highest overlap. We therefore devised two pun-specific tie-breaking strategies. The first is motivated by the informal observation that, though the two meanings of a pun may have different parts of speech, at least one of the parts

[5] In our implementation, the sense definitions are formed by concatenating the synonyms, gloss, and example sentences provided by WordNet.

of speech is grammatical in the context of the sentence, and so would probably be the one assigned by a stochastic or rule-based POS tagger. Our "POS" tie-breaker therefore preferentially selects the best sense, or pair of senses, whose POS matches the one applied to the target by the Stanford POS tagger (Toutanova et al., 2003). For our second tie-breaking strategy, we posit that since humour derives from the resolution of semantic incongruity (Raskin, 1985; Attardo, 1994), puns are more likely to exploit coarse-grained homonymy than than fine-grained systematic polysemy. Thus, following Matuschek et al. (2014), we induced a clustering of WordNet senses by aligning WordNet to the more coarse-grained OmegaWiki LSR.[6] Our "cluster" fallback works the same as the "POS" one, with the addition that any remaining ties among senses with the second-highest overlap are resolved by preferentially selecting those which are not in the same induced cluster as, and which in WordNet's semantic network are at least three edges distant from, the sense with the highest overlap.

5 Evaluation

5.1 Scoring

In traditional word sense disambiguation, *in vitro* evaluations are conducted by comparing the senses assigned by the disambiguation system to the gold-standard senses assigned by the human annotators. For the case that the system and gold-standard assignments consist of a single sense each, the exact-match criterion is used: the system receives a score of 1 if it chose the sense specified by the gold standard, and 0 otherwise. Where the system selects a single sense for an instance for which there is more than one correct gold standard sense, the multiple tags are interpreted disjunctively—that is, the system receives a score of 1 if it chose any one of the gold-standard senses, and 0 otherwise. Overall performance is reported in terms of coverage (the number of targets for which a sense assignment was attempted), precision (the sum of scores divided by the number of attempted targets), recall (the sum of scores divided by the total number of targets in the data set), and F_1 (the harmonic mean of precision and recall) (Palmer et al., 2006).

The traditional approach to scoring individual targets is not usable as-is for pun disambiguation, because each pun carries two disjoint but equally valid sets of sense annotations. Instead, since our systems assign exactly one sense to each of the pun's two sense sets, we count this as a match (scoring 1) only if each chosen sense can be found in one of the gold-standard sense sets, and no two gold-standard sense sets contain the same chosen sense. (As with traditional WSD scoring, various approaches could be used to assign credit for partially correct assignments, though we leave exploration of these to future work.)

5.2 Baselines

System performance in WSD is normally interpreted with reference to one or more baselines. To our knowledge, ours is the very first study of automatic pun disambiguation on any scale, so at this point there are no previous systems against which to compare our results. However, traditional WSD systems are often compared with two naïve baselines (Gale et al., 1992) which can be adapted for our purposes.

The first of these naïve baselines is to randomly select from among the candidate senses. In traditional WSD, the score for a random disambiguator which selects a single sense for a given target t is the number of gold-standard senses divided by the number of candidate senses: $\text{score}(t) = g(t) \div \delta(t)$. In our pun disambiguation task, however, a random disambiguator must select *two* senses—one for each of the sense sets $g_1(t)$ and $g_2(t)$—and these senses must be distinct. There are $\binom{\delta(t)}{2}$ possible ways of selecting two unique senses, so the random score for any given instance is $\text{score}(t) = g_1(t) \cdot g_2(t) \div \binom{\delta(t)}{2}$.

The second naïve baseline for WSD, known as *most frequent sense* (MFS), is a supervised baseline, meaning that it depends on a manually sense-annotated background corpus. As its name suggests, it involves always selecting from the candidates that sense which has the highest frequency in the corpus. As with our test algorithms, we adapt this technique to pun disambiguation by having it select the two most frequent senses (according to WordNet's built-in sense frequency counts). In traditional WSD, MFS baselines are notoriously difficult to beat, even for supervised disambiguation systems, and since they rely on expensive sense-tagged data they are not normally considered a benchmark for the performance of knowledge-based disambiguators.

6 Results

Using the freely available DKPro WSD framework (Miller et al., 2013), we implemented our pun disambiguation algorithms, ran them on our full data set, and compared their annotations against those of our manually produced gold standard. Table 1 shows the coverage, precision, recall, and F_1 for simplified Lesk (SL), simplified extended Lesk (SEL), simplified lexically expanded Lesk (SLEL), and the random and most frequent sense baselines; for SEL we also report results for each of our pun-specific tie-breaking strategies. All metrics are reported as percentages, and the highest score for each metric (excluding baseline coverage, which is always 100%) is highlighted in boldface.

Accuracy for the random baseline annotator was about 9%; for the MFS baseline it was just over 13%. These figures are considerably lower than what is typically seen with traditional WSD corpora, where random baselines achieve accuracies of 30 to 60%, and MFS baselines 65 to 80% (Palmer et al., 2001; Snyder and Palmer, 2004; Navigli et al., 2007). Our baselines' low figures are the result of them having to consider senses from every possible lemmatization and part of speech of the target, and underscore the difficulty of our task.

The simplest knowledge-based algorithm we tested, simplified Lesk, was over twice as accurate as the random baseline in terms of precision (19.74%), but predictably had very low coverage (35.52%), leading in turn to very low recall (7.01%). Manual examination of the unassigned instances confirmed that failure was usually due to the lack of any lexical overlap whatsoever between the context and definitions. The use of a tie-breaking strategy would not help much here, though some way of bridging the lexical gap would. This is, in fact, the strategy employed by the extended and lexically expanded variants of simplified Lesk, and we observed that both were successful to some degree. Simplified lexically expanded Lesk almost completely closed the lexical gap, with nearly complete coverage (98.69%), though this came at the expense of a large drop in precision (to 13.43%). Given the near-total coverage, use of a tie-breaking strategy here would have no appreciable effect on the accuracy.

Simplified extended Lesk, on the other hand, saw significant increases in coverage, precision, and recall (to 42.45%, 19.96%, and 8.47%, respectively). Its recall is statistically indistinguishable[7] from the random baseline, though spot-checks of its unassigned instances show that the problem is very frequently not the lexical gap but rather multiple senses tied for the greatest overlap with the context. We therefore tested our two pun-specific backoff strategies to break this system's ties. Using the "POS" strategy increased coverage by 41%, relatively speaking, and gave us our highest observed precision of 21.21%. Our "cluster" strategy effected a relative increase in coverage of over 60%, and gave us the best recall (14.10%). This strategy also had the best tradeoff between precision and recall, with an F_1 of 16.77%.

Significance testing shows the recall scores for SLEL, SEL+POS, and SEL+cluster to be significantly better than the random baseline, and statistically indistinguishable from that of MFS. This is excellent news, especially in light of the fact that supervised approaches (even baselines like MFS) usually outperform their knowledge-based counterparts. Though the three knowledge-based systems are not statistically distinguishable from each other in terms of recall, they do show a statistically significant improvement over SL and SEL, and the two implementing pun-specific tie-breaking strategies were markedly more accurate than SLEL for those targets where they attempted an assignment. These two systems would therefore be preferable for applications where precision is more important than recall.

We also examined the results of our generally best-performing system, SEL+cluster, to see whether there was any relationship with the targets' part of speech. We filtered the results according to whether both gold-standard meanings of the pun contain senses for nouns only, verbs only, adjec-

[7] All significance statements in this section are based on McNemar's test at a confidence level of 5%.

POS	C	P	R	R_{rand}
noun	66.60	20.89	13.91	10.44
verb	65.61	14.54	9.54	5.12
adj.	68.87	39.73	27.36	16.84
adv.	100.00	75.00	75.00	46.67
pure	66.77	21.44	14.31	9.56
mult.	72.58	18.43	13.38	12.18

Table 2: Coverage, precision, and recall for SEL+cluster, and random baseline recall, according to part of speech.

tives only, or adverbs only; these amounted to 539, 346, 106, and 8 instances, respectively. These results are shown in Table 2. Also shown there is a row which aggregates the 999 targets with "pure" POS, and another for the remaining 608 instances ("mult."), where one or both of the two meanings contain senses for multiple parts of speech, or where the two meanings have different parts of speech. The last column of each row shows the recall of the random baseline for comparison.

Accuracy was lowest on the verbs, which had the highest candidate polysemy (21.6) and are known to be particularly difficult to disambiguate even in traditional WSD. Still, as with all the other single parts of speech, performance of SEL+cluster exceeded the random baseline. While recall was lower on targets with mixed POS than those with pure POS, coverage was significantly higher. Normally such a disparity could be attributed to a difference in polysemy: Lesk-like systems are more likely to attempt a sense assignment for highly polysemous targets, since there is a greater likelihood of one of the candidate definitions matching the context, though the probability of the assignment being correct is reduced. In this case, however, the multi-POS targets actually had lower average polysemy than the single-POS ones (13.2 *vs.* 15.8).

7 Conclusion

In this paper we have introduced the novel task of pun disambiguation and have proposed and evaluated several computational approaches for it. The major contributions of this work are as follows: First, we have produced a new data set consisting of manually sense-annotated homographic puns. The data set is large enough, and the manual annotations reliable enough, for a principled evaluation of automatic pun disambiguation systems. Second, we have shown how evaluation metrics, baselines, and disambiguation algorithms from traditional WSD can be adapted to the task of pun disambiguation, and we have tested these adaptations in a controlled experiment. The results show pun disambiguation to be a particularly challenging task for NLP, with baseline results far below what is commonly seen in traditional WSD. We showed that knowledge-based disambiguation algorithms naïvely adapted from traditional WSD perform poorly, but that extending them with strategies that rely on pun-specific features brings about dramatic improvements in accuracy: their recall becomes comparable to that of a supervised baseline, and their precision greatly exceeds it.

There are a number of avenues we intend to explore in future work. First, we would like to try adapting and evaluating some additional WSD algorithms for use with puns. Though our data set is probably too small to use with machine learning–based approaches, we are particularly interested in testing knowledge-based disambiguators which rely on measures of graph connectivity rather than gloss overlaps. Second, we would like to investigate alternative tie-breaking strategies, such as the domain similarity measures used by Mihalcea et al. (2010). Finally, whereas in this paper we have treated only the task of sense disambiguation for the case where a word is known *a priori* to be a pun, we are interested in exploring the requisite problem of *pun detection*, where the object is to determine whether or not a given context contains a pun, and more precisely whether any given word in a context is a pun.

Abstract

Meaning of a word varies from one domain to another. Despite this important domain dependence in word semantics, existing word representation learning methods are bound to a single domain. Given a pair of *source-target* domains, we propose an unsupervised method for learning domain-specific word representations that accurately capture the domain-specific aspects of word semantics. First, we select a subset of frequent words that occur in both domains as *pivots*. Next, we optimize an objective function that enforces two constraints: (a) for both source and target domain documents, pivots that appear in a document must accurately predict the co-occurring non-pivots, and (b) word representations learnt for pivots must be similar in the two domains. Moreover, we propose a method to perform domain adaptation using the learnt word representations. Our proposed method significantly outperforms competitive baselines including the state-of-the-art domain-insensitive word representations, and reports best sentiment classification accuracies for all domain-pairs in a benchmark dataset.

1 Introduction

Learning semantic representations for words is a fundamental task in NLP that is required in numerous higher-level NLP applications (Collobert et al., 2011). Distributed word representations have gained much popularity lately because of their accuracy as semantic representations for words (Mikolov et al., 2013a; Pennington et al., 2014). However, the meaning of a word often varies from one domain to another. For example, the phrase *lightweight* is often used in a positive sentiment in the portable electronics domain because a lightweight device is easier to carry around, which is a positive attribute for a portable electronic device. However, the same phrase has a negative sentiment assocition in the *movie* domain because movies that do not invoke deep thoughts in viewers are considered to be lightweight (Bollegala et al., 2014). However, existing word representation learning methods are agnostic to such domain-specific semantic variations of words, and capture semantics of words only within a single domain. To overcome this problem and capture domain-specific semantic orientations of words, we propose a method that learns separate distributed representations for each domain in which a word occurs.

Despite the successful applications of distributed word representation learning methods (Pennington et al., 2014; Collobert et al., 2011; Mikolov et al., 2013a) most existing approaches are limited to learning only a single representation for a given word (Reisinger and Mooney, 2010). Although there have been some work on learning multiple *prototype* representations (Huang et al., 2012; Neelakantan et al., 2014) for a word considering its multiple senses, such methods do not consider the semantics of the domain in which the word is being used.

If we can learn separate representations for a word for each domain in which it occurs, we can use the learnt representations for domain adaptation tasks such as cross-domain sentiment classification (Bollegala et al., 2011b), cross-domain POS tagging (Schnabel and Schütze, 2013), cross-domain dependency parsing (McClosky et al., 2010), and domain adaptation of relation extractors (Bollegala et al., 2013a; Bollegala et al., 2013b; Bollegala et al., 2011a; Jiang and Zhai, 2007a; Jiang and Zhai, 2007b).

We introduce the *cross-domain word represen-*

tation learning task, where given two domains, (referred to as the *source* ($\mathcal{S}$) and the *target* ($\mathcal{T}$)) the goal is to learn two separate representations $\boldsymbol{w}_{\mathcal{S}}$ and $\boldsymbol{w}_{\mathcal{T}}$ for a word w respectively from the source and the target domain that capture *domain-specific* semantic variations of w. In this paper, we use the term *domain* to represent a collection of documents related to a particular topic such as user-reviews in Amazon for a product category (e.g. *books*, *dvds*, *movies*, etc.). However, a domain in general can be a field of study (e.g. *biology*, *computer science*, *law*, etc.) or even an entire source of information (e.g. *twitter*, *blogs*, *news articles*, etc.). In particular, we do not assume the availability of any labeled data for learning word representations.

This problem setting is closely related to unsupervised domain adaptation (Blitzer et al., 2006), which has found numerous useful applications such as, sentiment classification and POS tagging. For example, in unsupervised cross-domain sentiment classification (Blitzer et al., 2006; Blitzer et al., 2007), we train a binary sentiment classifier using positive and negative labeled user reviews in the source domain, and apply the trained classifier to predict sentiment of the target domain's user reviews. Although the distinction between the source and the target domains is not important for the word representation learning step, it is important for the domain adaptation tasks in which we subsequently evaluate the learnt word representations. Following prior work on domain adaptation (Blitzer et al., 2006), high-frequent features (unigrams/bigrams) common to both domains are referred to as *domain-independent* features or *pivots*. In contrast, we use *non-pivots* to refer to features that are specific to a single domain.

We propose an unsupervised cross-domain word representation learning method that jointly optimizes two criteria: (a) given a document d from the source or the target domain, we must accurately predict the non-pivots that occur in d using the pivots that occur in d, and (b) the source and target domain representations we learn for pivots must be similar. The main challenge in domain adaptation is *feature mismatch*, where the features that we use for training a classifier in the source domain do not necessarily occur in the target domain. Consequently, prior work on domain adaptation (Blitzer et al., 2006; Pan et al., 2010) learn lower-dimensional mappings from non-pivots to pivots, thereby overcoming the feature mismatch problem. Criteria (a) ensures that word representations for domain-specific non-pivots in each domain are related to the word representations for domain-independent pivots. This relationship enables us to discover pivots that are similar to target domain-specific non-pivots, thereby overcoming the feature mismatch problem.

On the other hand, criteria (b) captures the prior knowledge that high-frequent words common to two domains often represent domain-independent semantics. For example, in sentiment classification, words such as *excellent* or *terrible* would express similar sentiment about a product irrespective of the domain. However, if a pivot expresses different semantics in source and the target domains, then it will be surrounded by dissimilar sets of non-pivots, and reflected in the first criteria. Criteria (b) can also be seen as a regularization constraint imposed on word representations to prevent overfitting by reducing the number of free parameters in the model.

Our contributions in this paper can be summarized as follows.

- We propose a distributed word representation learning method that learns separate representations for a word for each domain in which it occurs. To the best of our knowledge, ours is the first-ever *domain-sensitive distributed* word representation learning method.

- Given domain-specific word representations, we propose a method to learn a cross-domain sentiment classifier.

  Although word representation learning methods have been used for various related tasks in NLP such as similarity measurement (Mikolov et al., 2013c), POS tagging (Collobert et al., 2011), dependency parsing (Socher et al., 2011a), machine translation (Zou et al., 2013), sentiment classification (Socher et al., 2011b), and semantic role labeling (Roth and Woodsend, 2014), to the best of our knowledge, word representations methods have not yet been used for cross-domain sentiment classification.

Experimental results for cross-domain sentiment classification on a benchmark dataset show that the word representations learnt using the proposed method statistically significantly outperform a state-of-the-art domain-insensitive word representation learning method (Pennington et al., 2014), and several competitive baselines. In particular, our proposed cross-domain word representation learning method is not specific to a particular task such as sentiment classification, and in principle, can be in applied to a wide-range of domain adaptation tasks. Despite this task-independent nature of the proposed method, it achieves the best sentiment classification accuracies on all domain-pairs, reporting statistically comparable results to the current state-of-the-art unsupervised cross-domain sentiment classification methods (Pan et al., 2010; Blitzer et al., 2006).

2 Related Work

Representing the semantics of a word using some algebraic structure such as a vector (more generally a tensor) is a common first step in many NLP tasks (Turney and Pantel, 2010). By applying algebraic operations on the word representations, we can perform numerous tasks in NLP, such as composing representations for larger textual units beyond individual words such as phrases (Mitchell and Lapata, 2008). Moreover, word representations are found to be useful for measuring semantic similarity, and for solving proportional analogies (Mikolov et al., 2013c). Two main approaches for computing word representations can be identified in prior work (Baroni et al., 2014): *counting-based* and *prediction-based*.

In counting-based approaches (Baroni and Lenci, 2010), a word w is represented by a vector $\boldsymbol{w}$ that contains other words that co-occur with w in a corpus. Numerous methods for selecting co-occurrence contexts such as proximity or dependency relations have been proposed (Turney and Pantel, 2010). Despite the numerous successful applications of co-occurrence counting-based distributional word representations, their high dimensionality and sparsity are often problematic in practice. Consequently, further post-processing steps such as dimensionality reduction, and feature selection are often required when using counting-based word representations.

On the other hand, prediction-based approaches first assign each word, for example, with a d-dimensional real-vector, and learn the elements of those vectors by applying them in an auxiliary task such as language modeling, where the goal is to predict the next word in a given sequence. The dimensionality d is fixed for all the words in the vocabulary, and, unlike counting-based word representations, is much smaller (e.g. $d \in [10, 1000]$ in practice) compared to the vocabulary size. The neural network language model (NNLM) (Bengio et al., 2003) uses a multi-layer feed-forward neural network to predict the next word in a sequence, and uses backpropagation to update the word vectors such that the prediction error is minimized.

Although NNLMs learn word representations as a by-product, the main focus on language modeling is to predict the next word in a sentence given the previous words, and not learning word representations that capture semantics. Moreover, training multi-layer neural networks using large text corpora is time consuming. To overcome those limitations, methods that specifically focus on learning word representations that model word co-occurrences in large corpora have been proposed (Mikolov et al., 2013a; Mnih and Kavukcuoglu, 2013; Huang et al., 2012; Pennington et al., 2014). Unlike the NNLM, these methods use *all* the words in a contextual window in the prediction task. Methods that use one or no hidden layers are proposed to improve the scalability of the learning algorithms. For example, the skip-gram model (Mikolov et al., 2013b) predicts the words c that appear in the local context of a word w, whereas the continuous bag-of-words model (CBOW) predicts a word w conditioned on all the words c that appear in w's local context (Mikolov et al., 2013a). Methods that use global co-occurrences in the entire corpus to learn word representations have shown to outperform methods that use only local co-occurrences (Huang et al., 2012; Pennington et al., 2014). Overall, prediction-based methods have shown to outperform counting-based methods (Baroni et al., 2014).

Despite their impressive performance, existing methods for word representation learning do not consider the semantic variation of words across different domains. However, as described in Section 1, the meaning of a word vary from one domain to another, and must be considered. To the best of our knowledge, the only prior work studying the problem of word representation variation across domains is due to Bollegala et al. (2014). Given a source and a target domain, they first select a set of pivots using pointwise mutual information, and create two distributional representations for each pivot using their co-occurrence contexts in a particular domain. Next, a projection matrix from the source to the target domain feature spaces is learnt using partial least squares regression. Finally, the learnt projection matrix is used to find the nearest neighbors in the source domain for each target domain-specific features. However, unlike our proposed method, their method *does not* learn domain-specific word representations, but simply uses co-occurrence counting when creating in-domain word representations.

Faralli et al. (2012) proposed a domain-driven word sense disambiguation (WSD) method where they construct glossaries for several domain using a pattern-based bootstrapping technique. This work demonstrates the importance of considering the domain specificity of word senses. However, the focus of their work is not to learn representations for words or their senses in a domain, but to construct glossaries. It would be an interesting future research direction to explore the possibility of using such domain-specific glossaries for learning domain-specific word representations.

Neelakantan et al. (2014) proposed a method that jointly performs WSD and word embedding learning, thereby learning multiple embeddings per word type. In particular, the number of senses per word type is automatically estimated. However, their method is limited to a single domain, and does not consider how the representations vary across domains. On the other hand, our proposed method learns a single representation for a particular word for each domain in which it occurs.

Although in this paper we focus on the monolingual setting where source and target domains belong to the same language, the related setting where learning representations for words that are translational pairs across languages has been studied (Hermann and Blunsom, 2014; Klementiev et al., 2012; Gouws et al., 2015). Such representations are particularly useful for cross-lingual information retrieval (Duc et al., 2010). It will be an interesting future research direction to extend our proposed method to learn such cross-lingual word representations.

3 Cross-Domain Representation Learning

We propose a method for learning word representations that are sensitive to the semantic variations of words across domains. We call this problem *cross-domain word representation learning*, and provide a definition in Section 3.1. Next, in Section 3.2, given a set of pivots that occurs in both a source and a target domain, we propose a method for learning cross-domain word representations. We defer the discussion of pivot selection methods to Section 3.4. In Section 3.5, we propose a method for using the learnt word representations to train a cross-domain sentiment classifier.

3.1 Problem Definition

Let us assume that we are given two sets of documents $\mathcal{D}_{\mathcal{S}}$ and $\mathcal{D}_{\mathcal{T}}$ respectively for a source ($\mathcal{S}$) and a target ($\mathcal{T}$) domain. We do not consider the problem of retrieving documents for a domain, and assume such a collection of documents to be given. Then, given a particular word w, we define cross-domain representation learning as the task of learning two separate representations $\boldsymbol{w}_{\mathcal{S}}$ and $\boldsymbol{w}_{\mathcal{T}}$ capturing w's semantics in respectively the source $\mathcal{S}$ and the target $\mathcal{T}$ domains.

Unlike in domain adaptation, where there is a clear distinction between the source (i.e. the domain on which we train) vs. the target (i.e. the domain on which we test) domains, for representation learning purposes we do not make a distinction between the two domains. In the *unsupervised* setting of the cross-domain representation learning that we study in this paper, we do not assume the availability of labeled data for any domain for the purpose of learning word representations. As an extrinsic evaluation task, we apply the trained word representations for classifying sentiment related to user-reviews (Section 3.5). However, for this evaluation task we require sentiment-labeled user-reviews from the source domain.

Decoupling of the word representation learning from any tasks in which those representations are subsequently used, simplifies the problem as well as enables us to learn *task-independent* word representations with potential generic applicability. Although we limit the discussion to a pair of domains for simplicity, the proposed method can be easily extended to jointly learn word representations for more than two domains. In fact, prior work on cross-domain sentiment analysis show that incorporating multiple source domains improves sentiment classification accuracy on a target domain (Bollegala et al., 2011b; Glorot et al., 2011).

3.2 Proposed Method

To describe our proposed method, let us denote a pivot and a non-pivot feature respectively by c and w. Our proposed method does not depend on a specific pivot selection method, and can be used with all previously proposed methods for selecting pivots as explained later in Section 3.4. A pivot c is represented in the source and target domains respectively by vectors $\boldsymbol{c}_{\mathcal{S}} \in \mathbb{R}^n$ and $\boldsymbol{c}_{\mathcal{T}} \in \mathbb{R}^n$. Likewise, a source specific non-pivot w is represented by $\boldsymbol{w}_{\mathcal{S}}$ in the source domain, whereas a target specific non-pivot w is represented by $\boldsymbol{w}_{\mathcal{T}}$ in the target domain. By definition, a non-pivot occurs only in a single domain. For notational convenience we use w to denote non-pivots in both domains when the domain is clear from the context. We use $\mathcal{C}_{\mathcal{S}}$, $\mathcal{W}_{\mathcal{S}}, \mathcal{C}_{\mathcal{T}}$, and $\mathcal{W}_{\mathcal{T}}$ to denote the sets of word representation vectors respectively for the source pivots, source non-pivots, target pivots, and target non-pivots.

Let us denote the set of documents in the source and the target domains respectively by $\mathcal{D}_{\mathcal{S}}$ and $\mathcal{D}_{\mathcal{T}}$. Following the bag-of-features model, we assume that a document D is represented by the set of pivots and non-pivots that occur in D ($w \in d$ and $c \in d$). We consider the co-occurrences of a pivot c and a non-pivot w within a fixed-size contextual window in a document. Following prior work on representation learning (Mikolov et al., 2013a), in our experiments, we set the window size to 10 tokens, without crossing sentence boundaries. The notation $(c, w) \in d$ denotes the co-occurrence of a pivot c and a non-pivot w in a document d.

We learn domain-specific word representations by maximizing the prediction accuracy of the non-pivots w that occur in the local context of a pivot c. The hinge loss, $L(\mathcal{C}_{\mathcal{S}}, \mathcal{W}_{\mathcal{S}})$, associated with predicting a non-pivot w in a source document $d \in \mathcal{D}_{\mathcal{S}}$ that co-occurs with pivots c is given by:

$$\sum_{d \in \mathcal{D}_{\mathcal{S}}} \sum_{(c,w) \in d} \sum_{w^* \sim p(w)} \max\left(0, 1 - {\boldsymbol{c}_{\mathcal{S}}}^\top \boldsymbol{w}_{\mathcal{S}} + {\boldsymbol{c}_{\mathcal{S}}}^\top \boldsymbol{w}^*_{\mathcal{S}}\right) \tag{1}$$

Here, $\boldsymbol{w}^*_{\mathcal{S}}$ is the source domain representation of a non-pivot w^* that *does not occur* in d. The loss function given by Eq. 1 requires that a non-pivot w that co-occurs with a pivot c in the document d is assigned a higher ranking score as measured by the inner-product between $\boldsymbol{c}_{\mathcal{S}}$ and $\boldsymbol{w}_{\mathcal{S}}$ than a non-pivot w^* that does not occur in d. We randomly sample k non-pivots from the set of all source domain non-pivots that do not occur in d as w^*.

Specifically, we use the marginal distribution of non-pivots $p(w)$, estimated from the corpus counts, as the sampling distribution. We raise $p(w)$ to the $3/4$-th power as proposed by Mikolov et al. (2013a), and normalize it to unit probability mass prior to sampling k non-pivots w^* per each co-occurrence of $(c, w) \in d$. Because non-occurring non-pivots w^* are randomly sampled, prior work on noise contrastive estimation has found that it requires more negative samples than positive samples to accurately learn a prediction model (Mnih and Kavukcuoglu, 2013). We experimentally found $k = 5$ to be an acceptable trade-off between the prediction accuracy and the number of training instances.

Likewise, the loss function $L(\mathcal{C}_{\mathcal{T}}, \mathcal{W}_{\mathcal{T}})$ for predicting non-pivots using pivots in the target domain is given by:

$$\sum_{d \in \mathcal{D}_{\mathcal{T}}} \sum_{(c,w) \in d} \sum_{w^* \sim p(w)} \max\left(0, 1 - {\boldsymbol{c}_{\mathcal{T}}}^\top \boldsymbol{w}_{\mathcal{T}} + {\boldsymbol{c}_{\mathcal{T}}}^\top \boldsymbol{w}^*_{\mathcal{T}}\right) \tag{2}$$

Here, w^* denotes target domain non-pivots that *do not occur* in d, and are randomly sampled from $p(w)$ following the same procedure as in the source domain.

The source and target loss functions given respectively by Eqs. 1 and 2 can be used on their own to independently learn source and target domain word representations. However, by definition, pivots are common to both domains. We use this property to relate the source and target word representations via a *pivot-regularizer*, $R(\mathcal{C}_{\mathcal{S}}, \mathcal{C}_{\mathcal{T}})$, defined as:

$$R(\mathcal{C}_{\mathcal{S}}, \mathcal{C}_{\mathcal{T}}) = \frac{1}{2} \sum_{i=1}^{K} ||\boldsymbol{c}^{(i)}_{\mathcal{S}} - \boldsymbol{c}^{(i)}_{\mathcal{T}}||^2 \tag{3}$$

Here, $||\boldsymbol{x}||$ represents the l_2 norm of a vector $\boldsymbol{x}$, and $c^{(i)}$ is the i-th pivot in a total collection of K pivots. Word representations for non-pivots in the source and target domains are linked via the pivot regularizer because, the non-pivots in each domain are predicted using the word representations for the pivots in each domain, which in turn are regularized by Eq. 3. The overall objective function, $L(\mathcal{C}_{\mathcal{S}}, \mathcal{W}_{\mathcal{S}}, \mathcal{C}_{\mathcal{T}}, \mathcal{W}_{\mathcal{T}})$, we minimize is the sum[1] of

[1] Weighting the source and target loss functions by the respective dataset sizes did not result in any significant increase in performance. We believe that this is because the benchmark dataset contains approximately equal numbers of documents for each domain.

the source and target loss functions, regularized via Eq. 3 with coefficient λ, and is given by:

$$L(\mathcal{C}_{\mathcal{S}}, \mathcal{W}_{\mathcal{S}},) + L(\mathcal{C}_{\mathcal{T}}, \mathcal{W}_{\mathcal{T}}) + \lambda R(\mathcal{C}_{\mathcal{S}}, \mathcal{C}_{\mathcal{T}}) \quad (4)$$

3.3 Training

Word representations of pivots c and non-pivots w in the source ($\boldsymbol{c}_{\mathcal{S}}$, $\boldsymbol{w}_{\mathcal{S}}$) and the target ($\boldsymbol{c}_{\mathcal{T}}$, $\boldsymbol{w}_{\mathcal{T}}$) domains are parameters to be learnt in the proposed method. To derive parameter updates, we compute the gradients of the overall loss function in Eq. 4 w.r.t. to each parameter as follows:

$$\frac{\partial L}{\partial \boldsymbol{w}_{\mathcal{S}}} = \begin{cases} 0 & \text{if } \ {\boldsymbol{c}_{\mathcal{S}}}^{\top}(\boldsymbol{w}_{\mathcal{S}} - \boldsymbol{w}^{*}_{\mathcal{S}}) \geq 1 \\ -\boldsymbol{c}_{\mathcal{S}} & \text{otherwise} \end{cases} \quad (5)$$

$$\frac{\partial L}{\partial \boldsymbol{w}^{*}_{\mathcal{S}}} = \begin{cases} 0 & \text{if } \ {\boldsymbol{c}_{\mathcal{S}}}^{\top}(\boldsymbol{w}_{\mathcal{S}} - \boldsymbol{w}^{*}_{\mathcal{S}}) \geq 1 \\ \boldsymbol{c}_{\mathcal{S}} & \text{otheriwse} \end{cases} \quad (6)$$

$$\frac{\partial L}{\partial \boldsymbol{w}_{\mathcal{T}}} = \begin{cases} 0 & \text{if } \ {\boldsymbol{c}_{\mathcal{T}}}^{\top}(\boldsymbol{w}_{\mathcal{T}} - \boldsymbol{w}^{*}_{\mathcal{T}}) \geq 1 \\ -\boldsymbol{c}_{\mathcal{T}} & \text{otherwise} \end{cases} \quad (7)$$

$$\frac{\partial L}{\partial \boldsymbol{w}^{*}_{\mathcal{T}}} = \begin{cases} 0 & \text{if } \ {\boldsymbol{c}_{\mathcal{T}}}^{\top}(\boldsymbol{w}_{\mathcal{T}} - \boldsymbol{w}^{*}_{\mathcal{T}}) \geq 1 \\ \boldsymbol{c}_{\mathcal{T}} & \text{otherwise} \end{cases} \quad (8)$$

$$\frac{\partial L}{\partial \boldsymbol{c}_{\mathcal{S}}} = \begin{cases} \lambda(\boldsymbol{c}_{\mathcal{S}} - \boldsymbol{c}_{\mathcal{T}}) & \text{if } \ {\boldsymbol{c}_{\mathcal{S}}}^{\top}(\boldsymbol{w}_{\mathcal{S}} - \boldsymbol{w}^{*}_{\mathcal{S}}) \geq 1 \\ \boldsymbol{w}^{*}_{\mathcal{S}} - \boldsymbol{w}_{\mathcal{S}} + \lambda(\boldsymbol{c}_{\mathcal{S}} - \boldsymbol{c}_{\mathcal{T}}) & \text{otherwise} \end{cases} \quad (9)$$

$$\frac{\partial L}{\partial \boldsymbol{c}_{\mathcal{T}}} = \begin{cases} \lambda(\boldsymbol{c}_{\mathcal{T}} - \boldsymbol{c}_{\mathcal{S}}) & \text{if } \ {\boldsymbol{c}_{\mathcal{T}}}^{\top}(\boldsymbol{w}_{\mathcal{T}} - \boldsymbol{w}^{*}_{\mathcal{T}}) \geq 1 \\ \boldsymbol{w}^{*}_{\mathcal{T}} - \boldsymbol{w}_{\mathcal{T}} + \lambda(\boldsymbol{c}_{\mathcal{T}} - \boldsymbol{c}_{\mathcal{S}}) & \text{otherwise} \end{cases} \quad (10)$$

Here, for simplicity, we drop the arguments inside the loss function and write it as L. We use mini batch stochastic gradient descent with a batch size of 50 instances. AdaGrad (Duchi et al., 2011) is used to schedule the learning rate. All word representations are initialized with n dimensional random vectors sampled from a zero mean and unit variance Gaussian. Although the objective in Eq. 4 is not jointly convex in all four representations, it is convex w.r.t. the representation of a particular feature (pivot or non-pivot) when the representations for all the other features are held fixed. In our experiments, the training converged in all cases with less than 100 epochs over the dataset.

The rank-based predictive hinge loss (Eq. 1) is inspired by the prior work on word representation learning for a single domain (Collobert et al., 2011). However, unlike the multilayer neural network in Collobert et al. (2011), the proposed method uses a computationally efficient single layer to reduce the number of parameters that must be learnt, thereby scaling to large datasets. Similar to the skip-gram model (Mikolov et al., 2013a), the proposed method predicts occurrences of contexts (non-pivots) w within a fixed-size contextual window of a target word (pivot) c.

Scoring the co-occurrences of two words c and w by the bilinear form given by the inner-product is similar to prior work on domain-insensitive word-representation learning (Mnih and Hinton, 2008; Mikolov et al., 2013a). However, unlike those methods that use the softmax function to convert inner-products to probabilities, we directly use the inner-products without any further transformations, thereby avoiding computationally expensive distribution normalizations over the entire vocabulary.

3.4 Pivot Selection

Given two sets of documents $\mathcal{D}_{\mathcal{S}}$, $\mathcal{D}_{\mathcal{T}}$ respectively for the source and the target domains, we use the following procedure to select pivots and non-pivots. First, we tokenize and lemmatize each document using the Stanford CoreNLP toolkit[2]. Next, we extract unigrams and bigrams as features for representing a document. We remove features listed as stop words using a standard stop words list. Stop word removal increases the effective co-occurrence window size for a pivot. Finally, we remove features that occur less than 50 times in the entire set of documents.

Several methods have been proposed in the prior work on domain adaptation for selecting a set of pivots from a given pair of domains such as the minimum frequency of occurrence of a feature in the two domains, mutual information (MI), and the entropy of the feature distribution over the documents (Pan et al., 2010). In our preliminary experiments, we discovered that a normalized version of the PMI (NPMI) (Bouma, 2009) to work consistently well for selecting pivots from different pairs of domains. NPMI between two features x and y is given by:

$$\mathrm{NPMI}(x, y) = \log\left(\frac{p(x, y)}{p(x)p(y)}\right)\frac{1}{-\log(p(x, y))} \quad (11)$$

Here, the joint probability $p(x, y)$, and the marginal probabilities $p(x)$ and $p(y)$ are estimated using the number of co-occurrences of x and y in the sentences in the documents. Eq. 11 normalizes both the upper and lower bounds of the PMI.

[2] `http://nlp.stanford.edu/software/corenlp.shtml`

We measure the appropriateness of a feature as a pivot according to the score given by:

$$\mathrm{score}(x) = \min\left(\mathrm{NPMI}(x, \mathcal{S}), \mathrm{NPMI}(x, \mathcal{T})\right). \tag{12}$$

We rank features that are common to both domains in the descending order of their scores as given by Eq. 12, and select the top $N_{\mathcal{P}}$ features as pivots. We rank features x that occur only in the source domain by $\mathrm{NPMI}(x, \mathcal{S})$, and select the top ranked $N_{\mathcal{S}}$ features as source-specific non-pivots. Likewise, we rank the features x that occur only in the target domain by $\mathrm{NPMI}(x, \mathcal{T})$, and select the top ranked $N_{\mathcal{T}}$ features as target-specific non-pivots.

The pivot selection criterion described here differs from that of Blitzer et al. (2006; 2007), where pivots are defined as features that behave similarly both in the source and the target domains. They compute the mutual information between a feature (i.e. unigrams or bigrams) and the sentiment labels using source domain labeled reviews. This method is useful when selecting pivots that are closely associated with positive or negative sentiment in the source domain. However, in unsupervised domain adaptation we do not have labeled data for the target domain. Therefore, the pivots selected using this approach are not guaranteed to demonstrate the same sentiment in the target domain as in the source domain. On the other hand, the pivot selection method proposed in this paper focuses on identifying a subset of features that are closely associated with both domains.

It is noteworthy that our proposed cross-domain word representation learning method (Section 3.2) *does not* assume any specific pivot/non-pivot selection method. Therefore, in principle, our proposed word representation learning method could be used with any of the previously proposed pivot selection methods. We defer a comprehensive evaluation of possible combinations of pivot selection methods and their effect on the proposed word representation learning method to future work.

3.5 Cross-Domain Sentiment Classification

As a concrete application of cross-domain word representations, we describe a method for learning a cross-domain sentiment classifier using the word representations learnt by the proposed method. Existing word representation learning methods that learn from only a single domain are typically evaluated for their accuracy in measuring semantic similarity between words, or by solving word analogy problems. Unfortunately, such gold standard datasets capturing cross-domain semantic variations of words are unavailable. Therefore, by applying the learnt word representations in a cross-domain sentiment classification task, we can conduct an indirect extrinsic evaluation.

The train data available for unsupervised cross-domain sentiment classification consists of unlabeled data for both the source and the target domains as well as labeled data for the source domain. We train a binary sentiment classifier using those train data, and apply it to classify sentiment of the target test data.

Unsupervised cross-domain sentiment classification is challenging due to two reasons: *feature-mismatch*, and *semantic variation*. First, the sets of features that occur in source and target domain documents are different. Therefore, a sentiment classifier trained using source domain labeled data is likely to encounter unseen features during test time. We refer to this as the feature-mismatch problem. Second, some of the features that occur in both domains will have different sentiments associated with them (e.g. *lightweight*). Therefore, a sentiment classifier trained using source domain labeled data is likely to incorrectly predict similar sentiment (as in the source) for such features. We call this the semantic variation problem. Next, we propose a method to overcome both problems using cross-domain word representations.

Let us assume that we are given a set $\{(\boldsymbol{x}_{\mathcal{S}}^{(i)}, y^{(i)})\}_{i=1}^{n}$ of n labeled reviews $\boldsymbol{x}_{\mathcal{S}}^{(i)}$ for the source domain $\mathcal{S}$. For simplicity, let us consider binary sentiment classification where each review $\boldsymbol{x}^{(i)}$ is labeled either as positive (i.e. $y^{(i)} = 1$) or negative (i.e. $y^{(i)} = -1$). Our cross-domain binary sentiment classification method can be easily extended to multi-class classification. First, we lemmatize each word in a source domain labeled review $\boldsymbol{x}_{\mathcal{S}}^{(i)}$, and extract unigrams and bigrams as features to represent $\boldsymbol{x}_{\mathcal{S}}^{(i)}$ by a binary-valued feature vector. Next, we train a binary linear classifier, $\boldsymbol{\theta}$, using those feature vectors. Any binary classification algorithm can be used for this purpose. We use $\boldsymbol{\theta}(z)$ to denote the weight learnt by the classifier for a feature z. In our experiments, we used l_2 regularized logistic regression.

At test time, we represent a test target review by a binary-valued vector $\boldsymbol{h}$ using a the set of unigrams and bigrams extracted from that review. Then, the activation score, $\psi(\boldsymbol{h})$, of $\boldsymbol{h}$ is defined by:

$$\psi(\boldsymbol{h}) = \sum_{c \in \boldsymbol{h}} \sum_{c' \in \boldsymbol{\theta}} \boldsymbol{\theta}(c') f(\boldsymbol{c}'_{\mathcal{S}}, \boldsymbol{c}_{\mathcal{S}}) + \sum_{w \in \boldsymbol{h}} \sum_{w' \in \boldsymbol{\theta}} \boldsymbol{\theta}(w') f(\boldsymbol{w}'_{\mathcal{S}}, \boldsymbol{w}_{\mathcal{T}}) \tag{13}$$

Here, f is a similarity measure between two vectors. If $\psi(\boldsymbol{h}) > 0$, we classify $\boldsymbol{h}$ as positive, and negative otherwise. Eq. 13 measures the similarity between each feature in $\boldsymbol{h}$ against the features in the classification model $\boldsymbol{\theta}$. For pivots $c \in \boldsymbol{h}$, we use the the source domain representations to measure similarity, whereas for the (target-specific) non-pivots $w \in \boldsymbol{h}$, we use their target domain representations. We experimented with several popular similarity measures for f and found cosine similarity to perform consistently well. We can interpret Eq. 13 as a method for *expanding* a test target document using nearest neighbor features from the source domain labeled data. It is analogous to query expansion used in information retrieval to improve document recall (Fang, 2008). Alternatively, Eq. 13 can be seen as a linearly-weighted additive kernel function over two feature spaces.

4 Experiments and Results

For train and evaluation purposes, we use the Amazon product reviews collected by Blitzer et al. (2007) for the four product categories: books (**B**), DVDs (**D**), electronic items (**E**), and kitchen appliances (**K**). There are 1000 positive and 1000 negative sentiment labeled reviews for each domain. Moreover, each domain has on average $17,547$ unlabeled reviews. We use the standard split of 800 positive and 800 negative labeled reviews from each domain as training data, and the rest (200+200) for testing. For validation purposes we use *movie* (source) and *computer* (target) domains, which were also collected by Blitzer et al. (2007), but not part of the train/test domains.

Experiments conducted using this validation dataset revealed that the performance of the proposed method is relatively insensitive to the value of the regularization parameter $\lambda \in [10^{-3}, 10^{3}]$. For the non-pivot prediction task we generate positive and negative instances using the procedure described in Section 3.2. As a typical example, we have $88,494$ train instances from the books source domain and $141,756$ train instances from the target domain (1:5 ratio between positive and negative instances in each domain). The number of pivots and non-pivots are set to $N_{\mathcal{P}} = N_{\mathcal{S}} = N_{\mathcal{T}} = 500$.

In Figure 1, we compare the proposed method against two baselines (**NA**, **InDomain**), current state-of-the-art methods for unsupervised cross-domain sentiment classification (**SFA**, **SCL**), word representation learning (**GloVe**), and cross-domain similarity prediction (**CS**). The **NA** (no-adapt) lower baseline uses a classifier trained on source labeled data to classify target test data without any domain adaptation. The **InDomain** baseline is trained using the labeled data for the target domain, and simulates the performance we can expect to obtain if target domain labeled data were available. Spectral Feature Alignment (**SFA**) (Pan et al., 2010) and Structural Correspondence Learning (**SCL**) (Blitzer et al., 2007) are the state-of-the-art methods for cross-domain sentiment classification. However, those methods do not learn word representations.

We use Global Vector Prediction (**GloVe**) (Pennington et al., 2014), the current state-of-the-art word representation learning method, to learn word representations separately from the source and target domain unlabeled data, and use the learnt representations in Eq. 13 for sentiment classification. In contrast to the *joint* word representations learnt by the proposed method, **GloVe** simulates the level of performance we would obtain by learning representations *independently*. **CS** denotes the cross-domain vector prediction method proposed by Bollegala et al. (2014). Although **CS** can be used to learn a vector-space translation matrix, it *does not* learn word representations. Vertical bars represent the classification accuracies (i.e. percentage of the correctly classified test instances) obtained by a particular method on target domain's test data, and Clopper-Pearson 95% binomial confidence intervals are superimposed.

Differences in data pre-processing (tokenization/lemmatization), selection (train/test splits), feature representation (unigram/bigram), pivot selection (MI/frequency), and the binary classification algorithms used to train the final classifier make it difficult to directly compare results published in prior work. Therefore, we re-run the original algorithms on the same processed dataset under the same conditions such that any differences reported in Figure 1 can be directly attributable to the domain adaptation, or word-representation learning methods compared.

All methods use l_2 regularized logistic regression as the binary sentiment classifier, and the reg-

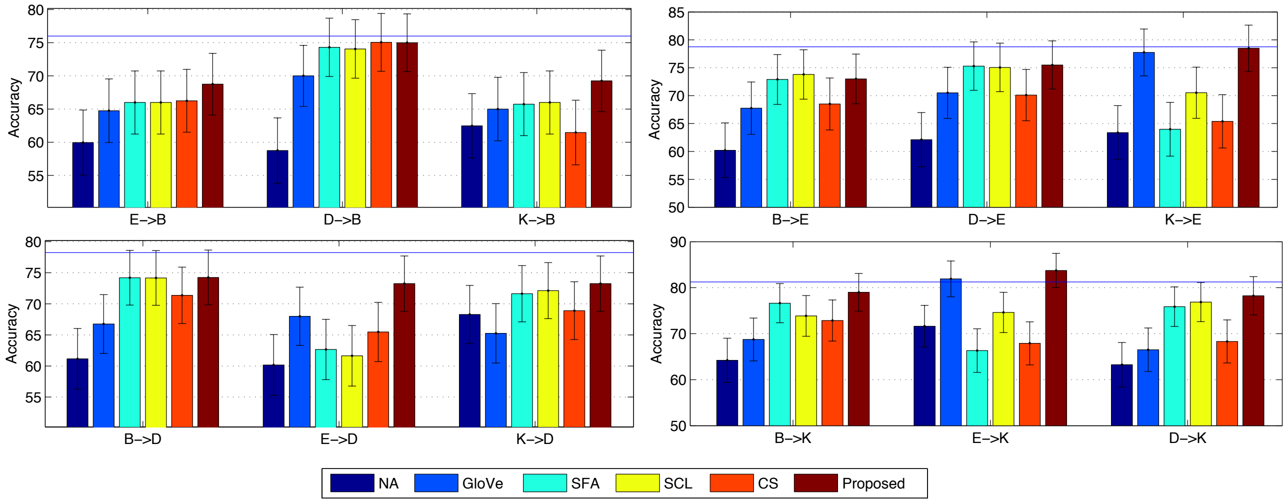

Figure 1: Accuracies obtained by different methods for each source-target pair in cross-domain sentiment classification.

ularization coefficients are set to their optimal values on the validation dataset. **SFA**, **SCL**, and **CS** use the same set of 500 pivots as used by the proposed method selected using NPMI (Section 3.4). Dimensionality n of the representation is set to 300 for both **GloVe** and the proposed method.

From Fig. 1 we see that the proposed method reports the highest classification accuracies in all 12 domain pairs. Overall, the improvements of the proposed method over **NA**, **GloVe**, and **CS** are statistically significant, and is comparable with **SFA**, and **SCL**. The proposed method's improvement over **CS** shows the importance of *predicting* word representations instead of *counting*. The improvement over **GloVe** shows that it is inadequate to simply apply existing word representation learning methods to learn independent word representations for the source and target domains.

We must consider the correspondences between the two domains as expressed by the pivots to jointly learn word representations. As shown in Fig. 2, the proposed method reports superior accuracies over **GloVe** across different dimensionalities. Moreover, we see that when the dimensionality of the representations increases, initially accuracies increase in both methods and saturates after 200 − 600 dimensions. However, further increasing the dimensionality results in unstable and some what poor accuracies due to overfitting when training high-dimensional representations. Although our word representations learnt by the proposed method are not specific to sentiment classification, the fact that it clearly outperforms **SFA** and **SCL** in all domain pairs is encouraging, and implies the wider-applicability of the proposed method for domain adaptation tasks beyond sentiment classification.

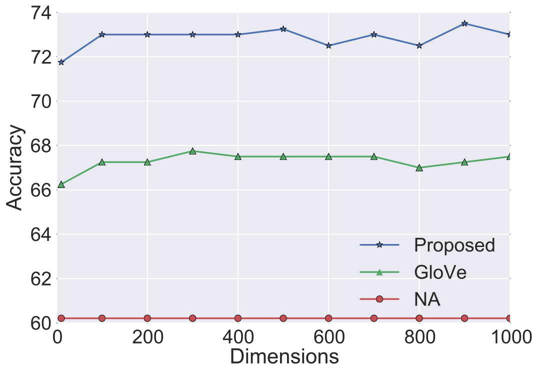

Figure 2: Accuracy vs. dimensionality of the representation.

5 Conclusion

We proposed an unsupervised method for learning cross-domain word representations using a given set of pivots and non-pivots selected from a source and a target domain. Moreover, we proposed a domain adaptation method using the learnt word representations.

Experimental results on a cross-domain sentiment classification task showed that the proposed method outperforms several competitive baselines and achieves best sentiment classification accuracies for all domain pairs. In future, we plan to apply the proposed method to other types of domain adaptation tasks such as cross-domain part-of-speech tagging, named entity recognition, and relation extraction.

Source code and pre-processed data etc. for this publication are publicly available[3].

A Unified Multilingual Semantic Representation of Concepts

José Camacho-Collados, Mohammad Taher Pilehvar and **Roberto Navigli**

Sapienza University of Rome
{collados,pilehvar,navigli}@di.uniroma1.it

Abstract

Semantic representation lies at the core of several applications in Natural Language Processing. However, most existing semantic representation techniques cannot be used effectively for the representation of individual word senses. We put forward a novel multilingual concept representation, called MUFFIN, which not only enables accurate representation of word senses in different languages, but also provides multiple advantages over existing approaches. MUFFIN represents a given concept in a unified semantic space irrespective of the language of interest, enabling cross-lingual comparison of different concepts. We evaluate our approach in two different evaluation benchmarks, semantic similarity and Word Sense Disambiguation, reporting state-of-the-art performance on several standard datasets.

1 Introduction

Semantic representation, i.e., the task of representing a linguistic item (such as a word or a word sense) in a mathematical or machine-interpretable form, is a fundamental problem in Natural Language Processing (NLP). The Vector Space Model (VSM) is a prominent approach for semantic representation, with widespread popularity in numerous NLP applications. The prevailing methods for the computation of a vector space representation are based on distributional semantics (Harris, 1954). However, these approaches, whether in their conventional co-occurrence based form (Salton et al., 1975; Turney and Pantel, 2010; Landauer and Dooley, 2002), or in their newer predictive branch (Collobert and Weston, 2008; Mikolov et al., 2013; Baroni et al., 2014), suffer from a major drawback: they are unable to model individual word senses or concepts, as they conflate different meanings of a word into a single vectorial representation. This hinders the functionality of this group of vector space models in tasks such as Word Sense Disambiguation (WSD) that require the representation of individual word senses. There have been several efforts to adapt and apply distributional approaches to the representation of word senses (Pantel and Lin, 2002; Brody and Lapata, 2009; Reisinger and Mooney, 2010; Huang et al., 2012). However, none of these techniques provides representations that are already linked to a standard sense inventory, and consequently such mapping has to be carried out either manually, or with the help of sense-annotated data. Chen et al. (2014) addressed this issue and obtained vectors for individual word senses by leveraging WordNet glosses. NASARI (Camacho-Collados et al., 2015) is another approach that obtains accurate sense-specific representations by combining the complementary knowledge from WordNet and Wikipedia. Graph-based approaches have also been successfully utilized to model individual words (Hughes and Ramage, 2007; Agirre et al., 2009; Yeh et al., 2009), or concepts (Pilehvar et al., 2013; Pilehvar and Navigli, 2014), drawing on the structural properties of semantic networks. The applicability of all these techniques, however, is usually either constrained to a single language (usually English), or to a specific task.

We put forward MUFFIN (Multilingual, UniFied and Flexible INterpretation), a novel method that exploits both structural knowledge derived from semantic networks and distributional statistics from text corpora, to produce effective representations of individual word senses or concepts. Our approach provides multiple advantages in comparison to the previous VSM techniques:

1. *Multilingual*: it enables sense representation in dozens of languages;
2. *Unified*: it represents a linguistic item, irrespective of its language, in a unified seman-

tic space having concepts as its dimensions, permitting direct comparison of different representations across languages, and hence enabling cross-lingual applications;

3. *Flexible*: it can be readily applied to different NLP tasks with minimal adaptation.

We evaluate our semantic representation on two different tasks in lexical semantics: semantic similarity and Word Sense Disambiguation. To assess the multilingual capability of our approach, we also perform experiments on languages other than English on both tasks, and across languages for semantic similarity. We report state-of-the-art performance on multiple datasets and settings in both frameworks, which confirms the reliability and flexibility of our representations.

2 Methodology

Figure 1 illustrates our procedure for constructing the vector representation of a given concept. We use BabelNet[1] (version 2.5) as our main sense repository. BabelNet (Navigli and Ponzetto, 2012a) is a multilingual encyclopedic dictionary which merges WordNet with other lexical resources, such as Wikipedia and Wiktionary, thanks to its use of an automatic mapping algorithm. BabelNet extends the WordNet synset model to take into account multilinguality: a BabelNet synset contains the words that, in the various languages, express the given concept.

Our approach for modeling a BabelNet synset consists of two main steps. First, for the given synset we gather contextual information from Wikipedia by exploiting knowledge from the BabelNet semantic network (Section 2.1). Then, by analyzing the corresponding contextual information and comparing and contrasting it with the whole Wikipedia corpus, we obtain a vectorial representation of the given synset (Section 2.2).

2.1 A Wikipedia sub-corpus for each concept

Let c be a concept, which in our setting is a BabelNet synset, and let $\mathcal{W}_c$ be the set containing the Wikipedia page p corresponding to the concept c and all the Wikipedia pages having an outgoing link to p. We further enrich $\mathcal{W}_c$ with the corresponding Wikipedia pages of the hypernyms and hyponyms of c in the BabelNet network. $\mathcal{W}_c$ is the set of Wikipedia pages whose contents are exploited to build a representation for the concept c. We refer to the bag of content words in all the Wikipedia pages in $\mathcal{W}_c$ as the sub-corpus $\mathcal{SC}_c$ for the concept c.

2.2 Vector construction: lexical specificity

Lexical specificity (Lafon, 1980) is a statistical measure based on the hypergeometric distribution. Due to its efficiency in extracting a set of highly relevant words from a sub-corpus, the measure has recently gained popularity in different NLP applications, such as textual data analysis (Lebart et al., 1998), term extraction (Drouin, 2003), and domain-based term disambiguation (Camacho-Collados et al., 2014; Billami et al., 2014). We leverage lexical specificity to compute the weights in our vectors. In our earlier work (Camacho-Collados et al., 2015), we conducted different experiments which demonstrated the improvement that lexical specificity can provide over the popular term frequency-inverse document frequency weighting scheme (Jones, 1972, *tf-idf*). Lexical specificity computes the vector weights for an item, i.e., a word or a set of words, by comparing and contrasting its contextual information with a reference corpus. In our setting, we take the whole Wikipedia as our reference corpus $\mathcal{RC}$ (we use the October 2012 Wikipedia dump).

[1] http://www.babelnet.org

Let T and t be the respective total number of tokens in $\mathcal{RC}$ and $\mathcal{SC}_c$, while F and f denote the frequency of a given item in $\mathcal{RC}$ and $\mathcal{SC}_c$, respectively. Our goal is to compute a weight denoting the association of an item to the concept c. For notational brevity, we use the following expression to refer to positive lexical specificity:

$$\textit{specificity}(T, t, F, f) = -\log_{10} P(X \geq f) \quad (1)$$

where X represents a random variable following a hypergeometric distribution of parameters F, t and T. As we are only interested in a set of items that are representative of the concept being modeled, we follow Billami et al. (2014) and only consider in our final vector the items which are relevant to $\mathcal{SC}_c$ with a confidence higher than 99% according to the hypergeometric distribution ($P(X \geq f) \leq 0.01$).

On the basis of lexical specificity we put forward two types of representations: *lexical* and *unified*. The lexical vector representation lex_c of a concept c has lemmas as its individual dimensions. To this end, we apply lexical specificity to every lemma in $\mathcal{SC}_c$ in order to estimate the relevance of each lemma to our concept c. We use the lexical representation for the task of WSD (see Section 3.2). We describe the unified representation in the next subsection.

2.3 Unified representation

Unlike the lexical version, our *unified* representation has concepts as individual dimensions. Algorithm 1 shows the construction process of a concept's unified vector. The algorithm first clusters together those words that have a sense sharing the same hypernym (h in the algorithm) according to the BabelNet taxonomy (lines 2-4). Next, the specificity is computed for the set of all the hyponyms of h, even those that do not appear in the sub-corpus $\mathcal{SC}_c$ (lines 6-14). Here, F and f denote the aggregated frequencies of all the hyponyms of h in the whole Wikipedia (i.e., reference corpus $\mathcal{RC}$) and the sub-corpus $\mathcal{SC}_c$, respectively.

Our binding of a set of sibling words into a single cluster represented by their common hypernym provides two advantages. Firstly, it transforms the representations to a unified semantic space. This space has concepts as its dimensions, enabling their comparability across languages. Secondly, the clustering can be viewed as an implicit disambiguation process, whereby a set of potentially ambiguous words are disambiguated into their intended sense on the basis of the contextual clues of the neighbouring content words, resulting in more accurate representations of meaning.

Algorithm 1 Unified Vector Construction

```
Input: a concept $c$
Output: the unified vector $u_c$ where $u_c(h)$ is the dimension
    corresponding to concept $h$
 1: $H \leftarrow \emptyset$
 2: for each lemma $l \in \mathcal{SC}_c$
 3:     for each hypernym $h$ of $l$ in BabelNet
 4:         $H \leftarrow H \cup \{h\}$
 5: vector $u_c \leftarrow$ null vector
 6: for each $h \in H$
 7:     if $\exists\, l_1, l_2 \in \mathcal{SC}_c$: $l_1, l_2$ hyponyms of $h$ and $l_1 \neq l_2$
        then
 8:         $F \leftarrow 0$
 9:         $f \leftarrow 0$
10:         for each hyponym $hypo$ of $h$
11:             for each lexicalization $lex$ of $hypo$
12:                 $F \leftarrow F + \textit{freq}(lex, \mathcal{RC})$
13:                 $f \leftarrow f + \textit{freq}(lex, \mathcal{SC}_c)$
14:         $u_c(h) \leftarrow \textit{specificity}(T, t, F, f))$
15: return vector $u_c$
```

Example. Table 1 lists the top-weighted concepts, represented by their relevant lexicalizations, in the unified vectors generated for the bird and machine senses of the noun *crane* and for three different languages.[2] A comparison of concepts across the two senses indicates the effectiveness of our representation in identifying relevant concepts in different languages, while guaranteeing a clear distinction between the two meanings.

3 Applications

Thanks to their VSM nature and the sense-level functionality, our concept representations are highly flexible, allowing us to adapt and apply them to different NLP tasks with minimal adaptation. In this section we explain how we use our representations in the tasks of semantic similarity (Section 3.1) and WSD (Section 3.2).

Associating concepts with words. Given that our representations are for individual word senses, a preliminary step for both tasks would be to associate the set of concepts, i.e., BabelNet synsets, $\mathcal{C}_w = \{c_1, ..., c_n\}$ with a given word w. In the case when w exists in the BabelNet dictionary, we obtain the set of associated senses of the word as defined in the BabelNet sense inventory.

In order to enhance the coverage in the case of

[2] We use the sense notation of Navigli (2009): $\textit{word}_n^p$ is the n^{th} sense of the *word* with part of speech p.

Table 1: Top-weighted concepts, i.e., BabelNet synsets, for the bird and machine senses of the noun *crane*. We represent each synset by one of its word senses. Word senses marked with the same symbol across languages correspond to the same BabelNet synset.

words that are not defined in the BabelNet dictionary, we also exploit the so-called Wikipedia piped links. A piped link is a hyperlink appearing in the body of a Wikipedia article, providing a link to another Wikipedia article. For example, the piped link [[dockside_crane|Crane_(machine)]] is a hyperlink that appears as *dockside_crane* in the text, but takes the user to the Wikipedia page titled *Crane_(machine)*. These links provide Wikipedia editors with the ability to represent a Wikipedia article through a suitable lexicalization that preserves the grammatical structure, contextual coherency, and flow of the sentence. This property provides an effective means of obtaining a set of concepts for the words not covered by BabelNet. For the case of our example, the BabelNet out-of-vocabulary word w = *dockside_crane* will have in its set of associated concepts $\mathcal{C}_w$ the BabelNet synset corresponding to the Wikipedia page titled *Crane_(machine)*.

3.1 Semantic Similarity

Once we have the set $\mathcal{C}_w$ of concepts associated with each word w, we first retrieve the set of corresponding unified vector representations. We then follow Camacho-Collados et al. (2015) and use square-rooted Weighted Overlap (Pilehvar et al., 2013, WO) as our vector comparison method, a metric that has been shown to suit specificity-based vectors more than the conventional cosine. WO compares two vectors on the basis of their overlapping dimensions, which are harmonically weighted by their relative ranking:

$$WO(v_1, v_2) = \frac{\sum_{q \in O} \left(rank(q, v_1) + rank(q, v_2) \right)^{-1}}{\sum_{i=1}^{|O|} (2i)^{-1}} \quad (2)$$

where O is the set of overlapping dimensions (i.e. concepts) between the two vectors and $rank(q, v_i)$ is the rank of dimension q in the vector v_i.

Finally, the similarity between two words w_1 and w_2 is calculated as the similarity of their closest senses, a prevailing approach in the literature (Resnik, 1995; Budanitsky and Hirst, 2006):

$$sim(w_1, w_2) = \max_{v_1 \in \mathcal{C}_{w_1}, v_2 \in \mathcal{C}_{w_2}} \sqrt{WO(v_1, v_2)} \quad (3)$$

where w_1 and w_2 can belong to different languages. This cross-lingual similarity measurement is possible thanks to the unified language-independent space of concepts of our semantic representations.

3.2 Multilingual Word Sense Disambiguation

In order to be able to apply our approach to WSD, we use the lexical vector *lex*$_c$ for each concept c. The reason for our choice of lexical vectors in this setting is that they enable a direct comparison of a candidate sense's representation with the context, which is also in the same lexical form. Algorithm 2 summarizes the general framework of our approach. Given a target word w to disambiguate, our approach proceeds by the following steps:

1. Retrieve $\mathcal{C}_w$, the set of associated concepts with the target word w (line 1);
2. Obtain the lexical vector *lex*$_c$ for each concept $c \in \mathcal{C}_w$ (cf. Section 2);
3. Calculate, for each candidate concept c, a confidence score (*score*$_c$) based on the harmonic sum of the ranks of the overlapping words between its lexical vector *lex*$_c$ and the context of the target word (line 5 in Algorithm 2).

Algorithm 2 MUFFIN for WSD

```
Input: a target word $w$ and a document $d$ (context of $w$)
Output: $\hat{c}$, the intended sense of $w$
for each concept $c \in \mathcal{C}_w$
    $score_c \leftarrow 0$
    for each lemma $l \in d$
        if $l \in lex_c$ then
            $score_c \leftarrow score_c + \big(rank(l, lex_c)\big)^{-1}$
$\hat{c} \leftarrow \arg\max_{c \in \mathcal{C}_w} score_c$
return $\hat{c}$
```

Thanks to the use of BabelNet, our approach is applicable to arbitrary languages. For the task of WSD, we focus on two major sense inventories integrated in BabelNet: Wikipedia and WordNet.

Wikipedia sense inventory. In this case, we obtain the set of candidate senses for a target word by following the procedure described in the beginning of this Section (i.e., associating concepts with words). However, we do not consider those BabelNet synsets that are not associated with Wikipedia pages.

WordNet sense inventory. Similarly, when restricted to the WordNet inventory, we discard those BabelNet synsets that do not contain a WordNet synset. In this setting, we also leverage relations from WordNet's semantic network and its disambiguated glosses[3] in order to obtain a richer set of Wikipedia articles in the sub-corpus construction. The enrichment of the semantic network with the disambiguated glosses has been shown to be beneficial in various graph-based disambiguation tasks (Navigli and Velardi, 2005; Agirre and Soroa, 2009; Pilehvar et al., 2013).

4 Experiments

We assess the reliability of MUFFIN in two standard evaluation benchmarks: semantic similarity (Section 4.1) and Word Sense Disambiguation (Section 4.2).

4.1 Semantic Similarity

As our semantic similarity experiment we opted for word similarity, which is one of the most popular evaluation frameworks in lexical semantics. Given a pair of words, the task in word similarity is to automatically judge their semantic similarity and, ideally, this judgement should be close to that given by humans.

4.1.1 Datasets

Monolingual. We picked the RG-65 dataset (Rubenstein and Goodenough, 1965) as our monolingual word similarity dataset. The dataset comprises 65 English word pairs which have been manually annotated by several annotators according to their similarity on a scale of 0 to 4. We also perform evaluations on the French (Joubarne and Inkpen, 2011) and German (Gurevych, 2005) adaptations of this dataset.

Cross-lingual. Hassan and Mihalcea (2009) developed two sets of cross-lingual datasets based on the English MC-30 (Miller and Charles, 1991) and WordSim-353 (Finkelstein et al., 2002) datasets, for four different languages: English, German, Romanian, and Arabic. However, the construction procedure they adopted, consisting of translating the pairs to other languages while preserving the original similarity scores, has led to inconsistencies in the datasets. For instance, the Spanish dataset contains the identical pair *mediodia-mediodia* with a similarity score of 3.42 (in the scale [0,4]). Additionally, the datasets contain several orthographic errors, such as *despliege* and *grua* (instead of *despliegue* and *grúa*) and incorrect translations (e.g., the English noun *implement* translated into the Spanish verb *implementar*).

Kennedy and Hirst (2012) proposed a more reliable procedure that leverages two existing aligned monolingual word similarity datasets for the construction of a new cross-lingual dataset. To this end, for each two word pairs *a-b* and *a'-b'* in the two datasets, if the difference in the corresponding scores is greater than one, the pairs are discarded. Otherwise, two new pairs *a-b'* and *a'-b* are created with a score equal to the average of the two original pairs' scores. In the case of repeated pairs, we merge them into a single pair with a similarity equal to their average scores. Using this procedure as a basis, Kennedy and Hirst (2012) created an English-French dataset consisting of 100 pairs. We followed the same procedure and built two datasets for English-German (consisting of 125 pairs) and German-French (comprising 96 pairs) language pairs.[4]

4.1.2 Comparison systems

Monolingual. We benchmark our system against four other approaches that exploit

Table 2: Spearman (ρ) and Pearson (r) correlation performance of different systems on the English, German and French RG-65 datasets.

Wikipedia as their main knowledge resource: SSA[5] (Hassan and Mihalcea, 2011), ESA (Gabrilovich and Markovitch, 2007), Wiki-wup (Ponzetto and Strube, 2007), and LSA-Wiki (Granada et al., 2014). We also provide results for systems that use distributional semantics for modeling words, both the conventional co-occurrence based approach, i.e., PMI-SVD (Baroni et al., 2014), PMI and SOC-PMI (Joubarne and Inkpen, 2011), and Retrofitting (Faruqui et al., 2015), and the newer word embeddings, i.e., Word2Vec (Mikolov et al., 2013). For Word2Vec and PMI-SVD, we use the pre-trained models obtained by Baroni et al. (2014).[6] As for WordNet-based approaches, we report results for Resnik (Resnik, 1995) and ADW (Pilehvar et al., 2013), which take advantage of its structural information, and Lesk_hyper (Gurevych, 2005), which leverages definitional information in WordNet for similarity computation. Finally, we also report the performance of our earlier work NASARI (Camacho-Collados et al., 2015), which combines knowledge from WordNet and Wikipedia for the English language in its setting without the Wiktionary synonyms module.

Cross-lingual. We compare the performance of our approach against the best configuration of the CL-MSR-2.0 system (Kennedy and Hirst, 2012), which exploits Pointwise Mutual Information (PMI) on a parallel corpus obtained from the English and French versions of WordNet. Since two of our cross-lingual datasets are newly-created, we developed three baseline systems to enable a more meaningful comparison. To this end, we first use Google Translate to translate the non-English side of the dataset to the English language. Accordingly, three state-of-the-art graph-based and corpus-based approaches were used to measure the similarity of the resulting English pairs. As English similarity measurement systems, we opted for ADW (Pilehvar et al., 2013), and the best predictive (Mikolov et al., 2013, Word2Vec) and co-occurrence (i.e., PMI-SVD) models obtained by Baroni et al. (2014).[7] In our experiments we refer to these systems as *pivot*, since they use English as a pivot for computing semantic similarity. As a comparison, we also show results for MUFFIN$_{pivot}$, which is the variant of our system applied to the same automatically translated monolingual datasets.

4.1.3 Results

Monolingual. We show in Table 2 the performance of different systems in terms of Spearman and Pearson correlations on the English, German, and French RG-65 datasets. On the German and French datasets, our system outperforms the comparison systems according to both evaluation measures. It achieves considerable Spearman and Pearson correlation leads of 0.1 and 0.2, respectively, on the French dataset in comparison to the best system. Also on the English RG-65 dataset, our system attains competitive performance according to both Spearman and Pearson correla-

[5] SSA involves several parameters tuned on datasets that are constructed on the basis of MC-30 and RG-65.

[6] We report the best configuration of the systems on the RG-65 dataset out of their 48 configurations. The corpus used to train the models contained 2.8 billion tokens, including Wikipedia (Baroni et al., 2014).

[7] http://clic.cimec.unitn.it/composes/semantic-vectors.html

Measure	FR-EN	EN-DE	DE-FR
MUFFIN	**0.83**	**0.76**	**0.83**
MUFFIN$_{pivot}$	**0.83**	0.73	0.79
ADW$_{pivot}$	0.80	0.73	0.72
Word2Vec$_{pivot}$	0.75	0.69	0.77
PMI-SVD$_{pivot}$	0.76	0.72	0.65
CL-MSR-2.0	0.30	–	–

Table 3: Pearson correlation performance of different similarity measures on the three cross-lingual RG-65 datasets.

tions. We note that most state-of-the-art systems on the dataset (e.g., ADW) are restricted to the English language only.

Cross-lingual. Pearson correlation results on the three cross-lingual RG-65 datasets are presented in Table 3. Similarly to the monolingual experiments, our system proves highly reliable in the cross-lingual setting, improving the performance of the comparison systems on all three language pairs. Moreover, MUFFIN$_{pivot}$ attains the best results among the *pivot* systems on all datasets, confirming the reliability of our system in the monolingual setting. We note that since the cross-lingual datasets were built by translating the word pairs in the original English RG-65 dataset, the pivot-based comparison systems proved to be highly competitive, outperforming the CL-MSR-2.0 system by a considerable margin.

4.2 Word Sense Disambiguation

4.2.1 Wikipedia

In this setting, we selected the SemEval 2013 all-words WSD task (Navigli et al., 2013) as our evaluation benchmark. The task provides datasets for five different languages: Italian, English, French, Spanish and German. There are on average 1123 words to disambiguate in each language's dataset. As comparison system, we provide results for the best-performing participating system on each language. We also show results for the state-of-the-art WSD system of Moro et al. (2014, Babelfy), which relies on random walks on the BabelNet semantic network and a set of graph heuristic algorithms. Finally, we also report results for the Most Frequent Sense (MFS) baseline provided by the task organizers.

We follow Moro et al. (2014) and back off to the MFS baseline in the case when our system's judgement does not meet a threshold θ. Similarly to Babelfy, we tuned the value of the threshold θ on the trial dataset provided by the organizers of the task. We tuned θ with step size 0.05 (hence, 21 possible values in [0,1]), obtaining an optimal value of 0.85 in the trial set, a value which we use across all languages.

Table 4 lists the F1 percentage performance of different systems on the five datasets of the SemEval-2013 all-words WSD task. Despite not being tuned to the task, our representations provide competitive results on all datasets, outperforming the sophisticated Babelfy system on the Spanish and German languages. The variant of our system not utilizing the MFS information in the disambiguation process ($\theta = 0$), i.e., MUFFIN⋆, also shows competitive results, outperforming the best system in the SemEval-2013 dataset on all languages. Interestingly, MUFFIN⋆ proves highly effective on the French language, surpassing not only the performance of our system using the MFS information, but also attaining the best overall performance.

4.2.2 WordNet

As regards the WordNet disambiguation task, we take as our benchmark the two recent SemEval English all-words WSD tasks: the SemEval-2013 task on Multilingual WSD (Navigli et al., 2013) and the SemEval-2007 English Lexical Sample, SRL and All-Words task (Pradhan et al., 2007). The all-words datasets of the two tasks contain 1644 instances (SemEval-2013) and 162 noun instances (SemEval-2007), respectively.

As comparison system, we report the performance of the best configuration of the top-performing system in the SemEval-2013 task, i.e., UMCC-DLSI (Gutiérrez et al., 2013). We also show results for the state-of-the-art supervised system (Zhong and Ng, 2010, IMS), as well as for two graph-based approaches that are based on random walks on the WordNet graph (Agirre and Soroa, 2009, UKB w2w) and the BabelNet semantic network (Moro et al., 2014, Babelfy). We follow Babelfy and also exploit the WordNet's sense frequency information from the SemCor sense-annotated corpus (Miller et al., 1993). However, instead of simply backing off to the most frequent sense, we propose a more meaningful exploitation of this information. To this end, we compute the relevance of a specific sense as the average of its normalized sense frequency and its corresponding

System	MFS Back off	Italian	English	French	Spanish	German
MUFFIN	✓	81.9	84.5	71.4	**85.1**	**83.1**
MUFFIN$\star$		67.9	73.5	**72.3**	81.1	76.1
Babelfy	✓	**84.3**	**87.4**	71.6	83.8	81.6
Best SemEval 2013 system	✓	58.3	54.8	60.5	58.1	61.0
MFS	-	82.2	80.2	69.1	82.1	83.0

Table 4: F1 percentage performance on the SemEval-2013 Multilingual WSD datasets using Wikipedia as sense inventory.

System	SemEval-2013	SemEval-2007
MUFFIN	**66.0**	66.0
UKB	61.3	56.0
UMCC-DLSI	64.7	–
IMS	65.3	**67.3**
Babelfy	65.9	62.7
MFS	63.2	65.8
MUFFIN+IMS	66.9	68.5

Table 5: F1 percentage performance on the SemEval-2013 and SemEval-2007 (noun instances) English All-words WSD datatets using WordNet as sense inventory.

score (*score*$_c$ in Algorithm 2) given by our system. The sense with the highest overall relevance value is then picked as the intended sense.

Additionally, we put forward a hybrid system that combines our system with IMS, hence benefiting from the judgements made by two systems that utilize complementary information. Our system makes judgements based on global contexts, whereas IMS exploits the local context of the target word. To this end, we compute the relevance of a specific sense as the average of the normalized scores given by IMS and our system (*score*$_c$ in Algorithm 2). We refer to this hybrid system as MUFFIN+IMS.

Table 5 reports the F1 percentage performance of different systems on the datasets of SemEval-2013 and SemEval-2007 English all-words WSD tasks. We also report the results for the MFS baseline, which always picks the most frequent sense of a word. Similarly to the disambiguation task on the Wikipedia sense inventory, MUFFIN proves to be quite competitive on the WordNet disambiguation task, while surpassing the performance of all the comparison systems on the SemEval-2013 dataset. On the SemEval-2007 dataset, IMS achieves the best performance, thanks to its usage of large amounts of manually and semi-automatically tagged data. Finally, our hybrid system, MUFFIN+IMS, provides the best overall performance on the two datasets, showing that our combination of the two WSD systems that utilize different types of knowledge was beneficial.

5 Related work

We briefly review the recent literature on the two NLP tasks to which we applied our representations, i.e., Word Sense Disambiguation and semantic similarity.

WSD. There are two main categories of WSD techniques: knowledge-based and supervised (Navigli, 2009). Supervised systems such as IMS (Zhong and Ng, 2010) analyze sense-annotated data and model the context in which the various senses of a word usually appear. Despite their accuracy for the words that are provided with suitable amounts of sense-annotated data, their applicability is limited to those words and languages for which such data is available, practically limiting them to a small subset of words mainly in the English language. Knowledge-based approaches (Sinha and Mihalcea, 2007; Navigli and Lapata, 2007; Agirre and Soroa, 2009) significantly improve the coverage of supervised systems. However, similarly to their supervised counterparts, knowledge-based techniques are usually limited to the English language.

Recent years have seen a growing interest in cross-lingual and multilingual WSD (Lefever and Hoste, 2010; Lefever and Hoste, 2013; Navigli et al., 2013). Multilinguality is usually offered by methods that exploit the structural information of large-scale multilingual lexical resources such as Wikipedia (Gutiérrez et al., 2013; Manion and Sainudiin, 2013; Hovy et al., 2013). Babelfy (Moro et al., 2014) is an approach with state-of-the-art performance that relies on random walks on BabelNet multilingual semantic network (Navigli and Ponzetto, 2012a) and densest subgraph heuristics. However, the approach is limited to the WSD and Entity Linking tasks. In contrast, our approach is global as it can be used in different NLP tasks, including WSD.

Semantic similarity. Semantic similarity of word pairs is usually computed either on the basis of the structural properties of lexical databases and thesauri, or by comparing vectorial representations of words learned from massive text corpora. Structural approaches usually measure the similarity on the basis of the distance information on semantic networks, such as WordNet (Budanitsky and Hirst, 2006), or thesauri, such as Roget's (Morris and Hirst, 1991; Jarmasz and Szpakowicz, 2003). The semantic network of WordNet has also been used in more sophisticated techniques such as those based on random graph walks (Ramage et al., 2009; Pilehvar et al., 2013), or coupled with the complementary knowledge from Wikipedia (Camacho-Collados et al., 2015). However, these techniques are either limited in the languages to which they can be applied, or in their applicability to tasks other than semantic similarity (Navigli and Ponzetto, 2012b).

Corpus-based techniques are more flexible, enabling the training of models on corpora other than English. However, these approaches, either in their conventional co-occurrence based form (Gabrilovich and Markovitch, 2007; Landauer and Dumais, 1997; Turney and Pantel, 2010; Bullinaria and Levy, 2012), or the more recent predictive models (Mikolov et al., 2013; Collobert and Weston, 2008; Pennington et al., 2014), are restricted in two ways: (1) they cannot be used to compare word senses; and (2) they cannot be directly applied to cross-lingual semantic similarity. Though the first problem has been solved by multi-prototype models (Huang et al., 2012), or by the sense-specific representations obtained as a result of exploiting WordNet glosses (Chen et al., 2014), the second problem remains unaddressed. In contrast, our approach models word senses and concepts effectively, while providing a unified representation for different languages that enables cross-lingual semantic similarity.

6 Conclusions

This paper presented MUFFIN, a new multilingual, unified and flexible representation of individual word senses. Thanks to its effective combination of distributional statistics and structured knowledge, the approach can compute efficient representations of arbitrary word senses, with high coverage and irrespective of their language. We evaluated our representations on two different NLP tasks, i.e., semantic similarity and Word Sense Disambiguation, reporting state-of-the-art performance on several datasets. Experimental results demonstrated the reliability of our unified representation approach, while at the same time also highlighting its main advantages: multilinguality, owing to its effective application within and across multiple languages; and flexibility, owing to its robust performance on two different tasks.

Demographic Factors Improve Classification Performance

Dirk Hovy
Center for Language Technology
University of Copenhagen, Denmark
Njalsgade 140
dirk@cst.dk

Abstract

Extra-linguistic factors influence language use, and are accounted for by speakers and listeners. Most natural language processing (NLP) tasks to date, however, treat language as uniform. This assumption can harm performance. We investigate the effect of including demographic information on performance in a variety of text-classification tasks. We find that by including age or gender information, we consistently and significantly improve performance over demographic-agnostic models. These results hold across three text-classification tasks in five languages.

1 Introduction

When we use language, we take demographic factors of the speakers into account. In other words, we do have certain expectations as to who uses “super cute,” “rather satisfying,” or “rad, dude.” Sociolinguistics has long since studied the interplay between demographic factors and language use (Labov, 1964; Milroy and Milroy, 1992; Holmes, 1997; Macaulay, 2001; Macaulay, 2002; Barbieri, 2008; Wieling et al., 2011; Rickford and Price, 2013, inter alia).[1] These factors greatly influence word choice, syntax, and even semantics.

In natural language processing (NLP), however, we have largely ignored demographic factors, and treated language as a uniform medium. It was irrelevant, (and thus not modeled) whether a text was produced by a middle-aged man, an elderly lady, or a teenager. These three groups, however, differ along a whole host of demographic axes, and these differences are reflected in their language use.

A model that is agnostic to demographic differences will lose these distinctions, and performance suffers whenever the model is applied to a new demographic. Historically, the demographics of training and test data (newswire) were relatively homogenous, language was relatively uniform, and information the main objective. Under these uniform conditions, the impact of demographics on performance was small.

Lately, however, NLP is increasingly applied to other domains, such as social media, where language is less canonical, demographic information about the author is available, and the authors' goals are no longer purely informational. The influence of demographic factors in this medium is thus much stronger than on the data we have traditionally used to induce models. The resulting performance drops have often been addressed via various domain adaptation approaches (Blitzer et al., 2006; Daume III and Marcu, 2006; Reichart and Rappoport, 2007; Chen et al., 2009; Daumé et al., 2010; Chen et al., 2011; Plank and Moschitti, 2013; Plank et al., 2014; Hovy et al., 2015b, inter alia). However, the authors and target demographics of social media differ radically from those in newswire text, and domain might in some case be a secondary effect to demographics. In this paper, we thus ask whether we also need *demographic adaptation*.
Concretely, we investigate

1. how we can encode demographic factors, and
2. what effect they have on the performance of text-classification tasks

We focus on **age** and **gender**, and similarly to Bamman et al. (2014a), we use distributed word representations (embeddings) conditioned on these demographic factors (see Section 2.1) to incorporate the information.

We evaluate the effect of demographic information on classification performance in three NLP

[1] Apart from the demographic factors, other factors such as mood, interpersonal relationship, authority, language attitude, etc. contribute to our perception of language.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 752–762,

tasks: sentiment analysis (Section 2.2), topic detection (Section 2.3), and author attribute classification (Section 2.4). [2]

We compare F_1-performance of classifiers a) trained with access to demographic information, or b) under agnostic conditions. We find that demographic-aware models consistently outperform their agnostic counterparts in all tasks.

Our contributions

We investigate the effect of demographic factors on classification performance. We show that NLP systems benefit from demographic awareness, i.e., that information about age and gender can lead to significant performance improvements in three different NLP tasks across five different languages.

2 Data

We use data from an international user review website, Trustpilot. It contains information both about the review (text and star rating), as well as the reviewer, in form of a profile. The profile included a screen name, and potentially information about gender and birth year.

Since demographic factors are extra-linguistic, we assume that the same effects hold irrespective of language. To investigate this hypothesis, we use data from several languages (Danish, French, and German) and varieties (American English, British English).

We use data from the countries with most users, i.e., Great Britain, Denmark, Germany, France, and the US. The selection was made based on the availability of sufficient amounts of training data (see Table 1 for more details). The high number of users in Denmark (one tenth of the country's population) might be due to the fact that Trustpilot is a Danish company and thus existed there longer than in other countries. Danish users also provide (in relative terms) more information about themselves than users of any other country, so that even in absolute numbers, there is oftentimes more information available than for larger countries like France or Germany, where users are more reluctant to disclose information.

While most of this profile information is voluntary, we have good coverage for both age and gender. In case of missing gender values, we base a guess on the first name (if given), by choosing the gender most frequently associated with that name in the particular language. We do require that one gender is prevalent (accounting for 95% of all mentions), and that there is enough support (at least 3 attributed instances), though. For age, coverage is less dense, so the resulting data sets are smaller, but still sufficient.

	USERS	AGE	GENDER	PLACE	ALL
UK	1,424k	7%	62%	5%	4%
France	741k	3%	53%	2%	1%
Denmark	671k	23%	87%	17%	16%
US	648k	8%	59%	7%	4%
Germany	329k	8%	47%	6%	4%

Table 1: Number of users and % per variable per country (after applying augmentations).

For more information on Trustpilot as a resource, see Hovy et al. (2015a).

We split each review into sentences, tokenize, replace numbers with a 0, lowercase the data, and join frequent bigrams with an underscore to form a single token.

