Preface: General Chair

It was fifteen years ago when ACL first came to Asia in 2000. The conference in Hong Kong was a very excited one and attracted lots of people. It was a great opportunity for a number of Asian NLP researchers to meet face-to-face in such a large scale meeting. Establishment of AFNLP (Asian Federation of Natural Language Processing) was discussed soon after this wonderful event, and then AFNLP started IJCNLP (the International Joint Conference of Natural Language Processing) as a biennial flagship conference of AFNLP. ACL's three year regional rotation and IJCNLP's two year cycle meet every six years, and this is the second joint ACL-IJCNLP conference following the first held in Singapore in 2009. ACL meetings in Asia and IJNCLPs are now a propelling force of NLP research in Asian regions, and provide valuable experiences especially to young researchers and students who first attend this size of a big conference.

The success of ACL-IJCNLP owes a great deal to the hard work and dedication of many people. I would like to thank all of them for their time and contribution to this joint ACL-AFNLP conference.

Priscilla Rasmussen (the ACL Business Manager), Gertjan van Noord (ACL Past President), Chris Manning (ACL President), Graeme Hirst (ACL Treasurer), Dragomir Radev (ACL Secretary), Keh-Yih Su (AFNLP Past President), Fam-Fai Wong (AFNLP President), all other ACL and AFNLP Executive Committee members and ACL-AFNLP Conference Coordinating Committee members (forgive me for not listing all their names) have always been very helpful and guided me anytime I missed something or was behind the schedule, and given me appropriate advice. Without their help, I could not fulfill even half my duty.

I was very lucky to have a wonderful team of chairs, who have done a fantastic job for leading this conference to an invaluable one. I would like to express my deepest gratitude to Michael Strube and Chengqing Zong (Program Committee Co-Chairs), Le Sun and Yang Liu (Local Arrangement Co-Chairs), Hang Li and Sebastian Riedel (Workshop Co-Chairs), Kevin Duh and Eneko Agirre (Tutorial Co-Chairs), Hsin-His Chen and Katja Markert (System Demonstration Co-Chairs), Wanxiang Che and Guodong Zhou (Publications Co-Chairs), Stephan Oepen, Chin-Yew Lin and Emily Bender (Student Research Workshop Faculty Advisors), Kuan-Yu Chen, Angelina Ivanova and Ellie Pavlick (Student Research Workshop Co-Chairs), Francis Bond (Mentoring Chair), Xianpei Han and Kang Liu (Publicity Co-Chairs), Zhiyuan Liu (Webmaster), and all the team members of the Local Organizing Committee. Thanks to their dedicated efforts, we now have a great conference consisting of the Presidential Address (by Chris Manning), two Keynote Addresses (by Marti Hearst and Jiawei Han), 173 long and 145 short papers, 12 TACL papers, 7 Student Research Workshop papers, 25 system demonstrations, 8 tutorials, 15 workshops, one collocated conference (CoNLL-2015), and a not yet known Lifetime Achievement Awardee's speech.

I am also grateful to our sponsors for their generous contributions. ACL-IJCNLP-2015 is supported by six Platinum Sponsors (CreditEase, Baidu, Tencent, Alibaba Group, SAMSUNG, and Microsoft), four Gold Sponsors (Google, Facebook, SinoVoice, and Huawei), three Silver Sponsors (Nuance, Amazon, and Sogou), one Bronze Sponsor (Yandex), one Oversea Student Fellowship Sponsor (Baobab), and one Best Paper Sponsor (IBM). I would express special thanks to Yiqun Liu (Local Sponsorship Chair) and all members of the International Sponsorship Committee (Ting Liu, Hideto Kazawa, Asli Celikyilmaz, Julia Hochenmaier, and Alessandro Moschitti).

Finally, I would like to thank two keynote speakers, the area chairs of the main conference, the workshop organizers, the tutorial presenters, the authors of main conference and demo papers, the reviewers for their contribution, and all the attendees for participation. I hope everyone have a great time and enjoy this conference.

ACL-IJCNLP 2015 General Chair
Yuji Matsumoto
Nara Institute of Science and Technology

Preface: Program Committee Co-Chairs

Welcome to the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing of the Asian Federation of Natural Language Processing (ACL-IJCNLP)! This year ACL-IJCNLP received 692 long paper submissions and 648 short paper submissions which sets a new record for ACL for both long and short papers! We are pleased to observe that our community continues to grow. Of the long papers, 173 were accepted for presentation at ACL-IJCNLP – 105 as oral and 68 as poster presentations. 145 short papers were accepted – 50 as oral and 95 as poster presentations. In addition, ACL-IJCNLP also features 12 presentations of papers accepted in the Transactions of the Association for Computational Linguistics (TACL).

The submissions were reviewed under different categories and using different review forms for empirical/data-driven, theoretical, applications/tools, resources/evaluation, and survey papers. This year we introduced the item "MENTORING" to the review form to indicate whether a paper needs the help of a mentor in its writing, organization or presentation. For short papers, following up on last year's successful experiences, we also welcomed submissions describing negative results. We are glad to see that the community is becoming more open towards negative results so that such papers have the chance to be published, so that other researchers do not fall in the same trap.

We view posters as an integral part of ACL-IJCNLP. Half of the papers have been accepted as posters. Hence, we spent a great deal of time to ensure that the poster session will be a good experience for poster presenters and their audience. Following last year's exciting poster session, we also organized the posters in two large poster sessions to accommodate the high-quality submissions accepted in poster presentation format. We hope attendees and authors will benefit from this additional time to present and have more time to discuss with each other.

ACL-IJCNLP 2015 will have two distinguished invited speakers. Marti Hearst (professor at UC Berkeley in the School of Information and EECS) and Jiawei Han (Abel Bliss Professor at University of Illinois at Urbana-Champaign). We are grateful that they accepted our invitation.

There are many individuals to thank for their contributions to ACL-IJCNLP 2015. We would like to thank the 37 area chairs for their hard work on recruiting reviewers, leading the discussion process, and carefully ranking the submissions. We would also like to thank the 749 primary and the 137 secondary reviewers on whose efforts we depended to select high-quality and timely scientific work. This year we specifically acknowledge around 18.2% of the reviewers who went the extra mile and provided extremely helpful reviews (their names are marked with a * in the organization section of the proceedings). The ACL coordinating committee members, including Dragomir Radev, Graeme Hirst, Jian Su, and Gertjan van Noord were invaluable on various issues relating to the organization. We would like to thank the prior conference chairs Kristina Toutanova and Hua Wu and their predecessors for their advice. We are very grateful for the guidance and support of the general chair Yuji Matsumoto, to the ACL Business Manager Priscilla Rasmussen who knew practically everything, to the local chairs Le Sun and Yang Liu, the publication chairs Wanxiang Che and Guodong Zhou, and webmaster Zhiyuan Liu. We would also like to thank Jiajun Zhang who helped with reviewer assignment and numerous other tasks. Rich Gerber and Paolo Gai from Softconf were extremely responsive to all of our requests, and we are grateful for that.

We are indebted to the best paper award committee which consisted of Eneko Agirre, Tim Baldwin, Philipp Koehn, Joakim Nivre, and Yue Zhang. They read the candidate papers, ranked them and provided comments on a very short notice.

We hope you will enjoy ACL-IJCNLP 2015 in Beijing!

ACL-IJCNLP 2015 Program Co-Chairs
Chengqing Zong, Chinese Academy of Sciences
Michael Strube, Heidelberg Institute for Theoretical Studies

Organizing Committee

General Chair

Yuji Matsumoto, Nara Institute of Science and Technology

Program Committee Co-Chairs

Chengqing Zong, Institute of Automation, Chinese Academy of Sciences
Michael Strube, Heidelberg Institute for Theoretical Studies

Local Co-Chairs

Le Sun, Institute of Software, Chinese Academy of Sciences
Yang Liu, Tsinghua University

Workshop Co-Chairs

Hang Li, Huawei
Sebastian Riedel, University College London

Tutorial Co-Chairs

Kevin Duh, Nara Institute of Science and Technology
Eneko Agirre, University of the Basque Country

Publications Chairs

Wanxiang Che, Harbin Institute of Technology
Guodong Zhou, Suzhou University

Demonstration Co-Chairs

Hsin-Hsi Chen, National Taiwan University
Katja Markert, University of Leeds

Sponsorship Chair

Yiqun Liu, Tsinghua University

Publicity Co-Chairs

Xianpei Han, Institute of Software, Chinese Academy of Sciences
Kang Liu, Institute of Automation, Chinese Academy of Sciences

Student Research Workshop Faculty Advisors

Stephan Oepen, University of Oslo
Chin-Yew Lin, Microsoft Research Asia
Emily Bender, University of Washington

Student Co-Chairs (Student Research Workshop)

Kuan-Yu Chen, National Taiwan University
Angelina Ivanova, University of Oslo
Ellie Pavlick, University of Pennsylvania

Mentoring Chair

Francis Bond, Nanyang Technological University

Student Volunteer Co-Chairs

Erhong Yang, Beijing Language and Culture University
Dong Yu, Beijing Language and Culture University

Webmasters

Zhiyuan Liu, Tsinghua University
Qi Zhang, Fudan University

Entertainment Chair

Binyang Li, University of International Relations

Space Management Co-Chairs

Jiajun Zhang, Institute of Automation, Chinese Academy of Sciences
Wenbin Jiang, Institute of Computing Technology, Chinese Academy of Sciences
Qiuye Zhao, Institute of Computing Technology, Chinese Academy of Sciences

Graphic Design

Yi Han, Tsinghua University
Ying Lin, Beijing University of Posts and Telecommunications

Program Committee

Program Committee Co-Chairs

Chengqing Zong, Institute of Automation, Chinese Academy of Sciences
Michael Strube, Heidelberg Institute for Theoretical Studies

Area Chairs

Invited Talk: Can Natural Language Processing Become Natural LanguageCoaching?

Marti A. Hearst

School of Information and EECS, UC Berkeley

Abstract

How we teach and learn is undergoing a revolution, due to changes in technology and connectivity. Education may be one of the best application areas for advanced NLP techniques, and NLP researchers have much to contribute to this problem, especially in the areas of learning to write, mastery learning, and peer learning. In this talk I consider what happens when we convert natural language processors into natural language coaches.

Biography

Marti Hearst is a Professor at UC Berkeley in the School of Information and EECS. She received her PhD in CS from UC Berkeley in 1994 and was a member of the research staff at Xerox PARC form 1994-1997. Her research is in computational linguistics, search user interfaces, information visualization, and improving learning at scale. Her NLP work includes automatic acquisition of hypernym relations ("Hearst Patterns"), TextTiling discourse segmentation, abbreviation recognition, and multiword semantic relations. She wrote the book "Search User Interfaces" (Cambridge) in 2009, co-founded the ACM Conference on Learning at Scale in 2014, and was named an ACM Fellow in 2013. She has received four student-initiated Excellence in Teaching Awards, including in 2014 and 2015.

Invited Talk: Construction and Mining of Heterogeneous Information Networks from Text Data

Jiawei Han

Department of Computer Science, University of Illinois at Urbana-Champaign

Abstract

The real-world data are unstructured but interconnected. The majority of such data is in the form of natural language text. One of the grand challenges is to turn such massive data into actionable knowledge. In this talk, we present our vision on how to turn massive unstructured, text-rich, but interconnected data into knowledge. We propose a data-to-network-to-knowledge (i.e., D2N2K) paradigm, which is to first turn data into relatively structured heterogeneous information networks, and then mine such text-rich and structure-rich heterogeneous networks to generate useful knowledge. We show why such a paradigm represents a promising direction and present some recent progress on the development of effective methods for construction and mining of structured heterogeneous information networks from text data.

Biography

Jiawei Han is Abel Bliss Professor in the Department of Computer Science, University of Illinois at Urbana-Champaign. He has been researching into data mining, information network analysis, database systems, and data warehousing, with over 600 journal and conference publications. He has chaired or served on many program committees of international conferences, including PC co-chair for KDD, SDM, and ICDM conferences, and Americas Coordinator for VLDB conferences. He also served as the founding Editor-In-Chief of ACM Transactions on Knowledge Discovery from Data and is serving as the Director of Information Network Academic Research Center supported by U.S. Army Research Lab, and Director of KnowEnG, an NIH funded Center of Excellence in Big Data Computing. He is a Fellow of ACM and Fellow of IEEE, and received 2004 ACM SIGKDD Innovations Award, 2005 IEEE Computer Society Technical Achievement Award, 2009 IEEE Computer Society Wallace McDowell Award, and 2011 Daniel C. Drucker Eminent Faculty Award at UIUC. His co-authored book "Data Mining: Concepts and Techniques" has been adopted as a textbook popularly worldwide.

Table of Contents

Conference Program

Sunday, July 26

18:00–21:00 Welcome Reception

Monday, July 27

07:30–18:00 Registration

08:45–09:00 Welcome to ACL-IJCNLP 2015

09:00–09:40 Presidential Address: Christopher D. Manning

09:40–10:10 Coffee Break

10:10–11:50 Session 1: TACL and Long Papers

Session 1A: 10:10–11:50 Machine Translation: Neural Networks

On Using Very Large Target Vocabulary for Neural Machine Translation
Sébastien Jean, Kyunghyun Cho, Roland Memisevic and Yoshua Bengio

Addressing the Rare Word Problem in Neural Machine Translation
Thang Luong, Ilya Sutskever, Quoc Le, Oriol Vinyals and Wojciech Zaremba

Encoding Source Language with Convolutional Neural Network for Machine Translation
Fandong Meng, Zhengdong Lu, Mingxuan Wang, Hang Li, Wenbin Jiang and Qun Liu

Statistical Machine Translation Features with Multitask Tensor Networks
Hendra Setiawan, Zhongqiang Huang, Jacob Devlin, Thomas Lamar, Rabih Zbib, Richard Schwartz and John Makhoul

Monday, July 27 (continued)

Session 1B: 10:10–11:50 Language and Vision/NLP Applications

Describing Images using Inferred Visual Dependency Representations
Desmond Elliott and Arjen de Vries

Text to 3D Scene Generation with Rich Lexical Grounding
Angel Chang, Will Monroe, Manolis Savva, Christopher Potts and Christopher D. Manning

MultiGranCNN: An Architecture for General Matching of Text Chunks on Multiple Levels of Granularity
Wenpeng Yin and Hinrich Schütze

Weakly Supervised Models of Aspect-Sentiment for Online Course Discussion Forums
Arti Ramesh, Shachi H. Kumar, James Foulds and Lise Getoor

Session 1C: 10:10–11:50 Semantics: Embeddings

[TACL] Improving Distributional Similarity with Lessons Learned from Word Embeddings
Omer Levy, Yoav Goldberg, Ido Dagan

Semantically Smooth Knowledge Graph Embedding
Shu Guo, Quan Wang, Bin Wang, Lihong Wang and Li Guo

SensEmbed: Learning Sense Embeddings for Word and Relational Similarity
Ignacio Iacobacci, Mohammad Taher Pilehvar and Roberto Navigli

Revisiting Word Embedding for Contrasting Meaning
Zhigang Chen, Wei Lin, Qian Chen, Xiaoping Chen, Si Wei, Hui Jiang and Xiaodan Zhu

Session 1D: 10:10–11:50 Machine Learning

Joint Models of Disagreement and Stance in Online Debate
Dhanya Sridhar, James Foulds, Bert Huang, Lise Getoor and Marilyn Walker

Low-Rank Regularization for Sparse Conjunctive Feature Spaces: An Application to Named Entity Classification
Audi Primadhanty, Xavier Carreras and Ariadna Quattoni

Learning Word Representations by Jointly Modeling Syntagmatic and Paradigmatic Relations
Fei Sun, Jiafeng Guo, Yanyan Lan, Jun Xu and Xueqi Cheng

Learning Dynamic Feature Selection for Fast Sequential Prediction
Emma Strubell, Luke Vilnis, Kate Silverstein and Andrew McCallum

Session 1E: 10:10–11:50 Information Extraction 1

Compositional Vector Space Models for Knowledge Base Completion
Arvind Neelakantan, Benjamin Roth and Andrew McCallum

Event Extraction via Dynamic Multi-Pooling Convolutional Neural Networks
Yubo Chen, Liheng Xu, Kang Liu, Daojian Zeng and Jun Zhao

Stacked Ensembles of Information Extractors for Knowledge-Base Population
Vidhoon Viswanathan, Nazneen Fatema Rajani, Yinon Bentor and Raymond Mooney

Generative Event Schema Induction with Entity Disambiguation
Kiem-Hieu Nguyen, Xavier Tannier, Olivier Ferret and Romaric Besançon

Monday, July 27 (continued)

11:50–13:20 Lunch Break; Student Lunch

13:20–15:00 Session 2: TACL and Long Papers

Session 2A: 13:20–15:00 Machine Translation

Syntax-based Simultaneous Translation through Prediction of Unseen Syntactic Constituents
Yusuke Oda, Graham Neubig, Sakriani Sakti, Tomoki Toda and Satoshi Nakamura

Efficient Top-Down BTG Parsing for Machine Translation Preordering
Tetsuji Nakagawa

Online Multitask Learning for Machine Translation Quality Estimation
José G. C. de Souza, Matteo Negri, Elisa Ricci and Marco Turchi

A Context-Aware Topic Model for Statistical Machine Translation
Jinsong Su, Deyi Xiong, Yang Liu, Xianpei Han, Hongyu Lin, Junfeng Yao and Min Zhang

Session 2B: 13:20–15:00 Question Answering

Learning Answer-Entailing Structures for Machine Comprehension
Mrinmaya Sachan, Kumar Dubey, Eric Xing and Matthew Richardson

Learning Continuous Word Embedding with Metadata for Question Retrieval in Community Question Answering
Guangyou Zhou, Tingting He, Jun Zhao and Po Hu

Question Answering over Freebase with Multi-Column Convolutional Neural Networks
Li Dong, Furu Wei, Ming Zhou and Ke Xu

[TACL] Higher-order Lexical Semantic Models for Non-factoid Answer Reranking
Daniel Fried, Peter Jansen, Gustave Hahn-Powell, Mihai Surdeanu, Peter Clark

Monday, July 27 (continued)

Session 2C: 13:20–15:00 Semantics: Distributional Approaches

Hubness and Pollution: Delving into Cross-Space Mapping for Zero-Shot Learning
Angeliki Lazaridou, Georgiana Dinu and Marco Baroni

[TACL] Learning a Compositional Semantics for Freebase with an Open Predicate Vocabulary
Jayant Krishnamurthy and Tom M. Mitchell

A Generalisation of Lexical Functions for Composition in Distributional Semantics
Antoine Bride, Tim Van de Cruys and Nicholas Asher

Simple Learning and Compositional Application of Perceptually Grounded Word Meanings for Incremental Reference Resolution
Casey Kennington and David Schlangen

Session 2D: 13:20–15:00 Parsing: Neural Networks

Neural CRF Parsing
Greg Durrett and Dan Klein

An Effective Neural Network Model for Graph-based Dependency Parsing
Wenzhe Pei, Tao Ge and Baobao Chang

Structured Training for Neural Network Transition-Based Parsing
David Weiss, Chris Alberti, Michael Collins and Slav Petrov

Transition-Based Dependency Parsing with Stack Long Short-Term Memory
Chris Dyer, Miguel Ballesteros, Wang Ling, Austin Matthews and Noah A. Smith

Session 2E: 13:20–15:00 Information Extraction 2

Leveraging Linguistic Structure For Open Domain Information Extraction
Gabor Angeli, Melvin Jose Johnson Premkumar and Christopher D. Manning

Joint Information Extraction and Reasoning: A Scalable Statistical Relational Learning Approach
William Yang Wang and William W Cohen

A Knowledge-Intensive Model for Prepositional Phrase Attachment
Ndapandula Nakashole and Tom M. Mitchell

A Convolution Kernel Approach to Identifying Comparisons in Text
Maksim Tkachenko and Hady Lauw

15:00–15:30 Coffee Break

15:30–16:45 Session 3: TACL and Long Papers

Session 3A: 15:30–16:45 Language Resources

[TACL] A New Corpus and Imitation Learning Framework for Context-Dependent Semantic Parsing
Andreas Vlachos and Stephen Clark

It Depends: Dependency Parser Comparison Using A Web-based Evaluation Tool
Jinho D. Choi, Joel Tetreault and Amanda Stent

Generating High Quality Proposition Banks for Multilingual Semantic Role Labeling
Alan Akbik, laura chiticariu, Marina Danilevsky, Yunyao Li, Shivakumar Vaithyanathan and Huaiyu Zhu