For each language, we collect four sub-corpora, namely two for gender (male and female) and two for age (under 35 and over 45). The sub-corpora for the discrete variable gender are relatively straightforward (although see (Bamman et al., 2014b)), but the split for the continuous age variable are less clear. While the effect of age on language use is undisputed (Barke, 2000; Barbieri, 2008; Rickford and Price, 2013), providing a clear cut-off is hard. We therefore use age ranges that result in roughly equally sized data sets for both groups, and that are not contiguous.

For each independent variable (age and gender), we induce embeddings for the two sub-groups (see section 2.1), as well as a "mixed" setting. We also extract labeled data for each task (see sections 2.2, 2.3, and 2.4). Each of these data sets is randomly split into training and test data, 60:40. Note that we do *not* set any parameters on development data, but instead use off-the-shelf software with default parameters for classification. Table 2 gives an overview of the number of training and test instances for each task and both variables (gender and age).

Note that this setup is somewhat artificial: the vocabulary of the embeddings can subsume the

[2] We selected these tasks to represent a range of text-classification applications, and based on the availability of suitable data with respect to target and demographic variables.

		GENDER		AGE

vocabulary of the tasks (there is some loss due to frequency cut-offs in `word2vec`). The out-of-vocabulary rate on the tasks is thus artificially low and can inflate results. In a standard "improvement over baseline"-setup, this would be problematic. However, the results should not be interpreted with respect to their absolute value on the respective tasks, but with respect to the relative differences.

2.1 Conditional Embeddings

COUNTRY	AGE	GENDER
Denmark	495k	1.6m
France	36k	490k
Germany	47k	211k
UK	232k	1.63m
US	70k	576k
total	880k	4.51m

Table 3: Number of sentences used to induce embeddings

Embeddings are distributed representations of words in a vector space, capturing syntactic and semantic regularities among the words. We learn our word embeddings by using `word2vec`[3] (Mikolov et al., 2013) on unlabeled review data. Our corpora are relatively small, compared to the language modeling tasks the tool was developed for (see Table 3 for the number of instances used for each language and variable). We thus follow the suggestions in the `word2vec` documentation and use the skip-gram model and hierarchical softmax rather than the standard continuous-bag-of-words model. This setting penalizes low-frequent words less. All out-of-vocabulary (OOV) words are replaced with an "unknown" token, which is represented as the averaged vector over all other words.

In this paper, we want to use embeddings to capture group-specific differences. We therefore train embeddings on each of the sub-corpora (e.g., *male*, *female*, and *U35*, *O45*) separately. As comparison, we create a mixed setting. For each variable, we combine half of both sub-corpora (say, men and women) to form a third corpus with no demographic distinction. We also train embeddings on this data. This setting assumes that there are no demographic differences, which is the common approach in NLP to date.

Since embeddings depend crucially on the

[3] `https://code.google.com/p/word2vec/`

size of the available training data, and since we want to avoid modeling size effects, we balance the three corpora we use to induce embeddings such that all three contain the same number of instances.[4]

Note that while we condition the embeddings on demographic variables, they are *not* task-specific. While general-purpose embeddings are widely used in the NLP community, task-specific embeddings are known to lead to better results for various tasks, including sentiment analysis (Tang et al., 2014). Inducing task-specific embeddings carries the risk of overfitting to a task and data set, though, and would make it harder to attribute performance differences to demographic factors.

Since we are only interested in the *relative* difference between demographic-aware and unaware systems, not in the absolute performance on the tasks, we do not use task-specific embeddings.

2.2 Sentiment Analysis

Sentiment analysis is the task of determining the polarity of a document. In our experiments, we use three polarity values: positive, negative, and neutral. To collect data for the sentiment analysis task, we select all reviews that contain the target variable (gender or age), and a star-rating. Following previous work on similar data (Blitzer et al., 2007; Hardt and Wulff, 2012; Elming et al., 2014), we use one, three, or five star ratings, corresponding to negative, neutral, and positive sentiment, respectively.

We balance the data sets so that both training and test set contain equal amounts of all three labels. We do this in order to avoid demographic-specific label distributions (women and people over 45 tend to give more positive ratings than men and people under 35, see Section 3.1).

2.3 Topic Identification

Topic identification is the task of assigning a high-level concept to a document that captures its content. In our case, the topic labels are taken from the Trustpilot taxonomy for companies (e.g., *Electronics*, *Pets*, etc.). Again, there is a strong gender bias: the most common topic for men is *Computer & Accessories*, the most common topic among women is *Pets*. There is thus considerably less overlap between the groups than for the other tasks. In order not to model gender-specific topic bias and to eliminate topic frequency as a confounding factor, we restrict ourselves to the five most frequent labels that occur in both groups. We also ensure that we have the same number of examples for each label in both groups. However, in the interest of data size, we do not enforce a uniform distribution over the five labels (i.e., the classes are not balanced).

2.4 Author Attribute Identification

Author attribute identification is the task of inferring demographic factors from linguistic features (Alowibdi et al., 2013; Ciot et al., 2013; Liu and Ruths, 2013). It is often used in author profiling (Koppel et al., 2002) and stylometrics (Goswami et al., 2009; Sarawgi et al., 2011). Rosenthal and McKeown (2011) have shown that these attributes are correlated.

In this paper, we restrict ourselves to using gender to predict age, and age to predict gender. This serves as an additional test case. Again, we balance the class labels to minimize the effect of any confounding factors.

3 Experiments

3.1 Data Analysis

Before we analyze the effect of demographic differences on NLP performance, we investigate whether there is an effect on the non-linguistic correlates, i.e., ratings and topics. To measure the influence of demographic factors on these values, we quantify the distributions over the three sentiment labels and the five topic labels. We analyze both gender and age groups separately, but in the interest of space average across all languages.

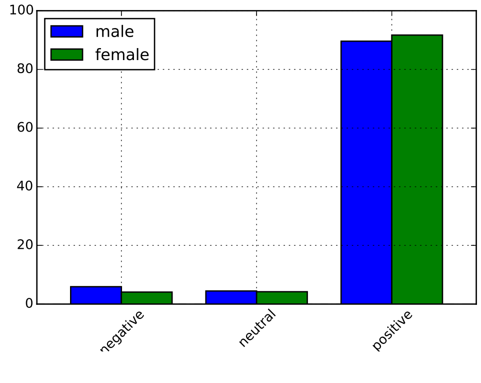

Figure 1: Label distribution for gender

[4] Note, however, that the vocabulary sizes still vary among languages and between age and gender.

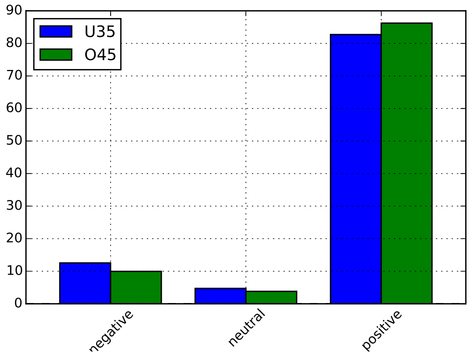

Figure 2: Label distribution for age groups

Figures 1 and 2 show the distributions over sentiment labels. We note that men give more negative and fewer positive ratings than women. The same holds for people in the younger group, who are more skewed towards negative ratings than people in the older group. While the differences are small, they suggest that demographics correlate with rating behavior have a measurable effect on model performance.

The gender distributions over categories exhibit a very different tendency. Table 3 shows that the review categories (averaged over all languages) are highly gender-specific. With the exception of *Hotels* and *Fashion Accessories*, the two distributions are almost bimodal opposites. However, they are still significantly correlated (Spearman ρ is 0.49 at $p < 0.01$).

The difference in the two distributions illustrates why we need to control for topic frequency in our experiments.

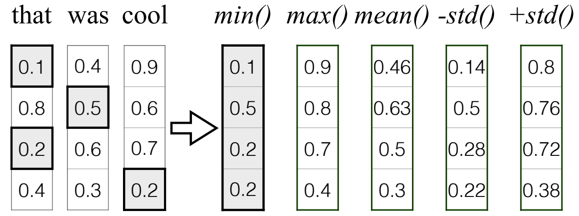
3.2 Models

Classifiers For all tasks, we use logistic regression models[5] with standard parameter settings. In order to isolate the effect of demographic differences on performance in all text classification tasks, we need to represent variable length documents based *only* upon the embeddings of the words they contain.

We follow Tang et al. (2014) in using convolutional layers over word embeddings (Collobert et al., 2011) to generate fixed-length input representations. Figure 4 schematically shows the procedure for the minimum of a 4-dimensional toy example. For each instance, we collect five N-dimensional statistics over the t by N input matrix, where N is the dimensionality of the embeddings (here: 100), and t is the sentence length in words.

From the matrix representation, we compute the dimension-wise minimum, maximum, and mean representation, as well as one standard deviation above and below the mean. We then concatenate those five 100-dimensional vectors to a 500-dimensional vector thats represents each instance (i.e., review) as input to the logistic regression classifier.

Taking the maximum and minimum across all embedding dimensions is equivalent to representing the exterior surface of the "instance manifold" (the volume in embedding space within which all words in the instance reside). Adding the mean and standard deviation summarizes the density per-dimension within the manifold. This way, we can represent any input sentence solely based on the embeddings, and with the same feature vector dimensionality.



that	was	cool	*min()*	*max()*	*mean()*	*-std()*	*+std()*
0.1	0.4	0.9	0.1	0.9	0.46	0.14	0.8
0.8	0.5	0.6	0.5	0.8	0.63	0.5	0.76
0.2	0.6	0.7	0.2	0.7	0.5	0.28	0.72
0.4	0.3	0.2	0.2	0.4	0.3	0.22	0.38

Figure 4: Example for deriving embedding statistics from sentence in 4-dimensional space. Minimum shaded

The approach is the same for all three tasks, and we did not tune any parameters to maximize performance. The results are thus maximally comparable to each other, albeit far from state-of-the-art. Overall performance could be improved with task-specific features and more sophisticated models, but it would make the results less comparable, and complicate identifying the source of performance differences. We leave this for future research.

Comparison In order to compare demographic-aware and agnostic models, we use the following setup for each task and language:

1. In the *"agnostic"* setting, we train a logistic-regression model using the joint embeddings (i.e., embeddings induced on the corpus containing both sub-groups, e.g. male and fe-

[5] `http://scikit-learn.org/stable/modules/generated/sklearn.linear_model.LogisticRegression.html`

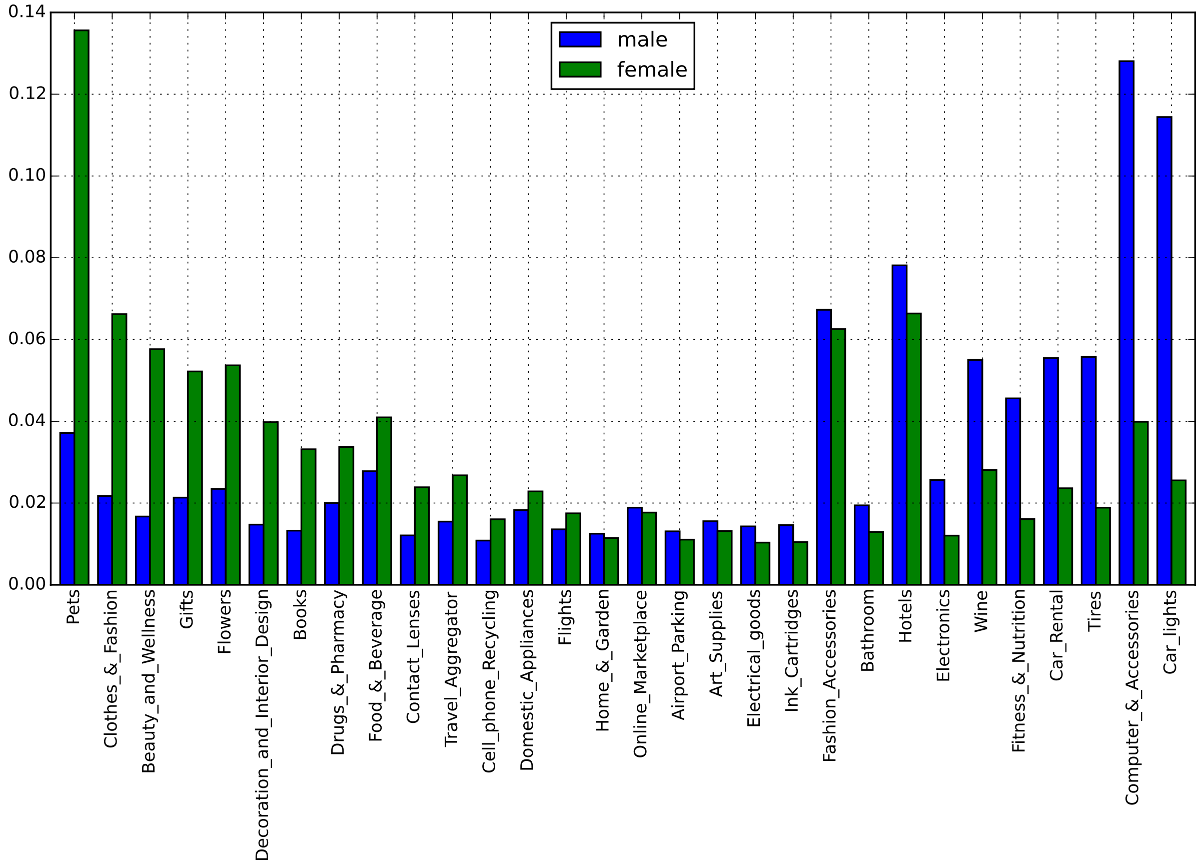


Figure 3: Distribution of the 30 most frequent categories per gender over all languages

male) and group-agnostic training data (i.e., data that contains an equal amount of instances from either sub-group).

2. In the *demographic-aware* setting, we train a logistic-regression model for each of the two sub-groups (e.g., male and female). For each sub-group, we use the group-specific embeddings (i.e., embeddings induced on, say, male data) and group-specific training data (i.e., instances collected from male data).

We measure F_1-performance for both settings (agnostic and demographic-aware) on the test set. The test data contains an equal amount of instances from both sub-groups (say, male and female). We use the demographic-aware classifier appropriate for each instance (e.g., male classifier for male instances), i.e., we assume that the model has access to this information. For many user-generated content settings, this is realistic, since demographic information *is* available. However, we only predict the target variable (sentiment, topic, or author attribute). We do *not* require the model to predict the sub-group (age or gender group).

We assume that demographic factors hold irrespective of language. We thus compute a *macro*-F_1 over all languages. *Micro*-F_1 would favor languages for which there is more data available, i.e., performance on those languages would dominate the average performance. Since we do not want to ascribe more importance to any particular language, macro-F_1 is more appropriate.

Even if there is a difference in performance between the agnostic and aware settings, this difference could still be due to the specific data set. In order to test whether the difference is also statistically significant, we use a *bootstrap-sampling test*. In a bootstrap-sampling test, we sample subsets of the predictions of both settings (with replacement) 10,000 times. For each sample, we measure F_1 of both systems, and compare the winning system of the sample to the winning system on the entire data set. The number of times

avg	61.92	**62.16**	55.95	**56.43**	59.15	**59.53**

Table 4: F_1 for **gender**-aware and agnostic models on tasks. Averages are macro average. * : $p < 0.05$

the sample winner differs from the entire data set, divided by $10,000$, is the reported p-value. Bootstrap-sampling essentially simulates runs of the two systems on different data sets. If one system outperforms the other under most of these conditions (i.e., the test returns a low p-value), we can be reasonably sure that the difference is not due to chance.

As discussed in Berg-Kirkpatrick et al. (2012) and Søgaard et al. (2014), this test is the most appropriate for NLP data, since it does not make any assumptions about the underlying distributions, and directly takes performance into account. Note that the test still depends on data size, though, so that small differences in performance on larger data sets can be significant, while larger differences on small sets might not.

We test for significance with the standard cutoff of $p < 0.05$. However, even under a bootstrap-sampling test, we can only limit the number of likely false positives. If we run enough tests, we increase the chance of reporting a type-I error. In order to account for this effect, we use Bonferroni corrections for each of the tasks.

4 Results

For each task, we compare the demographic-aware setting to an agnostic setting. The latter is equivalent to the currently common approach in NLP. For each task and language, the setting with the higher performance is marked in bold. Statistically significant differences (at $p < 0.05$) are marked with a star (*). Note that for the macro-averaged scores, we cannot perform bootstrap significance testing.

4.1 Gender

Table 4 shows the F_1 scores for the different tasks. In the left column of each task (labeled AGNOSTIC), the system is trained on embeddings and data from *both* genders, in the same ratios as in the test data. This column is similar to the configuration normally used in NLP to date, where – at least in theory – data comes from a uniformly distributed sample.

In the right column (labeled AWARE), the classification is based on the classifier trained on embeddings and data from the respective gender.

While the improvements are small, they are consistent. We do note some variance in consistency across tasks.

The largest average improvement among the three tasks is on topic classification. This improvement is interesting, since we have seen stark differences for the topic distribution between genders. Note, however that we controlled for this factor in our experiments (cf. Table 3). The results thus show that taking gender into account improves topic classification performance even *after* controlling for prior topic distribution as a confounding factor.

The improvements in age classification are the most consistent. This consistency is likely due to the fact that author attributes are often correlated. The fact that the attributes are related can be exploited in stacking approaches, where the attributes are predicted together.

Analyzing the errors, the misclassifications for sentiment analysis (the weakest task) seem to be system-independent. Mistakes are mainly due to the simplicity of the system. Since we do not explicitly model negation, we incur errors such as "I will never order anywhere else again" classified as negative, even though it is in fact rather positive.

	SENTIMENT ANALYSIS		TOPIC CLASSIFICATION		GENDER CLASSIFICATION

Table 5: F_1 for **age**-aware and agnostic models on tasks. Averages are macro average. $^*: p < 0.05$

4.2 Age

Table 5 presents the results for systems with age as independent demographic variable. Again, we show the difference between the agnostic and age-aware setting in parallel columns for each task.

The improvements are similar to the ones for gender. The smaller magnitude across tasks indicates that knowledge of age offers less discriminative power than knowledge of gender. This in itself is an interesting result, suggesting that the age gap is much smaller than the gender gap when it comes to language variation (i.e., older people's language is more similar to younger people than the language of men is to women). The difference between groups could be a domain-effect, though, caused by the fact that all subjects are using a form of "reviewese" when leaving their feedback. Why this effect would be more prevalent across ages than across genders is not obvious from the data.

When averaged over all languages, the age-aware setup again consistently outperforms the agnostic setup, as it did for gender. While the final numbers are lower than in the gender setting, average improvements tend to be just as decisive.

5 Related Work

Most work in NLP that has dealt with demographic factors has either a) looked at the correlation of socio-economic attributes with linguistic features (Eisenstein et al., 2011; Eisenstein, 2013a; Eisenstein, 2013b; Doyle, 2014; Bamman et al., 2014a; Eisenstein, to appear), or b) used linguistic features to infer socio-economic attributes (Rosenthal and McKeown, 2011; Nguyen et al., 2011; Alowibdi et al., 2013; Ciot et al., 2013; Liu and Ruths, 2013; Bergsma et al., 2013; Volkova et al., 2015).

Our approach is related to the work by Eisenstein (2013a) and Doyle (2014), in that we investigate the influence of extralinguistic factors. Both of them work on Twitter and use geocoding information, whereas we focus on age and gender. Also, rather than correlating with census-level statistics, as in (Eisenstein et al., 2011; Eisenstein, 2013a; Eisenstein, to appear), we take individual information of each author into account.

Volkova et al. (2013) also explore the influence of gender and age on text-classification. They include demographic-specific features into their model and show improvements on sentiment analysis in three languages. Our work extends to more languages and three different text-classification tasks. We also use word representations trained on corpora from the various demographic groups, rather than incorporating the differences explicitly as features in our model.

Recently, Bamman et al. (2014a) have shown how regional lexical differences (i.e., *situated language*) can be learned and represented via distributed word representations (embeddings). They evaluate the conditional embeddings intrinsically, to show that the regional representatives of sports teams, parks, etc. are more closely associated with the respective hypernyms than other representatives. We also use embeddings conditioned on demographic factors (age and gender instead of location), but evaluate their effect on performance extrinsically, when used as input to an NLP system, rather than intrinsically (i.e., for discovering correlations between language use and demographic statistics).

Tang et al. (2014) learn embeddings for sentiment analysis by splitting up their data by rating.

We follow their methodology in using embeddings to represent variable length inputs for classification.

The experiments on author attribute identification are inspired by a host of previous work (Rosenthal and McKeown, 2011; Nguyen et al., 2011; Alowibdi et al., 2013; Ciot et al., 2013; Liu and Ruths, 2013; Volkova et al., 2015, inter alia). The main difference is that we use embeddings trained on another demographic variable rather than n-gram based features, and that our goal is not to build a state-of-the-art system.

6 Discussion

The results in Section 4 have shown that incorporating information on age and gender improves performance across a host of text-classification tasks. Even though the improvements are small and vary from task to task, they hold consistently across three tasks and languages. The magnitude of the improvements could be improved by using task-specific embeddings, additional features, and more sophisticated models. This would obscure the influence of the individual factors, though.

The observed improvements are solely due to the fact that different demographic groups use language quite differently. Sociolinguistic research suggests that younger people and women tend to be more creative in their language use than men and older groups. The former are thus often the drivers of language change (Holmes, 2013; Nguyen et al., 2014). Modeling language as uniform loses these distinctions, and thus causes performance drops.

As NLP systems are increasingly used for business intelligence and decision making, systematic performance differences carry the danger of disadvantaging minority groups whose language use differs from the norm.

7 Conclusion

In this paper, we investigate the influence of age and gender on topic identification, sentiment analysis, and author attribute identification. We induce embeddings conditioned on the respective demographic variable and use those embeddings as sole input to classifiers to build both demographic-agnostic and aware models. We evaluate our models on five languages.

Our results show that the models using demographic information perform on average better than the agnostic models. The improvements are small, but consistent, and in 8/30 cases, also statistically significant at $p < 0.05$, according to bootstrap sampling tests.

The results indicate that NLP systems can improve classification performance by incorporating demographic information, where available. In most of situated texts (social media, etc.), this is the case. While the improvements vary among tasks, the results suggest that similar to domain adaptation, we should start addressing the problem of *demographic* adaptation in NLP.

Vector-space calculation of semantic surprisal for predicting word pronunciation duration

Abstract

In order to build psycholinguistic models of processing difficulty and evaluate these models against human data, we need highly accurate language models. Here we specifically consider *surprisal*, a word's predictability in context. Existing approaches have mostly used n-gram models or more sophisticated syntax-based parsing models; this largely does not account for effects specific to semantics. We build on the work by Mitchell et al. (2010) and show that the semantic prediction model suggested there can successfully predict spoken word durations in naturalistic conversational data.

An interesting finding is that the training data for the semantic model also plays a strong role: the model trained on in-domain data, even though a better language model for our data, is not able to predict word durations, while the out-of-domain trained language model does predict word durations. We argue that this at first counter-intuitive result is due to the out-of-domain model better matching the "language models" of the speakers in our data.

1 Introduction

The Uniform Information Density (UID) hypothesis holds that speakers tend to maintain a relatively constant rate of information transfer during speech production (e.g., Jurafsky et al., 2001; Aylett and Turk, 2006; Frank and Jaeger, 2008). The rate of information transfer is thereby quantified using as each words' *Surprisal* (Hale, 2001), that is, a word's negative log probability in context.

$$Surprisal(w_i) = -\log P(w_i|w_1..w_{i-1})$$

This work makes use of an existing measure of semantic surprisal calculated from a distributional space in order to test whether this measure accounts for an effect of UID on speech production. Our hypothesis is that a word in a semantically surprising context is pronounced with a slightly longer duration than the same word in a semantically less-expected context. In this way, a more uniform rate of information transfer is achieved, because the higher information content of the unexpected word is stretched over a slightly longer time. To our knowledge, the use of this form of surprisal as a pronunciation predictor has never been investigated.

The intuition is thus: in a sentence like *the sheep ate the long grass*, the word *grass* will have relatively high surprisal if the context only consists of *the long*. However, a distributional representation that retains the other content words in the sentence, thus representing the contextual similarity of *grass* to *sheep ate*, would able to capture the relevant context for content word prediction more easily. In the approach taken here, both types of models are combined: a standard language model is reweighted with semantic similarities in order to capture both short- and more long-distance dependency effects within the sentence.

The semantic surprisal model, a reimplementation of Mitchell (2011), uses a word vector w and a history or context vector h to calculate the language model $p(w|h)$, defining this probability in vector space via cosine similarity. Words that have a higher distributional similarity to their context are thus represented as having a higher probability than words that do not. Thus, we calculate probabilities for words in the context of a sentence in a framework of distributional semantics.

Regarding our main hypothesis—that speakers adapt their speech rate as a function of a word's information content—it is particularly important to

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 763–773,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

us to test this hypothesis on fully "natural" conversational data. Therefore, we use the AMI corpus, which contains transcripts of English-language conversations with orthographically correct transcriptions and precise word pronunciation boundaries in terms of time.

We will explain the calculation of semantic surprisal in section 4 (this is so far only described in Mitchell's 2011 PhD thesis), and then evaluate the effect of an in-domain semantic surprisal model in section 7. Next, we will compare this to the effect of an out-of-domain semantic surprisal model in section 8. The hypothesis is only confirmed for the out-of-domain model, which we argue is due to this model being more similar to the speaker's internal "model" than the in-domain model.

2 Background

2.1 Surprisal and UID

Surprisal is defined in terms of the negative logarithm of the probability of a word in context: $S(w) = -\log P(w|context)$, where $P(w|context)$ is the probability of a word given its previous (linguistic) context. It is a measure of information content in which a high surprisal implies low predictability. The use of surprisal in psycholinguistic research goes back to Hale (2001), who used a probabilistic Earley Parser to model the difficulty in parsing so-called garden path sentences (e.g. "The horse raced past the barn fell"), wherein the unexpectedness of an upcoming word or structure influences the language processor's difficulty. Recent work in psycholinguistics has provided increasing support (e.g., Levy (2008); Demberg and Keller (2008); Smith and Levy (2013); Frank et al. (2013)) for the hypothesis that the surprisal of a word is proportional to the processing difficulty (measured in terms of reading times and EEG event-related potentials) it causes to a human.

The Uniform Information Density (UID) hypothesis (Frank and Jaeger, 2008) holds that speakers tend distribute information uniformly across an utterance (in the limits of grammaticality). Information density is quantified in terms of the surprisal of each word (or other linguistic unit) in the utterance. These notions go back to Shannon (1948), who showed that conveying information uniformly close to channel capacity is optimal for communication through a (noisy) communication channel.

Frank and Jaeger (2008) investigated UID effects in the SWITCHBOARD corpus at a morphosyntactic level wherein speakers avoid using English contracted forms ("you are" vs. "you're") when the contractible phrase is also transmitting a high degree of information in context. In this case, n-gram surprisal was used as the information density measure. Related hypotheses have been suggested by Jurafsky et al. (2001), who related speech durations to bigram probabilities on the Switchboard corpus, and Aylett and Turk (2006), who investigated information density effects at the syllable level. They used a read-aloud English speech synthesis corpus, and they found that there is an inverse relationship between the pronunciation duration and the N-gram predictability. Demberg et al. (2012) also use the AMI corpus used in this work, and show that syntactic surprisal (i.e., the surprisal estimated from Roark's (2009) PCFG parser) can predict word durations in natural speech.

Our work expands upon the existing efforts in demonstrating the UID hypothesis by applying surprisal to the level of lexical semantics.

2.2 Distributional semantics

Given a means of evaluating the similarity of linguistic units (e.g., words, sentences, texts) in some numerical space that represents the contexts in which they appear, it is possible to approximate the semantics in distributional terms. This is usually done by collecting statistics from a corpus using techniques developed for information retrieval. Using these statistics as a model of semantics is justified in terms of the "distributional hypothesis", which holds that words used in similar contexts have similar meanings (Harris, 1954).

A simple and widely-used type of distributional semantic model is the vector space model (Turney and Pantel, 2010). In such a model, all words are represented each in terms of vectors in a single high-dimensional space. The semantic similarity of words can then be calculated via the cosine of the angle between the vectors in this manner: $\cos(\varphi) = \frac{\vec{a} \cdot \vec{b}}{|\vec{a}||\vec{b}|}$. Closed-class function words are usually excluded from this calculation. Until relatively recently (Erk, 2012), distributional semantic models did not take into account the fine-grained details of syntactic and semantic structure construed in formal terms.

3 Corpus

The AMI Meeting Corpus (Carletta, 2007) is a multimodal English-language corpus. It contains videos and transcripts of simulated workgroup meetings accompanied by various kinds of annotations. The corpus is available along with its annotations under a free license[1].

Two-thirds of the videos contain simulated meetings of 4-person design teams assigned to talk about the development of a fictional television remote control. The remaining meetings discuss various other topics. The majority of speakers were non-native speakers of English, although all the conversations were held in English. The corpus contains about 100 hours of material.

An important characteristic of this corpus for our work is that the transcripts make use of consistent English orthography (as opposed to being phonetic transcripts). This enables the use of natural language processing techniques that require the reliable identification of words. Grammatical errors, however, remain in the corpus. The corpus includes other annotations such as gesture and dialog acts. Most important for our work are the time spans of word pronunciation, which are precise to the hundredth of a second.

We removed interjections, incomplete words, and transcriptions that were still misspelled from the corpus, and we took out all incomplete sentences. This left 951,769 tokens (15,403 types) remaining in the corpus.

4 Semantic surprisal model

We make use of a re-implementation of the semantic surprisal model presented in Mitchell et al. (2010). As this paper does not provide a detailed description of how to calculate semantic surprisal, our re-implementation is based on the description in Mitchell's PhD thesis (2011).

In order to calculate surprisal, we need to be able to obtain a good estimate of a word given previous context. Mitchell uses the following concepts in his model:

- h_{n-1} is the *history* and represents all the previous words in the sentence. If w_n is the current word, then $h_{n-1} = w_1 \dots w_{n-1}$. The vector-space semantic representation of h_{n-1} is calculated from the composition of individual word vectors, which we call $\vec{h}_{n-1}$.
- *context words* represent the dimensions of the word vectors. The value of a word vector's component is the co-occurrence of that word with a context word. The context words consist of the most frequent words in the corpus.
- we use *word class* and distinguish between content words and function words, for which we use open and closed classes as a proxy.

4.1 Computing the vector components

The proportion between two probabilities $\frac{p(c_i|w)}{p(c_i)}$ is used for calculating vector components, where c_i is the ith context dimension and w is the given word in the current position. We can calculate each vector component v_i for a word vector $\vec{v}$ according to the following equation:

$$v_i = \frac{p(c_i|w)}{p(c_i)} = \frac{f_{c_i w} f_{total}}{f_w f_{c_i}} \tag{1}$$

where $f_{c_i w}$ is the cooccurrence frequency of w and c_i together, f_{total} is the total corpus size, and c_i represents the unigram frequencies of w. All future steps in calculating our language model rely on this definition of v_i.

4.2 Semantic probabilities

For the goal of computing $p(w|h)$, we use the basic idea that the more "semantically coherent" a word is with its history, the more likely it is. Cosine similarity is a common way to define this similarity mathematically in a distributional space, producing a value in the interval $[-1, 1]$. We use the following definitions, wherein φ is the angle between $\vec{w}$ and $\vec{h}$:

$$\cos(\varphi) = \frac{\vec{w} \cdot \vec{h}}{|\vec{w}||\vec{h}|} \tag{2}$$

$$\vec{w} \cdot \vec{h} = \sum_i w_i h_i \tag{3}$$

Mitchell notes that there are at least three problems with using cosine similarity in connection with the construction of a probabilistic model: (a) the sum of all cosine values is not unity, (b) word frequency does not pay a role in the calculation, such that a rare synonym of a frequent word might get a high similarity rating, despite low predictability, and (c) the calculation can result in negative values.

[1] http://groups.inf.ed.ac.uk/ami/download/

This problem is addressed by two changes to the notion of dot product used in the calculation of the cosine:

$$\vec{w} \cdot \vec{h} = \sum_i \frac{p(c_i|w)}{p(c_i)} \frac{p(c_i|h)}{p(c_i)} \tag{4}$$

The influence of word frequencies is then restored using $p(w)$ and $p(c_i)$:

$$p(w|h) = p(w) \sum_i \frac{p(c_i|w)}{p(c_i)} \frac{p(c_i|h)}{p(c_i)} p(c_i) \tag{5}$$

This expression reweights the new scalar product with the likelihood of the given words and the context words. We refer the reader to Mitchell (2011) in order to see that this is a true probability. The application of Bayes' Rule allows us to rewrite the formula as $p(w|h) = \sum_i p(w|c_i)p(c_i|h)$. Nevertheless, equation (5) is better suited to our task, as it operates directly over our word vectors.

4.3 Incremental processing

Equation (5) provides a conditional probability for a word w and its history h. To calculate the product $\frac{p(c_i|w)}{p(c_i)} \frac{p(c_i|h)}{p(c_i)}$, we need the components of the vectors for w and h at the current position in the sentence. We can get $\vec{w}$ from directly from the vector space of words. However, $\vec{h}$ does not have a direct representation in that space, and it must be constructed compositionally:

$$\vec{h}_1 = \vec{w}_1 \qquad \text{Initialization} \tag{6}$$

$$\vec{h}_n = f(\vec{h}_{n-1}, \vec{w}_n) \qquad \text{Composition} \tag{7}$$

f is a vector composition function that can be chosen independently from the model. The history is initialized using the vector of the first word and combined step-by-step with the vectors of the following words. History vectors that arise from the composition step are normalized[2]:

$$h_i = \frac{\hat{h}_i}{\sum_j \hat{h}_j p(c_j)} \qquad \text{Normalization} \tag{8}$$

The equations (5), (6), (7), and (8) represent a simple language model, assuming calculation of vector components with equation (1).

4.4 Accounting for word order

The model described so far is based on semantic coherence and mostly ignores word order. Consequently, it has poor predictive power. In this section, we describe how a notion of word order is included in the model through the integration of an n-gram language model.

Specifically, equation (5) can be represented as the product of two factors:

$$p(w|h) = p(w)\Delta(w,h) \tag{9}$$

$$\Delta(w,h) = \sum_i \frac{p(c_i|w)}{p(c_i)} \frac{p(c_i|h)}{p(c_i)} p(c_i) \tag{10}$$

where Δ is the semantic component that scales $p(w)$ in function of the context. A word w that has a close semantic similarity to a history h should receive higher or lower probability depending on whether Δ is higher or lower than 1. In order to make this into a prediction, $p(w)$ is replaced with a trigram probability.

$$\hat{p}(w_n, h_{n-1}, w_{n-2}^{n-1}) = p(w_n|w_{n-2}^{n-1})\Delta(w_n, h_{n-1}) \tag{11}$$

However, this change means that the result is no longer a true probability. Instead, equation 11 can be seen as an estimate of semantic similarity. In order to restore its status as a probability, Mitchell includes another normalization step:

$$p(w_n|h_{n-3}, w_{n-2}^{n-1}) = \begin{cases} p(w_n|w_{n-2}^{n-1}) \\ \qquad \text{Function words} \\ \frac{\hat{p}(w_n, h_{n-3}, w_{n-2}^{n-1})}{\sum\limits_{w_c} \hat{p}(w_c, h_{n-3}, w_{n-2}^{n-1})} \\ \qquad \sum\limits_{w_c} p(w_c|w_{n-2}^{n-1}) \\ \qquad \text{Content words} \end{cases} \tag{12}$$

The model hence simply uses the trigram model probability for function words, making the assumption that the distributional representation of such words does not include useful information. On the other hand, content words obtain a portion of the probability mass whose size depends on its similarity estimate $\hat{p}(w_n, h_{n-3}, w_{n-2}^{n-1})$ relative to the similarity estimates of all other words $\sum_{w_c} \hat{p}(w_c, h_{n-3}, w_{n-2}^{n-1})$. The factor $\sum_{w_c} p(w_c|w_{n-2}^{n-1})$ ensures that not all of the probability mass is divided up among the content words w_c; rather, only the mass assigned by the n-gram model at position w_{n-2}^{n-1} is re-distributed. The

[2] This equation is slightly different from what appears in Mitchell (2011). We present here a corrected formula based on private communication with the author.

probability mass of the function words remains unchanged.

Mitchell (2011) restricts the history so that only words outside the trigram window are taken into account in order to keep the n-gram model and the semantic similarity model independent. Thus, the n-gram model represents local dependencies, and the semantic model represents longer-distance dependencies.

The final model that we use in our experiment consists of equations (1), (6), (7), (8) and (12).

5 Evaluation Methods

Our goal is to test whether semantically reweighted surprisal can explain spoken word durations over and above more simple factors that are known to influence word durations, such as word length, frequency and predictability using a simpler language model. Our first experiment tests whether semantic surprisal based on a model trained using in-domain data is predictive of word pronunciation duration, considering the UID hypothesis. For our in-domain model, we estimate surprisal using 10-fold cross-validation over the AMI corpus: we divide the corpus into ten equally-sized segments and produce surprisal values for each word in each segment based on a model trained from the other nine segments. We then use linear mixed effects modeling (LME) via the lme4 package in R (Pinheiro and Bates, 2000; Bates et al., 2014) in order to account for word pronunciation length. We follow the approach of Demberg et al. (2012).

Linear mixed effects modelling is a generalization of linear regression modeling and includes both fixed effects and random effects. This is particularly useful when we have a statistical units (e.g., speakers) each with their own set of repeated measures (e.g., word duration), but each such unit has its own particular characteristics (e.g., some speakers naturally speak more slowly than others). These are the random effects. The fixed effects are those characteristics that are expected not to vary across such units. LME modeling learns coefficients for all of the predictors, defining a regression equation that should account for the data in the dependent variable (in our case, word pronunciation duration). The variance in the data that a model cannot explain is referred to as the residual. We denote statistical significances in the following way: *** means a p-value ≤ 0.001, ** means p $\leq$ 0.01, * means p ≤ 0.05, and no stars means that the predictor is not significant (p > 0.05).

In our regression models, all the variables are centered and scaled to reduce effects of correlations between predictors. Furthermore, we log-transformed the response variable (actual spoken word durations from the corpus) as well as the duration estimates from the MARY speech synthesis system to obtain more normal distributions, which are prerequisite for applying the LME models. All conclusions drawn here also hold for versions of the model where no log transformation is used.

From the AMI corpus, we filter out data points (words) that have a pronunciation duration of zero or those that are longer than two seconds, the latter in order to avoid including such things as pauses for thought. We also remove items that are not represented in Gigaword. That leaves us with 790,061 data points for further analysis. However, in our semantic model, function words are not affected by the Δ semantic similarity adjustment and are therefore not analyzable for the effect of semantically-weighted trigram predictability. That leaves 260k data points for analysis in the models.

6 Baseline model

As a first step, we estimate a baseline model which does not include the in-domain semantic surprisal. The response variable in this model are the word durations observed in the corpus. Predictor variables include D_{MARY} (the context-dependent spoken word duration as estimated by the MARY speech synthesis system), word frequency estimates from the same domain as well as the GigaWord corpus (F_{AMI} and F_{Giga}, both as log relative frequencies), the interaction between estimated word durations and in-domain frequency, (D_{MARY}:F_{AMI}) and a domain-general trigram model ($S_{\text{AMI-3}}$). Our model also includes a random intercept for each speaker, as well as random slopes under speaker for D_{MARY} and $S_{\text{AMI-3}}$. The baseline model is shown in Table 1.

All predictors in the baseline model shown in Table 1 significantly improve model fit. We can see that the MARY-TTS estimated word durations are a positive highly significant predictor in the model. Furthermore, the word frequency estimates from the domain general corpus as well as the in-domain frequency estimates are significant negative predictors of word durations, this means

Predictor	Coefficient	t-value	Sig.
(Intercept)	0.034	4.90	***
D_{MARY}	0.427	143.97	***
F_{AMI}	-0.137	-60.26	***
F_{Giga}	-0.051	-18.92	***
$S_{\text{Giga-3gram}}$	0.032	10.94	***
D_{MARY}:F_{AMI}	-0.003	-2.12	*

Table 1: Fixed effects of a baseline model including the data points for which we could calculate semantic surprisal.

that as expected, words durations are shorter for more frequent words. We can furthermore see that n-gram surprisal is a significant positive predictor of spoken word durations; i.e., more unexpected words have longer durations than otherwise predicted. Finally, there is also a significant interaction between estimated word durations and in-domain word frequency, which means that the duration of long and frequent words is corrected slightly downward.

7 Experiment 1: in-domain model

The AMI corpus contains spoken conversations, and is thus quite different from the written corpora we have available. When we train an n-gram model in domain (using 10-fold cross validation), perplexities for the in-domain model (67.9) are much lower than for a language model trained on gigaword (359.7), showing that the in-domain model is a better language model for the data[3].

In order to see the effect of semantic surprisal estimated based on the in-domain language model and reweighted for semantic similarity within the same sentence as described in Section 3, we then expand the baseline model, adding $S_{\text{Semantics}}$ as a predictor. Table 2 shows the fixed effects of this expanded model. The predictor for semantic surprisal is significant, but the coefficient is negative. This apparently contradicts our hypothesis that semantic surprisal has a UID effect on pronunciation duration, so that higher $S_{\text{Semantics}}$ means higher D_{AMI}. We found that these results are very stable—in particular, the same results also hold if we estimate a separate model with $S_{\text{Semantics}}$ as a predictor and residuals of the baseline model as a response variable, and when we include in-domain semantic surprisal in a model where there ngram surprisal on the out of domain corpus is not included as a predictor variable.

Predictor	Coefficient	t-value	Sig.
(Intercept)	0.031	4.53	**
D_{MARY}	0.428	144.06	***
F_{AMI}	-0.148	-59.15	***
F_{Giga}	-0.043	-15.10	***
$S_{\text{Giga-3gram}}$	0.047	14.60	***
$S_{\text{Semantics}}$	-0.028	-9.78	***
D_{MARY}:F_{AMI}	-0.003	-2.27	*

Table 2: Fixed effects of the baseline model with semantic surprisal (including also a random slope for semantic surprisal under subject).

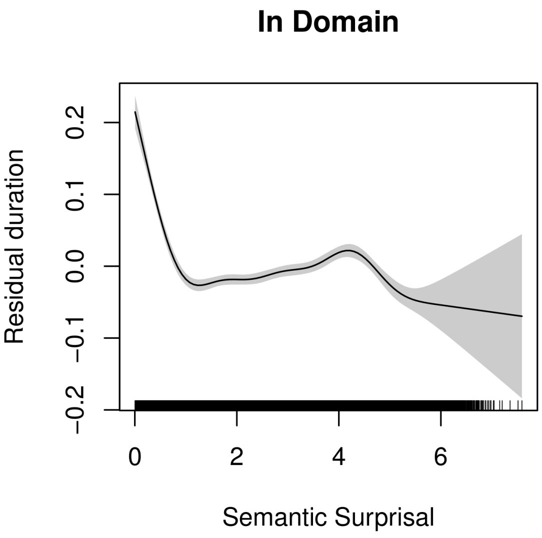

Figure 1: GAM-calculated spline for $S_{\text{Semantics}}$ for the in-domain model.

In order to understand the unexpected behaviour of $S_{\text{Semantics}}$, we make use of a generalized additive model (GAM) with the R package mgcv. Compared to LME models, GAMs are parameter-free and do not assume a linear form of the predictors. Instead, for every predictor, GAMs can fit a spline. We learn a GAM using the residuals of the baseline model as a response variable and fitting semantic surprisal based on the in-domain model; see Table 2.

In figure 1, we see that $S_{\text{Semantics}}$ is poorly fit by a linear function. In particular, there are two intervals in the curve. Between surprisal values 0

[3] Low perplexity estimates are reflective of the spoken conversational domain. Perplexities on content words are much higher: 357.3 for the in-domain model and 2169.8 for the out of domain model.

and 1.5, the curve falls, but between 1.5 and 4, it rises. (For high surprisal values, there are too few data points from which to draw conclusions.)

Therefore, we decided to divide the data up into datapoints with $\mathrm{S}_{\mathrm{Semantics}}$ above 1.5 and below 1.5. We then modelled the effect of $\mathrm{S}_{\mathrm{Semantics}}$ on the residuals of the baseline model, with $\mathrm{S}_{\mathrm{Semantics}}$ as a random effect. This is to remove a possible effect of collinearity between $\mathrm{S}_{\mathrm{Semantics}}$ and the other predictors.

Interval of $\mathrm{S}_{\mathrm{Semantics}}$	Predictor	Coef.	t-value	Sig.
$[0, \infty[$	(Intercept)	0	0	
	$\mathrm{S}_{\mathrm{Semantics}}$	-0.013	-7.01	***

	$\mathrm{S}_{\mathrm{Semantics}}$	0.013	5.50	***

Table 3: Three models of $\mathrm{S}_{\mathrm{Semantics}}$ as a random effect over the residuals of baseline models learned from the remaining fixed effects. The first model is over the entire range.

Table 3 shows that the random effect of semantic surprisal is positive and significant in the range of semantic surprisal above 1.5. That low surprisals have the opposite effect compared to what we expect suggests to us that using the AMI corpus as an in-domain source of training data presents a problem. The observed result for the relationship between semantic surprisal and spoken word durations does not only hold for the semantic surprisal model, but also for the standard non-weight-adjusted in-domain trigram model. We therefore hypothesize that our semantic surprisal model is producing surprisal values that are low because they are common in this domain (both higher frequency and higher similarities), but speakers are coming to the AMI task with "models" trained on out-of-domain data. Thus, words that are apparently very low-surprisal display longer pronunciation durations as an artifact of the model. To test this, we conducted a second experiment, for which we built a model with out-of-domain data.

8 Experiment 2: out-of-domain training

In order to test for the effect of possible underestimation of surprisal due to in-domain training, we also tested the semantic surprisal model when trained on more domain-general text. As training data for our semantic model, we use a randomly selected 1% (by sentence) of the English Gigaword 5.0 corpus. This is lowercased, with hapax legomena treated as unknown words. We test the model against the entire AMI corpus. Furthermore, we also compare our semantic surprisal values to the syntactic surprisal values calculated by Demberg et al. (2012) for the AMI corpus, which we obtained from the authors. As noted above, the out-of-domain language model has higher perplexity on the AMI corpus—that is, it is a lower-performing language model. On the other hand, it may represent overall speaker experience more accurately than the in-domain model; in other words, it may be a better model of the speaker.

8.1 Results

Once again, the semantic surprisal model is only different from a general n-gram model on content words. We therefore first compare whether the model that is reweighted for semantic surprisal can explain more of the variance than the same model without semantic reweighting.

We again use the same baseline model as for the in-domain experiment, see table 1. As the semantic surprisal model represents a reweighted trigram model, there is a high correlation between the trigram model and the semantic surprisal model. We thus need to know whether the semantically reweighted model is **better** than the simple trigram model. When we compare a model that contains both trigram surprisal and semantic surprisal as a predictor, we find that this model is significantly better than the model including only trigram surprisal (AIC of baseline model: 618427; AIC of model with semantic surprisal: 618394; $\chi^2 = 35.8; p < 0.00001$). On the other hand, the model including both predictors is only marginally better than the model including semantic surprsial (AIC of semantic surprisal model: 618398). This means that the simpler trigram surprisal model does not contribute anything over the semantic model, and that the semantic model fits the word duration data better. Table 4 shows the model with semantic surprisal as a predictor.

Furthermore, we wanted to check whether our hypothesis about the negative result for the in-domain model was indeed due to an under-estimation of surprisal of in-domain words for the

in-domain model. We again calculate a GAM model showing the effect of out-of-domain semantic surprisal in a model containing also the baseline predictors, see figure 2.

We can see that word durations increase with increasing semantic surprisal, and that there is in particular no effect of longer word durations for low surprisal words. This result is also confirmed by LME models splitting up the data in small and large surprisal values, as done for the in-domain model in Table 3; semantic surprisal based on the out-of-domain model is a significant positive predictor in both data ranges.

Table 5: Linear mixed effects model for spoken word durations in the AMI corpus, for a model including both syntactic and semantic surprisal as a predictor as well as a random intercept and slope for D_{MARY} and $\text{S}_{\text{Semantics}}$ under speaker.

Next, we tested whether the semantic similarity model improves model fit over and above a model also containing syntactic surprisal as a predictor. We find that syntactic surprisal improves model fit over and above the model including semantic surprisal ($\chi^2 = 309.5; p < 0.00001$), and that semantic surprisal improves model fit over and above a model including syntactic surprisal and trigram surprisal ($\chi^2 = 28.5; p < 0.00001$). Table 5 shows the model containing both syntactic based on the Roark parser ((Roark et al., 2009); see also Demberg et al. (2012) for use of syntactic surprisal for estimating spoken word durations) and semantic surprisal.

Finally, we split our dataset into data from native and non-native speakers of English (305 native speakers, vs. 376 non-native speakers). Table 6 shows generally larger effects for native than non-native speakers. In particular, the interaction between duration estimates and word frequencies, and semantic surprisal were not significant predictors in the non-native speaker model (however, random slopes for semantic surprisal under speaker still improved model fit very strongly, showing that non-native speakers differ in whether and how they take into account semantic surprisal during language production).

9 Discussion

Our analysis shows that high information density at one linguistic level of description (for example, syntax or semantics) can lead to a compensatory effect at a different linguistic level (here, spoken word durations). Our data also shows however, that the choice of training data for the models is important. A language model trained exclusively in a specific domain, while a good language model, may not be representative of speaker's overall language experience. This is particularly relevant for the AMI corpus, in which groups of

researchers are discussing the design of a remote control, but where it is not necessarily the case that these people discuss remote controls very frequently. Furthermore, none of the speakers were present in the whole corpus, and most of the > 600 speakers participated only in very few meetings. This means that the in-domain language model strongly over-estimates people's familiarity with the domain.

Words that are highly predictable for the in-domain model (but which are not highly predictable in general) were not pronounced faster, as evident in our first analysis. When semantic surprisal is however estimated based on a more domain-general text like Gigaword, we find a significant positive effect of semantic surprisal on spoken word durations across the complete spectrum from very predictable to unpredictable words.

These results also point to an interesting scientific question: to what extent to people use their domain-general model for adapting their language and speech production in a specific situation, and to what extent do they use a domain-specific model for adaptation? Do people adapt during a conversation, such that in-domain models would be more relevant for language production in situations where speakers are more versed in the domain?

10 Conclusions and future work

We have described a method by which it is possible to connect a semantic level of representation (estimated using a distributional model) to observations about speech patterns at the word level. From a language science or psycholinguistic perspective, we have shown that semantic surprisal affects spoken word durations in natural conversational speech, thus providing additional supportive evidence for the uniform information density hypothesis. In particular, we find evidence that UID effects connect linguistic levels of representation, providing more information about the architecture of the human processor or generator.

This work also has implications for designers of speech synthesis systems: our results point towards using high-level information about the rate of information transfer measured in terms of surprisal for estimating word durations in order to make artificial word pronunciation systems sound more natural.

Finally, the strong effect of training data domain raises scientific questions about how speakers use domain-general and -specific knowledge in communicative cooperation with listeners at the word pronunciation level.

One possible next step would be to expand this work to more complex semantic spaces which include stronger notions of compositionality, semantic roles, and so on, such as the distributional approaches of Baroni and Lenci (2010), Sayeed and Demberg (2014), and Greenberg et al. (2015) that contain grammatical information but rely on vector operations.

Efficient Methods for Inferring Large Sparse Topic Hierarchies

Doug Downey, Chandra Sekhar Bhagavatula, Yi Yang

Abstract

Latent variable topic models such as Latent Dirichlet Allocation (LDA) can discover topics from text in an unsupervised fashion. However, scaling the models up to the many distinct topics exhibited in modern corpora is challenging. "Flat" topic models like LDA have difficulty modeling sparsely expressed topics, and richer hierarchical models become computationally intractable as the number of topics increases.

In this paper, we introduce efficient methods for inferring large topic hierarchies. Our approach is built upon the Sparse Backoff Tree (SBT), a new prior for latent topic distributions that organizes the latent topics as leaves in a tree. We show how a document model based on SBTs can effectively infer accurate topic spaces of over a million topics. We introduce a collapsed sampler for the model that exploits sparsity and the tree structure in order to make inference efficient. In experiments with multiple data sets, we show that scaling to large topic spaces results in much more accurate models, and that SBT document models make use of large topic spaces more effectively than flat LDA.

1 Introduction

Latent variable topic models, such as Latent Dirichlet Allocation (Blei et al., 2003), are popular approaches for automatically discovering topics in document collections. However, learning models that capture the large numbers of distinct topics expressed in today's corpora is challenging. While efficient methods for learning large topic models have been developed (Li et al., 2014; Yao et al., 2009; Porteous et al., 2008), these methods have focused on "flat" topic models such as LDA. Flat topic models over large topic spaces are prone to overfitting: even in a Web-scale corpus, some words are expressed rarely, and many documents are brief. Inferring a large topic distribution for each word and document given such sparse data is challenging. As a result, LDA models in practice tend to consider a few thousand topics at most, even when training on billions of words (Mimno et al., 2012).

A promising alternative to flat topic models is found in recent *hierarchical* topic models (Paisley et al., 2015; Blei et al., 2010; Li and McCallum, 2006; Wang et al., 2013; Kim et al., 2013; Ahmed et al., 2013). Topics of words and documents can be naturally arranged into hierarchies. For example, an article on the topic of the *Chicago Bulls* is also relevant to the more general topics of *NBA*, *Basketball*, and *Sports*. Hierarchies can combat data sparsity: if data is too sparse to place the term "Pau Gasol" within the Chicago Bulls topic, perhaps it can be appropriately modeled at somewhat less precision within the Basketball topic. A hierarchical model can make fine-grained distinctions where data is plentiful, and back-off to more coarse-grained distinctions where data is sparse. However, current hierarchical models are hindered by computational complexity. The existing inference methods for the models have runtimes that increase at least linearly with the number of topics, making them intractable on large corpora with large numbers of topics.

In this paper, we present a hierarchical topic model that can scale to large numbers of distinct topics. Our approach is built upon a new prior for latent topic distributions called a Sparse Backoff Tree (SBT). SBTs organize the latent topics as leaves in a tree, and smooth the distributions for each topic with those of similar topics nearby in the tree. SBT priors use absolute discounting and learned backoff distributions for

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 774–784,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

smoothing sparse observation counts, rather than the fixed additive discounting utilized in Dirichlet and Chinese Restaurant Process models. We show how the SBT's characteristics enable a novel collapsed sampler that exploits the tree structure for efficiency, allowing SBT-based document models (SBTDMs) that scale to hierarchies of over a million topics.

We perform experiments in text modeling and hyperlink prediction, and find that SBTDM is more accurate compared to LDA and the recent nested Hierarchical Dirichlet Process (nHDP) (Paisley et al., 2015). For example, SBTDMs with a hundred thousand topics achieve perplexities 28-52% lower when compared with a standard LDA configuration using 1,000 topics. We verify that the empirical time complexity of inference in SBTDM increases sub-linearly in the number of topics, and show that for large topic spaces SBTDM is more than an order of magnitude more efficient than the hierarchical Pachinko Allocation Model (Mimno et al., 2007) and nHDP. Lastly, we release an implementation of SBTDM as open-source software.[1]

2 Previous Work

The intuition in SBTDM that topics are naturally arranged in hierarchies also underlies several other models from previous work. Paisley et al. (2015) introduce the nested Hierarchical Dirichlet Process (nHDP), which is a tree-structured generative model of text that generalizes the nested Chinese Restaurant Process (nCRP) (Blei et al., 2010). Both the nCRP and nHDP model the tree structure as a random variable, defined over a flexible (potentially infinite in number) topic space. However, in practice the infinite models are truncated to a maximal size. We show in our experiments that SBTDM can scale to larger topic spaces and achieve greater accuracy than nHDP. To our knowledge, our work is the first to demonstrate a hierarchical topic model that scales to more than one million topics, and to show that the larger models are often much more accurate than smaller models. Similarly, compared to other recent hierarchical models of text and other data (Petinot et al., 2011; Wang et al., 2013; Kim et al., 2013; Ahmed et al., 2013; Ho et al., 2010), our focus is on scaling to larger data sets and topic spaces.

The Pachinko Allocation Model (PAM) introduced by Li & McCallum (Li and McCallum, 2006) is a general approach for modeling correlations among topic variables in latent variable models. Hierarchical organizations of topics, as in SBT, can be considered as a special case of a PAM, in which inference is particularly efficient. We show that our model is much more efficient than an existing PAM topic modeling implementation in Section 5.

Hu and Boyd-Graber (2012) present a method for augmenting a topic model with known hierarchical correlations between words (taken from e.g. WordNet synsets). By contrast, our focus is on automatically learning a hierarchical organization of topics from data, and we demonstrate that this technique improves accuracy over LDA. Lastly, SparseLDA (Yao et al., 2009) is a method that improves the efficiency of inference in LDA by only generating portions of the sampling distribution when necessary. Our collapsed sampler for SBTDM utilizes a related intuition at each level of the tree in order to enable fast inference.

3 Sparse Backoff Trees

In this section, we introduce the Sparse Backoff Tree, which is a prior for a multinomial distribution over a latent variable. We begin with an example showing how an SBT transforms a set of observation counts into a probability distribution. Consider a latent variable topic model of text documents, similar to LDA (Blei et al., 2003) or pLSI (Hofmann, 1999). In the model, each token in a document is generated by first sampling a discrete latent topic variable Z from a document-specific topic distribution, and then sampling the token's word type from a multinomial conditioned on Z.

We will focus on the document's distribution over topics, ignoring the details of the word types for illustration. We consider a model with 12 latent topics, denoted as integers from the set $\{1, \ldots, 12\}$. Assume we have assigned latent topic values to five tokens in the document, specifically the topics $\{1, 4, 4, 5, 12\}$. We indicate the number of times topic value z has been selected as n_z (Figure 1).

Given the five observations, the key question faced by the model is: what is the topic distribution over a sixth topic variable from the same document? In the case of the Dirichlet prior utilized for the topic distribution in LDA, the probability

Figure 1: An example Sparse Backoff Tree over 12 latent variable values.

that the sixth topic variable has value z is proportional to $n_z + \alpha$, where α is a hyperparameter of the model.

SBT differs from LDA in that it organizes the topics into a tree structure in which the topics are leaves (see Figure 1). In this paper, we assume the tree structure, like the number of latent topics, is manually selected in advance. With an SBT prior, the estimate of the probability of a topic z is increased when nearby topics in the tree have positive counts. Each interior node a of the SBT has a *discount* δ_a associated with it. The SBT transforms the observation counts n_z into pseudo-counts (shown in the last row in the figure) by subtracting δ_a from each non-zero descendent of each interior node a, and re-distributing the subtracted value uniformly among the descendants of a. For example, the first state has a total of 0.90 subtracted from its initial count $n_1 = 1$, and then receives $0.30/3$ from its parent, $1.08/6$ from its grandparent, and $0.96/12$ from the root node for a total pseudo-count of 0.46. The document's distribution over a sixth topic variable is then proportional to these pseudo-counts.

When each document tends to discuss a set of related topics, the SBT prior will assign a higher likelihood to the data when related topics are located nearby in the tree. Thus, by inferring latent variable values to maximize likelihood, nearby leaves in the tree will come to represent related topics. SBT, unlike LDA, encodes the intuition that a topic becomes more likely in a document that also discusses other, related topics. In the example, the pseudo-count the SBT produces for topic six (which is related to other topics that occur in the document) is almost three times larger than that of topic eight, even though the observation counts are zero in each case. In LDA, topics six and eight would have equal pseudo-counts (proportional to α).

3.1 Definitions

Let Z be a discrete random variable that takes integer values in the set $\{1, \ldots, L\}$. Z is drawn from a multinomial parameterized by a vector θ of length L.

Definition 1 *A Sparse Backoff Tree $SBT(\mathcal{T}, \delta^\theta, Q(z))$ for the discrete random variable Z consists of a rooted tree $\mathcal{T}$ containing L leaves, one for each value of Z; a coefficient $\delta_a > 0$ for each interior node* a *of $\mathcal{T}$; and a backoff distribution $Q(z)$.*

Figure 1 shows an example SBT. The example includes simplifications we also utilize in our experiments, namely that all nodes at a given depth in the tree have the same number of children and the same δ value. However, the inference techniques we present in Section 4 are applicable to any tree $\mathcal{T}$ and set of coefficients $\{\delta_a\}$.

For a given SBT S, let $\Delta_S(z)$ indicate the sum of all δ_a values for all ancestors a of leaf node z (i.e., all interior nodes on the path from the root to z). For example, in the figure, $\Delta_S(z) = 0.90$ for all z. This amount is the total absolute discount that the SBT applies to the random variable value z.

We define the SBT prior implicitly in terms of the posterior distribution it induces on a random variable Z drawn from a multinomial θ with an SBT prior, after θ is integrated out. Let the vector $\mathbf{n} = [n_1, \ldots, n_L]$ denote the sufficient statistics for any given observations drawn from θ, where n_z is the number of times value z has been observed. Then, the distribution over a subsequent draw of Z

given SBT prior S and observations $\mathbf{n}$ is defined as:

$$P(Z=z|S,\mathbf{n}) \equiv \frac{\max(n_z - \Delta_S(z), 0) + B(S,z,\mathbf{n})Q(z)}{K(S, \sum_i n_i)} \tag{1}$$

where $K(S, \sum_i n_i)$ is a normalizing constant that ensures the distribution sums to one for any fixed number of observations $\sum_i n_i$, and $B(S,z,\mathbf{n})$ and $Q(z)$ are defined as below.

The quantity $B(S,z,\mathbf{n})$ expresses how much of the discounts from all other leaves z' contribute to the probability of z. For an interior node a, let $desc(a)$ indicate the number of leaves that are descendants of a, and let $desc^+(a)$ indicate the number of leaf descendants z of a that have non-zero values n_z. Then the contribution of the discount δ_a of node a to *each* of its descendent leaves is $b(a,\mathbf{n}) = \delta_a desc^+(a)/desc(a)$. We then define $B(S,z,\mathbf{n})$ to be the sum of $b(a,\mathbf{n})$ over all interior nodes a on the path from the root to z.

The function $Q(z)$ is a *backoff distribution*. It allows the portion of the discount probability mass that is allocated to z to vary with a proposed distribution $Q(z)$. This is useful because in practice the SBT is used as a prior for a conditional distribution, for example the distribution $P(Z|w)$ over topic Z given a word w in a topic model of text. In that case, an estimate of $P(Z|w)$ for a rare word w may be improved by "mixing in" the marginal topic distribution $Q(z) = P(Z=z)$, analogous to backoff techniques in language modeling. Our document model described in the following section utilizes two different Q functions, one uniform ($Q(z) = 1/T$) and another related to the marginal topic distribution $P(z)$.

4 The SBT Document Model

We now present the SBT document model, a probabilistic latent variable model of text documents that utilizes SBT priors. We then provide a collapsed sampler for the model that exploits the tree structure to make inference more efficient.

Our document model follows the Latent Dirichlet Allocation (LDA) Model (Blei et al., 2003), illustrated graphically in Figure 2 (left). In LDA, a corpus of documents is generated by sampling a topic distribution θ_d for each document d, and also a distribution over words ϕ_z for each topic. Then, in document d each token w is generated by first sampling a topic z from the multinomial $P(Z|\theta_d)$, and then sampling w from the multinomial $P(W|Z,\phi_z)$.

The SBTDM is the same as LDA, with one significant difference. In LDA, the parameters θ and ϕ are sampled from two Dirichlet priors, with separate hyperparameters α and β. In SBTDM, the parameters are instead sampled from particular SBT priors. Specifically, the generative model is:

$$\begin{aligned}
\theta &\sim SBT(\mathcal{T}, \delta^\theta, Q_\theta(z) = 1/T) \\
\phi' &\sim SBT(\mathcal{T}, \delta^\phi, Q_\phi(z) = P^*(z)) \\
\lambda &\sim \text{Dirichlet}(\alpha') \\
Z|\theta &\sim \text{Discrete}(\theta) \\
W|z,\phi',\lambda &\sim \text{Discrete}(\lambda\phi'_{\cdot,z}/P(z|\phi'))
\end{aligned}$$

The variable ϕ' represents the distribution of topics given words, $P(Z|W)$. The SBTDM samples a distribution ϕ'_w over topics for each word type w in the vocabulary (of size V). In SBTDM, the random variable ϕ'_w has dimension L, rather than V for ϕ_z as in LDA. We also draw a prior word frequency distribution, $\lambda = \{\lambda_w\}$ for each word w. [2] We then apply Bayes Rule to obtain the conditional distributions $P(W|Z,\phi')$ required for inference. The expression $\lambda\phi'_{\cdot,z}/P(z|\phi')$ denotes the normalized element-wise product of two vectors of length V: the prior distribution λ over words, and the vector of probabilities $P(z|w) = \phi'_{w,z}$ over words w for the given topic z.

The SBT priors for ϕ' and θ share the same tree structure $\mathcal{T}$, which is fixed in advance. The SBTs have different discount factors, denoted by the hyperparameters δ^θ and δ^ϕ. Finally, the backoff distribution for θ is uniform, whereas ϕ's backoff distribution P^* is defined below.

4.1 Backoff distribution $P^*(z)$

SBTDM requires choosing a backoff distribution $P^*(z)$ for ϕ'. As we now show, it is possible to select a natural backoff distribution $P^*(z)$ that enables scalable inference.

Given a set of observations $\mathbf{n}$, we will set $P^*(z)$ proportional to $P(z|S^\phi,\mathbf{n})$. This is a recursive definition, because $P(z|S^\phi,\mathbf{n})$ depends on $P^*(z)$. Thus, we define:

$$P^*(z) \equiv \frac{\sum_w \max(n_z^w - \Delta_S(z), 0)}{C - \sum_w B_w(S^\phi, z, \mathbf{n})} \tag{2}$$

[2] The word frequency distribution does not impact the inferred topics (because words are always observed), and in our experiments we simply use maximum likelihood estimates for λ_w (i.e., setting α' to be negligibly small). Exploring other word frequency distributions is an item of future work.

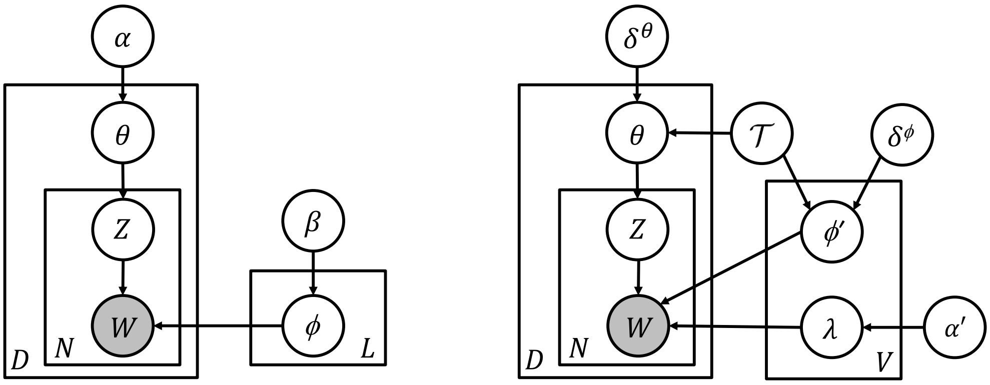

Figure 2: The Latent Dirichlet Allocation Model (left) and our SBT Document Model (right).

where $C > \sum_w B_w(S^\phi, z, \mathbf{n})$ is a hyperparameter, n_z^w is the number of observations of topic z for word w in $\mathbf{n}$, and B_w indicates the function $B(S^\phi, z, \mathbf{n})$ defined in Section 3.1, for the particular word w. That is, $\sum_w B_w(S^\phi, z, \mathbf{n})$ is the total quantity of smoothing distributed to topic z across all words, *before* the backoff distribution $P^*(z)$ is applied.

The form of $P^*(z)$ has two key advantages. The first is that setting $P^*(z)$ proportional to the marginal topic probability allows SBTDM to back-off toward marginal estimates, a successful technique in language modeling (Katz, 1987) (where it has been utilized for word probabilities, rather than topic probabilities). Secondly, setting the backoff distribution in this way allows us to simplify inference, as described below.

Algorithm 1 Compute the sampling distribution for a product of two multinomials with SBT priors with $Q(z) = 1$

```
function INTERSECT(SBT Node $a_r$, SBT Node $a_l$)
    if $a_r, a_l$ are leaves then
        $\tau(i) \leftarrow \tau(a_r)\tau(a_l)$
        return i
    end if
    $i.r \leftarrow a_r$
    $r(i) \leftarrow b(a_l) * \tau(a_r)$
    $i.l \leftarrow a_l$ ; $b(i.l) \leftarrow 0$
    $l(i) \leftarrow b(a_r) * \tau(a_l) - b(a_r)b(a_l)desc(a_r)$
    $\tau(i)+ = r(i) + l(i)$
    for all child $c$ non-zero for $a_r$ and $a_l$ do
        $i_c \leftarrow$ INTERSECT($a_r.c$, $a_l.c$)
        $i$.children += $i_c$
        $\tau(i)$ += $\tau(i_c)$
    end for
    return $i$
end function
```

4.2 Inference with Collapsed Sampling

Given a corpus of documents D, we infer the values of the hidden variables Z using the collapsed Gibbs sampler popular in Latent Dirichlet Allocation models (Griffiths and Steyvers, 2004). Each variable Z_i is sampled given the settings of all other variables (denoted as $\mathbf{n}_{-i}$):

$$P(Z_i = z|\mathbf{n}_{-i}, D) \propto P(z|\mathbf{n}_{-i}, \mathcal{T}, \delta^\theta) \cdot P(w_i|z, \mathbf{n}_{-i}, \mathcal{T}, \delta^\phi) \quad (3)$$

The first term on the right-hand side is given by Equation 1. The second can be rewritten as:

$$P(w_i|z, \mathbf{n}_{-i}, \mathcal{T}, \delta^\phi) = \frac{P(z, w_i|\mathbf{n}_{-i}, \mathcal{T}, \delta^\phi)}{P(z|\mathbf{n}_{-i}, \mathcal{T}, \delta^\phi)} \quad (4)$$

4.3 Efficient Inference Implementation

The primary computational cost when scaling to large topic spaces involves constructing the sampling distribution. Both LDA with collapsed sampling and SBTDM share an advantage in space complexity: the model parameters are specified by a sparse set of non-zero counts denoting how often tokens of each word or document are assigned to each topic. However, in general the sampling distribution for SBTDM has non-uniform probabilities for each of L different latent variable values. Thus, even if many parameters are zero, a naive approach that computes the complete sampling distribution will still take time linear in L.

However, in SBTs the sampling distribution can be constructed efficiently using a simple recursive algorithm that exploits the structure of the tree. The result is an inference algorithm that often requires far less than linear time in L, as we verify in our experiments.

First, we note that $P(z, w_i|\mathbf{n}_{-i}, \mathcal{T}, \delta^\phi)$ is proportional to the sum of two quantities: the discounted count $\max(n_z - \Delta_S, 0)$ and the smoothing probability mass $B(S, z, \mathbf{n})Q(z)$. By choosing $Q(z) = P^*(z)$, we can be ensured that $P^*(z)$ normalizes this sum. Thus, the backoff distribution cancels through the normalization. This means we can normalize the SBT for ϕ' in advance by scaling the non-zero counts by a factor of $1/P^*(z)$, and then at inference time we need only multiply pointwise two multinomials with SBT priors and *uniform* backoff distributions.

The intersection of two multinomials drawn from SBT priors with uniform backoff distributions can be performed efficiently for sparse trees. The algorithm relies on two quantities defined for each node of each tree. The first, $b(a, \mathbf{n})$, was defined in Section 3. It denotes the smoothing that the interior node a distributes (uniformly) to each of its descendent leaves. We denote $b(a, \mathbf{n})$ as $b(a)$ in this section for brevity. The second quantity, $\tau(a)$, expresses the total count mass of all leaf descendants of a, *excluding* the smoothing from ancestors of a.

With the quantities $b(a)$ and $\tau(a)$ for all a, we can efficiently compute the sampling distribution of the product of two SBT-governed multinomials (which we refer to as an SBTI). The method is shown in Algorithm 1. It takes two SBT nodes as arguments; these are corresponding nodes from two SBT priors that share the same tree structure $\mathcal{T}$. It returns an SBTI, a data structure representing the sampling distribution.

The efficiency of Algorithm 1 is reflected in the fact that the algorithm only recurses for child nodes c with non-zero $\tau(c)$ for *both* of the SBT node arguments. Because such cases will be rare for sparse trees, often Algorithm 1 only needs to traverse a small portion of the original SBTs in order to compute the sampling distribution exactly. Our experiments illustrate the efficiency of this algorithm in practice.

Finally, we can efficiently sample from either an SBTI or a single SBT-governed multinomial. The sampling methods are straightforward recursive methods, supplied in Algorithms 2 and 3.

Algorithm 2 Sample(SBT Node a)

```
procedure SAMPLE(SBT Node $a$)
    if $a$ is a leaf then return $a$
    end if
    Sample from $\{b(a)desc(a), \tau(a) - b(a)desc(a)\}$.
    if back-off distribution $b(a)desc(a)$ selected then
        return Uniform[$a$'s descendents]
    else
        Sample $a$'s child $c \sim \tau(c)$
        return SAMPLE($c$)
    end if
end procedure
```

Algorithm 3 Sampling from an SBTI

```
function SAMPLE(SBTI Node $i$)
    if $i$ is a leaf then return $i$
    end if
    Sample from $\{r(i), l(i), \tau(i) - r(i) - l(i)\}$
    if right distribution $r(i)$ selected then
        return SAMPLE($i.r$)
    else
        if left distribution $l(i)$ selected then
            return SAMPLE($i.l$)
        else
            Sample $i$'s child $c \sim \tau(c)$
            return SAMPLE($c$)
        end if
    end if
end function
```

4.4 Expansion

Much of the computational expense encountered in inference with SBTDM occurs shortly after initialization. After a slow first several sampling passes, the conditional distributions over topics for each word and document become concentrated on a sparse set of paths through the SBT. From that point forward, sampling is faster and requires much less memory.

We utilize the hierarchical organization of the topic space in SBTs to side-step this computational complexity by adding new leaves to the SBTs of a trained SBTDM. This is a "coarse-to-fine" (Petrov and Charniak, 2011) training approach that we refer to as *expansion*. Using expansion, the initial sampling passes of the larger model can be much more time and space efficient, because they leverage the already-sparse structure of the smaller trained SBTDM.

Our expansion method takes as input an inferred sampling distribution $\mathbf{n}$ for a given tree $\mathcal{T}$. The algorithm adds k new branches to each leaf of $\mathcal{T}$ to obtain a larger tree $\mathcal{T}'$. We then transform the sampling state by replacing each $n_i \in \mathbf{n}$ with one of its children in $\mathcal{T}'$. For example, in Figure 1, expanding with $k = 3$ would result in a new tree containing 36 topics, and the single observation of topic 4 in $\mathcal{T}$ would be re-assigned randomly to one of the topics $\{10, 11, 12\}$ in $\mathcal{T}'$.

5 Experiments

We now evaluate the efficiency and accuracy of SBTDM. We evaluate SBTs on two data sets, the RCV1 Reuters corpus of newswire text (Lewis et al., 2004), and a distinct data set of Wikipedia links, WPL. We consider two disjoint subsets of RCV1, a small training set (RCV1s) and a larger training set (RCV1).

We compare the accuracy and efficiency of SBTDM against flat LDA and two existing hierarchical models, the Pachinko Allocation Model (PAM) and nested Hierarchical Dirichlet Process (nHDP).

To explore how the SBT structure impacts modeling performance, we experiment with two different SBTDM configurations. **SBTDM-wide** is a shallow tree in which the branching factor increases from the root downward in the sequence $3, 6, 6, 9, 9, 12, 12$. Thus, the largest model we consider has $3 \cdot 6 \cdot 6 \cdot 9 \cdot 9 \cdot 12 \cdot 12 =$ 1,259,712 distinct latent topics. **SBTDM-tall** has lower branching factors of either 2 or 3 (so in our evaluation its depth ranges from 3 to 15). As in SBTDM-wide, in SBTDM-tall the lower branching factors occur toward the root of the tree. We vary the number of topics by considering balanced subtrees of each model. For nHDP, we use the same tree structures as in SBT-wide. In preliminary experiments, using the tall structure in nHDP yielded similar accuracy but was somewhat slower.

Similar to our LDA implementation, SBTDM optimizes hyperparameter settings as sampling proceeds. We use local beam search to choose new hyperparameters that maximize leave-one-out likelihood for the distributions $P(Z|d)$ and $P(Z|w)$ on the training data, evaluating the parameters against the current state of the sampler.

We trained all models by performing 100 sampling passes through the full training corpus (i.e., approximately 10 billion samples for RCV1, and 8 billion samples for WPL). We evaluate performance on held-out test sets of 998 documents for RCV1 (122,646 tokens), and 200 documents for WPL (84,610 tokens). We use the left-to-right algorithm (Wallach et al., 2009) over a randomized word order with 20 particles to compute perplexity. We re-optimize the LDA hyperparameters at regular intervals during sampling.

5.1 Small Corpus Experiments

We begin with experiments over a small corpus to highlight the efficiency advantages of SBTDM.

Data Set	Tokens	Vocabulary	Documents
RCV1s	2,669,093	46,130	22,149
RCV1	101,184,494	283,911	781,262
WPL	82,154,551	1,141,670	199,000

Table 1: Statistics of the three training corpora.

As argued above, existing hierarchical models require inference that becomes expensive as the topic space increases in size. We illustrate this by comparing our model with PAM and nHDP. We also compare against a fast “flat” LDA implementation, SparseLDA, from the MALLET software package (McCallum, 2002).

For SBTDM we utilize a parallel inference approach, sampling all variables using a fixed estimate of the counts $\mathbf{n}$, and then updating the counts after each full sampling pass (as in (Wang et al., 2009)). The SparseLDA and nHDP implementations are also parallel. All parallel methods use 15 threads. The PAM implementation provided in MALLET is single-threaded.

Our efficiency measurements are shown in Figure 3. We plot the mean wall-clock time to perform 100 sampling passes over the RCV1s corpus, starting from randomly initialized models (i.e. *without* expansion in SBTDM). For the largest plotted topic sizes for PAM and nHDP, we estimate total runtime using a small number of iterations. The results show that SBTDM's time to sample increases well below linear in the number of topics. Both SBTDM methods have runtimes that increase at a rate substantially below that of the square root of the number of topics (plotted as a blue line in the figure for reference). For the largest numbers of topics in the plot, when we increase the number of topics by a factor of 12, the time to sample increases by less than a factor of 1.7 for both SBT configurations.

We also evaluate the accuracy of the models on the small corpus. We do not compare against PAM, as the MALLET implementation lacks a method for computing perplexity for a PAM model. The results are shown in Table 3. The SBT models tend to achieve lower perplexity than LDA, and SBTDM-tall performs slightly better than SBTDM-wide for most topic sizes. The best model, SBT-wide with 8,748 topics, achieves perplexity 14% lower than the best LDA model and 2% lower than the best SBTDM-tall model. The LDA model overfits for the largest topic configuration, whereas at that size both SBT models remain at least as accurate as any of the LDA models in Table 3.

We also evaluated using the topic coherence measure from (Mimno et al., 2011), which reflects how well the learned topics reflect word co-occurrence statistics in the training data. Follow-

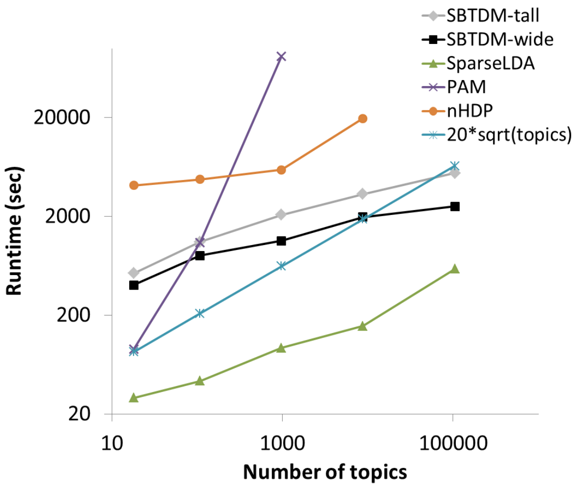

Figure 3: Time (in seconds) to perform a sampling pass over the RCV1s corpus as number of topics varies, plotted on a log-log scale. The SBT models scale sub-linearly in the number of topics.

ing recent experiments with the measure (Stevens et al., 2012), we use $\epsilon = 10^{-12}$ pseudo-co-occurrences of each word pair and we evaluate the average coherence using the top 10 words for each topic. Table 2 shows the results. PAM, LDA, and nHDP have better coherence at smaller topic sizes, but SBT maintains higher coherence as the number of topics increases.

Topics	LDA	PAM	nHDP	SBTDM -wide	SBTDM -tall
18	-420.8	-421.2	-422.9	-444.3	-440.2
108	-434.8	-430.9	-554.3	-445.4	-445.8
972	-451.2	-	-548.1	-443.3	-443.8
8748	-615.3	-	-	-444.3	-444.1

Table 2: Average topic coherence on the small RCV1s corpus.

5.1.1 Evaluating Expansion

The results discussed above do not utilize expansion in SBTDM. To evaluate expansion, we performed separate experiments in which we expanded a 972-topic model trained on RCV1s to initialize a 8,748-topic model. Compared to random initialization, expansion improved efficiency and accuracy. Inference in the expanded model executed approximately 30% faster and used 70% less memory, and the final 8,748-topic models had approximately 10% lower perplexity.

5.2 Large Corpus Results

Our large corpus experiments are reported in Table 4. Here, we compare the test set perplexity of a single model for each topic size and model type. We focus on SBTDM-tall for the large corpora. We utilize expansion (see Section 4.4) for SBTDM-tall models with more than a thousand topics on each data set. The results show that on both data sets, SBTDM-tall utilizes larger numbers of topics more effectively. On RCV1, LDA improves only marginally between 972 and 8,748 topics, whereas SBTDM-tall improves dramatically. For 8,748 topics, SBTDM-tall achieves a perplexity score 17% lower than LDA model on RCV1, and 29% lower on WPL. SBT improves even further in larger topic configurations. Training and testing LDA with our implementation using over a hundred thousand topics was not tractable on our data sets due to space complexity (the MALLET implementation exceeded our maximum 250G of heap space). As discussed above, expansion enables SBTDM to dramatically reduce space complexity for large topic spaces.

The results highlight the accuracy improvements found from utilizing larger numbers of topics than are typically used in practice. For example, an SBTDM with 104,976 topics achieves perplexity 28-52% lower when compared with a standard LDA configuration using only 1,000 topics.

	RCV1		WPL	
# Topics	LDA	SBTDM-tall	LDA	SBTDM-tall
108	**1,121**	1,148	**7,049**	7,750
972	**820**	841	2,598	**2,095**
8,748	772	**637**	1,730	**1,236**
104,976	-	593	-	1,242
1,259,712	-	626	-	-

Table 4: Model accuracy on large corpora (corpus perplexity measure). The SBT model utilizes larger numbers of topics more effectively.

5.3 Exploring the Learned Topics

Lastly, we qualitatively examine whether the SBTDM's learned topics reflect meaningful hierarchical relationships. From an SBTDM of 104,976 topics trained on the Wikipedia links data set, we examined the first 108 leaves (these are contained in a single subtree of depth 5). 760 unique terms (i.e. Wikipedia pages) had positive counts for the topics, and 500 of these terms were related to radio stations.

The leaves appear to encode fine-grained subcategorizations of the terms. In Figure 4, we provide examples from one subtree of six topics (topics 13-18). For each topic t, we list the top three

	Number of Topics				
Model	18	108	972	8,748	104,976
LDA	**1420** (16.3)	**1016** (9.8)	844 (1.8)	845 (3.3)	1058 (4.1)
nHDP	1433 (19.6)	1446 (53.3)	1583 (157.7)	-	-
SBTDM-wide	1510 (31.5)	1091 (31.8)	797 (3.5)	**723** (18.2)	844 (60.1)
SBTDM-tall	1480 (13.5)	1051 (9.1)	**787** (10.5)	736 (3.2)	**776** (14.1)

Table 3: Small training corpus (RCV1s) performance. Shown is perplexity averaged over three runs for each method and number of topics, with standard deviation in parens. Both SBTDM models achieve lower perplexity than LDA and nHDP for the larger numbers of topics.

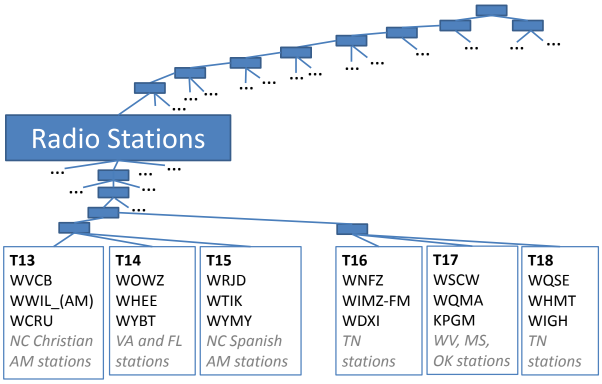

Figure 4: An example of topics from a 104,976-topic SBTDM defined over Wikipedia pages.

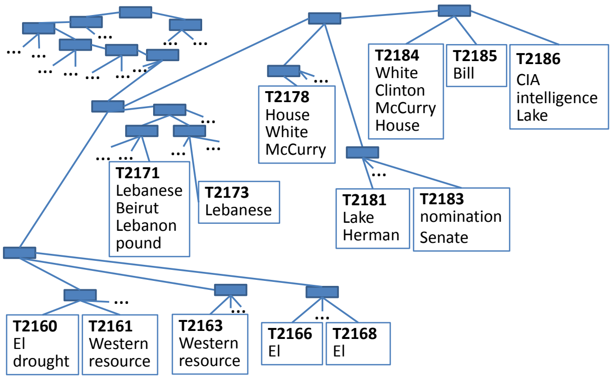

Figure 5: An example of topics from an 8,748-topic SBTDM defined over the RCV1 corpus.

terms w (ranked by symmetric conditional probability, $P(w|t)P(t|w)$), and a specific categorization that applies to the three terms. Interestingly, as shown in the figure, the top terms for the six topics we examined were all four-character "call letters" for particular radio stations. Stations with similar content or in nearby locations tend to cluster together in the tree. For example, the two topics focused on radio stations in Tennessee (TN) share the same parent, as do the topics focused on North Carolina (NC) AM stations. More generally, all six topics focus on radio stations in the southern US.

Figure 5 shows a different example, from a model trained on the RCV1 corpus. In this example, we first select only those terms that occur at least 2,000 times in the corpus and have a statistical association with their topic that exceeds a threshold, and we again rank terms by symmetric conditional probability. The 27-topic subtree detailed in the figure appears to focus on terms from major storylines in United States politics in early 1997, including El Niño, Lebanon, White House Press Secretary Mike McCarry, and the Senate confirmation hearings of CIA Director nominee Tony Lake.

6 Conclusion and Future Work

We introduced the Sparse Backoff Tree (SBT), a prior for latent topic distributions that organizes the latent topics as leaves in a tree. We presented and experimentally analyzed a document model based on the SBT, called an SBTDM. The SBTDM was shown to utilize large topic spaces more effectively than previous techniques.

There are several directions of future work. One limitation of the current work is that the SBT is defined only implicitly. We plan to investigate explicit representations of the SBT prior or related variants. Other directions include developing methods to learn the SBT structure from data, as well as applying the SBT prior to other tasks, such as sequential language modeling.

Abstract

Language modeling (LM) involves determining the joint probability of words in a sentence. The conditional approach is dominant, representing the joint probability in terms of conditionals. Examples include n-gram LMs and neural network LMs. An alternative approach, called the random field (RF) approach, is used in whole-sentence maximum entropy (WSME) LMs. Although the RF approach has potential benefits, the empirical results of previous WSME models are not satisfactory. In this paper, we revisit the RF approach for language modeling, with a number of innovations. We propose a trans-dimensional RF (TDRF) model and develop a training algorithm using joint stochastic approximation and trans-dimensional mixture sampling. We perform speech recognition experiments on Wall Street Journal data, and find that our TDRF models lead to performances as good as the recurrent neural network LMs but are computationally more efficient in computing sentence probability.

1 Introduction

Language modeling is crucial for a variety of computational linguistic applications, such as speech recognition, machine translation, handwriting recognition, information retrieval and so on. It involves determining the joint probability $p(x)$ of a sentence x, which can be denoted as a pair $x = (l, x^l)$, where l is the length and $x^l = (x_1, \ldots, x_l)$ is a sequence of l words.

Currently, the dominant approach is conditional modeling, which decomposes the joint probability of x^l into a product of conditional probabilities [1] by using the chain rule,

$$p(x_1, \ldots, x_l) = \prod_{i=1}^{l} p(x_i | x_1, \ldots, x_{i-1}). \quad (1)$$

To avoid degenerate representation of the conditionals, the history of x_i, denoted as $h_i = (x_1, \cdots, x_{i-1})$, is reduced to equivalence classes through a mapping $\phi(h_i)$ with the assumption

$$p(x_i|h_i) \approx p(x_i|\phi(h_i)). \quad (2)$$

Language modeling in this conditional approach consists of finding suitable mappings $\phi(h_i)$ and effective methods to estimate $p(x_i|\phi(h_i))$. A classic example is the traditional n-gram LMs with $\phi(h_i) = (x_{i-n+1}, \ldots, x_{i-1})$. Various smoothing techniques are used for parameter estimation (Chen and Goodman, 1999). Recently, neural network LMs, which have begun to surpass the traditional n-gram LMs, also follow the conditional modeling approach, with $\phi(h_i)$ determined by a neural network (NN), which can be either a feedforward NN (Schwenk, 2007) or a recurrent NN (Mikolov et al., 2011).

Remarkably, an alternative approach is used in whole-sentence maximum entropy (WSME) language modeling (Rosenfeld et al., 2001). Specifically, a WSME model has the form:

$$p(x; \lambda) = \frac{1}{Z} \exp\{\lambda^T f(x)\} \quad (3)$$

Here $f(x)$ is a vector of features, which can be arbitrary computable functions of x, λ is the corresponding parameter vector, and Z is the global normalization constant. Although WSME models have the potential benefits of being able to naturally express sentence-level phenomena and integrate features from a variety of knowledge

[1] And the joint probability of x is modeled as $p(x) = p(x^l)p(\langle EOS\rangle|x_l)$, where $\langle EOS\rangle$ is a special token placed at the end of every sentence. Thus the distribution of the sentence length is implicitly modeled.

sources, their performance results ever reported are not satisfactory (Rosenfeld et al., 2001; Amaya and Benedí, 2001; Ruokolainen et al., 2010).

The WSME model defined in (3) is basically a Markov random field (MRF). A substantial challenge in fitting MRFs is that evaluating the gradient of the log likelihood requires high-dimensional integration and hence is difficult even for moderately sized models (Younes, 1989), let alone the language model (3). The sampling methods previously tried for approximating the gradient are the Gibbs sampling, the Independence Metropolis-Hasting sampling and the importance sampling (Rosenfeld et al., 2001). Simple applications of these methods are hardly able to work efficiently for the complex, high-dimensional distribution such as (3), and hence the WSME models are in fact poorly fitted to the data. This is one of the reasons for the unsatisfactory results of previous WSME models.

In this paper, we propose a new language model, called the trans-dimensional random field (TDRF) model, by explicitly taking account of the empirical distributions of lengths. This formulation subsequently enables us to develop a powerful Markov chain Monte Carlo (MCMC) technique, called trans-dimensional mixture sampling and then propose an effective training algorithm in the framework of stochastic approximation (SA) (Benveniste et al., 1990; Chen, 2002). The SA algorithm involves jointly updating the model parameters and normalization constants, in conjunction with trans-dimensional MCMC sampling. Section 2 and 3 present the model definition and estimation respectively.

Furthermore, we make several additional innovations, as detailed in Section 4, to enable successful training of TDRF models. First, the diagonal elements of hessian matrix are estimated during SA iterations to rescale the gradient, which significantly improves the convergence of the SA algorithm. Second, word classing is introduced to accelerate the sampling operation and also improve the smoothing behavior of the models through sharing statistical strength between similar words. Finally, multiple CPUs are used to parallelize the training of our RF models.

In Section 5, speech recognition experiments are conducted to evaluate our TDRF LMs, compared with the traditional 4-gram LMs and the recurrent neural network LMs (RNNLMs) (Mikolov et al., 2011) which have emerged as a new state-of-art of language modeling. We explore the use of a variety of features based on word and class information in TDRF LMs. In terms of word error rates (WERs) for speech recognition, our TDRF LMs alone can outperform the KN-smoothing 4-gram LM with 9.1% relative reduction, and perform comparably to the RNNLM with a slight 0.5% relative reduction. To our knowledge, this result represents the first strong empirical evidence supporting the power of using the whole-sentence language modeling approach. Our open-source TDRF toolkit is released publicly [2].

2 Model Definition

Throughout, we denote [3] by $x^l = (x_1, \dots, x_l)$ a sentence (i.e., word sequence) of length l ranging from 1 to m. Each element of x^l corresponds to a single word. For $l = 1, \dots, m$, we assume that sentences of length l are distributed from an exponential family model:

$$p_l(x^l; \lambda) = \frac{1}{Z_l(\lambda)} e^{\lambda^T f(x^l)}, \tag{4}$$

where $f(x^l) = (f_1(x^l), f_2(x^l), \dots, f_d(x^l))^T$ is the feature vector and $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_d)^T$ is the corresponding parameter vector, and $Z_l(\lambda)$ is the normalization constant:

$$Z_l(\lambda) = \sum_{x^l} e^{\lambda^T f(x^l)} \tag{5}$$

Moreover, we assume that length l is associated with probability π_l for $l = 1, \dots, m$. Therefore, the pair (l, x^l) is jointly distributed as

$$p(l, x^l; \lambda) = \pi_l \, p_l(x^l; \lambda). \tag{6}$$

We provide several comments on the above model definition. First, by making explicit the role of lengths in model definition, it is clear that the model in (6) is a mixture of random fields on sentences of different lengths (namely on subspaces of different dimensions), and hence will be called a trans-dimensional random field (TDRF). Different from the WSME model (3), a crucial aspect of the TDRF model (6) is that the mixture weights π_l can be set to the empirical length probabilities in the training data. The WSME

[2] http://oa.ee.tsinghua.edu.cn/~ouzhijian/software.htm

[3] We add sup or subscript l, e.g. in $x^l, p_l()$, to make clear that the variables and distributions depend on length l.

model (3) is essentially also a mixture of RFs, but the mixture weights implied are proportional to the normalizing constants $Z_l(\lambda)$:

$$p(l, x^l; \lambda) = \frac{Z_l(\lambda)}{Z(\lambda)} \frac{1}{Z_l(\lambda)} e^{\lambda^T f(x^l)}, \qquad (7)$$

where $Z(\lambda) = \sum_{l=1}^m Z_l(\lambda)$.

A motivation for proposing (6) is that it is very difficult to sample from (3), namely (7), as a mixture distribution with unknown weights which typically differ from each other by orders of magnitudes, e.g. 10^{40} or more in our experiments. Setting mixture weights to the known, empirical length probabilities enables us to develop a very effective learning algorithm, as introduced in Section 3. Basically, the empirical weights serve as a control device to improve sampling from multiple distributions (Liang et al., 2007; Tan, 2015) .

Second, it can be shown that if we incorporate the length features [4] in the vector of features $f(x)$ in (3), then the distribution $p(x; \lambda)$ in (3) under the maximum entropy (ME) principle will take the form of (6) and the probabilities $(\pi_1, \ldots, \pi_m)$ in (6) implied by the parameters for the length features are exactly the empirical length probabilities.

Third, a feature $f_i(x^l)$, $1 \le i \le d$, can be any computable function of the sentence x^l, such as n-grams. In our current experiments, the features $f_i(x^l)$ and their corresponding parameters λ_i are defined to be position-independent and length-independent. For example, $f_i(x^l) = \sum_k f_i(x^l, k)$, where $f_i(x^l, k)$ is a binary function of x^l evaluated at position k. As a result, the feature $f_i(x^l)$ takes values in the non-negative integers.

3 Model Estimation

We develop a stochastic approximation algorithm using Markov chain Monte Carlo to estimate the parameters λ and the normalization constants $Z_1(\lambda), ..., Z_m(\lambda)$ (Benveniste et al., 1990; Chen, 2002). The core algorithms newly designed in this paper are the joint SA for simultaneously estimating parameters and normalizing constants (Section 3.2) and trans-dimensional mixture sampling (Section 3.3) which is used as Step I of the joint SA. The most relevant previous works that we borrowed from are (Gu and Zhu, 2001) on SA for fitting a single RF, (Tan, 2015) on sampling and estimating normalizing constants from multiple RFs of the same dimension, and (Green, 1995) on trans-dimensional MCMC.

3.1 Maximum likelihood estimation

Suppose that the training dataset consists of n_l sentences of length l for $l = 1, \ldots, m$. First, the maximum likelihood estimate of the length probability π_l is easily shown to be n_l/n, where $n = \sum_{l=1}^m n_l$. By abuse of notation, we set $\pi_l = n_l/n$ hereafter. Next, the log-likelihood of λ given the empirical length probabilities is

$$L(\lambda) = \frac{1}{n} \sum_{l=1}^m \sum_{x^l \in D_l} \log p_l(x^l; \lambda), \qquad (8)$$

where D_l is the collection of sentences of length l in the training set. By setting to 0 the derivative of (8) with respect to λ, we obtain that the maximum likelihood estimate of λ is determined by the following equation:

$$\frac{\partial L(\lambda)}{\partial \lambda} = \tilde{p}[f] - p_\lambda[f] = 0, \qquad (9)$$

where $\tilde{p}[f]$ is the expectation of the feature vector f with respect to the empirical distribution:

$$\tilde{p}[f] = \frac{1}{n} \sum_{l=1}^m \sum_{x^l \in D_l} f(x^l), \qquad (10)$$

and $p_\lambda[f]$ is the expectation of f with respect to the joint distribution (6) with $\pi_l = n_l/n$:

$$p_\lambda[f] = \sum_{l=1}^m \frac{n_l}{n} p_{\lambda,l}[f], \qquad (11)$$

and $p_{\lambda,l}[f] = \sum_{x^l} f(x^l) p_l(x^l; \lambda)$. Eq.(9) has the form of equating empirical expectations $\tilde{p}[f]$ with theoretical expectations $p_\lambda[f]$, as similarly found in maximum likelihood estimation of single random field models.

3.2 Joint stochastic approximation

Training random field models is challenging due to numerical intractability of the normalizing constants $Z_l(\lambda)$ and expectations $p_{\lambda,l}[f]$. We propose a novel SA algorithm for estimating the parameters λ by (9) and, simultaneously, estimating the log ratios of normalization constants:

$$\zeta_l^*(\lambda) = \log \frac{Z_l(\lambda)}{Z_1(\lambda)}, \quad l = 1, \ldots, m \qquad (12)$$

[4] The length feature corresponding to length l is a binary feature that takes one if the sentence x is of length l, and otherwise takes zero.

Algorithm 1 Joint stochastic approximation

```
Input: training set
set initial values $\lambda^{(0)} = (0, \dots, 0)^T$ and
    $\zeta^{(0)} = \zeta^*(\lambda^{(0)}) - \zeta_1^*(\lambda^{(0)})$
for $t = 1, 2, \dots, t_{max}$ do
    set $B^{(t)} = \emptyset$
    set $(L^{(t,0)}, X^{(t,0)}) = (L^{(t-1,K)}, X^{(t-1,K)})$
      Step I: MCMC sampling
    for $k = 1 \rightarrow K$ do
        sampling (See Algorithm 3)
        $(L^{(t,k)}, X^{(t,k)}) = SAMPLE(L^{(t,k-1)}, X^{(t,k-1)})$
        set $B^{(t)} = B^{(t)} \cup \{(L^{(t,k)}, X^{(t,k)})\}$
    end for
      Step II: SA updating
    Compute $\lambda^{(t)}$ based on (14)
    Compute $\zeta^{(t)}$ based on (15) and (16)
end for
```

where $Z_1(\lambda)$ is chosen as the reference value and can be calculated exactly. The algorithm can be obtained by combining the standard SA algorithm for training single random fields (Gu and Zhu, 2001) and a trans-dimensional extension of the self-adjusted mixture sampling algorithm (Tan, 2015).

Specifically, consider the following joint distribution of the pair (l, x^l):

$$p(l, x^l; \lambda, \zeta) \propto \frac{\pi_l}{e^{\zeta_l}} e^{\lambda^T f(x^l)}, \tag{13}$$

where π_l is set to n_l/n for $l = 1, \dots, m$, but $\zeta = (\zeta_1, \dots, \zeta_m)^T$ with $\zeta_1 = 0$ are hypothesized values of the truth $\zeta^*(\lambda) = (\zeta_1^*(\lambda), \dots, \zeta_m^*(\lambda))^T$ with $\zeta_1^*(\lambda) = 0$. The distribution $p(l, x^l; \lambda, \zeta)$ reduces to $p(l, x^l; \lambda)$ in (6) if ζ were identical to $\zeta^*(\lambda)$. In general, $p(l, x^l; \lambda, \zeta)$ differs from $p(l, x^l; \lambda)$ in that the marginal probability of length l is not necessarily π_l.

The joint SA algorithm, whose pseudo-code is shown in Algorithm 1, consists of two steps at each time t as follows.

Step I: MCMC sampling. Generate a sample set $B^{(t)}$ with $p(l, x^l; \lambda^{(t-1)}, \zeta^{(t-1)})$ as the stationary distribution (see Section 3.3).

Step II: SA updating. Compute

$$\lambda^{(t)} = \lambda^{(t-1)} + \gamma_\lambda \left\{ \tilde{p}[f] - \frac{\sum_{(l,x^l) \in B^{(t)}} f(x^l)}{K} \right\} \tag{14}$$

where γ_λ is a learning rate of λ; compute

$$\zeta^{(t-\frac{1}{2})} = \zeta^{(t)} + \gamma_\zeta \left\{ \frac{\delta_1(B^{(t)})}{\pi_1}, \dots, \frac{\delta_m(B^{(t)})}{\pi_m} \right\} \tag{15}$$

$$\zeta^{(t)} = \zeta^{(t-\frac{1}{2})} - \zeta_1^{(t-\frac{1}{2})} \tag{16}$$

where γ_ζ is a learning rate of ζ, and $\delta_l(B^{(t)})$ is the relative frequency of length l appearing in $B^{(t)}$:

$$\delta_l(B^{(t)}) = \frac{\sum_{(j,x^j) \in B^{(t)}} 1(j = l)}{K}. \tag{17}$$

The rationale in (15) is to adjust ζ based on how the relative frequencies of lengths $\delta_l(B^{(t)})$ are compared with the desired length probabilities π_l. Intuitively, if the relative frequency of some length l in the sample set $B^{(t)}$ is greater (or respectively smaller) than the desired length probability π_l, then the hypothesized value $\zeta_l^{(t-1)}$ is an underestimate (or overestimate) of $\zeta_l^*(\lambda^{(t-1)})$ and hence should be increased (or decreased).

Following Gu & Zhu (2001) and Tan (2015), we set the learning rates in two stages:

$$\gamma_\lambda = \begin{cases} t^{-\beta_\lambda} & \text{if } t \le t_0 \\ \frac{1}{t - t_0 + t_0^{\beta_\lambda}} & \text{if } t > t_0 \end{cases} \tag{18}$$

$$\gamma_\zeta = \begin{cases} (0.1t)^{-\beta_\zeta} & \text{if } t \le t_0 \\ \frac{1}{0.1(t-t_0) + (0.1t_0)^{\beta_\zeta}} & \text{if } t > t_0 \end{cases} \tag{19}$$

where $0.5 < \beta_\lambda, \beta_\zeta < 1$. In the first stage ($t \le t_0$), a slow-decaying rate of $t^{-\beta}$ is used to introduce large adjustments. This forces the estimates $\lambda^{(t)}$ and $\zeta^{(t)}$ to fall reasonably fast into the true values. In the second stage ($t > t_0$), a fast-decaying rate of t^{-1} is used. The iteration number t is multiplied by 0.1 in (19), to make the the learning rate of ζ decay more slowly than λ. Commonly, t_0 is selected to ensure there is no more significant adjustment observed in the first stage.

3.3 Trans-dimensional mixture sampling

We describe a trans-dimensional mixture sampling algorithm to simulate from the joint distribution $p(l, x^l; \lambda, \zeta)$, which is used with $(\lambda, \zeta) = (\lambda^{(t-1)}, \zeta^{(t-1)})$ at time t for MCMC sampling in the joint SA algorithm. The name "mixture sampling" reflects the fact that $p(l, x^l; \lambda, \zeta)$ represents a labeled mixture, because l is a label indicating that x^l is associated with the distribution $p_l(x^l; \zeta)$. With fixed (λ, ζ), this sampling algorithm can be seen as formally equivalent to reversible jump MCMC (Green, 1995), which was originally proposed for Bayes model determination.

The trans-dimensional mixture sampling algorithm consists of two steps at each time t: local jump between lengths and Markov move of sentences for a given length. In the following, we denote by $L^{(t-1)}$ and $X^{(t-1)}$ the length and sequence before sampling, but use the short notation (λ, ζ) for $(\lambda^{(t-1)}, \zeta^{(t-1)})$.

Step I: Local jump. The Metropolis-Hastings method is used in this step to sample the length. Assuming $L^{(t-1)} = k$, first we draw a new length $j \sim \Gamma(k, \cdot)$. The jump distribution $\Gamma(k, l)$ is defined to be uniform at the neighborhood of k :

$$\Gamma(k,l) = \begin{cases} \frac{1}{3}, \text{if } k \in [2, m-1], l \in [k-1, k+1] \\ \frac{1}{2}, \text{if } k = 1, l \in [1,2] \text{ or } k = m, l \in [m-1, m] \\ 0, \text{otherwise} \end{cases} \tag{20}$$

where m is the maximum length. Eq.(20) restricts the difference between j and k to be no more than one. If $j = k$, we retain the sequence and perform the next step directly, i.e. set $L^{(t)} = k$ and $X^{(t)} = X^{(t-1)}$. If $j = k+1$ or $j = k-1$, the two cases are processed differently.

If $j = k + 1$, we first draw an element (i.e., word) Y from a proposal distribution: $Y \sim g_{k+1}(y|X^{(t-1)})$. Then we set $L^{(t)} = j\ (= k+1)$ and $X^{(t)} = \{X^{(t-1)}, Y\}$ with probability

$$\min\left\{1, \frac{\Gamma(j,k)}{\Gamma(k,j)} \frac{p(j, \{X^{(t-1)}, Y\}; \lambda, \zeta)}{p(k, X^{(t-1)}; \lambda, \zeta) g_{k+1}(Y|X^{(t-1)})}\right\} \tag{21}$$

where $\{X^{(t-1)}, Y\}$ denotes a sequence of length $k+1$ whose first k elements are $X^{(t-1)}$ and the last element is Y.

If $j = k-1$, we set $L^{(t)} = j\ (= k-1)$ and $X^{(t)} = X^{(t-1)}_{1:j}$ with probability

$$\min\left\{1, \frac{\Gamma(j,k)}{\Gamma(k,j)} \frac{p(j, X^{(t-1)}_{1:j}; \lambda, \zeta) g_k(X^{(t-1)}_k | X^{(t-1)}_{1:j})}{p(k, X^{(t-1)}; \lambda, \zeta)}\right\} \tag{22}$$

where $X^{(t-1)}_{1:j}$ is the first j elements of $X^{(t-1)}$ and $X^{(t-1)}_k$ is the kth element of $X^{(t-1)}$.

In (21) and (22), $g_{k+1}(y|x^k)$ can be flexibly specified as a proper density function in y. In our application, we find the following choice works reasonably well:

$$g_{k+1}(y|x^k) = \frac{p(k+1, \{x^k, y\}; \lambda, \zeta)}{\sum_w p(k+1, \{x^k, w\}; \lambda, \zeta)}. \tag{23}$$

Step II: Markov move. After the step of local jump, we obtain

$$X^{(t)} = \begin{cases} X^{(t-1)} & \text{if } L^{(t)} = k \\ \{X^{(t-1)}, Y\} & \text{if } L^{(t)} = k+1 \\ X^{(t-1)}_{1:k-1} & \text{if } L^{(t)} = k-1 \end{cases} \tag{24}$$

Then we perform Gibbs sampling on $X^{(t)}$, from the first element to the last element (Algorithm 2)

Algorithm 2 Markov Move

```
for $i = 1 \to L^{(t)}$ do
    draw $W \sim p(L^{(t)}, \{X^{(t)}_{1:i-1}, w, X^{(t)}_{i+1:L^{(t)}}\}; \lambda, \zeta)$
    set $X^{(t)}_i = W$
end for
```

4 Algorithm Optimization and Acceleration

The joint SA algorithm may still suffer from slow convergence, especially when λ is high-dimensional. We introduce several techniques for improving the convergence of the algorithm and reducing computational cost.

4.1 Improving SA recursion

We propose two techniques to effectively improve the convergence of SA recursion.

The first technique is to incorporate Hessian information, similarly as in related works on stochastic approximation (Gu and Zhu, 2001) and stochastic gradient descent algorithms (Byrd et al., 2014). But we only use the diagonal elements of the Hessian matrix to re-scale the gradient, due to high-dimensionality of λ.

Taking the second derivatives of $L(\lambda)$ yields

$$H_i = -\frac{d^2 L(\lambda)}{d\lambda_i^2} = p[f_i^2] - \sum_{l=1}^{m} \pi_l (p_l[f_i])^2 \tag{25}$$

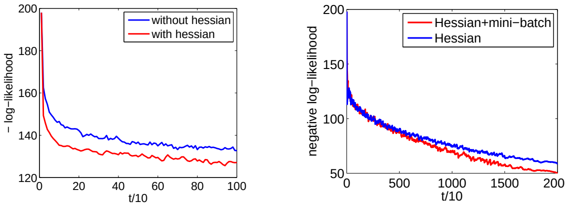
where H_i denotes the ith diagonal element of Hessian matrix. At time t, before updating the parameter λ (Step II in Section 3.2), we compute

$$H_i^{(t-\frac{1}{2})} = \frac{1}{K} \sum_{(l,x^l) \in B^{(t)}} f_i(x^l)^2 - \sum_{l=1}^{m} \pi_l (\bar{p}_l[f_i])^2, \tag{26}$$

$$H_i^{(t)} = H_i^{(t-1)} + \gamma_H (H_i^{(t-\frac{1}{2})} - H_i^{(t-1)}), \tag{27}$$

where $\bar{p}_l[f_i] = |B_l^{(t)}|^{-1} \sum_{(l,x^l) \in B_l^{(t)}} f_i(x^l)$, and $B_l^{(t)}$ is the subset, of size $|B_l^{(t)}|$, containing all sentences of length l in $B^{(t)}$.

The second technique is to introduce the "mini-batch" on the training set. At each iteration, a subset $D^{(t)}$ of K sentences are randomly selected from the training set. Then the gradient is approximated with the overall empirical expectation $\tilde{p}[f]$ being replaced by the empirical expectation over the subset $D^{(t)}$. This technique is reminiscent of stochastic gradient descent using a random subsample of training data to achieve fast convergence



(a) (b)

Figure 1: Examples of convergence curves on training set after introducing hessian and training set mini-batching.

of optimization algorithms (Bousquet and Bottou, 2008).

By combining the two techniques, we revise the updating equation (14) of λ to

$$\lambda_i^{(t)} = \lambda_i^{(t-1)} + \frac{\gamma_\lambda}{\max(H_i^{(t)}, h)} \times \left\{ \frac{\sum_{(l,x^l)\in D^{(t)}} f_i(x^l)}{K} - \frac{\sum_{(l,x^l)\in B^{(t)}} f_i(x^l)}{K} \right\} \tag{28}$$

where $0 < h < 1$ is a threshold to avoid $H_i^{(t)}$ being too small or even zero. Moreover, a constant t_c is added to the denominator of (18), to avoid too large adjustment of λ, i.e.

$$\gamma_\lambda = \begin{cases} \frac{1}{t_c + t^{\beta_\lambda}} & \text{if } t \le t_0, \\ \frac{1}{t_c + t - t_0 + t_0^{\beta_\lambda}} & \text{if } t > t_0. \end{cases} \tag{29}$$

Fig.1(a) shows the result after introducing hessian estimation, and Fig.1(b) shows the effect of training set mini-batching.

4.2 Sampling acceleration

For MCMC sampling in Section 3.3, the Gibbs sampling operation of drawing $X_i^{(t)}$ (Step 2 in Algorithms 2) involves calculating the probabilities of all the possible elements in position i. This is computationally costly, because the vocabulary size $|\mathcal{V}|$ is usually 10 thousands or more in practice. As a result, the Gibbs sampling operation presents a bottleneck limiting the efficiency of sampling algorithms.

We propose a novel method of using class information to effectively reduce the computational cost of Gibbs sampling. Suppose that each word in vocabulary $\mathcal{V}$ is assigned to a single class. If the total class number is $|\mathcal{C}|$, then there are, on average, $|\mathcal{V}|/|\mathcal{C}|$ words in each class. With the class information, we can first draw the class of $X_i^{(t)}$, denoted by $c_i^{(t)}$, and then draw a word belonging to class $c_i^{(t)}$. The computational cost is reduced from $|\mathcal{V}|$ to $|\mathcal{C}| + |\mathcal{V}|/|\mathcal{C}|$ on average.

Algorithm 3 Class-based MCMC sampling

```
 1: function SAMPLE($(L^{(t-1)}, X^{(t-1)})$)
 2:     set $k = L^{(t-1)}$
 3:     init $(L^{(t)}, X^{(t)}) = (k, X^{(t-1)})$
            Step I: Local jump
 4:     generate $j \sim \Gamma(k, \cdot)$ (Eq.(20))
 5:     if $j = k + 1$ then
 6:         generate $C \sim Q_{k+1}(c)$
 7:         generate $Y \sim \breve{g}_{k+1}(y|X^{(t-1)}, C)$ (Eq.31)
 8:         set $L^{(t)} = j$ and $X^{(t)} = \{X^{(t-1)}, Y\}$ with probability (Eq.21) and (Eq.32)
 9:     end if
10:     if $j = k - 1$ then
11:         set $L^{(t)} = j$ and $X^{(t)} = X^{(t-1)}_{1:k-1}$ with probability Eq.(22) and (Eq.32)
12:     end if
            Step II: Markov move
13:     for $i = 1 \to L^{(t)}$ do
14:         draw $C \sim Q_i(c)$
15:         set $c_i^{(t)} = C$ with probability (Eq.30)
16:         draw $W \in \mathcal{V}_{c_i^{(t)}}$
17:         set $X_i^{(t)} = W$
18:     end for
19:     return $(L^{(t)}, X^{(t)})$
20: end function
```

The idea of using class information to accelerate training has been proposed in various contexts of language modeling, such as maximum entropy models (Goodman, 2001b) and RNN LMs (Mikolov et al., 2011). However, the realization of this idea is different for training our models.

The pseudo-code of the new sampling method is shown in Algorithm 3. Denote by $\mathcal{V}_c$ the subset of $\mathcal{V}$ containing all the words belonging to class c. In the Markov move step (Step 13 to 18 in Algorithm 3), at each position i, we first generate a class C from a proposal distribution $Q_i(c)$ and then accept C as the new $c_i^{(t)}$ with probability

$$\min\left\{1, \frac{Q_i(c_i^{(t)})}{Q_i(C)} \frac{p_i(C)}{p_i(c_i^{(t)})}\right\} \tag{30}$$

where

$$p_i(c) = \sum_{w\in\mathcal{V}_c} p(L^{(t)}, \{X^{(t)}_{1:i-1}, w, X^{(t)}_{i+1:L^{(t)}}\}; \lambda, \zeta).$$

The probabilities $Q_i(c)$ and $p_i(c)$ depend on $\{X^{(t)}_{1:i-1}, X^{(t)}_{i+1:L^{(t)}}\}$, but this is suppressed in the notation. Then we normalize the probabilities of words belonging to class $c_i^{(t)}$ and draw a word as the new $X_i^{(t)}$ from the class $c_i^{(t)}$.

Similarly, in the local jump step with $k = L^{(t-1)}$, if the proposal $j = k + 1$ (Step 5 to 9 in Algorithm 3), we first generate $C \sim Q_{k+1}(c)$ and then generate Y from class C by

$$\breve{g}_{k+1}(y|x^k, C) = \frac{p(k+1, \{x^k, y\}; \lambda, \zeta)}{\sum_{w \in \mathcal{V}_C} p(k+1, \{x^k, w\}; \lambda, \zeta)} \quad (31)$$

with $x^k = X^{(t-1)}$. Then we set $L^{(t)} = j$ and $X^{(t)} = \{X^{(t-1)}, Y\}$ with probability as defined in (21), by setting

$$g_{k+1}(y|x^k) = Q_{k+1}(C)\breve{g}_{k+1}(y|x^k, C). \quad (32)$$

If the proposal $j = k - 1$, similarly we use acceptance probability (22) with (32).

In our application, we construct $Q_i(c)$ dynamically as follows. Write x^l for $\{X^{(t-1)}, Y\}$ in Step 8 or for $X^{(t)}$ in Step 11 of Algorithm 3. First, we construct a reduced model $p_l^c(x^l)$, by including only the features that depend on x_i^l through its class and retaining the corresponding parameters in $p_l(x^l; \lambda, \zeta)$. Then we define the distribution

$$Q_i(c) = p_l^c(\{x_{1:i-1}^l, c, x_{i+1:l}^l\}),$$

which can be directly calculated without knowing the value of x_i^l.

4.3 Parallelization of sampling

The sampling operation can be easily parallelized in SA Algorithm 1. At each time t, both the parameters λ and log normalization constants ζ are fixed at $\lambda^{(t-1)}$ and $\zeta^{(t-1)}$. Instead of simulating one Markov Chain, we simulate J Markov Chains on J CPU cores separately. As a result, to generate a sample set $B^{(t)}$ of size K, only K/J sampling steps need to be performed on each CPU core. By parallelization, the sampling operation is completed J times faster than before.

5 Experiments

5.1 PTB perplexity results

In this section, we evaluate the performance of LMs by perplexity (PPL). We use the Wall Street Journal (WSJ) portion of Penn Treebank (PTB). Sections 0-20 are used as the training data (about 930K words), sections 21-22 as the development data (74K) and section 23-24 as the test data (82K). The vocabulary is limited to 10K words, with one special token $\langle UNK \rangle$ denoting words not in the vocabulary. This setting is the same as that used in other studies (Mikolov et al., 2011).

The baseline is a 4-gram LM with modified Kneser-Ney smoothing (Chen and Goodman, 1999), denoted by KN4. We use the RNNLM toolkit[5] to train a RNNLM (Mikolov et al., 2011). The number of hidden units is 250 and other configurations are set by default[6].

Type	Features
w	$(w_{-3}w_{-2}w_{-1}w_0)(w_{-2}w_{-1}w_0)(w_{-1}w_0)(w_0)$
c	$(c_{-3}c_{-2}c_{-1}c_0)(c_{-2}c_{-1}c_0)(c_{-1}c_0)(c_0)$
ws	$(w_{-3}w_0)(w_{-3}w_{-2}w_0)(w_{-3}w_{-1}w_0)(w_{-2}w_0)$
cs	$(c_{-3}c_0)(c_{-3}c_{-2}c_0)(c_{-3}c_{-1}c_0)(c_{-2}c_0)$
wsh	$(w_{-4}w_0)$ $(w_{-5}w_0)$
csh	$(c_{-4}c_0)$ $(c_{-5}c_0)$
cpw	$(c_{-3}c_{-2}c_{-1}w_0)$ $(c_{-2}c_{-1}w_0)(c_{-1}w_0)$

Table 1: Feature definition in TDRF LMs

Word classing has been shown to be useful in conditional ME models (Chen, 2009). For our TDRF models, we consider a variety of features as shown in Table 1, mainly based on word and class information. Each word is deterministically assigned to a single class, by running the automatic clustering algorithm proposed in (Martin et al., 1998) on the training data.

In Table 1, $w_i, c_i, i = 0, -1, \ldots, -5$ denote the word and its class at different position offset i, e.g. w_0, c_0 denotes the current word and its class. We first introduce the classic word/class n-gram features (denoted by "w"/"c") and the word/class skipping n-gram features (denoted by "ws"/"cs") (Goodman, 2001a). Second, to demonstrate that long-span features can be naturally integrated in TDRFs, we introduce higher-order features "wsh"/"csh", by considering two words/classes separated with longer distance. Third, as an example of supporting heterogenous features that combine different information, the crossing features "cpw" (meaning class-predict-word) are introduced. Note that for all the feature types in Table 1, only the features observed in the training data are used.

The joint SA (Algorithm 1) is used to train the TDRF models, with all the acceleration methods described in Section 4 applied. The minibatch size $K = 300$. The learning rates γ_λ and γ_ζ are configured as (29) and (19) respectively with $\beta_\lambda = \beta_\zeta = 0.6$ and $t_c = 3000$. For t_0, it is first initialized to be 10^4. During iterations, we monitor the smoothed log-likelihood (moving average of 1000 iterations) on the PTB development data.

[5] `http://rnnlm.org/`

[6] Minibatch size=10, learning rate=0.1, BPTT steps=5. 17 sweeps are performed before stopping, which takes about 25 hours. No word classing is used, since classing in RNNLMs reduces computation but at cost of accuracy. RNNLMs were experimented with varying numbers of hidden units (100-500). The best result from using 250 hidden units is reported.

models	PPL (± std. dev.)
KN4	142.72
RNN	128.81
TDRF w+c	130.69±1.64

Table 2: The PPLs on the PTB test data. The class number is 200.

We set t_0 to the current iteration number once the rising percentage of the smoothed log-likelihoods within 100 iterations is below 20%, and then continue 5000 further iterations before stopping. The configuration of hessian estimation (Section 4.1) is $\gamma_H = \gamma_\lambda$ and $h = 10^{-4}$. L_2 regularization with constant 10^{-5} is used to avoid over-fitting. 8 CPU cores are used to parallelize the algorithm, as described in Section 4.3, and the training of each TDRF model takes less than 20 hours.

The perplexity results on the PTB test data are given in Table 2. As the normalization constants of TDRF models are estimated stochastically, we report the Monte Carlo mean and standard deviation from the last 1000 iterations for each PPL. The TDRF model using the basic "w+c" features performs close to the RNNLM in perplexity. To be compact, results with more features are presented in the following WSJ experiment.

5.2 WSJ speech recognition results

In this section, we continue to use the LMs obtained above (using PTB training and development data), and evaluate their performance measured by WERs in speech recognition, by rescoring 1000-best lists from WSJ'92 test data (330 sentences). The oracle WER of the 1000-best lists is 3.4%, which are generated from using the Kaldi toolkit[7] with a DNN-based acoustic model.

TDRF LMs using a variety of features and different number of classes are tested. The results are shown in Table 3. Different types of features, like the skipping features, the higher-order features and the crossing features can all be easily supported in TDRF LMs, and the performance is improved to varying degrees. Particularly, the TDRF using the "w+c+ws+cs+cpw" features with class number 200 performs comparable to the RNNLM in both perplexity and WER. Numerically, the relative reduction is 9.1% compared with the KN4 LMs, and 0.5% compared with the RNN LM.

model	WER	PPL (± std. dev.)	#feat
KN4	8.71	295.41	1.6M
RNN	7.96	256.15	5.1M
WSMEs (200c)			
w+c+ws+cs	8.87	$\approx 2.8 \times 10^{12}$	5.2M
w+c+ws+cs+cpw	8.82	$\approx 6.7 \times 10^{12}$	6.4M
TDRFs (100c)			
w+c	8.56	268.25±3.52	2.2M
w+c+ws+cs	8.16	265.81±4.30	4.5M
w+c+ws+cs+cpw	8.05	265.63±7.93	5.6M
w+c+ws+cs+wsh+csh	8.03	276.90±5.00	5.2M
TDRFs (200c)			
w+c	8.46	257.78±3.13	2.5M
w+c+ws+cs	8.05	257.80±4.29	5.2M
w+c+ws+cs+cpw	**7.92**	264.86±8.55	6.4M
w+c+ws+cs+wsh+csh	**7.94**	266.42±7.48	5.9M
TDRFs (500c)			
w+c	8.72	261.02±2.94	2.8M
w+c+ws+cs	8.29	266.34±6.13	5.9M

Table 3: The WERs and PPLs on the WSJ'92 test data. "#feat" denotes the feature number. Different TDRF models with class number 100/200/500 are reported (denoted by "100c"/"200c"/"500c")

5.3 Comparison and discussion

TDRF vs WSME. For comparison, Table 3 also presents the results from our implementation of the WSME model (3), using the same features as in Table 1. This WSME model is the same as in (Rosenfeld, 1997), but different from (Rosenfeld et al., 2001), which uses the traditional n-gram LM as the priori distribution p_0.

For the WSME model (3), we can still use a SA training algorithm, similar to that developed in Section 3.2, to estimate the parameters λ. But in this case, there is no need to introduce ζ_l, because the normalizing constants $Z_l(\lambda)$ are canceled out as seen from (7). Specifically, the learning rate γ_λ and the L_2 regularization are configured the same as in TDRF training. A fixed number of iterations with $t_0 = 5000$ is performed. The total iteration number is 10000, which is similar to the iteration number used in TDRF training.

In order to calculate perplexity, we need to estimate the global normalizing constant $Z(\lambda) = \sum_{l=1}^{m} Z_l(\lambda)$ for the WSME model. Similarly as in (Tan, 2015), we apply the SA algorithm in Section 3.2 to estimate the log normalizing constants ζ, while fixing the parameters λ to be those already estimated from the WSME model and using uniform probabilities $\pi_l \equiv m^{-1}$.

The resulting PPLs of these WSME models are extremely poor. The average test log-likelihoods per sentence for these two WSME models are

[7] http://kaldi.sourceforge.net/

-494 and -509 respectively. However, the WERs from using the trained WSME models in hypothesis re-ranking are not as poor as would be expected from their PPLs. This appears to indicate that the estimated WSME parameters are not so bad for relative ranking. Moreover, when the estimated λ and ζ are substituted into our TDRF model (6) with the empirical length probabilities π_l, the "corrected" average test log-likelihoods per sentence for these two sets of parameters are improved to be -152 and -119 respectively. The average test log-likelihoods are both -96 for the two corresponding TDRF models in Table 3. This is some evidence for the model deficiency of the WSME distribution as defined in (3), and introducing the empirical length probabilities gives a more reasonable model assumption.

TDRF vs conditional ME. After training, TDRF models are computationally more efficient in computing sentence probability, simply summing up weights for the activated features in the sentence. The conditional ME models (Khudanpur and Wu, 2000; Roark et al., 2004) suffer from the expensive computation of local normalization factors. This computational bottleneck hinders their use in practice (Goodman, 2001b; Rosenfeld et al., 2001). Partly for this reason, although building conditional ME models with sophisticated features as in Table 1 is theoretically possible, such work has not been pursued so far.

TDRF vs RNN. The RNN models suffer from the expensive softmax computation in the output layer [8]. Empirically in our experiments, the average time costs for re-ranking of the 1000-best list for a sentence are 0.16 sec vs 40 sec, based on TDRF and RNN respectively (no GPU used).

6 Related Work

While there has been extensive research on conditional LMs, there has been little work on the whole-sentence LMs, mainly in (Rosenfeld et al., 2001; Amaya and Benedí, 2001; Ruokolainen et al., 2010). Although the whole-sentence approach has potential benefits, the empirical results of previous WSME models are not satisfactory, almost the same as traditional n-gram models. After incorporating lexical and syntactic information, a mere relative improvement of 1% and 0.4% respectively in perplexity and in WER is reported for the resulting WSEM (Rosenfeld et al., 2001). Subsequent studies of using WSEMs with grammatical features, as in (Amaya and Benedí, 2001) and (Ruokolainen et al., 2010), report perplexity improvement above 10% but no WER improvement when using WSEMs alone.

Most RF modeling has been restricted to fixed-dimensional spaces [9]. Despite recent progress, fitting RFs of moderate or large dimensions remains to be challenging (Koller and Friedman, 2009; Mizrahi et al., 2013). In particular, the work of (Pietra et al., 1997) is inspiring to us, but the improved iterative scaling (IIS) method for parameter estimation and the Gibbs sampler are not suitable for even moderately sized models. Our TDRF model, together with the joint SA algorithm and trans-dimensional mixture sampling, are brand new and lead to encouraging results for language modeling.

7 Conclusion

In summary, we have made the following contributions, which enable us to successfully train TDRF models and obtain encouraging performance improvement.

- The new TDRF model and the joint SA training algorithm, which simultaneously updates the model parameters and normalizing constants while using trans-dimensional mixture sampling.
- Several additional innovations including accelerating SA iterations by using Hessian information, introducing word classing to accelerate the sampling operation and improve the smoothing behavior of the models, and parallelization of sampling.

In this work, we mainly explore the use of features based on word and class information. Future work with other knowledge sources and larger-scale experiments is needed to fully exploit the advantage of TDRFs to integrate richer features.

8 Acknowledgments

This work is supported by Toshiba Corporation, National Natural Science Foundation of China (NSFC) via grant 61473168, and Tsinghua Initiative. We thank the anonymous reviewers for helpful comments on this paper.

[8] This deficiency could be partly alleviated with some speed-up methods, e.g. using word clustering (Mikolov, 2012) or noise contrastive estimation (Mnih and Kavukcuoglu, 2013).

[9] Using local fixed-dimensional RFs in sequential models was once explored, e.g. temporal restricted Boltzmann machine (TRBM) (Sutskever and Hinton, 2007).

Gaussian LDA for Topic Models with Word Embeddings

Rajarshi Das[*], Manzil Zaheer[*], Chris Dyer

Abstract

Continuous space word embeddings learned from large, unstructured corpora have been shown to be effective at capturing semantic regularities in language. In this paper we replace LDA's parameterization of "topics" as categorical distributions over opaque word types with multivariate Gaussian distributions on the embedding space. This encourages the model to group words that are *a priori* known to be semantically related into topics. To perform inference, we introduce a fast collapsed Gibbs sampling algorithm based on Cholesky decompositions of covariance matrices of the posterior predictive distributions. We further derive a scalable algorithm that draws samples from stale posterior predictive distributions and corrects them with a Metropolis–Hastings step. Using vectors learned from a domain-general corpus (English Wikipedia), we report results on two document collections (20-newsgroups and NIPS). Qualitatively, Gaussian LDA infers different (but still very sensible) topics relative to standard LDA. Quantitatively, our technique outperforms existing models at dealing with OOV words in held-out documents.

1 Introduction

Latent Dirichlet Allocation (LDA) is a Bayesian technique that is widely used for inferring the topic structure in corpora of documents. It conceives of a document as a mixture of a small number of topics, and topics as a (relatively sparse) distribution over word types (Blei et al., 2003). These priors are remarkably effective at producing useful results. However, our intuitions tell us that while documents may indeed be conceived of as a mixture of topics, we should further expect topics to be *semantically coherent*. Indeed, standard human evaluations of topic modeling performance are designed to elicit assessment of semantic coherence (Chang et al., 2009; Newman et al., 2009). However, this prior preference for semantic coherence is not encoded in the model, and any such observation of semantic coherence found in the inferred topic distributions is, in some sense, accidental. In this paper, we develop a variant of LDA that operates on continuous space embeddings of words—rather than word types—to impose a prior expectation for semantic coherence. Our approach replaces the opaque word types usually modeled in LDA with continuous space embeddings of these words, which are generated as draws from a multivariate Gaussian.

How does this capture our preference for semantic coherence? Word embeddings have been shown to capture lexico-semantic regularities in language: words with similar syntactic and semantic properties are found to be close to each other in the embedding space (Agirre et al., 2009; Mikolov et al., 2013). Since Gaussian distributions capture a notion of centrality in space, and semantically related words are localized in space, our Gaussian LDA model encodes a prior preference for semantically coherent topics. Our model further has several advantages. Traditional LDA assumes a fixed vocabulary of word types. This modeling assumption drawback as it cannot handle *out of vocabulary* (OOV) words in "held out" documents. Zhai and Boyd-Graber (2013) proposed an approach to address this problem by drawing topics from a Dirichlet Process with a base distribution over all possible character strings (i.e., words). While this model can in principle handle unseen words, the only bias toward being included in a particular topic comes from the topic assignments in the rest

[*]Both student authors had equal contribution.

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 795–804,

of the document. Our model can exploit the contiguity of semantically similar words in the embedding space and can assign high topic probability to a word which is similar to an existing topical word even if it has never been seen before.

The main contributions of our paper are as follows: We propose a new technique for topic modeling by treating the document as a collection of word embeddings and topics itself as multivariate Gaussian distributions in the embedding space (§3). We explore several strategies for collapsed Gibbs sampling and derive scalable algorithms, achieving asymptotic speed-up over the naïve implementation (§4). We qualitatively show that our topics make intuitive sense and quantitatively demonstrate that our model captures a better representation of a document in the topic space by outperforming other models in a classification task (§5).

2 Background

Before going to the details of our model we provide some background on two topics relevant to our work: vector space word embeddings and LDA.

2.1 Vector Space Semantics

According to the **distributional hypothesis** (Harris, 1954), words occurring in similar contexts tend to have similar meaning. This has given rise to data-driven learning of word vectors that capture lexical and semantic properties, which is now a technique of central importance in natural language processing. These word vectors can be used for identifying semantically related word pairs (Turney, 2006; Agirre et al., 2009) or as features in downstream text processing applications (Turian et al., 2010; Guo et al., 2014). Word vectors can either be constructed using low rank approximations of cooccurrence statistics (Deerwester et al., 1990) or using internal representations from neural network models of word sequences (Collobert and Weston, 2008). We use a recently popular and fast tool called `word2vec`[1], to generate skip-gram word embeddings from unlabeled corpus. In this model, a word is used as an input to a log-linear classifier with continuous projection layer and words within a certain window before and after the words are predicted.

2.2 Latent Dirichlet Allocation (LDA)

LDA (Blei et al., 2003) is a probabilistic topic model of corpora of documents which seeks to represent the underlying thematic structure of the document collection. They have emerged as a powerful new technique of finding useful structure in an unstructured collection as it learns distributions over words. The high probability words in each distribution gives us a way of understanding the contents of the corpus at a very high level. In LDA, each document of the corpus is assumed to have a distribution over K topics, where the discrete topic distributions are drawn from a symmetric dirichlet distribution. The generative process is as follows.

1. for k = 1 to K
   (a) Choose topic $\boldsymbol{\beta}_k \sim \mathsf{Dir}(\boldsymbol{\eta})$
2. for each document d in corpus D
   (a) Choose a topic distribution $\boldsymbol{\theta}_d \sim \mathsf{Dir}(\boldsymbol{\alpha})$
   (b) for each word index n from 1 to N_d
      i. Choose a topic $z_n \sim \mathsf{Categorical}(\boldsymbol{\theta}_d)$
      ii. Choose word $w_n \sim \mathsf{Categorical}(\boldsymbol{\beta}_{z_n})$

As it follows from the definition above, a topic is a discrete distribution over a fixed vocabulary of word types. This modeling assumption precludes new words to be added to topics. However modeling topics as a continuous distribution over word embeddings gives us a way to address this problem. In the next section we describe Gaussian LDA, a straightforward extension of LDA that replaces categorical distributions over word types with multivariate Gaussian distributions over the word embedding space.

3 Gaussian LDA

As with multinomial LDA, we are interested in modeling a collection of documents. However, we assume that rather than consisting of sequences of word types, documents consist of sequences of word embeddings. We write $\mathbf{v}(w) \in \mathbb{R}^M$ as the embedding of word of type w or $\mathbf{v}_{d,i}$ when we are indexing a vector in a document d at position i.

Since our observations are no longer discrete values but continuous vectors in an M-dimensional space, we characterize each topic k as a multivariate Gaussian distribution with mean $\boldsymbol{\mu}_k$ and covariance $\boldsymbol{\Sigma}_k$. The choice of a Gaussian parameterization is justified by both analytic convenience and observations that Euclidean distances

[1] `https://code.google.com/p/word2vec/`

$$p(z_{d,i} = k \mid \boldsymbol{z}_{-(d,i)}, \mathbf{V}_d, \boldsymbol{\zeta}, \boldsymbol{\alpha}) \propto (n_{k,d} + \alpha_k) \times t_{\nu_k - M+1} \left(\mathbf{v}_{d,i} \middle| \boldsymbol{\mu}_k, \frac{\kappa_k + 1}{\kappa_k} \boldsymbol{\Sigma}_k \right) \tag{1}$$

Figure 1: Sampling equation for the collapsed Gibbs sampler; refer to text for a description of the notation.

between embeddings correlate with semantic similarity (Collobert and Weston, 2008; Turney and Pantel, 2010; Hermann and Blunsom, 2014). We place conjugate priors on these values: a Gaussian centered at zero for the mean and an inverse Wishart distribution for the covariance. As before, each document is seen as a mixture of topics whose proportions are drawn from a symmetric Dirichlet prior. The generative process can thus be summarized as follows:

1. for k = 1 to K
   (a) Draw topic covariance $\boldsymbol{\Sigma}_k \sim \mathcal{W}^{-1}(\boldsymbol{\Psi}, \nu)$
   (b) Draw topic mean $\boldsymbol{\mu}_k \sim \mathcal{N}(\boldsymbol{\mu}, \frac{1}{\kappa}\boldsymbol{\Sigma}_k)$

This model has previously been proposed for obtaining indexing representations for audio retrieval (Hu et al., 2012). They use variational/EM method for posterior inference. Although we don't do any experiment to compare the running time of both approaches, the per-iteration computational complexity is same for both inference methods. We propose a faster inference technique using Cholesky decomposition of covariance matrices which can be applied to both the Gibbs and variational/EM method. However we are not aware of any straightforward way of applying the aliasing trick proposed by (Li et al., 2014) on the variational/EM method which gave us huge improvement on running time (see Figure 2). Another work which combines embedding with topic models is by (Wan et al., 2012) where they jointly learn the parameters of a neural network and a topic model to capture the topic distribution of low dimensional representation of images.

4 Posterior Inference

In our application, we observe documents consisting of word vectors and wish to infer the posterior distribution over the topic parameters, proportions, and the topic assignments of individual words. Since there is no analytic form of the posterior, approximations are required. Because of our choice of conjugate priors for topic parameters and proportions, these variables can be analytically integrated out, and we can derive a collapsed Gibbs sampler that resamples topic assignments to individual word vectors, similar to the collapsed sampling scheme proposed by Griffiths and Steyvers (2004).

The conditional distribution we need for sampling is shown in Figure 1. Here, $\boldsymbol{z}_{-(d,i)}$ represents the topic assignments of all word embeddings, excluding the one at i^{th} position of document d; $\mathbf{V}_d$ is the sequence of vectors for document d; $t_{\nu'}(\mathbf{x} \mid \boldsymbol{\mu}', \boldsymbol{\Sigma}')$ is the multivariate t - distribution with ν' degrees of freedom and parameters $\boldsymbol{\mu}'$ and $\boldsymbol{\Sigma}'$. The tuple $\boldsymbol{\zeta} = (\boldsymbol{\mu}, \kappa, \boldsymbol{\Sigma}, \nu)$ represents the parameters of the prior distribution.

It should be noted that the first part of the equation which expresses the probability of topic k in document d is the same as that of LDA. This is because the portion of the model which generates a topic for each word (vector) from its document topic distribution is still the same. The second part of the equation which expresses the probability of assignment of topic k to the word vector $\mathbf{v}_{d,i}$ given the current topic assignments (aka posterior predictive) is given by a multivariate t distribution with parameters $(\boldsymbol{\mu}_k, \kappa_k, \boldsymbol{\Sigma}_k, \nu_k)$. The parameters of the posterior predictive distribution are given as (Murphy, 2012):

$$\begin{aligned}
\kappa_k &= \kappa + N_k \qquad \boldsymbol{\mu}_k = \frac{\kappa\boldsymbol{\mu} + N_k\bar{\mathbf{v}}_k}{\kappa_k} \\
\nu_k &= \nu + N_k \qquad \boldsymbol{\Sigma}_k = \frac{\boldsymbol{\Psi}_k}{(\nu_k - M + 1)} \\
\boldsymbol{\Psi}_k &= \boldsymbol{\Psi} + \mathbf{C}_k + \frac{\kappa N_k}{\kappa_k}(\bar{\mathbf{v}}_k - \boldsymbol{\mu})(\bar{\mathbf{v}}_k - \boldsymbol{\mu})^\top
\end{aligned} \tag{2}$$

where $\bar{\mathbf{v}}_k$ and $\mathbf{C}_k$ are given by,

$$\bar{\mathbf{v}}_k = \frac{\sum_d \sum_{i:z_{d,i}=k}(\mathbf{v}_{d,i})}{N_k}$$

$$\mathbf{C}_k = \sum_d \sum_{i:z_{d,i}=k} (\mathbf{v}_{d,i} - \bar{\mathbf{v}}_k)(\mathbf{v}_{d,i} - \bar{\mathbf{v}}_k)^\top$$

Here $\bar{\mathbf{v}}_k$ is the sample mean and $\mathbf{C}_k$ is the scaled form of sample covariance of the vectors with topic assignment k. N_k represents the count of words assigned to topic k across all documents. Intuitively the parameters $\boldsymbol{\mu}_k$ and $\boldsymbol{\Sigma}_k$ represents the posterior mean and covariance of the topic distribution and κ_k, ν_k represents the strength of the prior for mean and covariance respectively.

Analysis of running time complexity

As can be seen from (1), for computation of the posterior predictive we need to evaluate the determinant and inverse of the posterior covariance matrix. Direct naïve computation of these terms require $O(M^3)$ operations. Moreover, during sampling as words get assigned to different topics, the parameters $(\boldsymbol{\mu}_k, \kappa_k, \boldsymbol{\Psi}_k, \nu_k)$ associated with a topic changes and hence we have to recompute the determinant and inverse matrix. Since these step has to be recomputed several times (as many times as number of words times number of topics in one Gibbs sweep, in the worst case), it is critical to make the process as efficient as possible. We speed up this process by employing a combination of modern computational techniques and mathematical (linear algebra) tricks, as described in the following subsections.

4.1 Faster sampling using Cholesky decomposition of covariance matrix

Having another look at the posterior equation for $\boldsymbol{\Psi}_k$, we can re-write the equation as:

$$\begin{aligned}\boldsymbol{\Psi}_k &= \boldsymbol{\Psi} + \mathbf{C}_k + \frac{\kappa N_k}{\kappa_k}(\bar{\mathbf{v}}_k - \boldsymbol{\mu})(\bar{\mathbf{v}}_k - \boldsymbol{\mu})^\top \\ &= \boldsymbol{\Psi} + \sum_d \sum_{i:z_{d,i}=k} \mathbf{v}_{d,i}\mathbf{v}_{d,i}^\top - \kappa_k \boldsymbol{\mu}_k \boldsymbol{\mu}_k^\top \\ &\quad + \kappa \boldsymbol{\mu}\boldsymbol{\mu}^\top. \end{aligned} \tag{3}$$

During sampling when we are computing the assignment probability of topic k to $\mathbf{v}_{d,i}$, we need to calculate the updated parameters of the topic. Using (3) it can be shown that $\boldsymbol{\Psi}_k$ can be updated from current value of $\boldsymbol{\Psi}_k$, after updating $\kappa_k.\nu_k$ and μ_k, as follows:

$$\boldsymbol{\Psi}_k \leftarrow \boldsymbol{\Psi}_k + \frac{\kappa_k}{\kappa_k - 1}\left(\boldsymbol{\mu}_k - \mathbf{v}_{d,i}\right)\left(\boldsymbol{\mu}_k - \mathbf{v}_{d,i}\right)^\top . \tag{4}$$

This equation has the form of a rank 1 update, hinting towards use of Cholesky decomposition. If we have the Cholesky decomposition of $\boldsymbol{\Psi}_k$ computed, then we have tools to update $\boldsymbol{\Psi}_k$ cheaply. Since $\boldsymbol{\Psi}_k$ and $\boldsymbol{\Sigma}_k$ are off by only a scalar factor, we can equivalently talk about $\boldsymbol{\Sigma}_k$. Equation (4) can also be understood in the following way. During sampling, when a word embedding $\mathbf{v}_{d,i}$ gets a new assignment to a topic, say k, then the new value of the topic covariance can be computed from the current one using just a rank 1 update.[2] We next describe how to exploit the Cholesky decomposition representation to speed up computations.

For sake of completeness, any symmetric $M \times M$ real matrix $\boldsymbol{\Sigma}_k$ is said to be positive definite if $\forall \mathbf{z} \in \mathbb{R}^M : \mathbf{z}^\top \boldsymbol{\Sigma}_k \mathbf{z} > 0$. The Cholesky decomposition of such a symmetric positive definite matrix $\boldsymbol{\Sigma}_k$ is nothing but its decomposition into the product of some lower triangular matrix $\mathbf{L}$ and its transpose, i.e.

$$\boldsymbol{\Sigma}_k = \mathbf{L}\mathbf{L}^\top.$$

Finding this factorization also take cubic operation. However given Cholesky decomposition of $\boldsymbol{\Sigma}_k$, after a rank 1 update (or downdate), i.e. the operation:

$$\boldsymbol{\Sigma}_k \leftarrow \boldsymbol{\Sigma}_k + \mathbf{z}\mathbf{z}^\top$$

we can find the factorization of new $\boldsymbol{\Sigma}_k$ in just quadratic time (Stewart, 1998). We will use this trick to speed up the computations[3]. Basically, instead of computing determinant and inverse again in cubic time, we will use such rank 1 update (downdate) to find new determinant and inverse in an efficient manner as explained in details below.

To compute the density of the posterior predictive $t-$distribution, we need to compute the determinant $|\boldsymbol{\Sigma}_k|$ and the term of the form $(\mathbf{v}_{d,i} - \boldsymbol{\mu}_k)^\top \boldsymbol{\Sigma}_k^{-1} (\mathbf{v}_{d,i} - \boldsymbol{\mu}_k)$. The Cholesky decomposition of the covariance matrix can be used for efficient computation of these expression as shown below.

[2] Similarly the covariance of the old topic assignment of the word w can be computed using a rank 1 downdate

[3] For our experiments, we set the prior covariance to be 3*$\mathcal{I}$, which is a positive definite matrix.

Computation of determinant: The determinant of $\mathbf{\Sigma}_k$ can be computed from from its Cholesky decomposition $\mathbf{L}$ as:

$$\log(|\mathbf{\Sigma}_k|) = 2 \times \sum_{i=1}^{M} \log\left(\mathbf{L}_{i,i}\right).$$

This takes linear time in the order of dimension and is clearly a significant gain from cubic time complexity.

Computation of $(\mathbf{v}_{d,i} - \boldsymbol{\mu}_k)^\top \mathbf{\Sigma}_k^{-1}(\mathbf{v}_{d,i} - \boldsymbol{\mu})$: Let $\mathbf{b} = (\mathbf{v}_{d,i} - \boldsymbol{\mu}_k)$. Now $\mathbf{b}^\top \mathbf{\Sigma}^{-1}\mathbf{b}$ can be written as

$$\begin{aligned} \mathbf{b}^\top \mathbf{\Sigma}^{-1}\mathbf{b} &= \mathbf{b}^\top (\mathbf{L}\mathbf{L}^\top)^{-1}\mathbf{b} \\ &= \mathbf{b}^T (\mathbf{L}^{-1})^\top \mathbf{L}^{-1}\mathbf{b} \\ &= (\mathbf{L}^{-1}\mathbf{b})^\top (\mathbf{L}^{-1}\mathbf{b}) \end{aligned}$$

Now $(\mathbf{L}^{-1}\mathbf{b})$ is the solution of the equation $\mathbf{L}\mathbf{x} = \mathbf{b}$. Also since $\mathbf{L}$ is a lower triangular matrix, this equation can be solved easily using forward substitution. Lastly we will have to take an inner product of $\mathbf{x}$ and $\mathbf{x}^\top$ to get the value of $(\mathbf{v}_{d,i} - \boldsymbol{\mu}_k)^\top \mathbf{\Sigma}^{-1}(\mathbf{v}_{d,i} - \boldsymbol{\mu}_k)$. This step again takes quadratic time and is again a savings from the cubic time complexity.

4.2 Further reduction of sampling complexity using Alias Sampling

Although Cholesky trick helps us to reduce the sampling complexity of a embedding to $O(KM^2)$, it can still be impractical.In Gaussian LDA, the Gibbs sampling equation (1) can be split into two terms. The first term $n_{k,d} \times t_{\nu_k - M+1}\left(\mathbf{v}_{d,i} \middle| \boldsymbol{\mu}_k, \frac{\kappa_k+1}{\kappa_k}\mathbf{\Sigma}_k\right)$ denotes the document contribution and the second term $\alpha_k \times t_{\nu_k - M+1}\left(\mathbf{v}_{d,i} \middle| \boldsymbol{\mu}_k, \frac{\kappa_k+1}{\kappa_k}\mathbf{\Sigma}_k\right)$ denotes the language model contribution. Empirically one can make two observations about these terms. First, $n_{k,d}$ is often a sparse vector, as a document most likely contains only a few of the topics. Secondly, topic parameters (μ_k, Σ_k) captures global phenomenon, and rather change relatively slowly over the iterations. We can exploit these findings to avoid the naive approach to draw a sample from (1).

In particular, we compute the document-specific sparse term exactly and for the remainder language model term we borrow idea from (Li et al., 2014). We use a slightly stale distribution for the language model. Then Metropolis Hastings (MH) algorithm allows us to convert the stale sample into a fresh one, provided that we compute ratios between successive states correctly. It is sufficient to run MH for a few number of steps because the stale distribution acting as the proposal is very similar to the target. This is because, as pointed out earlier, the language model term does not change too drastically whenever we resample a single word. The number of words is huge, hence the amount of change per word is concomitantly small. (Only if one could convert stale bread into fresh one, it would solve world's food problem!)

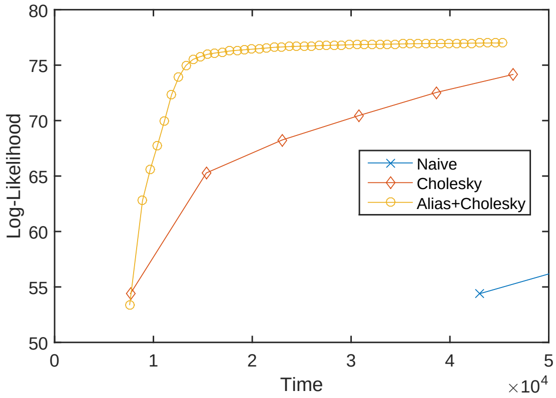

Figure 2: Plot comparing average log-likelihood vs time (in sec) achieved after applying each trick on the NIPS dataset. The shapes on each curve denote end of each iteration.

The exercise of using stale distribution and MH steps is advantageous because sampling from it can be carried out in $O(1)$ amortized time, thanks to alias sampling technique (Vose, 1991). Moreover, the task of building the alias tables can be outsourced to other cores.

With the combination of both Cholesky and Alias tricks, the sampling complexity can thus be brought down to $O(K_d M^2)$ where K_d represents the number of actually instantiated topics in the document and $K_d \ll K$. In particular, we plot the sampling rate achieved naively, with Cholesky (CH) trick and with Cholesky+Alias (A+CH) trick in figure 2 demonstrating better likelihood at much less time. Also after initial few iterations, the time per iteration of A+CH trick is 9.93 times less than CH and 53.1 times less than naive method. This is because initially we start with random initialization of words to topics, but after few iterations the $n_{k,d}$ vector starts to become sparse.

5 Experiments

In this section we evaluate our Word Vector Topic Model on various experimental tasks. Specifically we wish to determine:

- Is our model is able to find coherent and meaningful topics?
- Is our model able to infer the topic distribution of a held-out document even when the document contains words which were previously unseen?

We run our experiments[4] on two datasets 20-NEWSGROUP[5] and NIPS[6]. All the datasets were tokenized and lowercased with `cdec` (Dyer et al., 2010).

5.1 Topic Coherence

Quantitative Analysis Typically topic models are evaluated based on the likelihood of held-out documents. But in this case, it is not correct to compare perplexities with models which do topic modeling on words. Since our topics are continuous distributions, the probability of a word vector is given by its density w.r.t the normal distribution based on its topic assignment, instead of a probability mass from a discrete topic distribution. Moreover, (Chang et al., 2009) showed that higher likelihood of held-out documents doesn't necessarily correspond to human perception of topic coherence. Instead to measure topic coherence we follow (Newman et al., 2009) to compute the Pointwise Mutual Information (PMI) of topic words w.r.t wikipedia articles. We extract the document co-occurrence statistics of topic words from Wikipedia and compute the score of a topic by averaging the score of the top 15 words of the topic. A higher PMI score implies a more coherent topic as it means the topic words usually co-occur in the same document. In the last line of Table 1, we present the PMI score for some of the topics for both Gaussian LDA and traditional multinomial LDA. It can be seen that Gaussian LDA is a clear winner, achieving an average 275% higher score on average.

However, we are using embeddings trained on Wikipedia corpus itself, and the PMI measure is computed from co-occurrence in the Wikipedia corpus. As a result, our model is definitely biased towards producing higher PMI. Nevertheless Wikipedia PMI is a believed to be a good measure of semantic coherence.

Qualitative Analysis Table 1 shows some top words from topics from Gaussian-LDA and LDA on the 20-news dataset for $K = 50$. The words in Gaussian-LDA are ranked based on their density assigned to them by the posterior predictive distribution in the final sample. As shown, Gaussian LDA is able to capture several intuitive topics in the corpus such as sports, government, 'religion', 'universities', 'tech', 'finance' etc. One interesting topic discovered by our model (on both 20-news and NIPS dataset) is the collection of human names, which was not captured by classic LDA. While one might imagine that names associated with particular topics might be preferable to a 'names-in-general' topic, this ultimately is a matter of user preference. More substantively, classic LDA failed to identify the 'finance' topics. We also noticed that there were certain words ('don', 'writes', etc) which often came as a top word in many topics in classic LDA. However our model was not able to capture the 'space' topics which LDA was able to identify.

Also we visualize a part of the continuous space where the word embedding is performed. For this task we performed the Principal Component Analysis (PCA) over all the word vectors and plot the first two components as shown in Figure 3. We can see clear separations between some of the clusters of topics as depicted. The other topics would be separated in other dimensions.

5.2 Performance on document containing new words

In this experiment we evaluate the performance of our model on documents which contains previously unseen words. It should be noted that traditional topic modeling algorithms will typically ignore such words while inferring the topic distribution and hence might miss out important words. The continuous topic distributions of the Word Vector Topic Model on the other hand, will be able

Table 1: Top words of some topics from Gaussian-LDA and multinomial LDA on 20-newsgroups for $K = 50$. Words in Gaussian LDA are ranked based on density assigned to them by the posterior predictive distribution. The last row for each method indicates the PMI score (w.r.t. Wikipedia co-occurence) of the topics fifteen highest ranked words.

to assign topics to an unseen word, if we have the vector representation of the word. Given the recent development of fast and scalable methods of estimating word embeddings, it is possible to train them on huge text corpora and hence it makes our model a viable alternative for topic inference on documents with new words.

Experimental Setup: Since we want to capture the strength of our model on documents containing unseen words, we select a subset of documents and replace words of those documents by its synonyms if they haven't occurred in the corpus before. We obtain the synonym of a word using two existing resources and hence we create two such datasets. For the first set, we use the Paraphrase Database (Ganitkevitch et al., 2013) to get the lexical paraphrase of a word. The paraphrase database[7] is a semantic lexicon containing around 169 million paraphrase pairs of which 7.6 million are lexical (one word to one word) paraphrases. The dataset comes in varying size ranges starting from S to XXXL in increasing order of size and decreasing order of paraphrasing confidence. For our experiments we selected the L size of the paraphrase database.

The second set was obtained using WordNet (Miller, 1995), a large human annotated lexicon for English that groups words into sets of synonyms called synsets. To obtain the synonym of a word, we first label the words with their part-of-speech using the Stanford POS tagger (Toutanova et al., 2003). Then we use the WordNet database

[7] http://www.cis.upenn.edu/~ccb/ppdb/

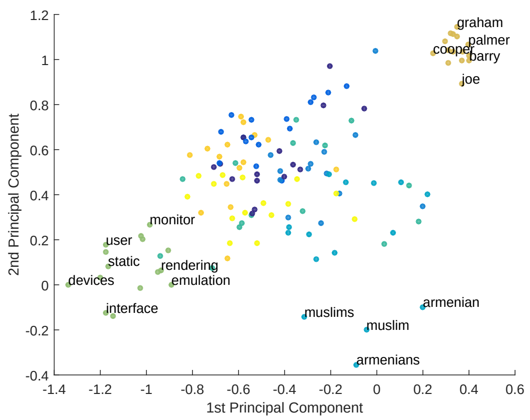

Figure 3: The first two principal components for the word embeddings of the top words of topics shown in Table 1 have been visualized. Each blob represents a word color coded according to its topic in the Table 1.

to get the synonym from its sysnset.[8] We select the first synonym from the synset which hasn't occurred in the corpus before. On the 20-news dataset (vocab size = 18,179 words, test corpus size = 188,694 words), a total of 21,919 words (2,741 distinct words) were replaced by synonyms from PPDB and 38,687 words (2,037 distinct words) were replaced by synonyms from Wordnet.

Evaluation Benchmark: As mentioned before traditional topic model algorithms cannot handle OOV words. So comparing the performance of our document with those models would be unfair. Recently (Zhai and Boyd-Graber, 2013) proposed an extension of LDA (*infvoc*) which can incorporate new words. They have shown better performances in a document classification task which uses the topic distribution of a document as features on the 20-news group dataset as compared to other fixed vocabulary algorithms. Even though, the *infvoc* model can handle OOV words, it will most likely not assign high probability to a new topical word when it encounters it for the first time since it is directly proportional to the number of times the word has been observed On the other hand, our model could assign high probability to the word if its corresponding embedding gets a high probability from one of the topic gaussians. With the experimental setup mentioned before, we want to evaluate performance of this property of our model. Using the topic distribution of a document as features, we try to classify the document into one of the 20 news groups it belongs to. If the document topic distribution is modeled well, then our model should be able to do a better job in the classification task.

To infer the topic distribution of a document we follow the usual strategy of fixing the learnt topics during the training phase and then running Gibbs sampling on the test set (G-LDA (*fix*) in table 2). However *infvoc* is an online algorithm, so it would be unfair to compare our model which observes the entire set of documents during test time. Therefore we implement the online version of our algorithm using Gibbs sampling following (Yao et al., 2009). We input the test documents in batches and do inference on those batches independently also sampling for the topic parameter, along the lines of *infvoc*. The batch size for our experiments are mentioned in parentheses in table 2. We classify using the multi class logistic regression classifier available in `Weka` (Hall et al., 2009).

It is clear from table 2 that we outperform *infvoc* in all settings of our experiments. This implies that even if new documents have significant amount of new words, our model would still do a better job in modeling it. We also conduct an experiment to check the actual difference between the topic distribution of the original and synthetic documents. Let h and h' denote the topic vectors of the original and synthetic documents. Table 3 shows the average l_1, l_2 and l_∞ norm of $(h - h')$ of the test documents in the NIPS dataset. A low value of these metrics indicates higher similarity. As shown in the table, Gaussian LDA performs better here too.

6 Conclusion and Future Work

While word embeddings have been incorporated to produce state-of-the-art results in numerous supervised natural language processing tasks from the word level to document level ; however, they have played a more minor role in unsupervised learning problems. This work shows some of the promise that they hold in this domain. Our model can be extended in a number of potentially useful, but straightforward ways. First, DPMM models of word emissions would better model the fact that identical vectors will be generated multiple times, and perhaps add flexibility to the topic distributions that can be captured, without sacrificing our

[8] We use the `JWI` toolkit (Finlayson, 2014)

Model	Accuracy	
	PPDB	WordNet
infvoc	28.00%	19.30%
G-LDA (*fix*)	44.51%	43.53%
G-LDA (*1*)	44.66%	43.47%
G-LDA (*100*)	43.63%	43.11%
G-LDA (*1932*)	44.72%	42.90%

Table 2: Accuracy of our model and *infvoc* on the synthetic datasets. In Gaussian LDA *fix*, the topic distributions learnt during training were fixed; G-LDA(*1, 100, 1932*) is the online implementation of our model where the documents comes in mini-batches. The number in parenthesis denote the size of the batch. The full size of the test corpus is 1932.

Model	PPDB (Mean Deviation)		
	L_1	L_2	L_∞
infvoc	94.95	7.98	1.72
G-LDA (*fix*)	15.13	1.81	0.66
G-LDA (*1*)	15.71	1.90	0.66
G-LDA (*10*)	15.76	1.97	0.66
G-LDA (*174*)	14.58	1.66	0.66

Table 3: This table shows the Average L_1 Deviation, Average L_2 Deviation, Average L_∞ Deviation for the difference of the topic distribution of the actual document and the synthetic document on the NIPS corpus. Compared to *infvoc*, G-LDA achieves a lower deviation of topic distribution inferred on the synthetic documents with respect to actual document. The full size of the test corpus is 174.

preference for topical coherence. More broadly still, running LDA on documents consisting of different modalities than just text is facilitated by using the *lingua franca* of vector space representations, so we expect numerous interesting applications in this area. An interesting extension to our work would be the ability to handle polysemous words based on multi-prototype vector space models (Neelakantan et al., 2014; Reisinger and Mooney, 2010) and we keep this as an avenue for future research.

Abstract

We present a novel framework for machine translation evaluation using neural networks in a pairwise setting, where the goal is to select the better translation from a pair of hypotheses, given the reference translation. In this framework, lexical, syntactic and semantic information from the reference and the two hypotheses is compacted into relatively small distributed vector representations, and fed into a multi-layer neural network that models the interaction between each of the hypotheses and the reference, as well as between the two hypotheses. These compact representations are in turn based on word and sentence embeddings, which are learned using neural networks. The framework is flexible, allows for efficient learning and classification, and yields correlation with humans that rivals the state of the art.

1 Introduction

Automatic machine translation (MT) evaluation is a necessary step when developing or comparing MT systems. *Reference*-based MT evaluation, i.e., comparing the system output to one or more human reference translations, is the most common approach. Existing MT evaluation measures typically output an absolute quality score by computing the similarity between the machine and the human translations. In the simplest case, the similarity is computed by counting word n-gram matches between the translation and the reference. This is the case of BLEU (Papineni et al., 2002), which has been the standard for MT evaluation for years. Nonetheless, more recent evaluation measures take into account various aspects of linguistic similarity, and achieve better correlation with human judgments.

Having absolute quality scores at the sentence level allows to rank alternative translations for a given source sentence. This is useful, for instance, for statistical machine translation (SMT) parameter tuning, for system comparison, and for assessing the progress during MT system development. The quality of automatic MT evaluation metrics is usually assessed by computing their correlation with human judgments. To that end, quality rankings of alternative translations have been created by human judges. It is known that assigning an absolute score to a translation is a difficult task for humans. Hence, ranking-based evaluations, where judges are asked to rank the output of 2 to 5 systems, have been used in recent years, which has yielded much higher inter-annotator agreement (Callison-Burch et al., 2007).

These human quality judgments can be used to train automatic metrics. This supervised learning can be oriented to predict absolute scores, e.g., using regression (Albrecht and Hwa, 2008), or rankings (Duh, 2008; Song and Cohn, 2011). A particular case of the latter is used to learn in a pairwise setting, i.e., given a reference and two alternative translations (or hypotheses), the task is to decide which one is better. This setting emulates closely how human judges perform evaluation assessments in reality, and can be used to produce rankings for an arbitrarily large number of hypotheses. In this pairwise setting, the challenge is to learn, from a pair of hypotheses, which are the features that help to discriminate the better from the worse translation. Although the pairwise setting does not produce absolute quality scores (i.e., it is not an evaluation metric applicable to a single translation), it is useful and arguably sufficient for most evaluation and MT development scenarios.[1]

[1] We do not argue that the pairwise approach is better than the direct estimation of human quality scores. Both approaches have pros and cons; we see them as complementary.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 805–814,
Beijing, China, July 26-31, 2015.

Recently, Guzmán et al. (2014a) presented a learning framework for this pairwise setting, based on preference kernels and support vector machines (SVM). They obtained promising results using syntactic and discourse-based structures. However, using convolution kernels over complex structures comes at a high computational cost both at training and at testing time because the use of kernels requires that the SVM operate in the much slower dual space. Thus, some simplification is needed to make it practical. While there are some solutions in the kernel-based learning framework to alleviate the computational burden, in this paper we explore an entirely different direction.

We present a novel neural-based architecture for learning in the pairwise setting for MT evaluation. Lexical, syntactic and semantic information from the reference and the two hypotheses is compacted into relatively small distributed vector representations and fed into the input layer, together with a set of individual real-valued features coming from simple pre-existing MT evaluation metrics. A hidden layer, motivated by our intuitions on the pairwise ranking problem, is used to capture interactions between the relevant input components. Finally, we present a task-oriented cost function, specifically tailored for this problem.

Our evaluation results on the *WMT12 metrics task* benchmark datasets (Callison-Burch et al., 2012) show very high correlation with human judgments. These results clearly surpass (Guzmán et al., 2014a) and are comparable to the best previously reported results for this dataset, achieved by DiscoTK (Joty et al., 2014), which is a much heavier combination-based metric.

Another advantage of the proposed architecture is efficiency. Due to the vector-based compression of the linguistic structure and the relatively reduced size of the network, testing is fast, which would greatly facilitate the practical use of this approach in real MT evaluation and development. Finally, we empirically show that syntactically- and semantically-oriented embeddings can be incorporated to produce sizeable and cumulative gains in performance over a strong combination of pre-existing MT evaluation measures (BLEU, NIST, METEOR, and TER). This is promising evidence towards our longer-term goal of defining a general platform for integrating varied linguistic information and for producing more informed MT evaluation measures.

2 Related Work

Contemporary MT evaluation measures have evolved beyond simple lexical matching, and now take into account various aspects of linguistic structures, including synonymy and paraphrasing (Lavie and Denkowski, 2009), syntax (Giménez and Màrquez, 2007; Popović and Ney, 2007; Liu and Gildea, 2005), semantics (Giménez and Màrquez, 2007; Lo et al., 2012), and even discourse (Comelles et al., 2010; Wong and Kit, 2012; Guzmán et al., 2014b; Joty et al., 2014). The combination of several of these aspects has led to improved results in metric evaluation campaigns, such as the *WMT metrics task* (Bojar et al., 2014).

In this paper, we present a general framework for learning to rank translations in the pairwise setting, using information from several linguistic representations of the translations and references. This work has connections with the ranking-based approaches for learning to reproduce human judgments of MT quality. In particular, our setting is similar to that of Duh (2008), but differs from it both in terms of the feature representation and of the learning framework. For instance, we integrate several layers of linguistic information, while Duh (2008) only used lexical and POS matches as features. Secondly, we use information about both the reference and the two alternative translations simultaneously in a neural-based learning framework capable of modeling complex interactions between the features.

Another related work is that of Kulesza and Shieber (2004), in which lexical and syntactic features, together with other metrics, e.g., BLEU and NIST, are used in an SVM classifier to discriminate good from bad translations. However, their setting is not pairwise comparison, but a classification task to distinguish *human-* from *machine-produced* translations. Moreover, in their work, using syntactic features decreased the correlation with human judgments dramatically (although classification accuracy improved), while in our case the effect is positive.

In our previous work (Guzmán et al., 2014a), we introduced a learning framework for the pairwise setting, based on preference kernels and SVMs. We used lexical, POS, syntactic and discourse-based information in the form of tree-like structures to learn to differentiate better from worse translations.

However, in that work we used convolution kernels, which is computationally expensive and does not scale well to large datasets and complex structures such as graphs and enriched trees. This inefficiency arises both at training and testing time. Thus, here we use neural embeddings and multilayer neural networks, which yields an efficient learning framework that works significantly better on the same datasets (although we are not using exactly the same information for learning).

To the best of our knowledge, the application of structured neural embeddings and a neural network learning architecture for MT evaluation is completely novel. This is despite the growing interest in recent years for deep neural nets (NNs) and word embeddings with application to a myriad of NLP problems. For example, in SMT we have observed an increased use of neural nets for language modeling (Bengio et al., 2003; Mikolov et al., 2010) as well as for improving the translation model (Devlin et al., 2014; Sutskever et al., 2014).

Deep learning has spread beyond language modeling. For example, recursive NNs have been used for syntactic parsing (Socher et al., 2013a) and sentiment analysis (Socher et al., 2013b). The increased use of NNs by the NLP community is in part due to (*i*) the emergence of tools such as word2vec (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014), which have enabled NLP researchers to learn word embeddings, and (*ii*) unified learning frameworks, e.g., (Collobert et al., 2011), which cover a variety of NLP tasks such as part-of-speech tagging, chunking, named entity recognition, and semantic role labeling.

While in this work we make use of widely available pre-computed structured embeddings, the novelty of our work goes beyond the type of information considered as input, and resides on the way it is integrated to a neural network architecture that is inspired by our intuitions about MT evaluation.

3 Neural Ranking Model

Our motivation for using neural networks for MT evaluation is twofold. First, to take advantage of their ability to model complex non-linear relationships efficiently. Second, to have a framework that allows for easy incorporation of rich syntactic and semantic representations captured by word embeddings, which are in turn learned using deep learning.

3.1 Learning Task

Given two translation hypotheses t_1 and t_2 (and a reference translation r), we want to tell which of the two is better.[2] Thus, we have a binary classification task, which is modeled by the class variable y, defined as follows:

$$y = \begin{cases} 1 & \text{if } t_1 \text{ is better than } t_2 \text{ given } r \\ 0 & \text{if } t_1 \text{ is worse than } t_2 \text{ given } r \end{cases} \tag{1}$$

We model this task using a feed-forward neural network (NN) of the form:

$$p(y|t_1, t_2, r) = \mathrm{Ber}(y|f(t_1, t_2, r)) \tag{2}$$

which is a Bernoulli distribution of y with parameter $\sigma = f(t_1, t_2, r)$, defined as follows:

$$f(t_1, t_2, r) = \mathrm{sig}(\mathbf{w_v^T}\phi(t_1, t_2, r) + b_v) \tag{3}$$

where sig is the sigmoid function, $\phi(x)$ defines the transformations of the input x through the hidden layer, $\mathbf{w_v}$ are the weights from the hidden layer to the output layer, and b_v is a bias term.