Session 3B: 15:30–16:45 Sentiment Analysis: Cross-/Multi Lingual

Aligning Opinions: Cross-Lingual Opinion Mining with Dependencies
Mariana S. C. Almeida, Claudia Pinto, Helena Figueira, Pedro Mendes and André F. T. Martins

Learning to Adapt Credible Knowledge in Cross-lingual Sentiment Analysis
Qiang Chen, Wenjie Li, Yu Lei, Xule Liu and Yanxiang He

Learning Bilingual Sentiment Word Embeddings for Cross-language Sentiment Classification
HuiWei Zhou, Long Chen, Fulin Shi and Degen Huang

Session 3C: 15:30–16:45 Natural Language Generation

Content Models for Survey Generation: A Factoid-Based Evaluation
Rahul Jha, Catherine Finegan-Dollak, Ben King, Reed Coke and Dragomir Radev

Training a Natural Language Generator From Unaligned Data
Ondřej Dušek and Filip Jurcicek

Event-Driven Headline Generation
Rui Sun, Yue Zhang, Meishan Zhang and Donghong Ji

Session 3D: 15:30–16:45 Spoken Language Processing and Understanding

New Transfer Learning Techniques for Disparate Label Sets
Young-Bum Kim, Karl Stratos, Ruhi Sarikaya and Minwoo Jeong

Matrix Factorization with Knowledge Graph Propagation for Unsupervised Spoken Language Understanding
Yun-Nung Chen, William Yang Wang, Anatole Gershman and Alexander Rudnicky

Efficient Disfluency Detection with Transition-based Parsing
Shuangzhi Wu, Dongdong Zhang, Ming Zhou and Tiejun Zhao

Monday, July 27 (continued)

Session 3E: 15:30–16:45 Information Extraction 3/Information Retrieval

S-MART: Novel Tree-based Structured Learning Algorithms Applied to Tweet Entity Linking
Yi Yang and Ming-Wei Chang

[TACL] Design Challenges for Entity Linking
Xiao Ling, Sameer Singh, Daniel S. Weld

Entity Retrieval via Entity Factoid Hierarchy
Chunliang Lu, Wai Lam and Yi Liao

16:45–17:00 **Short Break**

17:00–18:00 **Session 4: Short Papers**

18:00–21:00 **Poster and Dinner Session 1: TACL Papers, Long Papers, System Demonstrations**

Session P1.01: 18:00–21:00 Poster: Pragmatics

Encoding Distributional Semantics into Triple-Based Knowledge Ranking for Document Enrichment
Muyu Zhang, Bing Qin, Mao Zheng, Graeme Hirst and Ting Liu

A Strategic Reasoning Model for Generating Alternative Answers
Jon Stevens, Anton Benz, Sebastian Reuße and Ralf Klabunde

Modeling Argument Strength in Student Essays
Isaac Persing and Vincent Ng

Session P1.02: 18:00–21:00 Poster: Information Retrieval

Summarization of Multi-Document Topic Hierarchies using Submodular Mixtures
Ramakrishna Bairi, Rishabh Iyer, Ganesh Ramakrishnan and Jeff Bilmes

Learning to Explain Entity Relationships in Knowledge Graphs
Nikos Voskarides, Edgar Meij, Manos Tsagkias, Maarten de Rijke and Wouter Weerkamp

Session P1.03: 18:00–21:00 Poster: Information Extraction

[TACL] Exploiting Parallel News Streams for Unsupervised Event Extraction
Congle Zhang, Stephen Soderland, Daniel Weld

Bring you to the past: Automatic Generation of Topically Relevant Event Chronicles
Tao Ge, Wenzhe Pei, Heng Ji, Sujian Li, Baobao Chang and Zhifang Sui

Context-aware Entity Morph Decoding
Boliang Zhang, Hongzhao Huang, Xiaoman Pan, Sujian Li, Chin-Yew Lin, Heng Ji, Kevin Knight, Zhen Wen, Yizhou Sun, Jiawei Han and Bulent Yener

Multi-Objective Optimization for the Joint Disambiguation of Nouns and Named Entities
Dirk Weissenborn, Leonhard Hennig, Feiyu Xu and Hans Uszkoreit

Building a Scientific Concept Hierarchy Database (SCHBase)
Eytan Adar and Srayan Datta

Sentiment-Aspect Extraction based on Restricted Boltzmann Machines
Linlin Wang, Kang Liu, Zhu Cao, Jun Zhao and Gerard de Melo

Classifying Relations by Ranking with Convolutional Neural Networks
Cicero dos Santos, Bing Xiang and Bowen Zhou

Semantic Representations for Domain Adaptation: A Case Study on the Tree Kernel-based Method for Relation Extraction
Thien Huu Nguyen, Barbara Plank and Ralph Grishman

Omnia Mutantur, Nihil Interit: Connecting Past with Present by Finding Corresponding Terms across Time
Yating Zhang, Adam Jatowt, Sourav Bhowmick and Katsumi Tanaka

Negation and Speculation Identification in Chinese Language
Bowei Zou, Qiaoming Zhu and Guodong Zhou

Learning Relational Features with Backward Random Walks
Ni Lao, Einat Minkov and William Cohen

Session P1.04: 18:00–21:00 Poster: Language and Vision

Learning the Semantics of Manipulation Action
Yezhou Yang, Yiannis Aloimonos, Cornelia Fermuller and Eren Erdal Aksoy

Session P1.05: 18:00–21:00 Poster: Language Resources

Knowledge Graph Embedding via Dynamic Mapping Matrix
Guoliang Ji, Shizhu He, Liheng Xu, Kang Liu and Jun Zhao

How Far are We from Fully Automatic High Quality Grammatical Error Correction?
Christopher Bryant and Hwee Tou Ng

Session P1.06: 18:00–21:00 Poster: Lexical Semantics and Ontology

Knowledge Portability with Semantic Expansion of Ontology Labels
Mihael Arcan, Marco Turchi and Paul Buitelaar

Automatic disambiguation of English puns
Tristan Miller and Iryna Gurevych

Unsupervised Cross-Domain Word Representation Learning
Danushka Bollegala, Takanori Maehara and Ken-ichi Kawarabayashi

A Unified Multilingual Semantic Representation of Concepts
José Camacho-Collados, Mohammad Taher Pilehvar and Roberto Navigli

Session P1.07: 18:00–21:00 Poster: Linguistic and Psycholinguistic Aspects of CL

Demographic Factors Improve Classification Performance
Dirk Hovy

Vector-space calculation of semantic surprisal for predicting word pronunciation duration
Asad Sayeed, Stefan Fischer and Vera Demberg

Session P1.08: 18:00–21:00 Poster: Machine Learning and Topic Modeling

Efficient Methods for Inferring Large Sparse Topic Hierarchies
Doug Downey, Chandra Bhagavatula and Yi Yang

Trans-dimensional Random Fields for Language Modeling
Bin Wang, Zhijian Ou and Zhiqiang Tan

Gaussian LDA for Topic Models with Word Embeddings
Rajarshi Das, Manzil Zaheer and Chris Dyer

Session P1.09: 18:00–21:00 Poster: Machine Translation

Pairwise Neural Machine Translation Evaluation
Francisco Guzmán, Shafiq Joty, Lluís Màrquez and Preslav Nakov

String-to-Tree Multi Bottom-up Tree Transducers
Nina Seemann, Fabienne Braune and Andreas Maletti

Non-linear Learning for Statistical Machine Translation
Shujian Huang, Huadong Chen, Xin-Yu Dai and Jiajun Chen

Unifying Bayesian Inference and Vector Space Models for Improved Decipherment
Qing Dou, Ashish Vaswani, Kevin Knight and Chris Dyer

Non-projective Dependency-based Pre-Reordering with Recurrent Neural Network for Machine Translation
Antonio Valerio Miceli Barone and Giuseppe Attardi

Session P1.10: 18:00–21:00 Poster: NLP Applications

Detecting Deceptive Groups Using Conversations and Network Analysis
Dian Yu, Yulia Tyshchuk, Heng Ji and William Wallace

WikiKreator: Improving Wikipedia Stubs Automatically
Siddhartha Banerjee and Prasenjit Mitra

Language to Code: Learning Semantic Parsers for If-This-Then-That Recipes
Chris Quirk, Raymond Mooney and Michel Galley

Deep Questions without Deep Understanding
Igor Labutov, Sumit Basu and Lucy Vanderwende

The NL2KR Platform for building Natural Language Translation Systems
Nguyen Vo, Arindam Mitra and Chitta Baral

Session P1.12: 18:00–21:00 Poster: Morphology

Multiple Many-to-Many Sequence Alignment for Combining String-Valued Variables: A G2P Experiment
Steffen Eger

Session P1.11: 18:00–21:00 Poster: NLP for the Web and Social Media

Tweet Normalization with Syllables
Ke Xu, Yunqing Xia and Chin-Hui Lee

Improving Named Entity Recognition in Tweets via Detecting Non-Standard Words
Chen Li and Yang Liu

Session P1.13: 18:00–21:00 Poster: Question Answering

A Unified Kernel Approach for Learning Typed Sentence Rewritings
Martin Gleize and Brigitte Grau

Session P1.14: 18:00–21:00 Poster: Semantics

[TACL] From Visual Attributes to Adjectives through Decompositional Distributional Semantics
Angeliki Lazaridou, Georgiana Dinu, Adam Liska, Marco Baroni

Perceptually Grounded Selectional Preferences
Ekaterina Shutova, Niket Tandon and Gerard de Melo

Joint Case Argument Identification for Japanese Predicate Argument Structure Analysis
Hiroki Ouchi, Hiroyuki Shindo, Kevin Duh and Yuji Matsumoto

Jointly optimizing word representations for lexical and sentential tasks with the C-PHRASE model
Nghia The Pham, Germán Kruszewski, Angeliki Lazaridou and Marco Baroni

Robust Subgraph Generation Improves Abstract Meaning Representation Parsing
Keenon Werling, Gabor Angeli and Christopher D. Manning

Environment-Driven Lexicon Induction for High-Level Instructions
Dipendra Kumar Misra, Kejia Tao, Percy Liang and Ashutosh Saxena

Structural Representations for Learning Relations between Pairs of Texts
Simone Filice, Giovanni Da San Martino and Alessandro Moschitti

Session P1.15: 18:00–21:00 Poster: Sentiment Analysis

[TACL] Joint Modeling of Opinion Expression Extraction and Attribute Classification
Bishan Yang and Claire Cardie

Learning Semantic Representations of Users and Products for Document Level Sentiment Classification
Duyu Tang, Bing Qin and Ting Liu

Towards Debugging Sentiment Lexicons
Andrew Schneider and Eduard Dragut

Sparse, Contextually Informed Models for Irony Detection: Exploiting User Communities, Entities and Sentiment
Byron C. Wallace, Do Kook Choe and Eugene Charniak

Sentence-level Emotion Classification with Label and Context Dependence
Shoushan Li, Lei Huang, Rong Wang and Guodong Zhou

Co-training for Semi-supervised Sentiment Classification Based on Dual-view Bags-of-words Representation
Rui Xia, Cheng Wang, Xin-Yu Dai and Tao Li

Improving social relationships in face-to-face human-agent interactions: when the agent wants to know user's likes and dislikes
Caroline Langlet and Chloé Clavel

Learning Word Representations from Scarce and Noisy Data with Embedding Subspaces
Ramón Astudillo, Silvio Amir, Wang Ling, Mario Silva and Isabel Trancoso

Monday, July 27 (continued)

Session P1.16: 18:00–21:00 Poster: Spoken Language Processing

Automatic Spontaneous Speech Grading: A Novel Feature Derivation Technique using the Crowd
Vinay Shashidhar, Nishant Pandey and Varun Aggarwal

Driving ROVER with Segment-based ASR Quality Estimation
Shahab Jalalvand, Matteo Negri, Falavigna Daniele and Marco Turchi

Session P1.17: 18:00–21:00 Poster: Natural Language Generation

A Hierarchical Neural Autoencoder for Paragraphs and Documents
Jiwei Li, Thang Luong and Dan Jurafsky

Session P1.18: 18:00–21:00 Poster: Tagging, Chunking, Parsing

[TACL]Domain Adaptation for Syntactic and Semantic Dependency Parsing Using Deep Belief Networks
Haitong Yang, Tao Zhuang, Chengqing Zong

Joint Dependency Parsing and Multiword Expression Tokenization
Alexis Nasr, Carlos Ramisch, José Deulofeu and André Valli

End-to-end learning of semantic role labeling using recurrent neural networks
Jie Zhou and Wei Xu

Feature Optimization for Constituent Parsing via Neural Networks
Zhiguo Wang, Haitao Mi and Nianwen Xue

Identifying Cascading Errors using Constraints in Dependency Parsing
Dominick Ng and James R. Curran

A Re-ranking Model for Dependency Parser with Recursive Convolutional Neural Network
Chenxi Zhu, Xipeng Qiu, Xinchi Chen and Xuanjing Huang

Transition-based Neural Constituent Parsing
Taro Watanabe and Eiichiro Sumita

Monday, July 27 (continued)

Feature Selection in Kernel Space: A Case Study on Dependency Parsing
Xian Qian and Yang Liu

Semantic Role Labeling Improves Incremental Parsing
Ioannis Konstas and Frank Keller

Discontinuous Incremental Shift-reduce Parsing
Wolfgang Maier

A Neural Probabilistic Structured-Prediction Model for Transition-Based Dependency Parsing
Hao Zhou, Yue Zhang, Shujian Huang and Jiajun Chen

Parsing Paraphrases with Joint Inference
Do Kook Choe and David McClosky

Cross-lingual Dependency Parsing Based on Distributed Representations
Jiang Guo, Wanxiang Che, David Yarowsky, Haifeng Wang and Ting Liu

Tuesday, July 28

07:30–18:00 Registration

09:00–10:00 Keynote Address: "Can Natural Language Processing Become Natural Language Coaching?" - Marti A. Hearst

Can Natural Language Processing Become Natural Language Coaching?
Marti A. Hearst

Tuesday, July 28 (continued)

10:00–10:30 Coffee Break

10:30–12:00 Session 5: Short Papers

12:00–13:30 Lunch Break

13:30–14:45 Session 6: Long Papers

Session 6A: 13:30–14:45 Discourse, Pragmatics

Machine Comprehension with Discourse Relations
Karthik Narasimhan and Regina Barzilay

Implicit Role Linking on Chinese Discourse: Exploiting Explicit Roles and Frame-to-Frame Relations
Ru Li, Juan Wu, Zhiqiang Wang and Qinghua Chai

Discourse-sensitive Automatic Identification of Generic Expressions
Annemarie Friedrich and Manfred Pinkal

Session 6B: 13:30–14:45 Machine Learning: Embeddings

Model-based Word Embeddings from Decompositions of Count Matrices
Karl Stratos, Michael Collins and Daniel Hsu

Entity Hierarchy Embedding
Zhiting Hu, Poyao Huang, Yuntian Deng, Yingkai Gao and Eric Xing

Orthogonality of Syntax and Semantics within Distributional Spaces
Jeff Mitchell and Mark Steedman

Session 6C: 13:30–14:45 Semantics: Semantic Parsing

Scalable Semantic Parsing with Partial Ontologies
Eunsol Choi, Tom Kwiatkowski and Luke Zettlemoyer

Semantic Parsing via Staged Query Graph Generation: Question Answering with Knowledge Base
Wen-tau Yih, Ming-Wei Chang, Xiaodong He and Jianfeng Gao

Building a Semantic Parser Overnight
Yushi Wang, Jonathan Berant and Percy Liang

Session 6D: 13:30–14:45 Sentiment Analysis: Learning

Predicting Polarities of Tweets by Composing Word Embeddings with Long Short-Term Memory
Xin Wang, Yuanchao Liu, Chengjie SUN, Baoxun Wang and Xiaolong Wang

Topic Modeling based Sentiment Analysis on Social Media for Stock Market Prediction
Thien Hai Nguyen and Kiyoaki Shirai

Learning Tag Embeddings and Tag-specific Composition Functions in Recursive Neural Network
Qiao Qian, Bo Tian, Minlie Huang, Yang Liu, Xuan Zhu and Xiaoyan Zhu

Session 6E: 13:30–14:45 Grammar Induction and Annotation

A convex and feature-rich discriminative approach to dependency grammar induction
Edouard Grave and Noémie Elhadad

Parse Imputation for Dependency Annotations
Jason Mielens, Liang Sun and Jason Baldridge

Probing the Linguistic Strengths and Limitations of Unsupervised Grammar Induction
Yonatan Bisk and Julia Hockenmaier

Tuesday, July 28 (continued)

14:45–15:15 Coffee Break

15:15–16:30 Session 7: TACL and Long Papers

Session 7A: 15:15–16:30 Discourse, Coreference

Entity-Centric Coreference Resolution with Model Stacking
Kevin Clark and Christopher D. Manning

Learning Anaphoricity and Antecedent Ranking Features for Coreference Resolution
Sam Wiseman, Alexander M. Rush, Stuart Shieber and Jason Weston

Transferring Coreference Resolvers with Posterior Regularization
André F. T. Martins

Session 7B: 15:15–16:30 Topic Modeling

Tea Party in the House: A Hierarchical Ideal Point Topic Model and Its Application to Republican Legislators in the 112th Congress
Viet-An Nguyen, Jordan Boyd-Graber, Philip Resnik and Kristina Miler

KB-LDA: Jointly Learning a Knowledge Base of Hierarchy, Relations, and Facts
Dana Movshovitz-Attias and William W. Cohen

A Computationally Efficient Algorithm for Learning Topical Collocation Models
Zhendong Zhao, Lan Du, Benjamin Börschinger, John K Pate, Massimiliano Ciaramita, Mark Steedman and Mark Johnson

Session 7C: 15:15–16:30 Semantics: Semantic Parsing

[TACL] Efficient Inference and Structured Learning for Semantic Role Labeling
Oscar Täckström, Kuzman Ganchev, Dipanjan Das

Compositional Semantic Parsing on Semi-Structured Tables
Panupong Pasupat and Percy Liang

Graph parsing with s-graph grammars
Jonas Groschwitz, Alexander Koller and Christoph Teichmann

Session 7D: 15:15–16:30 Lexical Semantics

Sparse Overcomplete Word Vector Representations
Manaal Faruqui, Yulia Tsvetkov, Dani Yogatama, Chris Dyer and Noah A. Smith

Learning Semantic Word Embeddings based on Ordinal Knowledge Constraints
Quan Liu, Hui Jiang, Si Wei, Zhen-Hua Ling and Yu Hu

Adding Semantics to Data-Driven Paraphrasing
Ellie Pavlick, Johan Bos, Malvina Nissim, Charley Beller, Benjamin Van Durme and Chris Callison-Burch

Session 7E: 15:15–16:30 Parsing

Parsing as Reduction
Daniel Fernández-González and André F. T. Martins

Optimal Shift-Reduce Constituent Parsing with Structured Perceptron
Le Quang Thang, Hiroshi Noji and Yusuke Miyao

A Data-Driven, Factorization Parser for CCG Dependency Structures
Yantao Du, Weiwei Sun and Xiaojun Wan

Tuesday, July 28 (continued)

16:30–19:30 **Poster and Dinner Session 2: Short Papers, Student Research Workshop Papers**

19:45–22:00 **Social Event**

Wednesday, July 29

07:30–18:00 **Registration**

09:00–10:00 **Keynote Address: "Construction and Mining of Heterogenous Information Networks from Data" - Jiawei Han**

10:00–10:30 **Coffee Break**

10:30–11:45 **Session 8: Long Papers**

Session 8A: 10:30–11:45 Machine Learning: Neural Networks

Improved Semantic Representations From Tree-Structured Long Short-Term Memory Networks
Kai Sheng Tai, Richard Socher and Christopher D. Manning

genCNN: A Convolutional Architecture for Word Sequence Prediction
Mingxuan Wang, Zhengdong Lu, Hang Li, Wenbin Jiang and Qun Liu

Neural Responding Machine for Short-Text Conversation
Lifeng Shang, Zhengdong Lu and Hang Li

Session 8B: 10:30–11:45 Automatic Summarization

Abstractive Multi-Document Summarization via Phrase Selection and Merging
Lidong Bing, Piji Li, Yi Liao, Wai Lam, Weiwei Guo and Rebecca Passonneau

Joint Graphical Models for Date Selection in Timeline Summarization
Giang Tran, Eelco Herder and Katja Markert

Predicting Salient Updates for Disaster Summarization
Chris Kedzie, Kathleen McKeown and Fernando Diaz

Session 8C: 10:30–11:45 Linguistic and Psycholinguistic Aspects of NLP

Unsupervised Prediction of Acceptability Judgements
Jey Han Lau, Alexander Clark and Shalom Lappin