3.2 Network Architecture

In order to decide which hypothesis is *better* given the tuple (t_1, t_2, r) as input, we first map the hypotheses and the reference to a fixed-length vector $[\mathbf{x}_{t_1}, \mathbf{x}_{t_2}, \mathbf{x}_r]$, using syntactic and semantic embeddings. Then, we feed this vector as input to our neural network, whose architecture is shown in Figure 1.

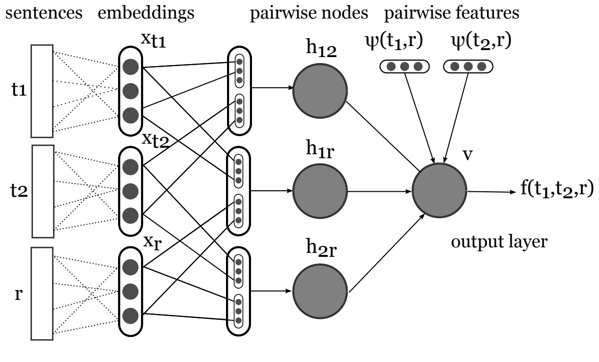

Figure 1: Overall architecture of the neural network.

In our architecture, we model three types of interactions, using different groups of nodes in the hidden layer. We have two *evaluation* groups $\mathbf{h_{1r}}$ and $\mathbf{h_{2r}}$ that model how similar each hypothesis t_i is to the reference r.

[2] In this work, we do not learn to predict ties, and ties are excluded from our training data.

The vector representations of the hypothesis (i.e., $\mathbf{x}_{t1}$ or $\mathbf{x}_{t2}$) together with the reference (i.e., $\mathbf{x}_r$) constitute the input to the hidden nodes in these two groups. The third group of hidden nodes $\mathbf{h_{12}}$, which we call *similarity* group, models how close t_1 and t_2 are. This might be useful as highly similar hypotheses are likely to be comparable in quality, irrespective of whether they are good or bad in absolute terms.

The input to each of these groups is represented by concatenating the vector representations of the two components participating in the interaction, i.e., $\mathbf{x_{1r}} = [\mathbf{x}_{t_1}, \mathbf{x}_r]$, $\mathbf{x_{2r}} = [\mathbf{x}_{t_2}, \mathbf{x}_r]$, $\mathbf{x_{12}} = [\mathbf{x}_{t_1}, \mathbf{x}_{t_2}]$. In summary, the transformation $\phi(t_1, t_2, r) = [\mathbf{h_{12}}, \mathbf{h_{1r}}, \mathbf{h_{2r}}]$ in our NN architecture can be written as follows:

$$\begin{aligned}\mathbf{h_{1r}} &= g(\mathbf{W_{1r}}\mathbf{x_{1r}} + \mathbf{b_{1r}})\\ \mathbf{h_{2r}} &= g(\mathbf{W_{2r}}\mathbf{x_{2r}} + \mathbf{b_{2r}})\\ \mathbf{h_{12}} &= g(\mathbf{W_{12}}\mathbf{x_{12}} + \mathbf{b_{12}})\end{aligned}$$

where $g(.)$ is a non-linear activation function (applied component-wise), $\mathbf{W} \in \mathbb{R}^{H\times N}$ are the associated weights between the input layer and the hidden layer, and $\mathbf{b}$ are the corresponding bias terms. In our experiments, we used $\tanh$ as an activation function, rather than sig, to be consistent with how parts of our input vectors were generated.[3]

In addition, our model allows to incorporate external sources of information by enabling *skip arcs* that go directly from the input to the output, skipping the hidden layer. In our setting, these arcs represent pairwise similarity features between the translation hypotheses and the reference (e.g., the BLEU scores of the translations). We denote these pairwise external feature sets as $\psi_{1r} = \psi(t_1, r)$ and $\psi_{2r} = \psi(t_2, r)$. When we include the external features in our architecture, the activation at the output, i.e., eq. (3), can be rewritten as follows:

$$f(t_1, t_2, r) = \mathrm{sig}(\mathbf{w_v^T}[\phi(t_1, t_2, r), \psi_{1r}, \psi_{2r}] + b_v)$$

3.3 Network Training

The negative log likelihood of the training data for the model parameters $\theta = (\mathbf{W_{12}}, \mathbf{W_{1r}}, \mathbf{W_{2r}}, \mathbf{w_v}, \mathbf{b_{12}}, \mathbf{b_{1r}}, \mathbf{b_{2r}}, b_v)$ can be written as follows:

$$J_\theta = -\sum_n y_n \log \hat{y}_{n\theta} + (1 - y_n)\log(1 - \hat{y}_{n\theta}) \tag{4}$$

In the above formula, $\hat{y}_{n\theta} = f_n(t_1, t_2, r)$ is the activation at the output layer for the n-th data instance. It is also common to use a regularized cost function by adding a weight decay penalty (e.g., L_2 or L_1 regularization) and to perform maximum aposteriori (MAP) estimation of the parameters. We trained our network with stochastic gradient descent (SGD), mini-batches and adagrad updates (Duchi et al., 2011), using Theano (Bergstra et al., 2010).

4 Experimental Setup

In this section, we describe the different aspects of our general experimental setup (we will discuss some extensions thereof in Section 6), starting with a description of the input representations we use to capture the syntactic and semantic characteristics of the two hypothesis translations and the corresponding reference, as well as the datasets used to evaluate the performance of our model.

4.1 Word Embedding Vectors

Word embeddings play a crucial role in our model, since they allow us to model complex relations between the translations and the reference using syntactic and semantic vector representations.

Syntactic vectors. We generate a syntactic vector for each sentence using the Stanford neural parser (Socher et al., 2013a), which generates a 25-dimensional vector as a by-product of syntactic parsing using a recursive NN. Below we will refer to these vectors as SYNTAX25.

Semantic vectors. We compose a semantic vector for a given sentence using the average of the embedding vectors for the words it contains (Mitchell and Lapata, 2010). We use pre-trained, fixed-length word embedding vectors produced by (*i*) GloVe (Pennington et al., 2014), (*ii*) COMPOSES (Baroni et al., 2014), and (*iii*) word2vec (Mikolov et al., 2013b).

Our primary representation is based on 50-dimensional GloVe vectors, trained on Wikipedia 2014+Gigaword 5 (6B tokens), to which below we will refer as WIKI-GW25.

Furthermore, we experiment with WIKI-GW300, the 300-dimensional GloVe vectors trained on the same data, as well as with the CC-300-42B and CC-300-840B, 300-dimensional GloVe vectors trained on 42B and on 840B tokens from Common Crawl.

[3] Many of our input representations consist of word embeddings trained with neural networks that used $\tanh$ as an activation function.

We also experiment with the pre-trained, 300-dimensional word2vec embedding vectors, or WORD2VEC300, trained on 100B words from Google News. Finally, we use COMPOSES400, the 400-dimensional COMPOSES vectors trained on 2.8 billion tokens from ukWaC, the English Wikipedia, and the British National Corpus.

4.2 Tuning and Evaluation Datasets

We experiment with datasets of segment-level human rankings of system outputs from the WMT11, WMT12 and WMT13 Metrics shared tasks (Callison-Burch et al., 2011; Callison-Burch et al., 2012; Macháček and Bojar, 2013). We focus on translating into English, for which the WMT11 and WMT12 datasets can be split by source language: Czech (cs), German (de), Spanish (es), and French (fr); WMT13 also has Russian (ru).

4.3 Evaluation Score

We evaluate our metrics in terms of correlation with human judgments measured using Kendall's τ. We report τ for the individual languages as well as macro-averaged across all languages.

Note that there were different versions of τ at WMT over the years. Prior to 2013, WMT used a strict version, which was later relaxed at WMT13 and further revised at WMT14. See (Macháček and Bojar, 2014) for a discussion. Here we use the strict version used at WMT11 and WMT12.

4.4 Experimental Settings

Datasets: We train our neural models on WMT11 and we evaluate them on WMT12. We further use a random subset of 5,000 examples from WMT13 as a validation set to implement early stopping.

Early stopping: We train on WMT11 for up to 10,000 epochs, and we calculate Kendall's τ on the development set after each epoch. We then select the model that achieves the highest τ on the validation set; in case of ties for the best τ, we select the latest epoch that achieved the highest τ.

Network parameters: We train our neural network using SGD with adagrad, an initial learning rate of $\eta = 0.01$, mini-batches of size 30, and L_2 regularization with a decay parameter $\lambda = 1e^{-4}$. We initialize the weights for our matrices by sampling from a uniform distribution following (Bengio and Glorot, 2010). We further set the size of each of our pairwise hidden layers H to four nodes, and we normalize the input data using min-max to map the feature values to the range $[-1, 1]$.

5 Experiments and Results

The main findings of our experiments are shown in Table 1. Section I of Table 1 shows the results for four commonly-used metrics for MT evaluation that compare a translation hypothesis to the reference(s) using primarily lexical information like word and n-gram overlap (even though some allow paraphrases): BLEU, NIST, TER, and METEOR (Papineni et al., 2002; Doddington, 2002; Snover et al., 2006; Denkowski and Lavie, 2011). We will refer to the set of these four metrics as 4METRICS. These metrics are not tuned and achieve Kendall's τ between 18.5 and 23.5.

Section II of Table 1 shows the results for multilayer neural networks trained on vectors from word embeddings only: SYNTAX25 and WIKI-GW25. These networks achieve modest τ values around 10, which should not be surprising: they use very general vector representations and have no access to word or n-gram overlap or to length information, which are very important features to compute similarity against the reference. However, as will be discussed below, their contribution is complementary to the four previous evaluation metrics and will lead to significant improvements in combination with them.

Section III of Table 1 shows the results for neural networks that combine the four metrics from 4METRICS with SYNTAX25 and WIKI-GW25. We can see that just combining the four metrics in a flat neural net (i.e., no hidden layer), which is equivalent to a logistic regression, yields a τ of 27.06, which is better than the best of the four metrics by 3.5 points absolute, and also better by over 1.5 points absolute than the best metric that participated at the WMT12 metrics task competition (SPEDE07PP with $\tau = 25.4$). Indeed, 4METRICS is a strong mix that involves not only simple lexical overlap but also approximate matching, paraphrases, edit distance, lengths, etc. Yet, adding to 4METRICS the embedding vectors yields sizeable further improvements: +1.5 and +2.0 points absolute when adding SYNTAX25 and WIKI-GW25, respectively. Finally, adding both yields even further improvements close to τ of 30 (+2.64 τ points), showing that lexical semantics and syntactic representations are complementary.

Section IV of Table 1 puts these numbers in perspective: it lists the τ for the top three systems that participated at WMT12, whose scores ranged between 22.9 and 25.4.

	System	**Details**	**Kendall's τ**

	AMBER	3rd at the WMT12 competition	19.1	24.8	23.1	24.5	22.9

Table 1: Kendall's tau (τ) on the WMT12 dataset for various metrics. Notes: (*i*) the version of METEOR that took part in the WMT12 competition (marked with * in section IV of the table) is different from the one used in our experiments (section I of the table), (*ii*) values marked as *na* were not reported by the authors.

We can see that 4METRICS is much stronger than the winner at WMT12, and thus arguably a baseline hard to improve upon. While our results are slightly behind those of DiscoTK (Joty et al., 2014), we should note that we only combine four metrics, plus the vectors, while DiscoTK combines over 20 metrics, many of which are costly to compute.

On the other hand, we work in a ranking framework, i.e., we are not interested in producing an absolute score, but in making pairwise decisions only. Mapping these pairwise decisions into an absolute score is challenging and in our experiments it leads to a slight drop in τ (results omitted here to save space).

The only other result on WMT12 by authors working with our pairwise framework is our own previous work (Guzmán et al., 2014a), where we used a preference kernel approach to combine syntactic and discourse trees with lexical information; as we can see, our earlier results are 6 absolute points lower than those we achieve here. Moreover, our NN approach offers advantages over SVMs in terms of computational cost.

Based on these results, we can conclude that word embeddings, whether syntactic or semantic, offer generalizations that efficiently complement very strong metric combinations, and thus should be considered when designing future MT evaluation metrics.

6 Discussion

In this section, we explore how different parts of our framework can be modified to improve its performance, or how it can be extended for further generalization. First, we explore variations of the feature sets from the perspective of both the pairwise features and the embeddings. Then, we analyze the role of the network architecture and of the cost function used for learning.

6.1 Fine-Grained Pairwise Features

We have shown that our NN can integrate syntactic and semantic vectors with scores from other metrics. In fact, ours is a more general framework, where one can integrate the *components of a metric* instead of its score, which could yield better learning. Below, we demonstrate this for BLEU.

BLEU has different components: the n-gram precisions, the n-gram matches, the total number of n-grams (n=1,2,3,4), the lengths of the hypotheses and of the reference, the length ratio between them, and BLEU's brevity penalty. We will refer to this decomposed BLEU as BLEUCOMP. Some of these features were previously used in SIMPBLEU (Song and Cohn, 2011).

The results of using the components of BLEUCOMP as features are shown in Table 2. We see that using a single-layer neural network, which is equivalent to logistic regression, outperforms BLEU by more than +1 τ points absolute.

System	Details	Kendall's τ				
		cz	de	es	fr	AVG
BLEU	no learning	15.88	18.56	18.57	20.83	18.46
BLEUCOMP	logistic regression	18.18	21.13	19.79	19.91	19.75
BLEUCOMP+SYNTAX25	multi-layer NN	20.75	25.32	24.85	23.88	23.70
BLEUCOMP+WIKI-GW25	multi-layer NN	22.96	26.63	25.99	24.10	24.92
BLEUCOMP+SYNTAX25+WIKI-GW25	multi-layer NN	22.84	28.92	27.95	24.90	**26.15**
BLEU+SYNTAX25+WIKI-GW25	*multi-layer NN*	*20.03*	*25.95*	*27.07*	*23.16*	*24.05*

Table 2: Kendall's τ on WMT12 for neural networks using BLEUCOMP, a decomposed version of BLEU. For comparison, the last line shows a combination using BLEU instead of BLEUCOMP.

Source	Alone	Comb.
WIKI-GW25	*10.01*	*29.70*
WIKI-GW300	9.66	**29.90**
CC-300-42B	**12.16**	29.68
CC-300-840B	**11.41**	**29.88**
WORD2VEC300	7.72	29.13
COMPOSES400	**12.35**	28.54

Table 3: Average Kendall's τ on WMT12 for semantic vectors trained on different text collections. Shown are results (*i*) when using the semantic vectors alone, and (*ii*) when combining them with 4METRICS and SYNTAX25. The improvements over WIKI-GW25 are marked in bold.

Details	Kendall's τ				
	cz	de	es	fr	AVG
single-layer	25.86	32.06	30.03	28.45	29.10
multi-layer	26.30	33.19	30.38	28.92	**29.70**

Table 4: Kendall's tau (τ) on the WMT12 dataset for alternative architectures using 4METRICS+SYNTAX25+WIKI-GW25 as input.

As before, adding SYNTAX25 and WIKI-GW25 improves the results, but now by a more sizable margin: +4 for the former and +5 for the latter. Adding both yields +6.5 improvement over BLEUCOMP, and almost 8 points over BLEU.

We see once again that the syntactic and semantic word embeddings are complementary to the information sources used by metrics such as BLEU, and that our framework can learn from richer pairwise feature sets such as BLEUCOMP.

6.2 Larger Semantic Vectors

One interesting aspect to explore is the effect of the dimensionality of the input embeddings. Here, we studied the impact of using semantic vectors of bigger sizes, trained on different and larger text collections. The results are shown in Table 3. We can see that, compared to the 50-dimensional WIKI-GW25, 300-400 dimensional vectors are generally better by 1-2 τ points absolute when used in isolation; however, when used in combination with 4METRICS+SYNTAX25, they do not offer much gain (up to +0.2), and in some cases, we observe a slight drop in performance. We suspect that the variability across the different collections is due to a domain mismatch. Yet, we defer this question for future work.

6.3 Deep vs. Flat Neural Network

One interesting question is how much of the learning is due to the rich input representations, and how much happens because of the architecture of the neural network. To answer this, we experimented with two settings: a single-layer neural network, where all input features are fed directly to the output layer (which is logistic regression), and our proposed multi-layer neural network.

The results are shown in Table 4. We can see that switching from our multi-layer architecture to a single-layer one yields an absolute drop of 0.6 τ. This suggests that there is value in using the deeper, pairwise layer architecture.

6.4 Task-Specific Cost Function

Another question is whether the log-likelihood cost function $J(\theta)$ (see Section 3.3) is the most appropriate for our ranking task, provided that it is evaluated using Kendall's τ as defined below:

$$\tau = \frac{concord. - disc. - ties}{concord + disc. + ties} \qquad (5)$$

where *concord.*, *disc.* and *ties* are the number of concordant, disconcordant and tied pairs.

Given an input tuple (t_1, t_2, r), the logistic cost function yields larger values of $\sigma = f(t_1, t_2, r)$ if $y = 1$, and smaller if $y = 0$, where $0 \leq \sigma \leq 1$ is the parameter of the Bernoulli distribution. However, it does not model *directly* the probability when the order of the hypotheses in the tuple is reversed, i.e., $\sigma' = f(t_2, t_1, r)$.

	Kendall's τ				
Details	**cz**	**de**	**es**	**fr**	**AVG**
Logistic	26.30	33.19	30.38	28.92	29.70
Kendall	27.04	33.60	29.48	28.54	29.53
Log.+Ken.	26.90	33.17	30.40	29.21	**29.92**

Table 5: Kendall's tau (τ) on WMT12 for alternative cost functions using 4METRICS+SYNTAX25+WIKI-GW25.

For our specific task, given an input tuple (t_1, t_2, r), we want to make sure that the difference between the two output activations $\Delta = \sigma - \sigma'$ is positive when $y = 1$, and negative when $y = 0$. Ensuring this would take us closer to the actual objective, which is Kendall's τ. One possible way to do this is to introduce a task-specific cost function that penalizes the disagreements similarly to the way Kendall's τ does.[4] In particular, we define a new *Kendall cost* as follows:

$$J_\theta = -\sum_n y_n \,\mathrm{sig}(-\gamma\Delta_n) + (1 - y_n)\,\mathrm{sig}(\gamma\Delta_n) \tag{6}$$

where we use the sigmoid function sig as a differentiable approximation to the step function.

The above cost function penalizes disconcordances, i.e., cases where (*i*) $y = 1$ but $\Delta < 0$, or (*ii*) when $y = 0$ but $\Delta > 0$. However, we also need to make sure that we discourage *ties*. We do so by adding a zero-mean Gaussian regularization term $\exp(-\beta\Delta^2/2)$ that penalizes the value of Δ getting close to zero. Note that the specific values for γ and β are not really important, as long as they are large. In particular, in our experiments, we used $\gamma = \beta = 100$.

Table 5 shows a comparison of the two cost functions: (*i*) the standard logistic cost, and (*ii*) our Kendall cost. We can see that using the Kendall cost enables effective learning, although it is eventually outperformed by the logistic cost. Our investigation revealed that this was due to a combination of slower convergence and poor initialization. Therefore, we further experimented with a setup where we first used the logistic cost to pretrain the neural network, and then we switched to the Kendall cost in order to perform some finer tuning. As we can see in Table 5 (last row), doing so yielded a sizable improvement over using the Kendall cost only; it also improved over using the logistic cost only.

7 Conclusions and Future Work

We have presented a novel framework for learning a tunable MT evaluation metric in a pairwise ranking setting, given pre-existing pairwise human preference judgments.

In particular, we used a neural network, where the input layer encodes lexical, syntactic and semantic information from the reference and the two translation hypotheses, which is efficiently compacted into relatively small embeddings. The network has a hidden layer, motivated by our intuition about the problem, which captures the interactions between the relevant input components. Unlike previously proposed kernel-based approaches, our framework allows us to do both training and inference efficiently. Moreover, we have shown that it can be trained to optimize a task-specific cost function, which is more appropriate for the pairwise MT evaluation setting.

The evaluation results have shown that our NN model yields state-of-the-art results when using lexical, syntactic and semantic features (the latter two based on compact embeddings). Moreover, we have shown that the contribution of the different information sources is additive, thus demonstrating that the framework can effectively integrate complementary information. Furthermore, the framework is flexible enough to exploit different granularities of features such as n-gram matches and other components of BLEU (which individually work better than using the aggregated BLEU score). Finally, we have presented evidence suggesting that using the pairwise hidden layers is advantageous over simpler flat models.

In future work, we would like to experiment with an extension that allows for multiple references. We further plan to incorporate features from the *source* sentence. We believe that our framework can support learning similarities between the two translations and the source, for an improved MT evaluation. Variations of this architecture might be useful for related tasks such as Quality Estimation and hypothesis re-ranking for Machine Translation, where no references are available.

Other aspects worth studying as a complement to the present work include (*i*) the impact of the quality of the syntactic analysis (translations are often just a "word salad"), (*ii*) differences across language pairs, and (*iii*) the relevance of the domain the semantic representations are trained on.

[4] Other variations for ranking tasks are possible, e.g., (Yih et al., 2011).

{seemanna,braunefe,maletti}@ims.uni-stuttgart.de

Abstract

We achieve significant improvements in several syntax-based machine translation experiments using a string-to-tree variant of multi bottom-up tree transducers. Our new parameterized rule extraction algorithm extracts string-to-tree rules that can be discontiguous and non-minimal in contrast to existing algorithms for the tree-to-tree setting. The obtained models significantly outperform the string-to-tree component of the Moses framework in a large-scale empirical evaluation on several known translation tasks. Our linguistic analysis reveals the remarkable benefits of discontiguous and non-minimal rules.

1 Introduction

We present an application of a variant of local multi bottom-up tree transducers (ℓMBOTs) as proposed in Maletti (2011) to statistical machine translation. ℓMBOTs allow discontinuities on the target language side since they have a sequence of target tree fragments instead of a single tree fragment in their rules. The original approach makes use of syntactic information on both the source and the target side (*tree-to-tree*) and a corresponding minimal rule extraction is presented in (Maletti, 2011). Braune et al. (2013) implemented it as well as a decoder inside the Moses framework (Koehn et al., 2007) and demonstrated that the resulting tree-to-tree ℓMBOT system significantly improved over its tree-to-tree baseline using minimal rules. We can see at least two drawbacks in this approach. First, experiments investigating the integration of syntactic information on both sides generally report quality deterioration. For example, Lavie et al. (2008), Liu et al. (2009), and Chiang (2010) noted that translation quality tends to decrease in tree-to-tree systems because the rules become too restrictive. Second, minimal rules (i.e., rules that cannot be obtained from other extracted rules) typically consist of a few lexical items only and are thus not the most suitable to translate idiomatic expressions and other fixed phrases. To overcome these drawbacks, we abolish the syntactic information for the source side and develop a string-to-tree variant of ℓMBOTs. In addition, we develop a new rule extraction algorithm that can also extract non-minimal rules. In general, the number of extractable rules explodes, so our rule extraction places parameterized restrictions on the extracted rules in the same spirit as in (Chiang, 2007). In this manner, we combine the advantages of the hierarchical phrase-based approach on the source side and the tree-based approach with discontinuiety on the target side.

We evaluate our new system in 3 large-scale experiments using translation tasks, in which we expect discontinuiety on the target. MBOTs are powerful but asymmetric models since discontinuiety is available only on the target. We chose to translate from English to German, Arabic, and Chinese. In all experiments our new system significantly outperforms the string-to-tree syntax-based component (Hoang et al., 2009) of Moses. The (potentially) discontiguous rules of our model are very useful in these setups, which we confirm in a quantitative and qualitative analysis.

2 Related work

Modern statistical machine translation systems (Koehn, 2009) are based on different translation models. Syntax-based systems have become widely used because of their ability to handle non-local reordering and other linguistic phenomena better than phrase-based models (Och and Ney, 2004). Synchronous tree substitution grammars (STSGs) of Eisner (2003) use a single source and target tree fragment per rule. In contrast, an ℓMBOT rule contains a single source tree

fragment and a sequence of target tree fragments. ℓMBOTs can also be understood as a restriction of the non-contiguous STSSGs of Sun et al. (2009), which allow a sequence of source tree fragments and a sequence of target tree fragments. ℓMBOT rules require exactly one source tree fragment.

While the mentioned syntax-based models use tree fragments for source and target (tree-to-tree), Galley et al. (2004) and Galley et al. (2006) use syntactic annotations only on the target language side (*string-to-tree*). Further research by DeNeefe et al. (2007) revealed that adding non-minimal rules improves translation quality in this setting. Here we improve statistical machine translation in this setting even further using non-minimal ℓMBOT rules.

3 Theoretical Model

As our translation model, we use a string-to-tree variant of the shallow local multi bottom-up tree transducer of Braune et al. (2013). We will call our variant MBOT for simplicity. Our MBOT is a synchronous grammar (Chiang, 2006) similar to a synchronous context-free grammar (SCFG), but instead of a single source and target fragment per rule, our rules are of the form $s \to (t_1, \dots, t_n)$ with a single *source string* s and potentially several *target tree fragments* $t_1, \dots, t_n$. Besides lexical items the source string can contain (several occurrences of) the placeholder X, which links to non-lexical leaves in the target tree fragments. In contrast to an SCFG each placeholder can have several such links. However, each non-lexical leaf in a target tree fragment has exactly one such link to a placeholder X. An MBOT is simply a finite collection of such rules. Several valid rules are depicted in Figure 1.

The sentential forms of our MBOTs, which occur during derivations, have exactly the same shape as our rules and each rule is a sentential form. We can combine sentential forms with the help of substitution (Chiang, 2006). Roughly speaking, in a sentential form ξ we can replace a placeholder X that is linked (left-to-right) to non-lexical leaves $C_1, \dots, C_k$ in the target tree fragments by the source string of any sentential form ζ, whose roots of the target tree fragments (left-to-right) read $C_1, \dots, C_k$. The target tree fragments of ζ will replace the respective linked leaves in the target tree fragments of the sentential form ξ. In other words, substitution has to respect the symbols in the linked target tree fragments and all linked leaves are replaced at the same time. We illustrate substitution in Figure 2, where we replace the placeholder X in the source string, which is linked to the underlined leaves NP and PP in the target tree fragments. The rule below (also in Figure 1) is also a sentential form and matches since its (underlined) root labels of the target tree fragments read "NP PP". Thus, we can substitute the latter sentential form into the former and obtain the sentential form shown at the bottom of Figure 2. Ideally, the substitution process is repeated until the complete source sentence is derived.

4 Rule Extraction

The rule extraction of Maletti (2011) extracts minimal tree-to-tree rules, which are rules containing both source and target tree fragments, from sentence pairs of a word-aligned and bi-parsed parallel corpus. In particular, this requires parses for both the source and the target language sentences which adds a source for errors and specificity potentially leading to lower translation performance and lower coverage (Wellington et al., 2006). Chiang (2010) showed that string-to-tree systems—

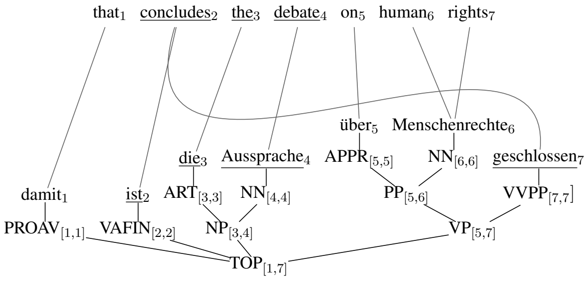

Figure 3: Word-aligned sentence pair with target-side parse.

which he calls fuzzy tree-to-tree-systems— generally yield higher translation quality compared to corresponding tree-to-tree systems.

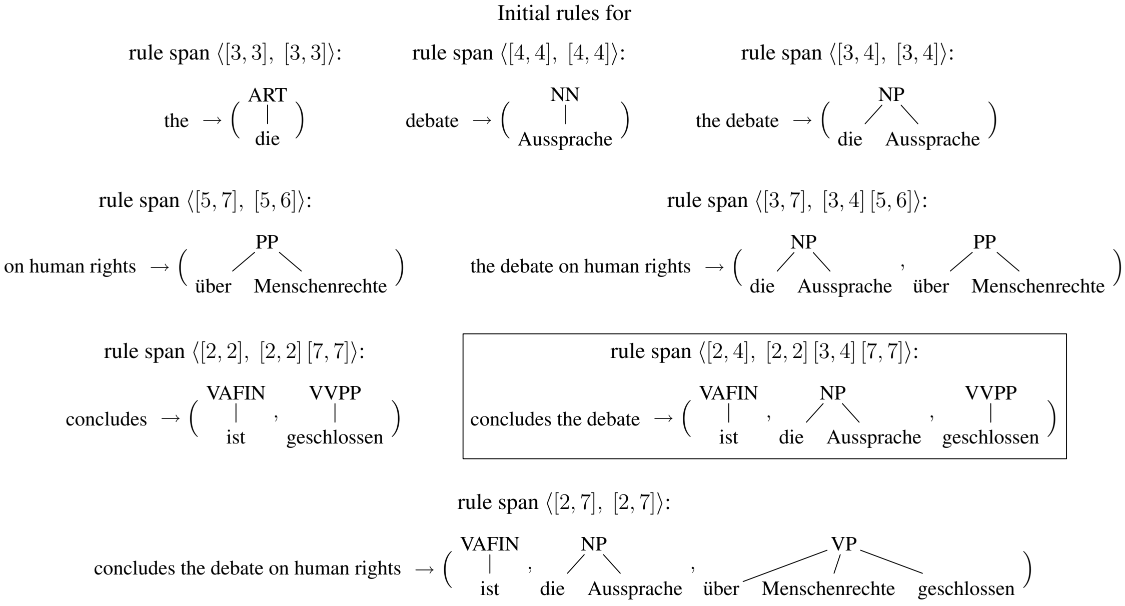
For efficiency reasons the rule extraction of Maletti (2011) only extracts *minimal* rules, which are the smallest tree fragments compatible with the given word alignment and the parse trees. Similarly, non-minimal rules are those that can be obtained from minimal rules by substitution. In particular, each lexical item of a sentence pair occurs in exactly one minimal rule extracted from that sentence pair. However, minimal rules are especially unsuitable for fixed phrases consisting of rare words because minimal rules encourage small fragments and thus word-by-word translation. Consequently, such fixed phrases will often be assembled inconsistently by substitution from small fragments. Non-minimal rules encourage a consistent translation by covering larger parts of the source sentence.

Here we want to develop an efficient rule extraction procedure for our string-to-tree MBOTs that avoids the mentioned drawbacks. Naturally, we could substitute minimal rules into each other to obtain non-minimal rules, but performing substitution for all combinations is clearly intractable. Instead we essentially follow the approach of Koehn et al. (2003), Och and Ney (2004), and Chiang (2007), which is based on consistently aligned phrase pairs. Our training corpus contains *word-aligned sentence pairs* $\langle e, A, f \rangle$, which contain a source language sentence e, a target language sentence f, and an alignment $A \subseteq [1, \ell_e] \times [1, \ell_f]$, where ℓ_e and ℓ_f are the lengths of the sentences e and f, respectively, and $[i, i'] = \{j \in \mathbb{Z} \mid i \leq j \leq i'\}$ is the span (closed interval of integers) from i to i' for all positive integers $i \leq i'$. Rules are extracted for each pair of the corpus, so in the following let $\langle e, A, f \rangle$ be a word-aligned sentence pair. A *source phrase* is simply a span $[i, i'] \subseteq [1, \ell_e]$ and correspondingly, a *target phrase* is a span $[j, j'] \subseteq [1, \ell_f]$. A *rule span* is a pair $\langle p, \varphi \rangle$ consisting of a source phrase p and a sequence $\varphi = p_1 \cdots p_n$ of (non-overlapping) target phrases $p_1, \ldots, p_n$. Spans overlap if their intersection is non-empty. If $n = 1$ (i.e., there is exactly one target phrase in φ) then $\langle p, \varphi \rangle$ is also a phrase pair (Koehn et al., 2003). We want to emphasize that formally phrases are spans and not the substrings occuring at that span.

Next, we lift the notion of consistently aligned phrase pairs to our rule spans. Simply put, for a consistently aligned rule span $\langle p, p_1 \cdots p_n \rangle$ we require that it respects the alignment A in the sense that the origin i of an alignment $(i, j) \in A$ is covered by p if and only if the destination j is covered by $p_1, \ldots, p_n$. Formally, the rule span $\langle p, p_1 \cdots p_n \rangle$ is *consistently aligned* if for every $(i, j) \in A$ we have $i \in p$ if and only if $j \in \bigcup_{k=1}^{n} p_k$. For example, given the word-aligned sentence pair in Figure 3, the rule span $\langle [2, 4],\ [2, 4]\,[7, 7] \rangle$ is consistently aligned, whereas the phrase pair $\langle [2, 4],\ [2, 7] \rangle$ is not.

Our MBOTs use rules consisting of a source string and a sequence of target tree fragments. The target trees are provided by a parser for the target language. For each word-aligned sentence pair $\langle e, A, f \rangle$ we thus have a parse tree t for f. An example is provided in Figure 3. We omit a formal definition of trees, but recall that each node η of the parse tree t *governs* a (unique) target phrase. In Figure 3 we have indicated those target phrases (spans) as subscript to the non-lexical node labels. A consistently aligned rule span $\langle p, p_1 \cdots p_n \rangle$ of $\langle e, A, f \rangle$ is *compatible with* t if there exist nodes $\eta_1, \ldots, \eta_n$ of t such that η_k governs p_k for all $1 \leq k \leq n$. For example, given the word-aligned sentence pair and parse tree t in Figure 3, the consistently aligned rule span $\langle [2, 4],\ [2, 4]\,[7, 7] \rangle$ is not compatible with t because there is no node in t that governs $[2, 4]$. However, for the same data, the rule span $\langle [2, 4],\ [2, 2]\,[3, 4]\,[7, 7] \rangle$ is consistently aligned and compatible with t. The required nodes of t are labeled VAFIN, NP, VVPP.

Now we are ready to start the rule extraction. For each consistently aligned rule span $\langle p, p_1 \cdots p_n \rangle$ that is compatible with t and each selection of nodes $\eta_1, \ldots, \eta_n$ of t such that n_k governs p_k for each $1 \leq k \leq n$, we can extract the rule $e(p) \to \big(\mathrm{flat}(t_{\eta_1}), \ldots, \mathrm{flat}(t_{\eta_n})\big)$, where



Initial rules for
rule span ⟨[3,3], [3,3]⟩:
the → (ART die)
rule span ⟨[4,4], [4,4]⟩:
debate → (NN Aussprache)
rule span ⟨[3,4], [3,4]⟩:
the debate → (NP die Aussprache)
rule span ⟨[5,7], [5,6]⟩:
on human rights → (PP über Menschenrechte)
rule span ⟨[3,7], [3,4] [5,6]⟩:
the debate on human rights → (NP die Aussprache , PP über Menschenrechte)
rule span ⟨[2,2], [2,2] [7,7]⟩:
concludes → (VAFIN ist , VVPP geschlossen)
rule span ⟨[2,4], [2,2] [3,4] [7,7]⟩:
concludes the debate → (VAFIN ist , NP die Aussprache , VVPP geschlossen)
rule span ⟨[2,7], [2,7]⟩:
concludes the debate on human rights → (VAFIN ist , NP die Aussprache , VP über Menschenrechte geschlossen)

Figure 4: Some initial rules extracted from the word-aligned sentence pair and parse of Figure 3.

- $e(p)$ is the substring of e at span p,[1]
- $\mathrm{flat}(u)$ removes all internal nodes from u (all nodes except the root and the leaves), and
- t_η is the subtree rooted in η for node η of t.

The rules obtained in this manner are called *initial rules for $\langle e, A, f\rangle$ and t.* For example, for the rule span $\langle[2,4],\ [2,2]\,[3,4]\,[7,7]\rangle$ we can extract only one initial rule. More precisely, we have

- $e([2,4])$ = concludes the debate
- t_{η_1} = (VAFIN ist)
- t_{η_2} = (NP (ART die) (NN Aussprache)),
- and t_{η_3} = (VVPP geschlossen).

The function flat leaves t_{η_1} and t_{η_3} unchanged, but $\mathrm{flat}(t_{\eta_2})$ = (NP die Aussprache). Thus, we obtain the boxed rule of Figure 4.

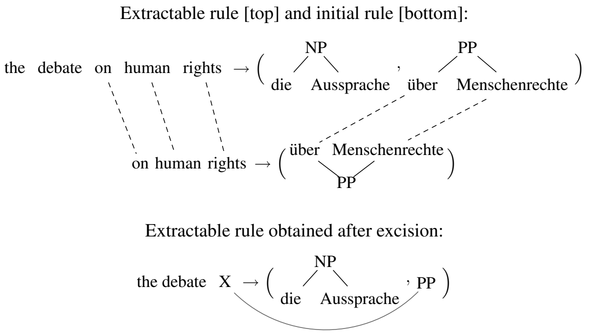
Clearly, the initial rules are just the start because they are completely lexical in the sense that they never contain the placeholder X in the source string nor a non-lexical leaf in any output tree fragment. We introduce non-lexical rules using the same approach as for the hierarchical rules of Chiang (2007). Roughly speaking, we obtain a new rule r'' by "excising" an initial rule r from another rule r' and replacing the removed part by

- the placeholder X in the source string,
- the root label of the removed tree fragment in the target tree fragments, and
- linking the removed parts appropriately,

so that the flatted substitution of r into r'' can yield r'. This "excision" process is illustrated in Figure 5, where we remove the middle initial rule from the topmost initial rule. The result is displayed at the bottom in Figure 5. Formally, the set of *extractable rules* R for a given word-aligned sentence pair $\langle e, A, f\rangle$ with parse tree t for f is the smallest set subject to the following two conditions:

- Each initial rule is in R and thus extractable.
- For every initial rule r and extractable rule $r' \in R$, any flat rule r'', into which we can substitute r to obtain ρ with $\mathrm{flat}(\rho) = r'$, is in R and thus extractable.[2]

For our running example depicted in Figure 3 we display some extractable rules in Figure 6.

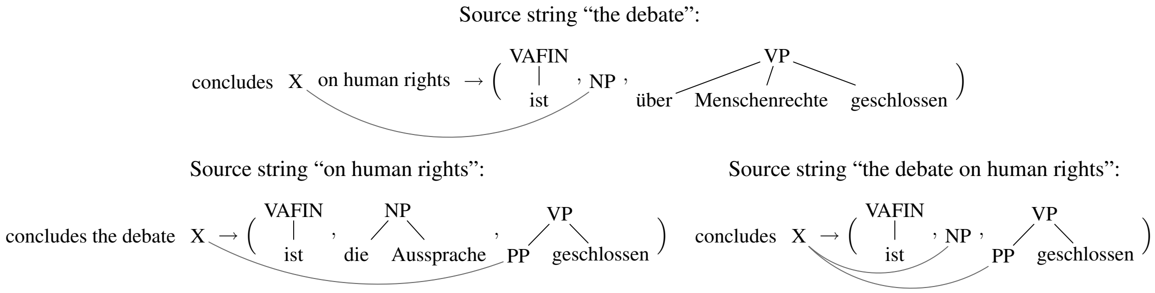


Extractable rule [top] and initial rule [bottom]:
the debate on human rights → (NP die Aussprache , PP über Menschenrechte)
on human rights → (über Menschenrechte PP)
Extractable rule obtained after excision:
the debate X → (NP die Aussprache , PP)

Figure 5: Excision of the middle initial rule from the topmost initial rule. Substituting the middle rule into the result yields the topmost rule.

[1] If $p = [i, i']$, then $e(p) = e[i, i']$ is the substring of e ranging from the i-th token to the i'-th token.

[2] A rule $\rho = s \to (t_1, \dots, t_n)$ is *flat* if $\mathrm{flat}(\rho) = \rho$, where $\mathrm{flat}(\rho) = s \to (\mathrm{flat}(t_1), \dots, \mathrm{flat}(t_n))$.



Source string “the debate”:
concludes X on human rights → (VAFIN ist , NP , VP über Menschenrechte geschlossen)
Source string “on human rights”:
concludes the debate X → (VAFIN ist , NP die Aussprache , VP PP geschlossen)
Source string “the debate on human rights”:
concludes X → (VAFIN ist , NP , VP PP geschlossen)

Figure 6: Extractable rules obtained by excising various initial rules (see Figure 4) from the initial rule displayed at the bottom of Figure 4.

Unfortunately, already Chiang (2007) points out that the set of all extractable rules is generally too large and keeping all extractable rules leads to slow training, slow decoding, and spurious ambiguity. Our MBOT rules are restricted by the parse tree for the target sentence, but the MBOT model permits additional flexibility due to the presence of multiple target tree fragments. Overall, we experience the same problems, and consequently, in the experiments we use the following additional constraints on rules $s \to (t_1, \dots, t_n)$:

(a) We only consider source phrases p of length at most 10 (i.e., $i' - i < 10$ for $p = [i, i']$).[3]
(b) The source string s contains at most 5 occurrences of lexical items or X (i.e. $\ell_s \leq 5$).
(c) The source string s cannot have consecutive Xs (i.e., XX is not a substring of s).
(d) The source string contains at least one lexical item that was aligned in $\langle e, A, f\rangle$.
(e) The left-most token of the source string s cannot be X (i.e., $s[1, 1] \neq$ X).

Our implementation can easily be modified to handle other constraints. Figure 7 shows extractable rules violating those additional constraints.

Table 1 gives an overview on how many rules are extracted. Our string-to-tree variant extracts 12–17 times more rules than the minimal tree-to-tree rule extraction. For our experiments (see Section 6), we filter all rule tables on the given input. The decoding times for the minimal ℓMBOT and our MBOT share the same order of magnitude.

5 Model Features

For each source language sentence e, we want to determine its most likely translation $\hat{f}$ given by

$$\hat{f} = \arg\max_f p(f \mid e) = \arg\max_f p(e \mid f) \cdot p(f)$$

for some unknown probability distributions p. We estimate $p(e \mid f) \cdot p(f)$ by a log-linear combination of features $h_i(\cdot)$ with weights λ_i scored on sentential forms $e \to (t)$ of our extracted MBOT M such that the leaves of t read (left-to-right) f.

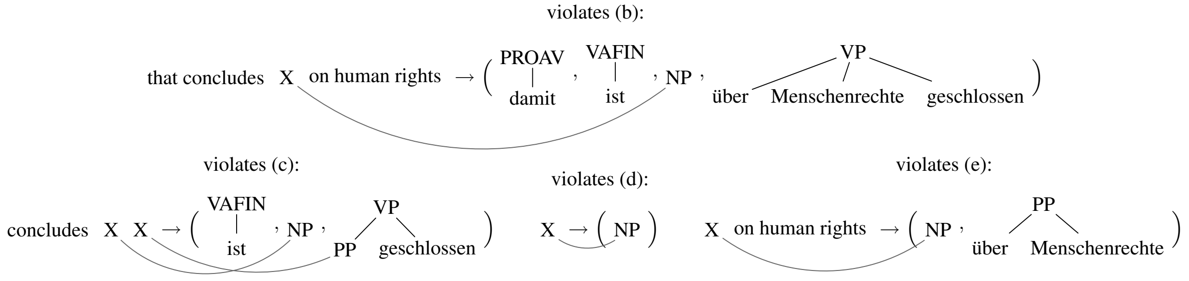
We use the decoder provided by MBOT-Moses of Braune et al. (2013) and its standard features, which includes all the common features (Koehn, 2009) and a gap penalty 100^{1-c}, where c is the number of target tree fragments that contributed to t. This feature discourages rules with many target tree fragments. As usual, all features are obtained as the product of the corresponding rule features for the rules used to derive $e \to (t)$ by means of substitution. The rule weights for the translation weights are obtained as relative frequencies normalized over all rules with the same right- and left-hand side. Good-Turing smoothing (Good, 1953) is applied to all rules that were extracted at most 10 times. The lexical translation weights are obtained as usual.

6 Experimental Results

We considered three reasonable baselines: (i) minimal ℓMBOT, (ii) non-contiguous STSSG (Sun et al., 2009), or (iii) a string-to-tree Moses system. We decided against the minimal ℓMBOT as a baseline since tree-to-tree systems generally get lower BLEU scores than string-to-tree systems. We nevertheless present its BLEU scores (see Table 3). Unfortunately, we could not compare to Sun et al. (2009) because their decoder and rule extraction algorithms are not publicly available. Furthermore, we have the impression that their system does not scale well:

- Only around 240,000 training sentences were used. Our training data contains between 1.8M and 5.7M sentence pairs.
- The development and test set were length-

[3] Note that this restricts the set of initial rules.



violates (b):
that concludes X on human rights → (PROAV damit , VAFIN ist , NP , über Menschenrechte geschlossen VP)
violates (c):
concludes X X → (VAFIN ist , NP , PP geschlossen VP)
violates (d):
X → (NP)
violates (e):
X on human rights → (NP , über Menschenrechte PP)

Figure 7: Showing extractable rules violating the restrictions.

System	number of extracted rules		
	English-To-German	English-To-Arabic	English-To-Chinese
minimal tree-to-tree ℓMBOT	12,478,160	28,725,229	10,162,325
non-minimal string-to-tree MBOT	143,661,376	491,307,787	162,240,663
string-to-tree Moses	14,092,729	55,169,043	17,047,570

Table 1: Overview of numbers of extracted rules with respect to the different extraction algorithms.

ratio filtered to sentences up to 50 characters. We do not modify those sets.

- Only rules with at most one gap were allowed which would be equivalent to restrict the number of target tree fragments to 2 in our system.

Hence we decided to use a string-to-tree Moses system as baseline (see Section 6.1).

6.1 Setup

As a baseline system for our experiments we use the syntax-based component (Hoang et al., 2009) of the Moses toolkit (Koehn et al., 2007). Our system is the presented translation system based on MBOTs. We use the MBOT-Moses decoder (Braune et al., 2013) which – similar to the baseline decoder – uses a CYK+ chart parsing algorithm using a standard X-style parse tree which is sped up by cube pruning (Chiang, 2007) with integrated language model scoring.

Our and the baseline system use linguistic syntactic annotation (parses) only on the target side (*string-to-tree*). During rule extraction we impose the restrictions of Section 4. Additional glue-rules that concatenate partial translations without performing any reordering are used in all systems.

For all experiments (English-to-German, English-to-Arabic, and English-to-Chinese), the training data was length-ratio filtered. The word alignments were generated by GIZA++ (Och and Ney, 2003) with the *grow-diag-final-and* heuristic (Koehn et al., 2005). The following language-specific processing was performed. The German text was true-cased and the functional and morphological annotations were removed from the parse. The Arabic text was tokenized with MADA (Habash et al., 2009) and transliterated according to Buckwalter (2002). Finally, the Chinese text was word-segmented using the Stanford Word Segmenter (Chang et al., 2008).

In all experiments the feature weights λ_i of the log-linear model were trained using minimum error rate training (Och, 2003). The remaining information for the experiments is presented in Table 2.

6.2 Quantitative Analysis

The overall translation quality was measured with 4-gram BLEU (Papineni et al., 2002) on true-cased data for German, on transliterated data for Arabic, and on word-segmented data for Chinese. Significance was computed with Gimpel's implementation (Gimpel, 2011) of pairwise bootstrap resampling with 1,000 samples. Table 3 lists the evaluation results. In all three setups the MBOT system significantly outperforms the baseline. For German we obtain a BLEU score of 15.90 which is a gain of 0.68 points. For Arabic we get an increase of 0.78 points which results in 49.10 BLEU. For Chinese we obtain a score of 18.35 BLEU gaining 0.66 points.[4] We also trained a vanilla phrase-based system for each language pair on the same data as described in Table 2.

To demonstrate the usefulness of the multiple

[4] NIST-08 also shows BLEU for word-segmented output (`http://www.itl.nist.gov/iad/mig/tests/mt/2008/doc/mt08_official_results_v0.html`). Best constrained system: 17.69 BLEU; best unconstrained system: 19.63 BLEU.

target tree fragments of MBOTs, we analyzed the MBOT rules that were used when decoding the test set. We distinguish several types of rules. A rule is *contiguous* if it has only 1 target tree fragment. All other rules are (potentially) *discontiguous*. Moreover, *lexical* rules are rules whose leaves are exclusively lexical items. All other rules (i.e., those that contain at least one non-lexical leaf) are *structural*. Table 4 reports how many rules of each type are used during decoding for both our MBOT system and the minimal ℓMBOT. Below, we focus on analyzing our MBOT system. Out of the rules used for German, 27% were (potentially) discontiguous and 5% were structural. For Arabic, we observe 67% discontiguous rules and 26% structural rules. For translating into Chinese 30% discontiguous rules were used and the structural rules account to 18%. These numbers show that the usage of discontiguous rules tunes to the specific language pair. For instance, Arabic utilizes them more compared to German and Chinese. Furthermore, German uses a lot of lexical rules which is probably due to the fact that it is a morphologically rich language. On the other hand, Arabic and Chinese make good use of structural rules. In addition, Table 4 presents a finer-grained analysis based on the number of target tree fragments. Only rules with at most 8 target tree fragments were used. While German and Arabic seem to require some rules with 6 target tree fragments, Chinese probably does not. We conclude that the number of target tree fragments can be restricted to a language-pair specific number during rule extraction.

6.3 Qualitative Analysis

In this section, we inspect some English-to-German translations generated by the Moses baseline and our MBOT system in order to provide some evidence for linguistic constructions that our system handles better. We identified (a) the realization of reflexive pronouns, relative pronouns, and particle verbs, (b) the realization of verbal material, and (c) local and long distance reordering to be better throughout than in the baseline system. All examples are (parts of) translations of sentences from the test data. Ungrammatical constructions are enclosed in brackets and marked with a star. We focus on instances that seem relevant to the new ability to use non-minimal rules.

We start with an example showing the realization of a reflexive pronoun.

Baseline: . . . [Waffen in den Fabriken nun]⋆, *die nicht einem Wettbewerb auf dem internationalen Markt* []⋆ und . . .
MBOT: . . . [Waffen Fabriken nun]⋆, *die Konkurrenz auf dem internationalen Markt nicht ertragen* und . . .

Figure 10 shows the rules which enable the MBOT system to produce the correct reordering.

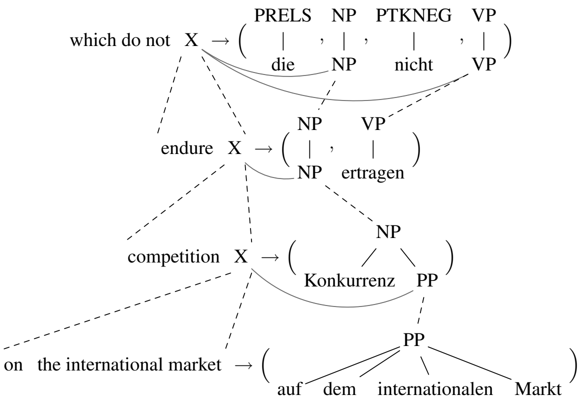

Figure 10: Long distance reordering.

7 Conclusion

We present an application of a string-to-tree variant of local multi bottom-up tree transducers, which are tree-to-tree models, to statistical machine translation. Originally, only minimal rules were extracted, but to overcome the typically lower translation quality of tree-to-tree systems and minimal rules, we abolish the syntactic annotation on the source side and develop a string-to-tree variant. In addition, we present a new parameterized rule extraction that can extract non-minimal rules, which are particularly helpful for translating fixed phrases. It would be interesting to know how much can be gained when using only one contribution at a time. Hence, we will explore the impact of string-to-tree and non-minimal rules in isolation.

We demonstrate that our new system significantly outperforms the standard Moses string-to-tree system on three different large-scale translation tasks (English-to-German, English-to-Arabic, and English-to-Chinese) with a gain between 0.53 and 0.87 BLEU points. An analysis of the rules used to decode the test sets suggests that the usage of discontiguous rules is tuned to each language pair. Furthermore, it shows that only discontiguous rules with at most 8 target tree fragments are used. Thus, further research could investigate a hard limit on the number of target tree fragments during rule extraction. We also perform a manual inspection of the obtained translations and confirm that our string-to-tree MBOT rules can adequately handle discontiguous phrases, which occur frequently in German, Arabic, and Chinese. Other languages that exhibit such phenomena include Czech, Dutch, Russian, and Polish. Thus, we hope that our approach can also be applied successfully to other language pairs.

To support further experimentation by the community, we publicly release our developed software and complete tool-chain (`http://www.ims.uni-stuttgart.de/forschung/ressourcen/werkzeuge/mbotmoses.html`).

Abstract

Modern statistical machine translation (SMT) systems usually use a linear combination of features to model the quality of each translation hypothesis. The linear combination assumes that all the features are in a linear relationship and constrains that each feature interacts with the rest features in an linear manner, which might limit the expressive power of the model and lead to a under-fit model on the current data. In this paper, we propose a non-linear modeling for the quality of translation hypotheses based on neural networks, which allows more complex interaction between features. A learning framework is presented for training the non-linear models. We also discuss possible heuristics in designing the network structure which may improve the non-linear learning performance. Experimental results show that with the basic features of a hierarchical phrase-based machine translation system, our method produce translations that are better than a linear model.

1 Introduction

One of the core problems in the research of statistical machine translation is the modeling of translation hypotheses. Each modeling method defines a score of a target sentence $\mathbf{e} = e_1 e_2 ... e_i ... e_I$, given a source sentence $\mathbf{f} = f_1 f_2 ... f_j ... f_J$, where each e_i is the ith target word and f_j is the jth source word. The well-known modeling method starts from the Source-Channel model (Brown et al., 1993)(Equation 1). The scoring of $\mathbf{e}$ decomposes to the calculation of a translation model and a language model.

$$Pr(\mathbf{e}|\mathbf{f}) = Pr(\mathbf{e})Pr(\mathbf{f}|\mathbf{e})/Pr(\mathbf{f}) \qquad (1)$$

The modeling method is extended to log-linear models by Och and Ney (2002), as shown in Equation 2, where $h_m(\mathbf{e}|\mathbf{f})$ is the mth feature function and λ_m is the corresponding weight.

$$\begin{aligned} Pr(\mathbf{e}|\mathbf{f}) &= p_{\lambda_1^M}(\mathbf{e}|\mathbf{f}) \\ &= \frac{exp[\sum_{m=1}^{M} \lambda_m h_m(\mathbf{e}|\mathbf{f})]}{\sum_{\mathbf{e}'} exp[\sum_{m=1}^{M} \lambda_m h_m(\mathbf{e}'|\mathbf{f})]} \end{aligned} \qquad (2)$$

Because the normalization term in Equation 2 is the same for all translation hypotheses of the same source sentence, the score of each hypothesis, denoted by s_L, is actually a linear combination of all features, as shown in Equation 3.

$$s_L(\mathbf{e}) = \sum_{m=1}^{M} \lambda_m h_m(\mathbf{e}|\mathbf{f}) \qquad (3)$$

The log-linear models are flexible to incorporate new features and show significant advantage over the traditional source-channel models, thus become the state-of-the-art modeling method and are applied in various translation settings (Yamada and Knight, 2001; Koehn et al., 2003; Chiang, 2005; Liu et al., 2006).

It is worth noticing that log-linear models try to separate good and bad translation hypotheses using a linear hyper-plane. However, complex interactions between features make it difficult to linearly separate good translation hypotheses from bad ones (Clark et al., 2014).

Taking common features in a typical phrase-based (Koehn et al., 2003) or hierarchical phrase-based (Chiang, 2005) machine translation system as an example, the language model feature favors shorter hypotheses; the word penalty feature encourages longer hypotheses. The phrase translation probability feature selects phrases that occurs more frequently in the training corpus, which sometimes is long with a lower translation probability, as in translating named entities or idioms;

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 825–835,
Beijing, China, July 26-31, 2015.

sometimes is short but with a high translation probability, as in translating verbs or pronouns. These three features jointly decide the choice of translations. Simply use the weighted sum of their values may not be the best choice for modeling translations. As a result, log-linear models may under-fit the data. This under-fitting may prevents the further improvement of translation quality.

In this paper, we propose a non-linear modeling of translation hypotheses based on neural networks. The traditional features of a machine translation system are used as the input to the network. By feeding input features to nodes in a hidden layer, complex interactions among features are modeled, resulting in much stronger expressive power than traditional log-linear models. (Section 3)

Employing a neural network for SMT modeling has two issues to be tackled. The first issue is the parameter learning. Log-linear models rely on minimum error rate training (MERT) (Och, 2003) to achieve best performance. When the scoring function become non-linear, the intersection points of these non-linear functions could not be effectively calculated and enumerated. Thus MERT is no longer suitable for learning the parameters. To solve the problem, we present a framework for effective training including several criteria to transform the training problem into a binary classification task, a unified objective function and an iterative training algorithm. (Section 4)

The second issue is the structure of neural network. Single layer neural networks are equivalent to linear models; two-layer networks with sufficient nodes are capable of learning any continuous function (Bishop, 1995). Adding more layers into the network could model complex functions with less nodes, but also brings the problem of vanishing gradient (Erhan et al., 2009). We adapt a two-layer feed-forward neural network to keep the training process efficient. We notice that one major problem that prevents a neural network training reaching a good solution is that there are too many local minimums in the parameter space. Thus we discuss how to constrain the learning of neural networks with our intuitions and observations of the features. (Section 5)

Experiments are conducted to compare various settings and verify the effectiveness of our proposed learning framework. Experimental results show that our framework could achieve better translation quality even with the same traditional features as previous linear models. (Section 6)

2 Related work

Many research has been attempting to bring non-linearity into the training of SMT. These efforts could be roughly divided into the following three categories.

The first line of research attempted to re-interpret original features via feature transformation or additional learning. For example, Maskey and Zhou (2012) use a deep belief network to learn representations of the phrase translation and lexical translation probability features. Clark et al. (2014) used discretization to transform real-valued dense features into a set of binary indicator features. Lu et al. (2014) learned new features using a semi-supervised deep auto encoder. These work focus on the explicit representation of the features and usually employ extra learning procedure. Our proposed method only takes the original features, with no transformation, as the input. Feature transformation or combination are performed implicitly during the training of the network and integrated with the optimization of translation quality.

The second line of research attempted to use non-linear models instead of log-linear models, which is most similar in spirit with our work. Duh and Kirchhoff (2008) used the boosting method to combine several results of MERT and achieved improvement in a re-ranking setting. Liu et al. (2013) proposed an additive neural network which employed a two-layer neural network for embedding-based features. To avoid local minimum, they still rely on a pre-training and post-training from MERT or PRO. Comparing to these efforts, our proposed method takes a further step that it is integrated with iterative training, instead of re-ranking, and works without the help of any pre-trained linear models.

The third line of research attempted to add non-linear features/components into the log-linear learning framework. Neural network based models are trained as language models (Vaswani et al., 2013; Auli and Gao, 2014), translation models (Gao et al., 2014) or joint language and translation models (Auli et al., 2013; Devlin et al., 2014). Liu et al. (2013) also introduced word embedding for source and target sides of the translation

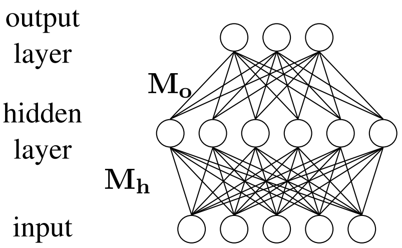

Figure 1: A two-layer feed-forward neural network.

rules as local features. In this paper, we focus on enhancing the expressive power of the modeling, which is independent of the research of enhancing translation systems with new designed features. We believe additional improvement could be achieved by incorporating more features into our framework.

3 Non-linear Translation

The non-linear modeling of translation hypotheses could be used in both phrase-based system and syntax-based systems. In this paper, we take the hierarchical phrase based machine translation system (Chiang, 2005) as an example and introduce how we fit the non-linearity into the system.

3.1 Two-layer Neural Networks

We employ a two-layer neural network as the non-linear model for scoring translation hypotheses. The structure of a typical two-layer feed-forward neural network includes an input layer, a hidden layer, and a output layer (as shown in Figure 1).

We use the input layer to accept input features, the hidden layer to combine different input features, the output layer with only one node to output the model score for each translation hypothesis based on the value of hidden nodes. More specifically, the score of hypothesis $\mathbf{e}$, denoted as s_N, is defined as:

$$s_N(\mathbf{e}) = \sigma_o(M_o \cdot \sigma_h(M_h \cdot h_1^m(\mathbf{e}|\mathbf{f}) + b_h) + b_o) \quad (4)$$

where M, b is the weight matrix, bias vector of the neural nodes, respectively; σ is the activation function, which is often set to non-linear functions such as the tanh function or sigmoid function; subscript h and o indicates the parameters of hidden layer and output layer, respectively.

3.2 Features

We use the standard features of a typical hierarchical phrase based translation system(Chiang, 2005). Adding new features into the framework is left as a future direction. The features as listed as following:

- $p(\alpha|\gamma)$ and $p(\gamma|\alpha)$: conditional probability of translating α as γ and translating α as γ, where α and γ is the left and right hand side of a initial phrase or hierarchical translation rule, respectively;
- $p_w(\alpha|\gamma)$ and $p_w(\gamma|\alpha)$: lexical probability of translating words in α as words in γ and translating words in γ as words in α;
- p_{lm}: language model probability;
- wc: accumulated count of individual words generated during translation;
- pc: accumulated count of initial phrases used;
- rc: accumulated count of hierarchical rule phrases used;
- gc: accumulated count of glue rule used in this hypothesis;
- uc: accumulated count of unknown source word. which has no entry in the translation table;
- nc: accumulated count of source phrases that translate into null;

3.3 Decoding

The basic decoding algorithm could be kept almost the same as traditional phrase-based or syntax-based translation systems (Yamada and Knight, 2001; Koehn et al., 2003; Chiang, 2005; Liu et al., 2006). For example, in the experiments of this paper, we use a CKY style decoding algorithm following Chiang (2005).

Our non-linear translation system is different from traditional systems in the way to calculate the score for each hypothesis. Instead of calculating the score as a linear combination, we use neural networks (Section 3.1) to perform a non-linear combination of feature values.

We also use the cube-pruning algorithm (Chiang, 2005) to keep the decoding efficient. Although the non-linearity in model scores may cause more search errors (Huang and Chiang,

2007) finding the highest scoring hypothesis, in practice it still achieves reasonable results.

4 Non-linear Learning Framework

Traditional machine translation systems rely on MERT to tune the weights of different features. MERT performs efficient search by enumerating the score function of all the hypotheses and using intersections of these linear functions to form the "upper-envelope" of the model score function (Och, 2003). When the scoring function is non-linear, it is not feasible to find the intersections of these functions. In this section, we discuss alternatives to train the parameters for non-linear models.

4.1 Training Criteria

The task of machine translation is a complex problem with structural output space. Decoding algorithms search for the translation hypothesis with the highest score, according to a given scoring function, from an exponentially large set of candidate hypotheses. The purpose of training is to select the scoring function, so that the function score the hypotheses "correctly". The correctness is often introduced by some extrinsic metrics, such as BLEU (Papineni et al., 2002).

We denote the scoring function as $s(\mathbf{f}, \mathbf{e}; \vec{\theta})$, or simply s, which is parameterized by $\vec{\theta}$; denote the set of all translation hypotheses as C; denote the extrinsic metric as $eval(\cdot)$ [1]. Note that, in linear cases, s is a linear function as in Equation 3, while in the non-linear case described in this paper, s is the scoring function in Equation 4.

Ideally, the training objective is to select a scoring function $\hat{s}$, from all functions $\mathcal{S}$, that scores the correct translation (or references) $\hat{\mathbf{e}}$, higher than any other hypotheses (Equation 5).

$$\hat{s} = \{s \in \mathcal{S} | s(\hat{\mathbf{e}}) > s(\mathbf{e}) \, \forall \mathbf{e} \in C\} \tag{5}$$

In practice, the candidate set C is exponentially large and hard to enumerate; the correct translation $\hat{\mathbf{e}}$ may not even exist in the current search space for various reasons, e.g. unknown source word. As a result, we use the n-best set C_{nbest} to approximate C, use the extrinsic metric $eval(\cdot)$ to evaluate the quality of hypotheses in C_{nbest} and use the following three alternatives as approximations to the ideal objective.

Best v.s. Rest (BR) To score the best hypothesis in the n-best set $\tilde{\mathbf{e}}$ higher than the rest hypotheses. This objective is very similar to MERT in that it tries to optimize the score of $\tilde{\mathbf{e}}$ and doesn't concern about the ranking of rest hypotheses. In this case, $\tilde{\mathbf{e}}$ is an approximation of $\hat{\mathbf{e}}$.

Best v.s. Worst (BW) To score the best hypothesis higher than the worst hypothesis in the n-best set. This objective is motivated by the practice of separating the "hope" and "fear" translation hypotheses (Chiang, 2012). We take a simpler strategy which uses the best and worst hypothesis in C_{nbest} as the "hope" and "fear" hypothesis, respectively, in order to avoid multi-pass decoding.

Pairwise (PW) To score the better hypothesis in sampled hypothesis pairs higher than the worse one in the same pair. This objective is adapted from the Pairwise Ranking Optimization (PRO) (Hopkins and May, 2011), which tries to ranking all the hypotheses instead of selecting the best one. We use the same sampling strategy as their original paper.

Note that each of the above criteria transforms the original problem of selecting best hypotheses from an exponential space to a certain pairwise comparison problem, which could be easily trained using binary classifiers.

4.2 Training Objective

For the binary classification task, we use a hinge loss following Watanabe (2012). Because the network has a lot of parameters compared with the linear model, we use a L_1 norm instead of L_2 norm as the regularization term, to favor sparse solutions. We define our training objective function in Equation 6.

$$\begin{aligned} & arg \min_{\theta} \frac{1}{N} \sum_{\mathbf{f} \in D} \sum_{(\mathbf{e}_1, \mathbf{e}_2) \in T(f)} \delta(\mathbf{f}, \mathbf{e}_1, \mathbf{e}_2; \theta) \\ & \qquad + \lambda \cdot ||\theta||_1 \\ & \text{with} \\ & \quad \delta(\cdot) = max\{s(\mathbf{f}, \mathbf{e}_1; \theta) - s(\mathbf{f}, \mathbf{e}_2; \theta) + 1, 0\} \end{aligned} \tag{6}$$

where D is the given training data; $(\mathbf{e}_1, \mathbf{e}_2)$ is a training hypothesis-pair, with $\mathbf{e}_1$ to be the one with

[1] In our experiments, we use sentence level BLEU with +1 smoothing as the evaluation metric.

higher $eval(\cdot)$ score; N is the total number of hypothesis-pairs in D; $T(f)$, or simply T, is the set of hypothesis-pairs for each source sentence f.

The set T is decided by the criterion used for training. For the BR setting, the best hypothesis is paired with every other hypothesis in the n-best list (Equation 7); while for the BW setting, it is only paired with the worst hypothesis (Equation 8). The generation of T in PW setting is the same with PRO sampling, we refer the readers to the original paper of Hopkins and May (2011).

$$T_{BR} = \{(\mathbf{e}_1, \mathbf{e}_2) | \mathbf{e}_1 = arg \max_{\mathbf{e} \in C_{nbest}} eval(\mathbf{e}), \\ \mathbf{e}_2 \in C_{nbest} \text{ and } \mathbf{e}_1 \neq \mathbf{e}_2\} \tag{7}$$

$$T_{BW} = \{(\mathbf{e}_1, \mathbf{e}_2) | \mathbf{e}_1 = arg \max_{\mathbf{e} \in C_{nbest}} eval(\mathbf{e}), \\ \mathbf{e}_2 = arg \min_{\mathbf{e} \in C_{nbest}} eval(\mathbf{e})\} \tag{8}$$

4.3 Training Procedure

In standard training algorithm for classification, the training instances stays the same in each iteration. In machine translation, decoding algorithms usually return a very different n-best set with different parameters. This is due to the exponentially large size of search space. MERT and PRO extend the current n-best set by merging the n-best set of all previous iterations into a pool (Och, 2003; Hopkins and May, 2011). In this way, the enlarged n-best set may give a better approximation of the true hypothesis set C and may lead to better and more stable training results.

We argue that the training should still focus on hypotheses obtained in current round, because in each iteration the searching for the n-best set is independent of previous iterations. To compromise the above two goals, in our practice, training hypothesis pairs are first generated from the current n-best set, then merged with the pairs generated from all previous iterations. In order to make the model focus more on pairs from current iteration, we assign pairs in previous iterations a small constant weight and assign pairs in current iteration a relatively large constant weight [2]. This is inspired by the AdaBoost algorithm (Schapire, 1999) in weighting instances.

Following the spirit of MERT, we propose a iterative training procedure (Algorithm 1). The training starts by randomly initialized model parameters θ^0 (line 1). In ith iteration, the decoding algorithm decodes each sentence $\mathbf{f}$ to get the n-best set C_{nbest} (line 5). Training hypothesis pairs T are extracted from C_{nbest} according to the training criterion described in Section 4.2 (line 6). Newly collected pairs T_i are combined with pairs from previous iterations before used for training (line 9). θ^{i+1} is obtained by solving Equation 6 using the Conjugate Sub-Gradient method (Le et al., 2011) (line 10).

Algorithm 1 Iterative Training Algorithm

```
Input: the set of training sentences $D$, max number of iteration $I$
 1: $\theta^0 \leftarrow$ RandomInit(),
 2: for $i = 0$ to $I$ do
 3:     $T_i \leftarrow \emptyset$;
 4:     for each $\mathbf{f} \in D$ do
 5:         $C_{nbest} \leftarrow$ NbestDecode($\mathbf{f}$ ; $\theta^i$)
 6:         $T \leftarrow$ GeneratePair($C_{nbest}$)
 7:         $T_i \leftarrow T_i \cup T$
 8:     end for
 9:     $T_{all} \leftarrow$ WeightedCombine($\cup_{k=0}^{i-1} T_k, T_i$)
10:     $\theta^{i+1} \leftarrow$ Optimize($T_{all}, \theta^i$)
11: end for
```

5 Structure of the Network

Although neural networks bring strong expressive power to the modeling of translation hypothesis, training a neural network is prone to resulting in local minimum which may affect the training results. We speculate that one reason for these local minimums is that the structure of a well-connected network has too many parameters. Take a neural network with k nodes in the input layer and m nodes in the hidden layer as an example. Every node in the hidden layer is connected to each of the k input nodes. This simple structure resulting in at least $k \times m$ parameters.

In Section 4.2, we use L_1 norm in the objective function in order to get sparser solutions. In this section, we propose some constrained network structures according to our prior knowledge of the features. These structures have much less parameters or simpler structures comparing to original neural networks, thus reduce the possibility of getting stuck in local minimums.

[2] In our experiments, we empirically set the constants to be 0.1 and 0.9, respectively.

5.1 Network with two-degree Hidden Layer

We find the first pitfall of the standard two-layer neural network is that each node in the hidden layer receives input from every input layer node. Features used in SMT are usually manually designed, which has their concrete meanings. For a network of several hidden nodes, combining every features into every hidden node may be redundant and not necessary to represent the quality of a hypothesis.

As a result, we take a harsh step and constrain the nodes in hidden layer to have a in-degree of two, which means each hidden node only accepts inputs from two input nodes. We do not use any other prior knowledge about features in this setting. So for a network with k nodes in the input layer, the hidden layer should contain $C_k^2 = k(k-1)/2$ nodes to accept all combinations from the input layer. We name this network structure as Two-Degree Hidden Layer Network (TDN).

It is easy to see that a TDN has $C_k^2 \times 2 = k(k-1)$ parameters for the hidden layer because of the constrained degree. This is one order of magnitude less than a standard two-layer network with the same number of hidden nodes, which has $C_k^2 \times k = k^2(k-1)/2$ parameters.

Note that we perform a 2-degree combination that looks similar in spirit with those combination of atomic features in large scale discriminative learning for other NLP tasks, such as POS tagging and parsing. However, unlike the practice in these tasks that directly combines values of different features to generate a new feature type, we first linearly combine the value of these features and perform non-linear transformation on these values via an activation function.

5.2 Network with Grouped Features

It might be a too strong constraint to require the hidden node have in-degree of 2. In order to relax this constraint, we need more prior knowledge from the features.

Our first observation is that there are different types of features. These types are different from each other in terms of value ranges, sources, importance, etc. For example, language model features usually take a very small value of probability, and word count feature takes a integer value and usually has a much higher weight in linear case than other count features.

The second observation is that features of the same type may not have complex interaction with each other. For example, it is reasonable to combine language model features with word count features in a hidden node. But it may not be necessary to combine the count of initial phrases and the count of unknown words into a hidden node.

Based on the above two intuitions, we design a new structure of network that has the following constraints: given a disjoint partition of features: G_1, G_2,..., G_k, every hidden node takes input from a set of input nodes, where any two nodes in this set come from two different feature groups. Under this constraint, the in-degree of a hidden node is at most k. We name this network structure as Grouped Network (GN).

In practice, we divide the basic features in Section 3.2 into five groups: language model features, translation probability features, lexical probability features, the word count feature, and the rest of count features. This division considers not only the value ranges, but also types of features and the possibility of them interact with each other.

6 Experiments and Results

6.1 General Settings

We conduct experiments on a large scale machine translation tasks. The parallel data comes from LDC, including LDC2002E18, LDC2003E14, LDC2004E12, LDC2004T08, LDC2005T10, LDC2007T09, which consists of 8.2 million of sentence pairs. Monolingual data includes Xinhua portion of Gigaword corpus. We use multi-references data MT03 as training data, MT02 as development data, and MT04, MT05 as test data. These data are mainly in the same genre, avoiding the extra consideration of domain adaptation.

Data	Usage	Sents.
LDC	TM train	8,260,093
Gigaword	LM train	14,684,074
MT03	train	919
MT02	dev	878
MT04	test	1,789
MT05	test	1,083

Table 1: Experimental data and statistics.

[3] http://ictclas.nlpir.org/

Criteria	MT03(train)	MT02(dev)	MT04	MT05
BR_c	35.02	36.63	34.96	34.15
BR	38.66	40.04	38.73	37.50
BW	39.55	39.36	38.72	37.81
PW	38.61	38.85	38.73	37.98

Table 2: BLEU4 in percentage on different training criteria (”BR”, ”BW” and ”PW” refer to experiments with ”Best v.s. Rest”, ”Best v.s. Worst” and ”Pairwise” training criteria, respectively. ”BR_c” indicates generate hypothesis pairs from n-best set of current iteration only presented in Section 4.3.

tem is an in-house implementation of the hierarchical phrase-based translation system(Chiang, 2005). We set the beam size to 20. We train a 5-gram language model on the monolingual data with MKN smoothing(Chen and Goodman, 1998). For each parameter tuning experiments, we ran the same training procedure 3 times and present the average results. The translation quality is evaluated use 4-gram case-insensitive BLEU (Papineni et al., 2002). Significant test is performed using bootstrap re-sampling implemented by Clark et al. (2011). We employ a two-layer neural network with 11 input layer nodes, corresponding to features listed in Section 3.2 and 1 output layer node. The number of nodes in the hidden layer varies in different settings. The sigmoid function is used as the activation function for each node in the hidden layer. For the output layer we use a linear activation function. We try different λ for the L_1 norm from 0.01 to 0.00001 and use the one with best performance on the development set. We solve the optimization problem with ALGLIB package[4].

6.2 Experiments of Training Criteria

This set experiments evaluates different training criteria discussed in Section 4.1. We generate hypothesis-pair according to BW, BR and PW criteria, respectively, and perform training with these pairs. In the PW criterion, we use the sampling method of PRO (Hopkins and May, 2011) and get the 50 hypothesis pairs for each sentence. We use 20 hidden nodes for all three settings to make a fair comparison.

The results are presented in Table 2. The first two rows compare training with and without the weighted combination of hypothesis pairs we discussed in Section 4.3. As the result suggested, with the weighted combination of hypothesis pairs from previous iterations, the performance improves significantly on both test sets.

Although the system performance on the dev set varies, the performance on test sets are almost comparable. This suggest that although the three training criteria are based on different assumptions, their are basically equivalent for training translation systems.

Criteria	Pairs/iteration	Accuracy(%)
BR	19	70.7
BW	1	79.5
PW	100	67.3

Table 3: Comparison of different training criteria in number of new instances per iteration and training accuracy.

We also compares the three training criteria in their number of new instances per iteration and final training accuracy (Table 3). Compared to BR which tries to separate the best hypothesis from the rest hypotheses in the n-best set, and PW which tries to obtain a correct ranking of all hypotheses, BW only aims at separating the best and worst hypothesis of each iteration, which is a easier task for learning a classifiers. It requires the least training instances and achieves the best performance in training. Note that, the accuracy for each system in Table 3 are the accuracy each system achieves after training stops. They are not calculated on the same set of instances, thus not directly comparable. We use the differences in accuracy as an indicator for the difficulties of the corresponding learning task.

For the rest of this paper, we use the BW criterion because it is much simpler compared to sampling method of PRO (Hopkins and May, 2011).

6.3 Experiments of Network Structures

We make several comparisons of the network structures and compare them with a baseline hierarchical phrase-based translation system (HPB).

Table 4 shows the translation performance of

different systems[5]. All 5 two-layer feed forward neural networks models could achieve comparable or better performance comparing to the baseline system. We can see that training a larger network may lead to better translation quality (from TLayer$_{20}$ and TLayer$_{30}$ to TLayer$_{50}$). However, increasing the number of hidden node to 100 and 200 does not bring further improvement. One possible reason is that training a larger network with arbitrary connections brings in too many parameters which may be difficult to train with limited training data.

TDN and GN are the two network structures proposed in Section 5. With the constraint that all input to the hidden node should be of degree 2, TDN performs comparable to the baseline system. With the grouped feature, we could design networks such as GN, which shows significant improvement over the baseline systems (+0.57) and achieves the best performance among all neural systems.

Table 4 shows statistics related to the efficiency issue of different systems. The baseline system (HPB) uses MERT for training. HPB has a very small number of parameters and searches for the best parameters exhaustively in each iteration. The non-linear systems with few nodes (TLayer$_{20}$ and TLayer$_{30}$) train faster than HPB in each iteration because they perform back-propagation instead of exhaustive search. We iterate 15 iterations for each non-linear system, while MERT takes about 10 rounds to reach its best performance.

When the number of nodes in the hidden layer increases (from 20 to 200), the number of parameters in the system also increases, which requires longer time to compute the score for each hypothesis and to update the parameters through back-propagation. The network with 200 hidden nodes takes about twice the time to train for each iteration, compared to the linear system[6].

TDN and GN have larger numbers of hidden

[5] TLayer$_{20}$ is the same system as BW in Table 2

[6] Matrix operation is CPU intensive. The cost will increase when multiple tasks are running.

nodes. However, because of our intuitions in designing the structure of the networks, the degree of the hidden node is constrained. So these two networks are sparser in parameters and take significant less training time than standard neural networks. For example, GN has a comparable number of hidden nodes with TLayer_{200}, but only has half of its parameters and takes about 70% time to train in each iteration. In other words, our proposed network structure provides more efficient training in these cases and achieve better results.

7 Conclusion

In this paper, we discuss a non-linear framework for modeling translation hypothesis for statistical machine translation system. We also present a learning framework including training criterion and algorithms to integrate our modeling into a state of the art hierarchical phrase based machine translation system. Compared to previous effort in bringing in non-linearity into machine translation, our method uses a single two-layer neural networks and performs training independent with any previous linear training methods (e.g. MERT). Our method also trains its parameters without any pre-training or post-training procedure. Experiment shows that our method could improve the baseline system even with the same feature as input, in a large scale Chinese-English machine translation task.

In training neural networks with hidden nodes, we use heuristics to reduce the complexity of network structures and obtain extra advantages over standard networks. It shows that heuristics and intuitions of the data and features are still important to a machine translation system.

Neural networks are able to perform feature learning by using hidden nodes to model the interaction among a large vector of raw features, as in image and speech processing (Krizhevsky et al., 2012; Hinton et al., 2012). We are trying to model the interaction between hand-crafted features, which is indeed similar in spirit with learning features from raw features. Although our features already have concrete meaning, e.g. the probability of translation, the fluency of target sentence, etc. Combining these features may have extra advantage in modeling the translation process.

As future work, it is necessary to integrate more features into our learning framework. It is also interesting to see how the non-linear modeling fits in to more complex learning tasks which involves domain specific learning techniques.

Abstract

We introduce into Bayesian decipherment a base distribution derived from similarities of word embeddings. We use Dirichlet multinomial regression (Mimno and McCallum, 2012) to learn a mapping between ciphertext and plaintext word embeddings from *non-parallel* data. Experimental results show that the base distribution is highly beneficial to decipherment, improving state-of-the-art decipherment accuracy from 45.8% to 67.4% for Spanish/English, and from 5.1% to 11.2% for Malagasy/English.

1 Introduction

Tremendous advances in Machine Translation (MT) have been made since we began applying automatic learning techniques to learn translation rules automatically from parallel data. However, reliance on parallel data also limits the development and application of high-quality MT systems, as the amount of parallel data is far from adequate in low-density languages and domains.

In general, it is easier to obtain non-parallel monolingual data. The ability to learn translations from monolingual data can alleviate obstacles caused by insufficient parallel data. Motivated by this idea, researchers have proposed different approaches to tackle this problem. They can be largely divided into two groups.

The first group is based on the idea proposed by Rapp (1995), in which words are represented as context vectors, and two words are likely to be translations if their context vectors are similar. Initially, the vectors contained only context words. Later extensions introduced more features (Haghighi et al., 2008; Garera et al., 2009; Bergsma and Van Durme, 2011; Daumé and Jagarlamudi, 2011; Irvine and Callison-Burch, 2013b; Irvine and Callison-Burch, 2013a), and used more abstract representation such as word embeddings (Klementiev et al., 2012).

Another promising approach to solve this problem is decipherment. It has drawn significant amounts of interest in the past few years (Ravi and Knight, 2011; Nuhn et al., 2012; Dou and Knight, 2013; Ravi, 2013) and has been shown to improve end-to-end translation. Decipherment views a foreign language as a cipher for English and finds a translation table that converts foreign texts into sensible English.

Both approaches have been shown to improve quality of MT systems for domain adaptation (Daumé and Jagarlamudi, 2011; Dou and Knight, 2012; Irvine et al., 2013) and low density languages (Irvine and Callison-Burch, 2013a; Dou et al., 2014). Meanwhile, they have their own advantages and disadvantages. While context vectors can take larger context into account, it requires high quality seed lexicons to learn a mapping between two vector spaces. In contrast, decipherment does not depend on any seed lexicon, but only looks at a limited n-gram context.

In this work, we take advantage of both approaches and combine them in a joint inference process. More specifically, we extend previous work in large scale Bayesian decipherment by introducing a better base distribution derived from similarities of word embedding vectors. The main contributions of this work are:

- We propose a new framework that combines the two main approaches to finding translations from monolingual data only.

- We develop a new base-distribution technique that improves state-of-the art decipherment accuracy by a factor of two for Spanish/English and Malagasy/English.
- We make our software available for future research, functioning as a kind of GIZA for non-parallel data.

2 Decipherment Model

In this section, we describe the previous decipherment framework that we build on. This framework follows Ravi and Knight (2011), who built an MT system using only non-parallel data for translating movie subtitles; Dou and Knight (2012) and Nuhn et al. (2012), who scaled decipherment to larger vocabularies; and Dou and Knight (2013), who improved decipherment accuracy with dependency relations between words.

Throughout this paper, we use f to denote target language or ciphertext tokens, and e to denote source language or plaintext tokens. Given ciphertext $\mathbf{f} : f_1...f_n$, the task of decipherment is to find a set of parameters $P(f_i|e_i)$ that convert f to sensible plaintext. The ciphertext $\mathbf{f}$ can either be full sentences (Ravi and Knight, 2011; Nuhn et al., 2012) or simply bigrams (Dou and Knight, 2013). Since using bigrams and their counts speeds up decipherment, in this work, we treat $\mathbf{f}$ as bigrams, where $\mathbf{f} = \{\mathbf{f}^n\}_{n=1}^N = \{f_1^n, f_2^n\}_{n=1}^N$.

Motivated by the idea from Weaver (1955), we model an observed cipher bigram $\mathbf{f}^n$ with the following generative story:

- First, a language model $P(\mathbf{e})$ generates a sequence of two plaintext tokens e_1^n, e_2^n with probability $P(e_1^n, e_2^n)$.
- Then, substitute e_1^n with f_1^n and e_2^n with f_2^n with probability $P(f_1^n \mid e_1^n) \cdot P(f_2^n \mid e_2^n)$.

Based on the above generative story, the probability of any cipher bigram $\mathbf{f^n}$ is:

$$P(\mathbf{f}^n) = \sum_{e_1 e_2} P(e_1 e_2) \prod_{i=1}^{2} P(f_i^n \mid e_i)$$

The probability of the ciphertext corpus,

$$P(\{\mathbf{f}^n\}_{n=1}^N) = \prod_{n=1}^{N} P(\mathbf{f}^n)$$

There are two sets of parameters in the model: the channel probabilities $\{P(f \mid e)\}$ and the bigram language model probabilities $\{P(e' \mid e)\}$, where f ranges over the ciphertext vocabulary and e, e' range over the plaintext vocabulary. Given a plaintext bigram language model, the training objective is to learn $P(f \mid e)$ that maximize $P(\{\mathbf{f}^n\}_{n=1}^N)$. When formulated like this, one can directly apply EM to solve the problem (Knight et al., 2006). However, EM has time complexity $O(N \cdot V_e^2)$ and space complexity $O(V_f \cdot V_e)$, where V_f, V_e are the sizes of ciphertext and plaintext vocabularies respectively, and N is the number of cipher bigrams. This makes the EM approach unable to handle long ciphertexts with large vocabulary size.