A Frame of Mind: Using Statistical Models for Detection of Framing and Agenda Setting Campaigns
Oren Tsur, Dan Calacci and David Lazer

Why discourse affects speakers' choice of referring expressions
Naho Orita, Eliana Vornov, Naomi Feldman and Hal Daumé III

Session 8D: 10:30–11:45 NLP for the Web: Social Media

Linguistic Harbingers of Betrayal: A Case Study on an Online Strategy Game
Vlad Niculae, Srijan Kumar, Jordan Boyd-Graber and Cristian Danescu-Niculescu-Mizil

Who caught a cold ? - Identifying the subject of a symptom
Shin Kanouchi, Mamoru Komachi, Naoaki Okazaki, Eiji ARAMAKI and Hiroshi Ishikawa

Weakly Supervised Role Identification in Teamwork Interactions
Diyi Yang, Miaomiao Wen and Carolyn Rose

Session 8E: 10:30–11:45 Text Categorization/Information Retrieval

Deep Unordered Composition Rivals Syntactic Methods for Text Classification
Mohit Iyyer, Varun Manjunatha, Jordan Boyd-Graber and Hal Daumé III

SOLAR: Scalable Online Learning Algorithms for Ranking
Jialei Wang, Ji Wan, Yongdong Zhang and Steven Hoi

Text Categorization as a Graph Classification Problem
Francois Rousseau, Emmanouil Kiagias and Michalis Vazirgiannis

11:45–13:00 Lunch Break

13:00–14:30 ACL Business Meeting

14:35–15:25 Session 9: TACL and Long papers

Session 9A: 14:35–15:25 Multilinguality

Inverted indexing for cross-lingual NLP
Anders Søgaard, Željko Agić, Héctor Martínez Alonso, Barbara Plank, Bernd Bohnet and Anders Johannsen

Multi-Task Learning for Multiple Language Translation
Daxiang Dong, Hua Wu, Wei He, Dianhai Yu and Haifeng Wang

Session 9B: 14:35–15:25 Word Segmentation

Accurate Linear-Time Chinese Word Segmentation via Embedding Matching
Jianqiang Ma and Erhard Hinrichs

Gated Recursive Neural Network for Chinese Word Segmentation
Xinchi Chen, Xipeng Qiu, Chenxi Zhu and Xuanjing Huang

Session 9C: 14:35–15:25 Morphology, Phonology

[TACL] An Unsupervised Method for Uncovering Morphological Chains
Karthik Narasimhan, Regina Barzilay, Tommi Jaakkola

[TACL] Modeling Word Forms Using Latent Underlying Morphs and Phonology
Ryan Cotterell, Nanyun Peng, Jason Eisner

Session 9D: 14:35–15:25 NLP for the Web: Twitter

An analysis of the user occupational class through Twitter content
Daniel Preoţiuc-Pietro, Vasileios Lampos and Nikolaos Aletras

Tracking unbounded Topic Streams
Dominik Wurzer, Victor Lavrenko and Miles Osborne

Session 9E: 14:35–15:25 POS Tagging

Inducing Word and Part-of-Speech with Pitman-Yor Hidden Semi-Markov Models
Kei Uchiumi, Hiroshi Tsukahara and Daichi Mochihashi

Coupled Sequence Labeling on Heterogeneous Annotations: POS Tagging as a Case Study

On Using Very Large Target Vocabulary for Neural Machine Translation

Sébastien Jean Kyunghyun Cho
Roland Memisevic
Université de Montréal

Yoshua Bengio
Université de Montréal
CIFAR Senior Fellow

Abstract

Neural machine translation, a recently proposed approach to machine translation based purely on neural networks, has shown promising results compared to the existing approaches such as phrase-based statistical machine translation. Despite its recent success, neural machine translation has its limitation in handling a larger vocabulary, as training complexity as well as decoding complexity increase proportionally to the number of target words. In this paper, we propose a method based on importance sampling that allows us to use a very large target vocabulary without increasing training complexity. We show that decoding can be efficiently done even with the model having a very large target vocabulary by selecting only a small subset of the whole target vocabulary. The models trained by the proposed approach are empirically found to match, and in some cases outperform, the baseline models with a small vocabulary as well as the LSTM-based neural machine translation models. Furthermore, when we use an ensemble of a few models with very large target vocabularies, we achieve performance comparable to the state of the art (measured by BLEU) on both the English→German and English→French translation tasks of WMT'14.

1 Introduction

Neural machine translation (NMT) is a recently introduced approach to solving machine translation (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2015; Sutskever et al., 2014). In neural machine translation, one builds a single neural network that reads a source sentence and generates its translation. The whole neural network is jointly trained to maximize the conditional probability of a correct translation given a source sentence, using the bilingual corpus. The NMT models have shown to perform as well as the most widely used conventional translation systems (Sutskever et al., 2014; Bahdanau et al., 2015).

Neural machine translation has a number of advantages over the existing statistical machine translation system, specifically, the phrase-based system (Koehn et al., 2003). First, NMT requires a minimal set of domain knowledge. For instance, all of the models proposed in (Sutskever et al., 2014), (Bahdanau et al., 2015) or (Kalchbrenner and Blunsom, 2013) do not assume any linguistic property in both source and target sentences except that they are sequences of words. Second, the whole system is jointly trained to maximize the translation performance, unlike the existing phrase-based system which consists of many separately trained features whose weights are then tuned jointly. Lastly, the memory footprint of the NMT model is often much smaller than the existing system which relies on maintaining large tables of phrase pairs.

Despite these advantages and promising results, there is a major limitation in NMT compared to the existing phrase-based approach. That is, the number of target words must be limited. This is mainly because the complexity of training and using an NMT model increases as the number of target words increases.

A usual practice is to construct a target vocabulary of the K most frequent words (a so-called shortlist), where K is often in the range of $30k$ (Bahdanau et al., 2015) to $80k$ (Sutskever et al., 2014). Any word not included in this vocabulary is mapped to a special token representing an *unknown* word [UNK]. This approach works well when there are only a few unknown words in the target sentence, but it has been observed

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 1–10,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

that the translation performance degrades rapidly as the number of unknown words increases (Cho et al., 2014a; Bahdanau et al., 2015).

In this paper, we propose an approximate training algorithm based on (biased) importance sampling that allows us to train an NMT model with a much larger target vocabulary. The proposed algorithm effectively keeps the computational complexity during training at the level of using only a small subset of the full vocabulary. Once the model with a very large target vocabulary is trained, one can choose to use either all the target words or only a subset of them.

We compare the proposed algorithm against the baseline shortlist-based approach in the tasks of English→French and English→German translation using the NMT model introduced in (Bahdanau et al., 2015). The empirical results demonstrate that we can potentially achieve better translation performance using larger vocabularies, and that our approach does not sacrifice too much speed for both training and decoding. Furthermore, we show that the model trained with this algorithm gets the best translation performance yet achieved by single NMT models on the WMT'14 English→French translation task.

2 Neural Machine Translation and Limited Vocabulary Problem

In this section, we briefly describe an approach to neural machine translation proposed recently in (Bahdanau et al., 2015). Based on this description we explain the issue of limited vocabularies in neural machine translation.

2.1 Neural Machine Translation

Neural machine translation is a recently proposed approach to machine translation, which uses a single neural network trained jointly to maximize the translation performance (Forcada and Ñeco, 1997; Kalchbrenner and Blunsom, 2013; Cho et al., 2014b; Sutskever et al., 2014; Bahdanau et al., 2015).

Neural machine translation is often implemented as the encoder–decoder network. The encoder reads the source sentence $x = (x_1, \ldots, x_T)$ and encodes it into a sequence of hidden states $h = (h_1, \cdots, h_T)$:

$$h_t = f\left(x_t, h_{t-1}\right). \qquad (1)$$

Then, the decoder, another recurrent neural network, generates a corresponding translation $y = (y_1, \cdots, y_{T'})$ based on the encoded sequence of hidden states h:

$$p(y_t \mid y_{<t}, x) \propto \exp\left\{q\left(y_{t-1}, z_t, c_t\right)\right\}, \qquad (2)$$

where

$$z_t = g\left(y_{t-1}, z_{t-1}, c_t\right), \qquad (3)$$
$$c_t = r\left(z_{t-1}, h_1, \ldots, h_T\right), \qquad (4)$$

and $y_{<t} = (y_1, \ldots, y_{t-1})$.

The whole model is jointly trained to maximize the conditional log-probability of the correct translation given a source sentence with respect to the parameters $\boldsymbol{\theta}$ of the model:

$$\boldsymbol{\theta}^* = \arg\max_{\boldsymbol{\theta}} \sum_{n=1}^{N} \sum_{t=1}^{T_n} \log p(y_t^n \mid y_{<t}^n, x^n),$$

where (x^n, y^n) is the n-th training pair of sentences, and T_n is the length of the n-th target sentence (y^n).

2.1.1 Detailed Description

In this paper, we use a specific implementation of neural machine translation that uses an attention mechanism, as recently proposed in (Bahdanau et al., 2015).

In (Bahdanau et al., 2015), the encoder in Eq. (1) is implemented by a bi-directional recurrent neural network such that

$$h_t = \left[\overleftarrow{h}_t; \overrightarrow{h}_t\right],$$

where

$$\overleftarrow{h}_t = f\left(x_t, \overleftarrow{h}_{t+1}\right), \overrightarrow{h}_t = f\left(x_t, \overrightarrow{h}_{t-1}\right).$$

They used a gated recurrent unit for f (see, e.g., (Cho et al., 2014b)).

The decoder, at each time, computes the context vector c_t as a convex sum of the hidden states $(h_1, \ldots, h_T)$ with the coefficients $\alpha_1, \ldots, \alpha_T$ computed by

$$\alpha_t = \frac{\exp\left\{a\left(h_t, z_{t-1}\right)\right\}}{\sum_k \exp\left\{a\left(h_k, z_{t-1}\right)\right\}}, \qquad (5)$$

where a is a feedforward neural network with a single hidden layer.

A new hidden state z_t of the decoder in Eq. (3) is computed based on the previous hidden state z_{t-1}, previous generated symbol y_{t-1} and the computed context vector c_t. The decoder also uses the gated recurrent unit, as the encoder does.

The probability of the next target word in Eq. (2) is then computed by

$$p(y_t \mid y_{<t}, x) = \frac{1}{Z} \exp\left\{ \mathbf{w}_t^\top \phi\left(y_{t-1}, z_t, c_t\right) + b_t \right\}, \tag{6}$$

where ϕ is an affine transformation followed by a nonlinear activation, and $\mathbf{w}_t$ and b_t are respectively the *target word vector* and the target word bias. Z is the normalization constant computed by

$$Z = \sum_{k: y_k \in V} \exp\left\{ \mathbf{w}_k^\top \phi\left(y_{t-1}, z_t, c_t\right) + b_k \right\}, \tag{7}$$

where V is the set of all the target words.

For the detailed description of the implementation, we refer the reader to the appendix of (Bahdanau et al., 2015).

2.2 Limited Vocabulary Issue and Conventional Solutions

One of the main difficulties in training this neural machine translation model is the computational complexity involved in computing the target word probability (Eq. (6)). More specifically, we need to compute the dot product between the feature $\phi\left(y_{t-1}, z_t, c_t\right)$ and the word vector w_t as many times as there are words in a target vocabulary in order to compute the normalization constant (the denominator in Eq. (6)). This has to be done for, on average, 20–30 words per sentence, which easily becomes prohibitively expensive even with a moderate number of possible target words. Furthermore, the memory requirement grows linearly with respect to the number of target words. This has been a major hurdle for neural machine translation, compared to the existing non-parametric approaches such as phrase-based translation systems.

Recently proposed neural machine translation models, hence, use a shortlist of 30k to 80k most frequent words (Bahdanau et al., 2015; Sutskever et al., 2014). This makes training more feasible, but comes with a number of problems. First of all, the performance of the model degrades heavily if the translation of a source sentence requires many words that are not included in the shortlist (Cho et al., 2014a). This also affects the performance evaluation of the system which is often measured by BLEU. Second, the first issue becomes more problematic with languages that have a rich set of words such as German or other highly inflected languages.

There are two *model-specific* approaches to this issue of large target vocabulary. The first approach is to stochastically approximate the target word probability. This has been proposed recently in (Mnih and Kavukcuoglu, 2013; Mikolov et al., 2013) based on noise-contrastive estimation (Gutmann and Hyvarinen, 2010). In the second approach, the target words are clustered into multiple classes, or hierarchical classes, and the target probability $p(y_t|y_{<t}, x)$ is factorized as a product of the class probability $p(c_t|y_{<t}, x)$ and the intraclass word probability $p(y_t|c_t, y_{<t}, x)$. This reduces the number of required dot-products into the sum of the number of classes and the words in a class. These approaches mainly aim at reducing the computational complexity during training, but do not often result in speed-up when decoding a translation during test time.[1]

Other than these model-specific approaches, there exist *translation-specific* approaches. A translation-specific approach exploits the properties of the rare target words. For instance, Luong et al. proposed such an approach for neural machine translation (Luong et al., 2015). They replace rare words (the words that are not included in the shortlist) in both source and target sentences into corresponding $\langle \text{OOV}_n \rangle$ tokens using the word alignment model. Once a source sentence is translated, each $\langle \text{OOV}_n \rangle$ in the translation will be replaced based on the source word marked by the corresponding $\langle \text{OOV}_n \rangle$.

It is important to note that the model-specific approaches and the translation-specific approaches are often complementary and can be used together to further improve the translation performance and reduce the computational complexity.

3 Approximate Learning Approach to Very Large Target Vocabulary

3.1 Description

In this paper, we propose a *model-specific* approach that allows us to train a neural machine translation model with a very large target vocabulary. With the proposed approach, the compu-

[1] This is due to the fact that the beam search requires the conditional probability of *every* target word at each time step regardless of the parametrization of the output probability.

tational complexity of training becomes constant with respect to the size of the target vocabulary. Furthermore, the proposed approach allows us to efficiently use a fast computing device with limited memory, such as a GPU, to train a neural machine translation model with a much larger target vocabulary.

As mentioned earlier, the computational inefficiency of training a neural machine translation model arises from the normalization constant in Eq. (6). In order to avoid the growing complexity of computing the normalization constant, we propose here to use only a small subset V' of the target vocabulary at each update. The proposed approach is based on the earlier work of (Bengio and Sénécal, 2008).

Let us consider the gradient of the log-probability of the output in Eq. (6). The gradient is composed of a positive and negative part:

$$\begin{aligned}&\nabla \log p(y_t \mid y_{<t}, x) \qquad (8)\\ &=\nabla \mathcal{E}(y_t) - \sum_{k:y_k \in V} p(y_k \mid y_{<t}, x) \nabla \mathcal{E}(y_k),\end{aligned}$$

where we define the energy $\mathcal{E}$ as

$$\mathcal{E}(y_j) = \mathbf{w}_j^\top \phi\left(y_{j-1}, z_j, c_j\right) + b_j.$$

The second, or negative, term of the gradient is in essence the expected gradient of the energy:

$$\mathbb{E}_P\left[\nabla \mathcal{E}(y)\right], \qquad (9)$$

where P denotes $p(y \mid y_{<t}, x)$.

The main idea of the proposed approach is to approximate this expectation, or the negative term of the gradient, by importance sampling with a small number of samples. Given a predefined proposal distribution Q and a set V' of samples from Q, we approximate the expectation in Eq. (9) with

$$\mathbb{E}_P\left[\nabla \mathcal{E}(y)\right] \approx \sum_{k:y_k \in V'} \frac{\omega_k}{\sum_{k':y_{k'} \in V'} \omega_{k'}} \nabla \mathcal{E}(y_k), \qquad (10)$$

where

$$\omega_k = \exp\left\{\mathcal{E}(y_k) - \log Q(y_k)\right\}. \qquad (11)$$

This approach allows us to compute the normalization constant during training using only a small subset of the target vocabulary, resulting in much lower computational complexity for each parameter update. Intuitively, at each parameter update, we update only the vectors associated with the correct word $\mathbf{w}_t$ and with the sampled words in V'. Once training is over, we can use the full target vocabulary to compute the output probability of each target word.

Although the proposed approach naturally addresses the computational complexity, using this approach naively does not guarantee that the number of parameters being updated for each sentence pair, which includes multiple target words, is bounded nor can be controlled. This becomes problematic when training is done, for instance, on a GPU with limited memory.

In practice, hence, we partition the training corpus and define a subset V' of the target vocabulary for each partition prior to training. Before training begins, we sequentially examine each target sentence in the training corpus and accumulate unique target words until the number of unique target words reaches the predefined threshold τ. The accumulated vocabulary will be used for this partition of the corpus during training. We repeat this until the end of the training set is reached. Let us refer to the subset of target words used for the i-th partition by V'_i.

This may be understood as having a separate proposal distribution Q_i for each partition of the training corpus. The distribution Q_i assigns equal probability mass to all the target words included in the subset V'_i, and zero probability mass to all the other words, i.e.,

$$Q_i(y_k) = \begin{cases} \frac{1}{|V'_i|} & \text{if } y_t \in V'_i \\ 0 & \text{otherwise.} \end{cases}$$

This choice of proposal distribution cancels out the correction term $-\log Q(y_k)$ from the importance weight in Eqs. (10)–(11), which makes the proposed approach equivalent to approximating the exact output probability in Eq. (6) with

$$\begin{aligned}&p(y_t \mid y_{<t}, x)\\ &=\frac{\exp\left\{\mathbf{w}_t^\top \phi\left(y_{t-1}, z_t, c_t\right) + b_t\right\}}{\sum_{k:y_k \in V'} \exp\left\{\mathbf{w}_k^\top \phi\left(y_{t-1}, z_t, c_t\right) + b_k\right\}}.\end{aligned}$$

It should be noted that this choice of Q makes the estimator biased.

The proposed procedure results in speed up against usual importance sampling, as it exploits the advantage of modern computers in doing matrix-matrix vs matrix-vector multiplications.

3.1.1 Informal Discussion on Consequence

The parametrization of the output probability in Eq. (6) can be understood as arranging the vectors associated with the target words such that the dot product between the most likely, or correct, target word's vector and the current hidden state is maximized. The exponentiation followed by normalization is simply a process in which the dot products are converted into proper probabilities.

As learning continues, therefore, the vectors of all the likely target words tend to align with each other but not with the others. This is achieved exactly by moving the vector of the correct word in the direction of $\phi(y_{t-1}, z_t, c_t)$, while pushing all the other vectors away, which happens when the gradient of the logarithm of the exact output probability in Eq. (6) is maximized. Our approximate approach, instead, moves the word vectors of the correct words and of only a subset of sampled target words (those included in V').

3.2 Decoding

Once the model is trained using the proposed approximation, we can use the full target vocabulary when decoding a translation given a new source sentence. Although this is advantageous as it allows the trained model to utilize the whole vocabulary when generating a translation, doing so may be too computationally expensive, e.g., for real-time applications.

Since training puts the target word vectors in the space so that they align well with the hidden state of the decoder only when they are likely to be a correct word, we can use only a subset of candidate target words during decoding. This is similar to what we do during training, except that at test time, we do not have access to a set of correct target words.

The most naïve way to select a subset of candidate target words is to take only the top-K most frequent target words, where K can be adjusted to meet the computational requirement. This, however, effectively cancels out the whole purpose of training a model with a very large target vocabulary. Instead, we can use an existing word alignment model to align the source and target words in the training corpus and build a dictionary. With the dictionary, for each source sentence, we construct a target word set consisting of the K-most frequent words (according to the estimated unigram probability) and, using the dictionary, at most K' likely target words for each source word. K and K' may be chosen either to meet the computational requirement or to maximize the translation performance on the development set. We call a subset constructed in either of these ways a *candidate list*.

3.3 Source Words for Unknown Words

In the experiments, we evaluate the proposed approach with the neural machine translation model called RNNsearch (Bahdanau et al., 2015) (see Sec. 2.1.1). In this model, as a part of decoding process, we obtain the alignments between the target words and source locations via the alignment model in Eq. (5).

We can use this feature to infer the source word to which each target word was most aligned (indicated by the largest α_t in Eq. (5)). This is especially useful when the model generated an [UNK] token. Once a translation is generated given a source sentence, each [UNK] may be replaced using a translation-specific technique based on the aligned source word. For instance, in the experiment, we try replacing each [UNK] token with the aligned source word or its most likely translation determined by another word alignment model. Other techniques such as transliteration may also be used to further improve the performance (Koehn, 2010).