An alternative approach is Bayesian decipherment (Ravi and Knight, 2011). We assume that $P(f \mid e)$ and $P(e' \mid e)$ are drawn from a Dirichet distribution with hyper-parameters $\alpha_{f,e}$ and $\alpha_{e,e'}$, that is:

$$P(f \mid e) \sim Dirichlet(\alpha_{f,e})$$
$$P(e \mid e') \sim Dirichlet(\alpha_{e,e'}).$$

The remainder of the generative story is the same as the noisy channel model for decipherment. In the next section, we describe how we learn the hyper parameters of the Dirichlet prior. Given $\alpha_{f,e}$ and $\alpha_{e,e'}$, The joint likelihood of the complete data and the parameters,

$$\begin{aligned}
&P(\{\mathbf{f}^n, \mathbf{e}^n\}_{n=1}^N, \{P(f \mid e)\}, \{P(e \mid e')\}) \\
&= P(\{\mathbf{f}^n \mid \mathbf{e}^n\}_{n=1}^N, \{P(f \mid e)\}) \\
&P(\{\mathbf{e}^n\}_{n=1}^N, P(e \mid e')) \\
&= \prod_e \frac{\Gamma\left(\sum_f \alpha_{f,e}\right)}{\prod_f \Gamma\left(\alpha_{e,f}\right)} \prod_f P(f \mid e)^{\#(e,f)+\alpha_{e,f}-1} \\
&\prod_e \frac{\Gamma\left(\sum_{e'} \alpha_{e,e'}\right)}{\prod_{e'} \Gamma\left(\alpha_{e,e'}\right)} \prod_f P(e \mid e')^{\#(e,e')+\alpha_{e,e'}-1},
\end{aligned} \tag{1}$$

where $\#(e, f)$ and $\#(e, e')$ are the counts of the translated word pairs and plaintext bigram pairs in the complete data, and $\Gamma(\cdot)$ is the Gamma function. Unlike EM, in Bayesian decipherment, we no longer search for parameters $P(f \mid e)$ that maximize the likelihood of the observed ciphertext. Instead, we draw samples from posterior distribution of the plaintext sequences given the ciphertext. Under the above Bayesian decipherment model, it turns out that the probability of a particular cipher word f_j having a value k, given the current plaintext word e_j, and the samples for all the other ciphertext and plaintext words, $\mathbf{f}_{-j}$ and $\mathbf{e}_{-j}$, is:

$$P(f_j = k \mid e_j, \mathbf{f}_{-j}, \mathbf{e}_{-j}) = \frac{\#(k, e_j)_{-j} + \alpha_{e_j,k}}{\#(e_j)_{-j} + \sum_f \alpha_{e_j,f}}.$$

Where, $\#(k, e_j)_{-j}$ and $\#(e_j)_{-j}$ are the counts of the ciphertext, plaintext word pair and plaintext word in the samples excluding f_j and e_j. Similarly, the probability of a plaintext word e_j taking a value l given samples for all other plaintext words,

$$P(e_j = l \mid \mathbf{e}_{-j}) = \frac{\#(l, e_{j-1})_{-j} + \alpha_{l,e_{j-1}}}{\#(e_{j-1})_{-j} + \sum_e \alpha_{e,e_{j-1}}}. \quad (2)$$

Since we have large amounts of plaintext data, we can train a high-quality dependency-bigram language model, $P_{LM}(e \mid e')$ and use it to guide our samples and learn a better posterior distribution. For that, we define $\alpha_{e,e'} = \alpha P_{LM}(e \mid e')$, and set α to be very high. The probability of a plaintext word (Equation 2) is now

$$P(e_j = l \mid \mathbf{e}_{-j}) \approx P_{LM}(l \mid e_{j-1}). \quad (3)$$

To sample from the posterior, we iterate over the observed ciphertext bigram tokens and use equations 2 and 3 to sample a plaintext token with probability

$$P(e_j \mid \mathbf{e}_{-j}, \mathbf{f}) \propto P_{LM}(e_j \mid e_{j-1}) \\ P_{LM}(e_{j+1} \mid e_j) P(f_j \mid e_j, \mathbf{f}_{-j}, \mathbf{e}_{-j}). \quad (4)$$

In previous work (Dou and Knight, 2012), the authors use symmetric priors over the channel probabilities, where $\alpha_{e,f} = \alpha \frac{1}{V_f}$, and they set α to 1. Symmetric priors over word translation probabilities are a poor choice, as one would not a-priori expect plaintext words and ciphertext words to cooccur with equal frequency. Bayesian inference is a powerful framework that allows us to inject useful prior information into the sampling process, a feature that we would like to use. In the next section, we will describe how we model and learn better priors using distributional properties of words. In subsequent sections, we show significant improvements over the baseline by learning better priors.

3 Base Distribution with Cross-Lingual Word Similarities

As shown in the previous section, the base distribution in Bayesian decipherment is given independent of the inference process. A better base distribution can improve decipherment accuracy. Ideally, we should assign higher base distribution probabilities to word pairs that are similar.

One straightforward way is to consider orthographic similarities. This works for closely related languages, e.g., the English word “new” is translated as “neu” in German and “nueva” in Spanish. However, this fails when two languages are not closely related, e.g., Chinese/English. Previous work aims to discover translations from comparable data based on word context similarities. This is based on the assumption that words appearing in similar contexts have similar meanings. The approach straightforwardly discovers monolingual synonyms. However, when it comes to finding translations, one challenge is to draw a mapping between the different context spaces of the two languages. In previous work, the mapping is usually learned from a seed lexicon.

There has been much recent work in learning distributional vectors (embeddings) for words. The most popular approaches are the skip-gram and continuous-bag-of-words models (Mikolov et al., 2013a). In Mikolov et al. (2013b), the authors are able to successfully learn word translations using *linear transformations* between the source and target word vector-spaces. However, unlike our learning setting, their approach relied on large amounts of translation pairs learned from *parallel* data to train their linear transformations. Inspired by these approaches, we aim to exploit high-quality monolingual word embeddings to help learn better posterior distributions in unsupervised decipherment, without any parallel data.

In the previous section, we incorporated our pre-trained language model in $\alpha_{e,e'}$ to steer our sampling. In the same vein, we model $\alpha_{e,f}$ using pre-trained word embeddings, enabling us to improve our estimate of the posterior distribution. In Mimno and McCallum (2012), the authors develop topic models where the base distribution over topics is a log-linear model of observed document features, which permits learning better priors over topic distributions for each document. Similarly, we introduce a latent cross-lingual linear mapping M and define:

$$\alpha_{f,e} = \exp\{v_e^T M v_f\}, \tag{5}$$

where v_e and v_f are the pre-trained plaintext word and ciphertext word embeddings. M is the similarity matrix between the two embedding spaces. $\alpha_{f,e}$ can be thought of as the affinity of a plaintext word to be mapped to a ciphertext word. Rewriting the channel part of the joint likelihood in equation 1,

$$\begin{aligned}
&P(\{\mathbf{f}^n \mid \mathbf{e}^n\}_{n=1}^N, \{P(f \mid e)\}) \\
&= \prod_e \frac{\Gamma\left(\sum_f \exp\{v_e^T M v_f\}\right)}{\prod_f \Gamma\left(\exp\{v_e^T M v_f\}\right)} \\
&\prod_f P(f \mid e)^{\#(e,f) + \exp\{v_e^T M v_f\} - 1}
\end{aligned}$$

Integrating out the channel probabilities, the complete data log-likelihood of the observed ciphertext bigrams and the sampled plaintext bigrams,

$$\begin{aligned}
&P(\{\mathbf{f}^n \mid \mathbf{e}^n\}) \\
&= \prod_e \frac{\Gamma\left(\sum_f \exp\{v_e^T M v_f\}\right)}{\prod_f \Gamma\left(\exp\{v_e^T M v_f\}\right)} \\
&\prod_e \frac{\prod_f \Gamma\left(\exp\{v_e^T M v_f\} + \#(e,f)\right)}{\Gamma\left(\sum_f \exp\{v_e^T M v_f\} + \#(e)\right)}.
\end{aligned}$$

We also add a $L2$ regularization penalty on the elements of M. The derivative of $\log P(\{\mathbf{f}^n \mid \mathbf{e}^n\} - \frac{\lambda}{2}\sum_{i,j} M_{i,j}^2$, where λ is the regularization weight, with respect to M,

$$\begin{aligned}
&\frac{\partial \log P(\{\mathbf{f}^n \mid \mathbf{e}^n\} - \frac{\lambda}{2}\sum_{i,j} M_{i,j}^2}{\partial M} \\
&= \sum_e \sum_f \exp\{v_e^T M v_f\} v_e v_f^T \big(\\
&\Psi\left(\sum_{f'} \exp\{v_e^T M v_{f'}\}\right) - \\
&\Psi\left(\sum_{f'} \exp\{v_e^T M v_{f'}\} + \#(e)\right) + \\
&+ \Psi\left(\exp\{v_e^T M v_f\} + \#(e,f)\right) - \\
&\Psi\left(exp\{v_e^T M v_f\}\right) - \lambda M,
\end{aligned}$$

where we use

$$\begin{aligned}
&\frac{\partial \exp\{v_e^T M v_f\}}{\partial M} \\
&= \exp\{v_e^T M v_f\} \frac{\partial v_e^T M v_f}{\partial M} \\
&= \exp\{v_e^T M v_f\} v_e v_f^T.
\end{aligned}$$

$\Psi(\cdot)$ is the Digamma function, the derivative of $\log\Gamma(\cdot)$. Again, following Mimno and McCallum (2012), we train the similarity matrix M with stochastic EM. In the E-step, we sample plaintext words for the observed ciphertext using equation 4 and in the M-step, we learn M that maximizes $\log P(\{\mathbf{f}^n \mid \mathbf{e}^n\})$ with stochastic gradient descent. The time complexity of computing the gradient is $\mathcal{O}(V_e V_f)$. However, significant speedups can be achieved by precomputing $v_e v_f^T$ and exploiting GPUs for Matrix operations.

After learning M, we can set

$$\begin{aligned}
\alpha_{e,f} &= \sum_{f'} \exp\{v_e^T M v_{f'}\} \frac{\exp\{v_e^T M v_f\}}{\sum_{f''} \exp\{v_e^T M v_{f''}\}} \\
&= \alpha_e m_{e,f},
\end{aligned} \tag{6}$$

where $\alpha_e = \sum_{f'} \exp\{v_e^T M v_{f'}\}$ is the concentration parameter and $m_{e,f} = \frac{\exp\{v_e^T M v_f\}}{\sum_{f''} \exp\{v_e^T M v_{f''}\}}$ is an element of the base measure $\mathbf{m}_e$ for plaintext word e. In practice, we find that α_e can be very large, overwhelming the counts from sampling when we only have a few ciphertext bigrams. Therefore, we use $\mathbf{m}_e$ and set α_e proportional to the data size.

4 Deciphering Spanish Gigaword

In this section, we describe our data and experimental conditions for deciphering Spanish into English.

4.1 Data

In our Spanish/English decipherment experiments, we use half of the Gigaword corpus as monolingual data, and a small amount of parallel data from Europarl *for evaluation*. We keep only the 10k most frequent word types for both languages and replace all other word types with "UNK". We also exclude sentences longer than 40 tokens, which significantly slow down our parser. After preprocessing, the size of data for each language is shown in Table 1. While we use all the monolingual data shown in Table 1 to learn word embeddings, we only parse the AFP (Agence France-Presse) section of the Gigaword corpus to extract

	Spanish	English
Training	992 million (Gigaword)	940 million (Gigaword)
Evaluation	1.1 million (Europarl)	1.0 million (Europarl)

Table 1: Size of data in tokens used in Spanish/English decipherment experiment

cipher dependency bigrams and build a plaintext language model. We also use GIZA (Och and Ney, 2003) to align Europarl parallel data to build a dictionary for evaluating our decipherment.

4.2 Systems

We implement a baseline system based on the work described in Dou and Knight (2013). The baseline system carries out decipherment on dependency bigrams. Therefore, we use the Bohnet parser (Bohnet, 2010) to parse the AFP section of both Spanish and English versions of the Gigaword corpus. Since not all dependency relations are shared across the two languages, we do not extract all dependency bigrams. Instead, we only use bigrams with dependency relations from the following list:

- Verb / Subject
- Verb / Object
- Preposition / Object
- Noun / Noun-Modifier

We denote the system that uses our new method as **DMRE** (Dirichlet Multinomial Regression with Embedings). The system is the same as the baseline except that it uses a base distribution derived from word embeddings similarities. Word embeddings are learned using word2vec (Mikolov et al., 2013a).

For all the systems, language models are built using the SRILM toolkit (Stolcke, 2002). We use the modified Kneser-Ney (Kneser and Ney, 1995) algorithm for smoothing.

4.3 Sampling Procedure

Motivated by the previous work, we use multiple random restarts and an iterative sampling process to improve decipherment (Dou and Knight, 2012). As shown in Figure 1, we start a few sampling processes each with a different random sample. Then results from different runs are combined to initiate the next sampling iteration. The details of the sampling procedure are listed below:

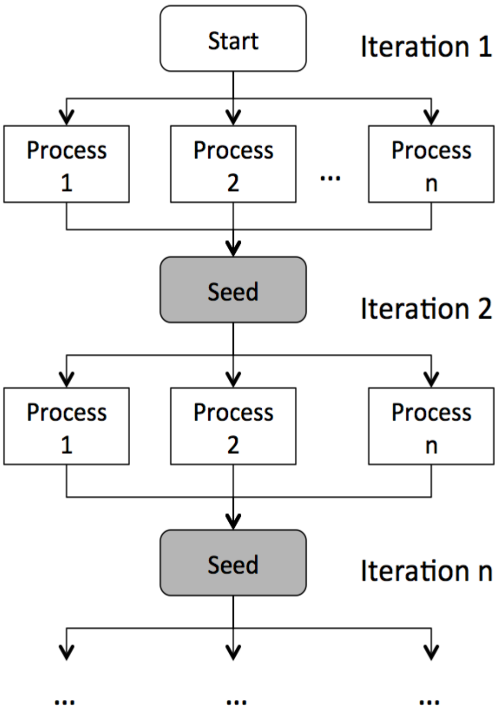

Figure 1: Iterative sampling procedures

1. Extract dependency bigrams from parsing outputs and collect their counts.
2. Keep bigrams whose counts are greater than a threshold t. Then start N different randomly seeded and initialized sampling processes. Perform sampling.
3. At the end of sampling, extract word translation pairs (f, e) from the final sample. Estimate translation probabilities $P(e|f)$ for each pair. Then construct a translation table by keeping translation pairs (f, e) seen in more than one decipherment and use the average $P(e|f)$ as the new translation probability.
4. Start N different sampling processes again. Initialize the first samples with the translation pairs obtained from the previous step (for each dependency bigram f_1, f_2, find an English sequence e_1, e_2, whose $P(e_1|f_1) \cdot P(e_2|f_2) \cdot P(e_1, e_2)$is the highest). Initialize similarity matrix M with one learned by previous sampling process whose posterior probability is highest. Go to the third step, repeat until it converges.
5. Lower the threshold t to include more bigrams into the sampling process. Go to the second step, and repeat until $t = 1$.

The sampling process consists of sampling and learning of similarity matrix M. The sampling process creates training examples for learning M, and the new M is used to update the base distribution for sampling. In our Spanish/English decipherment experiments, we use 10 different random starts. As pointed out in section 3, setting α_e to it's theoretical value (equation 6) gives poor results as it can be quite large. In experiments, we set α_e to a small value for the smaller data sets and increase it as more ciphtertext becomes available. We find that using the learned base distribution always improves decipherment accuracy, however, certain ranges are better for a given data size. We use α_e values of $1, 2$, and 5 for ciphertexts with 100k, 1 million, and 10 million tokens respectively. We leave automatic learning of α_e for future work.

5 Deciphering Malagasy

Despite spoken in Africa, Malagasy has its root in Asia, and belongs to the Malayo-Polynesian branch of the Austronesian language family. Malagasy and English have very different word order (VOS versus SVO). Generally, Malagasy is a typical head-initial language: Determiners precede nouns, while other modifiers and relative clauses follow nouns (e.g. ny "the" ankizilahy "boy" kely "little"). The significant differences in word order pose great challenges for both parsing and decipherment.

5.1 Data

Table 2 lists the sizes of monolingual and parallel data used in this experiment, released by Dou et al. (2014). The monolingual data in Malagasy contains news text collected from Madagascar websites. The English monolingual data contains Gigaword and an additional 300 million tokens of African news. Parallel data (used for evaluation) is collected from GlobalVoices, a multilingual news website, where volunteers translate news into different languages.

	Malagasy	English
Training	16 million (Web)	1.2 billion (Gigaword and Web)
Evaluation	2.0 million (GlobalVoices)	1.8 million (GlobalVoices)

Table 2: Size of data in tokens used in Malagasy/English decipherment experiment. GlobalVoices is a parallel corpus.

5.2 Systems

The baseline system is the same as the baseline used in Spanish/English decipherment experiments. We use data provided in previous work (Dou et al., 2014) to build a Malagasy dependency parser. For English, we use the Turbo parser, trained on the Penn Treebank (Martins et al., 2013).

Because the Malagasy parser does not predict dependency relation types, we use the following head-child part-of-speech (POS) tag patterns to select a subset of dependency bigrams for decipherment:

- Verb / Noun
- Verb / Proper Noun
- Verb / Personal Pronoun
- Preposition / Noun
- Preposision / Proper Noun
- Noun / Adjective
- Noun / Determiner
- Noun / Verb Particle
- Noun / Verb Noun
- Noun / Cardinal
- Noun / Noun

5.3 Sampling Procedure

We use the same sampling protocol designed for Spanish/English decipherment. We double the number of random starts to 20. Further more, compared with Spanish/English decipherment, we find the base distribution plays a more important role in achieving higher decipherment accuracy for Malagasy/English. Therefore, we set α_e to 10, 50, and 200 when deciphering 100k, 1 million, and 20 million token ciphtertexts, respectively.

6 Results

In this section, we first compare decipherment accuracy of the baseline with our new approach. Then, we evaluate the quality of the base distribution through visualization.

We use top-5 type accuracy as our evaluation metric for decipherment. Given a word type f in Spanish, we find top-5 translation pairs (f, e) ranked by $P(e|f)$ from the learned decipherent translation table. If any pair (f, e) can also be found in a gold translation lexicon T_{gold}, we treat

	Spanish/English				Malagasy/English			
Top	5k		10k		5k		10k	
System	Baseline	DMRE	Baseline	DMRE	Baseline	DMRE	Baseline	DMRE
100k	1.9	12.4	1.1	7.1	1.2	2.7	0.6	1.4
1 million	7.3	37.7	4.2	23.6	2.5	5.8	1.3	3.2
10 million	29.0	64.7	23.4	43.7	5.4	11.2	3.0	6.9
100 million	45.8	67.4	39.4	58.1	N/A	N/A	N/A	N/A

Table 3: Spanish/English, Malagasy/English decipherment top-5 accuracy (%) of 5k and 10k most frequent word types

the word type f as correctly deciphered. Let $|C|$ be the number of word types correctly deciphered, and $|V|$ be the total number of word types evaluated. We define type accuracy as $\frac{|C|}{|V|}$.

To create T_{gold}, we use GIZA to align a small amount of Spanish/English parallel text (1 million tokens for each language), and use the lexicon derived from the alignment as our gold translation lexicon. T_{gold} contains a subset of 4233 word types in the 5k most frequent word types, and 7479 word types in the top 10k frequent word types. We decipher the 10k most frequent Spanish word types to the 10k most frequent English word types, and evaluate decipherment accuracy on both the 5k most frequent word types as well as the full 10k word types.

We evaluate accuracy for the 5k and 10k most frequent word types for each language pair, and present them in Table 3.

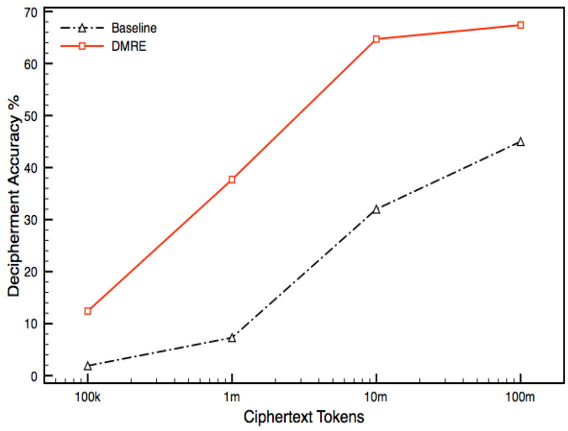

Figure 2: Learning curves of top-5 accuracy evaluated on 5k most frequent word types for Spanish/English decipherment.

We also present the learning curves of decipherment accuracy for the 5k most frequent word types. Figure 2 compares the baseline with **DMRE** in deciphering Spanish into English. Performance of the baseline is in line with previous work (Dou and Knight, 2013). (The accuracy reported here is higher as we evaluate top-5 accuracy for each word type.) With 100k tokens of Spanish text, the baseline achieves 1.9% accuracy, while **DMRE** reaches 12.4% accuracy, improving the baseline by over 6 times. Although the gains attenuate as we increase the number of ciphertext tokens, they are still large. With 100 million cipher tokens, the baseline achieves 45.8% accuracy, while **DMRE** reaches 67.4% accuracy.

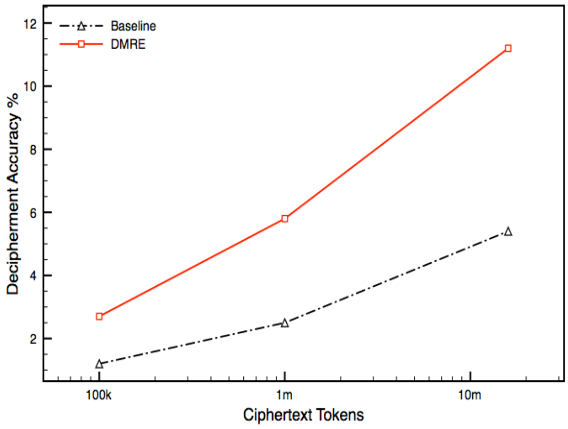

Figure 3: Learning curves of top-5 accuracy evaluated on 5k most frequent word types for Malagasy/English decipherment.

Figure 3 compares the baseline with our new approach in deciphering Malagasy into English. With 100k tokens of data, the baseline achieves 1.2% accuracy, and **DMRE** improves it to 2.4%. We observe consistent improvement throughout the experiment. In the end, the baseline accuracy obtains 5.8% accuracy, and **DMRE** improves it to 11.2%.

Low accuracy in Malagasy-English decipherment is attributed to the following factors: First, compared with the Spanish parser, the Malagasy parser has lower parsing accuracy. Second, word alignment between Malagasy and English is more challenging, producing less correct translation pairs. Last but not least, the domain of the English language model is much closer to the domain of the Spanish monolingual text compared with that of Malagasy.

Overall, we achieve large consistent gains across both language pairs. We hypothesize the gain comes from a better base distribution that considers larger context information. This helps prevent the language model driving deicpherment to a wrong direction.

Since our learned transformation matrix M significantly improves decipherment accuracy, it's likely that it is *translation preserving*, that is, plaintext words are transformed from their native vector space to points in the ciphertext such that translations are close to each other. To visualize this effect, we take the $5k$ most frequent plaintext words and transform them into new embeddings in the ciphertext embedding space $v_{e'} = v_e^T M$, where M is learned from 10 million Spanish bigram data. We then project the $5k$ most frequent ciphertext words and the projected plaintext words from the joint embedding space into a $2-$dimensional space using t-sne (**?**).

In Figure 4, we see an instance of a recurring phenomenon, where translation pairs are very close and sometimes even overlap each other, for example (judge, jueces), (secret, secretos). The word "magistrado" does not appear in our evaluation set. However, it is placed close to its possible translations. Thus, our approach is capable of learning word translations that cannot be discovered from limited parallel data.

We often also see *translation clusters*, where translations of groups of words are close to each other. For example, in Figure 5, we can see that time expressions in Spanish are quite close to their translations in English. Although better quality translation visualizations (Mikolov et al., 2013b) have been presented in previous work, they exploit large amounts of parallel data to learn the mapping between source and target words, while our transformation is learned on *non-parallel* data.

These results show that our approach can achieve high decipherment accuracy and discover novel word translations from non-parallel data.

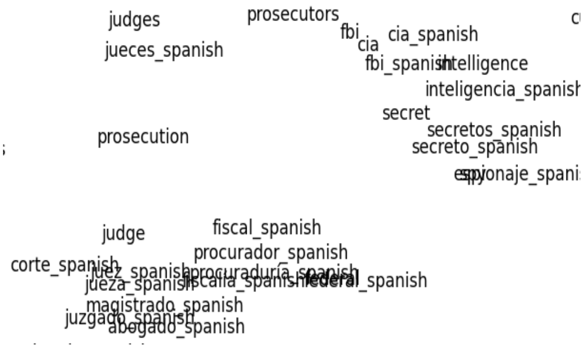

Figure 4: Translation pairs are often close and sometimes overlap each other. Words in spanish have been appended with _spanish

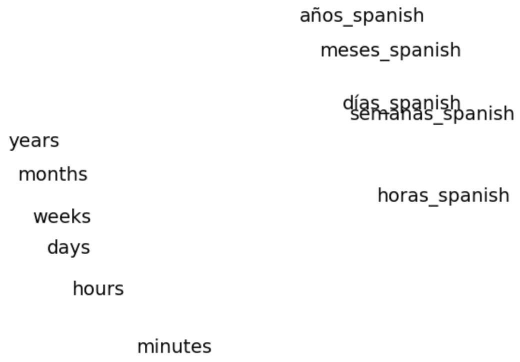

Figure 5: Semantic groups of word-translations appear close to each other.

7 Conclusion and Future Work

We proposed a new framework that simultaneously performs decipherment and learns a cross-lingual mapping of word embeddings. Our method is both theoretically appealing and practically powerful. The mapping is used to give decipherment a better base distribution.

Experimental results show that our new algorithm improved state-of-the-art decipherment accuracy significantly: from 45.8% to 67.4% for Spanish/English, and 5.1% to 11.2% for Malagasy/English. This improvement could lead to further advances in using monolingual data to improve end-to-end MT.

In the future, we will work on making the our approach scale to much larger vocabulary sizes using noise contrastive estimation (**?**), and apply it to improve MT systems.

Abstract

The quality of statistical machine translation performed with phrase based approaches can be increased by permuting the words in the source sentences in an order which resembles that of the target language. We propose a class of recurrent neural models which exploit source-side dependency syntax features to reorder the words into a target-like order. We evaluate these models on the German-to-English and Italian-to-English language pairs, showing significant improvements over a phrase-based Moses baseline. We also compare with state of the art German-to-English pre-reordering rules, showing that our method obtains similar or better results.

1 Introduction

Statistical machine translation is typically performed using phrase-based systems (Koehn et al., 2007). These systems can usually produce accurate local reordering but they have difficulties dealing with the long-distance reordering that tends to occur between certain language pairs (Birch et al., 2008).

The quality of phrase-based machine translation can be improved by reordering the words in each sentence of source-side of the parallel training corpus in a ”target-like” order and then applying the same transformation as a pre-processing step to input strings during execution.

When the source-side sentences can be accurately parsed, pre-reordering can be performed using hand-coded rules. This approach has been successfully applied to German-to-English (Collins et al., 2005) and other languages. The main issue with it is that these rules must be designed for each specific language pair, which requires considerable linguistic expertise.

Fully statistical approaches, on the other hand, learn the reordering relation from word alignments. Some of them learn reordering rules on the constituency (Dyer and Resnik, 2010) (Khalilov and Fonollosa, 2011) or projective dependency (Genzel, 2010), (Lerner and Petrov, 2013) parse trees of source sentences. The permutations that these methods can learn can be generally non-local (i.e. high distance) on the sentences but local (parent-child or sibling-sibling swaps) on the parse trees. Moreover, constituency or projective dependency trees may not be the ideal way of representing the syntax of non-analytic languages such as German or Italian, which could be better described using non-projective dependency trees (Bosco and Lombardo, 2004). Other methods, based on recasting reordering as a combinatorial optimization problem (Tromble and Eisner, 2009), (Visweswariah et al., 2011), can learn to generate in principle arbitrary permutations, but they can only make use of minimal syntactic information (part-of-speech tags) and therefore can’t exploit the potentially valuable structural syntactic information provided by a parser.

In this work we propose a class of reordering models which attempt to close this gap by

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 846–856,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

exploiting rich dependency syntax features and at the same time being able to process non-projective dependency parse trees and generate permutations which may be non-local both on the sentences and on the parse trees.
We represent these problems as sequence prediction machine learning tasks, which we address using recurrent neural networks.

We applied our model to reorder German sentences into an English-like word order as a pre-processing step for phrase-based machine translation, obtaining significant improvements over the unreordered baseline system and quality comparable to the hand-coded rules introduced by Collins et al. (2005). We also applied our model to Italian-to-English pre-reordering, obtaining a considerable improvement over the unreordered baseline.

2 Reordering as a walk on a dependency tree

In order to describe the non-local reordering phenomena that can occur between language pairs such as German-to-English and Italian-to-English, we introduce a reordering framework similar to (Miceli Barone and Attardi, 2013), based on a *graph walk* of the dependency parse tree of the source sentence. This framework doesn't restrict the parse tree to be projective, and allows the generation of arbitrary permutations.

Let $f \equiv (f_1, f_2, \ldots, f_{L_f})$ be a source sentence, annotated by a rooted dependency parse tree: $\forall j \in 1, \ldots, L_f, h_j \equiv PARENT(j)$

We define a *walker* process that walks from word to word across the edges of the parse tree, and at each steps optionally *emits* the current word, with the constraint that each word must be eventually emitted exactly once.
Therefore, the final string of emitted words f' is a permutation of the original sentence f, and any permutation can be generated by a suitable walk on the parse tree.

2.1 Reordering automaton

We formalize the walker process as a non-deterministic finite-state automaton.
The state v of the automaton is the tuple $v \equiv (j, E, a)$ where $j \in 1, \ldots, L_f$ is the current vertex (word index), E is the set of emitted vertices, a is the last action taken by the automaton.
The initial state is: $v(0) \equiv (root_f, \{\}, null)$ where $root_f$ is the root vertex of the parse tree.

At each step t, the automaton chooses one of the following actions:

- *EMIT*: emit the word f_j at the current vertex j. This action is enabled only if the current vertex has not been already emitted:

$$\frac{j \notin E}{(j, E, a) \overset{EMIT}{\rightarrow} (j, E \cup \{j\}, EMIT)} \tag{1}$$

- *UP*: move to the parent of the current vertex. Enabled if there is a parent and we did not just come down from it:

$$\frac{h_j \neq null, a \neq DOWN_j}{(j, E, a) \overset{UP}{\rightarrow} (h_j, E, UP_j)} \tag{2}$$

- $DOWN_{j'}$: move to the child j' of the current vertex. Enabled if the subtree $s(j')$ rooted at j' contains vertices that have not been already emitted and if we did not just come up from it:

$$\frac{h_{j'} = j, a \neq UP_{j'}, \exists k \in s(j') : k \notin E}{(j, E, a) \overset{DOWN_{j'}}{\rightarrow} (j', E, DOWN_{j'})} \tag{3}$$

The execution continues until all the vertices have been emitted.

We define the sequence of states of the walker automaton during one run as an *execution* $\bar{v} \in GEN(f)$. An execution also uniquely specifies the sequence of actions performed by the automation.

The preconditions make sure that all execution of the automaton always end generating a permutation of the source sentence. Furthermore, no cycles are possible: progress is made at every step, and it is not possible to enter in an execution that later turns out to be invalid.
Every permutation of the source sentence can be generated by some execution. In fact, each permutation f' can be generated by exactly one execution, which we denote as $\bar{v}(f')$.

We can split the execution $\bar{v}(f')$ into a sequence of L_f *emission fragments* $\bar{v}_j(f')$, each ending with an *EMIT* action.
The first fragment has zero or more $DOWN_*$ actions followed by one *EMIT* action, while each other fragment has a non-empty sequence of *UP* and $DOWN_*$ actions (always zero or more UPs followed by zero or more DOWNs) followed by one *EMIT* action.

Finally, we define an action in an execution as *forced* if it was the only action enabled at the step where it occurred.

2.2 Application

Suppose we perform reordering using a typical syntax-based system which processes source-side projective dependency parse trees and is limited to swaps between pair of vertices which are either in a parent-child relation or in a sibling relation. In such execution the *UP* actions are always forced, since the ″walker″ process never leaves a subtree before all its vertices have been emitted.

Suppose instead that we could perform reordering according to an ″oracle″. The executions of our automaton corresponding to these permutations will in general contain *unforced UP* actions. We define these actions, and the execution fragments that exhibit them, as *non-tree-local*.

In practice we don't have access to a reordering ″oracle″, but for sentences pairs in a parallel corpus we can compute heuristic ″pseudo-oracle″ reference permutations of the source sentences from word-alignments.

Following (Al-Onaizan and Papineni, 2006), (Tromble and Eisner, 2009), (Visweswariah et al., 2011), (Navratil et al., 2012), we generate word alignments in both the source-to-target and the target-to-source directions using IBM model 4 as implemented in GIZA++ (Och et al., 1999) and then we combine them into a symmetrical word alignment using the ″grow-diag-final-and″ heuristic implemented in Moses (Koehn et al., 2007).

Given the symmetric word-aligned corpus, we assign to each source-side word an integer index corresponding to the position of the leftmost target-side word it is aligned to (attaching unaligned words to the following aligned word) and finally we perform a stable sort of source-side words according to this index.

2.3 Reordering example

Consider the segment of a German sentence shown in fig. 1. The English-reordered segment ″**die Währungsreserven anfangs lediglich dienen sollten zur Verteidigung**″ corresponds to the English: ″**the reserve assets were originally intended to provide protection**″.

In order to compose this segment from the original German, the reordering automaton described in our framework must perform a complex sequence of moves on the parse tree:

- Starting from ″**sollten**″, descend to ″**dienen**″, descent to ″**Währungsreserven**″ and finally to ″**die**″. Emit it, then go up to ″**Währungsreserven**″, emit it and go up to ″**dienen**″ and up again to ″**sollten**″. Note that the last *UP* is *unforced* since ″**dienen**″ has not been emitted at that point and has also unemitted children. This unforced action indicates non-tree-local reordering.

- Go down to ″**anfangs**″. Note that the in the parse tree edge crosses another edge, indicating non-projectivity. Emit ″**anfangs**″ and go up (forced) back to ″**sollten**″.

- Go down to ″**dienen**″, down to ″**zur**″, down to ″**lediglich**″ and emit it. Go up (forced) to ″**zur**″, up (unforced) to ″**dienen**″, emit it, go up (unforced) to ″**sollten**″, emit it. Go down to ″**dienen**″, down to ″**zur**″ emit it, go down to ″**Verteidigung**″ and emit it.

Correct reordering of this segment would be difficult both for a phrase-based system (since the words are further apart than both the typical maximum distortion distance and maximum phrase length) and for a syntax-based system (due to the presence of non-projectivity and non-tree-locality).

3 Recurrent Neural Network reordering models

Given the reordering framework described above, we could try to directly predict the executions as Miceli Barone and Attardi (2013) attempted with their version of the framework. However, the executions of a given sentence can have widely different lengths, which could make incremental inexact decoding such as beam search difficult due to the need to prune over partial hypotheses that have different numbers of emitted words.

Therefore, we decided to investigate a different class of models which have the property that state transition happen only in correspondence with word emission. This enables us to leverage the technology of incremental *language models*.

Using language models for reordering is not something new (Feng et al., 2010), (Durrani et al., 2011), (Bisazza and Federico, 2013), but instead of using a more or less standard n-gram language model, we are going to base our model on *recurrent neural network language models* (Mikolov et al., 2010).

Neural networks allow easy incorporation of multiple types of features and can be trained more specifically on the types of sequences that will occur during decoding, hence they can avoid wasting model space to represent the probabilities of non-permutations.

3.1 Base RNN-RM

Let $f \equiv (f_1, f_2, \ldots, f_{L_f})$ be a source sentence. We model the reordering system as a deterministic single hidden layer recurrent neural network:

$$v(t) = \tau(\Theta^{(1)} \cdot x(t) + \Theta^{REC} \cdot v(t-1)) \quad (4)$$

where $x(t) \in \mathcal{R}^n$ is a feature vector associated to the t-th word in a permutation f', $v(0) \equiv v_{init}$, $\Theta^{(1)}$ and Θ^{REC} are parameters[1] and $\tau(\cdot)$ is the hyperbolic tangent function.

If we know the first $t-1$ words of the permutation f' in order to compute the probability distribution of the t-th word we do the following:

- Iteratively compute the state $v(t-1)$ from the feature vectors $x(1), \ldots, x(t-1)$.
- For the all the indices of the words that haven't occurred in the permutation so far $j \in J(t) \equiv ([1, L_f] - \bar{i}_{t-1:})$, compute a score $h_{j,t} \equiv h_o(v(t-1), x_o(j))$, where $x_o(\cdot)$ is the feature vector of the candidate target word.
- Normalize the scores using the logistic softmax function: $P(\bar{I}_t = j | f, \bar{i}_{t-1:}, t) = \frac{\exp(h_{j,t})}{\sum_{j' \in J(t)} \exp(h_{j',t})}$.

The scoring function $h_o(v(t-1), x_o(j))$ applies a feed-forward hidden layer to the feature inputs $x_o(j)$, and then takes a weighed inner product between the activation of this layer and the state $v(t-1)$. The result is then linearly combined to an additional feature equal to the logarithm of the remaining words in the permutation $(L_f - t)$,[2] and to a bias feature:

$$\begin{aligned} h_{j,t} \equiv & < \tau(\Theta^{(o)} \cdot x_o(j)), \theta^{(2)} \odot v(t-1) > \\ & + \theta^{(\alpha)} \cdot \log(L_f - t) + \theta^{(bias)} \end{aligned} \quad (5)$$

where $h_{j,t} \equiv h_o(v(t-1), x_o(j))$.

[1] we don't use a bias feature since it is redundant when the layer has input features encoded with the "one-hot" encoding

[2] since we are then passing this score to a softmax of variable size $(L_f - t)$, this feature helps the model to keep the score already approximately scaled.

We can compute the probability of an entire permutation f' just by multiplying the probabilities for each word: $P(f'|f) = P(\bar{I} = \bar{i}|f) = \prod_{t=1}^{L_f} P(\bar{I}_t = \bar{i}_t|f, t)$

3.1.1 Training

Given a training set of pairs of sentences and reference permutations, the training problem is defined as finding the set of parameters $\theta \equiv (v_{init}, \Theta^{(1)}, \theta^{(2)}, \Theta^{REC}, \Theta^{(o)}, \theta^{(\alpha)}, \theta^{(bias)})$ which minimize the per-word empirical cross-entropy of the model w.r.t. the reference permutations in the training set. Gradients can be efficiently computed using *backpropagation through time* (BPTT).

In practice we used the following training architecture:
Stochastic gradient descent, with each training pair (f, f') considered as a single minibatch for updating purposes. Gradients computed using the automatic differentiation facilities of Theano (Bergstra et al., 2010) (which implements a generalized BPTT). No truncation is used. L2-regularization [3]. Learning rates dynamically adjusted per scalar parameter using the *AdaDelta* heuristic (Zeiler, 2012). Gradient clipping heuristic to prevent the "exploding gradient" problem (Graves, 2013). Early stopping w.r.t. a validation set to prevent overfitting. Uniform random initialization for parameters other than the recurrent parameter matrix Θ^{REC}. Random initialization with *echo state property* for Θ^{REC}, with contraction coefficient $\sigma = 0.99$ (Jaeger, 2001), (Gallicchio and Micheli, 2011).

Training time complexity is $O(L_f^2)$ per sentence, which could be reduced to $O(L_f)$ using truncated BTTP at the expense of update accuracy and hence convergence speed. Space complexity is $O(L_f)$ per sentence.

3.1.2 Decoding

In order to use the RNN-RM model for prereordering we need to compute the most likely permutation $\overset{*}{f'}$ of the source sentence f:

$$\overset{*}{f'} \equiv \underset{f' \in GEN(f)}{\operatorname{argmax}} P(f'|f) \qquad (6)$$

Solving this problem to the global optimum is computationally hard[4], hence we solve it to a local optimum using a *beam search* strategy.

We generate the permutation incrementally from left to right. Starting from an initial state consisting of an empty string and the initial state vector v_{init}, at each step we generate all possible successor states and retain the B-most probable of them (histogram pruning), according to the probability of the entire prefix of permutation they represent.

Since RNN state vectors do not decompose in a meaningful way, we don't use any hypothesis recombination.
At step t there are $L_f - t$ possible successor states, and the process always takes exactly L_f steps[5], therefore time complexity is $O(B \cdot L_f^2)$ and space complexity is $O(B)$.

3.1.3 Features

We use two different feature configurations: *unlexicalized* and *lexicalized*.

In the *unlexicalized* configuration, the state transition input feature function $x(j)$ is composed by the following features, all encoded using the "one-hot" encoding scheme:

- Unigram: $POS(j)$, $DEPREL(j)$, $POS(j) * DEPREL(j)$. Left, right and parent unigram: $POS(k)$, $DEPREL(k)$, $POS(k) * DEPREL(k)$, where k is the index of respectively the word at the left (in the original sentence), at the right and the dependency parent of word j. Unique tags are used for padding.
- Pair features: $POS(j) * POS(k)$, $POS(j) * DEPREL(k)$, $DEPREL(j) * POS(k)$, $DEPREL(j) * DEPREL(k)$, for k defined as above.
- Triple features $POS(j) * POS(left_j) * POS(right_j)$, $POS(j) * POS(left_j) * POS(parent_j)$, $POS(j) * POS(right_j) * POS(parent_j)$.
- Bigram: $POS(j) * POS(k)$, $POS(j) * DEPREL(k)$, $DEPREL(j) * POS(k)$ where k is the previous emitted word in the permutation.

[3] $\lambda = 10^{-4}$ on the recurrent matrix, $\lambda = 10^{-6}$ on the final layer, per minibatch.

[4] NP-hard for at least certain choices of features and parameters

[5] actually, $L_f - 1$, since the last choice is forced

- Topological features: three binary features which indicate whether word j and the previously emitted word are in a parent-child, child-parent or sibling-sibling relation, respectively.

The target word feature function $x_o(j)$ is the same as $x(j)$ except that each feature is also conjoined with a quantized signed distance[6] between word j and the previous emitted word. Feature value combinations that appear less than 100 times in the training set are replaced by a distinguished "rare" tag.

The *lexicalized* configuration is equivalent to the unlexicalized one except that $x(j)$ and $x_o(j)$ also have the surface form of word j (not conjoined with the signed distance).

3.2 Fragment RNN-RM

The *Base RNN-RM* described in the previous section includes dependency information, but not the full information of reordering fragments as defined by our automaton model (sec. 2). In order to determine whether this rich information is relevant to machine translation pre-reordering, we propose an extension, denoted as *Fragment RNN-RM*, which includes reordering fragment features, at expense of a significant increase of time complexity.

We consider a hierarchical recurrent neural network. At top level, this is defined as the previous RNN. However, the $x(j)$ and $x_o(j)$ vectors, in addition to the feature vectors described as above now contain also the final states of another recurrent neural network.

This internal RNN has a separate clock and a separate state vector. For each step t of the top-level RNN which transitions between word $f'(t-1)$ and $f'(t)$, the internal RNN is reinitialized to its own initial state and performs multiple internal steps, one for each action in the fragment of the execution that the walker automaton must perform to walk between words $f'(t-1)$ and $f'(t)$ in the dependency parse (with a special shortcut of length one if they are adjacent in f with monotonic relative order).

The state transition of the inner RNN is defined as:

$$v_r(t) = \tau(\Theta^{(r_1)} \cdot x_r(t_r) + \Theta^{r_{REC}} \cdot v_r(t_r - 1)) \quad (7)$$

where $x_r(t_r)$ is the feature function for the word traversed at inner time t_r in the execution fragment. $v_r(0) = v_r^{init}$, $\Theta^{(r_1)}$ and $\Theta^{r_{REC}}$ are parameters.

Evaluation and decoding are performed essentially in the same was as in Base RNN-RM, except that the time complexity is now $O(L_f^3)$ since the length of execution fragments is $O(L_f)$.

Training is also essentially performed in the same way, though gradient computation is much more involved since gradients propagate from the top-level RNN to the inner RNN. In our implementation we just used the automatic differentiation facilities of Theano.

3.2.1 Features

The *unlexicalized* features for the inner RNN input vector $x_r(t_r)$ depend on the current word in the execution fragment (at index t_r), the previous one and the action label: *UP*, *DOWN* or *RIGHT* (shortcut). *EMIT* actions are not included as they always implicitly occur at the end of each fragment.

Specifically the features, encoded with the "one-hot" encoding are: $A * POS(t_r) * POS(t_r - 1)$, $A * POS(t_r) * DEPREL(t_r - 1)$, $A * DEPREL(t_r) * POS(t_r - 1)$, $A * DEPREL(t_r) * DEPREL(t_r - 1)$.

These features are also conjoined with the quantized signed distance (in the original sentence) between each pair of words.

The *lexicalized* features just include the surface form of each visited word at t_r.

3.3 Base GRU-RM

We also propose a variant of the Base RNN-RM where the standard recurrent hidden layer is replaced by a *Gated Recurrent Unit* layer, recently proposed by Cho et al. (2014) for machine translation applications.

The Base GRU-RM is defined as the Base RNN-RM of sec. 3.1, except that the recurrence relation 4 is replaced by fig. 2

Features are the same of unlexicalized Base RNN-RM (we experienced difficulties training the Base GRU-RM with lexicalized features).

[6] values greater than 5 and smaller than 10 are quantized as 5, values greater or equal to 10 are quantized as 10. Negative values are treated similarly.

$$
\begin{aligned}
v_{rst}(t) &= \pi(\Theta^{(1)}_{rst} \cdot x(t) + \Theta^{REC}_{rst} \cdot v(t-1)) \\
v_{upd}(t) &= \pi(\Theta^{(1)}_{upd} \cdot x(t) + \Theta^{REC}_{upd} \cdot v(t-1)) \\
v_{raw}(t) &= \tau(\Theta^{(1)} \cdot x(t) + \Theta^{REC} \cdot v(t-1) \odot v_{upd}(t)) \\
v(t) &= v_{rst}(t) \odot v(t-1) + (1 - v_{rst}(t)) \odot v_{raw}(t)
\end{aligned} \tag{8}
$$

Figure 2: GRU recurrence equations. $v_{rst}(t)$ and $v_{upd}(t)$ are the activation vectors of the "reset" and "update" gates, respectively, and $\pi(\cdot)$ is the logistic sigmoid function.

.

Training is also performed in the same way except that we found more beneficial to convergence speed to optimize using *Adam* (Kingma and Ba, 2014) [7] rather than AdaDelta.

In principle we could also extend the Fragment RNN-RM into a Fragment GRU-RM, but we did not investigate that model in this work.

4 Experiments

We performed German-to-English pre-reordering experiments with Base RNN-RM (both unlexicalized and lexicalized), Fragment RNN-RM and Base GRU-RM.

In order to validate the experimental results on a different language pair, we additionally performed an Italian-to-English pre-reordering experiment with the Base GRU-RM, after assessing that this was the model that obtained the largest improvement on German-to-English.

4.1 Setup

The German-to-English baseline phrase-based system was trained on the Europarl v7 corpus (Koehn, 2005). We randomly split it in a 1,881,531 sentence pairs training set, a 2,000 sentence pairs development set (used for tuning) and a 2,000 sentence pairs test set. The English language model was trained on the English side of the parallel corpus augmented with a corpus of sentences from AP News, for a total of 22,891,001 sentences.

The baseline system is phrase-based Moses in a default configuration with maximum distortion distance equal to 6 and lexicalized reordering enabled. Maximum phrase size is equal to 7.

The language model is a 5-gram IRSTLM/KenLM.

The pseudo-oracle system was trained on the training and tuning corpus obtained by permuting the German source side using the heuristic described in section 2.2 and is otherwise equal to the baseline system.

In addition to the test set extracted from Europarl, we also used a 2,525 sentence pairs test set ("news2009") a 3,000 sentence pairs "challenge" set used for the WMT 2013 translation task ("news2013").

The Italian-to-English baseline system was trained on a parallel corpus assembled from Europarl v7, JRC-ACQUIS v2.2 (Steinberger et al., 2006) and additional bilingual articles crawled from online newspaper websites[8], totaling 3,081,700 sentence pairs, which were split into a 3,075,777 sentence pairs phrase-table training corpus, a 3,923 sentence pairs tuning corpus, and a 2,000 sentence pairs test corpus.

Non-projective dependency parsing for our models, both for German and Italian was performed with the DeSR transition-based parser (Attardi, 2006).

We also trained a German-to-English Moses system with pre-reordering performed by Collins et al. (2005) rules, implemented by Howlett and Dras (2011).

Constituency parsing for Collins et al. (2005) rules was performed with the Berkeley parser (Petrov et al., 2006). For Italian-to-English we did not compare with a hand-coded reordering system as we are not aware of any strong pre-reordering baseline for this language pair.

For our experiments, we extract approxi-

[7] with learning rate $2 \cdot 10^{-5}$ and all the other hyperparameters equal to the default values in the article.

[8] Corriere.it and Asianews.it

mately 300,000 sentence pairs from the Moses training set based on a heuristic confidence measure of word-alignment quality (Huang, 2009), (Navratil et al., 2012). We randomly removed 2,000 sentences from this filtered dataset to form a validation set for early stopping, the rest were used for training the pre-reordering models.

4.2 Results

The hidden state size s of the RNNs was set to 100 while it was set to 30 for the GRU model, validation was performed every 2,000 training examples. After 50 consecutive validation rounds without improvement, training was stopped and the set of training parameters that resulted in the lowest validation cross-entropy were saved.

Training took approximately 1.5 days for the unlexicalized Base RNN-RM, 2.5 days for the lexicalized Base RNN-RM and for the unlexicalized Base GRU-RM and 5 days for the unlexicalized Fragment RNN-RM on a 24-core machine without GPU (CPU load never rose to more than 400%).

Decoding was performed with a beam size of 4. Decoding the whole German corpus took about 1.0-1.2 days for all the models except Fragment RNN-RM for which it took about 3 days. Decoding for the Italian corpus for the Base GRU-RM took approximately 1.5 days.

Effects on monolingual reordering score are shown in fig. 3 (German) and fig. 4 (Italian), effects on translation quality are shown in fig. 5 (German-to-English) and fig. 6 (Italian-to-English)[9].

4.3 Discussion and analysis

All our German-to-English models significantly improved over the phrase-based baseline, performing as well as or almost as well as (Collins et al., 2005), which is an interesting result since our models doesn't require any specific linguistic expertise.

Surprisingly, the lexicalized version of Base RNN-RM performed worse than the unlexicalized one. This goes contrary to expectation as neural language models are usually lexicalized and in fact often use nothing but lexical features.

The unlexicalized Fragment RNN-RM was quite accurate but very expensive both during training and decoding, thus it may not be practical.

The unlexicalized Base GRU-RM performed very well, especially on the Europarl dataset (where all the scores are much higher than the other datasets) and it never performed significantly worse than the unlexicalized Fragment RNN-RM which is much slower.

We also performed exploratory experiments with different feature sets (such as lexical-only features) but we couldn't obtain a good training error. Larger network sizes should increase model capacity and may possibly enable training on simpler feature sets.

The Italian-to-English experiment with Base GRU-RM confirmed that this model performs very well on a language pair with different reordering phenomena than German-to-English.

5 Conclusions

We presented a class of statistical syntax-based, non-projective, non-tree-local pre-reordering systems for machine translation.

Our systems processes source sentences parsed with non-projective dependency parsers and permutes them into a target-like word order, suitable for translation by an appropriately trained downstream phrase-based system.

The models we proposed are completely trained with machine learning approaches and is, in principle, capable of generating arbitrary permutations, without the hard constraints that are commonly present in other statistical syntax-based pre-reordering methods.

Practical constraints depend on the choice of features and are therefore quite flexible, allowing a trade-off between accuracy and speed.

In our experiments with the RNN-RM and GRU-RM models we managed to achieve translation quality improvements compara-

[9] Although the baseline systems were trained on the same datasets used in Miceli Barone and Attardi (2013), the results are different since we used a different version of Moses

Abstract

Deception detection has been formulated as a supervised binary classification problem on single documents. However, in daily life, millions of fraud cases involve detailed conversations between deceivers and victims. Deceivers may dynamically adjust their deceptive statements according to the reactions of victims. In addition, people may form groups and collaborate to deceive others. In this paper, we seek to identify deceptive groups from their conversations. We propose a novel subgroup detection method that combines linguistic signals and signed network analysis for dynamic clustering. A social-elimination game called *Killer Game* is introduced as a case study[1]. Experimental results demonstrate that our approach significantly outperforms human voting and state-of-the-art subgroup detection methods at dynamically differentiating the deceptive groups from truth-tellers.

1 Introduction

Deception generally entails messages and information intentionally transmitted to create a false conclusion (Buller et al., 1994). Deception detection is an important task for a wide range of applications including law enforcement, intelligence gathering, and financial fraud. Most of the previous work (*e.g.*, (Ott et al., 2011; Feng et al., 2012)) focused on content analysis of a single document in isolation (*e.g.*, a product review). The promoters of a product may post fake complimentary reviews, while their competitors may hire people to write fake negative reviews (Ott et al., 2011).

However, when we want to detect deception from text or voice conversations, the deception behavior may be affected by the following factors beyond textual statements.

1. *Dynamic*. Recent research in social science suggests that deception communication is dynamic and involves interactions among people (*e.g.*, (Buller and Burgoon, 1996)). Additionally, the research postulates that human's capacity to learn by observation enables him to acquire large, integrated units of behavior by example (Bandura, 1971). Therefore, a person's behavior concerning deception or truth-telling can change constantly, while he learns from others' statements during conversations.
2. *Global*. People may form groups for purpose of deception. Research in social psychology has shown that an individual's object-related behavior may be affected by the attitudes of other people due to group dynamics (Friedkin, 2010).

Recent studies typically have been conducted over "*static*" written or oral deceptive statements. There is no obligatory requirement for communication between the author and the readers of these statements (Yancheva and Rudzicz, 2013). As a result, a victim of deception tends to trust the story mainly based on the statement he reads (Ott et al., 2011). However, in daily life, millions of fraud cases involve detailed conversations between deceivers and victims. A deceiver may make a statement, which is partially true in order to deceive or mislead victims and adjust his deceptive strategies based on the reactions of victims (Zhou et al., 2004). Therefore, it is more challenging to identity a deceiver in an interactive process of deception.

Most deception detection research addressed individual deceivers, but deceivers often act in pairs or larger groups (Vrij et al., 2010). The interac-

tions within a deceptive group have been ignored. For example, a product review from a deceiver may be supported by his teammates so that his deceptive comments can be read by more potential buyers. In this case, we can identify a deceptive group based on their collaborations and common characteristics, which is more promising than the typical methods of classifying individual statements as deceptive or trustworthy.

In order to identify deceptive groups by analyzing the evolution of a person's deception strategy during his interactions with victims and the interactions within the deceptive group from conversations, we use a social-elimination game called *Killer Game* which contains the ground-truth of subgroups.

The killer game has many variants that involve different roles and skills. We choose a classical version played by three roles/teams: detectives, citizens, and killers. The role of each *player* (game participant) is randomly assigned by a third-party game judge. Every killer/detective is given the identities of his teammates. There are two alternating phases of the game: "*night*", when killers may covertly "*murder*" a player and detectives may learn one player's role; and "*day*", when surviving players are informed of who was killed last "*night*" and then asked to speculate about the roles of other surviving players. Before a "*day*" ends, every surviving player should vote for a suspect. The candidate with the most votes is eliminated. A player's identity is not exposed after his "*death*". The game continues until all killers have been eliminated or all detectives have been killed. The killers are treated as deceivers, and citizens and detectives as truth-tellers.

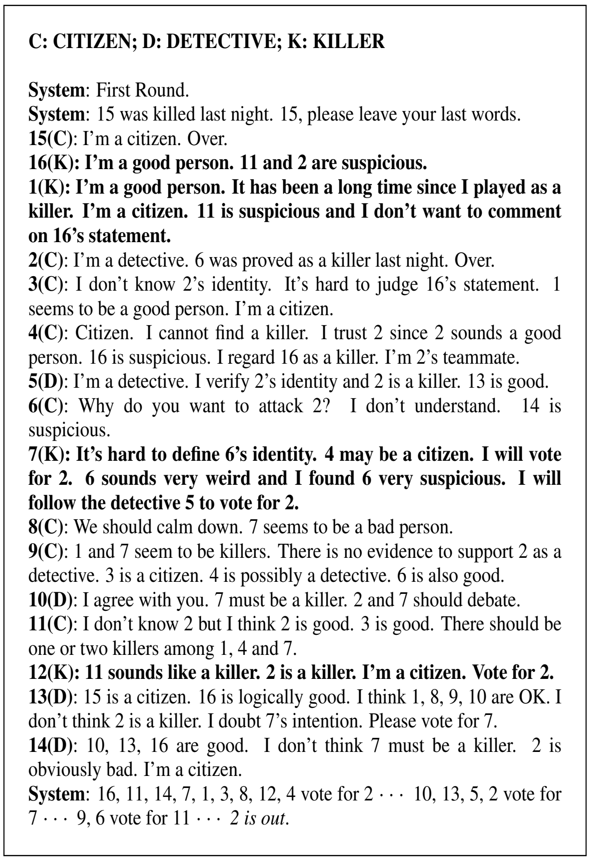
In this paper, we present an unsupervised approach for differentiating the deceptive groups from truth-tellers in a game. During each round, we use Natural Language Processing (NLP) techniques to identify a player's attitude toward other players (Section 2), which are used to construct a vector of attitudes for each surviving player (Section 3.1) and a signed social network representation (Section 3.2) for the discussions. Then we use a clustering algorithm to cluster the attitude vector space and obtain results for each round (Section 3.1). We also implement a greedy optimization algorithm to partition the singed network based on the attitude clustering result (Section 3.2). Finally, we apply a pairwise-similarity approach that makes use of the predicted co-occurrence relations between players to combine all results from each round (Section 3.3). Figure 1 provides an overview of our system pipeline.

The major novel contributions of this paper are as follows.

- This is the first study to investigate conversations and deceptive groups for computerized deception detection.
- The proposed clustering technique is shown to be successful in separating deceptive groups from truth-tellers.
- The method can be applied to dynamically detect subgroups in a network with discussants who tend to change their opinions.

2 Attitude Identification

In this section, we describe how we take a player's statement in a single round as input to extract his attitudes toward other players and represent them by an attitude 3-tuple (speaker, target, polarity) list. For this work, the polarity of attitudes (Balahur et al., 2009) can be positive (1), negative (-1) or neutral (0). A game log from a single round will be used as our illustrative example, as shown in Figure 2.



C: CITIZEN; D: DETECTIVE; K: KILLER

System: First Round.
System: 15 was killed last night. 15, please leave your last words.
15(C): I'm a citizen. Over.
16(K): I'm a good person. 11 and 2 are suspicious.
1(K): I'm a good person. It has been a long time since I played as a killer. I'm a citizen. 11 is suspicious and I don't want to comment on 16's statement.
2(C): I'm a detective. 6 was proved as a killer last night. Over.
3(C): I don't know 2's identity. It's hard to judge 16's statement. 1 seems to be a good person. I'm a citizen.
4(C): Citizen. I cannot find a killer. I trust 2 since 2 sounds a good person. 16 is suspicious. I regard 16 as a killer. I'm 2's teammate.
5(D): I'm a detective. I verify 2's identity and 2 is a killer. 13 is good.
6(C): Why do you want to attack 2? I don't understand. 14 is suspicious.
7(K): It's hard to define 6's identity. 4 may be a citizen. I will vote for 2. 6 sounds very weird and I found 6 very suspicious. I will follow the detective 5 to vote for 2.
8(C): We should calm down. 7 seems to be a bad person.
9(C): 1 and 7 seem to be killers. There is no evidence to support 2 as a detective. 3 is a citizen. 4 is possibly a detective. 6 is also good.
10(D): I agree with you. 7 must be a killer. 2 and 7 should debate.
11(C): I don't know 2 but I think 2 is good. 3 is good. There should be one or two killers among 1, 4 and 7.
12(K): 11 sounds like a killer. 2 is a killer. I'm a citizen. Vote for 2.
13(D): 15 is a citizen. 16 is logically good. I think 1, 8, 9, 10 are OK. I don't think 2 is a killer. I doubt 7's intention. Please vote for 7.
14(D): 10, 13, 16 are good. I don't think 7 must be a killer. 2 is obviously bad. I'm a citizen.
System: 16, 11, 14, 7, 1, 3, 8, 12, 4 vote for 2 $\cdots$ 10, 13, 5, 2 vote for 7 $\cdots$ 9, 6 vote for 11 $\cdots$ *2 is out.*

Figure 2: Killer game sample log (the 1st round).

2.1 Target and Attitude Word Identification

We start by identifying targets and attitude words from conversations. In the killer game, a target is represented by his unique ID[2] and game terms are regarded as attitude words. We collected 41 terms in total from the game's website [3] and related discussion forum posts. ICTCLAS (Zhang et al., 2003) is used for word segmentation and part-of-speech (POS) tagging. There are two kinds of game terms: positive and negative. Positive terms include "*citizen*", "*good person*", "*good person certified by the detectives*" and "*detective*". Negative terms include "*killer*", "*killer verified by the detectives*" and "*a killer who claimed himself/herself to be a detective*". We assign the polarity score +1, -1 to positive and negative terms respectively.

2.2 Attitude-Target Pairing

Then we associate each attitude word with its corresponding target. We remove interrogative and exclamatory sentences and only keep the sentences that include at least one attitude word from a player's statement during each round.

We develop a rule-based approach for attitude-target pairing: if there is at least one ID in the sentence, we associate all attitude words in that sentence with it. Otherwise, if "I" is the only subject or there are no subjects at all, we associate attitude words with the ID of the speaker. We reverse the polarity of an attitude word if it appears in a negation context.

Previous methods pair a target and an attitude word if they satisfy at least one dependency rule (*e.g.*, (Somasundaran and Wiebe, 2009)). We check the POS tag sequence between them. For each attitude-target pair, if there exists an attitude word, a belief-oriented verb such as "*think*", "*believe*", "*feel*", or more than two verbs in the sequence, we will discard this pair. The assumption is that POS tag sequences can be used to summarize dependency rules when statements are relatively short.

For those targets, the speaker didn't mention or there is no positive/negative attitude word used when they are mentioned, the attitude polarity score is set to 0. For instance, given Player 16's statement in Figure 2, its attitude tuple list is: [(16, 16, +1), (16, 11, -1), (16, 2, -1), (16, 1, 0), (16, 3, 0), . . . , (16, 15, 0)].

3 Clustering

Since the statements in conversations are relatively short and concise, it is difficult to identify which one is deceptive, even using deep linguistic features such as the language style.

In this section, we introduce a method to construct an attitude profile for each player and a signed network based on the attitude tuple list in Section 2, and combine them to analyze a dynamic network with discussants telling lies and truths.

3.1 Clustering based on Attitude Profile

We use a vector containing numerical values to represent each player's attitude toward identified targets in each round. The values correspond to the polarity scores in a player's attitude tuple list. For example, the polarity score of player 16's attitude toward target 11 is -1 as shown in Figure 2.

[2] Each player has a game ID, assigned by the online game system based on when he entered the game room.

[3] e.g., http://www.3j3f.com/how/

We call this vector as the discussant attitude profile (DAP) following (Abu-Jbara et al., 2012a).

Suppose there are n players who participate in a single game. Since a player's identity is not exposed to the public after his death[4], people can still analyze the identity of a "*dead*" player. Therefore, the number of possibly mentioned targets in each round equals to n. Given all the statements from m surviving players in a single round, each player's DAP has $n+1$ dimensions including his vote and thus we can have a $m \times (n+1)$ attitude matrix A where A_{ij} represents the attitude polarity of i toward j we got from Section 2. $A_{i(n+1)}$ represents i's vote.

In a certain round, given a set of m surviving players $X = \{x_1, x_2, \cdots, x_m\}$ to be clustered and their respective DAPs, we can modify the Euclidean metric to compute the differences in attitudes and get an $m \times m$ distance matrix M:

$$M_{ij} = \sqrt{\sum_{k=1}^{n}(A_{ik} - A_{jk})^2 + (2 - 2\delta_{A_{i(n+1)},A_{j(n+1)}})^2} \tag{1}$$

The Kronecker delta function δ is:

$$\delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases} \tag{2}$$

We use this function to compare the votes of two players separately because a player's vote can be inconsistent with his previous statements. We assume that there is a larger distance between two players when they vote for different suspects.

A common assumption in previous research was that a member is more likely to show a positive attitude toward other members in the same group, and a negative attitude toward the opposing groups (Abu-Jbara et al., 2012a). However, a deceiver may pretend to be innocent by supporting those truth-tellers and attacking his teammates, whose identities have already been exposed. Therefore, it is not enough to judge the relationship between two players by simply measuring the distance between their DAPs.

In addition to comparing DAPs between players i and j, we also consider the attitudes of other players toward i and j, as well as their attitudes toward each other. We modify M_{ij} as follows and show it in Figure 3:

$$M_{ij}^{'} = M_{ij} + \sqrt{\sum_{k=1}^{m}(A_{ki} - A_{kj})^2 + (h(A_{ij}) + h(A_{ji}))^2} \tag{3}$$

where the function h detects the negative attitudes. $h(x) = 0$ if $x \geq 0$ and $h(x) = -1$ otherwise.

We perform hierarchical clustering on the condensed distance matrix of M and use the complete linkage method to compute the distance between two clusters (Voorhees, 1986). We set the number of clusters as 3 since there are three natural groups in the game. We focus on separating deceivers (killers) from truth-tellers (citizens and detectives).

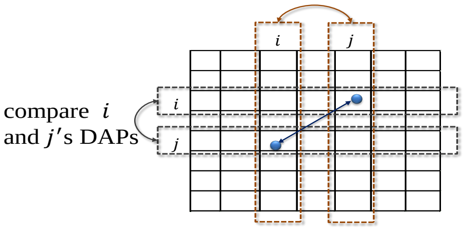


Figure 3: Computation of the distance between player i and j based on the attitude matrix.

3.2 Signed Network Partition

When we computed the distance between two players in Section 3.1, we did not consider the network structure among all the players. For example, if A supports C, B supports D and C and D dislike each other, A and B may belong to different groups. Thus, we propose to capture the interactions in the social network to further improve the attitude-profile-based clustering result.

We can easily convert the attitude matrix A into a signed network by adding a directed edge $i \rightarrow j$ between i and j if $A_{ij} \neq 0$. We denote a directed graph corresponding to a signed network as $G = (V, S, N, W)$, where V is the set of nodes, S is the set of positive edges, N is the set of negative edges and $W : (V \times V) \rightarrow \{-1, 1\}$ is a function that maps every directed edge to a value, $W(i,j) = A_{ij}$.

We use a greedy optimization algorithm (Doreian and Mrvar, 1996) to find partitions. A criterion function for an optimal partitioning procedure

[4] Each round, the player killed by killers and the player with the most votes are out.

is constructed such that positive links are dense within groups and negative links are dense between groups. For any potential partition $\mathbb{C}$, we seek to minimize the following error function:

$$E(\mathbb{C}) = \sum_{C\in\mathbb{C}}[(1-\gamma)\sum_{\substack{i\in C\\ j\notin C}} W(i,j)S_{i,j} - \gamma\sum_{i,j\in C} W(i,j)N_{i,j}] \tag{4}$$

where $\gamma \in [0,1]$ controls the balance of the penalty difference between putting a positive edge across and a negative edge within a group. We regard these two types of errors as equally important and set $\gamma = 0.5$ for our experiments.

Initially, we use the clustering result in Section 3.1 to partition nodes into three different groups and an error function, E, is evaluated for that cluster. Every cluster has a set of neighbor clusters in the cluster space. A neighbor cluster is obtained by moving a node from one group to another, or exchanging two nodes in two different groups. E is evaluated for all the neighbor clusters of the current cluster and the one with the lowest value is set as the new cluster. The algorithm is repeated until it finds a minimal solution[5]. We set the upper limit for the number of subgroups to 3.

3.3 Cluster Ensembles

The relationships between players are dynamic throughout the game. For example, a killer tends to hide his identity and pretends to be friendly to others at later stages in order to survive. Thus, it is insufficient to rely on a single round's discussion to cluster players. In addition, for each single round, we also need to combine the clustering results from the attitude profiles of the players and the signed network.

In a game with information gathered from up to r rounds, let $P = \{P_1, P_2, \cdots, P_r\}$ be the set of r clusterings (partitionings) based on attitude profiles and $P^{'} = \{P_1^{'}, P_2^{'}, \cdots, P_r^{'}\}$ be the set of r clusterings based on the signed network.

Using the co-occurrence relations between players, we can generate a $n \times n$ pairwise similarity matrix T based on the information of all r rounds:

$$T_{ij}^{r} = \frac{\lambda \cdot vote_{ij} + (1-\lambda) \cdot vote_{ij}^{'}}{r_{ij}} \tag{5}$$

where $vote_{ij}$, $vote_{ij}^{'}$ are the number of times that player i and j are assigned to the same cluster in P and $P^{'}$ respectively. r_{ij} denotes the number of rounds when both of them survived ($r_{ij} \leq r$). $T_{ij}^{r} \in [0,1]$. We assign a higher weight to the result of P_1 and set $\lambda = 2/3$ in our experiments.

Given the input in Figure 2, x_3 and x_4 are assigned to the same cluster in P_1 ($vote_{34} = 1$) and in $P_1^{'}$ ($vote_{34}^{'} = 1$) respectively as shown in Figure 4. x_3 and x_4 co-occurred in the first round ($r_{34} = 1$). $T_{34}^{1} = (2/3 \times 1 + 1/3 \times 1)/1 = 1$.

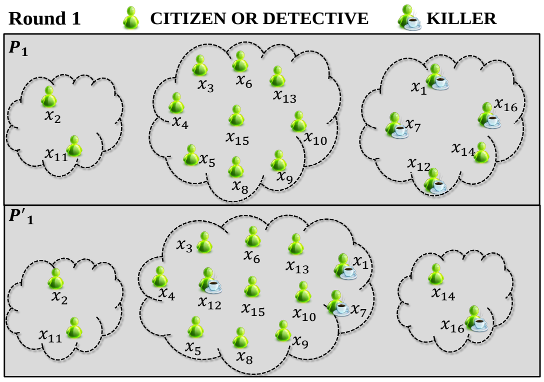

Figure 4: Example of cluster ensemble for a single round.

We apply hierarchical clustering (Voorhees, 1986) to the similarity matrix above to obtain the final global clustering results.

4 Experiments

4.1 Dataset Construction

We recorded 10 games from 3J3F[6], one of the most popular Chinese online killer game websites [7]. A screenshot of the game system interface is shown in Figure 5. There are 16 participating players per game: 4 detectives, 4 killers and 8 citizens. Each player occupies a position in ①. All the surviving players can express their attitudes via a voice channel using ②, while detectives and killers can also communicate with teammates in their respective private team channels ③ via texts. The system provides real-time updates on the game progress, voting results, and so on using the public channel ④. We manually transcribed speech and stored the text information in the public channel, which contains the voting and death information. The average game length

[5] Since our graphs are small, we search through all partitions. We repeated 1000 times in our experiment.

[6] http://www.3j3f.com

[7] All data sets and resources will be made available for research purposes upon the acceptance of the paper.

4.2 Evaluation Metrics

We use two metrics to evaluate the clustering accuracy: Purity and Entropy. Purity (Manning et al., 2008) is a metric in which each cluster is assigned to the class with the majority vote in the cluster, and then the accuracy of this assignment is measured by dividing the number of correctly assigned instances by the total number of instances N. More formally:

$$purity(\Omega, C) = \frac{1}{N} \sum_{k} max_j |w_k \cap c_j| \qquad (6)$$

where $\Omega = \{w_1, w_2, \cdots, w_k\}$ is the set of clusters and $C = \{c_1, c_2, \cdots, c_j\}$ is the set of classes. w_k is interpreted as the set of instances in w_k and c_j is the set of instances in c_j. The purity increases as the quality of clustering improves.

Entropy (Steinbach et al., 2000) measures the uniformity of a cluster. The entropy for all clusters is defined by the weighted sum of the entropy of each cluster:

$$Entropy = -\sum^{j} \frac{n_j}{n} \sum^{i} P(i,j) \times log_2 P(i,j) \qquad (7)$$

where $P(i,j)$ is the probability of finding an element from the category i in the cluster j, n_j is the number of items in cluster j and n is the total number of items in the distribution. The entropy decreases as the quality of clustering improves.

4.3 Overall Performance

We compare our approach with two state-of-the-art subgroup detection methods and human performance as follows:

1. DAPC: In Section 3.1, we introduced our implementation of the discussant attitude profile clustering (DAPC) method proposed in (Abu-Jbara et al., 2012a). In the original DAPC method, for each opinion target, there are 3 dimensions in the feature vector, corresponding to (1) the number of positive expressions, (2) negative expressions toward the target from the online posts and (3) the number of times the discussant mentioned the target. For our experiment, we only keep one dimension representing the discussant's attitude (positive, negative, neutral) toward the target since a discussant attitude remains the same in his statement within a single round.
2. Network: We also implemented the signed network partition method for subgroup detection proposed by (Hassan et al., 2012). To determine the number of subgroups t, we set an upper limit of $t = 3$ in order to minimize the optimization function.

3. Human_Voting: We also compare our methods with human voting results. There are two subgroups based on the voting results. The players with the highest votes each round belong to one subgroup and the rest of the players are in the other subgroup.

Table 1 shows the overall performance of various methods on subgroup detection and Figure 6 depicts the average performance. We can see that our method significantly outperforms two baseline methods and human voting. The human performance is not satisfying, which indicates it's very challenging even for a human to identify a deceiver whose deceptive statement is mixed with plenty of truthful opinions (Xu and Zhao, 2012).

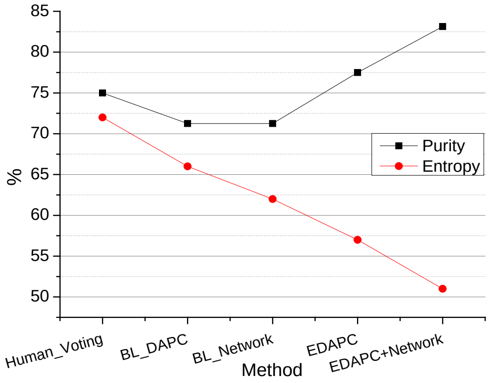

Figure 6: An overview of the average performance of all the methods.

By extending the DAPC method (EDPAC), we can estimate the distance between two players more accurately by considering the attitudes of other players toward them and their attitudes toward each other. Given the log in Figure 2 as input, players 5 (detective) and 7 (killer) are clustered into one group when DAPC is applied since they don't have conflicting views on the identities of other players. However, 5 voted for 7 and is supported by more players compared with 7, which indicates that they are less likely to be teammates. We can successfully separate them after re-computing the distance between them.

Adding network information provided 5.7% further gain in Purity. In some cases, the performance remains the same when EDAPC clustering result is already optimal with the minimum value of the criterion function.

4.4 Dynamic Subgroup Detection

As shown in Figure 7, the performance of our approach improves as the game proceeds. Players seldom maintain their opinions throughout a game. Figure 2 shows that most killers (16,1,12) insisted that citizen 11 should be a killer except 7. As a response to the group pressure (Asch, 1951), 7 changed his opinion and stated that 11 could be a killer in the following round.

In reality, a discussant who participates in an online discussion tends to change his opinions about a target as he learns more information, which shows both the necessity and importance of the dynamic detection of subgroups. Our method can be applied to detect subgroups dynamically by grouping posts into multiple discussion "*rounds*" based on their timestamps.

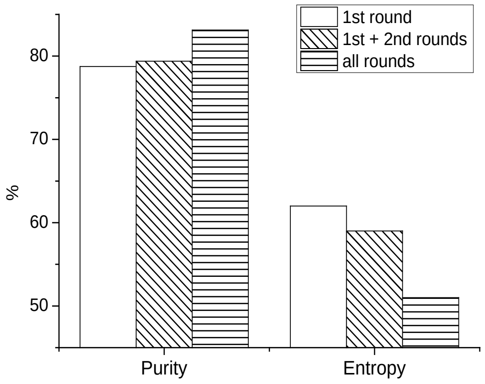

Figure 7: Average performance based on different rounds.

5 Related Work

5.1 Opinion Analysis

Our work on mining a player's attitude toward other players is related to opinion mining. Attitudes and opinions are related and can be regarded as the same in our task. Compared with the previous work (*e.g.*,(Qiu et al., 2011; Kim and Hovy, 2006)), the opinion words and targets in our task are relatively easier to recognize due to the simplicity of statements. Some recent work (*e.g.*, (Somasundaran and Wiebe, 2009; Abu-Jbara et al., 2012a)) developed syntactic rules to pair an opinion word and a target if they satisfy at least one specific dependency rule. We use POS tag sequences to efficiently help us filter out irrelevant pairs.

5.2 Deception Detection

Most of the previous computational work for deception detection used supervised/semi-supervised classification methods (Li et al., 2013b). Besides lexical and syntactical features (Ott et al., 2011; Feng et al., 2012; Yancheva and Rudzicz, 2013), Feng and Hirst (2013) proposed using profile compatibility to distinguish fake and genuine reviews. Xu and Zhao (2012) used deep linguistic features such as text genre to detect deceptive opinion spams. Banerjee et al. (2014) used extended linguistic signals such as keystroke patterns. Li et al. (2013a) used topic models to detect the difference between deceptive and truthful topic-word distribution. Researchers have began to realize the importance of analyzing computer-mediated communication in deception detection. Zhou and Sung (2008) conducted an empirical study on deception cues using the killer game as a task scenario and obtained many interesting findings (*e.g.*, deceivers send fewer messages than truth-tellers).

Our work is most related to the work of Chittaranjan and Hung (2010) on detecting deceptive roles in the Werewolf Game which is another variant of the killer game. They created a Werewolf data set by audio-visual recording 8 games played by 2 groups of people face-to-face and extracted audio features and interaction features for their experiments. However, we should note that non face-to-face deception detection emphasizes verbal and linguistic cues over less controllable non-verbal communication cues (Walther, 1996).

5.3 Subgroup Detection

In online discussions, people usually split into subgroups based on various topics. The member of a subgroup is more likely to show positive attitude to the members of the same subgroup, and negative attitude to the members of opposing subgroups (Abu-Jbara et al., 2012a). Previous work also studied subgroup detection in social media sites. Abu-Jbara et al. (2012a) constructed a discussant attitude profile (DAP) for each discussant and then used clustering techniques to cluster their attitudes. Hassan et al. (2012; 2012b; 2013) proposed various methods to automatically construct a signed social network representation of discussions and then identify subgroups by partitioning their signed networks. Qiu et al. (2013) applied collaborative filtering through Probabilistic Matrix Factorization (PMF) to generalize and improve extracted opinion matrices.

An underlying assumption of the previous work was that a participant will not tell lies nor hide his own stance. Moreover, their work did not take into account that a person's attitude or stance will change as he learns more by reading the comments from others and acquiring more background knowledge (Bandura, 1971). Our contribution is that we extend the DAP method and combine it with the signed network partition in order to cluster the hidden group members. We also develop a novel cluster ensemble approach in order to analyze the dynamic network.

6 Conclusions and Future Work

Using the killer game as a case study, we present an effective clustering method to detect subgroups from dynamic conversations with lies and truths. This is the first work to utilize the dynamics of group conversations for deception detection. Experiments demonstrated that truth-tellers and deceptive groups are separable and the proposed method significantly outperforms baseline approaches and human voting.

Our work builds a pathway to future work in deception detection in content-rich dynamic environments such as electronic commerce and repeated interrogation which will require sophisticated content and network analysis. In real-life suspects may be interrogated about particular events on numerous occasions. Our method can potentially be modified to find criminals who act in groups based on their statements. Other applications of this research include law enforcement, financial fraud, fraudulent ad campaigns and social engineering.

This study focuses on analyzing the verbal content in conversations. It will be interesting to study non-verbal features such as blink rate, gaze aversion and pauses (Granhag and Strömwall, 2002) when people play this game face-to-face and combine the non-verbal and verbal features for deception detection. In addition, it is worth exploring the impact of cross-cultural analysis in detecting deception. When attempting to detect deceit in people of other ethnic origin than themselves, people perform even worse in terms of lie detection accuracy than when judging people of their own ethnic origin (Vrij, 2000). For the future work, we aim to use automatic prediction of deceivers to help truth-tellers win games more easily.

Abstract

Stubs on Wikipedia often lack comprehensive information. The huge cost of editing Wikipedia and the presence of only a limited number of active contributors curb the consistent growth of Wikipedia. In this work, we present WikiKreator, a system that is capable of generating content automatically to improve existing stubs on Wikipedia. The system has two components. First, a text classifier built using topic distribution vectors is used to assign content from the web to various sections on a Wikipedia article. Second, we propose a novel abstractive summarization technique based on an optimization framework that generates section-specific summaries for Wikipedia stubs. Experiments show that WikiKreator is capable of generating well-formed informative content. Further, automatically generated content from our system have been appended to Wikipedia stubs and the content has been retained successfully proving the effectiveness of our approach.

1 Introduction

Wikipedia provides comprehensive information on various topics. However, a significant percentage of the articles are stubs[1] that require extensive effort in terms of adding and editing content to transform them into complete articles. Ideally, we would like to create an automatic Wikipedia content generator, which can generate a comprehensive overview on any topic using available information from the web and append the generated content to the stubs. Addition of automatically generated content can provide a useful starting point for contributors on Wikipedia, which can be improved upon later.

Several approaches to automatically generate Wikipedia articles have been explored (Sauper and Barzilay, 2009; Banerjee et al., 2014; Yao et al., 2011). To the best of our knowledge, all the above mentioned methods identify information sources from the web using keywords and directly use the most relevant excerpts in the final article. Information from the web cannot be directly copied into Wikipedia due to copyright violation issues (Banerjee et al., 2014). Further, keyword search does not always satisfy information requirements (Baeza-Yates et al., 1999). To address the above-mentioned issues, we present WikiKreator – a system that can automatically generate content for Wikipedia stubs. First, WikiKreator does not operate using keyword search. Instead, we use a classifier trained using topic distribution features to identify relevant content for the stub. Topic-distribution features are more effective than keyword search as they can identify relevant content based on word distributions (Song et al., 2010). Second, we propose a novel abstractive summarization (Dalal and Malik, 2013) technique to summarize content from multiple snippets of relevant information.[2]

Figure 1 shows a stub that we attempt to improve using WikiKreator. Generally, in stubs, only the introductory content is available; other sections ($s_1, ..., s_r$) are absent. The stub also belongs to several categories (C_1,C_2, etc. in Figure) on Wikipedia. In this work, we address the following research question: *Given the introductory content, the title of the stub and information on the categories - how can we transform the stub into a com-*

Figure 1: Overview of our word-graph based generation (left) to populate Wikipedia template (right)

prehensive Wikipedia article?

Our proposed approach consists of two stages. First, a text classifier assigns content retrieved from the web into specific sections of the Wikipedia article. We train the classifier using a set of articles within the same category. Currently, we limit the system to learn and assign content into the 10 most frequent sections in any given category. The training set includes content from the most frequent sections as instances and their corresponding section titles as the class labels. We extract topic distribution vectors using Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and use the features to train a Random Forest (RF) Classifier (Liaw and Wiener, 2002). To gather web content relevant to the stub, we formulate queries and retrieve top 20 search results (pages) from Google. We use boilerplate detection (Kohlschütter et al., 2010) to retain the important excerpts (text elements) from the pages. The RF classifier classifies the excerpts into one of the most frequent classes (section titles). Second, we develop a novel Integer Linear Programming (ILP) based abstractive summarization technique to generate text from the classified content. Previous work only included the most informative excerpt in the article (Sauper and Barzilay, 2009); in contrast, our abstractive summarization approach minimizes loss of information that should ideally be in an Wikipedia article by fusing content from several sentences. As shown in Figure 1, we construct a word-graph (Filippova, 2010) using all the sentences (WG_1) assigned to a specific class (*Epidemiology*) by the classifier. Multiple paths (sentences) between the *start* and *end* nodes in the graph are generated (WG_2). We represent the generated paths as variables in the ILP problem. The coefficients of each variable in the objective function of the ILP problem is obtained by combining the information score and the linguistic quality score of the path. We introduce several constraints into our ILP model. We limit the summary for each section to a maximum of 5 sentences. Further, we avoid redundant sentences in the summary that carry similar information. The solution to the optimization problem decides the paths that are selected in the final section summary. For example, in Figure 1, the final paths determined by the ILP solution, – 1 and 2 in WG_2, are assigned to a section (s_r), where (s_r) is the section title *Epidemiology*.