4 Experiments

We evaluate the proposed approach in English→French and English→German translation tasks. We trained the neural machine translation models using only the bilingual, parallel corpora made available as a part of WMT'14. For each pair, the datasets we used are:

- English→French:[2]
  - Common Crawl
  - News Commentary
  - Gigaword
  - Europarl v7
  - UN
- English→German:
  - Common Crawl
  - News Commentary
  - Europarl v7

[2] The preprocessed data can be found and downloaded from `http://www-lium.univ-lemans.fr/~schwenk/nnmt-shared-task/README`.

	English-French		English-German	
	Train	Test	Train	Test
15k	93.5	90.8	88.5	83.8
30k	96.0	94.6	91.8	87.9
50k	97.3	96.3	93.7	90.4
500k	99.5	99.3	98.4	96.1
All	100.0	99.6	100.0	97.3

Table 1: Data coverage (in %) on target-side corpora for different vocabulary sizes. ”All” refers to all the tokens in the training set.

To ensure fair comparison, the English→French corpus, which comprises approximately 12 million sentences, is identical to the one used in (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2015; Sutskever et al., 2014). As for English→German, the corpus was preprocessed, in a manner similar to (Peitz et al., 2014; Li et al., 2014), in order to remove many poorly translated sentences.

We evaluate the models on the WMT'14 test set (news-test 2014),[3] while the concatenation of news-test-2012 and news-test-2013 is used for model selection (development set). Table 1 presents data coverage w.r.t. the vocabulary size, on the target side.

Unless mentioned otherwise, all reported BLEU scores (Papineni et al., 2002) are computed with the multi-bleu.perl script[4] on the cased tokenized translations.

4.1 Settings

As a baseline for English→French translation, we use the **RNNsearch** model proposed by (Bahdanau et al., 2015), with 30k source and target words.[5] Another RNNsearch model is trained for English→German translation with 50k source and target words.

For each language pair, we train another set of RNNsearch models with much larger vocabularies of 500k source and target words, using the proposed approach. We call these models **RNNsearch-LV**. We vary the size of the shortlist used during training (τ in Sec. 3.1). We tried 15k and 30k for English→French, and 15k and 50k for English→German. We later report the results for the best performance on the development set, with models generally evaluated every twelve hours. The training speed is approximately the same as for RNNsearch. Using a 780 Ti or Titan Black GPU, we could process 100k mini-batches of 80 sentences in about 29 and 39 hours respectively for $\tau = 15k$ and $\tau = 50k$.

For both language pairs, we also trained new models, with $\tau = 15k$ and $\tau = 50k$, by reshuffling the dataset at the beginning of each epoch. While this causes a non-negligible amount of overhead, such a change allows words to be contrasted with different sets of other words each epoch.

To stabilize parameters other than the word embeddings, at the end of the training stage, we freeze the word embeddings and tune only the other parameters for approximately two more days after the peak performance on the development set is observed. This helped increase BLEU scores on the development set.

We use beam search to generate a translation given a source. During beam search, we keep a set of 12 hypotheses and normalize probabilities by the length of the candidate sentences, as in (Cho et al., 2014a).[6] The candidate list is chosen to maximize the performance on the development set, for $K \in \{15k, 30k, 50k\}$ and $K' \in \{10, 20\}$. As explained in Sec. 3.2, we test using a bilingual dictionary to accelerate decoding and to replace unknown words in translations. The bilingual dictionary is built using *fast_align* (Dyer et al., 2013). We use the dictionary only if a word starts with a lowercase letter, and otherwise, we copy the source word directly. This led to better performance on the development sets.

Note on ensembles For each language pair, we began training four models from each of which two points corresponding to the best and second-best performance on the development set were collected. We continued training from each point, while keeping the word embeddings fixed, until the best development performance was reached, and took the model at this point as a single model in an ensemble. This procedure resulted in a total of eight models from which we averaged the length-normalized log-probabilities. Since much of training had been shared, the composition of

[3] To compare with previous submissions, we use the filtered test sets.

Table 2: The translation performances in BLEU obtained by different models on (a) English→French and (b) English→German translation tasks. RNNsearch is the model proposed in (Bahdanau et al., 2015), RNNsearch-LV is the RNNsearch trained with the approach proposed in this paper, and Google is the LSTM-based model proposed in (Sutskever et al., 2014). Unless mentioned otherwise, we report single-model RNNsearch-LV scores using $\tau = 30k$ (English→French) and $\tau = 50k$ (English→German). For the experiments we have run ourselves, we show the scores on the development set as well in the brackets. ($\star$) (Sutskever et al., 2014), ($\circ$) (Luong et al., 2015), ($\bullet$) (Durrani et al., 2014), ($*$) Standard Moses Setting (Cho et al., 2014b), ($\diamond$) (Buck et al., 2014).

such ensembles may be sub-optimal. This is supported by the fact that higher cross-model BLEU scores (Freitag et al., 2014) are observed for models that were partially trained together.

4.2 Translation Performance

In Table 2, we present the results obtained by the trained models with very large target vocabularies, and alongside them, the previous results reported in (Sutskever et al., 2014), (Luong et al., 2015), (Buck et al., 2014) and (Durrani et al., 2014). Without translation-specific strategies, we can clearly see that the RNNsearch-LV outperforms the baseline RNNsearch.

In the case of the English→French task, RNNsearch-LV approached the performance level of the previous best single neural machine translation (NMT) model, even without any translation-specific techniques (Sec. 3.2–3.3). With these, however, the RNNsearch-LV outperformed it. The performance of the RNNsearch-LV is also better than that of a standard phrase-based translation system (Cho et al., 2014b). Furthermore, by combining 8 models, we were able to achieve a translation performance comparable to the state of the art, measured in BLEU.

For English→German, the RNNsearch-LV outperformed the baseline before unknown word replacement, but after doing so, the two systems performed similarly. We could reach higher large-vocabulary single-model performance by reshuffling the dataset, but this step could potentially also help the baseline. In this case, we were able to surpass the previously reported best translation result on this task by building an ensemble of 8 models.

With $\tau = 15k$, the RNNsearch-LV performance worsened a little, with best BLEU scores, without reshuffling, of 33.76 and 18.59 respectively for English→French and English→German.

The English→German ensemble described in this paper has also been used for the shared translation task of the 10$^{\text{th}}$ Workshop on Statistical Machine Translation (WMT'15), where it was ranked first in terms of BLEU score. The translations by this ensemble can be found online.[7]

4.3 Analysis

4.3.1 Decoding Speed

In Table 3, we present the timing information of decoding for different models. Clearly, decoding from RNNsearch-LV with the full target vocab-

RNNsearch-LV +Candidate list	0.12 s	0.05 s

Table 3: The average per-word decoding time. Decoding here does not include parameter loading and unknown word replacement. The baseline uses 30k words. The candidate list is built with $K = 30k$ and $K' = 10$. ($\star$) i7-4820K (single thread), ($\circ$) GTX TITAN Black

ulary is slowest. If we use a candidate list for decoding each translation, the speed of decoding substantially improves and becomes close to the baseline RNNsearch.

A potential issue with using a candidate list is that for each source sentence, we must re-build a target vocabulary and subsequently replace a part of the parameters, which may easily become time-consuming. We can address this issue, for instance, by building a common candidate list for multiple source sentences. By doing so, we were able to match the decoding speed of the baseline RNNsearch model.

4.3.2 Decoding Target Vocabulary

For English→French ($\tau = 30k$), we evaluate the influence of the target vocabulary when translating the test sentences by using the union of a fixed set of $30k$ common words and (at most) K' likely candidates for each source word according to the dictionary. Results are presented in Figure 1. With $K' = 0$ (not shown), the performance of the system is comparable to the baseline when not replacing the unknown words (30.12), but there is not as much improvement when doing so (31.14). As the large vocabulary model does not predict [UNK] as much during training, it is less likely to generate it when decoding, limiting the effectiveness of the post-processing step in this case. With $K' = 1$, which limits the diversity of allowed uncommon words, BLEU is not as good as with moderately larger K', which indicates that our models can, to some degree, correctly choose between rare alternatives. If we rather use $K = 50k$, as we did for testing based on validation performance, the improvement over $K' = 1$ is approximately 0.2 BLEU.

When validating the choice of K, we found it to be correlated with the value of τ used during training. For example, on the English→French validation set, with $\tau = 15k$ (and $K' = 10$), the BLEU score is 29.44 with $K = 15k$, but drops to 29.19 and 28.84 respectively for $K = 30k$ and $50k$. For $\tau = 30k$, the score increases moderately from $K = 15k$ to $K = 50k$. A similar effect was observed for English→German and on the test sets. As our implementation of importance sampling does not apply the usual correction to the gradient, it seems beneficial for the test vocabularies to resemble those used during training.

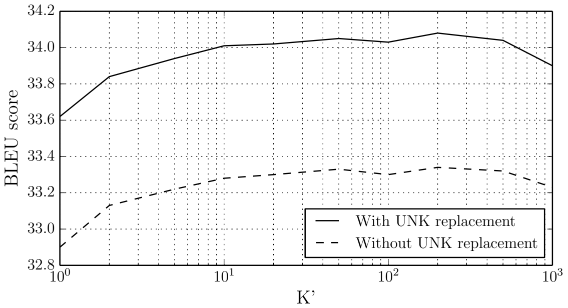

Figure 1: Single-model test BLEU scores (English→French) with respect to the number of dictionary entries K' allowed for each source word.

5 Conclusion

In this paper, we proposed a way to extend the size of the target vocabulary for neural machine translation. The proposed approach allows us to train a model with much larger target vocabulary without any substantial increase in computational complexity. It is based on the earlier work in (Bengio and Sénécal, 2008) which used importance sampling to reduce the complexity of computing the normalization constant of the output word probability in neural language models.

On English→French and English→German translation tasks, we observed that the neural machine translation models trained using the proposed method performed as well as, or better than, those using only limited sets of target words, even when replacing unknown words. As performance of the RNNsearch-LV models increased when only a selected subset of the target vocabulary was used during decoding, this makes the proposed learning algorithm more practical.

When measured by BLEU, our models showed translation performance comparable to the state-of-the-art translation systems on both the English→French task and English→German task. On the English→French task, a model trained with the proposed approach outperformed the best single neural machine translation (NMT) model from (Luong et al., 2015) by approximately 1 BLEU point. The performance of the ensemble of multiple models, despite its relatively less diverse composition, is approximately 0.3 BLEU points away from the best system (Luong et al., 2015). On the English→German task, the best performance of 21.59 BLEU by our model is higher than that of the previous state of the art (20.67) reported in (Buck et al., 2014).

Finally, we release the source code used in our experiments to encourage progress in neural machine translation.[8]

Abstract

Neural Machine Translation (NMT) is a new approach to machine translation that has shown promising results that are comparable to traditional approaches. A significant weakness in conventional NMT systems is their inability to correctly translate very rare words: end-to-end NMTs tend to have relatively small vocabularies with a single *unk* symbol that represents every possible out-of-vocabulary (OOV) word. In this paper, we propose and implement an effective technique to address this problem. We train an NMT system on data that is augmented by the output of a word alignment algorithm, allowing the NMT system to emit, for each OOV word in the target sentence, the position of its corresponding word in the source sentence. This information is later utilized in a post-processing step that translates every OOV word using a dictionary. Our experiments on the WMT'14 English to French translation task show that this method provides a substantial improvement of up to 2.8 BLEU points over an equivalent NMT system that does not use this technique. With 37.5 BLEU points, our NMT system is the first to surpass the best result achieved on a WMT'14 contest task.

1 Introduction

Neural Machine Translation (NMT) is a novel approach to MT that has achieved promising results (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015; Jean et al., 2015). An NMT system is a conceptually simple large neural network that reads the entire source sentence and produces an output translation one word at a time. NMT systems are appealing because they use minimal domain knowledge which makes them well-suited to any problem that can be formulated as mapping an input sequence to an output sequence (Sutskever et al., 2014). In addition, the natural ability of neural networks to generalize implies that NMT systems will also generalize to novel word phrases and sentences that do not occur in the training set. In addition, NMT systems potentially remove the need to store explicit phrase tables and language models which are used in conventional systems. Finally, the decoder of an NMT system is easy to implement, unlike the highly intricate decoders used by phrase-based systems (Koehn et al., 2003).

Despite these advantages, conventional NMT systems are incapable of translating rare words because they have a fixed modest-sized vocabulary[1] which forces them to use the *unk* symbol to represent the large number of out-of-vocabulary (OOV) words, as illustrated in Figure 1. Unsurprisingly, both Sutskever et al. (2014) and Bahdanau et al. (2015) have observed that sentences with many rare words tend to be translated much more poorly than sentences containing mainly frequent words. Standard phrase-based systems (Koehn et al., 2007; Chiang, 2007; Cer et al., 2010; Dyer et al., 2010), on the other hand, do not suffer from the rare word problem to the same extent because they can support a much larger vocabulary, and because their use of explicit alignments and phrase tables allows them to memorize the translations of even extremely rare words.

Motivated by the strengths of standard phrase-

*Work done while the authors were in Google. † indicates equal contribution.

[1] Due to the computationally intensive nature of the softmax, NMT systems often limit their vocabularies to be the top 30K-80K most frequent words in each language. However, Jean et al. (2015) has very recently proposed an efficient approximation to the softmax that allows for training NTMs with very large vocabularies. As discussed in Section 2, this technique is complementary to ours.

nn: Le `unk` de `unk` à `unk` , . . . [truncated] . . . , a été pris le jeudi matin

Figure 1: **Example of the rare word problem** – An English source sentence (*en*), a human translation to French (*fr*), and a translation produced by one of our neural network systems (*nn*) before handling OOV words. We highlight *words* that are unknown to our model. The token `unk` indicates an OOV word. We also show a few important alignments between the pair of sentences.

based system, we propose and implement a novel approach to address the rare word problem of NMTs. Our approach annotates the training corpus with explicit alignment information that enables the NMT system to emit, for each OOV word, a "pointer" to its corresponding word in the source sentence. This information is later utilized in a post-processing step that translates the OOV words using a dictionary or with the identity translation, if no translation is found.

Our experiments confirm that this approach is effective. On the English to French WMT'14 translation task, this approach provides an improvement of up to 2.8 (if the vocabulary is relatively small) BLEU points over an equivalent NMT system that does not use this technique. Moreover, our system is the first NMT that outperforms the winner of a WMT'14 task.

2 Neural Machine Translation

A neural machine translation system is any neural network that maps a source sentence, $s_1, \ldots, s_n$, to a target sentence, $t_1, \ldots, t_m$, where all sentences are assumed to terminate with a special "end-of-sentence" token <eos>. More concretely, an NMT system uses a neural network to parameterize the conditional distributions

$$p(t_j|t_{<j}, s_{\leq n}) \tag{1}$$

for $1 \leq j \leq m$. By doing so, it becomes possible to compute and therefore maximize the log probability of the target sentence given the source sentence

$$\log p(t|s) = \sum_{j=1}^{m} \log p\left(t_j|t_{<j}, s_{\leq n}\right) \tag{2}$$

There are many ways to parameterize these conditional distributions. For example, Kalchbrenner and Blunsom (2013) used a combination of a convolutional neural network and a recurrent neural network, Sutskever et al. (2014) used a deep Long Short-Term Memory (LSTM) model, Cho et al. (2014) used an architecture similar to the LSTM, and Bahdanau et al. (2015) used a more elaborate neural network architecture that uses an attentional mechanism over the input sequence, similar to Graves (2013) and Graves et al. (2014).

In this work, we use the model of Sutskever et al. (2014), which uses a deep LSTM to encode the input sequence and a separate deep LSTM to output the translation. The encoder reads the source sentence, one word at a time, and produces a large vector that represents the entire source sentence. The decoder is initialized with this vector and generates a translation, one word at a time, until it emits the end-of-sentence symbol <eos>.

None the early work in neural machine translation systems has addressed the rare word problem, but the recent work of Jean et al. (2015) has tackled it with an efficient approximation to the softmax to accommodate for a very large vocabulary (500K words). However, even with a large vocabulary, the problem with rare words, e.g., names, numbers, etc., still persists, and Jean et al. (2015) found that using techniques similar to ours are beneficial and complementary to their approach.

3 Rare Word Models

Despite the relatively large amount of work done on pure neural machine translation systems, there has been no work addressing the OOV problem in NMT systems, with the notable exception of Jean et al. (2015)'s work mentioned earlier.

We propose to address the rare word problem by training the NMT system to track the origins of the unknown words in the target sentences. If we knew the source word responsible for each un-en: The $\underline{\texttt{unk}}_1$ portico in $\underline{\texttt{unk}}_2$ ...

fr: Le $\underline{\texttt{unk}}_\emptyset$ $\underline{\texttt{unk}}_1$ de $\underline{\texttt{unk}}_2$ ...

Figure 2: **Copyable Model** – an annotated example with two types of unknown tokens: “copyable” $\underline{\texttt{unk}}_n$ and null $\underline{\texttt{unk}}_\emptyset$.

en: The $\underline{\texttt{unk}}$ portico in $\underline{\texttt{unk}}$ ...

fr: Le $\texttt{p}_0$ $\underline{\texttt{unk}}$ $\texttt{p}_{-1}$ $\underline{\texttt{unk}}$ $\texttt{p}_1$ de $\texttt{p}_\emptyset$ $\underline{\texttt{unk}}$ $\texttt{p}_{-1}$ ...

Figure 3: **Positional All Model** – an example of the PosAll model. Each word is followed by the relative positional tokens $\texttt{p}_d$ or the null token $\texttt{p}_\emptyset$.

known target word, we could introduce a post-processing step that would replace each $\underline{\texttt{unk}}$ in the system's output with a translation of its source word, using either a dictionary or the identity translation. For example, in Figure 1, if the model knows that the second unknown token in the NMT (line *nn*) originates from the source word `ecotax`, it can perform a word dictionary lookup to replace that unknown token by `écotaxe`. Similarly, an identity translation of the source word `Pont-de-Buis` can be applied to the third unknown token.

We present three annotation strategies that can easily be applied to any NMT system (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014). We treat the NMT system as a black box and train it on a corpus annotated by one of the models below. First, the alignments are produced with an unsupervised aligner. Next, we use the alignment links to construct a word dictionary that will be used for the word translations in the post-processing step.[2] If a word does not appear in our dictionary, then we apply the identity translation.

The first few words of the sentence pair in Figure 1 (lines *en* and *fr*) illustrate our models.

3.1 Copyable Model

In this approach, we introduce multiple tokens to represent the various unknown words in the source and in the target language, as opposed to using only one $\underline{\texttt{unk}}$ token. We annotate the OOV words in the source sentence with $\underline{\texttt{unk}}_1$, $\underline{\texttt{unk}}_2$, $\underline{\texttt{unk}}_3$, in that order, while assigning repeating unknown words identical tokens. The annotation of the unknown words in the target language is slightly more elaborate: (a) each unknown target word that is aligned to an unknown source word is assigned the same unknown token (hence, the “copy” model) and (b) an unknown target word that has no alignment or that is aligned with a known word uses the special null token $\underline{\texttt{unk}}_\emptyset$. See Figure 2 for an example. This annotation enables us to translate every non-null unknown token.

3.2 Positional All Model (PosAll)

The copyable model is limited by its inability to translate unknown target words that are aligned to *known* words in the source sentence, such as the pair of words, “portico” and “portique”, in our running example. The former word is known on the source sentence; whereas latter is not, so it is labelled with $\underline{\texttt{unk}}_\emptyset$. This happens often since the source vocabularies of our models tend to be much larger than the target vocabulary since a large source vocabulary is cheap. This limitation motivated us to develop an annotation model that includes the complete alignments between the source and the target sentences, which is straightforward to obtain since the complete alignments are available at training time.

Specifically, we return to using only a single universal $\underline{\texttt{unk}}$ token. However, on the target side, we insert a positional token $\texttt{p}_d$ after every word. Here, d indicates a relative position ($d = -7, \ldots, -1, 0, 1, \ldots, 7$) to denote that a target word at position j is aligned to a source word at position $i = j - d$. Aligned words that are too far apart are considered unaligned, and unaligned words rae annotated with a null token $\texttt{p}_n$. Our annotation is illustrated in Figure 3.

3.3 Positional Unknown Model (PosUnk)

The main weakness of the PosAll model is that it doubles the length of the target sentence. This makes learning more difficult and slows the speed of parameter updates by a factor of two. However, given that our post-processing step is concerned only with the alignments of the unknown words, so it is more sensible to only annotate the unknown words. This motivates our *positional unknown* model which uses $\texttt{unkpos}_d$ tokens (for d in $-7, \ldots, 7$ or $\emptyset$) to simultaneously denote (a)

[2] When a source word has multiple translations, we use the translation with the highest probability. These translation probabilities are estimated from the unsupervised alignment links. When constructing the dictionary from these alignment links, we add a word pair to the dictionary only if its alignment count exceeds 100.

the fact that a word is unknown and (b) its relative position d with respect to its aligned source word. Like the PosAll model, we use the symbol $\underline{\texttt{unkpos}_\emptyset}$ for unknown target words that do not have an alignment. We use the universal $\underline{\texttt{unk}}$ for all unknown tokens in the source language. See Figure 4 for an annotated example.

en: The $\underline{\texttt{unk}}$ portico in $\underline{\texttt{unk}}$ ...

fr: Le $\underline{\texttt{unkpos}_1}$ $\underline{\texttt{unkpos}_{-1}}$ de $\underline{\texttt{unkpos}_1}$ ...

Figure 4: **Positional Unknown Model** – an example of the PosUnk model: only aligned unknown words are annotated with the $\texttt{unkpos}_d$ tokens.

It is possible that despite its slower speed, the PosAll model will learn better alignments because it is trained on many more examples of words and their alignments. However, we show that this is not the case (see §5.2).

4 Experiments

We evaluate the effectiveness of our OOV models on the WMT'14 English-to-French translation task. Translation quality is measured with the BLEU metric (Papineni et al., 2002) on the newstest2014 test set (which has 3003 sentences).

4.1 Training Data

To be comparable with the results reported by previous work on neural machine translation systems (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015), we train our models on the same training data of 12M parallel sentences (348M French and 304M English words), obtained from (Schwenk, 2014). The 12M subset was selected from the full WMT'14 parallel corpora using the method proposed in Axelrod et al. (2011).

Due to the computationally intensive nature of the naive softmax, we limit the French vocabulary (the *target* language) to the either the 40K or the 80K most frequent French words. On the *source* side, we can afford a much larger vocabulary, so we use the 200K most frequent English words. The model treats all other words as unknowns.[3]

We annotate our training data using the three schemes described in the previous section. The alignment is computed with the Berkeley aligner (Liang et al., 2006) using its default settings. We discard sentence pairs in which the source or the target sentence exceed 100 tokens.

4.2 Training Details

Our training procedure and hyperparameter choices are similar to those used by Sutskever et al. (2014). In more details, we train multi-layer deep LSTMs, each of which has 1000 cells, with 1000 dimensional embeddings. Like Sutskever et al. (2014), we reverse the words in the source sentences which has been shown to improve LSTM memory utilization and results in better translations of long sentences. Our hyperparameters can be summarized as follows: (a) the parameters are initialized uniformly in [-0.08, 0.08] for 4-layer models and [-0.06, 0.06] for 6-layer models, (b) SGD has a fixed learning rate of 0.7, (c) we train for 8 epochs (after 5 epochs, we begin to halve the learning rate every 0.5 epoch), (d) the size of the mini-batch is 128, and (e) we rescale the normalized gradient to ensure that its norm does not exceed 5 (Pascanu et al., 2012).

We also follow the GPU parallelization scheme proposed in (Sutskever et al., 2014), allowing us to reach a training speed of 5.4K words per second to train a depth-6 model with 200K source and 80K target vocabularies ; whereas Sutskever et al. (2014) achieved 6.3K words per second for a depth-4 models with 80K source and target vocabularies. Training takes about 10-14 days on an 8-GPU machine.

4.3 A note on BLEU scores

We report BLEU scores based on both: (a) *detokenized* translations, i.e., WMT'14 style, to be comparable with results reported on the WMT website[4] and (b) *tokenized translations*, so as to be consistent with previous work (Cho et al., 2014; Bahdanau et al., 2015; Schwenk, 2014; Sutskever et al., 2014; Jean et al., 2015).[5]

The existing WMT'14 state-of-the-art system (Durrani et al., 2014) achieves a detokenized BLEU score of 35.8 on the newstest2014 test set for English to French language pair (see Table 2). In terms of the tokenized BLEU, its performance is 37.0 points (see Table 1).

[3] When the French vocabulary has 40K words, there are on average 1.33 unknown words per sentence on the target side of the test set.

[4] `http://matrix.statmt.org/matrix`

[5] The `tokenizer.perl` and `multi-bleu.pl` scripts are used to tokenize and score translations.

System	Vocab	Corpus	BLEU
State of the art in WMT'14 (Durrani et al., 2014)	All	36M	**37.0**
Standard MT + neural components			
Schwenk (2014) – neural language model	All	12M	33.3
Cho et al. (2014)– phrase table neural features	All	12M	34.5
Sutskever et al. (2014) – 5 LSTMs, reranking 1000-best lists	All	12M	36.5
Existing end-to-end NMT systems			
Bahdanau et al. (2015) – single gated RNN with search	30K	12M	28.5
Sutskever et al. (2014) – 5 LSTMs	80K	12M	34.8
Jean et al. (2015) – 8 gated RNNs with search + UNK replacement	500K	12M	37.2
Our end-to-end NMT systems			
Single LSTM with 4 layers	40K	12M	29.5
Single LSTM with 4 layers + PosUnk	40K	12M	31.8 (+2.3)
Single LSTM with 6 layers	40K	12M	30.4
Single LSTM with 6 layers + PosUnk	40K	12M	32.7 (+2.3)
Ensemble of 8 LSTMs	40K	12M	34.1
Ensemble of 8 LSTMs + PosUnk	40K	12M	36.9 (+2.8)
Single LSTM with 6 layers	80K	36M	31.5
Single LSTM with 6 layers + PosUnk	80K	36M	33.1 (+1.6)
Ensemble of 8 LSTMs	80K	36M	35.6
Ensemble of 8 LSTMs + PosUnk	80K	36M	**37.5 (+1.9)**

Table 1: **Tokenized BLEU on newstest2014** – Translation results of various systems which differ in terms of: (a) the architecture, (b) the size of the vocabulary used, and (c) the training corpus, either using the full WMT'14 corpus of 36M sentence pairs or a subset of it with 12M pairs. We highlight the performance of our best system in bolded text and state the improvements obtained by our technique of handling rare words (namely, the PosUnk model). Notice that, for a given vocabulary size, the more accurate systems achieve a greater improvement from the post-processing step. This is the case because the more accurate models are able to pin-point the origin of an unknown word with greater accuracy, making the post-processing more useful.

System	BLEU
Existing SOTA (Durrani et al., 2014)	35.8
Ensemble of 8 LSTMs + PosUnk	**36.6**

Table 2: **Detokenized BLEU on newstest2014** – translation results of the existing state-of-the-art system and our best system.

4.4 Main Results

We compare our systems to others, including the current state-of-the-art MT system (Durrani et al., 2014), recent end-to-end neural systems, as well as phrase-based baselines with neural components.

The results shown in Table 1 demonstrate that our unknown word translation technique (in particular, the PosUnk model) significantly improves the translation quality for both the individual (non-ensemble) LSTM models and the ensemble models.[6] For 40K-word vocabularies, the performance gains are in the range of 2.3-2.8 BLEU points. With larger vocabularies (80K), the performance gains are diminished, but our technique can still provide a nontrivial gains of 1.6-1.9 BLEU points.

It is interesting to observe that our approach is more useful for ensemble models as compared to the individual ones. This is because the usefulness of the PosUnk model directly depends on the ability of the NMT to correctly locate, for a given OOV target word, its corresponding word in the source sentence. An ensemble of large models identifies these source words with greater accuracy. This is why for the same vocabulary size, better models obtain a greater performance gain

[6] For the 40K-vocabulary ensemble, we combine 5 models with 4 layers and 3 models with 6 layers. For the 80K-vocabulary ensemble, we combine 3 models with 4 layers and 5 models with 6 layers. Two of the depth-6 models are regularized with dropout, similar to Zaremba et al. (2015) with the dropout probability set to 0.2.

our post-processing step. e Except for the very recent work of Jean et al. (2015) that employs a similar unknown treatment strategy[7] as ours, our best result of 37.5 BLEU outperforms all other NMT systems by a arge margin, and more importantly, our system has established a new record on the WMT'14 English to French translation.

5 Analysis

We analyze and quantify the improvement obtained by our rare word translation approach and provide a detailed comparison of the different rare word techniques proposed in Section 3. We also examine the effect of depth on the LSTM architectures and demonstrate a strong correlation between perplexities and BLEU scores. We also highlight a few translation examples where our models succeed in correctly translating OOV words, and present several failures.

5.1 Rare Word Analysis

To analyze the effect of rare words on translation quality, we follow Sutskever et al. (Sutskever et al., 2014) and sort sentences in newstest2014 by the average inverse frequency of their words. We split the test sentences into groups where the sentences within each group have a comparable number of rare words and evaluate each group independently. We evaluate our systems before and after translating the OOV words and compare with the standard MT systems – we use the best system from the WMT'14 contest (Durrani et al., 2014), and neural MT systems – we use the ensemble systems described in (Sutskever et al., 2014) and Section 4.

Rare word translation is challenging for neural machine translation systems as shown in Figure 5. Specifically, the translation quality of our model before applying the postprocessing step is shown by the green curve, and the current best NMT system (Sutskever et al., 2014) is the purple curve. While (Sutskever et al., 2014) produces better translations for sentences with frequent words (the left part of the graph), they are worse than best system (red curve) on sentences with many rare words (the right side of the graph). When applying our unknown word translation technique (purple curve), we significantly improve the translation quality of our NMT: for the last group of 500 sentences which have the greatest proportion of OOV words in the test set, we increase the BLEU score of our system by 4.8 BLEU points. Overall, our rare word translation model interpolates between the SOTA system and the system of Sutskever et al. (2014), which allows us to outperform the winning entry of WMT'14 on sentences that consist predominantly of frequent words and approach its performance on sentences with many OOV words.

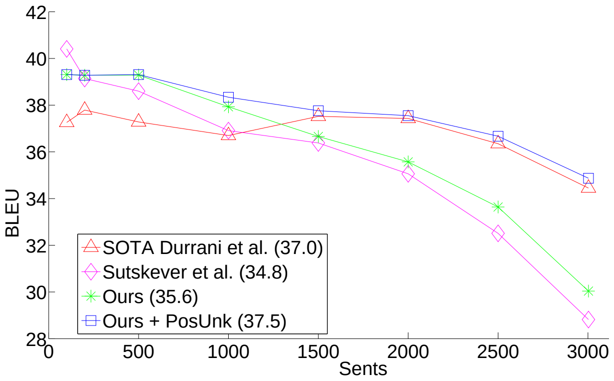

Figure 5: **Rare word translation** – On the x-axis, we order newstest2014 sentences by their *average frequency rank* and divide the sentences into groups of sentences with a comparable prevalence of rare words. We compute the BLEU score of each group independently.

5.2 Rare Word Models

We examine the effect of the different rare word models presented in Section 3, namely: (a) *Copyable* – which aligns the unknown words on both the input and the target side by learning to copy indices, (b) the Positional All (*PosAll*) – which predicts the aligned source positions for every target word, and (c) the Positional Unknown (*PosUnk*) – which predicts the aligned source positions for only the unknown target words.[8] It is also interest-

[7] Their unknown replacement method and ours both track the locations of target unknown words and use a word dictionary to post-process the translation. However, the mechanism used to achieve the "tracking" behavior is different. Jean et al. (2015)'s uses the attentional mechanism to track the origins of all target words, not just the unknown ones. In contrast, we only focus on tracking unknown words using unsupervised alignments. Our method can be easily applied to any sequence-to-sequence models since we treat any model as a blackbox and manipulate only at the input and output levels.

[8] In this section and in section 5.3, all models are trained on the unreversed sentences, and we use the following hyperparameters: we initialize the parameters uniformly in [-0.1, 0.1], the learning rate is 1, the maximal gradient norm is 1, with a source vocabulary of 90k words, and a target vocabulary of 40k (see Section 4.2 for more details). While these LSTMs do not achieve the best possible performance, it is still useful to analyze them.

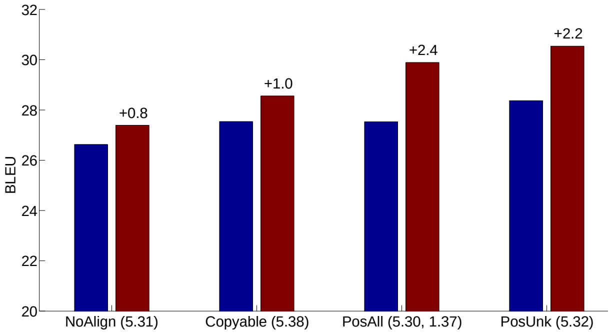

Figure 6: **Rare word models** – translation performance of 6-layer LSTMs: a model that uses no alignment (*NoAlign*) and the other rare word models (*Copyable, PosAll, PosUnk*). For each model, we show results before (*left*) and after (*right*) the rare word translation as well as the perplexity (in parentheses). For *PosAll*, we report the perplexities of predicting the words and the positions.

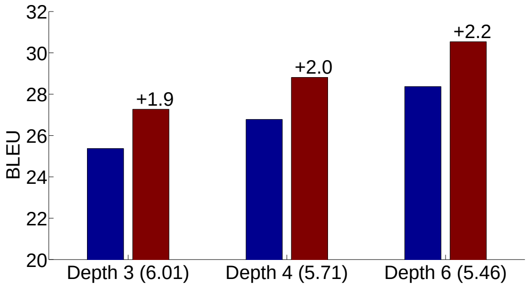

Figure 7: **Effect of depths** – BLEU scores achieved by *PosUnk* models of various depths (3, 4, and 6) before and after the rare word translation. Notice that the PosUnk model is more useful on more accurate models.

ing to measure the improvement obtained when no alignment information is used during training. As such, we include a baseline model with no alignment knowledge (*NoAlign*) in which we simply assume that the i^{th} unknown word on the target sentence is aligned to the i^{th} unknown word in the source sentence.

From the results in Figure 6, a simple monotone alignment assumption for the *NoAlign* model yields a modest gain of 0.8 BLEU points. If we train the model to predict the alignment, then the *Copyable* model offers a slightly better gain of 1.0 BLEU. Note, however, that English and French have similar word order structure, so it would be interesting to experiment with other language pairs, such as English and Chinese, in which the word order is not as monotonic. These harder language pairs potentially imply a smaller gain for the NoAlign model and a larger gain for the Copyable model. We leave it for future work.

The positional models (*PosAll* and *PosUnk*) improve translation performance by more than 2 BLEU points. This proves that the limitation of the copyable model, which forces it to align each unknown output word with an unknown input word, is considerable. In contrast, the positional models can align the unknown target words with any source word, and as a result, post-processing has a much stronger effect. The PosUnk model achieves better translation results than the PosAll model which suggests that it is easier to train the LSTM on shorter sequences.

5.3 Other Effects

Deep LSTM architecture – We compare PosUnk models trained with different number of layers (3, 4, and 6). We observe that the gain obtained by the PosUnk model increases in tandem with the overall accuracy of the model, which is consistent with the idea that larger models can point to the appropriate source word more accurately. Additionally, we observe that on average, each extra LSTM layer provides roughly 1.0 BLEU point improvement as demonstrated in Figure 7.

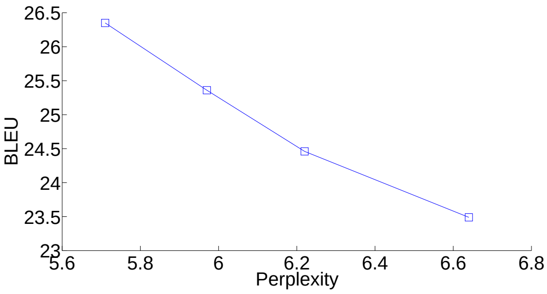

Figure 8: **Perplexity vs. BLEU** – we show the correlation by evaluating an LSTM model with 4 layers at various stages of training.

Perplexity and BLEU – Lastly, we find it interesting to observe a strong correlation between the perplexity (our training objective) and the translation quality as measured by BLEU. Figure 8 shows the performance of a 4-layer LSTM, in which we compute both perplexity and BLEU scores at different points during training. We find that on average, a reduction of 0.5 perplexity gives us roughly 1.0 BLEU point improvement.

Table 3: **Sample translations** – the table shows the source (*src*) and the translations of our best model before (*trans*) and after (*+unk*) unknown word translations. We also show the human translations (*tgt*) and italicize words that are involved in the unknown word translation process.

5.4 Sample Translations

We present three sample translations of our best system (with 37.5 BLEU) in Table 3. In our first example, the model translates all the unknown words correctly: *2600*, *orthopédiques*, and *cataracte*. It is interesting to observe that the model can accurately predict an alignment of distances of 5 and 6 words. The second example highlights the fact that our model can translate long sentences reasonably well and that it was able to correctly translate the unknown word for *JPMorgan* at the very far end of the source sentence. Lastly, our examples also reveal several penalties incurred by our model: (a) incorrect entries in the word dictionary, as with *négociateur* vs. *trader* in the second example, and (b) incorrect alignment prediction, such as when $\texttt{unkpos}_{3}$ is incorrectly aligned with the source word *was* and not with *abandoning*, which resulted in an incorrect translation in the third sentence.

6 Conclusion

We have shown that a simple alignment-based technique can mitigate and even overcome one of the main weaknesses of current NMT systems, which is their inability to translate words that are not in their vocabulary. A key advantage of our technique is the fact that it is applicable to any NMT system and not only to the deep LSTM model of Sutskever et al. (2014). A technique like ours is likely necessary if an NMT system is to achieve state-of-the-art performance on machine translation.

We have demonstrated empirically that on the

WMT'14 English-French translation task, our technique yields a consistent and substantial improvement of up to 2.8 BLEU points over various NMT systems of different architectures. Most importantly, with 37.5 BLEU points, we have established the first NMT system that outperformed the best MT system on a WMT'14 contest dataset.

Acknowledgments

We thank members of the Google Brain team for thoughtful discussions and insights. The first author especially thanks Chris Manning and the Stanford NLP group for helpful comments on the early drafts of the paper. Lastly, we thank the annonymous reviewers for their valuable feedback.

Abstract

The recently proposed neural network joint model (NNJM) (Devlin et al., 2014) augments the n-gram target language model with a heuristically chosen source context window, achieving state-of-the-art performance in SMT. In this paper, we give a more systematic treatment by summarizing the relevant source information through a convolutional architecture guided by the target information. With different guiding signals during decoding, our specifically designed convolution+gating architectures can pinpoint the parts of a source sentence that are relevant to predicting a target word, and fuse them with the context of entire source sentence to form a unified representation. This representation, together with target language words, are fed to a deep neural network (DNN) to form a stronger NNJM. Experiments on two NIST Chinese-English translation tasks show that the proposed model can achieve significant improvements over the previous NNJM by up to +1.08 BLEU points on average.

1 Introduction

Learning of continuous space representation for source language has attracted much attention in both traditional statistical machine translation (SMT) and neural machine translation (NMT). Various models, mostly neural network-based, have been proposed for representing the source sentence, mainly as the encoder part in an encoder-decoder framework (Bengio et al., 2003; Auli et al., 2013; Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014). There has been some quite recent work on encoding only "relevant" part of source sentence during the decoding process, most notably neural network joint model (NNJM) in (Devlin et al., 2014), which extends the n-grams target language model by additionally taking a fixed-length window of source sentence, achieving state-of-the-art performance in statistical machine translation.

In this paper, we propose novel convolutional architectures to dynamically encode the relevant information in the source language. Our model covers the entire source sentence, but can effectively find and properly summarize the relevant parts, guided by the information from the target language. With the guiding signals during decoding, our specifically designed convolution architectures can pinpoint the parts of a source sentence that are relevant to predicting a target word, and fuse them with the context of entire source sentence to form a unified representation. This representation, together with target words, are fed to a deep neural network (DNN) to form a stronger NNJM. Since our proposed joint model is purely lexicalized, it can be integrated into any SMT decoder as a feature.

Two variants of the joint model are also proposed, with coined name tagCNN and inCNN, with different guiding signals used from the decoding process. We integrate the proposed joint models into a state-of-the-art dependency-to-string translation system (Xie et al., 2011) to evaluate their effectiveness. Experiments on NIST Chinese-English translation tasks show that our model is able to achieve significant improvements of +2.0 BLEU points on average over the baseline. Our model also outperforms Devlin et al. (2014)'s NNJM by up to +1.08 BLEU points.

(a) *tag*CNN (b) *in*CNN

Figure 1: Illustration for joint LM based on CNN encoder.

RoadMap: In the remainder of this paper, we start with a brief overview of joint language model in Section 2, while the convolutional encoders, as the key component of which, will be described in detail in Section 3. Then in Section 4 we discuss the decoding algorithm with the proposed models. The experiment results are reported in Section 5, followed by Section 6 and 7 for related work and conclusion.