To the best of our knowledge, this work is the first to address the issue of generating content automatically to transform Wikipedia stubs into comprehensive articles. Further, we address the issue of abstractive text summarization for Wikipedia content generation. We evaluate our approach by generating articles in three different categories: *Diseases and Disorders*[3], *American Mathematicians*[4] and *Software companies of the United States*[5]. Our LDA-based classi-

[4] https://en.wikipedia.org/wiki/Category:American_mathematicians

[5] https://en.wikipedia.org/wiki/Category:Software_companies_of_the_United_States

fier outperforms a TFIDF-based classifier in all the categories. We use ROUGE (Lin, 2004) to compare content generated by WikiKreator and the corresponding Wikipedia articles. The results of our evaluation confirm the benefits of using abstractive summarization for content generation over approaches that do not use summarization. WikiKreator outperforms other comparable approaches significantly in terms of content selection. On ROUGE-1 scores, WikiKreator outperforms the perceptron-based baseline (Sauper and Barzilay, 2009) by ~20%. We also analyze reviewer reactions, by appending content into several stubs on Wikipedia, most of which (~77%) have been retained by reviewers.

2 Related Work

Wikipedia has been used to compute semantic relatedness (Gabrilovich and Markovitch, 2007), index topics (Medelyan et al., 2008), etc. However, the problem of enhancing the content of a Wikipedia article has not been addressed adequately. Learning structures of templates from the Wikipedia articles have been attempted in the past (Sauper and Barzilay, 2009; Yao et al., 2011). Both these efforts use queries to extract excerpts from the web and the excerpts ranked as the most relevant are added into the article. However, as already pointed out, current standards of Wikipedia requires rewriting of web content to avoid copyright violation issues.

To address the issue of copyright violation, multi-document abstractive summarization is required. Various abstractive approaches have been proposed till date (Nenkova et al., 2011). However, these methods suffer from severe deficiencies. Template-based summarization methods work well, but, it assumes prior domain knowledge (Li et al., 2013). Writing style across articles vary widely; hence learning templates automatically is difficult. In addition, such techniques require handcrafted rules for sentence realization (Gerani et al., 2014). Alternatively, we can use text-to-text generation (T2T) (Ganitkevitch et al., 2011) techniques. WikiKreator constructs a word-graph structure similar to (Filippova, 2010) using all the sentences that are assigned to a particular section by a text classifier. Multiple paths (sentences) from the graph are generated. WikiKreator selects few sentences from this set of paths using an optimization problem formulation that jointly maximizes the informativeness and readability of section-specific snippets and generates output that is informative, well-formed and readable.

3 Proposed Approach

Figure 2 shows the system architecture of WikiKreator. We are required to generate content to populate sections of the stubs (S_1, S_2, etc.) that belong to category C_1. Categories on Wikipedia group together pages on similar subjects. Hence, categories characterize Wikipedia articles surprisingly well (Zesch and Gurevych, 2007). Naturally, we leverage knowledge existing in the categories to build our text classifier. To learn category specific templates, the system should learn from articles contained within the same or similar categories. WikiKreator learns category-specific templates using all the articles that can be reached using a top-down approach from the particular category. For example, in addition to C_1, WikiKreator also learns templates from articles in C_2 and C_3 (the subcategories of C_1). As shown in the Figure 2, we deploy a two stage process to generate content for a stub:
[i] Content Retrieval and
[ii] Content Summarization.
In the first stage, our focus is to retrieve content that is relevant to the stub, say, S_1 that belongs to C_1. We extract all the articles that belong to C_1 and the subcategories, namely, C_2 and C_3. A training set is created with the contents in the sections of the articles as instances and the section titles as the corresponding classes. Topic distribution vectors for each section content are generated using LDA (Blei et al., 2003). We train a Random Forest

(RF) classifier using the topic distribution vectors. As mentioned earlier, only the top 10 most frequent sections are considered for the multi-class classification task. We retrieve relevant excerpts from the web by formulating queries. The topic model infers the topic distribution features of each excerpt and the RF classifier predicts the section (s_1, s_2, etc.) of the excerpt. All web automation tasks are performed using HTMLUnit[6]. In the second stage, our ILP based summarization approach synthesizes information from multiple excerpts assigned to a section and presents the most informative and linguistically well-formed summary as the corresponding content for each section. A word-graph is constructed that generates several sentences; only a few of the sentences are retained based on the ILP solution. The predicted section is entered in the stub article along with the final sentences selected by the ILP solution as the corresponding section-specific content on Wikipedia.

3.1 Content Retrieval

Article Extraction: Wikipedia provides an API[7] to download articles in the XML format. Given a category, the API is capable of extracting all the articles under it. We recursively extract articles by identifying all the categories in the hierarchy that can be reached by the crawler using top-down traversal. We use a simple python script[8] to extract the section titles and the corresponding text content from the XML dump.

Classification model: WikiKreator uses Latent Dirichlet Allocation (LDA) to represent each document as a vector of topic distributions. Each topic is further represented as a vector of probabilities of word distributions. Our intuition is that the topic distribution vectors of the same sections across different articles would be similar. Our objective is to learn these topic representations, such that we can accurately classify any web excerpt by inferring the topics in the text. Say C, a category on Wikipedia, has k Wikipedia articles (W).

$$(C) = \{W_1, W_2, W_3, W_4, ..., W_k\}$$

Each article W_j has several sections denoted as $s_{ji}c_{ji}$ where s_{ji} and c_{ji} refer to the section title and content of the ith section in the jth article, respectively. We concentrate on the 10 most frequent sections in any category. Training using content from sections that are not frequent might result in sub-optimal classification models. In our experiments, each frequent section had enough instances to optimally train a classifier. Let us denote the 10 most frequent sections in any category as $\boldsymbol{S}$. If any s_{ji} from W_j exists in $\boldsymbol{S}$, the content (c_{ji}) is included in the training set along with the section title (s_{ji}) as the corresponding class label. These steps are repeated for all the articles in the category. Each instance is then represented as:

$$c_{ji} = \{p_{ji}(t_1), p_{ji}(t_2), p_{ji}(t_3), \ldots, p_{ji}(t_m)\}$$

where m is the number of topics. s_{ji} is the corresponding label for this training instance. The set of topics are t_1, t_2, t_3,. . ., t_m while $p_{ji}(t_m)$ refers to the probability of topic m of content c_{ji}. Contents from the most frequent sections are each considered as a document and LDA is applied to generate document-topic distributions. We experiment with several values of m and use the value that generates the best classification model in each category. The topic vectors and the corresponding labels are used to train a Random Forest (RF) classifier. As the classes might be unbalanced, we apply resampling on the training set.

Predicting sections: In this step, we search the web for relevant content on the stub and assign them to their respective sections. We formulate search queries to retrieve web pages using a search engine. We extract multiple excerpts from the pages and then the RF classifier predicts the class (section label) for each excerpt.

(i) Query Generation: To search the web, we formulate queries by combining the stub title and keyphrases extracted from the first sentence of the introductory content of the stub. The first sentence generally contains the most important keywords that represent the article. Focused queries increases relevance of extraction as well as helps in disambiguation of content. We use the topia term extractor (Chatti et al., 2014) to extract keyphrases. For example, the query generated for a stub on *Hereditary hyperbilirubinemia* is *Hereditary hyperbilirubinemia bilirubin metabolic disorder* where *bilirubin metabolic disorder* are the keyphrases generated from the first sentence of the stub from Wikipedia. The query is used to identify the top 20 URLs (search results) from Google[9].

(ii) Boilerplate removal: Web content from the search results obtained in the previous step re-

[6] `http://htmlunit.sourceforge.net/`

[7] `https://en.wikipedia.org/wiki/Special:Export`

[8] `http://medialab.di.unipi.it/wiki/Wikipedia_Extractor`

[9] `http://www.google.com`

quires cleaning to retain only the relevant information. Removal of irrelevant content is done using boilerplate detection (Kohlschütter et al., 2010). The web pages contain several excerpts (text elements) in between the HTML tags. Only the excerpts that are classified as relevant by the boilerplate detection technique are retained.

(iii) Classification and assignment of excerpts: The LDA model generated earlier infers topic distribution of each excerpt based on word distributions. The RF classifier predicts the class (section title) for each excerpt based on the topic distribution. However, predictions that do not have a high level of confidence might lead to excerpts being appended to inappropriate sections. Therefore, we set the minimum confidence level at 0.5. If the prediction confidence of the RF classifier for a particular excerpt is above the minimum confidence level, the excerpt is assigned to the class; otherwise, the excerpt is discarded.

In the next step, we apply summarization on the excerpts assigned to each section.

3.2 Content Summarization

To summarize content for Wikipedia effectively, we formulate an ILP problem to generate abstractive summaries for each section with the objective of maximizing linguistic quality and information content.

Word-graph: A word-graph is constructed using all the sentences included in the excerpts assigned to a particular section. We used the same technique to construct the word-graph as (Filippova, 2010) where the nodes represent the words (along with parts-of-speech (POS)) and directed edges between the nodes are added if the words are adjacent in the input sentences. Each sentence is connected to dummy *start* and *end* nodes to mark the beginning and ending of the sentences. The sentences from the excerpts are added to the graph in an iterative fashion. Once the first sentence is added, words from the following sentences are mapped onto a node in the graph provided that they have the exact same word form and the same POS tag. Inclusion of POS information prevents ungrammatical mappings. The words are added to the graph in the following order:

- Content words are added for which there are no candidates in the existing graph;
- Content words for which multiple mappings are possible or such words that occur more than once in the sentence;
- Stopwords.

If multiple mappings are possible, the context of the word is checked using word overlaps to the left and right within a window of two words. Eventually, the word is mapped to that node that has the highest context. We also changed Filippova's method by adding punctuations as nodes to the graph. Figure 1 shows a simple example of the word-graph generation technique. We do not show POS and punctuations in the figure for the sake of clarity. The Figure also shows that several possible paths (sentences) exist between the dummy *start* and *end* nodes in the graph. Ideally, excerpts for any section would contain multiple common words as they belong to the same topic and have been assigned the same section. The presence of common words ensure that new sentences can be generated from the graph by fusing original set of sentences in the graph. Figure 1 shows an illustration of our approach where the set of sentences assigned to a particular section (WG_1) are used to create the word-graph. The word-graph generates several possible paths between the dummy nodes; we show only three such paths (WG_2). To obtain abstractive summaries, we remove generated paths from the graph that are same or very similar to any of the original sentences. If the cosine similarity of a generated path to any of the original sentences is greater than 0.8, we do not retain the path. We compute cosine similarity after applying stopword removal. However, we do not apply stemming as our graph construction is based on words existing in the same form in multiple sentences. Similar to Filippova's work, we set the minimum path length (in words) to eight to avoid incomplete sentences. Paths without verbs are discarded. The final set of generated paths after discarding the ineligible ones are used in the next step of summary generation.

3.2.1 ILP based Path Selection

Our goal is to select paths that maximize the informativeness and linguistic quality of the generated summaries. To select the best multiple possible sentences, we apply an *overgenerate and select* (Walker et al., 2001) strategy. We formulate an optimization problem that 'selects' a few of the many generated paths in between the dummy nodes from the word-graph. Let p_i denote each path obtained from the word-graph. We introduce three different factors to judge the relevance of a path – *Local informativeness* ($I^{loc}(p_i)$), *Global informativeness* ($I^{glob}(p_i)$) and *Linguistic quality* ($LQ(p_i)$). Any sentence path should be relevant to the central topic of the article; this relevance is tackled using $I^{glob}(p_i)$. $I^{loc}(p_i)$ models the importance of a sentence among several possible sentences that are generated from the word-graph. Linguistic quality ($LQ(p_i)$) is computed using a trigram language model (Song and Croft, 1999) that assigns a logarithmic score of probabilities of occurrences of three word sequences in the sentences.

Local Informativeness: In principle, we can use any existing method that computes sentence importance to account for *Local Informativeness*. In our model, we use TextRank scores (Mihalcea and Tarau, 2004) to generate an importance value of each path. TextRank creates a graph of words from the sentences. The score of each node in the graph is calculated as shown in Equation (1):

$$S(V_i) = (1-d) + d \times \textstyle\sum_{V_j \in adj(V_i)} \frac{w_{ji}}{\sum_{V_k \in adj(V_i)} w_{jk}} S(V_i) \tag{1}$$

where V_i represents the words and $adj(V_i)$ denotes the adjacent nodes of V_i. Setting d to 0.80 in our experiments provided the best content selection results. The computation convergences to return final word importance scores. The informativeness score of a path $I^{loc}(p_i)$ is obtained by adding the importance scores of the individual words in the path.

Global Informativeness: To compute global informativeness, we compute the relevance of a sentence with respect to the query to assign higher weights to sentences that explicitly mention the main title or mention certain keywords that are relevant to the article. We compute the cosine similarity using TFIDF features between each sentence and the original query that was formulated during the web search stage. We define global informativeness as follows:

$$I^{glob}(p_i) = CosineSimilarity(Q, p_i) \tag{2}$$

where Q denotes the formulated query.

Linguistic Quality: In order to compute *Linguistic quality*, we use a language model that assigns probabilities to sequence of words to compute linguistic quality. Suppose a path contains a sequence of q words $\{w_1, w_2, ..., w_q\}$. The score $LQ(p_i)$ assigned to each path is defined as follows:

$$LQ(p_i) = \frac{1}{1 - LL(w_1, w_2, ..., w_q)}, \tag{3}$$

where $LL(w_1, w_2, ..., w_q)$ is defined as:

$$LL(w_1, \ldots, w_q) = \frac{1}{L} \cdot \log_2 \textstyle\prod_{t=3}^{q} P(w_t | w_{t-1} w_{t-2}). \tag{4}$$

As can be seen from Equation (4), we combine the conditional probability of different sets of 3-grams (trigrams) in the sentence and averaged the value by L – the number of conditional probabilities computed. The $LL(w_1, w_2, \ldots, w_q)$ scores are negative; with higher magnitude implying lower importance. Therefore, in Equation (3), we take the reciprocal of the logarithmic value with smoothing to compute $LQ(p_i)$. In our experiments, we used a 3-gram model[10] that is trained on the English Gigaword corpus. Trigram models have been successfully used in several text-to-text generation tasks (Clarke and Lapata, 2006; Filippova and Strube, 2008) earlier.

ILP Formulation: To select the best paths, we combine all the above mentioned factors $I^{loc}(p_i)$, $I^{glob}(p_i)$ and linguistic quality $LQ(p_i)$ in an optimization framework. We maximize the following objective function:

$$F(p_1, \ldots, p_K) = \textstyle\sum_{i=1}^{K} \frac{1}{T(p_i)} \cdot I^{loc}(p_i) \cdot I^{glob}(p_i) \cdot LQ(p_i) \cdot p_i \tag{5}$$

where K represents the total number of generated paths. Each p_i represents a binary variable, that can be either 0 or 1, depending on whether the path is selected in the final summary or not. In addition, $T(p_i)$ – the number of tokens in a path, is included in the objective function. The term $\frac{1}{T(p_i)}$ normalizes the Textrank scores by the length of the sentences. First, we ensure that a maximum of S_{max} sentences are selected in the summary using Equation (6).

$$\sum_{i=1}^{K} p_i \leq S_{max} \tag{6}$$

In our experiments, we set S_{max} to 5 to generate short concise summaries in each section. Using a length constraint enables us to only populate the sections using the most informative content. We introduce Equation (7) to prevent similar information (cosine similarity $\geq$ 0.5) from being conveyed

[10] The model is available here: `http://www.keithv.com/software/giga/`. We used the VP 20K vocab version.

Category	Most Frequent Sections
American Mathematicians	*Awards, Awards and honors, Biography, Books, Career, Education, Life, Publications, Selected publications, Work*
Diseases and Disorders	*Causes, Diagnosis, Early life, Epidemiology, History, Pathophysiology, Prognosis, Signs and symptoms, Symptoms, Treatment*
US Software companies	*Awards, Criticism, Features, Games, History, Overview, Products, Reception, Services, Technology*

Table 1: Data characteristics of three domains on Wikipedia

Category	#Articles	#Instances
American Mathematicians	$\sim$ 2100	1493
Diseases and Disorders	$\sim$ 7000	9098
US Software companies	$\sim$ 3600	2478

Table 2: Dataset used for classification

by different sentences. This constraint reduces redundancy. If two sentences have a high degree of similarity, only one out of the two can be selected in the summary.

$$\forall i, i' \in [1, K], i \neq i', \\ p_i + p_{i'} \leq 1 \text{ if } sim(p_i, p_{i'}) \geq 0.5. \quad (7)$$

The ILP problem is solved using the Gurobi optimizer (2015). The solution to the problem decides the paths that should be included in the final summary. We populate the sections on Wikipedia using the final summaries generated for each section along with the section title. All the references that have been used to generate the sentences are appended along with the content generated on Wikipedia.

4 Experimental Results

To evaluate the effectiveness of our proposed technique, we conduct several experiments. First, we evaluate our content generation approach by generating content for comprehensive articles that already exist on Wikipedia. Second, we analyze reviewer reactions on our system generated articles by adding content to several stubs on Wikipedia. Our experiments were designed to answer the following questions:

(i)*What are the optimal number of topic distribution features for each category? What are the classification accuracies in each domain?*

(ii)*To what extent can our technique generate the content for articles automatically?*

(iii)*What are the general reviewer reactions on Wikipedia and what percentage of automatically generated content on Wikipedia is retained?*

Dataset Construction: As mentioned earlier in Section 3.1, we crawl Wikipedia articles by traversing the category graph. Articles that contain at least three sections were included in the training set; other articles having lesser number of sections are generally labeled as stubs and hence not used for training. Table 1 shows the most frequent sections in each category. Further, Table 2 shows the total number of articles retrieved from Wikipedia in each category. The total number of instances are also shown. The number of instances denotes the total number of the most frequent sections in each category. As can be seen from the table, the number of instances is higher than the number of articles only in case of the category on *diseases*. This implies that there are generally more common sections in the diseases category than the other categories.

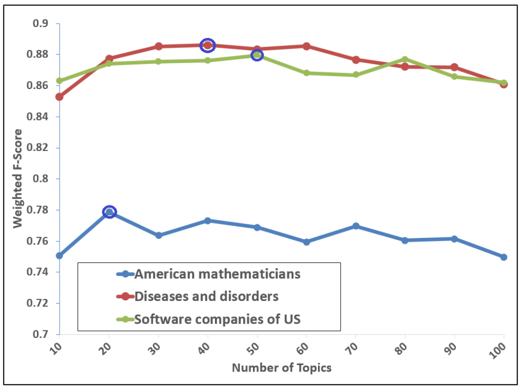

Figure 3: Performance of Classifier in the three categories based on the number of topics.

In each category, the content from only the most frequent sections were used to generate a topic model. The topic model is further used to infer topic distribution vectors from the training instances. We used the MALLET toolkit (McCallum, 2002) for generating topic distribution vectors and the WEKA package (Hall et al., 2009) for the classification tasks.

Optimal number of topics: The LDA model requires a pre-defined number of topics. We experiment with several values of the number of topics ranging from 10 to 100. The topic distribution features of the content of the instances are used to train a Random Forest Classifier with the corresponding section titles as the class labels. As can be seen in the Figure 3, the classification performance varies across domains as well as on the number of topics. The optimal number of topics based on the dataset are marked in *blue* cir-

Category	LDA-RF	SVM-WV
American Mathematicians	**0.778**	0.478
Diseases and Disorders	**0.886**	0.801
US Software companies	**0.880**	0.537

Table 3: Classification: Weighted F-Scores

cles (40, 50 and 20 topics for *Diseases*, *Software Companies in US* and *American mathematicians*, respectively) in the Figure. We classify web excerpts using the best performing classifiers trained using the optimal number of topic features in each category.

Classification performance: We use 10-fold cross validation to evaluate the accuracy of our classifier. According to the F-Scores, our classifier **(LDA-RF)** performs similarly in the categories on *Diseases* and *US Software companies*. However, the accuracy is lower in the *American Mathematicians* category. We also experimented with a baseline classifier, that is trained on TFIDF features (upto trigrams). A Support vector machine (Cortes and Vapnik, 1995) classifier obtained the best performance using the TFIDF features. The baseline system is referred to as **SVM-WV**. We experimented with several other combinations of classifiers; however, we show only the best performing systems using the LDA and TFIDF features. As can be seen from the Table 3, our classifier **(LDA-RF)** outperforms **SVM-WV** significantly in all the domains. **SVM-WV** performs better in the category on diseases than the other two categories and the performance is comparable to **(LDA-RF)**. The diseases category has more uniformity in terms of the section titles, hence specific words or phrases characterize the sections well. In contrast, word distributions (LDA) work significantly better than TFIDF features in the other two categories.

Error Analysis: We performed error analysis to understand the reason for misclassifications. As can be seen from the Table 1, all the categories have several overlapping sections. For example, *Awards and honors* and *Awards* contain similar content. Authors use various section names for similar content in the articles within the same category. We analyzed the confusion matrices, and found that multiple instances in *Awards* were classified into the class of *Awards and honors*. Similar observations are made on the *Books* and *Publications* classes – which are related sections in the context of academic biographies. In future, we plan to use semantic measures to relate similar classes automatically and group them in the same class during classification.

	Perceptron	0.421	0.228
	Extractive	0.484	0.257

Table 4: ROUGE-1 and 2 Recall values – Comparing system generated articles to model articles

Content Selection Evaluation: To evaluate the effectiveness of our content generation process, we generated the content of 500 randomly selected articles that already exist on Wikipedia in each of the categories. We compare WikiKreator's output against the current content of those articles on Wikipedia using ROUGE (Lin, 2004). ROUGE matches N-gram sequences that exist in both the system generated articles and the original Wikipedia articles (gold standard). We also compare WikiKreator's output with an existing Wikipedia generation system [**Perceptron**] of Sauper and Barzilay (2009)[11] that employs a perceptron learning framework to learn topic specific extractors. Queries devised using the conjunction of the document title and the section title were used to obtain excerpts from the web using a search engine, which were used in the perceptron model. In *Perceptron*, the most important sections in the category was determined using a bisectioning algorithm to identify clusters of similar sections. To understand the effectiveness of our abstractive summarizer, we design a system (**Extractive**) that uses an extractive summarization module. In *Extractive*, we use LexRank (Erkan and Radev, 2004) as the summarizer instead of our ILP based abstractive summarization model. We restrict the extractive summaries to 5 sentences for accurate comparison of both the systems. The same content was received as input from the classifier by the *Extractive* as well as our ILP-based system.

As can be seen from the Table 4, the ROUGE scores obtained by WikiKreator is higher than that of the other comparable systems in all the categories. The higher ROUGE scores imply that *WikiKreator* is generally able to retrieve useful information from the web, synthesize them and present the important information in the article.

[11] The system is available here: `https://github.com/csauper/wikipedia`

Statistics	Count
Number of stubs edited	40
Number of stubs retained without any changes	21
Number of stubs that required minor editing	6
Number of stubs where edits were modified by reviewers	4
Number of stubs in which content was removed	9
Average change in size of stubs	515 bytes
Average number of edits made post content-addition	~3

Table 5: Statistics of Wikipedia generation

However, it may also be noted that the *Extractive* system outperforms the Perceptron framework. Summarization from multiple sources generates more informative summaries and is more effective than 'selection' of the most informative excerpt, which is often inadequate due to potential loss of information. WikiKreator performs better than the extractive system on all the categories. Our ILP-based abstractive summarization system fuses and selects content from multiple sentences, thereby aggregating information successfully from multiple sources. In contrast, LexRank 'extracts' the top 5 sentences that results in some information loss.

Analysis of Wikipedia Reviews: To compare our method with the other techniques, it is necessary to generate content and append to Wikipedia stubs using all the techniques. However, recent work on article generation (Banerjee et al., 2014) has already shown that content directly copied from web sources cannot be used on Wikipedia. Further, bots using copyrighted content might be banned and real-users would have to read sub-standard articles due to the internal tests we perform. Due to the above mentioned reasons, we appended content generated only using our abstractive summarization technique.

We published content generated by WikiKreator on Wikipedia and appended the content to 40 randomly selected stubs. As can be seen from the Table 5, the content generated using our system was generally accepted by the reviewers. Half of the articles did not require any further changes; while in 6 cases (15%) the reviewers asked us to fix grammatical issues. In 9 stubs, the reliability of the cited references was questioned. Information sources on Wikipedia need to satisfy a minimum reliability standard, which our algorithm currently cannot determine. On an average, 3 edits were made to the Wikipedia articles that we generated. In general, there is an average increase in the content size of the stubs that we edited showing that our method is capable of producing content that generally satisfy Wikipedia criterion.

Analysis of section assignment: We manually inspected generated content of 20 articles in each category. Generated summaries are both informative and precise. However, in certain cases, the generated section title is not the same as the section title in the original Wikipedia article. For example, we generated content for the section "Causes" for the article on Middle East Respiratory Syndrome (MERS)[12]:

Milk or meat may play a role in the transmission of the virus . People should avoid drinking raw camel milk or meat that has not been properly cooked . There is growing evidence that contact with live camels or meat is causing MERS.

The corresponding content on the Wikipedia is in a section labeled as "Transmission". Section titles at the topmost level in a category might not be relevant to all the articles. Instead of using a top-down approach of traversing the category-graph, we can also use a bottom-up approach where we learn from all the categories that an article belongs to. For example, the article on MERS belongs to two categories: *Viral respiratory tract infection* and *Zoonoses*. Training using all the categories will allow context-driven section identification. Most frequent sections at a higher level in the category graph might not always be relevant to all the articles within a category.

5 Conclusions and Future Work

In this work, we presented WikiKreator that can generate content automatically to improve Wikipedia stubs. Our technique employes a topic-model based text classifier that assigns web excerpts into various sections on an article. The excerpts are summarized using a novel abstractive summarization technique that maximizes informativeness and linguistic quality of the generated summary. Our experiments reveal that WikiKreator is capable of generating well-formed informative content. The summarization step ensures that we avoid any copyright violation issues. The ILP based sentence generation strategy ensures that we generate novel content by synthesizing information from multiple sources and thereby improve content selection. In future, we plan to cluster related sections using semantic relatedness measures. We also plan to estimate reliabilities of sources to retrieve information only from reliable sources.

Language to Code:
Learning Semantic Parsers for If-This-Then-That Recipes

Abstract

Using natural language to write programs is a touchstone problem for computational linguistics. We present an approach that learns to map natural-language descriptions of simple "if-then" rules to executable code. By training and testing on a large corpus of naturally-occurring programs (called "recipes") and their natural language descriptions, we demonstrate the ability to effectively map language to code. We compare a number of semantic parsing approaches on the highly noisy training data collected from ordinary users, and find that loosely synchronous systems perform best.

1 Introduction

The ability to program computers using natural language would clearly allow novice users to more effectively utilize modern information technology. Work in *semantic parsing* has explored mapping natural language to some formal domain-specific programming languages such as database queries (Woods, 1977; Zelle and Mooney, 1996; Berant et al., 2013), commands to robots (Kate et al., 2005), operating systems (Branavan et al., 2009), smartphones (Le et al., 2013), and spreadsheets (Gulwani and Marron, 2014). Developing such language-to-code translators has generally required specific dedicated efforts to manually construct parsers or large corpora of suitable training examples.

An interesting subset of the possible program space is if-then "recipes," simple rules that allow users to control many aspects of their digital life including smart devices. Automatically parsing these recipes represents a step toward complex natural language programming, moving beyond single commands toward compositional statements with control flow.

Several services, such as Tasker and IFTTT, allow users to create simple programs with "triggers" and "actions." For example, one can program their Phillips Hue light bulbs to flash red and blue when the Cubs hit a home run. A somewhat complicated GUI allows users to construct these recipes based on a set of information "channels." These channels represent many types of information. Weather, news, and financial services have provided constant updates through web services. Home automation sensors and controllers such as motion detectors, thermostats, location sensors, garage door openers, etc. are also available. Users can then describe the recipes they have constructed in natural language and publish them.

Our goal is to build semantic parsers that allow users to describe recipes in natural language and have them automatically mapped to executable code. We have collected 114,408 recipe-description pairs from the http://ifttt.com website. Because users often provided short or incomplete English descriptions, the resulting data is extremely noisy for the task of training a semantic parser. Therefore, we have constructed semantic-parser learners that utilize and adapt ideas from several previous approaches (Kate and Mooney, 2006; Wong and Mooney, 2006) to learn an effective interpreter from such noisy training data. We present results on our collected IFTTT corpus demonstrating that our best approach produces more accurate programs than several competing baselines. By exploiting such "found data" on the web, semantic parsers for natural-language programming can potentially be developed with minimal effort.

2 Background

We take an approach to semantic parsing that directly exploits the formal grammar of the target meaning representation language, in our case IFTTT recipes. Given supervised training data in the form of natural-language sentences each paired with their corresponding IFTTT recipe, we learn to introduce productions from the formal-language grammar into the derivation of the target program based on expressions in the natural-language input. This approach originated with the SILT system (Kate et al., 2005) and was further developed in the WASP (Wong and Mooney, 2006; Wong and Mooney, 2007b) and KRISP (Kate and Mooney, 2006) systems.

WASP casts semantic parsing as a syntax-based *statistical machine translation* (SMT) task, where a *synchronous context-free grammar* (SCFG) (Wu, 1997; Chiang, 2005; Galley et al., 2006) is used to model the translation of natural language into a formal meaning representation. It uses statistical models developed for syntax-based SMT for lexical learning and parse disambiguation. Productions in the formal-language grammar are used to construct synchronous rules that simultaneously model the generation of the natural language. WASP was subsequently "inverted" to use the same synchronous grammar to generate natural language from the formal language (Wong and Mooney, 2007a).

KRISP uses classifiers trained using a Support-Vector Machine (SVM) to introduce productions in the derivation of the formal translation. The productions of the formal-language grammar are treated like semantic concepts to be recognized from natural-language expressions. For each production, an SVM classifier is trained using a *string subsequence kernel* (Lodhi et al., 2002). Each classifier can then estimate the probability that a given natural-language substring introduces a production into the derivation of the target representation. During semantic parsing, these classifiers are employed to estimate probabilities on different substrings of the sentence to compositionally build the most probable meaning representation for the sentence. Unlike WASP whose synchronous grammar needs to be able to directly parse the input, KRISP's approach to "soft matching" productions allows it to produce a parse for *any* input sentence. Consequently, KRISP was shown to be much more robust to noisy training data than previous approaches to semantic parsing (Kate and Mooney, 2006).

Since our "found data" for IFTTT is extremely noisy, we have taken an approach similar to KRISP; however, we use a probabilistic log-linear text classifier rather than an SVM to recognize productions.

This method of assembling well-formed programs guided by a natural language query bears some resemblance to Keyword Programming (Little and Miller, 2007). In that approach, users enter natural language queries in the middle of an existing program; this query drives a search for programs that are relevant to the query and fit within the surrounding program. However, the function used to score derivations is a simple matching heuristic relying on the overlap between query terms and program identifiers. Our approach uses machine learning to build a correspondence between queries and recipes based on parallel data.

There is also a large body of work applying Combinatory Categorical Grammars to semantic parsing, starting with Zettlemoyer and Collins (2005). Depending on the set of combinators used, this approach can capture more expressive languages than synchronous context-free MT. In practice, however, synchronous MT systems have competitive accuracy scores (Andreas et al., 2013). Therefore, we have not yet evaluated CCG on this task.

3 If-this-then-that recipes

The recipes considered in this paper are diverse and powerful despite being simple in structure. Each recipe always contains exactly one trigger and one action. Whenever the conditions of the trigger are satisfied, the action is performed. The resulting recipes can perform tasks such as home automation ("turn on my lights when I arrive home"), home security ("text me if the door opens"), organization ("add receipt emails to a spreadsheet"), and much more ("remind me to drink water if I've been at a bar for more than two hours"). Triggers and actions are drawn from a wide range of channels that must be activated by each user. These channels can represent many entities and services, including devices (such as Android devices or WeMo light switches) and knowledge sources (such as ESPN or Gmail). Each channel exposes a set of functions for both trigger and action.

Several services such as IFTTT, Tasker, and Llama allow users to author if-this-then-that recipes. IFTTT is unique in that it hosts a large set of recipes along with descriptions and other metadata. Users of this site construct recipes using a GUI interface to select the trigger, action, and the parameters for both trigger and action. After the recipe is authored, the user must provide a description and optional set of notes for this recipe and publish the recipe. Other users can browse and use these published recipes; if a user particularly likes a recipe, they can mark it as a favorite.

As of January 2015, we found 114,408 recipes on http://ifttt.com. Among the available recipes we encountered a total of 160 channels. In total, we found 552 trigger functions from 128 of those channels, and 229 action functions from 99 channels, for a total of 781 functions. Each recipe includes a number of pieces of information: description[1], note, author, number of uses, etc. 99.98% of the entries have a description, and 35% contain a note. Based on availability, we focused primarily on the description, though there are cases where the note is a more explicit representation of program intent.

The recipes at http://ifttt.com are represented as HTML forms, with combo boxes, inline maps, and other HTML UI components allowing end users to select functions and their parameters. This is convenient for end users, but difficult for automated approaches. We constructed a *formal grammar* of possible program structures, and from each HTML form we extracted an abstract syntax tree (AST) conforming to this grammar. We model this as a context-free grammar, though this assumption is violated in some cases. Consider the program in Figure 1, where some of the parameters used the action are provided by the trigger.

This data could be used in a variety of ways. Recipes could be suggested to users based on their activities or interests, for instance, or one could train a natural language generation system to give a readable description of code.

In this paper, the paired natural language descriptions and abstract syntax trees serve as training data for semantic parsing. Given a description, a system must produce the AST for an IFTTT recipe. We note in passing that the data was constructed in the opposite direction: users first implemented the recipe and then provided a description afterwards. Ideal data for our application would instead start with the description and construct the recipe based on this description. Yet the data is unusually large and diverse, making it interesting training data for mapping natural language to code.

4 Program synthesis methods

We consider a number of methods to map the natural language description of a problem into its formal program representation.

4.1 Program retrieval

One natural baseline is retrieval. Multiple users could potentially have similar needs and therefore author similar or even identical programs. Given a novel description, we can search for the closest description in a table of program-description pairs, and return the associated program. We explored several text-similarity metrics, and found that string edit distance over the unmodified character sequence achieved best performance on the development set. As the corpus of program-description pairs becomes larger, this baseline should increase in quality and coverage.

4.2 Machine Translation

The downside to retrieval is that it cannot generalize. Phrase-based SMT systems(Och et al., 1999; Koehn et al., 2003) can be seen as an incremental step beyond retrieval: they segment the training data and attempt to match and assemble those segments at runtime. If the phrase length is unbounded, retrieval is almost a special case: it could return whole programs from the training data when the description matches exactly. In addition, they can find subprograms that are relevant to portions of the input, and assemble those subprograms into whole programs.

As a baseline, we adopt a recent approach (Andreas et al., 2013) that casts semantic parsing as phrasal translation. First, the ASTs are converted into flat sequences of code tokens using a pre-order left-to-right traversal. The tokens are annotated with their arity, which is sufficient to reconstruct the tree given a well formed sequence of tokens using a simple stack algorithm. Given this parallel corpus of language and code tokens, we train a conventional statistical machine translation system that is similar in structure and performance to Moses (Koehn et al., 2007). We gather the k-best translations, retaining the first such output that can be successfully converted into a well-formed program according to the formal grammar. Integration of the well-formedness constraint into decoding would likely produce better translations, but would require more modifications to the MT system.

Approaches to semantic parsing inspired by machine translation have proven effective when the

[1] The IFTTT site refers to this as "title".

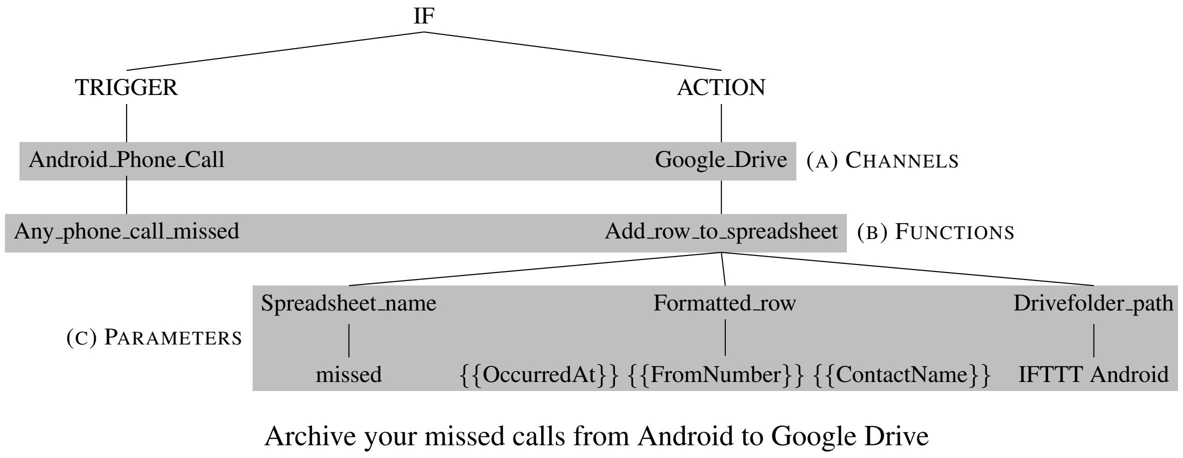

Figure 1: Example recipe with description, with nodes corresponding to (a) Channels, (b) Functions, and (c) Parameters indicated with specific boxes. Note how some of the fields in braces, such as OccurredAt, depend on the trigger.

data is very parallel. In the IFTTT dataset, however, the available pairs are not particularly clean. Word alignment quality suffers, and production extraction suffers in turn. Descriptions in this corpus are often quite telegraphic (e.g., "Instagram to Facebook") or express unnecessary pieces of information, or are downright unintelligible ("_2Mrl14"). Approaches that rely heavily on lexicalized information and assume a one-to-one correspondence between source and target (at the phrase, if not the word level) struggle in this setting.

4.3 Generation without alignment

An alternate approach is to treat the source language as context and a general direction, rather than a hard constraint. The target derivation can be produced primarily according to the formal grammar while guided by features from the source language.

For each production in the formal grammar, we can train a binary classifier intended to predict whether that production should be present in the derivation. This classifier uses general features of the source sentence. Note how this allows productions to be inferred based on context: although a description might never explicitly say that a production is necessary, the surrounding context might strongly imply it.

We assign probabilities to derivations by looking at each production independently. A derivation either uses or does not use each production. For each production used in the derivation, we multiply by the probability of its inclusion. Likewise for each production *not* used in the derivation, we multiply by one minus the probability of its inclusion.

Let $G = (V, \Sigma, R, S)$ be the formal grammar with non-terminals V, terminal vocabulary Σ, productions R and start symbol S. E represents a source sentence, and D, a formal derivation tree for that sentence. $R(D)$ is the set of productions in that derivation. The score of a derivation is the following product:

$$P(D|E) = \prod_{r \in R(D)} P(r|E) \prod_{r \in R \setminus R(D)} P(\neg r|E)$$

The binary classifiers are log-linear models over features, F, of the input string: $P(r|E) \propto \exp\left(\theta_r^\top F(E)\right)$.

4.3.1 Training

For each production, we train a binary classifier predicting its presence or absence. Given a training set of parallel descriptions and programs, we create $|R|$ binary classifier training sets, one for each classifier. We currently use a small set of simple features: word unigrams and bigrams, and character trigrams.

4.3.2 Inference

When presented with a novel utterance, E, our system must find the best code corresponding to that utterance. We use a top-down, left-to-right generation strategy, where each search node contains a stack of symbols yet to be expanded and a log probability. The initial node is $\langle [S], 0 \rangle$; and a node is complete when its stack of non-terminals is empty.

Given a search node with a non-terminal as its first symbol on the stack, we expand with any production for that symbol, putting its yield onto the stack and updating the node cost to include its derivation score:

$$\frac{\langle [X, \alpha], p\rangle \;\; (X \rightarrow \beta) \in R}{\langle [\beta, \alpha], p + \log P(X \rightarrow \beta | E)\rangle\rangle}$$

If the first stack item is a terminal, it is scanned:

$$\frac{\langle [a, \alpha], p\rangle \;\; a \in \Sigma}{\langle [\alpha], p\rangle}$$

Using these inference rules, we utilize a simple greedy approach that only accounts for the productions included in the derivation. To account for the negative $\prod_{r \in R \setminus R(D)} P(\neg r|E)$ factors, we use a beam search, and rerank the n-best final outcomes from this search based on the probability of all productions that are not included. Partial derivations are grouped into beams according to the number of productions in that derivation.

4.4 Loosely synchronous generation

The above method learns distributions over productions given the input, but treats the sentence as an undifferentiated bag of linguistic features. The syntax of the source sentence is not leveraged at all, nor is any correspondence between the language syntax and the program structure used. Often the pairs are not in sufficient correspondence to suggest synchronous approaches, but some loose correspondence to maintain at least a notion of coverage could be helpful.

We pursue an approach similar to KRISP (Kate and Mooney, 2006), with several differences. First, rather than a string kernel SVM, we use a log-linear model with character and word n-gram features. [2] Second, we allow the model to consider both span-internal features and contextual features.

This approach explicitly models the correspondence between nodes in the code side and tokens in the language. Unlike standard MT systems, word alignment is not used as a hard constraint. Instead, this phrasal correspondence is induced as part of model training.

We define a semantic derivation D of a natural language sentence E as a program AST where each production in the AST is augmented with a span. The substrings covered by the children of a production must not overlap, and the substring covered by the parent must be the concatenation of the substrings covered by the children. Figure 2 shows a sample semantic derivation.

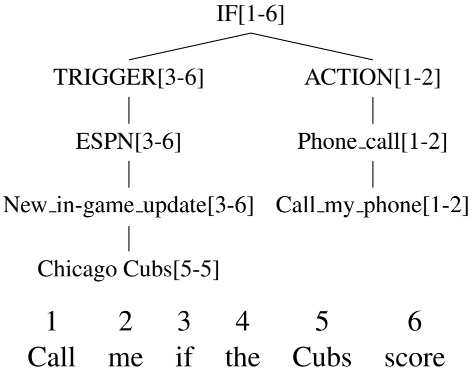

Figure 2: An example training pair with its semantic derivation. Note the correspondence between formal language and natural language denoted with indices and spans.

The core components of KRISP are string-kernel classifiers $P(r, i..j|E)$ denoting the probability that a production r in the AST covers the span of words $i..j$ in the sentence E. Here, $i < j$ are positions in the sentence indicating the span of tokens most relevant to this production. In other words, the substring $E[i..j]$ denotes the production r with probability $P(r, i..j|E)$. The probability of a semantic derivation D is defined as follows:

$$P(D|E) = \prod_{(r,i..j) \in D} P(r, i..j|E)$$

That is, we assume that each production is independent of all others, and is conditioned only on the string to which it is aligned. This can be seen as a refinement of the above production classification approach using a notion of correspondence.

Rather than using string kernels, we use logistic regression classifiers with word unigram, word bigram, and character trigram features. Unlike KRISP, we include features from both inside and outside the substring. Consider the production "Phone_call → Call_my_phone" with span 1-2 from Figure 2. Word unigram features indicate that "call" and "me" are inside the span; the remaining words are outside the span. Word bigram features indicate that "call me" is inside the span, "me if" is on the boundary of the span, and all remaining bigrams are outside the span.

4.4.1 Training

These classifiers are trained in an iterative EM-like manner (Kate and Mooney, 2006). Starting with some initial classifiers and a training set of NL and AST pairs, we search for the most likely derivation. If the AST underlying this derivation matches the gold AST, then this derivation is added

[2] We have a preference for log-linear models given their robustness to hyperparameter settings, ease of optimization, and flexible incorporation of features. An SVM trained with similar features should have similar performance, though.

to the set of positive instances. Otherwise, it is added to the set of negative instances, and the best derivation constrained to match the gold standard AST is found and added to the positive instances. Given this revised training data, the classifiers are retrained. After each pass through the training data, we evaluate the current model on the development set. This procedure is repeated until development-set performance begins to fall.

4.4.2 Inference

To find the most probable derivation according to the grammar, KRISP uses a variation on Earley parsing. This is similar to the inference method from Section 4.3.2, but each item now additionally maintains a position and a span. Inference proceeds left-to-right through the source string. The natural language may present information in a different order than the formal language, so all permutations of rules are considered during inference.

We found this inference procedure to be quite slow for larger data sets, especially because wide beams were needed to prevent search failure. To speed up inference, we used scores from the position-independent classifiers as completion-cost estimates.

The completion-cost estimate for a given symbol is defined recursively. Terminals have a cost of zero. Productions have a completion cost of the log probability of the production given the sentence, plus the completion cost of all non-terminal symbols. The completion cost for a non-terminal is the max cost of any production rooted in that non-terminal. Computing this cost requires traversing all productions in the grammar for each sentence.

Given a partial hypothesis, we use exact scores for the left-corner subtree that has been fully constructed, and completion estimates for all the symbols and productions whose left and right spans are not yet fully instantiated.

5 Experimental Evaluation

Next we evaluate the accuracy of these approaches. The 114,408 recipes described in Section 3 were first cleaned and tokenized. We kept only one recipe per unique description, after mapping to lowercase and normalizing punctuation.[3] Finally the recipes were split by author, randomly assigning each to training, development, or test, to prevent overfitting to the linguistic style of a particular author. Table 1 presents summary statistics for the resulting data.

		Language	**Code**
Train	Recipes	77,495	77,495
	Tokens	527,368	1,776,010
	Vocabulary	58,102	140,871
Dev	Recipes	5,171	5,171
	Tokens	37,541	110,074
	Vocabulary	7,741	14,804
Test	Recipes	4,294	4,294
	Tokens	28,214	94,367
	Vocabulary	6,782	13,969

Table 1: Statistics of the data after cleaning and separating into training, development, and test sets. In each case, the number of recipes, tokens (including punctuation, etc.) and vocabulary size are included.

Although certain trigger-action pairs occur much more often than others, the recipes in this data are quite diverse. The top 10 trigger-action pairs account for 14% of the recipes; the top 100 account for 37%; the top 1000 account for 72%.

5.1 Metrics

To evaluate system performance, several different measures are employed. Ideally a system would output exactly the correct abstract syntax tree. One measure is to count the number of exact matches, though almost all methods receive a score of 0.[4]

Alternatively, we can look at the AST as a set of productions, computing balanced F-measure. This is a much more forgiving measure, giving partial credit for partially correct results, though it has the caveat that all errors are counted equally.

Correctly assigning the trigger and action is the most important, especially because some of the parameter values are tailored for particular users. For example, “turn off my lights when I leave home” requires a “home” location, which varies for each user. Therefore, we also measure accuracy at identifying the correct trigger and action, both at the channel and function level.

5.2 Human comparison

One remaining difficulty is that multiple programs may be equally correct. Some descriptions are very difficult to interpret, even for humans. Second,

[3] We found many recipes with the same description, likely copies of some initial recipe made by different users. We selected one representative using a deterministic heuristic.

[4] Retrieval gets an exact match 3.7% of the time, likely due to near-duplicates from copied recipes.

multiple channels may provide similar functionality: both Phillips Hue and WeMo channels provide the ability to turn on lights. Even a well-authored description may not clarify which channel should be used. Finally, many descriptions are underspecified. For instance, the description "notify me if it rains" does not specify whether the user should receive an Android notification, an iOS notification, an email, or an SMS. This is difficult to capture with an automatic metric.

To address the prevalence and impact of underspecification and ambiguity in descriptions, we asked humans to perform a very similar task. Human annotators on Amazon Mechanical Turk ("turkers") were presented with recipe descriptions and asked to identify the correct channel and function (but not parameters). Turkers received careful instructions and several sample description-recipe pairs, then were asked to specify the best recipe for each input. We requested they try their best to find an action and a trigger even when presented with vague or ambiguous descriptions, but they could tag inputs as 'unintelligible' if they were unable to make an educated guess. Turkers created recipes only for English descriptions, applying the label 'non-English' otherwise. Five recipes were gathered for each description. The resulting recipes are not exactly gold, as they have limited training at the task. However, we imposed stringent qualification requirements to control the annotation quality.[5]

Our workers were in fair agreement with one another and the gold standard, producing high quality annotation at wages calibrated to local minimum wage. We measure turker agreement with Krippendorff's α (Krippendorff, 1980), which is a statistical measure of agreement between any number of coders. Unlike Cohen's κ (Cohen, 1960), the α statistic does not require that coders be the same for each unit of analysis. This property is particularly desirable in our case, since turkers generally differ across HITs. A value of $\alpha = 1$ indicates perfect agreement, while $\alpha \leq 0$ suggests the absence of agreement or systematic disagreement. Agreement measures on the Mechanical Turk data are shown in Table 2. This shows encouraging levels of agreement for both the trigger and the action, especially considering the large number of categories. Krippendorff (1980) advocates a 0.67 cutoff to allow "tentative conclusion" of agreement, and turkers are relatively close to that level for both trigger and action channels. However, it is important to note that the coding scheme used by turkers is not mutually exclusive, as several triggers and actions (e.g., "SMS" vs. "Android SMS" actions) accomplish similar effects. Thus, our levels of agreement are likely to be greater than suggested by measures in the table. Finally, we also measured agreement on the English and intelligible subset of the data, as we found that confusion between the two labels "non-English" and "unintelligible" was relatively high. As shown in the table, this substantially increased levels of agreement, up to the point where α for both trigger and action channels are above the 0.67 cutoff drawing tentative conclusion of agreement.

	Trigger		**Action**	
	C	**C+F**	**C**	**C+F**
# of categories	*128*	*552*	*99*	*229*
all	.592	.492	.596	.532
Intelligible English	.687	.528	.731	.627

Table 2: Annotator agreement as measured by Krippendorff's α coefficient (Krippendorff, 1980). Agreement is measured on either channel (C) or channel and function (C+F), and on either the full test set (4294 recipes) or its English and intelligible subset (2262 recipes).

5.3 Systems and baselines

The **retrieval** method searches for the closest description in the training data based on character string-edit-distance and returns the recipe for that training program. The **phrasal** method uses phrase-based machine translation to generate candidate outputs, searching the resulting n-best candidates for the first well-formed recipe. After exploring multiple word alignment approaches, we found that an unsupervised feature-rich method (Berg-Kirkpatrick et al., 2010) worked best, leveraging features of string similarity between the description and the code. We ran MERT on the development data to tune parameters. We used a phrasal decoder with performance similar to Moses. The **sync**hronous grammar method, a recreation of WASP, uses the same word alignment as above, but extracts a synchronous grammar rules from the parallel data (Wong and Mooney, 2006). The **classifier** approach described in Section 4.3 is independent of word alignment. Finally, the **posclass** approach from Section 4.4 derives its own deriva-

[5] Turkers must have 95% HIT approval rating and be native speakers of English (As an approximation of the latter, we required Turkers be from the U.S.). Manual inspection of annotation on a control set drawn from the training data ensured there was no apparent spam.

tion structure from the data.

The human annotations are used to establish the **mturk** human-performance baseline by taking the majority selection of the trigger and action over 5 HITs for each description and comparing the result to the gold standard. The **oracleturk** human-performance baseline shows how often at least one of the turkers agreed with the gold standard.

In addition, we evaluated all systems on a subset of the test data where at least three human-generated recipes agreed with the gold standard. This subset represents those programs that are easily reproducible by human workers. A good method should strive to achieve 100% accuracy on this set, and we should perhaps not be overly concerned about the remaining examples where humans disagree about the correct interpretation.

5.4 Results and discussion

Table 3 summarizes the main evaluation results. Most of the measures are in concordance.

	Channel	**+Func**	**Prod F1**
(a) All: 4,294 recipes			
retrieval	28.2	19.3	40.8
phrasal	17.3	10.0	34.8
sync	16.2	9.5	34.9
classifier	46.3	33.0	47.3
posclass	**47.4**	**34.5**	**48.0**
mturk	33.4	22.6	–n/a–
oracleturk	48.8	37.8	–n/a–
(b) Omit non-English: 3,741 recipes			
retrieval	28.9	20.2	41.7
phrasal	19.3	11.3	35.3
sync	18.1	10.6	35.1
classifier	48.8	35.2	48.4
posclass	**50.0**	**36.9**	**49.3**
mturk	38.4	26.0	–n/a–
oracleturk	56.0	43.5	–n/a–
(c) Omit non-English & unintelligible: 2,262 recipes			
retrieval	36.8	25.4	49.0
phrasal	27.8	16.4	39.9
sync	26.7	15.5	37.6
classifier	64.8	47.2	56.5
posclass	**67.2**	**50.4**	**57.7**
mturk	59.0	41.5	–n/a–
oracleturk	86.2	59.4	–n/a–
(d) ≥3 turkers agree with gold: 758 recipes			
retrieval	43.3	32.3	56.2
phrasal	37.2	23.5	45.5
sync	36.5	24.1	42.8
classifier	79.3	66.2	65.0
posclass	**81.4**	**71.0**	**66.5**
mturk	100.0	100.0	–n/a–
oracleturk	100.0	100.0	–n/a–

Table 3: Evaluation results. The first column measures how often the channels are selected correctly for both trigger and action (e.g. Android_Phone_Call and Google_Drive in Figure 1). The next column measures how often *both* the channel *and* function are correctly selected for both trigger and action (e.g. Android_Phone_Call::Any_phone_call_missed and Google_Drive::Add_row_to_spreadsheet). The last column shows balanced F-measure against the gold tree over all productions in the proposed derivation, from the root production down to the lowest parameter. We show results on (a) the full test data; (b) omitting descriptions marked as non-English by a majority of the crowdsourced workers; (c) omitting descriptions marked as either non-English or unintelligible by the crowd; and (d) only recipes where at least three of five workers agreed with the gold standard.

Interestingly, retrieval outperforms the phrasal MT baseline. With a sufficiently long phrase limit, phrasal MT approaches retrieval, but with a few crucial differences. First, phrasal requires an exact match of some substring of the input to some substring of the training data, where retrieval can skip over words. Second, the phrases are heavily dependent on word alignment; we find the word alignment techniques struggle with the noisy IFTTT descriptions. Sync performs similarly to phrasal. The underspecified descriptions challenge assumptions in synchronous grammars: much of the target structure is implied rather than stated.

In contrast, the classification method performs quite well. Some productions may be very likely given a prior alone, or may be inferred given other productions and the need for a well-formed derivation. Augmenting this information with positional information as in posclass can help with the attribution problem. Consider the input “Download Facebook Photos you’re tagged in to Dropbox”: we would like the token “Facebook” to invoke only the trigger, not the action. We believe further gains could come from better modeling of the correspondence between derivation and natural language.

We find that semantic parsing systems have accuracy nearly as high or even higher than turkers in certain conditions. There are several reasons for this. First, many of the channels overlap in functionality (Gmail vs. email, or Android SMS vs. SMS); likewise functions may be very closely related (Post a tweet vs. Post a tweet with an image). All the systems with access to thousands of training pairs are at a strong advantage; they can, for

(a)	INPUT	Park in garage when snow tomorrow		
	IFTTT	Weather : Tomorrow's_forecast_calls_for	⟹	SMS : Send_me_an_SMS
	OUTPUT	Weather : Tomorrow's_forecast_calls_for	⟹	SMS : Send_me_an_SMS
(b)	INPUT	Suas fotos do instagr.am salvas no dropbox		
	IFTTT	Instagram : Any_new_photo_by_you	⟹	Dropbox : Add_file_from_URL
	OUTPUT	Instagram : Any_new_photo_by_you	⟹	Dropbox : Add_file_from_URL
(c)	INPUT	Foursquare check-in archive		
	IFTTT	Foursquare : Any_new_check-in	⟹	Evernote : Create_a_note
	OUTPUT	Foursquare : Any_new_check-in	⟹	Google_Drive : Add_row_to_spreadsheet
(d)	INPUT	if i post something on blogger it will post it to wordpress		
	IFTTT	Blogger : Any_new_post	⟹	WordPress : Create_a_post
	OUTPUT	Feed : New_feed_item	⟹	Blogger : Create_a_post
(e)	INPUT	Endless loop!		
	IFTTT	Gmail : New_email_in_inbox_from	⟹	Gmail : Send_an_email
	OUTPUT	SMS : Send_IFTTT_any_SMS	⟹	Philips_hue : Turn_on_color_loop

Table 4: Example output from the posclass system. For each input instance, we show the original query, the recipe originally authored through IFTTT, and our system output. Instance (a) demonstrates a case where the correct program is produced even though the input is rather tricky. Even the Portuguese query of (b) is correctly predicted, though keywords help here. In instance (c), the query is underspecified, and the system predicts that archiving should be done in Google Drive rather than evernote. Instance (d) shows how we sometimes confuse the trigger and action. Certain queries, such as (e), would require very deep inference: the IFTTT recipe sets up an endless email loop, where our system assembles a strange interpretation based on keyword match.

instance, more effectively break such ties by learning a prior over which channels are more likely. Turkers, on the other hand, have neither specific training at this job nor a background corpus and more frequently disagree with the gold standard. Second, there are a number of non-English and unintelligible descriptions. Although the turkers were asked to skip these sentences, the machine-learning systems may still correctly predict the channel and action, since the training set also contains non-English and cryptic descriptions. For the cases where humans agree with each other and with the gold standard, the best automated system (posclass) does fairly well, getting 81% channel and 71% function accuracy.

Table 4 has some sample outputs from the posclass system, showing both examples where the system is effective and where it struggles to find the intended interpretation.

6 Conclusions

The primary goal of this paper is to highlight a new application and dataset for semantic parsing. Although if-this-then-that recipes have a limited structure, many potential recipes are possible. This is a small step toward broad program synthesis from natural language, but is driven by real user data for modern hi-tech applications. To encourage further exploration, we are releasing the URLs of recipes along with turker annotations at http://research.microsoft.com/lang2code/.

The best performing results came from a loosely synchronous approach. We believe this is a very promising direction: most work inspired by parsing or machine translation has assumed a strong connection between the description and the operable semantic representation. In practical situations, however, many elements of the semantic representation may only be implied by the description, rather than explicitly stated. As we tackle domains with greater complexity, identifying implied but necessary information will be even more important.

Underspecified descriptions open up new interface possibilities as well. This paper considered only single-turn interactions, where the user describes a request and the system responds with an interpretation. An important next step would be to engage the user in an interactive dialogue to confirm and refine the user's intent and develop a fully-functional correct program.

Abstract

We develop an approach for generating deep (i.e, high-level) comprehension questions from novel text that bypasses the myriad challenges of creating a full semantic representation. We do this by decomposing the task into an *ontology-crowd-relevance* workflow, consisting of first representing the original text in a low-dimensional ontology, then crowdsourcing candidate question templates aligned with that space, and finally ranking potentially relevant templates for a novel region of text. If ontological labels are not available, we infer them from the text. We demonstrate the effectiveness of this method on a corpus of articles from Wikipedia alongside human judgments, and find that we can generate relevant deep questions with a precision of over 85% while maintaining a recall of 70%.

1 Introduction

Questions are a fundamental tool for teachers in assessing the understanding of their students. Writing good questions, though, is hard work, and harder still when the questions need to be deep (i.e., high-level) rather than factoid-oriented. These deep questions are the sort of open-ended queries that require deep thinking and recall rather than a rote response, that span significant amounts of content rather than a single sentence. Unsurprisingly, it is these deep questions that have the greatest educational value (Anderson, 1975; Andre, 1979; McMillan, 2001). They are thus a key assessment mechanism for a spectrum of online educational options, from MOOCs to interactive tutoring systems. As such, the problem of automatic question generation has long been of interest to the online education community (Mitkov and Ha, 2003; Schwartz, 2004), both as a means of providing self-assessments directly to students and as a tool to help teachers with question authoring. Much work to date has focused on questions based on a single sentence of the text (Becker et al., 2012; Lindberg et al., 2013; Mazidi and Nielsen, 2014), and the ideal of creating deep, conceptual questions has remained elusive. In this work, we hope to take a significant step towards this challenge by approaching the problem in a somewhat unconventional way.

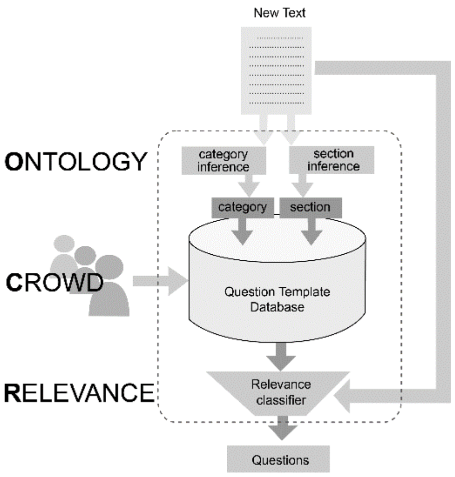

Figure 1: Overview of our ontology-crowd-relevance approach.

While one might expect the natural path to generating deep questions to involve first extracting a semantic representation of the entire text, the state-of-the-art in this area is at too early a stage to achieve such a representation effectively. Rather we take a step back from full understanding, and instead propose an *ontology-crowd-relevance* workflow for generating high-level questions, shown in Figure 1. This involves 1) decomposing a text into a meaningful, intermediate, low-dimensional *ontology*, 2) soliciting high-level templates from the *crowd*, aligned with this intermediate representation, and 3) for a target text segment, retrieving a subset of the collected templates based

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 889–898,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

on its ontological categories and then ranking these questions by estimating the relevance of each to the text at hand.

In this work, we apply the proposed workflow to the Wikipedia corpus. For our ontology, we use a Cartesian product of article categories (derived from Freebase) and article section names (directly from Wikipedia) as the intermediate representation (e.g. category: *Person*, section: *Early life*), henceforth referred to as *category-section pairs*. We use these pairs to prompt our crowd workers to create relevant templates; for instance, (*Person, Early Life)* might lead a worker to generate the question "Who were the key influences on <*Person*> in their childhood?", a good example of the sort of deep question that can't be answered from a single sentence in the article. We also develop classifiers for inferring these categories when explicit or matching labels are not available. Given a database of such *category-section*-specific question templates, we then train a binary classifier that can estimate the relevance of each to a new document. We hypothesize that the resulting ranked questions will be both high-level and relevant, without requiring full machine understanding of the text – in other words, deep questions without deep understanding.

In the sections that follow, we detail the various components of this method and describe the experiments showing their efficacy at generating high-quality questions. We begin by motivating our choice of ontology and demonstrating its coverage properties (Section 3). We then describe our crowdsourcing methodology for soliciting questions and question-article relevance judgments (Section 4), and outline our model for determining the relevance of these questions to new text (Section 5). After this we describe the two datasets that we construct for the evaluation of our approach and present quantitative results (Section 6) as well as examples of our output and an error analysis (Section 7) before concluding (Section 8).

2 Related Work

We consider three aspects of past research in automatic question generation: work that focuses on the grammaticality of natural language question generation, work that focuses on the semantic quality of generated questions, i.e. the "what to ask about" rather than "how to ask it," and finally work that builds a semantic representation of text in order to generate higher-level questions.

Approaches focusing on the grammaticality of question generation date back to the AUTOQUEST system (Wolfe, 1976), which examined the generation of Wh-questions from single sentences. Later systems addressing the same goal include methods that use transformation rules (Mitkov and Ha, 2003), template-based generation (Chen et al., 2009; Curto et al., 2011) and overgenerate-and-rank methods (Heilman and Smith, 2010a). Another approach has been to create fill-in-the-blank questions from single sentences to ensure grammaticality (Agarwal et al. 2011, Becker et al. 2012).

More relevant to our direction is work on the semantic aspect of question generation, which has become a more active research area in the past several years. Several authors (Mazidi and Nielsen 2014; Linberg et al. 2013) generate questions according to the semantic role patterns extracted from the source sentence. Becker et al. (2012) also leverage semantic role labeling within a sentence in a supervised setting. We hope to continue in this direction of semantic focus, but extend the capabilities of question generation to include open-ended questions that go far beyond the scope of a single sentence.

Other work has taken on the challenge of deeper questions by attempting to build a semantic representation of arbitrary text. This has included work using concept maps over keywords (Olney et al. 2012) and minimal recursion semantics (Yao 2010) to reason over concepts in the text. While the work of (Olney et al. 2012) is impressive in its possibilities, the range of the types of questions that can be generated is restricted by a relatively specific set of relations (e.g. Is-A, Part-Of) captured in the ontology of the domain (biology textbook). Mannem et al. (2010) observe as we have that "capturing the exact true meaning of a paragraph is beyond the reach of current NLP systems;" thus, in their system for Shared Task A (for paragraph-level questions (Rus et al. 2010)) they make use of predicate argument structures along with semantic role labeling. However, the generation of these questions is restricted to the first sentence of the paragraph. Though motivated by the same noble impulses of these authors to achieve higher-level questions, our hope is that we can bypass the challenges and constraints of semantic parsing and generate deep questions via a more holistic approach.

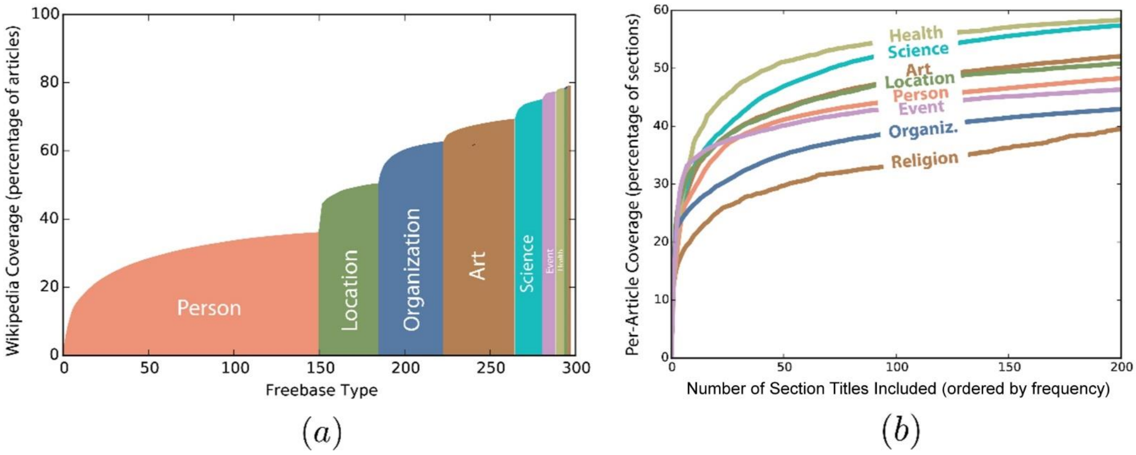

Figure 2: Coverage properties of our *category-section* representation: (a) fraction of Wikipedia articles covered by the top *j* most common Freebase types, grouped by our eight higher-level categories. (b) Average fraction of sections covered per document if only the top *k* most frequent sections are used; each line represents one of our eight categories.

3 An Ontology of Categories and Sections

The key insight of our approach is that we can leverage an easily interpretable (for crowd workers), low-dimensional ontology for text segments in order to crowdsource a set of high-level, reusable templates that generalize well to many documents. The choice of this representation must strike a balance between domain coverage and the crowdsourcing effort required to obtain that coverage. Inasmuch as Wikipedia is deemed to have broad coverage of human knowledge, we can estimate domain coverage by measuring what fraction of that corpus is covered by the proposed representation. In our work, we have developed a *category-section* ontology using annotations from Freebase and Wikipedia (English), and now describe its structure and coverage in detail.

For the high-level *categories*, we make use of the Freebase "notable type" for each Wikipedia article. In contrast to the noisy default Wikipedia categories, the Freebase "notable types" provide a clean high-level encapsulation of the topic or entity discussed in a Wikipedia article. As we wish to maximize coverage, we compute the histogram by type and take the 300 most common ones across Wikipedia. We further merge these into eight broad categories to reduce crowdsourcing effort: *Person, Location, Event, Organization, Art, Science, Health,* and *Religion*. These eight categories cover 78% of Wikipedia articles (see Figure 2a); the mapping between Freebase types and our categories will be made available as part of our corpus (see Section 8).

To achieve greater specificity of questions within the articles, we make use of Wikipedia *sections*, which offer a high-level segmentation of the content. The Cartesian product of our *categories* from above and the most common Wikipedia *section* titles (per category) then yield an interpretable, low-dimensional representation of the article. For instance, the set of *category-section* pairs for an article about *Albert Einstein* contains (*Person, Early_life*), (*Person, Awards*), and (*Person, Political_views*) as well as several others.

For each category, the section titles that occur most frequently represent central themes in articles belonging to that category. We therefore hypothesize that question templates authored for such high-coverage titles are likely to generalize to a large number of articles in that category. Table 1 below shows the four most frequent sections for each of our eight categories.

Person	**Location**	**Organization**	**Art**
Early life	History	History	Plot
Career	Geography	Geography	Reception
Pers. life	Economy	Academics	History
Biography	Demographics	Demographics	Production
Science	**Event**	**Health**	**Religion**
Descript.	Background	Treatment	Etymology
Taxonomy	Aftermath	Diagnosis	Icongraphy
History	Battle	Causes	Worship
Distributn.	Prelude	History	Mythology

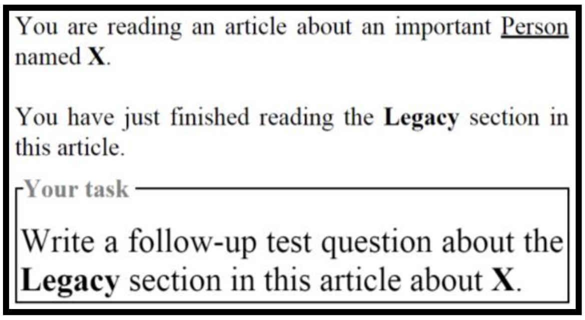
Table 1: Most frequent section titles by category.

As the crowdsourcing effort is directly proportional to the size of the ontology, our goal is to select the smallest set of pairs that will provide sufficient coverage. As with *categories*, the cutoff for the number of *sections* used for each *category* is guided by the trade-off between coverage and crowdsourcing costs. Figure 2b plots the average fraction of an article covered by the top *k* sections from each category. We found that the top 50 sections cover 30% to 55% of the sections of an individual article (on average) across our categories. This implies that by only crowdsourcing question templates for those 50 sections per category, we would be able to ask questions about a third to a half of the sections of any article.

Of course, if we were to limit ourselves to only segments with these labels at runtime, we would completely miss many articles as well as texts outside of Wikipedia. To extend our reach, we also develop the means for category and section *inference* from raw text in Section 5 below, for cases in which ontological labels are either not available or are not contained within our limited set.

4 Crowdsourcing Methodology

We designed a two-stage crowdsourcing pipeline to 1) collect templates targeted to a set of *category-section* pairs and 2) obtain binary relevance judgments for the generated templates in relation to a set of article *segments* (for Wikipedia, these are simply sections) that match in *category-section* labels. We recruit Mechanical Turk workers for both stages of the pipeline, filtering for workers from the United States due to native English proficiency. A total of 307 unique workers participated in the two tasks combined (78 and 229 workers for the generation and ratings tasks respectively).



You are reading an article about an important Person named **X**.

You have just finished reading the **Legacy** section in this article.

Your task

Write a follow-up test question about the **Legacy** section in this article about **X**.

Figure 3: Prompt for the generation task for the *category-section* pair (*Person, Legacy).*

4.1 Question generation task

Following the coverage analysis above, we select the 50 most frequent sections for the top two categories, *Person* and *Location*, yielding 100 *category-section* pairs. As these two *categories* cover nearly 50% of all articles on Wikipedia, we believe that they suffice in demonstrating the effectiveness of the proposed methodology. For each *category-section* pair, we instructed 10 (median) workers to generate a question regarding a hypothetical entity belonging to the target with the prompt in Figure 3. Additional instructions and an interactive tutorial were pre-administered, guiding the workers to formulate appropriately deep questions, i.e. questions that are likely to generalize to many articles, while avoiding factoid questions like “When was X born?”

In total, 995 question templates were added to our question database using this methodology (only 0.5% of all generated questions were exact repeats of existing questions). We confirm in section 4.2 that workers were able to formulate deep, interesting and relevant questions whose answers spanned more than a single sentence and that generalized to many articles using this prompt.

In earlier pilots, we tried an alternative prompt which also presented the text of a specific article segment. In Figure 4, we show the average scope and relevance of questions generated by workers under both prompt conditions. As the figure demonstrates, the alternative prompt showing specific article text resulted in questions that generalized less well (workers’ questions were found to be relevant to fewer articles), likely because the details in the text distracted the workers from thinking broadly about the domain. These questions also had a smaller scope on average, i.e., answers to these questions were contained in shorter spans in the text. The differences in scope and relevance between the two prompt designs were both significant (p-values: 0.006 and 4.5e-11 respectively, via two-sided Welch’s *t*-tests).

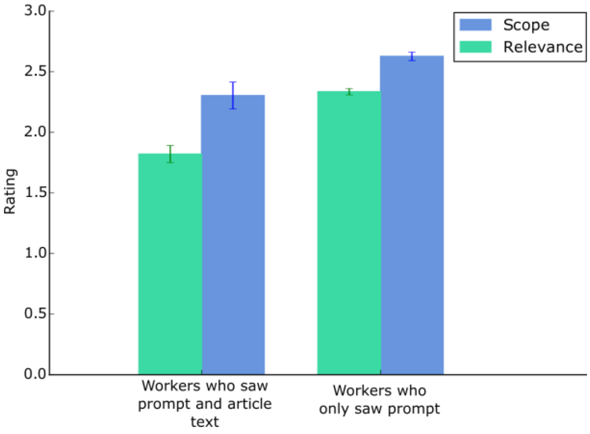


Figure 4: Average relevance and scope of worker-generated questions versus how the workers were prompted.

4.2 Question relevance rating task

For our 100 *category-section* pairs, 4 (median) article segments within reasonable length for a Mechanical Turk task (200-1000 tokens) were drawn at random from the Wikipedia corpus; this resulted in a set of 513 article segments. Each worker was then presented with one of these segments alongside at most 10 questions from the question template database matching in *category-section*; templates were converted into questions by filling in the article-specific entity extracted from the title. Workers were requested to rate each question along three dimensions: *relevance, quality,* and *scope,* as detailed below. Quality and scope ratings were only requested when the worker determined the question to be relevant.

- **Relevance:** *1 (not relevant) – 4 (relevant)*
  Does the article answer the question?
- **Quality:** *1 (poor) – 4 (excellent)*
  Is this question well-written?
- **Scope:** *1 (single-sentence) – 4 (multi-sentence/paragraph)*
  How long is the answer to this question?

A median of 3 raters provided an independent judgment for each question-article pair. The mean relevance, quality and scope ratings across the 995 questions were 2.3 (sd=0.83), 3.5 (sd=.65) and 2.6 (sd=1.0) respectively. Note that the sample sizes for scope and quality were smaller, 774 and 778 respectively, as quality/scope judgments were not gathered for questions deemed irrelevant. We note that 80% of the relevant crowd-sourced questions had a median scope rating larger than 1 sentence, and 23% had a median scope rating of 4, defined as “the answer to this question can be found in many sentences and paragraphs,” corresponding to the maximum attainable scope rating. Note that while in this work, we have only used the scope judgments to report summary statistics about the generated questions, in future work these ratings could be used to build a scope classifier to filter out questions targeting short spans of text.

As described in Section 5.2, the relevance judgments are converted to binary relevance ratings for training the relevance classifier (we consider relevance ratings {1, 2} as “not relevant” and {3, 4} as “relevant”). In terms of agreement between raters for these binary relevance labels, we obtained a Fleiss’ Kappa of 0.33, indicating fair agreement.

5 Model

There are two key models to our system: the first is for category and section inference of a novel article segment, which allows us to infer the keys to our question database when explicit labels are not available. The second is for question relevance prediction, which lets us decide which question templates from the database’s store for that *category-section* actually apply to the text at hand.

5.1 Category/section inference

Both category and section inference were cast as standard text-classification problems. *Category* inference is performed on the whole article, while *section* inference is performed on the individual article segments (i.e., sections). We trained individual logistic regression classifiers for the eight categories and the 50 top section types for each one (a total of 400) using the default L2 regularization parameter in LIBLINEAR (Fan, 2008). For section inference, a total of 736,947 article segments were sampled from Wikipedia (June 2014 snapshot), each belonging to one of the 400 section types and within the same length bounds from Section 4.2 (200-1000 tokens). For category inference, we sampled a total of 86,348 articles with at least 10 sentences and belonging to one of our eight categories.

In both cases, a binary dataset was constructed for a one-against-all evaluation, where the negative instances were sampled randomly from the negative categories or sections (there was an average 17% and 32% positive skew in the section and category datasets, respectively). Basic tf-idf features (using a vocabulary of 200,000 after eliminating stopwords) were used in both text classification tasks. Applying the category/section inference to held-out portions of the dataset (30% for each category/section) resulted in balanced accuracies of 83%/95% respectively, which gave us confidence in the inference. Keep in mind that this is not a strict bound on our question generation performance, since the inferred category/section, while not matching the label perfectly, could still be sufficiently close to produce relevant questions (for instance, we could misrecognize “Childhood” as “Early Life”). We explore the ramifications of this in our end-to-end experiments in Section 6.

5.2 Relevance Classification

We also cast the problem of question/article relevance prediction as one of binary classification, where we map a question-article pair to a relevance score; as such our features had to combine aspects of both the question and the article. Our core approach was to use a vector of the component-wise Euclidean distances between individual features of the question and article segment, i.e., the i^{th} feature vector component f_i is given by $f_i = (q_i - a_i)^2$, where q_i and a_i are the components of the question and article feature vectors. For the feature representation, we utilized a concatenation of continuous embedding features: 300 features from a Word2Vec embedding (Mikolov, 2013) and 200,000 tfidf features (as with category/section classification above).

As question templates are typically short, though, we found that this representation alone performed poorly. As a result, we augmented the vector by concatenating additional distance features between the target article segment and one specific instance of an entire article for which the question applied. This augmenting article was selected at random from all those for which the template was judged to be relevant. The resulting feature vector was thus doubled in length, where the first k distances were between the question template and the target segment, and the next k were between the augmenting article and the target segment. Note that the augmenting article segments were removed from the training/test sets.

To train this classifier, we assumed that we would be able to acquire at least n positive relevance labels for each question template, i.e., n article segments judged to be relevant to each template for inclusion in the training set. We explore the effect of increasing values of n, from 0 (where no relevance labels are available) to 3 (referred to as conditions T0..T3 in Figure 5). We then trained and evaluated the relevance classifier, a single logistic regression model using LIBLINEAR with default L2 regularization, using 10-fold cross-validation on DATASET I (see Section 6).

Figure 5 depicts a series of ROC curves summarizing the performance of our template relevance classifier on unseen article segments. As expected, we see increasing performance with increasing n. However, the benefit drops off after 3 instances (i.e., T4 is only marginally better than T3). While the character of the curves is modest, keep in mind we are already filtering questions by retrieving them from the database for the inferred category-section (which by itself gives us a precision of .74 – see green bars in Figure 6); this ROC represents the "lift" achieved by further filtering the questions with our relevance classifier, resulting in far higher precision (.85 to .95 – see blue bars in Figure 6).

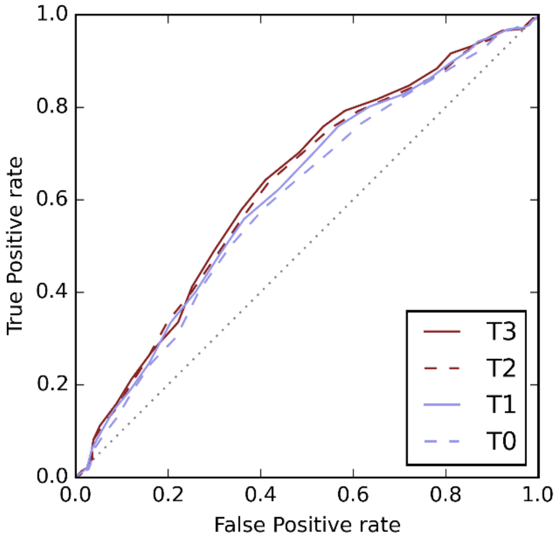

Figure 5: ROC curves for the task of question-to-article relevance prediction. Tn means that n positively labeled article segments were available for each question template during training.

6 Experiments and Results

In this section, we describe the datasets used for training the relevance classifier in Section 5.2 (DATASET I) as well as for end-to-end performance on unlabeled text segments (DATASET II). We then evaluate the performance on this second dataset under three settings: first, when the category and section are known, second, when those labels are unavailable, and third, when neither the labels nor the relevance classifier are available.

6.1 DATASET I: for the Relevance Classifier

The first dataset (DATASET I) was intended for training and evaluating the relevance classifier, and for this we assumed the category and section labels were known. As such, judgments were collected only for questions templates authored for a given article's actual category and section labels. After filtering out annotations from unreliable workers (based on their pre-test results) as well as those with inter-annotator agreement below 60%, we were left with a set of 995 rated questions, spanning across two categories (*Person* and *Location*) and 50 sections per category (100 *category-section* pairs total). This corresponded to a total of 4439 relevance tuples (*label*, *question*, *article*) where *label* is a binary relevance rating aggregated via majority vote across multiple raters. The relevance labels were skewed towards the positive (relevant) class with 63% relevant instances.

This is of course a mostly unrealistic data setting for applications of question generation (known category and section labels), but greatly useful in developing and evaluating the relevance classifier; we thus used this dataset only for that purpose (see Section 5.2 and Figure 5).

6.2 DATASET II: for End-to-End Evaluation

For an end-to-end evaluation we need to examine situations where the category and section labels are not available and we must rely on inference instead. As this is the more typical use case for our method, it is critical to understand how the performance will be affected. For DATASET II, then, we first sampled articles from the Wikipedia corpus at random (satisfying the constraints described in Section 3) and then performed category and section inference on the article segments. The category c with the highest posterior probability was chosen as the inferred category, while all section types s_i with a posterior probability greater than 0.6 were considered as sources for templates. Only articles whose inferred category was *Person* or *Location* were considered, but given the noise in inference there was no guarantee that the true labels were of these categories. We continued this process until we retrieved a total of 12 articles. For each article segment in these 12, we drew a random subset of at most 20 question templates from our database matching the inferred category and section(s), then ordered them by their estimated relevance for presentation to judges.

We then solicited an additional 62 Mechanical Turk workers to a rating task set up according to the same protocol as for DATASET I. After aggregation and filtering in the same way, the second dataset contained a total 256 (*label, question, article)* relevance tuples, skewed towards the positive class with 72% relevant instances.

6.3 Information Retrieval–based Evaluation

As our end-to-end task is framed as the retrieval of a set of relevant questions for a given article segment, we can measure performance in terms of an information retrieval-based metric. Consider a user who supplies an article segment (the "query" in IR terms) for which she wants to generate a quiz: the system then presents a ranked list of retrieved questions, ordered according to their estimated relevance to the article. As she makes her way down this ranked list of questions, adding a question at a time to the quiz (set Q), the behavior of the precision and recall (with respect to relevance to the article segment) of the questions in Q, summarizes the performance of the retrieval system (i.e. the Precision-Recall (PR) curve (Manning, 2008)). We summarize the performance of our system by averaging the individual article segments' PR curves (linearly interpolated) from DATASET II, and present the average precision over bins of recall values in Figure 6. We consider the following experimental conditions:

- **Known category/section, using relevance classifier (red):** This is the case in which the actual category and section labels of the query article are known, and only the questions that match exactly in category and section are considered for relevance classification (i.e. added to Q if found relevant by the classifier). Recall is computed with respect to the total number of relevant questions in DATASET II, including those corresponding to sections different from the section label of the article.
- **Inferred category/section, using relevance classifier (blue):** This is the expected use case, where the category/section labels are not known. Questions matching in category and section(s) to the inferred category and section of each article are considered and ranked in Q by their score from the relevance classifier. Recall is computed with respect to the total number of relevant questions in DATASET II.
- **Inferred category/section, ignoring relevance classifier (green):** This is a baseline where we only use category/section inference and then retrieve questions from the database without filtering: all questions that match in inferred category and section(s) of the article are added to Q in a random ranking order, without performing relevance classification.

As we examine Figure 6, it is important to point out a subtlety in our choice to calculate recall of the **known category/section** condition (red bars) with respect to the set of *all* relevant questions, including those that are matched to sections different from the original (labeled) sections. While this condition by construction does not have access to questions of any other section, the resulting limitation in recall underlines the importance of performing section inference: without inference, we achieve a recall of no greater than 0.4.

As we had hypothesized, while the labels of the sections play an instrumental role in instructing the crowd to generate relevant questions, the resulting questions often tend to be relevant to content found under different but semantically related sections as well. Leveraging the available questions of these related sections (by performing inference) boosts recall at the expense of only a small degree of precision (blue bars). If we forgo relevance classification entirely, we get a constant precision of 0.74 (green bars) as mentioned in

Section 5.2; it is clear that the relevance classifier results in a significant advantage.

While there is a slight drop in precision when using inference, this is at least partly due to the constraints that were imposed during data-collection and relevance classifier training, i.e., all pairs of articles and questions belonged to the same category and section. While this constraint made the crowdsourcing methodology proposed in this work tractable, it also prevented the inclusion of training examples for sections that could potentially be inferred at test time. One possible approach to remedy this would be sample from article segments that are similar in text (in terms of our distance metric) as opposed to only segments exactly matching in category and section.

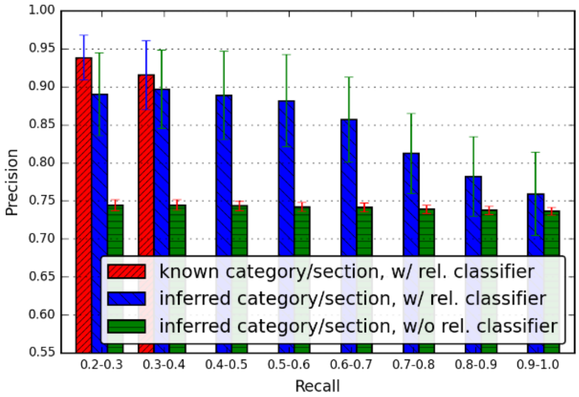

Figure 6: Precision-recall results for the end-to-end experiment, grouped in bins of recall ranges.

7 Examples and Error Analysis

In Table 2 we show a set of sample retrieved questions and the corresponding correctness of the relevance classifier's decision with respect to the judgment labels; examining the errors yields some interesting insights. Consider the false positive example shown in row 8, where the category correctly inferred as *Location*, but section title was inferred as *Transportation* instead of *Services*. This mismatch resulted in the following template authored for (*Location*, *Transportation*) being retrieved: "*What geographic factors influence the preferred transport methods in <entity>?"* To the relevance classifier, this particular template (containing the word "transport") appears to be relevant on the surface level to the text of an article segment about schedules (*Services)* at a railway station. However, as this template never appeared to judges in the context of a *Services* segment – a section that differs considerably in theme from the inferred section (*Transportation)* – the relevance classifier unsurprisingly makes the wrong call.

True section	Inferred section	Result	Generated Question
Honours	Later Life	TP	What accomplishments characterized the later career of Colin Cowdrey?
Acting Career	Television	TP	How did Corbin Bernstein's television career evolve over time?
Route Description	Geography	TP	What are some unique geographic features of Puerto Rico Highway 10?
Athletics	Athletics	TN	How much significance do people of DeMartha Catholic High School place on athletics?
Route Description	Geography	TN	How does the geography of Puerto Rico Highway 10 impact its resources?
Work	Reception	FN	What type of reaction did Thornton Dial receive?
Acting Career	Later Career	FP	What were the most important events in the later career of Corbin Berstein?
Services	Transportation	FP	What geographic factors influence the preferred transport methods in Weymouth Railway Station?
Later Career	Legacy	FP	How has Freddy Mitchell's legacy shaped current events?

Table 2: Examples of retrieved questions. TP, TN, FP, FN stand for true/false positive/negative with respect to the relevance classification.

In considering additional sources of relevance classification errors, recall that we employ a single relevant article segment for the purpose of augmenting a template's feature representation. In the case of the false negative example (row 6 in Table 2), the sensitivity of the classifier to the particular augmenting article used is apparent. Upon inspecting the target article segment (article: *Thornton Dial*, section: *Work*), and the augmenting article segment (article: *Syed Masood*, section: *Reception*), it's clear that the inferred section *Reception* is a reasonable title for the *Work* section of the article on *Thornton Dial*, making the question "What type of reaction did Thornton Dial receive?" a relevant question to the target article (as reflected in the human judgment). However, although both segments generally talk about "reception," the language across the two segments is distinct: the critical reception of Thornton Dial the visual artist is described in a different way from the reception of Syed Masood the actor, resulting in little overlap in surface text, and as a result the relevance classifier falsely rejects the question.

Reasonable substitutions for inferred sections can also lead to false positives, as in row 9, for the article *Freddy Mitchell*. In this case, while *Legacy* (the inferred section) is a believable substitute for the true label of *Later Career*, in this case the article segment did not discuss his legacy. However, there was a good match between the augmenting article for this template and the section. We hypothesize that in both this and the previous examples a broader sample of augmenting article segments for each category/section is likely to be effective at mitigating these types of errors.

8 Conclusion

We have presented an approach for generating relevant, deep questions that are broad in scope and apply to a wide range of documents, all without constructing a detailed semantic representation of the text. Our three primary contributions are 1) our insight that a low-dimensional ontological document representation can be used as an intermediary for retrieving and generalizing high-level question templates to new documents, 2) an efficient crowdsourcing scheme for soliciting such templates and relevance judgments (of templates to article) from the crowd in order to train a relevance classification model, and 3) using category/section inference and relevance prediction to retrieve and rank relevant deep questions for new text segments. Note that the approach and workflow presented here constitute a general framework that could potentially be useful in other language generation applications. For example, a similar setup could be used for high-level summarization, where question templates would be replaced with "summary snippets."

Finally, to encourage the community to further explore this approach as well as to compare it with others, we are releasing all of our data (category mappings, generated templates, and relevance judgments) at http://research.microsoft.com/~sumitb/questiongeneration .

Abstract

This paper presents the NL2KR platform to build systems that can translate text to different formal languages. It is freely-available[1], customizable, and comes with an Interactive GUI support that is useful in the development of a translation system. Our key contribution is a user-friendly system based on an interactive multistage learning algorithm. This effective algorithm employs Inverse-λ, Generalization and user provided dictionary to learn new meanings of words from sentences and their representations. Using the learned meanings, and the Generalization approach, it is able to translate new sentences. NL2KR is evaluated on two standard corpora, Jobs and GeoQuery and it exhibits state-of-the-art performance on both of them.

1 Introduction and Related Work

For natural language interaction with systems one needs to translate natural language text to the input language of that system. Since different systems (such as a robot or database system) may have different input language, we need a way to translate natural language to different formal languages as needed by the application. We have developed a user friendly platform, NL2KR, that takes examples of sentences and their translations (in a desired target language that varies with the application), and some bootstrap information (an initial lexicon), and constructs a translation system from text to that desired target language.

Our approach to translate natural language text to formal representation is inspired by Montague's work (Montague, 1974) where the meanings of words and phrases are expressed as λ-calculus expressions and the meaning of a sentence is built from semantics of constituent words through appropriate λ-calculus (Church, 1936) applications. A major challenge in using this approach has been the difficulty of coming up with the λ-calculus representation of words.

Montague's approach has been widely used in (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010) to translate natural language to formal languages. In ZC05 (Zettlemoyer and Collins, 2005) the learning algorithm requires the user to provide the semantic templates for all words. A semantic template is a λ-expression (e.g. $\lambda x.p(x)$ for an arity one predicate), which describes a particular pattern of representation in that formal language. With all these possible templates, the learning algorithm extracts the semantic representation of the words from the formal representation of a sentence. It then associates the extracted meanings to the words of the sentence in all possible ways and ranks the associations according to some goodness measure. While manually coming up with semantic templates for one target language is perhaps reasonable, manually doing it for different target languages corresponding to different applications may not be a good idea as manual creation of semantic templates requires deep understanding of translation to the target language. This calls for automating this process. In UBL (Kwiatkowski et al., 2010) this process is automated by restricting the choices of formal representation and learning the meanings in a brute force manner. Given, a sentence S and its representation M in the restricted formal language,

it breaks the sentence into two smaller substrings $S1, S2$ and uses higher-order unification to compute two λ-terms $M1, M2$ which combines to produce M. It then recursively learns the meanings of the words, from the sub-instance $< S1, M1 >$ and $< S2, M2 >$. Since, there are many ways to split the input sentence S and the choice of $M1, M2$ can be numerous, it needs to consider all possible splittings and their combinations; which produces many spurious meanings. Most importantly, their higher-order unification algorithm imposes various restrictions (such as limited number of conjunctions in a sentence, limited forms of functional application) on the meaning representation language which severely limits its applicability to new applications. Another common drawback of these two algorithms is that they both suffer when the test sentence contains words that are not part of the training corpus.

Our platform NL2KR uses a different automated approach based on Inverse-λ (section 2.1) and Generalization (section 2.2) which does not impose such restrictions enforced by their higher-order unification algorithm. Also, Generalization algorithm along with Combinatory Categorical Grammar (Steedman, 2000) parser, allows NL2KR to go beyond the training dictionary and translate sentences which contain previously unseen words. The main aspect of our approach is as follows: given a sentence, its semantic representation and an initial dictionary containing the meaning of some words, NL2KR first obtains several derivation of the input sentence in Combinatory Categorical Grammar (CCG). Each CCG derivation tree describes the rules of functional application through which constituents combine with each other. With the user provided initial dictionary, NL2KR then traverses the tree in a bottom-up fashion to compute the semantic expressions of intermediate nodes. It then traverses the augmented tree in a top-down manner to learn the meaning of missing words using Inverse-λ (section 2.1). If Inverse-λ is not sufficient to learn the meaning of all unknown words, it employs Generalization (section 2.2) to guess the meanings of unknown words with the meaning of known similar words. It then restarts the learning process with the updated knowledge. The learning process stops if it learns the meanings of all words or fails to learn any new meaning in an iteration. In the latter case, it shows the augmented tree to the user. The user can then provide meanings of some unknown words and resumes the learning process.

Another distinguishing feature of NL2KR is its user-friendly interface that helps users in creating their own translation system. The closest system to NL2KR is the UW Semantic Parsing Framework (UW SPF) (Artzi and Zettlemoyer, 2013) which incorporates the algorithms in (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010) . However, to use UW SPF for the development of a new system, the user needs to learn their coding guidelines and needs to write new code in their system. NL2KR does not require the users to write new code and guides the development process with its rich user interface.

We have evaluated NL2KR on two standard datasets: GeoQuery (Tang and Mooney, 2001) and Jobs (Tang and Mooney, 2001). GeoQuery is a database of geographical questions and Jobs contains sentences with job related query. Experiments demonstrate that NL2KR can exhibit state-of-the-art performance with fairly small initial dictionary. The rest of the paper is organized as follows: we first present the algorithms and architecture of the NL2KR platform in section 2; we discuss about the experiments in section 3; and finally, we conclude in section 4.

2 Algorithms and Architecture

The NL2KR architecture (Figure 1) has two subparts which depend on each other (1) NL2KR-L for learning and (2) NL2KR-T for translation. The NL2KR-L sub-part takes the following as input: (1) a set of training sentences and their target formal representations, and (2) an initial lexicon or dictionary consisting of some words, their CCG categories, and their meanings in terms of λ-calculus expressions. It then constructs the CCG parse trees and uses them for learning of word meanings.

Learning of word meanings is done by using Inverse-λ and Generalization (Baral et al., 2012; Baral et al., 2011) and ambiguity is addressed by a Parameter Learning module that learns the weights of the meanings. The learned meanings update the lexicon. The translation sub-part uses this updated lexicon to get the meaning of all the words in a new sentence, and combines them to get the meaning of the new sentence. Details of each module will be presented in the following subsections.

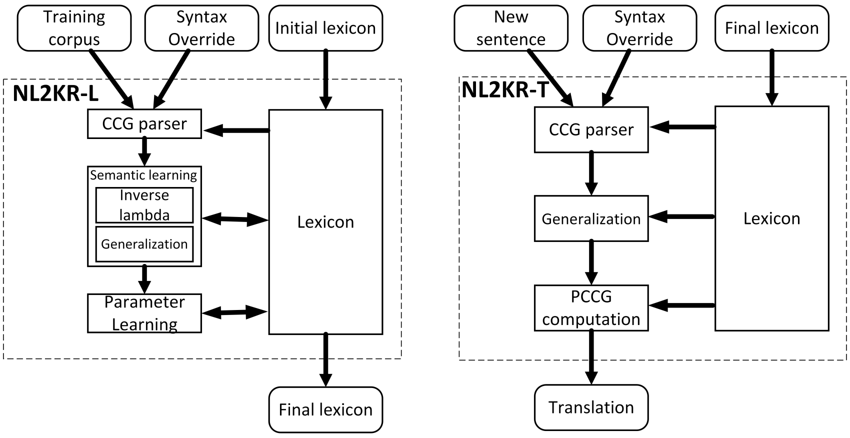

Figure 1: Architecture of NL2KR

The NL2KR platform provides a GUI (Figure 2) with six features: λ-application, Inverse-λ, Generalization, CCG-Parser, NL2KR-L and NL2KR-T. The fourth feature is a stand-alone CCG parser and the first four features can help on user with constructing the initial lexicon. The user can then use NL2KR-L to update the lexicon using training data and the NL2KR-T button then works as a translation system.

2.1 Inverse-λ

Inverse-λ plays a key role in the learning process. Formally, given two λ-expressions H and G with $H = F@G$ or $H = G@F$, the Inverse-λ operation computes the λ expression F. For example, given the meaning of "is texas" as $\lambda x2.x2@stateid(texas)$ and the meaning of "texas" as $stateid(texas)$, with the additional information that "is" acts as the function while "texas" is the argument, the Inverse-λ algorithm computes the meaning of "is" as $\lambda x3.\lambda x2.x2@x3$ (Figure 4). NL2KR implements the Inverse-λ algorithm specified in (Baral et al., 2012). The Inverse-λ module is separately accessible through the main GUI (Figure 2).

2.2 Generalization

Generalization (Baral et al., 2012; Baral et al., 2011) is used when Inverse-λ is not sufficient to learn new semantic representation of words. In contrast to Inverse-λ which learns the exact meaning of a word in a particular context, Generalization learns the meanings of a word from similar words with existing representations. Thus, Generalization helps NL2KR to learn meanings of words that are not even present in the training data set. In the current implementation, two words are considered as similar if they have the exact same CCG category. As an example, if we want to generalize the meaning of the word "plays" with CCG category $(S\backslash NP)/NP)$ and the lexicon already contains an entry for "eats" with the same CCG category, and the meaning $\lambda y.\lambda x.eats(x, y)$, the algorithm will extract the template $\lambda y.\lambda x.WORD(x, y)$ and apply the template to $plays$ to get the meaning $\lambda y.\lambda x.plays(x, y)$.

2.3 Combinatory Categorial Grammar

Derivation of a sentence in Combinatory Categorial Grammar (CCG) determines the way the constituents combine together to establish the meaning of the whole. CCG is a type of phrase structure grammar and clearly describes the predicate-argument structure of constituents.

Figure 3 shows an example output of NL2KR's CCG parser. In the figure, "John" and "home" have the category [N] (means noun) and can change to [NP] (means noun phrase). The phrase"walk home" has the category [S\NP], which means that it can combine with a constituent with category [NP] ("John" in this case) from left with the *backward application* to form category [S] (sentence). The word "walk" has the category [(S\NP)/NP], which means it can combine with a constituent with category [NP] ("home") from right through the *forward application* combinator to form category [S\NP] (of "walk home").

A detailed description on CCG goes beyond the scope of this paper (see (Steedman, 2000) for more details). Since, natural language sentences can have various CCG parse trees, each expressing a different meaning of the sentence, a key challenge

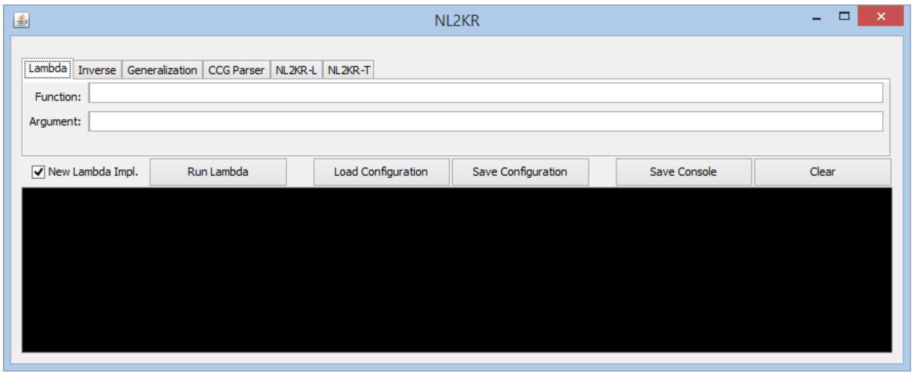

Figure 2: NL2KR's main GUI, Version 1.7.0001

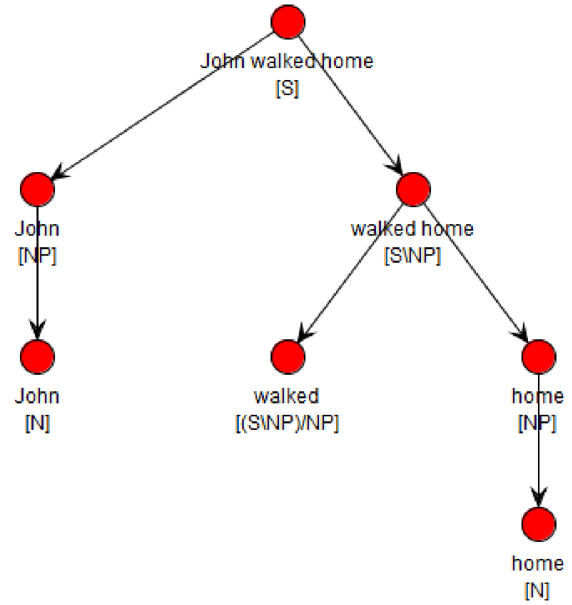

Figure 3: CCG parse tree of "John walked home".

in the learning and the translation process is to find a suitable CCG parse tree for a sentence in natural language. We overcome this impediment by allowing our learning and translation subsystem to work with multiple weighted parse trees for a given sentence and determining on the fly, the one that is most suitable. We discuss more on this in sections 2.4-2.6.

Existing CCG parsers (Curran et al., 2007; Lierler and Schüller, 2012) either return a single best parse tree for a given sentence or parse it in all possible ways with no preferential ordering among them. In order to overcome this shortcoming and generate more than one weighted candidate parse trees, we have developed a new parser using beam search with Cocke-Younger-Kasami(CYK) algorithm. NL2KRs CCG parser uses the C&C model (Curran et al., 2007) and constraints from the Stanford parser (Socher et al., 2013; Toutanova et al., 2003) to guide the derivation of a sentence. The output of the CCG parser is a set of k weighted parse trees, where the parameter k is provided by the user.

NL2KR system allows one to use the CCG parser independently through the interactive GUI. The output graphs look like the one in Figure 3. It can be zoomed in/out and its nodes can be moved around, making it easier to work with complex sentences.

2.4 Multistage learning approach

Learning meanings of words is the major component of our system. The inputs to the learning module are a list of training sentences, their target formal representations and an initial lexicon consisting of triplets of the form <*word, CCG category, meaning*>, where meanings are represented in terms of λ-calculus expressions. The output of the algorithm is a final dictionary containing a set of 4-tuples *(word, CCG category, meaning, weight)*.

Interactive Multistage Learning Algorithm (IMLA) NL2KR employs an Interactive Multistage Learning Algorithm (Algorithm 1) that runs many iterations on the input sentences. In each iteration, it goes through one or more of the following stages:

Stage 1 In Stage 1, it gets all the unfinished sentences. It then employs *Bottom Up-Top Down* algorithm (Algorithm 2) to learn new meanings (by Inverse-λ). For a sentence, if it has computed the meanings of all its constituents, which can be combined to produce the given representation, that sentence is considered as learned. Each

Algorithm 1 IMLA algorithm

```
function IMLA($initLexicon$,$sentences$, $sentsMeanings$)
  $regWords \leftarrow \emptyset$
  $generalize \leftarrow$ false
  $lexicon \leftarrow initLexicon$
  repeat
    repeat
      repeat
        for all s $\in sentences$ do
          $newMeanings \leftarrow$ BT(s,$lexicon$,$sentsMeanings$)
          $lexicon \leftarrow lexicon \cup newMeanings$
          for all $n \in newMeanings$ do
            $ms \leftarrow$ GENERALIZE($regWords$, $n$)
            $lexicon \leftarrow lexicon \cup ms$
          end for
        end for
      until $newMeanings = \emptyset$
      if $generalize$=false then
        $generalize \leftarrow$ true
        for all $t \in unfinishedSents$ do
          $words \leftarrow$ GETALLWORDS($t$)
          $ms \leftarrow$ GENERALIZE($words$)
          $lexicon \leftarrow lexicon \cup ms$
          $regWords \leftarrow regWords \cup words$
        end for
      end if
    until $newMeanings = \emptyset$
    INTERATIVELEARNING
  until $unfinishedSents = \emptyset$ OR userBreak
  $lexicon \leftarrow$ PARAMETERESTIMATION($lexicon$,$sentences$)
  return $lexicon$
end function
```

new meaning learned by this process is used to generalize the words in a waiting list. Initially, this waiting list is empty and is updated in stage 2. When no more new meaning can be learned by *Bottom Up-Top Down* algorithm, IMLA (Algorithm 1) enters stage 2.

Stage 2 In this stage, it takes all the sentences for which the learning is not yet finished and applies Generalization process on all the words of those sentences. At the same time, it populates those words into the waiting list, so that from now on, *Bottom Up-Top Down* will try to generalize new meanings for them when it learns some new meanings. It then goes back to stage 1. Next time, after exiting stage 1, it directly goes to stage 3.

Stage 3 When both aforementioned stages can not learn all the sentences, the *Interactive Learning* process is invoked and all the unfinished sentences are shown on the interactive GUI (Figure 4). Users can either skip or provide more information on the GUI and the learning process is continued.

After finishing all stages, IMLA (Algorithm 1) calls Parameter Estimation (section 2.5) algorithm to compute the weight of each lexicon tuple.

Bottom Up-Top Down learning For a given sentence, the CCG parser is used for the CCG parse trees like the one of *how big is texas* in Figure 4. For each parse tree, two main processes are called, namely “bottom up” and “top down”. In the first process, all the meanings of the words in the sentences are retrieved from the lexicon. These meanings are populated in the leaf nodes of a parse tree (see Figure 4), which are combined in a bottom-up manner to compute the meanings of phrases and full sentences. We call these meanings, the *current meanings*.

In the “top down” process, using Inverse-λ algorithm, the given meaning of the whole sentence (called the *expected meaning* of the sentence) and the current meanings of the phrases, we calculate the expected meanings of each of the phrases from the root of the tree to the leaves. For example, given the expected meaning of *how big is texas* and the current meaning of *how big*, we use Inverse-λ algorithm to get the meaning (expected) of *is texas*. This expected meaning is used together with current meanings of *is* (*texas*) to calculate the expected meanings of *texas* (*is*). The expected meanings of the leaf nodes we have just learned will be saved to the lexicon and will be used in the other sentences and in subsequent learning iteration. The “top down” process is stopped when the expected meanings are same as the current meanings. And in both “bottom up” and “top-down” processes, the beam search algorithm is used to speed-up the learning process.

Interactive learning In the interactive learning process it opens a GUI which shows the unfinished sentences. Users can see the current and expected meanings for the unfinished sentences. When the user gives additional meanings of word(s), the λ-application or Inverse-λ operation is automatically performed to update the new meaning(s) to related

Algorithm 2 BottomUp-TopDown (BT) algorithm

```
function BT($sentence, lexicon, sentsMeanings$)
    $parseTrees \leftarrow$ CCGPARSER($sentence$)
    for all $tree \in parseTrees$ do
        $t \leftarrow$ BOTTOMUP($tree$,$lexicon$)
        TOPDOWN($t$,$sentsMeanings$)
    end for
end function
```

word(s). Once satisfied, the user can switch back to the automated learning mode.

Example Let us consider the question "How big is texas?" with meaning $answer(size(stateid(texas)))$ (see Figure 4).

Let us assume that the initial dictionary has the following entries: *how* $:= NP/(N/N) : \lambda x.\lambda y.answer(x@y)$, *big* $:= N/N : \lambda x.size(x)$ and *texas* $:= NP : stateid(texas)$. The algorithm then proceeds as follows.

First, the meanings of "*how*" and "*big*" are combined to compute the current meaning of "*how big*" $:= NP : \lambda x.answer(size(x))$ in the "bottom up" process. Since the meaning of "*is*" is unknown, the current meaning of "*is texas*" still remains unknown.

It then starts the "top down" process where it knows the expected meaning of "*How big is texas*" $:= S : answer(size(stateid(texas)))$ and the current meaning of "*how big*". Using them in the Inverse-λ algorithm, it then compute the meaning of "*is texas*" $:= S\backslash NP : \lambda x1.x1@stateid(texas)$. Using this expected meaning and current meaning of "*texas*" $:= NP : stateid(texas)$, it then calculates the expected meaning of "*is*" as "*is*" $:= (S\backslash NP)/NP : \lambda x2.\lambda x1.x1@x2$. This newly learned expected meaning is then saved into the lexicon.

Since the meaning of all the words in the question are known, the learning algorithm stops here and the *Interactive Learning* is never called.

If initially, the dictionary contains only two meanings: "*big*" $:= N/N : \lambda x.size(x)$ and "*texas*" $:= NP : stateid(texas)$, NL2KR tries to first learn the sentence but fails to learn the complete sentence and switches to *Interactive Learning* which shows the interactive GUI (see Figure 4). If the user specifies that "*how*" means $\lambda x.\lambda y.answer(x@y)$, NL2KR combines its meaning with the meaning of "*big*" to get the meaning "*how big*" $:= NP : \lambda x.answer(size(x))$. It will then use Inverse-λ to figure out the meaning of "*is texas*" and then the meaning of "*is*". Now all the meanings are combined to compute the current meaning $answer(size(stateid(texas)))$ of "*How big is texas*". This meaning is same as the expected meaning, so we know that the sentence is successfully learned. Now, the user can press *Retry Learning* to switch back to automated learning.

2.5 Parameter Estimation

The Parameter Estimation module estimates a weight for each word-meaning pair such that the joint probability of the training sentences getting translated to their given representation is maximized. It implements the algorithm described in Zettlemoyer et. al.(2005).

2.6 Translation

The goal of this module is to convert input sentences into the target formalism using the lexicon previously learned. The algorithm used in Translation module (Algorithm 3) is similar to the bottom-up process in the learning algorithm. It first obtains several weighted CCG parse trees of the input sentence. It then computes a formal representation for each of the parse trees using the learned dictionary. Finally, it ranks the translations according to the weights of word-meaning pairs and the weights of the CCG parse trees. However, test sentences may contain words which were not present in the training set. In such cases, Generalization is used to guess the meanings of those unknown words from the meanings of the similar words present in the dictionary.

Algorithm 3 Translation algorithm

```
function TRANSLATE($sentence$, $lexicon$)
  $candidates \leftarrow \emptyset$
  $parseTrees \leftarrow$ CCGPARSER($sentence$)
  for all $tree \in parseTrees$ do
    GENERALIZE($tree$);
    $t \leftarrow$ BOTTOMUP($tree$)
    $candidates \leftarrow candidates \cup t$
  end for
  $output \leftarrow$ VERIFY-RANK($candidates$)
  return $output$
end function
```

3 Experimental Evaluation

We have evaluated NL2KR on two standard corpora: GeoQuery and Jobs. For both the corpus, the output generated by the learned system has been considered correct if it is an exact replica of the logical formula described in the corpus.

We report the performance in terms of precision (percentage of returned logical-forms that are correct), recall (percentage of sentences for which the correct logical-form was returned), F1-measure (harmonic mean of precision and recall) and the size of the initial dictionary.

We compare the performance of our system with recently published, directly-comparable works, namely, FUBL (Kwiatkowski et al., 2011), UBL (Kwiatkowski et al., 2010), λ-WASP (Wong and Mooney, 2007), ZC07 (Zettlemoyer and Collins, 2007) and ZC05 (Zettlemoyer and Collins, 2005) systems.

3.1 Corpora

GeoQuery GeoQuery (Tang and Mooney, 2001) is a corpus containing questions on geographical facts about the United States. It contains a total of 880 sentences written in natural language, paired with their meanings in a formal query language, which can be executed against a database of the geographical information of the United States. We follow the standard training/testing split of 600/280. An example sentence meaning pair is shown below.

Sentence: *How long is the Colorado river?*
Meaning: *answer(A,(len(B,A),const(B, riverid(colorado)), river(B)))*

Jobs The Jobs (Tang and Mooney, 2001) dataset contains a total of 640 job related queries written in natural language. The Prolog programming language has been used to represent the meaning of a query. Each query specifies a list of job criteria and can be directly executed against a database of job listings. An example sentence meaning pair from the corpus is shown below.

Question: *What jobs are there for programmers that know assembly?*
Meaning: *answer(J,(job(J),title(J,T), const(T,'Programmer'),language(J,L), const(L,'assembly'))))*

The dataset contains a training split of 500 sentences and a test split of 140 sentences.

3.2 Initial Dictionary Formulation

GeoQuery For GeoQuery corpus, we manually selected a set of 100 structurally different sentences from the training set and initiated the learning process with a dictionary containing the repre-

	GUI Driven	Initial Dictionary	Learned Dictionary
♯ <word, category >	31	118	401
♯ <word, category, meaning>	36	127	1572
♯ meaning	30	89	819

Table 1: Comparison of Initial and Learned dictionary for GeoQuery corpus on the basis of the number of entries in the dictionary, number of unique <word, CCG category> pairs and the number of unique meanings across all the entries. "GUI Driven" denotes the amount of the total meanings given through interactive GUI and is a subset of the Initial dictionary.

	GUI Driven	Initial Dictionary	Learned Dictionary
♯ <word, category>	58	103	226
♯ <word, category, meaning>	74	119	1793
♯ meaning	57	71	940

Table 2: Comparison of Initial and Learned dictionary for Jobs corpus.

sentation of the nouns and question words. These meanings were easy to obtain as they follow simple patterns. We then trained the translation system on those selected sentences. The output of this process was used as the initial dictionary for training step. Further meanings were provided on demand through interactive learning. A total of 119 word meanings tuples (Table 1, ♯ <*word, category, meaning* >) were provided from which the NL2KR system learned 1793 tuples. 45 of the 119 were representation of nouns and question words that were obtained using simple patterns. The remaining 74 were obtained by a human using the NL2KR GUI. These numbers illustrate the usefulness of the NL2KR GUI as well as the NL2KR learning component. One of our future goals is to further automate the process and reduce the GUI interaction part.

Table 1 compares the initial and learned dictionary for GeoQuery on the basis of number of unique <*word, category, meaning*> entries in dictionary, number of unique <*word, category*> pairs and the number of unique meanings across all the entries in the dictionary. Since each unique <word, CCG category> pair must have at least one meaning, the total number of unique <*word, category*> pairs in the training corpus provides a lower bound on the size of the ideal output dictionary. However, one <*word, category*> pair may have multiple meanings, so the ideal dictionary can be much bigger than the number of unique <*word, category*> pairs. Indeed, there were many words such as "of", "in" that had multiple meanings for the same CCG category. Table 1 clearly describes that the amount of initial effort is substantially less compared to the return.

Jobs For the Jobs dataset, we followed a similar process as in the GeoQuery dataset. A set of 120 structurally different sentences were selected and a dictionary was created which contained the representation of the nouns and the question words from the training corpus. A total of 127 word meanings were provided in the process. Table 2 compares the initial and learned dictionary for Jobs. Again, we can see that the amount of initial effort is substantially less in comparison to the return.

3.3 Precision, Recall and F1-measure

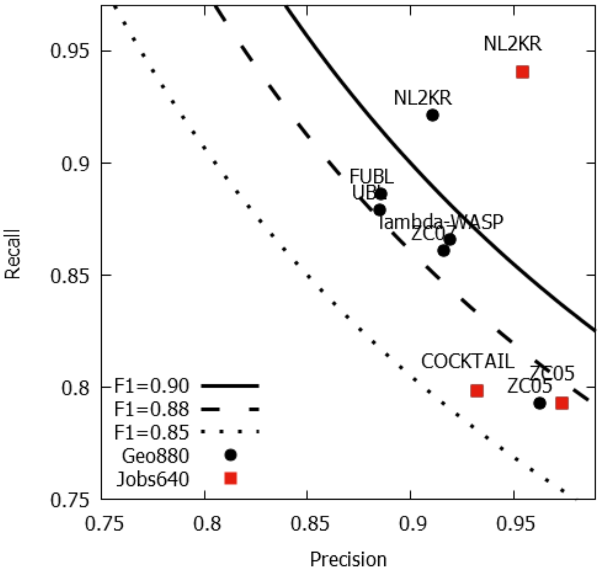

Figure 5: Comparison of Precision, Recall and F1-measure on GeoQuery and Jobs dataset.

Table 3, Table 4 and Figure 5 present the comparison of the performance of NL2KR on the GeoQuery and Jobs domain with other recent works. NL2KR obtained 91.1% precision value, 92.1%

System	Precision	Recall	F1
ZC05	0.963	0.793	0.87
ZC07	0.916	0.861	0.888
λ-WASP	0.9195	0.8659	0.8919
UBL	0.885	0.879	0.882
FUBL	0.886	0.886	0.886
NL2KR	0.911	0.921	0.916

Table 3: Comparison of Precision, Recall and F1-measure on GeoQuery dataset.

System	Precision	Recall	F1
ZC05	0.9736	0.7929	0.8740
COCKTAIL	0.9325	0.7984	0.8603
NL2KR	0.9543	0.9403	0.9472

Table 4: Comparison of Precision, Recall and F1-measure on Jobs dataset.

recall value and a F1-measure of 91.6% on GeoQuery (Figure 5, Geo880) dataset. For Jobs corpus, the precision, recall and F1-measure were 95.43%, 94.03% and 94.72% respectively. In all cases, NL2KR achieved state-of-the-art recall and F1 measures and it significantly outperformed FUBL (the latest work on translation systems) on GeoQuery.

For both GeoQuery and Jobs corpus, our recall is significantly higher than existing systems because meanings discovered by NL2KRs learning algorithm is more general and reusable. In other words, meanings learned from a particular sentence are highly likely to be applied again in the context of other sentences. It may be noted that, larger lexicons do not necessarily imply higher recall as lambda expressions for two phrases may not be suitable for functional application, thus failing to generate any translation for the whole. Moreover, the use of a CCG parser maximizes the recall by exhibiting consistency and providing a set of weighted parse trees. By consistency, we mean that the order of the weighted parse tree remains same over multiple parses of the same sentence and the sentences having similar syntactic structures have identical ordering of the derivations, thus making Generalization to be more effective in the process of translation.

The sentences for which NL2KR did not have a translation are the ones having structural difference with the sentences present in the training dataset. More precisely, their structure was not identical with any of the sentences present in the training dataset or could not be constructed by combining the structures observed in the training sentences.

We analyzed the sentences for which the translated meaning did not match the correct one and observed that the translation algorithm selected the wrong meaning, even though it discovered the correct one as one of the possible meanings the sentence could have had in the target formal language. Among the sentences for which NL2KR returned a translation, there were very few instances where it did not discover the correct meaning in the set of possible meanings.

It may be noted that even though our precision is lower than ZC05 and very close to ZC07 and WASP; we have achieved significantly higher F1 measure than all the related systems. In fact, ZC05, which achieves the best precision for both the datasets, is better by a margin of only 0.019 on the Jobs dataset and 0.052 on the GeoQuery dataset. We think one of the main reasons is that it uses manually predefined lambda-templates, which we try to automate as much as possible.

4 Conclusion

NL2KR is a freely available[2], user friendly, rich graphical platform for building translation systems to convert sentences from natural language to their equivalent formal representations in a wide variety of domains. We have described the system algorithms and architecture and its performance on the GeoQuery and Jobs datasets. As mentioned earlier, the NL2KR GUI and the NL2KR learning module help in starting from a small initial lexicon (for example, 119 in Table 2) and learning a much larger lexicon (1793 in Table 2). One of our future goals is to reduce the initial lexicon to be even smaller by further automating the NL2KR GUI interaction component .

Multiple Many-to-Many Sequence Alignment for Combining String-Valued Variables: A G2P Experiment

Abstract

We investigate *multiple many-to-many alignments* as a primary step in integrating supplemental information strings in string transduction. Besides outlining DP based solutions to the multiple alignment problem, we detail an approximation of the problem in terms of multiple sequence segmentations satisfying a coupling constraint. We apply our approach to boosting baseline G2P systems using homogeneous as well as heterogeneous sources of supplemental information.

1 Introduction

String-to-string translation (string transduction) is the problem of converting one string $\mathbf{x}$ over an alphabet Σ into another string $\mathbf{y}$ over a possibly different alphabet Γ. The most prominent applications of string-to-string translation in natural language processing (NLP) are grapheme-to-phoneme conversion, in which $\mathbf{x}$ is a letter-string and $\mathbf{y}$ is a string of phonemes, transliteration (Sherif and Kondrak, 2007), lemmatization (Dreyer et al., 2008), and spelling error correction (Brill and Moore, 2000). The classical learning paradigm in each of these settings is to train a model on pairs of strings $\{(\mathbf{x},\mathbf{y})\}$ and then to evaluate model performance on test data. Thereby, all state-of-the-art modelings we are aware of (e.g., (Jiampojamarn et al., 2007; Bisani and Ney, 2008; Jiampojamarn et al., 2008; Jiampojamarn et al., 2010; Novak et al., 2012)) proceed by first *aligning* the string pairs $(\mathbf{x},\mathbf{y})$ in the training data. Also, these modelings acknowledge that alignments may typically be of a rather complex nature in which several $\mathbf{x}$ sequence characters may be matched up with several $\mathbf{y}$ sequence characters; Table 1 illustrates. Once the training data is aligned, since $\mathbf{x}$ and $\mathbf{y}$ sequences are then segmented into equal number of segments, string-to-string translation may be seen as a sequence labeling (tagging) problem in which $\mathbf{x}$ (sub-)sequence characters are observed variables and $\mathbf{y}$ (sub-)sequence characters are hidden states (Jiampojamarn et al., 2007; Jiampojamarn et al., 2010).

f	i	n	ɪ	ks

Table 1: Sample monotone many-to-many alignment between $\mathbf{x} =$ phoenix and $\mathbf{y} =$ finɪks.

In this work, we extend the problem of classical string-to-string translation by assuming that, at training time, we have available $(M+2)$-tuples of strings $\{(\mathbf{x},\hat{\mathbf{y}}^{(1)},\ldots,\hat{\mathbf{y}}^{(M)},\mathbf{y})\}$, where $\mathbf{x}$ is the input string, $\hat{\mathbf{y}}^{(m)}$, for $1 \leq m \leq M$, are *supplemental information* strings, and $\mathbf{y}$ is the desired output string; at test time, we wish to predict $\mathbf{y}$ from $(\mathbf{x},\hat{\mathbf{y}}^{(1)},\ldots,\hat{\mathbf{y}}^{(M)})$. Generally, we may think of $\hat{\mathbf{y}}^{(1)},\ldots,\hat{\mathbf{y}}^{(M)}$ as arbitrary strings over arbitrary alphabets $\Sigma^{(m)}$, for $1 \leq m \leq M$. For example, $\mathbf{x}$ might be a letter-string and $\hat{\mathbf{y}}^{(m)}$ might be a transliteration of $\mathbf{x}$ in language L_m (cf. Bhargava and Kondrak (2012)). Alternatively, and this is our model scenario in the current work, $\mathbf{x}$ might be a letter input string and $\hat{\mathbf{y}}^{(m)}$ might be the predicted string of phonemes, given $\mathbf{x}$, produced by an (offline) system T_m. This situation is outlined in Table 3. In the table, we also illustrate a *multiple (monotone) many-to-many alignment* of $(\mathbf{x},\hat{\mathbf{y}}^{(1)},\ldots,\hat{\mathbf{y}}^{(M)},\mathbf{y})$. By this, we mean an alignment where (1) *subsequences* of all $M+2$ strings may be matched up with each other (many-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 909–919,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

to-many alignments), and where (2) the matching up of subsequences obeys monotonicity. Note that such a multiple alignment generalizes classical monotone many-to-many alignments between *pairs* of strings, as shown in Table 1. Furthermore, such an alignment may apparently be quite useful. For instance, while none of the strings $\hat{\mathbf{y}}^{(m)}$ in the table equals the true phonetic transcription $\mathbf{y}$ of $\mathbf{x}$, taking a position-wise majority vote of the multiple alignment of $(\hat{\mathbf{y}}^{(1)}, \ldots, \hat{\mathbf{y}}^{(M)})$ yields $\mathbf{y}$. Moreover, analogously as in the case of pairs of aligned strings, we may perceive the so extended string-to-string translation problem as a sequence labeling task once $(\mathbf{x}, \hat{\mathbf{y}}^{(1)}, \ldots, \hat{\mathbf{y}}^{(M)}, \mathbf{y})$ are multiply aligned, but now, with *additional observed variables* (or *features*), namely, (sub-)sequence characters of each string $\hat{\mathbf{y}}^{(m)}$.

To further motivate our approach, consider the situation of training a new G2P system on the basis of, e.g., Combilex (Richmond et al., 2009). For each letter form in its database, Combilex provides a corresponding phonetic transcription. Now, suppose that, in addition, we can poll an external knowledge source such as Wiktionary for (its) phonetic transcriptions of the respective Combilex letter words as outlined in Table 2. The central question we want to answer is: can we train a system using this *additional* information which performs better than the 'baseline' system that ignores the extra information? Clearly, a system with more information should not perform worse than a system with less information (unless the additional information is highly noisy), but it is a priori not clear at all how the extra information can be included, as Bhargava and Kondrak (2012) note: output predictions may be in distinct alphabets and/or follow different conventions, and simple rule-based conversions may even deteriorate a baseline system's performance. Their solution to the problem is to let the baseline system output its n-best phonetic transcriptions, and then to re-rank these n-best predictions via an SVM re-ranker trained on the supplemental representations (see their figure 2). Our approach is much different from this: we character (or substring) align the supplemental information strings with the input letter strings and then sequentially transduce input character substrings as in the standard G2P approach, but where the sequential transducer is aware of the corresponding subsequences of the supplemental information strings.

Our goals in the current work are first, in Section 2, to formally introduce the multiple many-to-many alignment problem, which, to our knowledge, has not yet been formally considered, and to indicate how it can be solved (by standard extensions of well-known DP recursions). Secondly, we outline an 'approximation algorithm', also in Section 2, with much better runtime complexity, to solving the multiple many-to-many alignment problem. This proceeds by optimally *segmenting* individual strings to align *under the global constraint that the number of segments must agree* across strings. Thirdly, we demonstrate experimentally, in Section 5, that multiple many-to-many alignments may be an extremely useful first step in boosting the performance of a G2P model. In particular, we show that by conjoining a base system with additional systems very high performance increases can be achieved. We also investigate the effects of using our introduced approximation algorithm instead of 'exactly' determining alignments. We discuss related work in Section 3, present data and systems in Section 4 and conclude in Section 6.

2 Mult. Many-to-Many Alignm. Models

We now formally define the problem of multiply aligning several strings in a *monotone and many-to-many alignment* manner. For notational convenience, in this section, let the N strings to align be denoted by $\mathbf{w}_1, \ldots, \mathbf{w}_N$ (rather than $\mathbf{x}, \hat{\mathbf{y}}^{(m)}, \mathbf{y}$, etc.). Let each $\mathbf{w}_n$, for $1 \leq n \leq N$, be an arbitrary string over some alphabet $\Sigma^{(n)}$. Let $\ell_n = |\mathbf{w}_n|$ denote the length of $\mathbf{w}_n$. Moreover, assume that a set $S \subseteq \prod_{n=1}^{N} \{0, \ldots, \ell_n\} \backslash \{\mathbf{0}_N\}$ of *allowable steps* is specified, where $\mathbf{0}_N = (\underbrace{0, \ldots, 0}_{N \text{ times}})$.[1] We interpret the elements of S as follows: if $(s_1, s_2, \ldots, s_N) \in S$, then subsequences of $\mathbf{w}_1$ of length s_1, subsequences of $\mathbf{w}_2$ of length s_2, …, subsequences of $\mathbf{w}_N$ of length s_N may be matched up with each other. In other words, S defines the types of valid 'many-to-many match-up operations'.[2] While we could drop S from consideration and simply allow every possible matching up of character subsequences, it is convenient to introduce S because algorithmic complexity may then be specified in terms of S, and by choosing particular S, one may retrieve special cases otherwise considered in the literature (see next section).

As indicated, for us, a multiple alignment of $(\mathbf{w}_1, \ldots, \mathbf{w}_N)$ is any scheme

$$\begin{matrix} \mathbf{w}_{1,1} & \mathbf{w}_{1,2} & \cdots & \mathbf{w}_{1,k} \\ \mathbf{w}_{2,1} & \mathbf{w}_{2,2} & \cdots & \mathbf{w}_{2,k} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{w}_{N,1} & \mathbf{w}_{N,2} & \cdots & \mathbf{w}_{N,k} \end{matrix}$$

such that $(|\mathbf{w}_{1,i}|, \ldots, |\mathbf{w}_{N,i}|) \in S$, for all $i = 1, \ldots, k$, and such that $\mathbf{w}_n = \mathbf{w}_{n,1} \cdots \mathbf{w}_{n,k}$, for all $1 \leq n \leq N$. Let $A_S = A_S(\mathbf{w}_1, \ldots, \mathbf{w}_N)$ denote the set of all multiple alignments of $(\mathbf{w}_1, \ldots, \mathbf{w}_N)$. For an alignment $a \in A_S$, denote by $\text{score}(a) = f(a)$ the *score* of alignment a under *alignment model* f, where $f : A_S(\mathbf{w}_1, \ldots, \mathbf{w}_N) \to \mathbb{R}$. We now investigate solutions to the *problem of finding the alignment with maximal score* under different choices of alignment models f, i.e., we search to efficiently solve

$$\max_{a \in A_S(\mathbf{w}_1, \ldots, \mathbf{w}_N)} f(a). \qquad (1)$$

Unigram alignment model For our first alignment model f, we assume that $f(a)$, for $a \in A_S$, is the score

$$f(a) = \sum_{i=1}^{k} \mathsf{sim}_1(\mathbf{w}_{1,i}, \ldots, \mathbf{w}_{N,i}) \qquad (2)$$

for a real-valued similarity function $\mathsf{sim}_1 : \prod_{n=1}^{N} \left(\Sigma^{(n)}\right)^* \to \mathbb{R}$. We call the model f in (2) a *unigram model* because $f(a)$ is the sum of the similarity scores of the matched-up subsequences $(\mathbf{w}_{1,i}, \ldots, \mathbf{w}_{N,i})$, ignoring context. Due to this independence assumption, solving maximization problem in Eq. (1) under specification (2) is straightforward via a dynamic programming (DP) recursion. To do so, define by $M_{S,\mathsf{sim}_1}(i_1, i_2, \ldots, i_N)$ the score of the best alignment, under alignment model $f = \sum \mathsf{sim}_1$ and set of steps S, of $(\mathbf{w}_1(1 : i_1), \ldots, \mathbf{w}_N(1 : i_N))$.[3] Then, $M_{S,\mathsf{sim}_1}(i_1, \ldots, i_N)$ is equal to

$$\max_{(j_1, \ldots, j_N) \in S} M_{S,\mathsf{sim}_1}(i_1 - j_1, \ldots, i_N - j_N) \\ + \mathsf{sim}_1\big(\mathbf{w}(i_1 - j_1 + 1 : i_1), \ldots, \mathbf{w}(i_N - j_N + 1 : j_N)\big). \qquad (3)$$

This recurrence directly leads to a DP algorithm, shown in Algorithm 1, for computing the *score* of the best alignment of $(\mathbf{w}_1, \ldots, \mathbf{w}_N)$; the actual alignment can be found by storing pointers to the maximizing steps taken. If similarity evaluations $\mathsf{sim}_1(\mathbf{w}_{1,i}, \ldots, \mathbf{w}_{N,i})$ are thought of as taking constant time, this algorithm's run time is $\mathcal{O}(\prod_{n=1}^{N} \ell_n \cdot |S|)$. When $\ell = \ell_1 = \cdots = \ell_n$ and $|S| = \ell^N - 1$ ('worst case' size of S), then the algorithm's runtime is thus $\mathcal{O}(\ell^{2N})$, which quickly becomes untractable as N, the number of strings to align, increases.

Of course, the unigram alignment model could be generalized to an m-gram alignment model. An m-gram alignment model would exhibit worst-case runtime complexity of $\mathcal{O}(\ell^{(m+1)N})$ under analogous DP recursions as for the unigram model.

Algorithm 1

```
procedure UNIGRAM-ALIGN($\mathbf{w}_1, \ldots, \mathbf{w}_N$; $S$, $\mathsf{sim}_1$)
    $M(i_1, \ldots, i_N) \leftarrow -\infty$ for all $(i_1, \ldots, i_N) \in \mathbb{Z}^N$
    $M(\mathbf{0}_N) \leftarrow 0$
    for $i_1 = 0 \ldots \ell_1$ do
        for $\cdots$ do
            for $i_N = 0 \ldots \ell_N$ do
                if $(i_1, \ldots, i_N) \neq \mathbf{0}_N$ then
                    $M(i_1, \ldots, i_N) \leftarrow$ Eq. (3)
    return $M(\ell_1, \ldots, \ell_N)$
```

Separable alignment models For our second model class, assume that, for any $a \in$

[1] Here, $\prod$ denotes the Cartesian product of sets.

[2] In the case of two strings, this is sometimes denoted in the manner M-N (e.g., 3-2, 1-0), indicating that M characters of one string may be matched up with N characters of the other string. Analogously, we could write here s_1-s_2-s_3-$\cdots$.

[3] We denote by $\mathbf{x}(a : b)$ the substring $x_a x_{a+1} \cdots x_b$ of the string $x_1 x_2 \cdots x_t$.

$A_S(\mathbf{w}_1,\ldots,\mathbf{w}_N)$, $f(a)$ decomposes into

$$f(a)=\Psi\Big(f_{\mathbf{w}_1}(\mathbf{w}_{1,1}\cdots\mathbf{w}_{1,k}),\ldots,f_{\mathbf{w}_N}(\mathbf{w}_{N,1}\cdots\mathbf{w}_{N,k})\Big) \tag{4}$$

for some models $f_{\mathbf{w}_1},\ldots,f_{\mathbf{w}_N}$ and where $\Psi:\mathbb{R}^N\rightarrow\mathbb{R}$ is non-decreasing in its arguments (e.g., $\Psi(f_{\mathbf{w}_1},\ldots,f_{\mathbf{w}_N})=\sum_{n=1}^N f_{\mathbf{w}_n}$). If $f(a)$ decomposes in such a manner, then $f(a)$ is called *separable*.[4] The advantage with separable models is that we can solve the 'subproblems' $f_{\mathbf{w}_1},\ldots,f_{\mathbf{w}_N}$ independently. Thus, in order to find optimal multiple alignments of $(\mathbf{w}_1,\ldots,\mathbf{w}_N)$ under such a specification, we would only have to find the best *segmentations* of sequences $\mathbf{w}_n$ under models $f_{\mathbf{w}_n}$, for $1\leq n\leq N$, subject to the constraint that the segmentations must agree in their *number* of segments (the *coupling variable*). Let $S_{\mathbf{w}_n}\subseteq\{0,1,\ldots,\ell_n\}$ denote the constraints on *segment lengths*, similar to the interpretation of steps in S. If $f_{\mathbf{w}_n}$ is a unigram segmentation model then the problem of finding the best segmentation of $\mathbf{w}_n$ with exactly j segments can be solved in time $\mathcal{O}(\ell_n\,|S_{\mathbf{w}_n}|\,j)$. Thus, if each $f_{\mathbf{w}_n}$ is a unigram segmentation model, worst-case time complexity for each subproblem would be $\mathcal{O}(\ell_n^3)$ (if string $\mathbf{w}_n$ can be segmented into at most ℓ_n segments) and then the overall problem (1) under specification (4) is solvable in worst-case time $N\cdot\mathcal{O}(\ell^3)$. More generally, if each $f_{\mathbf{w}_n}$ is an m-gram segmentation model, then worst-case time complexity amounts to $N\cdot\mathcal{O}(\ell^{m+2})$. Importantly, this scales *linearly* with the number N of strings to align, rather than *exponentially* as the $\mathcal{O}(\ell^{(m+1)N})$ under the (non-separable) m-gram alignment model discussed above.

Unsupervised alignments The algorithms presented may be applied iteratively in order to induce multiple alignments in an unsupervised (EM-like) fashion in which sim_1 is gradually learnt (e.g., starting from a uniform initialization of sim_1). *We skip details of this, as we do not make us of it in our current experiments.* Rather, in our experiments below, we directly specify sim_1 as a sum of pairwise similarity scores which we extract from alignments produced by an off-the-shelf *pairwise* aligner.

3 Related work

Monotone alignments have a long tradition, both in NLP and bioinformatics. The classical Needleman-Wunsch algorithm (Needleman and Wunsch, 1970) computes the optimal alignment between two sequences when only single character matches, mismatches, and skips are allowed. It is a special case of the unigram model (2) in optimization problem (1) for which $N=2$, $S=\{(1,0),(0,1),(1,1)\}$ and sim_1 takes on values from $\{0,-1\}$, depending on whether compared input subsequences match or not. As is well-known, this alignment specification is equivalent to the edit distance problem (Levenshtein, 1966) in which the minimal number of insertions, deletions and substitutions is sought that transforms one string into another. *Substring-to-substring edit operations* — or equivalently, (monotone) many-to-many alignments — have appeared in the NLP context, e.g., in (Deligne et al., 1995), (Brill and Moore, 2000), (Jiampojamarn et al., 2007), (Bisani and Ney, 2008), (Jiampojamarn et al., 2010), or, significantly earlier, in (Ukkonen, 1985), (Véronis, 1988). *Learning* edit distance/monotone alignments in an *unsupervised* manner has been the topic of, e.g., (Ristad and Yianilos, 1998), (Cotterell et al., 2014), besides the works already mentioned. All of these approaches are special cases of our unigram model outlined in Section 2 — i.e., they consider particular S (most prominently, $S=\{(1,0),(0,1),(1,1)\}$) and/or restrict attention to only $N=2$ strings.[5]

Alignments between multiple sequences, i.e., multiple sequence alignment, has also been an issue both in NLP (e.g., Covington (1998), Bhargava and Kondrak (2009)) and bioinformatics (e.g., Durbin et al. (1998)). An interesting application of alignments of multiple sequences is to determine what has been called *median string* (Kohonen, 1985) or *Steiner consensus string* (Gusfield, 1997), defined as the string $\bar{\mathbf{s}}$ that minimizes the sum of distances, for a given distance function $d(\mathbf{x},\mathbf{y})$, to a list of strings $\mathbf{s}_1,\ldots,\mathbf{s}_N$ (Jiang et al., 2012); typically, d is the standard edit distance. As Gusfield (1997) shows, the Steiner consensus string may be retrieved from a multiple align-

[4] Note the difference between Eqs. (2) and (4). While each $f_{\mathbf{w}_n}$ in (4) operates on a 'row' of an alignment scheme, sim_1 in (2) acts on the 'columns'. In other words, the unigram alignment model correlates the multiply matched-up subsequences, while the separable alignment model assumes independence here.

[5] In Cotterell et al. (2014), context influences alignments, so that the approach goes beyond the unigram model sketched in (2), but there, too, the focus is on the situation $N=2$ and $S=\{(1,0),(0,1),(1,1)\}$.

ment of $\mathbf{s}_1, \ldots, \mathbf{s}_N$ by concatenating the columnwise majority characters in the alignment, ignoring skips. Since median string computation (and hence also the multiple many-to-many alignment problem, as we consider) is an NP-hard problem (Sim and Park, 2003), designing approximations is an active field of research. For example, Marti and Bunke (2001) ignore part of the search space by declaring matches-up of distant characters as unlikely, and Jiang et al. (2012) apply an approximation based on string embeddings in vector spaces. Paul and Eisner (2012) apply dual decomposition to compute Steiner consensus strings. Via the approach taken in this paper, median strings may be computed in case d is a (distance) function taking *substring-to-substring edit operations* into account, a seemingly straightforward, yet extremely useful generalization in several NLP applications, as indicated in the introduction.

Our approach may also be seen in the context of classifier combination for string-valued variables. While ensemble methods for structured prediction have been considered in several works (see, e.g., Nguyen and Guo (2007), Cortes et al. (2014), and references therein), a typical assumption in this situation is that the sequences to be combined have equal length, which clearly cannot be expected to hold when, e.g., the outputs of several G2P, transliteration, etc., systems must be combined. In fact, the multiple many-to-many alignment models investigated in this work could act as a preprocessing step in this setup, since the alignment precisely serves the functionality of segmenting the strings into equal number of segments/substructures. Of course, combining outputs with varying number of elements is also an issue in machine translation (e.g., Macherey and Och (2007), Heafield et al. (2009)), but, there, the problem is harder due to the potential non-monotonicities in the ordering of elements, which typically necessitates (additional) heuristics. One approach for constructing multiple alignments is here *progressive multiple alignment* (Feng and Doolittle, 1987) in which a multiple (typically one-to-one) alignment is iteratively constructed from successive pairwise alignments (Bangalore et al., 2001). Matusov et al. (2006) apply word reordering and subsequent pairwise monotone one-to-one alignments for MT system combination.

4 Data and systems

4.1 Data

We conduct experiments on the General American (GA) variant of the Combilex data set (Richmond et al., 2009). This contains about 144,000 grapheme-phoneme pairs as exemplarily illustrated in Table 2. In our experiments, we split the data into two disjoint parts, one for testing (about 28,000 word pairs) and one for training/development (the remainder).

4.2 Systems

BASELINE Our baseline system is a linear-chain conditional random field model (CRF)[6] (Lafferty et al., 2001) which we apply in the manner indicated in the introduction: after many-to-many aligning the training data as in Table 1, at *training time*, we use the CRF as a tagging model that is trained to label each input character subsequence with an output character subsequence. As *features* for the CRF, we use all n-grams of subsequences of $\mathbf{x}$ that fit inside a window of size 5 centered around the current subsequence (*context features*). We also include *linear-chain features* which allow previously generated output character subsequences to influence current output character subsequences. In essence, our baseline model is a standard discriminative approach to G2P. It is, all in all, the same approach as described in Jiampojamarn et al. (2010), except that we do not include joint n-gram features. At *test time*, we first segment a new input string $\mathbf{x}$ and then apply the CRF. Thereby, we train the segmentation module on the segmented $\mathbf{x}$ sequences, as available from the aligned training data.[7]

BASELINE+X As competitors for the baseline system, we introduce systems that rely on the predictions of one or several additional (black box/offline) systems. *At training time*, we first multiply many-to-many align the input string $\mathbf{x}$, the predictions $\hat{\mathbf{y}}^{(1)}, \ldots, \hat{\mathbf{y}}^{(M)}$ and the true transcription $\mathbf{y}$ as illustrated in Table 3 (see Section 4.3 for details). Then, as for the baseline system, we train a CRF to label each input character

[6] We made use of the CRF++ package available at https://code.google.com/p/crfpp/.

[7] To be more precise on the training of the segmentation module, in an alignment as in Table 1, we consider the segmented $\mathbf{x}$ string — ph-oe-n-i-x — and then encode this segmentation in a binary string where 1's indicate splits. Thus, segmentation becomes, again, a sequence labling task; see, e.g., Bartlett et al. (2008) or Eger (2013) for details.

subsequence with the corresponding output character subsequence. However, this time, the CRF has access to the subsequence suggestions (as the alignments indicate) produced by the offline systems. As *features* for the extended models, we additionally include context features for all predicted strings $\hat{\mathbf{y}}^{(m)}$ (all n-grams in a window of size 3 centered around the current subsequence prediction). We also include a joint feature firing on the tuple of the current subsequence value of $\mathbf{x}$, $\hat{\mathbf{y}}^{(1)}, \ldots, \hat{\mathbf{y}}^{(M)}$. To illustrate, when BASELINE+X tags position 2 in the (split up) input string in Table 3, it sees that its value is *ch*, that the previous input position contains *s*, that the next contains *i*, that the next two contain (*i*,*z*), that the prediction of the first system at position 2 is k, that the first system's next prediction is ai, and so forth. *At test time*, we first multiply many-to-many align $\mathbf{x}, \hat{\mathbf{y}}^{(1)}, \ldots, \hat{\mathbf{y}}^{(M)}$, and then apply the enhanced CRF.

4.3 Alignments

To induce multiple monotone many-to-many alignments of input strings, offline system predictions and output strings, we proceed in one of two manners.

Exact alignments *Firstly*, we specify sim_1 in Eq. (2), as $\mathsf{sim}_1(\mathbf{x}_i, \hat{\mathbf{y}}_i^{(1)}, \ldots, \hat{\mathbf{y}}_i^{(M)}, \mathbf{y}_i) =$

$$\Big(\sum_{m=1}^{M} \mathsf{psim}(\mathbf{x}_i, \hat{\mathbf{y}}_i^{(m)})\Big) + \mathsf{psim}(\mathbf{x}_i, \mathbf{y}_i),$$

where psim is a pair-similarity function. The advantage with this specification is that the similarity of a tuple of subsequences is defined as the sum of *pairwise* similarity scores, which we can directly estimate from pairwise alignments of $(\mathbf{x}, \hat{\mathbf{y}}^{(m)})$ that an off-the-shelf pairwise aligner can produce (we use the Phonetisaurus aligner for this). We set $\mathsf{psim}(\mathbf{u}, \mathbf{v})$ as log-probability of observing the tuple $(\mathbf{u}, \mathbf{v})$ in the training data of pairwise aligned sequences. To illustrate, we define the similarity of (o,əʊ,əʊ,ə,əʊ,ə,əʊ) in the example in Table 3 as the pairwise similarity of (o,əʊ) (as inferred from pairwise alignments of $\mathbf{x}$ strings and system 1 transcriptions) plus the pairwise similarity of (o,əʊ) (as inferred from pairwise alignments of $\mathbf{x}$ strings and system 2 transcriptions), etc. At test time, we use the same procedure but drop the term $\mathsf{psim}(\mathbf{x}_i, \mathbf{y}_i)$ when inducing alignments. For our current purposes, we label the outlined modus as **exact (alignment) modus**.

Approx. alignments *Secondly*, we derive the optimal multiple many-to-many alignment of the strings in question by choosing an alignment that satisfies the condition that (1) each individual string $\mathbf{x}, \hat{\mathbf{y}}^{(1)}, \ldots, \hat{\mathbf{y}}^{(M)}, \mathbf{y}$ is optimally *segmented* (e.g., *ph-oe-n-i-x* rather than *pho-eni-x*, f-i-n-ɪ-ks rather than f-inɪk-s) subject to the global constraint that (2) the number of segments must agree across the strings to align. This constitutes a separable alignment model as discussed in Section 2, and thus has much lower runtime complexity as the first model. Segmentation models can be directly learned from the pairwise alignments that Phonetisaurus produces by focusing on either the segmented $\mathbf{x}$ or $\mathbf{y}/\hat{\mathbf{y}}^{(m)}$ sequences; we choose to implement bigram individual segmentation models. This second model type may be considered an *approximation* of the first, since in a good alignment, we would not only expect individually good segmentations and agreement of segment numbers but also that subsegments are *likely correlations* of each other, precisely as our first model type captures. Therefore, we shall call this alignment modus **approximate (alignment) modus**, for our present purposes.

5 Experiments

We now describe two sets of experiments, a **controlled experiment** on the Combilex data set where we can design our offline/black box systems ourselves and where the black box systems are trained on a similar distribution as the baseline and the extended baseline systems. In particular, the black box systems operate on the same output alphabet as the extended baseline systems, which constitutes an 'ideal' situation. Thereafter, we investigate how our extended baseline system performs in a **'real-world' scenario**: we train a system on Combilex that has as supplemental information corresponding Wiktionary (and PTE, as explained below) transcriptions.

Throughout, we use as accuracy measures for all our systems **word accuray** (WACC). Word accuracy is defined as the number of correctly transcribed strings among all transcribed strings in a test sample. WACC is a strict measure that penalizes even tiny deviations from the gold-standard transcriptions, but has nowadays become standard in G2P.

5.1 A controlled experiment

In our first set of experiments, we let our offline/black box systems be the Sequitur G2P modeling toolkit (Bisani and Ney, 2008) (S) and the Phonetisaurus modeling toolkit (Novak et al., 2012) (P). We train them on *disjoint sets* of 20,000 grapheme-to-phoneme Combilex string pairs each. The performance of these two systems, on the test set of size 28,000, is indicated in Table 4. Next, we train BASELINE on *disjoint* sets (disjoint from both the training sets of P and S) of size 2,000, 5,000, 10,000 and 20,000. Making BASELINE's training sets disjoint from the training sets of the offline systems is both realistic (since a black box system would typically follow a partially distinct distribution from one's own training set distribution) and also prevents the extended baseline systems from fully adapting to the predictions of either P or S, whose training set accuracy is an upward biased representation of their true accuracy. As baseline extensions, we consider the systems BASELINE+P (+P), and BASELINE+P+S (+P+S).[8]

	Phonetisaurus	Sequitur
WACC	72.12	71.70

Table 4: Word-accuracy (in %) on the test data, for the two systems indicated.

Results are shown in Figures 1 and 2. We see that conjoining the base system with the predictions of the offline Phonetisaurus and Sequitur models substantially increases the baseline WACC, *especially in the case of little training data*. In fact, WACC increases here by almost 100% when the baseline system is complemented by $\hat{\mathbf{y}}^{(\mathrm{P})}$ and $\hat{\mathbf{y}}^{(\mathrm{S})}$. As training set size increases, differences become less and less pronounced. Eventually, we would expect them to drop to zero, since beyond some training set size, the additional features may provide no new information.[9] We also note that conjoining the two systems is more valuable than conjoining only one system, and, in Figure 2, that the models which are based on exact multiple alignments outperform the models based on approximate alignments, but not by a wide margin.

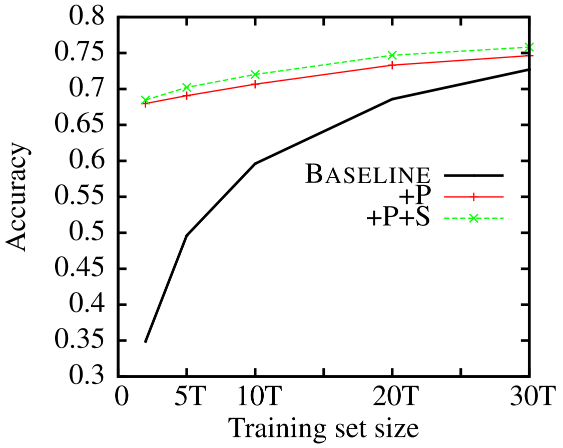

Figure 1: WACC as a function of training set size for the system indicated. Exact align. modus.

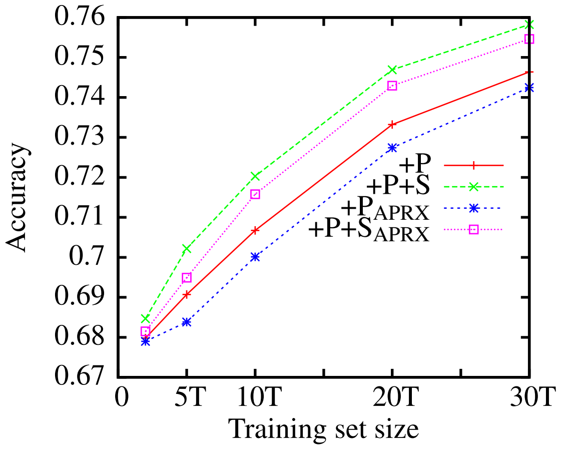

Figure 2: Comparison of models based on exact and approximate alignments; WACC as a function of training set size. APRX denotes the approximation alignment model.

Concerning differences in *alignments* between the two alignment types, exact vs. approximate, an illustrative example where the approximate model fails and the exact model does not is ('false' alignment based on the approximate model indicated):

r	ee	n	t	e	r	e	d
r	i	E	n	t	@‘	r	d
r	i	E	n	t	@‘	r	d

which nicely captures the inability of the approximate model to account for correlations between the matched-up subsequences. That is, while the segmentations of the three shown sequences appear acceptable, a matching of graphemic *t* with

[8] We omit BASELINE+S since it yielded similar results as BASELINE+P.

[9] In fact, in follow-up work, we find that the additional information may also confuse the base system when training set sizes are large enough.

phonemic n, etc., seems quite unlikely. Still, it is very promising to see that these differences in alignment quality translate into very small differences in overall string-to-string translation model performance, as Figure 2 outlines. Namely, differences in WACC are typically on the level of 1% or less (always in favor of the exact alignment model). This is a very important finding, as it indicates that string-to-string translation need not be (severely) negatively impacted by switching to the approximate alignment model, a tractable alternative to the exact models, which quickly become practically infeasible as the number of strings to align increases.

5.2 Real-world experiments

To test whether our approach may also succeed in a 'real-world setting', we use as offline/black box systems GA Wiktionary transcriptions of our input forms as well as PhotoTransEdit (PTE) transcriptions,[10] a lexicon-based G2P system which offers both GA and RP (received pronunciation) transcription of English strings. *We train and test on input strings for which both Combilex and PTE transcriptions are available, and for which both Combilex and Wiktionary transcriptions are available*.[11] Test set sizes are about 1,500 in the case of PTE and 3,500 in the case of Wiktionary. We only test here the performance of the exact alignment method, noting that, as before, approximate alignments produced slightly weaker results.

Clearly, Wiktionary and PTE differ from the Combilex data. First, both Wiktionary and PTE use different numbers of phonemic symbols than Combilex, as Table 5 illustrates. Some differences arise from the fact that, e.g., lengthening of vowels is indicated by two output letters in some data sets and only one in others. Also, phonemic transcription conventions differ, as becomes most strikingly evident in the case of RP vs. GA transcriptions — Table 6 illustrates. Finally, Wiktionary has many more phonetic symbols than the other datasets, a finding that we attribute to its crowd-sourced nature and lacking of normalization. Despite these differences in phonemic annotation standards between Combilex, Wiktionary and PTE, we observe that conjoining input strings with predicted Wiktionary or PTE transcriptions via multiple alignments leads to very good improvements in WACC over only using the input string as information source. Indeed, as shown in Table 7, for PTE, WACC increases by as much as 80% in case of small training sample (1,099 string pairs) and as much as 37% in case of medium-sized training sample (2,687 string pairs). Thus, comparing with the previous situation of homogenous systems, we also observe that the gain from including heterogeneous system is relatively weaker, as we would expect due to distinct underlying assumptions, but still impressive. Performance increases when including Wiktionary are slightly lower, most likely because it constitutes a very heterogenous source of phonetic transcriptions with user-idiosyncratic annotations (however, training set sizes are also different).[12]

Dataset	$\lvert\Sigma\rvert$
Combilex	54
Wiktionary$_{\text{GA}}$	107
Wiktionary$_{\text{RP}}$	116
PTE$_{\text{GA}}$	44
PTE$_{\text{RP}}$	57

6 Conclusion

We have generalized the task description of string transduction to include supplemental information strings. Moreover, we have suggested multiple

[10] Downloadable from http://www.photransedit.com/.

[11] This yields a clear method of comparison. An alternative would be to provide predictions for missing transcriptions. In any case, by our task definition, all systems must provide a hypothesis for an input string.

[12] To provide, for the interested reader, a comparison with Phonetisaurus and Sequitur: for the Wiktionary GA data, performance of Phonetisaurus is 41.80% (training set size 2,000), 55.70% (5,000) and 62.47% (10,000). Respective numbers for Sequitur are 40.58%, 54.84%, and 61.58%. On PTE, results are, similarly, slightly higher than our baseline, but substantially lower than the extended baseline.

Table 6: Multiple alignments of input string, predicted PTE transcription and true (Combilex) transcription. Differences may be due to alternative phonemic conventions (e.g., Combilex has a single phonemic character representing the sound tʃ) and/or due to differences in pronunciation in GA and RP, resp.

many-to-many alignments — and a subsequent standardly extended discriminative approach — for solving string transduction (here, G2P) in this generalized setup. We have shown that, in a real-world setting, our approach may significantly beat a standard discriminative baseline, e.g., when we add Wiktionary transcriptions or predictions of a rule-based system as additional information to the input strings. The appeal of this approach lies in the fact that almost *any sort of external knowledge source may be integrated to improve the performance of a baseline system*. For example, supplemental information strings may appear in the form of transliterations of an input string in other languages; they may be predictions of other G2P systems, whether carefully manually crafted or learnt from data; they might even appear in the form of phonetic transcriptions of the input string in other dialects or languages. What distinguishes our solution to integrating supplemental information strings in string transduction settings from other research (e.g., (Bhargava and Kondrak, 2011; Bhargava and Kondrak, 2012)) is that rather than integrating systems on the *global* level of *strings*, we integrate them on the *local* level of smaller units, namely, *substrings* appropriated to the domain of application (e.g., in our context, phonemes/grapheme substructures). Both approaches may be considered complementary. Finally, another important contribution of our work is to outline an 'approximation algorithm' to inducing multiple many-to-many alignments of strings, which is otherwise an NP-hard problem for which (most likely) no efficient exact solutions exist, and to investigate its suitability for the problem task. In particular, we have seen that exact alignments lead to better overall model performance, but that the margin over the approximation is not wide.

The scope for future research of our modeling is huge: multiple many-to-many alignments may be useful in aligning cognates in linguistic research; they may be the first necessary step for many other ensemble techniques in string transduction as we have considered (Cortes et al., 2014), and they may allow, on a large scale, to boost G2P (transliteration, lemmatization, etc.) systems by integrating them with many traditional (or modern) knowledge resources such as rule- and dictionary-based lemmatizers, crowd-sourced phonetic transcriptions (e.g., based on Wiktionary), etc., with the outlook of significantly outperforming current state-of-the-art models which are based solely on input string information.

Finally, we note that we have thus far shown that supplemental information strings may be beneficial in case of overall little training data and that improvements decrease with data size. Further investigating this relationship will be of importance. Morevoer, it will be insightful to compare the exact and approximate alignment algorithms presented here with other (heuristic) alignment methods, such as iterative pairwise alignments as employed in machine translation, and to investigate how alignment quality of multiple strings impacts overall G2P performance in the setup of additional information strings.

Abstract

In this paper, we propose a syllable-based method for tweet normalization to study the cognitive process of non-standard word creation in social media. Assuming that syllable plays a fundamental role in forming the non-standard tweet words, we choose syllable as the basic unit and extend the conventional noisy channel model by incorporating the syllables to represent the word-to-word transitions at both word and syllable levels. The syllables are used in our method not only to suggest more candidates, but also to measure similarity between words. Novelty of this work is three-fold: First, to the best of our knowledge, this is an early attempt to explore syllables in tweet normalization. Second, our proposed normalization method relies on unlabeled samples, making it much easier to adapt our method to handle non-standard words in any period of history. And third, we conduct a series of experiments and prove that the proposed method is advantageous over the state-of-art solutions for tweet normalization.

1 Introduction

Due to the casual nature of social media, there exists a large number of non-standard words in text expressions which make it substantially different from formal written text. It is reported in (Liu et al., 2011) that more than 4 million distinct out-of-vocabulary (OOV) tokens are found in the Edinburgh Twitter corpus (Petrovic et al., 2010). This variation poses challenges when performing natural language processing (NLP) tasks (Sproat et al., 2001) based on such texts. Tweet normalization, aiming at converting these OOV non-standard words into their in-vocabulary (IV) formal forms, is therefore viewed as a very important pre-processing task.

Researchers focus their studies in tweet normalization at different levels. A character-level tagging system is used in (Pennell and Liu, 2010) to solve deletion-based abbreviation. It was further extended in (Liu et al., 2012) using more characters instead of `Y` or `N` as labels. The character-level machine translation (MT) approach (Pennell and Liu, 2011) was modified in (Li and Liu, 2012a) into character-block. While a string edit distance method was introduced in (Contractor et al., 2010) to represent word-level similarity, and this orthographical feature has been adopted in (Han and Baldwin, 2011), and (Yang and Eisenstein, 2013).

Challenges are encountered in these different levels of tweet normalization. In the character-level sequential labeling systems, features are required for every character and their combinations, leading to much more noise into the later reverse table look-up process (Liu et al., 2012). In the character-block level MT systems equal number of blocks and their corresponding phonetic symbols are required for alignment (Li and Liu, 2012b). This strict restriction can result in a great difficulty in training set construction and a loss of useful information. Finally, word-level normalization methods cannot properly model how non-standard words are formed, and some patterns or consistencies within words can be omitted and altered.

We observe the cognitive process that, given non-standard words like `tmr`, people tend to first segment them into syllables like `t-m-r`. Then they will find the corresponding standard word with syllables like `to-mor-row`. Inspired by this cognitive observation, we propose a syllable based tweet normalization method, in which non-standard words are first segmented into syllables. Since we cannot predict the writers deterministic intention in using `tmr` as a segmentation of `tm-r`

(representing `tim-er`) or `t-m-r` (representing `to-mor-row`), every possible segmentation form is considered. Then we represent similarity of standard syllables and non-standard *syllables* using an exponential potential function. After every transition probabilities of standard syllable and non-standard syllable are assigned, we then use noisy channel model and Viterbi decoder to search for the most possible standard candidate in each tweet sentence.

Our empirical study reveals that syllable is a proper level for tweet normalization. The syllable is similar to character-block but it represents phonetic features naturally because every word is pronounced with syllables. Our syllable-based tweet normalization method utilizes effective features of both character- and word-level: (1) Like character-level, it can capture more detailed information about how non-standard words are generated; (2) Similar to word-level, it reduces a large amount of noisy candidates. Instead of using domain-specific resources, our method makes good use of standard words to extract linguistic features. This makes our method extendable to new normalization tasks or domains.

The rest of this paper is organized as follows: previous work in tweet normalization are reviewed and discussed in Section 2. Our approach is presented in Section 3. In Section 4 and Section 5, we provide implementation details and results. Then we make some analysis of the results in Section 6. This work is finally concluded in Section 7.

2 Related Work

Non-standard words exhibit different forms and change rapidly, but people can still figure out their original standard words. To properly model this human ability, researchers are studying what remain unchanged under this dynamic characteristic. Human normalization of an non-standard word can be as follows: After realizing the word is non-standard, people usually first figure out standard candidate words in various manners. Then they replace the non-standard words with the standard candidates in the sentence to check whether the sentence can carry a meaning. If not, they switch to a different candidate until a good one is found. Most normalization methods in existence follow the same procedure: candidates are first generated, and then put into the sentence to check whether a reasonable sentence can be formed. Differences lie in how the candidates are generated and weighted. Related work can be classified into three groups.

2.1 Orthographical similarity

Orthographical similarity is built upon the assumption that the non-standard words *look like* its standard counterparts, leading to a high *Longest Common Sequence* (LCS) and low *Edit Distance* (ED). This method is widely used in spell checker, in which the LCS and ED scores are calculated for weighting possible candidates. However, problems are that the correct word cannot always be the most *looked like* one. Taking the non-standard word `nite` for example, `note` looks more likely than the correct form `night`. To overcome this problem, an *exception dictionary* of strongly-associated word pairs are constructed in (Gouws et al., 2011). Further, these pairs are added into a unified log-linear model in (Yang and Eisenstein, 2013) and Monte Carlo sampling techniques are used to estimate parameters.

2.2 Phonetic similarity

The assumption underlying the phonetic similarity is that during transition, non-standard words *sound like* the standard counterparts, thus the pronunciation of non-standard words can be traced back to a standard dictionary. The challenge is the algorithm to annotate pronunciation of the non-standard words. Double Metaphone algorithm (Philips, 2000) is used to decode pronunciation and then to represent phonetic similarity by edit distance of these transcripts (Han and Baldwin, 2011). IPA symbols are utilized in (Li and Liu, 2012b) to represent sound of words and then word alignment-based machine translation is applied to generate possible pronunciation of non-standard words. And also, phoneme is used in (Liu et al., 2012) as one kind of features to train their CRF model.

2.3 Contextual similarity

It is accepted that after standard words are transformed into non-standard words, the meaning of a sentence remains unchanged. So the normalized standard word must carry a meaning. Most researchers use n-gram language model to normalize a sentence, and several researches use more contextual information. For example, training pairs are generated in (Liu et al., 2012) by a cosine contextual similarity formula whose items are defined by TF-IDF scheme. A bipartite graph is constructed in (Hassan and Menezes, 2013) to represent tokens (both non-standard and standard words) and their context. Thus, random walks on the graph can represent contextual-similarity between non-standard and standard words. Very recently, word-embedding (Mikolov et al., 2010; Mikolov et al., 2013) is utilized in (Li and Liu, 2014) to represent more complex contextual relationship.

In word-to-word candidate selection, most researches use orthographical similarity and phonetic similarity separately. In the log-linear model (Yang and Eisenstein, 2013), edit distance is modeled as major feature. In the character- and phone-based approaches (Li and Liu, 2012b), orthographical information and phonetic information were treated separately to generate candidates.

In (Han and Baldwin, 2011), candidates from lexical edit distance and phonemic edit distance are merged together. Then an up to 16% increasing recall was reported when adding candidates from phonetic measure. But improper processing level makes it difficult to model the two types of information simultaneously: (1) Single character can hardly reflect orthographical features of one word. (2) As fine-grained reasonable restrictions are lacked, as showed in (Han and Baldwin, 2011), several times of candidates are included when adding phonetic candidates and this will bring much more noise. To combine orthographical and phonetic measure in a fine-grained level, we proposed the syllable-level approach.

3 Approach

3.1 Framework

The framework of the proposed tweet normalization method is presented in Figure 1. The proposed method extends the basic HMM channel model (Choudhury et al., 2007; Cook and Stevenson, 2009) into syllable level. And the following four characteristics are very intersting.

(1) **Combination**: When reading a sentence, fast subvocalization will occur in our mind. In the process, some non-standard words generated by phonetic substitution are correctly pronounced and then normalized. And also, because subvocalization is fast, people tend to ignore some minor flaws in spelling intentionally or unintentionally. As this often occurs in people's real-life interacting with these social media language, we believe the combination of phonetic and orthographical information is of great significance.

(2) **Syllable level**: Inspired by Chinese normalization (Xia et al., 2006) using pinyin (phonetic transcripts of Chinese), syllable can be seen as basic unit when processing pronunciation. Different from mono-syllable Chinese words, English words can be multi-syllable; this will bring changes in our method that extra layers of syllables must be put into consideration. Thus, apart from word-based noisy-channel model, we extend it into a syllable-level framework.

(3) **Priori knowledge**: Priori knowledge is acquired from standard words, meaning that both standard syllabification and pronunciation can shed some lights to non-standard words. This assumption makes it possible to obtain non-standard syllables by standard syllabification and gain pronunciation of syllables by standard words and rules generated with them.

(4) **General patterns**: Social media language changes rapidly while labeled data is expensive thus limited. To effectively solve the problem, linguistic features instead of statistical features should be emphasized. We exploit standard words of their syllables, pronunciation and possible transition patterns and proposed the four-layer HMM-based model (see Figure 1).

In our method, non-standard words c_i are first segmented into syllables $sc_i^{(1)} \ldots sc_i^{(k)}$, and for standard syllable $sw_i^{(j)}$ mapping to non-standard syllable $sw_i^{(j)}$, we calculate their similarity by combining the orthographical and phonetic measures. Standard syllables $sw_i^{(1)} \ldots sw_i^{(k)}$ make up one standard candidates. Since candidates are generated and weighted, we can use Viterbi decoder to perform sentence normalization. Table 1 shows some possible candidates for the non-standard word `tmr`.

3.2 Method

We extend the noisy channel model to syllable-level as follows:

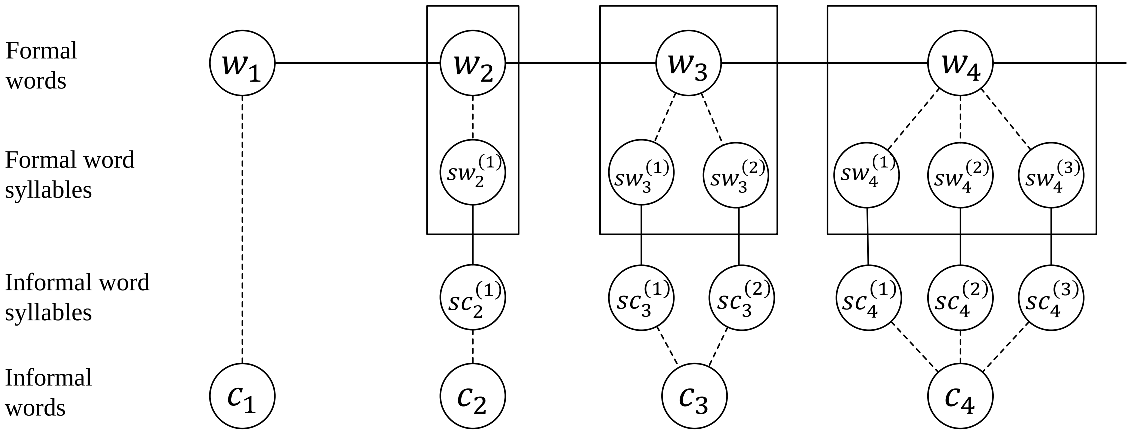

Figure 1: Framework of the propose tweet normalization method.

$$\begin{aligned} \widehat{w} &= argmax \quad p(w|c) \\ &= argmax \quad p(c|w) \times p(w) \\ &= argmax \quad p(\vec{sc}|\vec{sw}) \times p(\vec{sw}), \end{aligned} \tag{1}$$

where w indicates the standard word and c the non-standard word, and sw and sc represent their syllabic form, respectively. To simplify the problem, we restrict the number of standard syllables equals to the number of non-standard syllables in our method.

Assuming that syllables are independent of each other in transforming, we obtain:

$$p(\vec{sc}|\vec{sw}) = \prod_{j=1}^{k} p(sc_j|sw_j). \tag{2}$$

For syllable similarity, we use an exponential potential function to combine orthographical distance and phonetic distance. Because pronunciation can be represented using letter-to-phone transcripts, we can treat string similarity of these transcripts as phonetic similarity. Thus the syllable similarity can be calculated as follows.

tmr	t-mr	tm-r	t-m-r
tamer	ta-mer ti-mor ti-more tu-mor ...	tim-er tim-ber ton-er tem-per ...	to-mor-row tri-mes-ter tor-men-tor ta-ma-ra ...