2 Joint Language Model

Our joint model with CNN encoders can be illustrated in Figure 1 (a) & (b), which consists 1) a CNN encoder, namely *tag*CNN or *in*CNN, to represent the information in the source sentences, and 2) an NN-based model for predicting the next words, with representations from CNN encoders and the history words in target sentence as inputs.

In the joint language model, the probability of the target word $\mathbf{e}_n$, given previous k target words $\{\mathbf{e}_{n-k}, \cdots, \mathbf{e}_{n-1}\}$ and the representations from CNN-encoders for source sentence S are

$$tag\text{CNN:} \quad p(\mathbf{e}_n | \phi_1(S, \{a(\mathbf{e}_n)\}), \{\mathbf{e}\}_{n-k}^{n-1})$$

$$in\text{CNN:} \quad p(\mathbf{e}_n | \phi_2(S, h(\{\mathbf{e}\}_{n-k}^{n-1})), \{\mathbf{e}\}_{n-k}^{n-1}),$$

where $\phi_1(S, \{a(\mathbf{e}_n)\})$ stands for the representation given by *tag*CNN with the set of indexes $\{a(\mathbf{e}_n)\}$ of source words aligned to the target word $\mathbf{e}_n$, and $\phi_2(S, h(\{\mathbf{e}\}_{n-k}^{n-1}))$ stands for the representation from *in*CNN with the attention signal $h(\{\mathbf{e}\}_{n-k}^{n-1})$.

Let us use the example in Figure 1, where the task is to translate the Chinese sentence

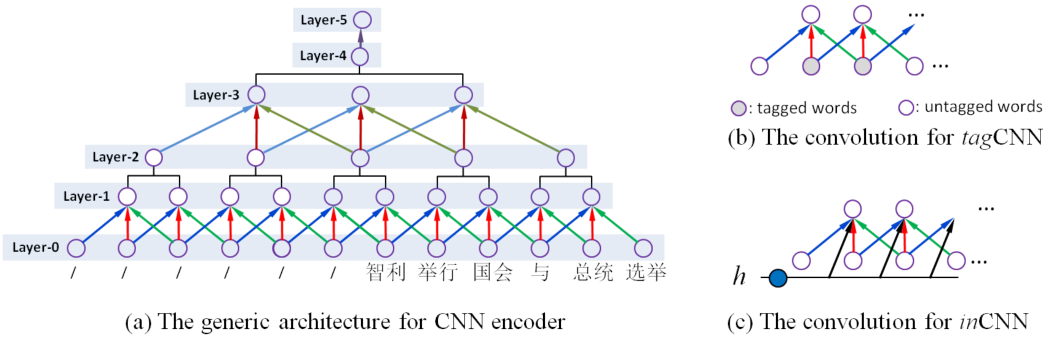
Chinese:	智利	举行	国会	与	总统	选举
Pinyin:	Zhìlì	Jǔxíng	Guóhuì	Yǔ	Zǒngtǒng	Xuǎnjǔ

into English. In evaluating a target language sequence "holds parliament and presidential", with "holds parliament and" as the proceeding words (assume 4-gram LM), and the affiliated source word[1] of "presidential" being "Zǒngtǒng" (determined by word alignment), *tag*CNN generates $\phi_1(S, \{4\})$ (the index of "Zǒngtǒng" is 4), and *in*CNN generates $\phi_2(S, h(\texttt{holds parliament and}))$. The DNN component then takes "holds parliament and" and (ϕ_1 or ϕ_2) as input to give the conditional probability for next word, e.g., $p(\texttt{"presidential"} | \phi_{1|2}, \{\texttt{holds}, \texttt{parliament}, \texttt{and}\})$.

3 Convolutional Models

We start with the generic architecture for convolutional encoder, and then proceed to *tag*CNN and *in*CNN as two extensions.

[1] For an aligned target word, we take its aligned source words as its affiliated source words. And for an unaligned word, we inherit its affiliation from the closest aligned word, with preference given to the right (Devlin et al., 2014). Since the word alignment is of many-to-many, one target word may has multi affiliated source words.



(a) The generic architecture for CNN encoder

(b) The convolution for *tag*CNN

(c) The convolution for *in*CNN

Figure 2: Illustration for the CNN encoders.

3.1 Generic CNN Encoder

The basic architecture is of a generic CNN encoder is illustrated in Figure 2 (a), which has a fixed architecture consisting of six layers:

Layer-0: the input layer, which takes words in the form of embedding vectors. In our work, we set the maximum length of sentences to 40 words. For sentences shorter than that, we put zero padding at the beginning of sentences.

Layer-1: a convolution layer after Layer-0, with window size = 3. As will be discussed in Section 3.2 and 3.3, the guiding signal are injected into this layer for "guided version".

Layer-2: a local gating layer after Layer-1, which simply takes a weighted sum over feature-maps in non-adjacent window with size = 2.

Layer-3: a convolution layer after Layer-2, we perform another convolution with window size = 3.

Layer-4: we perform a global gating over feature-maps on Layer-3.

Layer-5: fully connected weights that maps the output of Layer-4 to this layer as the final representation.

3.1.1 Convolution

As shown in Figure 2 (a), the convolution in Layer-1 operates on sliding windows of words (width k_1), and the similar definition of windows carries over to higher layers. Formally, for source sentence input $\mathbf{x} = \{\mathbf{x}_1, \cdots, \mathbf{x}_N\}$, the convolution unit for feature map of type-f (among F_ℓ of them) on Layer-ℓ is

$$z_i^{(\ell,f)}(\mathbf{x}) = \sigma(\mathbf{w}^{(\ell,f)}\hat{\mathbf{z}}_i^{(\ell-1)} + b^{(\ell,f)}),$$
$$\ell = 1, 3, \qquad f = 1, 2, \cdots, F_\ell \quad (1)$$

where

- $z_i^{(\ell,f)}(\mathbf{x})$ gives the output of feature map of type-f for location i in Layer-ℓ;
- $\mathbf{w}^{(\ell,f)}$ is the parameters for f on Layer-ℓ;
- $\sigma(\cdot)$ is the Sigmoid activation function;
- $\hat{\mathbf{z}}_i^{(\ell-1)}$ denotes the segment of Layer-$\ell-1$ for the convolution at location i , while

  $$\hat{\mathbf{z}}_i^{(0)} \overset{\text{def}}{=} [\mathbf{x}_i^\top, \ \mathbf{x}_{i+1}^\top, \ \mathbf{x}_{i+2}^\top]^\top$$

  concatenates the vectors for 3 words from sentence input $\mathbf{x}$.

3.1.2 Gating

Previous CNNs, including those for NLP tasks (Hu et al., 2014; Kalchbrenner et al., 2014), take a straightforward convolution-pooling strategy, in which the "fusion" decisions (e.g., selecting the largest one in max-pooling) are based on the values of feature-maps. This is essentially a soft template matching, which works for tasks like classification, but harmful for keeping the composition functionality of convolution, which is critical for modeling sentences. In this paper, we propose to use separate gating unit to release the score function duty from the convolution, and let it focus on composition.

We take two types of gating: 1) for Layer-2, we take a local gating with non-overlapping windows (size = 2) on the feature-maps of convolutional Layer-1 for representation of segments, and 2) for Layer-4, we take a global gating to fuse all the segments for a global representation. We found that this gating strategy can considerably improve the performance of both tagCNN and inCNN over pooling.

- **Local Gating:** On Layer-1, for every gating window, we first find its original input (before convolution) on Layer-0, and merge them for the input of the gating network. For example, for the two windows: word (3,4,5) and word (4,5,6) on Layer-0, we use concatenated vector consisting of embedding for word (3,4,5,6) as the input of the local gating network (a logistic regression model) to determine the weight for the convolution result of the two windows (on Layer-1), and the weighted sum are the output of Layer-2.

- **Global Gating:** On Layer-3, for feature-maps at each location i, denoted $\mathbf{z}_i^{(3)}$, the global gating network (essentially soft-max, parameterized $\mathbf{w}_g$), assigns a normalized weight

  $$\omega(\mathbf{z}_i^{(3)}) = e^{\mathbf{w}_g^\top \mathbf{z}_i^{(3)}} / \sum_j e^{\mathbf{w}_g^\top \mathbf{z}_j^{(3)}},$$

  and the gated representation on Layer-4 is given by the weighted sum $\sum_i \omega(\mathbf{z}_i^{(3)})\mathbf{z}_i^{(3)}$.

3.1.3 Training of CNN encoders

The CNN encoders, including tagCNN and inCNN that will be discussed right below, are trained in a joint language model described in Section 2, along with the following parameters

- the embedding of the words on source and the proceeding words on target;

- the parameters for the DNN of joint language model, include the parameters of soft-max for word probability.

The training procedure is identical to that of neural network language model, except that the parallel corpus is used instead of a monolingual corpus. We seek to maximize the log-likelihood of training samples, with one sample for every target word in the parallel corpus. Optimization is performed with the conventional back-propagation, implemented as stochastic gradient descent (LeCun et al., 1998) with mini-batches.

3.2 tagCNN

tagCNN inherits the convolution and gating from generic CNN (as described in Section 3.1), with the only modification in the input layer. As shown in Figure 2 (b), in tagCNN, we append an extra tagging bit (0 or 1) to the embedding of words in the input layer to indicate whether it is one of affiliated words

$$\mathbf{x}_i^{(\text{AFF})} = [\mathbf{x}_i^\top \ 1]^\top, \quad \mathbf{x}_j^{(\text{NON-AFF})} = [\mathbf{x}_j^\top \ 0]^\top.$$

Those extended word embedding will then be treated as regular word-embedding in the convolutional neural network. This particular encoding strategy can be extended to embed more complicated dependency relation in source language, as will be described in Section 5.4.

This particular "tag" will be activated in a parameterized way during the training for predicting the target words. In other words, the supervised signal from the words to predict will find, through layers of back-propagation, the importance of the tag bit in the "affiliated words" in the source language, and learn to put proper weight on it to make tagged words stand out and adjust other parameters in tagCNN accordingly for the optimal predictive performance. In doing so, the joint model can pinpoint the parts of a source sentence that are relevant to predicting a target word through the already learned word alignment.

3.3 inCNN

Unlike tagCNN, which directly tells the location of affiliated words to the CNN encoder, inCNN sends the information about the proceeding words in target side to the convolutional encoder to help retrieve the information relevant for predicting the next word. This is essentially a particular case of attention model, analogous to the automatic alignment mechanism in (Bahdanau et al., 2014), where the at-

"X_1:NN" indicates a substitution site that can be replaced by a subtree whose root has part-of-speech "NN". The underline denotes a leaf node.

tention signal is from the state of a generative recurrent neural network (RNN) as decoder.

Basically, the information from proceeding words, denoted as $h(\{\mathbf{e}\}_{n-k}^{n-1})$, is injected into every convolution window in the source language sentence, as illustrated in Figure 2 (c). More specifically, for the window indexed by t, the input to convolution is given by the concatenated vector

$$\hat{\mathbf{z}}_t = [h(\{\mathbf{e}\}_{n-k}^{n-1}),\ \mathbf{x}_t^\top,\ \mathbf{x}_{t+1}^\top,\ \mathbf{x}_{t+2}^\top]^\top.$$

In this work, we use a DNN to transform the vector concatenated from word-embedding for words $\{\mathbf{e}_{n-k}\cdots, \mathbf{e}_{n-k}\}$ into $h(\{\mathbf{e}\}_{n-k}^{n-1})$, with sigmoid activation function. Through layers of convolution and gating, inCNN can 1) retrieve the relevant segments of source sentences, and 2) compose and transform the retrieved segments into representation recognizable by the DNN in predicting the words in target language. Different from that of tagCNN, inCNN uses information from proceeding words, hence provides complementary information in the augmented joint language model of tagCNN. This has been empirically verified when using feature based on tagCNN and that based on inCNN in decoding with greater improvement.

4 Decoding with the Joint Model

Our joint model is purely lexicalized, and therefore can be integrated into *any* SMT decoders as a feature. For a hierarchical SMT decoder, we adopt the integrating method proposed by Devlin et al. (2014). As inherited from the n-gram language model for performing hierarchical decoding, the leftmost and rightmost $n-1$ words from each constituent should be stored in the state space. We extend the state space to also include the indexes of the affiliated source words for each of these edge words. For an aligned target word, we take its aligned source words as its affiliated source words. And for an unaligned word, we use the affiliation heuristic adopted by Devlin et al. (2014). In this paper, we integrate the joint model into the state-of-the-art dependency-to-string machine translation decoder as a case study to test the efficacy of our proposed approaches. We will briefly describe the dependency-to-string translation model and then the description of MT system.

4.1 Dependency-to-String Translation

In this paper, we use a state-of-the-art dependency-to-string (Xie et al., 2011) decoder (Dep2Str), which is also a hierarchical decoder. This dependency-to-string model employs rules that represent the source side as head-dependents relations and the target side as strings. A head-dependents relation (HDR) is composed of a head and all its dependents in dependency trees. Figure 3 shows a dependency tree (a) with three HDRs (in shadow), an example of HDR rule (b) for the top level of (a), and an example of head rule (c). HDR rules are constructed from head-dependents relations. HDR rules can act as both translation rules and reordering rules. And head rules are used for translating source words.

We adopt the decoder proposed by Meng et al. (2013) as a variant of Dep2Str translation that is easier to implement with comparable performance. Basically they extract the HDR rules with GHKM (Galley et al., 2004) algorithm. For the decoding procedure, given a source dependency tree T, the decoder transverses T in post-order. The bottom-up chart-based decoding algorithm with cube pruning (Chiang, 2007; Huang and Chiang, 2007) is used to find the k-best items for each node.

4.2 MT Decoder

Following Och and Ney (2002), we use a general loglinear framework. Let d be a derivation that convert a source dependency tree into a target string e. The probability of d is defined as:

$$P(d) \propto \prod_i \phi_i(d)^{\lambda_i} \tag{2}$$

where ϕ_i are features defined on derivations and λ_i are the corresponding weights. Our decoder contains the following features:
Baseline Features:

- translation probabilities $P(t|s)$ and $P(s|t)$ of HDR rules;
- lexical translation probabilities $P_{\text{LEX}}(t|s)$ and $P_{\text{LEX}}(s|t)$ of HDR rules;
- rule penalty $\exp(-1)$;
- pseudo translation rule penalty $\exp(-1)$;
- target word penalty $\exp(|e|)$;
- n-gram language model $P_{\text{LM}}(e)$;

Proposed Features:

- n-gram tagCNN joint language model $P_{\text{TLM}}(e)$;
- n-gram inCNN joint language model $P_{\text{ILM}}(e)$.

Our baseline decoder contains the first eight features. The pseudo translation rule (constructed according to the word order of a HDR) is to ensure the complete translation when no matched rules is found during decoding. The weights of all these features are tuned via minimum error rate training (MERT) (Och, 2003). For the dependency-to-string decoder, we set rule-threshold and stack-threshold to 10^{-3}, rule-limit to 100, stack-limit to 200.

5 Experiments

The experiments in this Section are designed to answer the following questions:

1. Are our tagCNN and inCNN joint language models able to improve translation quality, and are they complementary to each other?
2. Do inCNN and tagCNN benefit from their guiding signal, compared to a generic CNN?
3. For tagCNN, is it helpful to embed more dependency structure, e.g., dependency head of each affiliated word, as additional information?
4. Can our gating strategy improve the performance over max-pooling?

5.1 Setup

Data: Our training data are extracted from LDC data[2]. We only keep the sentence pairs that the length of source part no longer than 40 words, which covers over 90% of the sentence. The bilingual training data consist of 221K sentence pairs, containing 5.0 million Chinese words and 6.8 million English words. The development set is NIST MT03 (795 sentences) and test sets are MT04 (1499 sentences) and MT05 (917 sentences) after filtering with length limit.

Preprocessing: The word alignments are obtained with GIZA++ (Och and Ney, 2003) on the corpora in both directions, using the "grow-diag-final-and" balance strategy (Koehn et al., 2003). We adopt SRI Language Modeling

[2] The corpora include LDC2002E18, LDC2003E07, LDC2003E14, LDC2004T07, LDC2005T06.

Systems	MT04	MT05	Average
Moses	34.33	31.75	33.04
Dep2Str	34.89	32.24	33.57
+ BBN-JM (Devlin et al., 2014)	36.11	32.86	34.49
+ CNN (generic)	36.12*	33.07*	34.60
+ *tag*CNN	36.33*	**33.37***	34.85
+ *in*CNN	**36.92***	**33.72***	35.32
+ *tag*CNN + *in*CNN	**36.94***	**34.20***	35.57

Table 1: BLEU-4 scores (%) on NIST MT04-test and MT05-test, of Moses (default settings), dependency-to-string baseline system (Dep2Str), and different features on top of Dep2Str: neural network joint model (BBN-JM), generic CNN, *tag*CNN, *in*CNN and the combination of *tag*CNN and *in*CNN. The boldface numbers and superscript * indicate that the results are significantly better (p<0.01) than those of the BBN-JM and the Dep2Str baseline respectively. "+" stands for adding the corresponding feature to Dep2Str.

Toolkit (Stolcke and others, 2002) to train a 4-gram language model with modified Kneser-Ney smoothing on the Xinhua portion of the English Gigaword corpus (306 million words). We parse the Chinese sentences with Stanford Parser into projective dependency trees.

Optimization of NN: In training the neural network, we limit the source and target vocabulary to the most frequent 20K words for both Chinese and English, covering approximately 97% and 99% of two corpus respectively. All the out-of-vocabulary words are mapped to a special token UNK. We used stochastic gradient descent to train the joint model, setting the size of minibatch to 500. All joint models used a 3-word target history (i.e., 4-gram LM). The dimension of word embedding and the attention signal $h(\{\mathbf{e}\}_{n-k}^{n-1})$ for *in*CNN are 100. For the convolution layers (Layer 1 and Layer 3), we apply 100 filters. And the final representation of CNN encoders is a vector with dimension 100. The final DNN layer of our joint model is the standard multi-layer perceptron with softmax at the top layer.

Metric: We use the case-insensitive 4-gram NIST BLEU[3] as our evaluation metric, with statistical significance test with *sign-test* (Collins et al., 2005) between the proposed models and two baselines.

5.2 Setting for Model Comparisons

We use the *tag*CNN and *in*CNN joint language models as additional decoding features to a dependency-to-string baseline system (Dep2Str), and compare them to the neural network joint model with 11 source context words (Devlin et al., 2014). We use the implementation of an open source toolkit[4] with default configuration except the global settings described in Section 5.1. Since our *tag*CNN and *in*CNN models are source-to-target and left-to-right (on target side), we only take the source-to-target and left-to-right type NNJM in (Devlin et al., 2014) in comparison. We call this type NNJM as BBN-JM hereafter. Although the BBN-JM in (Devlin et al., 2014) is originally tested in the hierarchical phrase-based (Chiang, 2007) SMT and string-to-dependency (Shen et al., 2008) SMT, it is fairly versatile and can be readily integrated into Dep2Str.

5.3 The Main Results

The main results of different models are given in Table 1. Before proceeding to more detailed comparison, we first observe that

- the baseline Dep2Str system gives BLEU 0.5+ higher than the open-source phrase-based system Moses (Koehn et al., 2007);
- BBN-JM can give about +0.92 BLEU score over Dep2Str, a result similar as reported in (Devlin et al., 2014).

[4] http://nlg.isi.edu/software/nplm/

Systems	MT04	MT05	Average
Dep2str	34.89	32.24	33.57
+tagCNN	36.33	33.37	34.85
+tagCNN_dep	36.54	33.61	35.08

Table 2: BLEU-4 scores (%) of tagCNN model with dependency head words as additional tags (tagCNN_dep).

Clearly from Table 1, tagCNN and inCNN improve upon the Dep2Str baseline by +1.28 and +1.75 BLEU, outperforming BBN-JM in the same setting by respectively +0.36 and +0.83 BLEU, averaged on NIST MT04 and MT05. These indicate that tagCNN and inCNN can individually provide discriminative information in decoding. It is worth noting that inCNN appears to be more informative than the affiliated words suggested by the word alignment (GIZA++). We conjecture that this is due to the following two facts

- inCNN avoids the propagation of mistakes and artifacts in the already learned word alignment;
- the guiding signal in inCNN provides complementary information to evaluate the translation.

Moreover, when tagCNN and inCNN are both used in decoding, it can further increase its winning margin over BBN-JM to +1.08 BLEU points (in the last row of Table 1), indicating that the two models with different guiding signals are complementary to each other.