Table 1: Standard candidates of *tmr* in syllable level. The first row gives the different segmentations and the second row presents the candidates.

$$p(sc_j|sw_j, \lambda) = \frac{\Phi(sc_j, sw_j)}{Z(sw_j)} \tag{3}$$

$$Z(sw_j) = \sum_{sc_j} \Phi(sc_j, sw_j) \tag{4}$$

$$\begin{aligned} \Phi(sc, sw) = exp(\lambda(LCS(sc, sw) - ED(sc, sw)) \\ +(1-\lambda)(PLCS(sc, sw) - PED(sc, sw))) \end{aligned} \tag{5}$$

Exponential function grows tremendously as its argument increases, so much more weight can be assigned if syllables are more similar. The parameter λ here is used to empirically adjust relative contribution of letters and sounds. Longest common sequence (LCS) and edit distance (ED) are used to measure orthographical similarity, while phonetic longest common sequence (PLCS) and phonetic edit distant (PED) are used to measure phonetic similarity but based on letter-to-sound transcripts. The PLCS are defined as basic LCS but PED here is slightly different.

When performing phonetic similarity calculation based on syllables, we follow (Xia et al., 2006) in treating consonant and vowels separately because transition of consonants can make a totally different pronunciation. So if consonants of sc_j and sw_j are exactly the same or fit rules listed in Table 2, $PED(sc_j, sw_j)$ equals to edit

Description	Rules	Examples
1. -ng as suffix: g-dropping	-n/-ng	do-in/do-ing, go-in/go-ing, talk-in/talk-ing, mak-in/mak-ing
2. -ng as suffix: n-dropping	-g/-ng	tak-ig/tak-ing, likig/lik-ing
3. suffix: z/s equaling	-z/-s, -s/-z	jamz/james, plz/please
4. suffix: n/m equaling	-m/-n, -n/-m	in-portant/im-portant, get-tim/get-ting
5. suffix: t/d equaling	-t/-d, -d/-t	shid/shit, shult/should
6. suffix: t-dropping	-/-t	jus/just, wha/what, mus/must, ain/ain't
7. suffix: r-dropping	-/-r	holla/holler, t-m-r/tomorrow
8. prefix: th-/d- equaling	d-/th-, th-/d-	de/the, dat/that, dats/that's, dey/they

Table 2: The consonant rules.

distance of letter-to-phone transcripts, or it will be assigned infinity to indicate that their pronunciation are so different that this transition can seldom happen. For example, as consonantal transition between suffix z and s can always happen, PED(plz,please) equals string edit distance of their transcripts. But as consonatal transition of f and d is rare, phonetic distance of fly and sky is assigned infinity. Note the consonant rules in Table 2 are manually defined in our empirical study, which represent the most commonly used ones.

3.3 Parameter

Parameter in the proposed method is only the λ in Equation (5), which represents the relative contribution of orthographical similarity and phonetic similarity. Because the limited number of annotated corpus, we have to enumerate the parameter in {0, 0.1, 0.2, ..., 1} in the experiment to find the optimal setting.

4 Implementation

The method described in the previous section are implemented with the following details.

4.1 Preprocessing

Before performing normalization, we need to process several types of non-standard words:

- **Words containing numbers**: People usually substitute some kind of sounds with numbers like 4/four, 2/two and 8/eight or numbers can be replacement of some letters like 1/i, 4/a. So we replace numbers with its words or characters and then use them to generate possible candidates.

- **Words with repeating letters**: As our method is syllable-based, repeating letters for sentiment expressing (like cooool, (Brody and Diakopoulos, 2011)) can cause syllabifying failure. For repeating letters, we reduce it to both two and one to generate candidate separately. Then the two lists are merged together to form the whole candidate list.

4.2 Letter-to-sound conversion

Syllable in this work refers to orthographic syllables. For example, we convert word tomorrow into to-mor-row. However, when comparing the syllable of a standard word and that of a non-standard word, sound (i.e., phones) of the syllables are considered. Thus letter-to-sound conversion tools are required.

Several TTS system can perform the task according to some linguistic rules, even for non-standard words. The Double Metaphone algorithm used in (Han and Baldwin, 2011) is one of them. But it uses consonants to encode a word, which gives less information than we need. In our method, we use freeTTS (Walker et al., 2002) with CMU lexicon[1] to transform words into APRAbet[2] symbols. For example, word tomorrow is transcribed to {T-UW M-AA R-OW} and tmr to {T M R}.

4.3 Dictionary preparation

- **Dictionary #1: In-vocabulary (IV) words**

  Following (Yang and Eisenstein, 2013), our set of IV words is also based on the GNU aspell dictionary (v0.60.6). Differently, we use a collection of 100 million tweets (roughly the same size of Edinburgh Twitter corpus) because the Edinburgh Twitter corpus is no longer available due to Twitter policies. The

[1] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

[2] http://en.wikipedia.org/wiki/Arpabet

final IV dictionary contains 51,948 standard words.

- **Dictionary #2: Syllables for the standard words**

  Following (Pennell and Liu, 2010), we use the online dictionary[3] to extract syllables for each standard words. We encountered same problem when accessing words with prefixes or suffixes, which are not syllabified in the same format as the base words on the website. To address the issue, we simply regard these prefixes and suffixes as syllables.

- **Dictionary #3: Pronunciation of the syllables**

  Using the CMU pronouncing dictionary (Weide, 1998) and dictionary 2, and knowing all possible APRAbet symbol for all consonant characters, we can program to capture every possible pronunciation of all syllables in the standard dictionary.

4.4 Automatic syllabification of non-standard words

Automatic syllabification of non-standard words is a supervised problem. A straightforward idea is to train a CRF model on manually labeled syllables of non-standard words. Unfortunately, such a corpus is not available and very expensive to produce.

We assume that both standard and non-standard forms follow the same syllable rules (i.e., the cognitive process). Thus we propose to train the CRF model on the corpus of syllables of standard words (which is easy to obtain) to construct an automatic annotation system based on CRF++ (Kudo, 2005). In this work, we extract syllables of standard words from Dictionary #2 as training set. Annotations follow (Pennell and Liu, 2010) to identify boundaries of syllables and in our work, CRF++ can suggest several candidate solutions, rather than an optimal segmentation solution for syllable segmentation of the non-standard words. In the HMM channel model, the candidate solutions are included as part of the search space.

4.5 Language model

Using Tweets from our corpus that contain no OOV words besides hashtags and username mentions (following (Han and Baldwin, 2011)), the Kneser-Ney smoothed tri-gram language model is estimated using SRILM toolkit (Stolcke, 2002). Note that punctuations, hashtags, and username mentions have some syntactic value (Kaufmann and Kalita, 2010) to some extent, we replace them with '<PUNCT>', '<TOPIC>' and '<USER>'.

5 Evaluation

5.1 Datasets

We use two labeled twitter datasets in existence to evaluate our tweet normalization method.

- **LexNorm1.1** contains 549 complete tweets with 1184 non-standard tokens (558 unique word type) (Han and Baldwin, 2011).

- **LexNorm1.2** is a revised version of LexNorm1.1 (Yang and Eisenstein, 2013). Some inconsistencies and errors in LexNorm1.1 are corrected and some more non-standard words are properly recovered.

In both datasets, to-be-normalized non-standard words are detected manually as well as the corresponding standard words.

5.2 Evaluation criteria

Here we use precision, recall and F-score to evaluate our method. As normalization methods on these datasets focused on the labeled non-standard words (Yang and Eisenstein, 2013), recall is the proportion of words requiring normalization which are normalized correctly; precision is the proportion of normalizations which are correct. When we perform the tweet normalization methods, every error is both a false positive and false negative, so in the task, precision equals to recall.

5.3 Sentence level normalization

We choose the following prior normalization methods:

- (Liu et al., 2012): the extended character-level CRF tagging system;

- (Yang and Eisenstein, 2013): log-linear model using string edit distance and longest common sequence measures as major features;

- (Hassan and Menezes, 2013): bipartite graph major exploit contextual similarity;

[3] http://www.dictionary.com

Method	Dataset	Precision	Recall	F-measure
(Han and Baldwin, 2011)	LexNorm 1.1	75.30	75.30	75.30
(Liu et al., 2012)		84.13	78.38	81.15
(Hassan and Menezes, 2013)		85.37	56.4	69.93
(Yang and Eisenstein, 2013)		82.09	82.09	82.09
Syllable-based method		85.30	85.30	85.30
(Yang and Eisenstein, 2013)	LexNorm 1.2	82.06	82.06	82.06
Syllable-based method		86.08	86.08	86.08

Table 3: Experiment results of the tweet normalization methods.

- (Han and Baldwin, 2011): the orthography-phone combined system using lexical edit distance and phonemic edit distance.

In our method, we set λ=0.7 because it is found best in our experiments (see Figure 2). The experimental results are presented in Table 3, which indicate that our method outperforms the state-of-the-art methods. Details on how to adjust parameter is given in Section 5.4.

Recall we argue that combination of three similarity is necessary when performing sentence-level normalization. Apart from contextual similarity like language model or graphic model, methods in (Yang and Eisenstein, 2013) or (Hassan and Menezes, 2013) do not include phonetic measure, causing loss of important phonetic information. Though using phoneme, morpheme boundary and syllable boundary as features (Liu et al., 2012), the character-level reversed approach will bring much more noise into the later reversed look-up table, and also, features of whole word are omitted.

Like (Han and Baldwin, 2011), we also use lexical measure and phonetic measure. Great difference between the two approaches is the processing level: word level and syllable level. In their work, average candidates number suffers times of increase when adding phonetic measure. This is because when introducing phonemic edit distance, important pronunciations can be altered (phonemic edit distance of `night-need` and `night-kite` is equal). Syllable level allows us to reflect consistencies during transition in a finer-grained level. Thus the phonetic similarity can be more precisely modeled.

5.4 Contributions of phone and orthography

In our method, the parameter λ in Equation 5 is used to represent the relatively contributions of both phonetic and orthographical information. But as the lack of prior knowledge, we cannot judge an optimal λ. We choose to conduct experiments varying $\lambda = \{0, 0.1, ..., 1\}$ to find out how this adjustment can affect performance. The experimental results are presented in Figure 2.

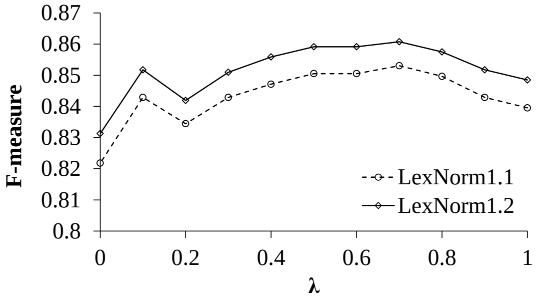

Figure 2: Contribution of phone and orthography.

As shown in Figure 2, when λ is set 0 or 1 (indicating no contribution of either orthographical or phonetic in assigning weight to candidates), our method performs much worse. In our experiment, when $\lambda = 0.7$, the models performs best, showing that orthographical measure makes relatively more contribution over phonetic measure, but the latter is indispensable. This justifies the effectiveness of combining orthographical and phonetic measure, indicating that human normalization process is properly modeled.

6 Analysis

6.1 Our exceptions

Deeper observation of our normalization results shows that there are several types of exceptions beyond our consonant-based rules. For example, `thanks` fails to be selected as a candidate for the non-standard word `thx` because the pronunciation of `thanks` contains an `N` but `thx` does not. The same situation happens when we process `stong/strong` because of the lacking `R`. We believe some more consonant should be exploited and more precisely described.

6.2 Non-standard words involving multiple syllables

There are one type of transition that we cannot solve like `acc/accelerate` and `bio/biology` because the mapping is between single-syllable word and multi-syllable word. We add possible standard syllable $sw_0^{(i)}$ and $sw_{k+1}^{(i)}$ to the head and tail of origin syllables, but this extended form failed to be assigned high probability because the string edit distances are too large. We leave this problem for further research.

6.3 Annotation issue

Though similar, our results of LexNorm1.2 is better than LexNorm1.1. After scrutinizing, we notice that several issues in LexNorm1.1 are fixed in LexNorm1.2. So our results like `meh/me` (meaning the non-standard word `meh` are corrected to `me`) in LexNorm1.1 is wrong but in LexNorm1.2 is right. Even in LexNorm1.2, there exist some inconsistencies and errors. For example, our result `buyed/bought` is wrong for both datasets, which is actually correct. For another example, `til` is normalized to `until` in some cases but to `till` in other cases. We show that the LexNorm test corpus is still imperfect. We appeal for systematic efforts to produce a standard dataset under a widely-accepted guideline.

6.4 Conventions

Social media language often contains words that are culture-specific and widely used in daily life. Some word like `congrats`, `tv` and `pic` are included into several dictionaries. We also observed several transitions like `atl/atlanta` or `wx/weather` in the datasets. These kinds of conventional abbreviations pose great difficulty to us. Normalization of those conventional non-standard words still needs further study.

7 Conclusion

In this paper, a syllable-based tweet normalization method is proposed for social media text normalization. Results on publicly available standard datasets justify our assumption that syllable plays a fundamental role in social media non-standard words. Advantage of our proposed method lies in that syllable is viewed as the basic processing unit and syllable-level similarity. This accords to the human cognition in creating and understanding the social non-standard words. Our method is domain independent. It is robust on non-standard words in any period of history. Furthermore, give the syllable transcription tool, our method can be easily adapted to a new language.

Abstract

Most previous work of text normalization on informal text made a strong assumption that the system has already known which tokens are non-standard words (NSW) and thus need normalization. However, this is not realistic. In this paper, we propose a method for NSW detection. In addition to the information based on the dictionary, e.g., whether a word is out-of-vocabulary (OOV), we leverage novel information derived from the normalization results for OOV words to help make decisions. Second, this paper investigates two methods using NSW detection results for named entity recognition (NER) in social media data. One adopts a pipeline strategy, and the other uses a joint decoding fashion. We also create a new data set with newly added normalization annotation beyond the existing named entity labels. This is the first data set with such annotation and we release it for research purpose. Our experiment results demonstrate the effectiveness of our NSW detection method and the benefit of NSW detection for NER. Our proposed methods perform better than the state-of-the-art NER system.

1 Introduction

Short text messages or comments from social media websites such as Facebook and Twitter have become one of the most popular communication forms in recent years. However, abbreviations, misspelled words and many other non-standard words are very common in short texts for various reasons (e.g., length limitation, need to convey much information, writing style). They post problems to many NLP techniques in this domain.

There are many ways to improve language processing performance on the social media data. One is to leverage normalization techniques to automatically convert the non-standard words into the corresponding standard words (Aw et al., 2006; Cook and Stevenson, 2009; Pennell and Liu, 2011; Liu et al., 2012a; Li and Liu, 2014; Sonmez and Ozgur, 2014). Intuitively this will ease subsequent language processing modules. For example, if '2mr' is converted to 'tomorrow', a text-to-speech system will know how to pronounce it, a part-of-speech (POS) tagger can label it correctly, and an information extraction system can identify it as a time expression. This normalization task has received an increasing attention in social media language processing.

However, most of previous work on normalization assumed that they already knew which tokens are NSW that need normalization. Then different methods are applied only to these tokens. To our knowledge, Han and Baldwin (2011) is the only previous work which made a pilot research on NSW detection. One straight forward method to do this is to use a dictionary to classify a token into in-vocabulary (IV) words and out-of-vocabulary (OOV) words, and just treat all the OOV words as NSW. The shortcoming of this method is obvious. For example, tokens like 'iPhone', 'PES'(a game name) and 'Xbox' will be considered as NSW, however, these words do not need normalization. Han and Baldwin (2011) called these OOV words correct-OOV, and named those OOV words that do need normalization as ill-OOV. We will follow their naming convention and use these two terms in our study. In this paper, we propose two methods to classify tokens in informal text into three classes: IV, correct-OOV, and ill-OOV. In the following, we call this task the NSW detection task, and these three labels NSW labels or classes. The novelty of our work is that we incorporate a token's normalization information to assist this clas-

and the 7th International Joint Conference on Natural Language Processing, pages 929–938,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

sification process. Our experiment results demonstrate that our proposed system gives a significant performance improvement on NSW detection compared with the dictionary baseline system.

On the other hand, the impact of normalization or NSW detection on NER has not been well studied in social media domain. In this paper, we propose two methods to incorporate the NSW detection information: one is a pipeline system that just uses the predicted NSW labels as additional features in an NER system; the other one uses joint decoding, where we can simultaneously decide a token's NSW and NER labels. Our experiment results show that our proposed joint decoding performs better than the pipeline method, and it outperforms the state-of-the-art NER system.

Our contributions in this paper are as follows: (1) We proposed a NSW detection model by leveraging normalization information of the OOV tokens. (2) We created a data set with new NSW and normalization information, in addition to the existing NER labels. (3) It is the first time to our knowledge that an effective and joint approach is proposed to combine the NSW detection and NER techniques to improve the performance of these two tasks at the same time on social media data. (4) We demonstrate the effectiveness of our proposed method. Our proposed NER system outperforms the state-of-the-art system.

2 Related Work

There has been a surge of interest in lexical normalization with the advent of social media data. Lots of approaches have been developed for this task, from using edit distance (Damerau, 1964; Levenshtein, 1966), to the noisy channel model (Cook and Stevenson, 2009; Pennell and Liu, 2010; Liu et al., 2012a) and machine translation method (Aw et al., 2006; Pennell and Liu, 2011; Li and Liu, 2012b; Li and Liu, 2012a). Normalization performance on some benchmark data has been improved a lot. Currently, unsupervised models are widely used to extract latent relationship between non-standard words and correct words from a huge corpus. Hassan and Menezes (2013) applied the random walk algorithm on a contextual similarity bipartite graph, constructed from n-gram sequences on a large unlabeled text corpus to build relation between non-standard tokens and correct words. Yang and Eisenstein (2013) presented a unified unsupervised statistical model, in which the relationship between the standard and non-standard words is characterized by a log-linear model, permitting the use of arbitrary features. Chrupała (2014) proposed a text normalization model based on learning edit operations from labeled data while incorporating features induced from unlabeled data via recurrent network derived character-level neural text embeddings.

These studies only focused on how to normalize a given ill-OOV word and did not address the problem of detecting an ill-OOV word. Han and Baldwin (2011) is the only previous study that conducted the detection work. For any OOV word, they replaced it with its possible correct candidate, then if the possible candidate together with OOV's original context adheres to the knowledge they learned from large formal corpora, the replacement could be considered as a better choice and that OOV token is classified as ill-OOV. In this paper, we propose a different method for NSW detection. Similar to (Han and Baldwin, 2011), we also use normalization information for OOV words, but we use a feature based learning approach.

In order to improve robustness of NLP modules in social media domain, some works chose to design specific linguistic information. For example, by designing or annotating POS, chunking and capitalized information on tweets, (Ritter et al., 2011) proposed a system which reduced the POS tagging error by 41% compared with Stanford POS Tagger, and by 50% in NER compared with the baseline systems. Gimpel et al. (2011) created a specific set of POS tags for twitter data. With this tag set and word cluster information extracted from a huge Twitter corpus, their proposed system obtained significant improvement on POS tagging accuracy in Twitter data.

At the same time, increasing research work has been done to integrate lexical normalization into the NLP tasks in social media data. Kaji and Kitsuregawa (2014) combined lexical normalization, word segmentation and POS tagging on Japanese microblog. They used rich character-level and word-level features from the state-of-the-art models of joint word segmentation and POS tagging in Japanese (Kudo et al., 2004; Neubig et al., 2011). Their model can also be trained on a partially annotated corpus. Li and Liu (2015) conducted a similar research on joint POS tagging and text normalization for English. Wang and Kan

(2013) proposed a method of joint ill-OOV word recognition and word segmentation in Chinese Microblog. But with their method, ill-OOV words are merely recognized and not normalized. Therefore, they did not investigate how to exploit the information that may be derived from normalization to increase word segmentation accuracy. Liu et al. (2012b) studied the problem of named entity normalization (NEN) for tweets. They proposed a novel graphical model to simultaneously conduct NER and NEN on multiple tweets. Although this work involved text normalization, it only focused on the NER task, and there was no reported result for normalization. On Turkish tweets, Kucuk and Steinberger (2014) adapted NER rules and resources to better fit Twitter language by relaxing its capitalization constraint, expanding its lexical resources based on diacritics, and using a normalization scheme on tweets. These showed positive effect on the overall NER performance. Rangarajan Sridhar et al. (2014) decoupled the SMS translation task into normalization followed by translation. They exploited bi-text resources, and presented a normalization approach using distributed representation of words learned through neural networks.

In this study, we propose new methods to effectively integrate information of OOV words and their normalization for the NER task. In particular, by adopting joint decoding for both NSW detection and NER, we are able to outperform state-of-the-art results for both tasks. This is the first study that systematically evaluates the effect of OOV words and normalization on NER in social media data.

3 Proposed Method

3.1 NSW Detection Methods

The task of NSW detection is to find those words that indeed need normalization. Note that in this study we only consider single-token ill-OOV words (both before and after normalization). For example, we would consider *snds* (*sounds*) as ill-OOV, but not *smh* (*shaking my head*).

For a data set, our annotation process is as follows. We first manually label whether a token is ill-OOV and if so its corresponding standard word. We only consider tokens consisting of *alphanumeric* characters. Then based on a dictionary, the tokes that are not labeled as ill-OOV can be categorized into IV and OOV words. These OOV words will be considered as correct-OOV. Therefore all the tokens will have these three labels: IV, ill-OOV, and correct-OOV.

Throughout this paper, we use GNU spell dictionary (v0.60.6.1) to determine whether a token is OOV.[1] Twitter mentions (e.g., @twitter), hashtags and urls are excluded from consideration for OOV. Dictionary lookup of Internet slang[2] is performed to filter those ill-OOV words whose correct forms are not single words.

We propose two methods for NSW detection. The first one is a two-step method, where we first label a token as IV or OOV based on the given dictionary and some filter rules, then a statistical classifier is applied on those OOV tokens to further decide their classes: ill-OOV or correct-OOV. We use a maximum entropy classifier for this. The second model directly does 3-way classification to predict a token's label to be IV, correct-OOV, or ill-OOV. We use a CRF model in this method.[3]

Table 1 shows the features used in these two methods. The first dictionary feature is not applicable for the two-step method because all the instances in that process have the same feature value 'OOV'. However, this dictionary feature is an important feature for the 3-way classification model – a token with a feature value 'IV' has a very high probability of being 'IV'. Lexical features focus on a token's surface information to judge whether it is a regular English word or not. It is because most of correct-OOV words (e.g., location and person names) are still some regular words, complying with the general rules of word formation. For example, features 5-8 consider English word formation rules that at least one vowel character is needed for a correct word[4]. Feature 9 considers that a correct English word does not contain more than three consecutive same character. The character level language model used in Feature 10 is trained from a dictionary. A higher probability may indicate that it is a correct word.

The motivation for the normalization features is

[1] We remove all the one-character tokens, except *a* and *I*.

[2] 5452 items are collected from http://www.noslang.com.

[3] We can also use a maximum entropy classifier to implement this model. Our experiments showed that using CRFs has slightly better results. But the main reason we adopt CRFs is because we use CRFs for NER, therefore we can easily integrate the two models in joint decoding in Section 3.2 for NER and NSW detection. We do not use CRFs in the two-step system because the labeling is performed on a subset of the words, not the entire sequence.

[4] Although some exceptions exist, this rule applies to most words.

Dictionary Feature
1. is token categorized as IV or OOV by the given dictionary (Only used in 3-way classification)
Lexical Features
2. word identity 3. whether token's first character is capitalized 4. token's length 5. how many vowel character chunks does this token have 6. how many consonant character chunks does this token have 7. the length of longest consecutive vowel character chunk 8. the length of longest consecutive consonant character chunk 9. whether this token contains more than 3 consecutive same character 10. character level probability of this token based on a character level language model
Normalization Features
11. whether each individual candidate list has any candidates for this token 12. how many candidates each individual candidate list has 13. whether each individual list's top 10 candidates contain this token itself 14. the max number of lists that have the same top one candidate 15. the similarity value between each individual normalization system's first candidate w and this token t, calculated by $\frac{longest\_common\_string(w,t)}{length(t)}$ 16. the similarity value between each individual normalization system's first candidate w and this token t, calculated by $\frac{longest\_common\_sequence(w,t)}{length(t)}$

Table 1: Features used in NSW detection system.

to leverage the normalization result of an OOV token to help its classification. Before we describe the reason why normalization information could benefit this task, we first introduce the normalization system we used. We apply a state-of-the-art normalization system proposed by (Li and Liu, 2014). Briefly, in this normalization system there are three supervised and two unsupervised subsystems for each OOV token, resulting in six candidate lists (one system provides two lists). Then a maximum entropy reranking model is adopted to combine and rerank these candidate lists, using a rich set of features. Please refer to (Li and Liu, 2014) for more details. By analyzing each individual system, we find that for ill-OOV words most normalization systems can generate many candidates, which may contain a correct candidate; for correct-OOV words, many normalization systems have few candidates or may not provide any candidates. For example, only two of the six lists have candidates for the token *Newsfeed* and *Metropcs*. Therefore, we believe the patterns of these normalization results contain useful information to classify OOVs. Note that this kind of feature is only applicable for those tokens that are judged as OOV by the given dictionary (normalization is done on these OOV words). The bottom of Table 1 shows the normalization features we designed.

3.2 NER Methods

The NER task we study in this paper is just about segmenting named entities, without identifying their types (e.g., person, location, organization). Following most previous work, we model it as a sequence-labeling task and use the BIO encoding method (each word either begins, is inside, or outside of a named entity).

Intuitively, NSW detection has an impact on NER, because many named entities may have the correct-OOV label. Therefore, we investigate if we can leverage NSW label information for NER. First, we adopt a pipeline method, where we first perform NSW detection and the results are used as features in the NER system. Table 2 shows the features we designed. One thing worth mentioning is that the POS tags we used are from (Gimpel et al., 2011). This POS tag set consists of 25 coarse-grained tags designed for social media text. We use CRFs for this NER system.

The above method simply incorporates a token's predicted NSW label as features in the NER model. Obviously it has an unavoidable limitation – the errors from the NSW detection model would affect the downstream NER process. Therefore we propose a second method, a joint decoding process to determine a token's NSW and NER label at the same time. The 3-way classification method for NSW detection and the above NER system both use CRFs. The decoding process for these two tasks is performed separately, using their corresponding trained models. The motivation of our proposed joint decoding process is to combine the two processes together, therefore we can avoid the error propagation in the pipeline system, and allow the two models to benefit from each other.

Part (A) and (B) of Figure 1 show the trellis for decoding word sequence 'Messi is well-known' in the NER and NSW detection systems respectively. As shown in (A), every black box with dashed line is a hidden state (possible BIO tag) for the corresponding token. Two sources of information are used in decoding. One is the label transition probability $p(y_i|y_j)$, from the trained model, where y_i and y_j are two BIO tags. The other is $p(y_i|t_i)$, where y_i is a BIO label for token t_i. Similarly, during decoding in NSW detection, we need the probability of $p(o_i|o_j)$ and $p(o_i|t_i)$. The only difference is that o_i is a NSW label. Part (C) of Figure 1 shows the trellis used in our proposed joint decoding approach for NSW detection and NER. In this figure, three places are worth pointing out: (1) the label is a combination of NSW and NER labels, and thus there are nine in total; (2) the label transition probability is a linear sum of the previous two transition probabilities: $p(y_i\_o_i|y_j\_o_j) = p(y_i|y_j) + \beta * p(o_i|o_j)$, where y_i and y_j are BIO tags and o_i and o_j are NSW tags; (3) similarly, $p(y_i\_o_i|t_i)$ equals to $p(y_i|t_i) + \alpha * p(o_i|t_i)$. Please note all these probabilities are log probabilities and they are trained separately from each system.

Basic Features
1. Lexical features (word n-gram): Unigram: $W_i(i = 0)$ Bigram: $W_iW_{i+1}(i = -2, -1, 0, 1)$ Trigram: $W_{i-1}W_iW_{i+1}(i = -2, -1, 0, 1)$ 2. POS features (POS n-gram): Unigram: $P_i(i = 0)$ Bigram: $P_iP_{i+1}(i = -2, -1, 0, 1)$ Trigram: $P_{i-1}P_iP_{i+1}(i = -2, -1, 0, 1)$ 3. Token's capitalization information: Trigram: $C_{i-1}C_iC_{i+1}(i = 0)$ ($C_i = 1$ means this token's first character is capitalized.)
Additional Features by Incorporating Predicted NSW Label
4. Token's dictionary categorization label: Unigram: $D_i(i = 0)$ Bigram: $D_iD_{i+1}(i = -2, -1, 0, 1)$ Trigram: $D_{i-1}D_iD_{i+1}(i = -2, -1, 0, 1)$ 5. Token's predicted NSW label: Unigram: $L_i(i = 0)$ Bigram: $L_iL_{i+1}(i = -2, -1, 0, 1)$ Trigram: $L_{i-1}L_iL_{i+1}(i = -2, -1, 0, 1)$ 6. Compound features using lexical and NSW labels: $W_iD_i, W_iL_i, W_iD_iL_i(i = 0)$ 7. Compound features using POS and NSW labels: $P_iD_i, P_iL_i, P_iD_iL_i(i = 0)$ 8. Compound features using word, POS, and NSW labels: $W_iP_iD_iL_i(i = 0)$

Table 2: Features used in the NER System. W and P represent word and POS. D and L represent labels classified by the dictionary and 3-way NSW detection system. Subscripts i, $i - 1$ and $i + 1$ indicate the word position. For example, when i equals to -1, $i + 1$ means the current word.

4 Data and Experiment

4.1 Data Set and Experiment Setup

The NSW detection model is trained using the data released by (Li and Liu, 2014). It has 2,577 Twitter messages (selected from the Edinburgh Twitter corpus (Petrovic et al., 2010)), in which there are 2,333 unique pairs of NSW and their standard words. This data is used for training the different normalization models. We labeled this data set using the given dictionary for NSW detection. 4,121 tokens are labeled as ill-OOV, 1,455 as correct-OOV, and the rest 33,740 tokens are IV words.

We have two test sets for evaluating the NSW detection system. One is from (Han and Baldwin, 2011), which includes 549 tweets. Each tweet contains at least one ill-OOV and the corresponding correct word. We call it Test set 1 in the following. The other is from (Li and Liu, 2015), who further processed the tweets data from (Owoputi et al., 2013). Briefly, Owoputi et al. (2013) released 2,347 tweets with their designed POS tags for social media text, and then Li and Liu (2015) further annotated this data with normalization information for each token. The released data by (Li and Liu, 2015) contains 798 tweets with ill-OOV. We use these 798 tweets as the second data set for NSW detection, and call it Test set 2 in the following. In addition, we use all of these 2,347 tweets to train a POS model which then is used to predict tokens' POS tags for NER (see Section 3.2 about the POS tags). The CRF model is implemented using the pocket-CRF toolkit[5]. The SRILM toolkit (Stolcke, 2002) is used to build the character-level language model (LM) for generating the LM features in NSW detection system.

[5] http://sourceforge.net/projects/pocket-crf-1/

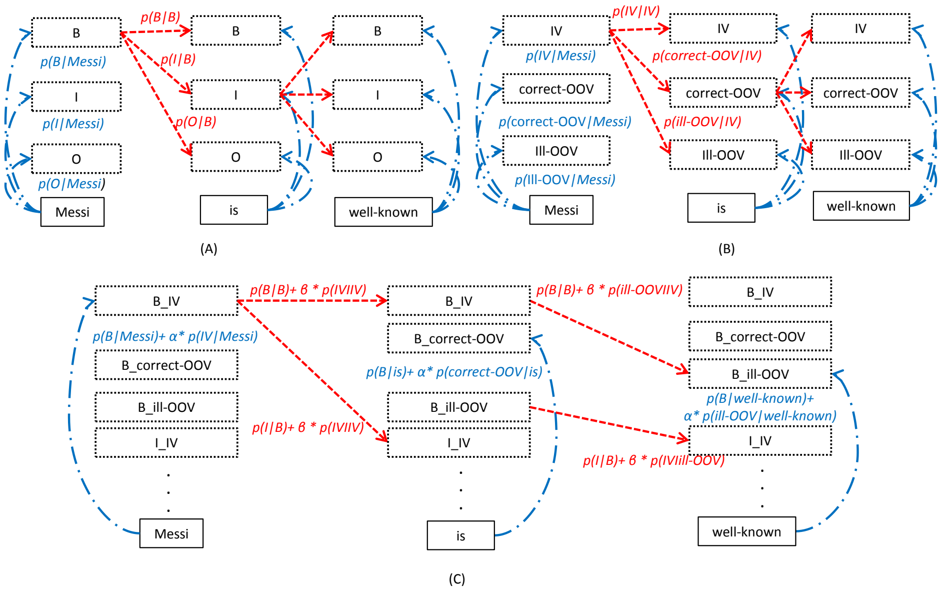

Figure 1: Trellis Viterbi decoding for different systems.

The data with the NER labels are from (Ritter et al., 2011) who annotated 2,396 tweets (34K tokens) with named entities, but there is no information on the tweets' ill-OOV words. In order to evaluate the impact of ill-OOV on NER, we ask six annotators to annotate the ill-OOV words and the corresponding standard words in this data. There are only 1,012 sentences with ill-OOV words. We use all the sentences (2,396) for the NER experiments. This data set,[6] to our knowledge, is the first one having both ill-OOV and NER annotation in social media domain. For joint decoding, the parameters α and β are empirically set as 0.95 and 0.5.

4.2 Experiment Results

4.2.1 NSW Detection Results

For NSW detection, we compared our two proposed systems on the two test sets described above, and also conducted different experiments to investigate the effectiveness of different features. We use the categorization of words by the dictionary as the baseline for this task. Table 3 shows the results for three NSW detection systems. We use Recall, Precision and F value for the ill-OOV class as the evaluation metrics. The Dictionary baseline can only recognize the token as IV and OOV, and thus label all the OOV words as ill-OOV. Both the two-step and the 3-way classification methods in Table 3 leverage all the features described in Table 1. First note because of the property of the two-step method (it further divides the OOV words from the dictionary-based method into ill-OOV and correct-OOV), the upper bound of its recall is the recall of the dictionary based method. We can see that in Test set 1, both the two-step and the 3-way classification methods have a significant improvement compared to the Dictionary method. However, in Test set 2, the two-step method performs much worse than that of the 3-way classification method, although it outperforms the dictionary method. This can be attributed to the characteristics of that data set and also the system's upper bounded recall. We will provide a more detailed analysis in the following feature analysis part.

Table 4 and 5 show the performance of the two systems on the two test sets with different features. Note that the dictionary feature is not applicable to the two-step method, and the results for the two-step method using dictionary feature (feature 1, first line in the tables) are the same as the dictionary baseline in Table 3. From these two tables, we can see that: (1) For both systems, normalization features (11∼16) and lexical features (2∼10) both perform better than the dictionary feature. (2) In general, the combination of any two kinds of features has better performance than any one feature type. Using all the features (results shown in Table 3) yields the best performance, which significantly improves the performance compared with the baseline. (3) There are some differences across

[6] http://www.hlt.utdallas.edu/∼chenli/normalization_ner

the two data sets in terms of the feature effectiveness on the two methods. On Test set 2, when lexical features are combined with other features (forth and fifth line of Table 5), the 3-way classification method significantly outperforms the two-step method. It is because this data set has a large number of ill-OOV words that are dictionary words. For example, token 'its' appears 31 times as ill-OOV, 'ya' 13 times, and 'bro' 10 times. Such ill-OOV words occur more than two hundred times in total. Since these tokens are included in the dictionary, they are already classified as IV by the dictionary, and their label will not change in the second step. This is also the reason why in Table 3, the performance of 3-way classification is significantly better than that of the two-step method using all the features. However, we also find that when we only use lexical features (2∼10), the two methods have similar performance on Test set 2, but the two-step method has much better performance than the 3-way classifier method on Test set 1. We believe this shows that lexical features themselves are not reliable for the NSW detection task, and other information such as normalization features may be more stable.

System	Test Set 1			Test Set 2		
	R	P	F	R	P	F
Dictionary	88.73	72.35	79.71	67.87	69.59	68.72

4.2.2 NER Results

For the NER task, in order to make a fair comparison with (Ritter et al., 2011), we conducted 4-fold cross validation experiments as they did. First we present the result on the NSW detection task on this date set when using our proposed joint decoding method integrating NER and NSW. This is done using the 1,012 sentences that contain ill-OOV words. Table 6 shows such results on the NER data described in Section 4.1. The 3-way classification method for NSW detection is used as a baseline here. It is the same model as used in the previous section, and applied to the entire NER data. For each cross validation experiment of the joint decoding method, the NSW detection model is kept the same (from 3-way classification method), but NER model is tested on 1/4 of the data and trained from the remaining 3/4 of the data. From the Table 6, we can see that joint decoding yields some marginal improvement for the NSW detection task.

Features	Two-Step			3-way Classification		
	R	P	F	R	P	F
1	67.86	69.59	68.72	66.45	64.27	65.34
2∼10	64.33	79.52	71.12	69.56	76.26	72.76

1,11∼16	56.40	92.35	70.03	56.68	92.81	70.38

Table 5: Feature impact on NSW detection on Test Set 2.

System	R	P	F
3-way classification	58.65	72.83	64.97
Joint decoding w all features	59.53	72.96	**65.56**

Table 6: NSW detection results on the data from (Ritter et al., 2011) with our new NSW annotation.

In the following, we will focus on the impact of NSW detection on NER. Table 7 shows the NER performance from different systems on the data with NER and NSW labels. From this table, we can see that when using our pipeline system, adding NSW label features has a significant improvement compared to the basic features. The F value of 67.4% when using all the features is even higher than the state-of-the-art performance from (Ritter et al., 2011). Please note that Ritter et al. (2011) used much more information than us for this task, such as dictionaries including a set of type lists gathered from Freebase, brown clusters, and outputs of their specifically designed chunk and capitalization labels components[7]. Then they

[7] The chunk and capitalization components are specially created by them for social media domain data. Then they created a data set to train these models.

improved their baseline performance from 65% to the reported best one at 67%. However, we only added our predicted NSW labels and related features, and we already achieved similar or slightly better results. Using joint decoding can further boost the performance to 69%.

System	R	P	F
Pipeline w basic features	55.85	74.33	63.76
Pipeline w all features	60.00	77.09	67.40
Joint decoding w all features	73.56	65.02	**69.00**
(Ritter et al., 2011)	73.00	61.00	67.00

Table 7: NER results from different systems on data from (Ritter et al., 2011).

Table 8 shows the impact of different features. This analysis is based on the pipeline system. First, we can see that adding feature 4 and 5 (Uni-, Bi- and Tri-gram of the dictionary and predicted NSW labels) yields the most improvement compared with other features, and between these two kinds of features, using predicted NSW labels is better than the dictionary labels. It also shows the effectiveness of our NSW detection system. Second, comparing adding feature 6 and 7, it shows that combination of word/POS and its dictionary or NSW label is not as good as only considering the label's n-gram. We also explored various other n-gram features, but did not find any that outperformed feature 4 or 5. Another finding is that the POS related features are not as good as that of words.

Features	R	P	F
Basic	55.85	74.33	63.76
Basic + 4	57.71	75.04	65.23
Basic + 5	57.47	75.87	65.37
Basic + 6	56.53	74.20	64.12
Basic + 7	56.13	74.66	64.06
Basic + 8	57.14	74.55	64.66

Table 8: Pipeline NER performance using different features. The feature number corresponds to that in Table 2.

4.2.3 Error Analysis

A detailed error analysis further shows what improvement our proposed method makes and what errors it is still making. For example, for the tweet *'Watching the VMA pre-show again ...'*, the token *VMA* is annotated as *B-tvshow* in NER labels. Without using predicted NSW labels, the baseline system labels this token as *O* (outside of named entity). However, after using the NSW predicted label *correct-OOV* and related features, the pipeline NER system predicts its label as *B*. We noticed that joint decoding can solve some complicated cases that are hard for the pipeline system, especially for some OOVs, or when there are consecutive named entity tokens. For example, in a tweet, *'Let's hope the Serie A continues to be on the tv schedule next week'*, *Seria A* is a proper noun (meaning Italian soccer league). The annotation for *Seria* and *A* is correct-OOV/*B* and IV/*I*. We find the joint decoding system successfully labels *A* as *I* after *Seria* is labeled as *B*. However, the pipeline system labels *A* as *O* even it correctly labels *Seria*. Take another example, in a tweet *'I was gonna buy a Zune HD ...'*, *Zune HD* is consecutive named entities. The pipeline system recognized *Zune* as correct-OOV and *HD* as ill-OOV, then labeled both them as *O*. But the joint decoding system identified *HD* as correct-OOV and labeled *'Zune HD'* as *B* and *I*. These changes may have happened because of adjusting the transition probability and observation probability during Viterbi decoding.

5 Conclusion and Future Work

In this paper, we proposed an approach to detect NSW. This makes the lexical normalization task as a complete applicable process. The proposed NSW detection system leveraged normalization information of an OOV and other useful lexical information. Our experimental results show both kinds of information can help improve the prediction performance on two different data sets. Furthermore, we applied the predicted labels as additional information for the NER task. In this task, we proposed a novel joint decoding approach to label every token's NSW and NER label in a tweet at the same time. Again, experimental results demonstrate that the NSW label has a significant impact on NER performance and our proposed method improves performance on both tasks and outperforms the best previous results in NER.

In future work, we propose to pursue a number of directions. First, we plan to consider how to conduct NSW detection and normalization at the same time. Second, we like to try a joint method to simultaneously train the NSW detection and NER models, rather than just combining models in decoding. Third, we want to investigate the impact of NSW and normalization on other NLP tasks such as parsing in social media data.

Abstract

Many high level natural language processing problems can be framed as determining if two given sentences are a rewriting of each other. In this paper, we propose a class of kernel functions, referred to as type-enriched string rewriting kernels, which, used in kernel-based machine learning algorithms, allow to learn sentence rewritings. Unlike previous work, this method can be fed external lexical semantic relations to capture a wider class of rewriting rules. It also does not assume preliminary syntactic parsing but is still able to provide a unified framework to capture syntactic structure and alignments between the two sentences. We experiment on three different natural sentence rewriting tasks and obtain state-of-the-art results for all of them.

1 Introduction

Detecting implications of sense between statements stands as one of the most sought-after goals in computational linguistics. Several high level tasks look for either one-way rewriting between single sentences, like recognizing textual entailment (RTE) (Dagan et al., 2006), or two-way rewritings like paraphrase identification (Dolan et al., 2004) and semantic textual similarity (Agirre et al., 2012). In a similar fashion, selecting sentences containing the answer to a question can be seen as finding the best rewritings of the question among answer candidates. These problems are naturally framed as classification tasks, and as such most current solutions make use of supervised machine learning. They have to tackle several challenges: picking an adequate language representation, aligning semantically equivalent elements and extracting relevant features to learn the final decision. Bag-of-words and by extension bag-of-ngrams are traditionally the most direct approach and features rely mostly on lexical matching (Wan et al., 2006; Lintean and Rus, 2011; Jimenez et al., 2013). Moreover, a good solving method has to account for typically scarce labeled training data, by enriching its model with lexical semantic resources like WordNet (Miller, 1995) to bridge gaps between surface forms (Mihalcea et al., 2006; Islam and Inkpen, 2009; Yih et al., 2013). Models based on syntactic trees remain the typical choice to account for the structure of the sentences (Heilman and Smith, 2010; Wang and Manning, 2010; Socher et al., 2011; Calvo et al., 2014). Usually the best systems manage to combine effectively different methods, like Madnani et al.'s meta-classifier with machine translation metrics (Madnani et al., 2012).

A few methods (Zanzotto et al., 2007; Zanzotto et al., 2010; Bu et al., 2012) use kernel functions to learn what makes two sentence pairs similar. Building on this work, we present a type-enriched string rewriting kernel giving the opportunity to specify in a fine-grained way how words match each other. Unlike previous work, rewriting rules learned using our framework account for syntactic structure, term alignments and lexico-semantic typed variations in a unified approach. We detail how to efficiently compute our kernel and lastly experiment on three different high-level NLP tasks, demonstrating the vast applicability of our method. Our system based on type-enriched string rewriting kernels obtains state-of-the-art results on paraphrase identification and answer sentence selection and outperforms comparable methods on RTE.

2 Type-Enriched String Rewriting Kernel

Kernel functions measure the similarity between two elements. Used in machine learning methods

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 939–949,
Beijing, China, July 26-31, 2015.

like SVM, they allow complex decision functions to be learned in classification tasks (Vapnik, 2000). The goal of a well-designed kernel function is to have a high value when computed on two instances of same label, and a low value for two instances of different label.

2.1 String rewriting kernel

String rewriting kernels (Bu et al., 2012) count the number of common rewritings between two pairs of sentences seen as sequences of words. The rewriting rule (A) in Figure 1 can be viewed as a kind of phrasal paraphrase with linked variables (Madnani and Dorr, 2010). Rule (A) rewrites (B)'s first sentence into its second but it does not however rewrite the sentences in (C), which is what we try to fix in this paper.

Following the terminology of string kernels, we use the term *string* and *character* instead of *sentence* and *word*. We denote $(s,t) \in (\Sigma^* \times \Sigma^*)$ an instance of string rewriting, with a source string s and a target string t, both finite sequences of elements in Σ the finite set of characters. Suppose that we are given training data of such instances labeled in $\{+1, -1\}$, for paraphrase/non-paraphrase or entailment/non-entailment in applications. We can use a kernel method to train on this data and learn to automatically classify unlabeled instances. A kernel on string rewriting instances is a map:

$$K : (\Sigma^* \times \Sigma^*) \times (\Sigma^* \times \Sigma^*) \to \mathbb{R}$$

such that for all $(s_1,t_1),(s_2,t_2) \in \Sigma^* \times \Sigma^*$,

$$K((s_1,t_1),(s_2,t_2)) = \langle \Phi(s_1,t_1), \Phi(s_2,t_2) \rangle \quad (1)$$

where Φ maps each instance into a high dimension feature space. Kernels allow us to avoid the potentially expensive explicit representation of Φ through the inner product space they define. The purpose of the string rewriting kernels is to measure the similarity between two pairs of strings in term of the number of rewriting rules of a set R that they share. Φ is thus naturally defined by $\Phi(s,t) = (\phi_r(s,t))_{r\in R}$ with $\phi_r(s,t) = n$ the number of contiguous substring pairs of (s,t) that rewriting rule r matches.

2.2 Typed rewriting rules

Let the wildcard domain $D \subseteq \Sigma^*$ be the set of strings which can be replaced by wildcards. We now present the formal framework of the type-enriched string rewriting kernels.

Let Γ_p be the set of *pattern types* and Γ_v the set of *variable types*.

To a type $\gamma_p \in \Gamma_p$, we associate the *typing relation* $\overset{\gamma_p}{\approx} \subseteq \Sigma \times \Sigma$.

To a type $\gamma_v \in \Gamma_v$,we associate the *typing relation* $\overset{\gamma_v}{\rightsquigarrow} \subseteq D \times D$.

Together with the typing relations, we call the association of Γ_p and Γ_v the *typing scheme* of the kernel. Let Σ_p be defined as

$$\Sigma_p = \bigcup_{\gamma\in\Gamma} \{[a|b] \mid \exists a,b \in \Sigma, a \overset{\gamma}{\approx} b\} \quad (2)$$

We finally define typed rewriting rules. A *typed rewriting rule* is a triple $r = (\beta_s, \beta_t, \tau)$, where $\beta_s, \beta_t \in (\Sigma_p \cup \{*\})^*$ denote source and target string typed patterns and $\tau \subseteq ind_*(\beta_s) \times ind_*(\beta_t)$ denotes the alignments between the wildcards in the two string patterns. Here $ind_*(\beta)$ denotes the set of indices of wildcards in β.

We say that a rewriting rule (β_s, β_t, τ) *matches* a pair of strings (s,t) if and only if the following conditions are true:

- string patterns β_s, resp. β_t, can be turned into s, resp. t, by:
  - substituting each element $[a|b]$ of Σ_p in the string pattern with an a or b ($\in \Sigma$)
  - substituting each wildcard in the string pattern with an element of the wildcard domain D
- $\forall(i,j) \in \tau$, s, resp. t, substitutes the wildcards at index i, resp. j, by $s_* \in D$, resp. t_*, such that there exists a variable type $\gamma \in \Gamma_v$ with $s_* \overset{\gamma}{\rightsquigarrow} t_*$.

A *type-enriched string rewriting kernel* (TESRK) is simply a string rewriting kernel as defined in Equation 1 but with R a set of typed rewriting rules. This class of kernels depends on wildcard domain D and the typed rewriting rules R which can be tuned to allow for more flexibility in the matching of pairs of characters in a rewriting rule. Within this framework, the k-gram bijective string rewriting kernel (kb-SRK) is defined by the wildcard domain $D = \Sigma$ and the ruleset

$$R = \{(\beta_s, \beta_t, \tau) \mid \beta_s, \beta_t \in (\Sigma_p \cup \{*\})^k, \tau \text{ bijective}\}$$

under $\Gamma_p = \Gamma_v = \{id\}$ with $a \overset{id}{\approx} b$, resp. $a \overset{id}{\rightsquigarrow} b$, if and only if $a = b$.

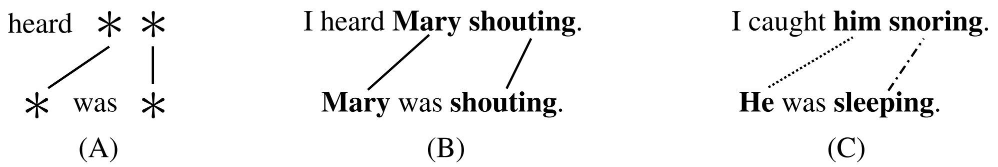

Figure 1: Rewriting rule (A) matches pair of strings (B) but does not match (C).

We now present an example of how kb-SRK is applied to real pairs of sentences, what its limitations are and how we can deal with them by reworking its typing scheme. Let us consider again Figure 1, (A) is a rewriting rule with $\beta_s =$ (*heard*, $*$, $*$), $\beta_t =$ ($*$, *was*, $*$), $\tau = \{(2,1);(3,3)\}$. Each string pattern has the same length, and pairs of wildcards in the two patterns are aligned bijectively. This is a valid rule for kb-SRK. It matches the pair of strings (B): each aligned pair of wildcards is substituted in source and target sentences by the same word and string patterns of (A) can indeed be turned into pairs of substrings of the sentences. However, it cannot match the pair of sentences (C) in the original kb-SRK. We change Γ_p to $\{$hypernym, id$\}$ where $a \overset{hypernym}{\approx} b$ if and only if a and b have a common hypernym in WordNet. And we change Γ_v to $\Gamma_v = \{$same_pronoun, entailment, id$\}$ where $a \overset{same\_pronoun}{\rightsquigarrow} b$ if and only if a and b are a pronoun of the same person and same number, and $a \overset{entailment}{\rightsquigarrow} b$ if and only if verb a has a relation of entailment with b in WordNet.
By redefining the typing scheme, rule (A) can now match (C).

3 Computing TESRK

3.1 Formulation

The k-gram bijective string rewriting kernel can be computed efficiently (Bu et al., 2012). We show that we can compute its type-enriched equivalent at the price of a seemingly insurmountable loosening of theoretical complexity boundaries. Experiments however show that its computing time is of the same order as the original kernel.
A type-enriched kb-SRK is parameterized by k the length of k-grams, and its typing scheme the sets Γ_p and Γ_v and their associated relations. The annotations of Γ_p and Γ_v to K_k and $\bar{K}_k$ will be omitted for clarity and because they typically will not change while we test different values for k.
We rewrite the inner product in Equation 1 to better fit the k-gram framework:

$$K_k((s_1,t_1),(s_2,t_2)) = \sum_{\substack{\alpha_{s_1}\in\text{k-grams}(s_1)\\ \alpha_{t_1}\in\text{k-grams}(t_1)}} \sum_{\substack{\alpha_{s_2}\in\text{k-grams}(s_2)\\ \alpha_{t_2}\in\text{k-grams}(t_2)}} \bar{K}_k((\alpha_{s_1},\alpha_{t_1}),(\alpha_{s_2},\alpha_{t_2})) \qquad (3)$$

where $\bar{K}_k$ is the number of different rewriting rules which match two pairs of k-grams (the same rule cannot trigger twice in k-gram substrings):

$$\bar{K}_k((\alpha_{s_1},\alpha_{t_1}),(\alpha_{s_2},\alpha_{t_2})) = \sum_{r\in R} \mathbb{1}_r(\alpha_{s_1},\alpha_{t_1})\mathbb{1}_r(\alpha_{s_2},\alpha_{t_2}) \qquad (4)$$

with $\mathbb{1}_r$ the indicator function of rule r: 1 if r matches the pair of k-grams, 0 otherwise.
Computing K_k as defined in Equation 3 is obviously intractable. There is $\mathcal{O}((n-k+1)^4)$ terms in the sum, where n is the length of the longest string, and each term involves enumerating every rewriting rule in R.

3.2 Computing $\bar{K}_k$ in type-enriched kb-SRK

Enumerating all rewriting rules in Equation 4 is itself intractable: there are more than $|\Sigma|^{2k}$ rules without wildcards, where $|\Sigma|$ is conceivably the size of a typical lexicon. In fact, we just have to constructively generate the rules which substitute their string patterns correctly to simultaneously produce both pairs of k-grams $(\alpha_{s_1},\alpha_{t_1})$ and $(\alpha_{s_2},\alpha_{t_2})$.

Let the operator $\otimes$ be such that $\alpha_1 \otimes \alpha_2 = ((\alpha_1[1],\alpha_2[1]),...,(\alpha_1[k],\alpha_2[k]))$. This operation is generally known as *zipping* in functional programming. We use the function *CountPerfectMatchings* computed by Algorithm 1 to recursively count the number of rewriting rules matching both $(\alpha_{s_1},\alpha_{t_1})$ and $(\alpha_{s_2},\alpha_{t_2})$. The workings of the algorithm will make clearer why we can compute $\bar{K}_k$ with the following formula:

$$\bar{K}_k((\alpha_{s_1},\alpha_{t_1}),(\alpha_{s_2},\alpha_{t_2})) = \text{CountPerfectMatchings}(\alpha_{s_1}\otimes\alpha_{s_2},\alpha_{t_1}\otimes\alpha_{t_2}) \qquad (5)$$

Algorithm 1: Counting perfect matchings

```
1  CountPerfectMatchings(remS, remT)
   Data: remS: remaining char. pairs in source
   remT: remaining char. pairs in target
   graph: $\alpha_{s_1} \otimes \alpha_{s_2}$ and $\alpha_{t_1} \otimes \alpha_{t_2}$ as a bipartite
   graph, not added in the arguments to avoid
   cluttering the recursive calls
   ruleSet: $\Gamma_p$ and $\Gamma_v$
   Result: Number of rewriting rules matching
           $(\alpha_{s_1}, \alpha_{t_1})$ and $(\alpha_{s_2}, \alpha_{t_2})$
2  if remS == $\emptyset$ and remT == $\emptyset$ then
3      return 1;
4  else if remS == $\emptyset$ then
5      $(b_1, b_2)$ = remT.first();
6      if $\exists \gamma \in \Gamma_p \mid b_1 \overset{\gamma}{\approx} b_2$ then
7          return CountPerfectMatchings($\emptyset$,
           remT - $\{(b_1, b_2)\}$);
8      else
9          return 0;
10 else
11     result = 0;
12     $(a_1, a_2)$ = remS.first();
13     if $\exists \gamma \in \Gamma_p \mid a_1 \overset{\gamma}{\approx} a_2$ then
14         res += CountPerfectMatchings(remS -
           $\{(a_1, a_2)\}$, remT);
15     for $(b_1, b_2) \in$ remT
16       $\mid \exists \gamma \in \Gamma_v \mid a_1 \overset{\gamma}{\rightsquigarrow} b_1$ and $a_2 \overset{\gamma}{\rightsquigarrow} b_2$ do
17         res += CountPerfectMatchings(
18             remS - $\{(a_1, a_2)\}$,
19             remT - $\{(b_1, b_2)\}$
20         );
```

Algorithm 1 takes as input remaining character pairs in $\alpha_{s_1} \otimes \alpha_{s_2}$ and $\alpha_{t_1} \otimes \alpha_{t_2}$, and outputs the number of ways they can substitute aligned wildcards in a matching rule.

First (lines 2 and 3) we have the base case where both remaining sets are empty. There is exactly 1 way the empty set's wildcards can be aligned with each other: nothing is aligned. In lines 4 to 9, there is no source pairs anymore, so the algorithm continues to deplete target pairs as long as they have a common pattern type, i.e. as long as they do not have to substitute a wildcard. If a candidate wildcard is found, as the opposing set is empty, we cannot align it and we return 0. In the general case (lines 11 to 19), consider the first character pair (a_1, a_2) in the reminder of $\alpha_{s_1} \otimes \alpha_{s_2}$ in line 12. What follows in the computation depends on its types. Every character pair in $\alpha_{t_1} \otimes \alpha_{t_2}$ that can be paired through variable types with (a_1, a_2) (lines 15 to 19) is a new potential wildcard alignment, so we try all the possible alignment and recursively continue the computation after removing both aligned pairs. And if (a_1, a_2) does not need to substitute a wildcard because it has common pattern types (lines 13 and 14), we can choose to not create any wildcard pairing with it and ignore it in the recursive call.

This algorithm enumerates all configurations such that each character pair has a common pattern type or is matched 1-for-1 with a character pair with common variable types, which is exactly the definition of a rewriting rule in TESRK.

This problem is actually equivalent to counting the perfect matchings of the bipartite graph of potential wildcards. It has been shown intractable (Valiant, 1979) and Algorithm 1 is a naive recursive algorithm to solve it. In our implementation we represent the graph with its biadjacency matrix, and if our typing relations are independent of k, the function has a $\mathcal{O}(k)$ time complexity without including its recursive calls. The number of recursive calls can be greater than $k!^2$ which is the number of perfect matchings in a complete bipartite graph of $2k$ vertices. In our experiments on linguistic data however, we observed a linear number of recursive calls for low values of k, and up to a quadratic number for $k > 10$ –which is way past the point where the kernel becomes ineffective.

As an example, Figure 2 shows the zipped k-grams for source and target as a bipartite graph with $2k$ vertices and potential wildcard edges. Assuming that vertices (a, a) and (b, b') have common pattern types, they can be ignored as in lines 7 and 14. (c_1, c_2) to (f_1, f_2) however must substitute wildcards in a matching rewriting rule. If we align (c_1, c_2) with (e_1, e_2) in line 16, the recursive call will return 0 because the other two pairs cannot be aligned. A valid rule is generated if c's are paired with f's and d's with e's. This kind of choices is the main source of computational cost.

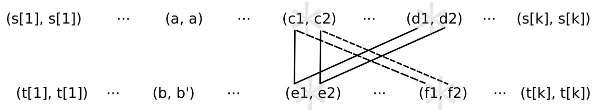

Figure 2: Bipartite graph of character pairs, with edges between potential wildcards

This problem did not arise in the original kb-SRK because of the transitivity of its only type (*identity*). In type-enriched kb-SRK, wildcard pairing is less constrained.

3.3 Computing K_k

Even with an efficient method for computing $\bar{K}_k$, implementing K_k directly by applying Equation 3 remains impractical. The main idea is to efficiently compute a reasonably sized set $\mathbb{C}$ of elements $((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2}))$ which has the essential property of including all elements such that $\bar{K}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2})) \neq 0$.
By definition of $\mathbb{C}$, we can compute efficiently

$$K_k((s_1, t_1), (s_2, t_2)) = \sum_{((\alpha_{s_1}, \alpha_{s_2}), (\alpha_{t_1}, \alpha_{t_2})) \in \mathbb{C}} \bar{K}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2})) \quad (6)$$

There are a number of ways to do it, with a trade-off between computation time and number of elements in the reduced domain $\mathbb{C}$. The main idea of our own algorithm is that $\bar{K}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2})) = 0$ if the character pairs $(a_1, a_2) \in \alpha_{s_1} \otimes \alpha_{s_2}$ with no common pattern type are not **all** matched with pairs $(b_1, b_2) \in \alpha_{t_1} \otimes \alpha_{t_2}$ such that $a_1 \overset{\gamma}{\rightsquigarrow} b_1$ and $a_2 \overset{\gamma}{\rightsquigarrow} b_2$ for some $\gamma \in \Gamma_v$. This is conversely true for character pairs in $\alpha_{t_1} \otimes \alpha_{t_2}$ with no common pattern type. More simply, character pairs with no common pattern type are mismatched and have to substitute a wildcard in a rewriting rule matching both $(\alpha_{s_1}, \alpha_{t_1})$ and $(\alpha_{s_2}, \alpha_{t_2})$. But introducing a wildcard on one side of the rule means that there is a matching wildcard on the other side, so we can eliminate k-gram quadruples that do not fill this wildcard inclusion. This filtering can be done efficiently and yields a manageable number of quadruples on which to compute $\bar{K}_k$.

Algorithm 2 computes a set $\mathbb{C}$ to be used in Equation 6 for computing the final value of kernel K_k. In our experiments, it efficiently produces a reasonable number of inputs. All maps in the algorithm are maps to multisets, and multisets are used extensively throughout. *Multisets* are an extension of sets where elements can appear multiple times, the number of times being called the *multiplicity*. Typically implemented as hash tables from set elements to integers, they allow for constant-time retrieval of the number of a given element. Union ($\cup$) and intersection ($\cap$) have special definitions on multisets. If $\mathbb{1}_A(x)$ is the multiplicity of x in A, we have $\mathbb{1}_{A \cup B}(x) = max(\mathbb{1}_A(x), \mathbb{1}_B(x))$ and $\mathbb{1}_{A \cap B}(x) = min(\mathbb{1}_A(x), \mathbb{1}_B(x))$.

Algorithm 2: Computing a set including all elements on which $\bar{K}_k \neq 0$

```
   Data: $s_1, t_1, s_2, t_2$ strings, and $k$ an integer
   Result: Set $\mathbb{C}$ which include all inputs such
           that $\bar{K}_k \neq 0$
1  Initialize maps $e^i_{s \to t}$ and maps $e^i_{t \to s}$, for
   $i \in \{1, 2\}$;
2  for $i \in \{1, 2\}$ do
3      for $a \in s_i, b \in t_i \mid a \overset{\gamma}{\rightsquigarrow} b, \gamma \in \Gamma_v$ do
4          $e^i_{s \to t}[a]$ += $(b, \gamma)$; $e^i_{t \to s}[b]$ += $(a, \gamma)$;
5  $w_{s \to t}, aP_t =$
   OneWayInclusion($s_1, s_2, t_1, t_2, e^1_{s \to t}, e^2_{s \to t}$);
6  $w_{t \to s}, aP_s =$
   OneWayInclusion($t_1, t_2, s_1, s_2, e^1_{t \to s}, e^2_{t \to s}$);
7  Initialize multiset res;

```

Let us now comment on how the algorithm unfolds. In lines 1 to 4, we index characters in source strings by characters in target strings which have common variable types, and vice versa. It allows in lines 15 to 19 to quickly map a character pair to the set of opposing k-gram pairs with a matching –in the sense of variable types– character pair, i.e. potential aligned wildcards. In lines 20 to 28 we keep only the k-gram quadruples whose wildcard candidates (character pairs with no common pattern) from one side **all** find matches on the other side. We do not check for the other inclusion, hence the name of the function *OneWayInclusion*. At line 26, we did not find any character pair with no common pattern, so we save the k-gram pair as "all-pattern". All-pattern k-grams will be paired in lines 8 to 10 in the result. Finally, in line 11, we add the union of one-way compatible k-gram quadruples; calling swap on all the pairs of one set is necessary to consistently have sources on the left side and targets on the right side in the result.

4 Experiments

4.1 Systems

We experimented on three tasks: paraphrase identification, recognizing textual entailment and answer sentence selection. The setup we used for all experiments was the same save for the few parameters we explored such as: k, and typing scheme. We implemented 2 kernels, kb-SRK, henceforth simply denoted *SRK*, and the type-enriched kb-SRK, denoted *TESRK*. All sentences were tokenized and POS-tagged using OpenNLP (Morton et al., 2005). Then they were stemmed using the Porter stemmer (Porter, 2001) in the case of SRK. Various other pre-processing steps were applied in the case of TESRK: they are considered as types in the model and are detailed in Table 1. We used LIBSVM (Chang and Lin, 2011) to train a binary SVM classifier on the training data with our two kernels. The default SVM algorithm in LIBSVM uses a parameter C, roughly akin to a regularization parameter. We 10-fold cross-validated this parameter on the training data, optimizing with a grid search for f-score, or MRR for question-answering. All kernels were normalized using $\tilde{K}(x,y) = \frac{K(x,y)}{\sqrt{K(x,x)}\sqrt{K(y,y)}}$. We denote by "+" a sum of kernels, with normalizations applied both before and after summing. Following Bu et al. (Bu et al., 2012) experimental setup, we introduced an auxiliary vector kernel denoted *PR* of features named *unigram precision* and *recall*, defined in (Wan et al., 2006). In our experiments a linear kernel seemed to yield the best results. Our Scala implementation of kb-SRKs has an average throughput of about 1500 original kb-SRK computations per second, versus 500 type-enriched kb-SRK computations per second on a 8-core machine. It typically takes a few hours on a 32-core machine to train, cross-validate and test on a full dataset.

Finally, Table 1 presents an overview of our types with how they are defined and implemented. Every type can be used both as a pattern type or as a variable type, but the two roles are different. Pattern types are useful to unify different surface forms of rewriting rules that are semantically equivalent, i.e. having semantically similar patterns. Variable types are useful for when the semantic relation between 2 entities across the same rewriting is more important than the entities themselves. That is why some types in Table 1 are inherently more fitted to be used for one role rather than the other. For example, it is unlikely that replacing a word in a pattern of a rewriting rule by one of its holonyms will yield a semantically similar rewriting rule, so *holonym* would not be a good pattern type for most applications. On the contrary, it can be very useful in a rewriting rule to type a wildcard link with the relation holonym, as this provides constrained semantic roles to the linked wildcards in the rule, thus *holonym* would be a good variable type.

4.2 Paraphrase identification

Paraphrase identification asks whether two sentences have the same meaning. The dataset we used to evaluate our systems is the MSR Paraphrase Corpus (Dolan and Brockett, 2005), containing 4,076 training pairs of sentences and 1,725 testing pairs. For example, the sentences *"An injured woman co-worker also was hospitalized and was listed in good condition."* and *"A woman was listed in good condition at Memorial's HealthPark campus, he said."* are paraphrases in this corpus. On the other hand, *"'There are a number of locations in our community, which are essentially vulnerable,' Mr Ruddock said."* and *"'There are a range of risks which are being seriously examined by competent authorities,' Mr Ruddock said."* are not paraphrases.

We report in Table 2 our best results, the system *TESRK + PR*, defined by the sum of PR and typed-enriched kb-SRKs with k from 1 to 4, with types $\Gamma_p = \Gamma_v = \{stem, synonym\}$. We observe

Type	Typing relation on words (a, b)	Tool/resources
id	words have same surface form and tag	OpenNLP tagger
idMinusTag	words have same surface form	OpenNLP tokenizer
lemma	words have same lemma	WordNetStemmer
stem	words have same stem	Porter stemmer
synonym, antonym	words are [type]	WordNet
hypernym, hyponym entailment, holonym	b is a [type] of a	WordNet
ne	a and b are both tagged with the same Named Entity	BBN Identifinder
lvhsn	words are at edit distance of 1	Levenshtein distance

Table 1: Types

Paraphrase system	Accuracy	F-score
All paraphrase	66.5	79.9
Wan et al. (2006)	75.6	83.0
Bu et al. (2012)	76.3	N/A
Socher et al. (2011)	76.8	83.6
Madnani et al. (2012)	**77.4**	**84.1**
PR	73.5	82.1
SRK + PR	76.2	83.6
TESRK	76.6	83.7
TESRK + PR	**77.2**	**84.0**

Table 2: Evaluation results on MSR Paraphrase

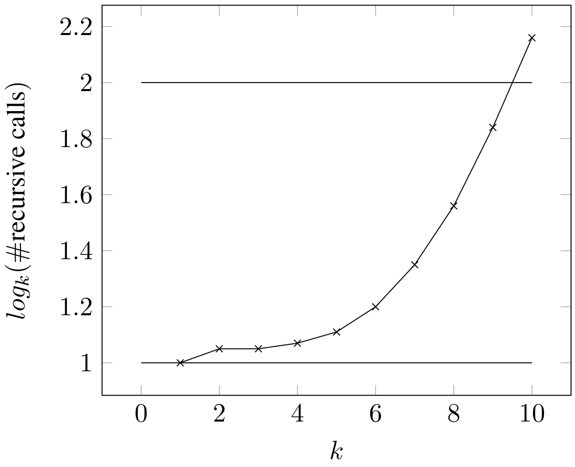

Figure 3: Evolution of the number of recursive calls to CountPerfectMatchings with k

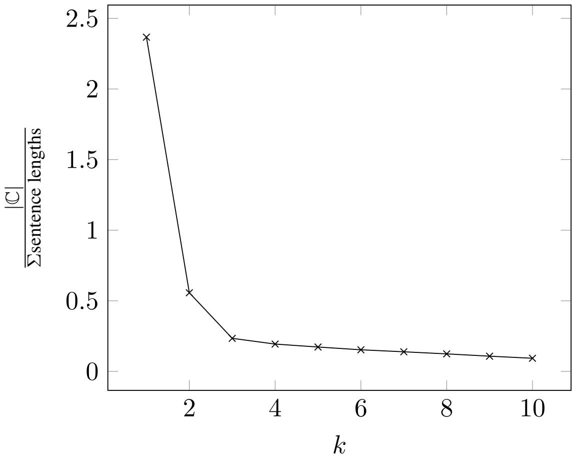

Figure 4: Evolution of the size of $\mathbb{C}$ with k

that our results are state-of-the-art and in particular, they improve on the orignal kb-SRK by a good margin. We tried other combinations of types but it did not yield good results, this is probably due to the nature of the MSR corpus, which did not contain much more advanced variations from WordNet. The only statistically significant improvement we obtained was between *TESRK + PR* and our PR baseline ($p < 0.05$). The performances obtained by all the cited systems and ours are not significantly different in any statistical sense. We made a special effort to try to reproduce as best as we could the original kb-SRK performances (Bu et al., 2012), although our implementation and theirs should theoretically be equivalent.

Figure 3 plots the average number of recursive calls to CountPerfectMatchings (algorithm 1) during a kernel computation, as a function of k. Composing with log_k, we can observe whether the empiric number of recursive calls is closer to $\mathcal{O}(k)$ or $\mathcal{O}(k^2)$. We conclude that this element of complexity is linear for low values of k, but tends to explode past $k = 7$. Thankfully, counting common rewriting rules on pairs of 7-to-10-grams rarely yields non-zero results, so in practice using high values of k is not interesting.

Figure 4 plots the average size of set $\mathbb{C}$ computed by algorithm 2, as a function of k (divided by the sum of lengths of the 4 sentences involved in the kernel computation). We can observe that this

RTE system	Accuracy
All entailments	51.2
Heilman and Smith (2010)	62.8
Bu et al. (2012)	65.1
Zanzotto et al. (2007)	65.8
Hickl et al. (2006)	**80.0**
PR	61.8
TESRK (All)	62.1
SRK + PR	63.8
TESRK (Syn) + PR	64.1
TESRK (All) + PR	66.1

Table 3: Evaluation results on RTE-3

quantity is small, except for a peak at low values of k, which is not an issue because the computation of $\bar{K}_k$ is very fast for those values of k.

4.3 Recognizing textual entailment

Recognizing Textual Entailment asks whether the meaning of a sentence *hypothesis* can be inferred by reading a sentence *text*. The dataset we used to evaluate our systems is RTE-3. Following similar work (Heilman and Smith, 2010; Bu et al., 2012), we took as training data (text, hypothesis) pairs from RTE-1 and RTE-2's whole datasets and from RTE-3's training data, which amounts to 3,767 sentence pairs. We tested on RTE-3 testing data containing 800 sentence pairs. For example, a valid textual entailment in this dataset is the pair of sentences *"In a move widely viewed as surprising, the Bank of England raised UK interest rates from 5% to 5.25%, the highest in five years."* and *"UK interest rates went up from 5% to 5.25%."*: the first entails the second. On the other hand, the pair *"Former French president General Charles de Gaulle died in November. More than 6,000 people attended a requiem mass for him at Notre Dame cathedral in Paris."* and *"Charles de Gaulle died in 1970."* does not constitute a textual entailment.

We report in Table 3 our best results, the system *TESRK (All) + PR*, defined by the sum of PR, 1b-SRK and typed-enriched kb-SRKs with k from 2 to 4, with types $\Gamma_p = \{\text{stem, synonym}\}$ and $\Gamma_v = \{\text{stem, synonym, hypernym, hyponym, entailment, holonym}\}$. Our results are to be compared with systems using techniques and resources of similar nature, but as reference the top performance at RTE-3 is still reported. This time we did not manage to fully reproduce Bu et al. 2012's performance, but we observe that type-enriched kb-SRK greatly improves upon our original implementation of kb-SRK and outperforms their system anyway. Combining TESRK and the PR baseline yields significantly better results than either one alone ($p < 0.05$), and performs significantly better than the system of (Heilman and Smith, 2010), the only one which was evaluated on the same three tasks as us ($p < 0.10$). We tried with less types in our system *TESRK (Syn) + PR* by removing all WordNet types but synonyms but got lower performance. This seems to indicate that rich types indeed help capturing more complex sentence rewritings. Note that we needed for $k = 1$ to replace the type-enriched kb-SRK by the original kernel in the sum, otherwise the performance dropped significantly. Our conclusion is that including richer types is only beneficial if they are captured within a context of a couple of words and that including all those variations on unigrams only add noise.

4.4 Answer sentence selection

Answer sentence selection is the problem of selecting among single candidate sentences the ones containing the correct answer to an open-domain factoid question. The dataset we used to evaluate our system on this task was created by (Wang et al., 2007) based on the QA track of past Text REtrieval Conferences (TREC-QA)[1]. The training set contains 4718 question/answer pairs, for 94 questions, originating from TREC 8 to 12. The testing set contains 1517 pairs for 89 questions. As an example, a correct answer to the question *"What do practitioners of Wicca worship?"* is *"An estimated 50,000 Americans practice Wicca, a form of polytheistic nature worship."* On the other hand, the answer candidate *"When people think of Wicca, they think of either Satanism or silly mumbo jumbo."* is incorrect. Sentences with more than 40 words and questions with only positive or only negative answers were filtered out (Yao et al., 2013). The average fraction of correct answers per question is 7.4% for training and 18.7% for testing. Performances are evaluated as for a re-ranking problem, in term of Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR). We report our results in Table 4. We evaluated several combinations of features. *IDF word-count* (IDF) is a baseline of

[1] Available at `http://nlp.stanford.edu/mengqiu/data/qg-emnlp07-data.tgz`

System	MAP	MRR
Random baseline	0.397	0.493
Wang et al. (2007)	0.603	0.685
Heilman and Smith (2010)	0.609	0.692
Wang and Manning (2010)	0.595	0.695
Yao et al. (2013)	0.631	0.748
Yih et al. (2013) LCLR	**0.709**	**0.770**
IDF word-count (IDF)	0.596	0.650
SRK	0.609	0.669
SRK + IDF	0.620	0.677
TESRK (WN)	0.642	0.725
TESRK (WN+NE)	0.656	0.744
TESRK (WN) + IDF	0.678	0.759
TESRK (WN+NE) + IDF	0.672	**0.768**

Table 4: Evaluation results on QA

IDF-weighted common word counting, integrated in a linear kernel. Then we implemented SRK and TESRK (with k from 1 to 5) with two typing schemes: *WN* stands for $\Gamma_p = \{\text{stem, synonym}\}$ and $\Gamma_v = \{\text{stem, synonym, hypernym, hyponym, entailment, holonym}\}$, and *WN+NE* adds type ne to both sets of types. We finally summed our kernels with the IDF baseline kernel. We observe that types which make use of WordNet variations seem to increase the most our performance. Our assumption was that named entities would be useful for question answering and that we could learn associations between question type and answer type through variations: NE does seem to help a little when combined with WN alone, but is less useful once TESRK is combined with our baseline of IDF-weighted common words. Overall, typing capabilities allow TESRK to obtain way better performances than SRK in both MAP and MRR, and our best system combining all our features is comparable to state-of-the-art systems in MRR, and significantly outperforms *SRK + IDF*, the system without types ($p < 0.05$).

5 Related work

Lodhi et al. (Lodhi et al., 2002) were among the first in NLP to use kernels: they apply *string kernels* which count common subsequences to text classification. Sentence pair classification however require the capture of 2 types of links: the link between sentences within a pair, and the link between pairs. Zanzotto et al. (Zanzotto et al., 2007) used a kernel method on syntactic tree pairs. They expanded on graph kernels in (Zanzotto et al., 2010). Their method first aligns tree nodes of a pair of sentences to form a single tree with placeholders. They then use *tree kernel* (Moschitti, 2006) to compute the number of common subtrees of those trees. Bu et al. (Bu et al., 2012) introduced a string rewriting kernel which can capture at once lexical equivalents and common syntactic dependencies on pair of sentences. All these kernel methods require an exact match or assume prior partial matches between words, thus limiting the kind of learned rewriting rules. Our contribution addresses this issue with a type-enriched string rewriting kernel which can account for lexico-semantic variations of words. Limitations of our rewriting rules include the impossibility to skip a pattern word and to replace wildcards by multiple words.

Some recent contributions (Chang et al., 2010; Wang and Manning, 2010) also provide a uniform way to learn both intermediary representations and a decision function using potentially rich feature sets. They use heuristics in the joint learning process to reduce the computational cost, while our kernel approach with a simple sequential representation of sentences has the benefit of efficiently computing an exact number of common rewriting rules between rewriting pairs. This in turn allows to precisely fine-tune the shape of desired rewriting rules through the design of the typing scheme.

6 Conclusion

We developed a unified kernel-based framework for solving sentence rewriting tasks. Types allow for an increased flexibility in counting common rewriting rules, and can also add a semantic layer to the rewritings. We show that we can efficiently compute a kernel which takes types into account, called type-enriched k-gram bijective string rewriting kernel. A SVM classifier with this kernel yields state-of-the-art results in paraphrase identification and answer sentence selection and outperforms comparable systems in recognizing textual entailment.

Abstract

Selectional preferences (SPs) are widely used in NLP as a rich source of semantic information. While SPs have been traditionally induced from textual data, human lexical acquisition is known to rely on both linguistic and perceptual experience. We present the first SP learning method that simultaneously draws knowledge from text, images and videos, using image and video descriptions to obtain visual features. Our results show that it outperforms linguistic and visual models in isolation, as well as the existing SP induction approaches.

1 Introduction

Selectional preferences (SPs) are the semantic constraints that a predicate places onto its arguments. This means that certain classes of entities are more likely to fill the predicate's argument slot than others. For instance, while the sentences "*The authors wrote a new paper.*" and "*The cat is eating your sausage!*" sound natural and describe plausible real-life situations, the sentences "*The carrot ate the keys.*" and "*The law sang a driveway.*" appear implausible and difficult to interpret, as the arguments do not satisfy the verbs' common preferences. SPs provide generalisations about word meaning and use and find a wide range of applications in natural language processing (NLP), including word sense disambiguation (Resnik, 1997; McCarthy and Carroll, 2003; Wagner et al., 2009), resolving ambiguous syntactic attachments (Hindle and Rooth, 1993), semantic role labelling (Gildea and Jurafsky, 2002; Zapirain et al., 2010), natural language inference (Zanzotto et al., 2006; Pantel et al., 2007), and figurative language processing (Fass, 1991; Mason, 2004; Shutova et al., 2013; Li et al., 2013). Automatic acquisition of SPs from linguistic data has thus become an active area of research. The community has investigated a range of techniques to tackle data sparsity and to perform generalisation from observed arguments to their underlying types, including the use of WordNet synsets as SP classes (Resnik, 1993; Li and Abe, 1998; Clark and Weir, 1999; Abney and Light, 1999; Ciaramita and Johnson, 2000), word clustering (Rooth et al., 1999; Bergsma et al., 2008; Sun and Korhonen, 2009), distributional similarity metrics (Erk, 2007; Peirsman and Padó, 2010), latent variable models (Ó Séaghdha, 2010; Ritter et al., 2010), and neural networks (Van de Cruys, 2014).

Little research, however, has been concerned with the sources of knowledge that underlie the learning of SPs. There is ample evidence in cognitive and neurolinguistics that our concept learning and semantic representation are grounded in perception and action (Barsalou, 1999; Glenberg and Kaschak, 2002; Barsalou, 2008; Aziz-Zadeh and Damasio, 2008). This suggests that word meaning and relational knowledge are acquired not only from linguistic input but also from our experiences in the physical world. Multi-modal models of word meaning have thus enjoyed a growing interest in semantics (Bruni et al., 2014), outperforming purely text-based models in tasks such as similarity estimation (Bruni et al., 2014; Kiela et al., 2014), predicting compositionality (Roller and Schulte im Walde, 2013), and concept categorization (Silberer and Lapata, 2014). However, to date these approaches relied on low-level image features such as color histograms or SIFT keypoints to represent the meaning of isolated words. To the best of our knowledge, there has not yet been a multimodal semantic approach performing extraction of

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 950–960,

predicate-argument relations from visual data. In this paper, we propose the first SP model integrating information about predicate-argument interactions from text, images, and videos. We expect it to outperform purely text-based models of SPs, which suffer from two problems: topic bias and figurative uses of words. Such bias stems from the fact that we typically write about abstract topics and events, resulting in high coverage of abstract senses of words and comparatively lower coverage of the original physical senses (Shutova, 2011). For instance, the verb *cut* is used predominantly in the domains of economics and finance and its most frequent direct objects are *cost* and *price*, according to the British National Corpus (BNC) (Burnard, 2007). Predicate-argument distributions acquired from text thus tend to be skewed in favour of abstract domains and figurative uses, inadequately reflecting our daily experiences with *cutting*, which guide human acquisition of meaning. Integrating predicate-argument relations observed in the physical world (in the form of image and video descriptions) with the more abstract text-based relations is likely to yield a more realistic semantic model, with real prospects of improving the performance of NLP applications that rely on SPs.

We use the BNC as an approximation of linguistic knowledge and a large collection of tagged images and videos from Flickr (`www.flickr.com`) as an approximation of perceptual knowledge. The human-annotated labels that accompany media on Flickr enable us to acquire predicate-argument co-occurrence information. Our experiments focus on verb preferences for their subjects and direct objects. In summary, our method (1) performs word sense disambiguation and part-of-speech (PoS) tagging of Flickr tag sequences to extract verb-noun co-occurrence; (2) clusters nouns to induce SP classes using linguistic and visual features; (3) quantifies the strength of preference of a verb for a given class by interpolating linguistic and visual SP distributions. We investigate the impact of perceptual information at different levels – from none (purely text-based model) to 100% (purely visual model). We evaluate our model directly against a dataset of human plausibility judgements of verb-noun pairs, as well as in the context of a semantic task: metaphor interpretation. Our results show that the interpolated model combining linguistic and visual relations outperforms the purely linguistic model in both evaluation settings.

2.1 Selectional preference induction

The widespread interest in automatic acquisition of SPs was triggered by the work of Resnik (1993), who treated SPs as probability distributions over all potential arguments of a predicate, rather than a single argument class assigned to the predicate. The original study used WordNet to define SP classes and to map the words in the corpus to those classes. Since then, the field has moved toward automatic induction of SP classes from corpus data. Rooth et al. (1999) presented a probabilistic latent variable model of verb preferences. In their approach, verb-argument pairs are generated from a latent variable, which represents a cluster of verb-argument interactions. The latent variable distribution and the probabilities that a latent variable generates the verb and the argument are learned from the data using Expectation Maximization (EM). The latent variables enable the model to recognise previously unseen verb-argument pairs. Ó Séaghdha (2010) and Ritter et al. (2010) similarly model SPs within a latent variable framework, but use Latent Dirichlet Allocation (LDA) to learn the probability distributions, for single-argument and multi-argument preferences respectively.

Padó et al. (2007) and Erk (2007) used similarity metrics to approximate selectional preference classes. Their underlying hypothesis is that a predicate-argument combination (p, a) is felicitous if the predicate p is frequently observed in the data with the arguments a' similar to a. The systems compute similarities between distributional representations of arguments in a vector space.

Bergsma et al. (2008) trained an SVM classifier to discriminate between felicitous and infelicitous verb-argument pairs. Their training data consisted of observed verb-argument pairs (positive examples) with unobserved, randomly-generated ones (negative examples). They classified nominal arguments of verbs, using their verb co-occurrence probabilities and information about their semantic classes as features. Bergsma and Goebel (2011) extended this method by incorporating image-driven noun features. They extract color and SIFT keypoint features from images found for a particular noun via Google image searches and add them to the feature vectors to classify nouns as felicitous or infelicitous arguments of a given verb. This method is the closest in spirit to ours and the only one so far to investigate the relevance of visual features to lexical preference learning. However, our work casts the problem in a different framework: rather than relying on low-level visual properties of nouns in isolation, we explicitly model interactions of predicates and arguments within an image or a video frame.