The Role of Guiding Signal It is slight surprising that the generic CNN can also achieve the gain on BLEU similar to that of BBN-JM, since intuitively generic CNN encodes the entire sentence and the representations should in general far from optimal representation for joint language model. The reason, as we conjecture, is CNN yields fairly informative summarization of the sentence (thanks to its sophisticated convolution and gating architecture), which makes up some of its loss on resolution and relevant parts of the source senescence. That said, the guiding signal in both tagCNN and inCNN are crucial to the power of CNN-based encoder, as can be easily seen from the difference between the BLEU scores achieved by generic CNN, tagCNN, and inCNN. Indeed, with the signal from the already learned word alignment, tagCNN can gain +0.25 BLEU over its generic counterpart, while for inCNN with the guiding signal from the proceeding words in target, the gain is more saliently +0.72 BLEU.

Systems	MT04	MT05	Average
Dep2Str	34.89	32.24	33.57
+inCNN	36.92	33.72	35.32
+inCNN-2-pooling	36.33	32.88	34.61
+inCNN-4-pooling	36.46	33.01	34.74
+inCNN-8-pooling	36.57	33.39	34.98

Table 3: BLEU-4 scores (%) of inCNN models implemented with gating strategy and k max-pooling, where k is of $\{2, 4, 8\}$.

5.4 Dependency Head in tagCNN

In this section, we study whether tagCNN can further benefit from encoding richer dependency structure in source language in the input. More specifically, the dependency head words can be used to further improve tagCNN model. As described in Section 3.2, in tagCNN, we append a tagging bit (0 or 1) to the embedding of words in the input layer as tags on whether they are affiliated source words. To incorporate dependency head information, we extend the tagging rule in Section 3.2 to add another tagging bit (0 or 1) to the word-embedding for original tagCNN to indicate whether it is part of dependency heads of the affiliated words. For example, if $\mathbf{x}_i$ is the embedding of an affiliated source word and $\mathbf{x}_j$ the dependency head of word $\mathbf{x}_i$, the extended input of tagCNN would contain

$$\begin{aligned}\mathbf{x}_i^{(\text{AFF, NON-HEAD})} &= [\mathbf{x}_i^\top \;\; 1 \;\; 0]^\top \\ \mathbf{x}_j^{(\text{NON-AFF, HEAD})} &= [\mathbf{x}_j^\top \;\; 0 \;\; 1]^\top\end{aligned}$$

If the affiliated source word is the root of a sentence, we only append 0 as the second tagging bit since the root has no dependency head. From Table 2, with the help of dependency head information, we can improve tagCNN by +0.23 BLEU points averagely on two test sets.

5.5 Gating Vs. Max-pooling

In this section, we investigate to what extent that our gating strategy can improve the translation performance over max pooling, with the comparisons on inCNN model as a case study. For implementation of inCNN with max-pooling, we replace the local-gating (Layer-2) with max-pooling with size 2 (2-pooling for short), and global gating (Layer-4) with k max-pooling ("k-pooling"), where k is of $\{2, 4, 8\}$. Then, we use the mean of the outputs of k-pooling as the final input of Layer-5. In doing so, we can guarantee the input dimension of Layer-5 is the same as the architecture with gating. From Table 3, we can clearly see that our gating strategy can improve translation performance over max-pooling by 0.34∼0.71 BLEU points. Moreover, we find 8-pooling yields performance better than 2-pooling. We conjecture that this is because the useful relevant parts for translation are mainly concentrated on a few words of the source sentence, which can be better extracted with a larger pool size.

6 Related Work

The seminal work of neural network language model (NNLM) can be traced to Bengio et al. (2003) on monolingual text. It is recently extended by Devlin et al. (2014) to include additional source context (11 source words) in modeling the target sentence, which is clearly most related to our work, with however two important differences: 1) instead of the ad hoc way of selecting a context window in (Devlin et al., 2014), our model covers the entire source sentence and automatically distill the context relevant for target modeling; 2) our convolutional architecture can effectively leverage guiding signals of vastly different forms and nature from the target.

Prior to our model there is also work on representing source sentences with neural networks, including RNN (Cho et al., 2014; Sutskever et al., 2014) and CNN (Kalchbrenner and Blunsom, 2013). These work typically aim to map the entire sentence to a vector, which will be used later by RNN/LSTM-based decoder to generate the target sentence. As demonstrated in Section 5, the representation learnt this way cannot pinpoint the relevant parts of the source sentences (e.g., words or phrases level) and therefore is inferior to be directly integrated into traditional SMT decoders.

Our model, especially inCNN, is inspired by is the automatic alignment model proposed in (Bahdanau et al., 2014). As the first effort to apply attention model to machine translation, it sends the state of a decoding RNN as attentional signal to the source end to obtain a weighted sum of embedding of source words as the summary of relevant context. In contrast, inCNN uses 1) a different attention signal extracted from proceeding words in partial translations, and 2) more importantly, a convolutional architecture and therefore a highly nonlinear way to retrieve and summarize the relevant information in source.

7 Conclusion and Future Work

We proposed convolutional architectures for obtaining a guided representation of the entire source sentence, which can be used to augment the n-gram target language model. With different guiding signals from target side, we devise tagCNN and inCNN, both of which are tested in enhancing a dependency-to-string SMT with +2.0 BLEU points over baseline and +1.08 BLEU points over the state-of-the-art in (Devlin et al., 2014). For future work, we will consider encoding more complex linguistic structures to further enhance the joint model.

Abstract

We present a three-pronged approach to improving Statistical Machine Translation (SMT), building on recent success in the application of neural networks to SMT. First, we propose new *features* based on neural networks to model various non-local translation phenomena. Second, we augment the *architecture* of the neural network with tensor layers that capture important higher-order interaction among the network units. Third, we apply multitask *learning* to estimate the neural network parameters jointly. Each of our proposed methods results in significant improvements that are complementary. The overall improvement is +2.7 and +1.8 BLEU points for Arabic-English and Chinese-English translation over a state-of-the-art system that already includes neural network features.

1 Introduction

Recent advances in applying Neural Networks to Statistical Machine Translation (SMT) have generally taken one of two approaches. They either develop neural network-based features that are used to score hypotheses generated from traditional translation grammars (Sundermeyer et al., 2014; Devlin et al., 2014; Auli et al., 2013; Le et al., 2012; Schwenk, 2012), or they implement the whole translation process as a single neural network (Bahdanau et al., 2014; Sutskever et al., 2014). The latter approach, sometimes referred to as *Neural Machine Translation*, attempts to overhaul SMT, while the former capitalizes on the strength of the current SMT paradigm and leverages the modeling power of neural networks to improve the scoring of hypotheses generated by phrase-based or hierarchical translation rules. This paper adopts the former approach, as *n*-best scores from state-of-the-art SMT systems often suggest that these systems can still be significantly improved with better features.

We build on (Devlin et al., 2014) who proposed a simple yet powerful feedforward neural network model that estimates the translation probability conditioned on the target history and a large window of source word context. We take advantage of neural networks' ability to handle sparsity, and to infer useful abstract representations automatically. At the same time, we address the challenge of learning the large set of neural network parameters. In particular,

- We develop new *Neural Network Features* to model non-local translation phenomena related to word reordering. Large fully-lexicalized contexts are used to model these phenomena effectively, making the use of neural networks essential. All of the features are useful individually, and their combination results in significant improvements (Section 2).
- We use a *Tensor Neural Network Architecture* (Yu et al., 2012) to automatically learn complex pairwise interactions between the network nodes. The introduction of the tensor hidden layer results in more powerful features with lower model perplexity and significantly improved MT performance for all of neural network features (Section 3).
- We apply *Multitask Learning* (MTL) (Caruana, 1997) to jointly train related neural network features by sharing parameters. This allows parameters learned for one feature to benefit the learning of the other features. This results in better trained models and achieves additional MT improvements (Section 4).

We apply the resulting *Multitask Tensor Networks* to the new features and to existing ones,

obtaining strong experimental results over the strongest previous results of (Devlin et al., 2014). We obtain improvements of +2.5 BLEU points for Arabic-English and +1.8 BLEU points for Chinese-English on the DARPA BOLT Web Forum condition. We also obtain improvements of +2.7 BLEU point for Arabic-English and +1.9 BLEU points for Chinese-English on the NIST Open12 test sets over the best previously published results in (Devlin et al., 2014). Both the tensor architecture and multitask learning are general techniques that are likely to benefit other neural network features.

2 New Non-Local SMT Features

Existing SMT features typically focus on local information in the source sentence, in the target hypothesis, or both. For example, the *n*-gram language model (LM) predicts the next target word by using previously generated target words as context (local on target), while the lexical translation model (LTM) predicts the translation of a source word by taking into account surrounding source words as context (local on source).

In this work, we focus on non-local translation phenomena that result from non-monotone reordering, where *local* context becomes *non-local* on the other side. We propose a new set of powerful MT features that are motivated by this simple idea. To facilitate the discussion, we categorize the features into *hypothesis-enumerating* features that estimates a probability for each generated target word (e.g., n-gram language model), and *source-enumerating* features that estimates a probability for each source word (e.g., lexical translation).

More concretely, we introduce a) *Joint Model with Offset Source Context* (JMO), a hypothesis enumerating feature that predicts the next target word the source context affiliated to the previous target words; and b) *Translation Context Model* (TCM), a source-enumerating feature that predicts the context of the translation of a source word rather than the translation itself. These two models extend pre-existing features: the Joint (language and translation) Model (JM) of (Devlin et al., 2014) and the LTM respectively respectively. We use a large lexicalized context for there features, making the choice of implementing them as neural networks essential. We also present neural-network implementations of pre-existing source-enumerating features: lexical translation, orientation and fertility models. We obtain additional gains from using tensor networks and multitask learning in the modeling and training of all the features.

2.1 Hypothesis-Enumerating Features

As mentioned, hypothesis-enumerating features score each word in the hypothesis, typically by conditioning it on a context of n-1 previous target words as in the n-gram language model. One recent such model, the joint model of Devlin et al. (2014) achieves large improvements to the state-of-the-art SMT by using a large context window of 11 source words and 3 target words. The Joint Model with Offset Source Context (JMO) is an extension of the JM that uses the source words affiliated with the n-gram target history as context. The source contexts of JM and JMO overlap highly when the translation is monotone, but are complementary when the translation requires word reordering.

2.1.1 Joint Model with Offset Source Context

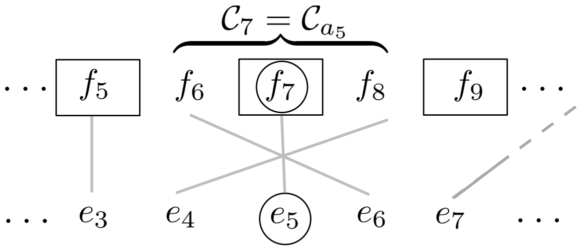
Formally, JMO estimates the probability of the target hypothesis E conditioned on the source sentence F and a target-to-source *affiliation* $\boldsymbol{A}$:

$$P(E|F,\boldsymbol{A}) \approx \prod_{i=1}^{|E|} P(e_i|e_{i-1}^{i-n+1}, \mathcal{C}_{a_{i-k}} = f_{a_{i-k}-m}^{a_{i-k}+m})$$

where e_i is the word being predicted; e_{i-1}^{i-n+1} is the string of $n-1$ previously generated words; $\mathcal{C}_{a_{i-k}}$ to the source context of m source words around $f_{a_{i-k}}$, the source word affiliated with e_{i-k}. We refer to k as the offset parameter. We use the definition of *word affiliation* introduced in Devlin et al. (2014). When no source context is used, the model is equivalent to an n-gram language model, while an offset parameter of $k = 0$ reduces the model to the JM of Devlin et al. (2014).

When $k > 0$, the JMO captures non-local context in the prediction of the next target word. More specifically, e_{i-k} and e_i, which are local on the target side, are affiliated to $f_{a_{i-k}}$ and f_{a_i} which may be distant from each other on the source side due to non-monotone translation, even for $k = 1$. The offset model captures reordering constraints by encouraging the predicted target word e_i to fit well with the previous affiliated source word $f_{a_{i-k}}$ and its surrounding words. We implement a separate feature for each value of k, and later train them jointly via multitask learning. As our experiments in Section 5.2.1 confirm, the history-affiliated source context results in stronger SMT improvement than just increasing the number of surrounding words in JM.

Fig. 1 illustrates the difference between JMO and JM. Assuming $n = 3$ and $m = 1$, then JM estimates $P(e_5|e_4, e_3, \mathcal{C}_{a_5} = \{f_6, f_7, f_8\})$. On the other hand, for $k = 1$, JMO$_{k=1}$ estimates $P(e_5|e_4, e_3, \mathcal{C}_{a_4} = \{f_8, f_9, f_{10}\})$.



$\mathcal{C}_7 = \mathcal{C}_{a_5}$
$\cdots$ f_5 f_6 f_7 f_8 f_9 $\cdots$
$\cdots$ e_3 e_4 e_5 e_6 e_7 $\cdots$

Figure 1: Example to illustrate features. f_5^9 is the source segment, e_3^7 is the corresponding translation and lines refer to the alignment. We show hypothesis-enumerating features that look at f_7 and source-enumerating features that look at e_5. We surround the source words affiliated with e_5 and its n-gram history with a bracket, and surround the source words affiliated with the history of e_5 with squares.

2.2 Source-Enumerating Features

Source-Enumerating Features iterate over words in the source sentence, including unaligned words, and assign it a score depending on what aspect of translation they are modeling. A source-enumerating feature can be formulated as follows:

$$P(E|F, \boldsymbol{A}) \approx \prod_{j=1}^{|F|} P(Y_j|\mathcal{C}_j = f_{j-m}^{j+m})$$

where $\mathcal{C}_{a_j}$ is the source context (similar to the hypothesis-enumerating features above) and Y_j is the label being predicted by the feature. We first describe pre-existing source-enumerating features: the lexical translation model, the orientation model and the fertility model, and then discuss a new feature: Translation Context Model (TCM), which is an extension of the lexical translation model.

2.2.1 Pre-existing Features

Lexical Translation model (LTM) estimates the probability of translating a source word f_j to a target word $l(f_j) = e_{b_j}$ given a source context $\mathcal{C}_j$, $b_j \in \boldsymbol{B}$ is the source-to-target word affiliation as defined in (Devlin et al., 2014). When f_j is translated to more than one word, we arbitrarily keep the left-most one. The target word vocabulary V is extended with a $NULL$ token to accommodate unaligned source words.

Orientation model (ORI) describes the probability of orientation of the translation of phrases surrounding a source word f_j relative to its own translation. We follow (Setiawan et al., 2013) in modeling the orientation of the left and right phrases of f_j with maximal orientation span (the longest neighboring phrase consistent with alignment), which we denote by L_j and R_j respectively. Thus, $o(f_j) = \langle o_{L_j}(f_j), o_{R_j}(f_j)\rangle$, where o_{L_j} and o_{R_j} refer to the orientation of L_j and R_j respectively. For unaligned f_j, we set $o(f_j) = o_{L_j}(R_j)$, the orientation of R_j with respect to L_j.

Fertility model (FM) models the probability that a source word f_j generates $\phi(f_j)$ words in the hypothesis. Our implemented model only distinguishes between aligned and unaligned source words (i.e., $\phi(f_j) \in \{0, 1\}$). The generalization of the model to account for multiple values of $\phi(f_i)$ is straightforward.

2.2.2 Translation Context Model

As with JMO in Section 2.1.1, we aim to capture translation phenomena that appear local on the target hypothesis but non-local on the source side. Here, we do so by extending the LTM feature to predict not only the translated word e_{b_j}, but also its surrounding context. Formally, we model $P(l(f_j)|\mathcal{C}_j)$, where $l(f_j) = e_{b_j - d}, \cdots, e_{b_j}, \cdots e_{b_j + d}$ is the hypothesis word window around e_{b_j}. In practice, we decompose TCM further into $\prod_{d'=-d}^{+d} P(e_{b_j+d'}|\mathcal{C}_j)$ and implemented each as a separate neural network-based feature. Note that TCM is equivalent to the LTM when $d = 0$. Because of word reordering, a given hypothesis word in $l(f_j)$ might not be affiliated with f_j or even to the words in $\mathcal{C}_j$. TCM can model non-local information in this way.

2.2.3 Combined Model

Since the feature label is undefined for unaligned source words, we make the model hierarchical, based on whether the source word is aligned or not, and thus arrive at the following formulation:

$$P(l(f_j)) \cdot P(ori(f_j)) \cdot P(\phi(f_j)) = \begin{cases} P(\phi_p(f_j) = 0) \cdot P(o_{L_j}(R_j)) \\ P(\phi_p(f_j) \geq 1) \cdot \prod_{d'=-d}^{+d} P(e_{b_j+d'}) \\ \quad \cdot P(o_{L_j}(f_j), o_{R_j}(f_j)) \end{cases}$$

We dropped the common context ($\mathcal{C}_j$) for readability.

We reuse Fig. 1 to illustrate the source-enumerating features. Assuming $d = 1$, the scores associated with f_7 are $P(\phi(f_7) \geq 1|\mathcal{C}_7)$ for the FM; $P(e_4|\mathcal{C}_7) \cdot P(e_5|\mathcal{C}_7) \cdot P(e_6)|\mathcal{C}_7)$ for the TCM; and $P(o(f_7) = \langle o_{L_7}(f_7) = RA, o_{R_7}(f_7) = RA\rangle)$ for the ORI(RA refers to *Reverse Adjacent*). L_7 and R_7 (i.e. f_6 and f_8^9 respectively), the longest neighboring phrase of f_7, are translated in reverse order and adjacent to e_5.

3 Tensor Neural Networks

The second part of this work improves SMT by improving the neural network architecture. Neural Networks derive their strength from their ability to learn a high-level representation of the input automatically from data. This high-level representation is typically constructed layer by layer through a weighted sum linear operation and a non-linear activation function. With sufficient training data, neural networks often achieve state-of-the-art performance on many tasks. This stands in sharp contrast to other algorithms that require tedious manual feature engineering. For the features presented in this paper, the context words are fed to the network network with minimal engineering.

We further strengthen the network's ability to learn rich interactions between its units by introducing tensors in the hidden layers. The multiplicative property of the tensor bares a close resemblance to collocation of context words which are useful in many natural language processing tasks.

In conventional feedforward neural networks, the output of hidden layer l is produced by multiplying the output vector from the previous layer with a weight matrix (W_l) and then applying the activation function σ to the product. Tensor Neural Networks generalize this formulation by using a tensor U_l of order 3 for the weights. The output of node k in layer l is computed as follows:

$$h_l[k] = \sigma\left(h_{l-1} \cdot U_l[k] \cdot h_{l-1}^T\right)$$

where $U_l[k]$, the k-th slice of U_l, is a square matrix.

In our implementation, we follow (Yu et al., 2012; Hutchinson et al., 2013) and use a low-rank approximation of $U_l[k] = Q_l[k] \cdot R_l[k]^T$, where $Q_l[k], R_l[k] \in \mathbb{R}^{n \times r}$. The output of node k becomes:

$$h_l[k] = \sigma\left(h_{l-1} \cdot Q_l[k] \cdot R_l[k]^T \cdot h_{l-1}^T\right)$$

In our experiments, we choose $r = 1$, and also apply the non-linear activation function σ distributively. We arrive at the following three equations for computing the hidden layer outputs $(0 < l < L)$:

$$\begin{aligned} v_l &= \sigma\left(h_{l-1} \cdot Q_l\right) \\ v'_l &= \sigma\left(h_{l-1} \cdot R_l\right) \\ h_l &= v_l \otimes v'_l \end{aligned}$$

where h_{l-1} is double-projected to v_l and v'_l, and the two projections are merged using the Hadamard element-wise product operator $\otimes$.

This formulation allows us to use the same infrastructure of the conventional neural networks by projecting the previous layer to two different spaces of the same dimensions, then multiplying them element-wise. The only component that is different from conventional feedforward neural networks is the multiplicative function, which is trivially differentiable with respect to the learnable parameters. Figure 3(b) illustrates the tensor architecture for two hidden layers.

The tensor network can learn collocation features more easily. For example, it can learn a collocation feature that is activated only if $h_{l-1}[i]$ collocates with $h_{l-1}[j]$ by setting $U_l[k][i][j]$ to some positive number. This results in SMT improvements as we describe in Section 5.

4 Multitask Learning

The third part of this paper addresses the challenge of effectively learning a large number of neural network parameters without overfitting. The challenge is even larger for tensor network since they practically doubles the number of parameters. In this section, we propose to apply Multitask Learning (MTL) to partially address this issue. We implement MTL as parameter sharing among the networks. This effectively reduces the number of parameters, and more importantly, it takes advantage of parameters learned for one feature to better

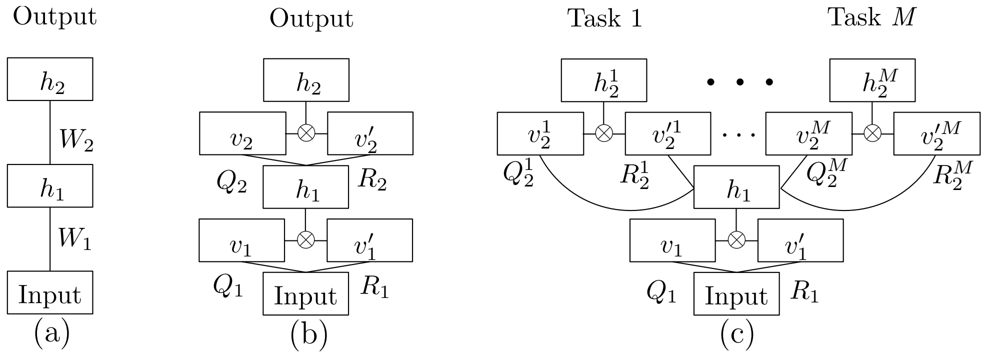


Figure 2: The network architecture for (a) a conventional feedforward neural network, (b) tensor hidden layers, and (c) multitask learning with M features that share the embedding and first hidden layers ($t = 1$).

learn the parameters of the other features. Another way of looking at this is that MTL facilitates regularization through learning the other tasks.

MTL is suitable for SMT features as they model different but closely related aspects of the same translation process. MTL has long been used by the wider machine learning community (Caruana, 1997) and more recently for natural language processing (Collobert and Weston, 2008; Collobert et al., 2011). The application of MTL to machine translation, however, has been much less restricted, which is rather surprising since SMT features arise from the same translation task and are naturally related.

We apply MTL for the features described in Section 2. We design all the features to also share the same neural network architecture (in this case, the tensor architecture described in Section 3) and the same input, thus resulting in two large neural networks: one for the hypothesis-enumerating features and another for the source-enumerating ones. This simplifies the implementation of MTL. Using this setup, it is possible to vary the number of shared hidden layers t from 0 (only sharing the embedding layer) to $L - 1$ (sharing all the layers except the output). Note that in principle MTL is applicable to other set of networks that have different architecture or even different input set. With MTL, the training procedure is the same as that of standard neural networks.

We use the back propagation algorithm, and use as the loss function the product of likelihood of each feature[1]:

$$Loss = \sum_i \sum_j^M \log\left(P\left(Y_j(X_i)\right)\right)$$

where X_i is the training sample and Y_j is one of the M models trained. We use the sum of log likelihoods since we assume that the features are independent.

Fig. 3(c) illustrates MTL between M models sharing the input embedding layer and the first hidden layer ($t = 1$) compared to the separately-trained conventional feedforward neural network and tensor neural network.

5 Experiments

We demonstrate the impact of our work with extensive MT experiments on Arabic-English and Chinese-English translation for the DARPA BOLT Web Forum and the NIST OpenMT12 conditions.

5.1 Baseline MT System

We run our experiments using a state-of-the-art string-to-dependency hierarchical decoder (Shen et al., 2010). The baseline we use includes a set of powerful features as follow:

- Forward and backward rule probabilities
- Contextual lexical smoothing (Devlin, 2009)
- 5-gram Kneser-Ney LM
- Dependency LM (Shen et al., 2010)
- Length distribution (Shen et al., 2010)
- Trait features (Devlin and Matsoukas, 2012)
- Factored source syntax (Huang et al., 2013)
- Discriminative sparse feature, totaling 50k features (Chiang et al., 2009)
- Neural Network Joint Model (NNJM) and Neural Network Lexical Translation Model

[1] In this and in the other parts of the paper, we add the normalization regularization term described in (Devlin et al., 2014) to the loss function to avoid computing the normalization constant at model query/decoding time.

(NNLTM) (Devlin et al., 2014)

As shown, our baseline system already includes neural network-based features. NNJM, NNLTM and use two hidden layers with 500 units and use embedding of size 200 for each input.

We use the MADA-ARZ tokenizer (Habash et al., 2013) for Arabic word tokenization. For Chinese tokenization, we use a simple longest-match-first lexicon-based approach. We align the training data using GIZA++ (Och and Ney, 2003). For tuning the weights of MT features including the new features, we use iterative k-best optimization with an ExpectedBLEU objective function (Rosti et al., 2010), and decode the test sets after 5 tuning iteration. We report the lower-cased BLEU and TER scores.

5.2 BOLT Discussion Forum

The bulk of our experiments is on the BOLT Web Discussion Forum domain, which uses data collected by the LDC. The parallel training data consists of all of the high-quality NIST training corpora, plus an additional 3 million words of translated forum data. The tuning and test sets consist of roughly 5000 segments each, with 2 independent references for Arabic and 3 for Chinese.

5.2.1 Effects of New Features

We first look at the effects of the proposed features compared to the baseline system. Table 1 summarizes the primary results of the Arabic-English and Chinese-English experiments for the BOLT condition. We show the experimental results related to hypothesis-enumerating features (HypEn) in rows S_2-S_5, those related to source-enumerating features (SrcEn) in rows S_6-S_9, and the combination of the two in row S_{10}. For all the features, we set the source context length to $m = 5$ (11-word window). For JM and JMO, we set the target context length to $n = 4$. For the offset parameter k of JMO, we use values 1 to 3. For TCM, we model one word around the translation ($d = 1$). Larger values of d did not result in further gains. The baseline is comparable to the best results of (Devlin et al., 2014).

In rows S_3 to S_5, we incrementally add a model with different offset source context, from $k = 1$ to $k = 3$. For AR-EN, adding JMOs with different offset source context consistently yields positive effects in BLEU score, while in ZH-EN, it yields positive effects in TER score. Utilizing all offset source contexts "+JMO$_{k\leq3}$" (row S_5) yields around 0.9 BLEU point improvement in AR-EN and around 0.3 BLEU in ZH-EN compared to the baseline. The JMO consistently provides better improvement compared to a larger JM context (row S_2), validating our hypothesis that using offset source context captures important non-local context.

Rows S_6 to S_9 present the improvements that result from implementing pre-existing source-enumerating SMT features as neural networks, and highlight the contribution of our translation context model (TCM). This set of experiments is orthogonal to the HypEn experiments (rows S_2-S_5). Each pre-existing model has a modest positive cumulative effect on both BLEU and TER. We see this result as further confirming the current trend of casting existing SMT features as neural network since our baseline already contains such features. The next row present the results of adding the translation context model, with one word surrounding the translation ($d = 1$). As shown, TCM yields a positive effect of around 0.5 BLEU and TER improvements in AR-EN and around 0.2 BLEU and TER improvements in ZH-EN.

Separately, the set of source-enumerating features and the set of target-enumerating features produce around 1.1 to 1.2 points BLEU gain in AR-EN and 0.3 to 0.5 points BLEU gain in ZH-EN. The combination of the two sets produces a complementary gain in addition to the gains of the individual models as Row (S_{10}) shows. The combined gain improves to 1.5 BLEU points in AR-EN and 0.7 BLEU points in ZH-EN.

System	AR-EN		ZH-EN	
	BL	TER	BL	TER
S_1: Baseline	43.2	45.0	30.2	58.3
S_2: S_1+JM$_{LC_8}$	43.5	45.0	30.2	58.5
S_3: S_1+JMO$_{k=1}$	43.9	44.7	30.8	57.8
S_4: S_3+JMO$_{k=2}$	43.9	44.7	30.7	57.8
S_5: S_4+JMO$_{k=3}$	44.4	44.5	30.5	57.5
S_6: S_1+LTM	43.5	44.7	30.3	58.0
S_7: S_6+ORI	43.7	44.6	30.4	57.8
S_8: S_7+FERT	43.8	44.7	30.5	57.8
S_9: S_8+TCM	44.3	44.2	30.7	57.5
S_{10}: S_9+JMO$_{k\leq3}$	44.7	44.1	30.9	57.3

Table 1: MT results of various model combination in BLEU and in TER.

5.2.2 Effects of Tensor Network and Multitask Learning

We first analyze the impact of tensor architecture and MTL intrinsically by reporting the models' average log-likelihood on the validation sets (a subset of the test set) in Table 2. As mentioned, we group the models to HypEn (JM and JMO$_{k\leq3}$) and SrcEn (LTM, ORI,FERT and TCM) as we perform MTL on these two groups. Likelihood of these two groups in the previous subsection are in column "NN" (for Neural Network), which serves as a baseline. The application of the tensor architecture improves their likelihood as shown in column "Tensor" for both languages and models.

	Feat.	Independent		MTL	
		NN	Tensor	$t = 0$ $L = 2$	$t = 1$ $L = 3$
AR	HypEn	-8.85	-8.54	-8.35	-
	SrcEn	-8.47	-8.32	-8.10	-8.09
ZH	HypEn	-11.48	-11.06	-10.87	-
	SrcEn	-10.77	-10.66	-10.54	-10.49

Table 2: Sum of the average log-likelihood of the models in HypEn and SrcEn. $t = 0$ refers to MTL that shares only the embedding layer, while $t = 1$ shares the first hidden layer as well. L refers to the network's depth. Higher value is better.

The likelihoods of the MTL-related experiments are in columns with "MTL" header. We present two set of results. In the first set (column "MTL,t=0,L=2"), we run MTL for features from column "Tensor" by sharing the embedding layer only ($t = 0$). This allows us to isolate the impact of MTL in the presence of Tensors. Column "MTL,t=1,l=3" corresponds to the experiment that produces the best intrinsic result, where each model uses Tensors with three hidden layers (500x500x500, $l = 3$) and the models share the embedding and the first hidden layers ($t = 1$). MTL consistently gives further intrinsic gain compared to tensors. More sharing provides an extra gain for SrcEn as shown in the last column. Note that we only experiment with different l and t for SrcEn and not for HypEn because the models in HypEn have different input sets. In our experiments, further sharing and more hidden layers resulted in no further gain. In total, we see a consistent positive effect in intrinsic evaluation from the tensor networks and multitask learning.

Moving on to MT evaluation, we summarize the experiments showing the impact of Tensors and MTL in Table 3. For MTL, we use $L = 3, t = 2$ since it gives the best intrinsic score. Employing tensors instead of regular neural networks gives a significant and consistent positive impact for all models and language pairs. For the system with the baseline features, we use the tensor architecture for both the joint model and the lexical translation model of Devlin et al. resulting in an improvement of around 0.7 BLEU points, and showing the wide applicability of the tensor architecture. On top of this improved baseline, we also observe an improvement of the same scale for other models (column "Tensor"), except for HypEn features in AR-EN experiment. Moving to MTL experiments, we see improvements, especially from SrcEn features. MTL gives around 0.5 BLEU point improvement for AR-EN and around 0.4 BLEU point for ZH-EN. When we employ both HypEn and SrcEn together, MTL gives around 0.4 BLEU point in AR-EN and 0.2 BLEU point in ZH-EN. In total, our work results in an improvement of 2.5 BLEU point for AR-EN and 1.8 for BLEU point in ZH-EN on top of the best results in (Devlin et al., 2014).

5.3 NIST OpenMT12

Our NIST system is compatible with the OpenMT12 constrained track, which consists of 10M words of high-quality parallel training for Arabic, and 25M words for Chinese. The n-gram LM is trained on 5B words of data from the English GigaWord. For test, we use the "Arabic-To-English Original Progress Test" (1378 segments) and "Chinese-to-English Original Progress Test + OpenMT12 Current Test" (2190 segments), which consists of a mix of newswire and web data. All test segments have 4 references. Our tuning set contains 5000 segments, and is a mix of the MT02-05 eval set as well as additional held-out parallel data from the training corpora.

We report the experiments for the NIST condition in Table 4. In particular, we investigate the impact of deploying our new features (column "Feat") and demonstrate the effects of the tensor architecture (column "Tensor") and multitask learning (column "MTL"). As shown the results are inline with the BOLT condition where we observe additive improvements from adding our new features, applying tensor network and multitask learning. On Arabic-English, we see a gain of 2.7

Feature set	AR-EN			ZH-EN		
	NN	Tensor	MTL	NN	Tensor	MTL
R_1: Baseline Features	*43.2*	43.9	-	*30.2*	30.8	-
R_2: R_1 + HypEn	44.4	44.4	44.5	30.5	31.5	31.3
R_3: R_1 + SrcEn	44.3	44.9	45.5	30.7	31.5	31.9
R_4: R_1 + HypEn + SrcEn	44.7	45.3	**45.7**	30.9	31.8	**32.0**

Table 3: Experimental results to investigate the effects of the new features, DTN and MTL. The top part shows the BOLT results, while the bottom part shows the NIST results. The best results for each conditions and each language-pair are in **bold**. The baselines are in *italics*. .

	Base.	Feat	Tensor	MTL
AR-EN	*53.7*	55.4	55.9	56.4
mixed-case	*51.8*	53.1	53.7	54.1
ZH-EN	*36.6*	37.8	38.2	38.5
mixed-case	*34.4*	35.5	35.9	36.1

Table 4: Experimental results for the NIST condition. Mixed-case scores are also reported. Baselines are in *italics*.

BLEU point and on Chinese-English, we see a 1.9 BLEU point gain. We also report the mixed-cased BLEU scores for comparison with previous best published results, i.e. Devlin et al. (2014) report 52.8 BLEU for Arabic-English and 34.7 BLEU for Chinese-English. Thus, our results are around 1.3-1.4 BLEU point better. Note that they use additional rescoring features but we do not.

6 Related Work

Our work is most closely related to Devlin et al. (2014). They use a simple feedforward neural network to model two important MT features: A joint language and translation model, and a lexical translation model. They show very large improvements on Arabic-English and Chinese-English web forum and newswire baselines. We improve on their work in 3 aspects. First, we model more features using neural networks, including two novel ones: a joint model with offset source context and a translation context model. Second, we enhance the neural network architecture by using tensor layers, which allows us to model richer interactions. Lastly, we improve the performance of the individual features by training them using multitask learning. In the remainder of this section, we describe previous work relating to the three aspect of our work, namely MT modeling, neural network architecture and model learning.

The features we propose in this paper address the major aspects of SMT modeling that have informed much of the research since the original IBM models (Brown et al., 1993): lexical translation, reordering, word fertility, and language models. Of particular relevance to our work are approaches that incorporate context-sensitivity into the models (Carpuat and Wu, 2007), formulate reordering as orientation prediction task (Tillman, 2004) and that use neural network language models (Bengio et al., 2003; Schwenk, 2010; Schwenk, 2012), and incorporate source-side context into them (Devlin et al., 2014; Auli et al., 2013; Le et al., 2012; Schwenk, 2012).

Approaches to incorporating source context into a neural network model differ mainly in how they represent the source sentence and in how long is the history they keep. In terms of representation of the source sentence, we follow (Devlin et al., 2014) in using a window around the *affiliated* source word. To name some other approaches, Auli et al. (2013) uses latent semantic analysis and source sentence embeddings learned from the recurrent neural network; Sundermeyer et al. (2014) take the representation from a bidirectional LSTM recurrent neural network; and Kalchbrenner and Blunsom (2013) employ a convolutional sentence model. For target context, recent work has tried to look beyond the classical *n*-gram history. (Auli et al., 2013; Sundermeyer et al., 2014) consider an unbounded history, at the expense of making their model only applicable for N-best rescoring. Another recent line of research (Bahdanau et al., 2014; Sutskever et al., 2014) departs more radically from conventional feature-based SMT and implements the MT system as a single neural network. These models use a representation of the whole input sentence.

We use a feedforward neural network in this work. Besides feedforward and recurrent networks, other network architectures that have been applied to SMT include convolutional networks (Kalchbrenner et al., 2014) and recursive networks (Socher et al., 2011). The simplicity of feedforward networks works to our advantage. More specifically, due to the absence of a feedback loop, the feedforward architecture allows us to treat individual decisions independently, which makes parallelization of the training easy and the querying the network at decoding time straightforward. The use of tensors in the hidden layers strengthens the neural network model, allowing us to model more complex feature interactions like collocation, which has been long recognized as important information for many NLP tasks (e.g. word sense disambiguation (Lee and Ng, 2002)). The tensor formulation we use is similar to that of (Yu et al., 2012; Hutchinson et al., 2013). Tensor Neural Networks have a wide application in other field, but have only been recently applied in NLP (Socher et al., 2013; Pei et al., 2014). To our knowledge, our work is the first to use tensor networks in SMT.

Our approach to multitask learning is related to work that is often labeled joint training or transfer learning. To name a few of these works, Finkel and Manning (2009) successfully train name entity recognizers and syntactic parsers jointly, and Singh et al. (2013) train models for coreference resolution, named entity recognition and relation extraction jointly. Both efforts are motivated by the minimization of cascading errors. Our work is most closely related to Collobert and Weston (2008; Collobert et al. (2011), who apply multitask learning to train neural networks for multiple NLP models: part-of-speech tagging, semantic role labeling, named-entity recognition and language model variations.

7 Conclusion

This paper argues that a relatively simple feedforward neural network can still provides significant improvement to Statistical Machine Translation (SMT). We support this argument by presenting a multi-pronged approach that addresses modeling, architectural and learning aspects of pre-existing neural network-based SMT features. More concretely, we paper present a new set of neural network-based SMT features to capture important translation phenomena, extend feedforward neural network with tensor layers, and apply multitask learning to integrate the SMT features more tightly. Empirically, all our proposals successfully produce an improvement over state-of-the-art machine translation system for Arabic-to-English and Chinese-to-English and for both BOLT web forum and NIST conditions. Building on the success of this paper, we plan to develop other neural-network-based features, and to also relax the limiteation of current rule extraction heuristics by generating translations word-by-word.

Describing Images using Inferred Visual Dependency Representations

Abstract

The Visual Dependency Representation (VDR) is an explicit model of the spatial relationships between objects in an image. In this paper we present an approach to training a VDR Parsing Model without the extensive human supervision used in previous work. Our approach is to find the objects mentioned in a given description using a state-of-the-art object detector, and to use successful detections to produce training data. The description of an unseen image is produced by first predicting its VDR over automatically detected objects, and then generating the text with a template-based generation model using the predicted VDR. The performance of our approach is comparable to a state-of-the-art multimodal deep neural network in images depicting actions.

1 Introduction

Humans typically write the text accompanying an image, which is a time-consuming and expensive activity. There are many circumstances in which people are well-suited to this task, such as captioning news articles (Feng and Lapata, 2008) where there are complex relationships between the modalities (Marsh and White, 2003). In this paper we focus on generating *literal* descriptions, which are rarely found alongside images because they describe what can easily be seen by others (Panofsky, 1939; Shatford, 1986; Hodosh et al., 2013). A computer that can automatically generate these literal descriptions, filling the gap left by humans, may improve access to existing image collections or increase information access for visually impaired users.

There has been an upsurge of research in this area, including models that rely on spatial relationships (Farhadi et al., 2010), corpus-based relationships (Yang et al., 2011), spatial and visual attributes (Kulkarni et al., 2011), n-gram phrase fusion from Web-scale corpora (Li et al., 2011), tree-substitution grammars (Mitchell et al., 2012), selecting and combining phrases from large image-description collections (Kuznetsova et al., 2012), using Visual Dependency Representations to capture spatial and corpus-based relationships (Elliott and Keller, 2013), and in a generative framework over densely-labelled data (Yatskar et al., 2014). The most recent developments have focused on deep learning the relationships between visual feature vectors and word-embeddings with language generation models based on recurrent neural networks or long-short term memory networks (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Mao et al., 2015; Fang et al., 2015; Donahue et al., 2015; Lebret et al., 2015). An alternative thread of research has focused on directly pairing images with text, based on kCCA (Hodosh et al., 2013) or multimodal deep neural networks (Socher et al., 2014; Karpathy et al., 2014).

We revisit the Visual Dependency Representation (Elliott and Keller, 2013, VDR), an intermediate structure that captures the spatial relationships between objects in an image. Spatial context has been shown to be useful in object recognition and naming tasks because humans benefit from the visual world conforming to their expectations (Biederman et al., 1982; Bar and Ullman, 1996). The spatial relationships defined in VDR are closely, but independently, related to cognitively plausible spatial templates (Logan and Sadler, 1996) and region connection calculus (Randell et al., 1992). In the image description task, explicitly modelling the spatial relationships between observed objects constrains how an image should be described. An example can be seen in Figure 1, where the training VDR identifies the defining relationship between the man and the laptop, which may be re-

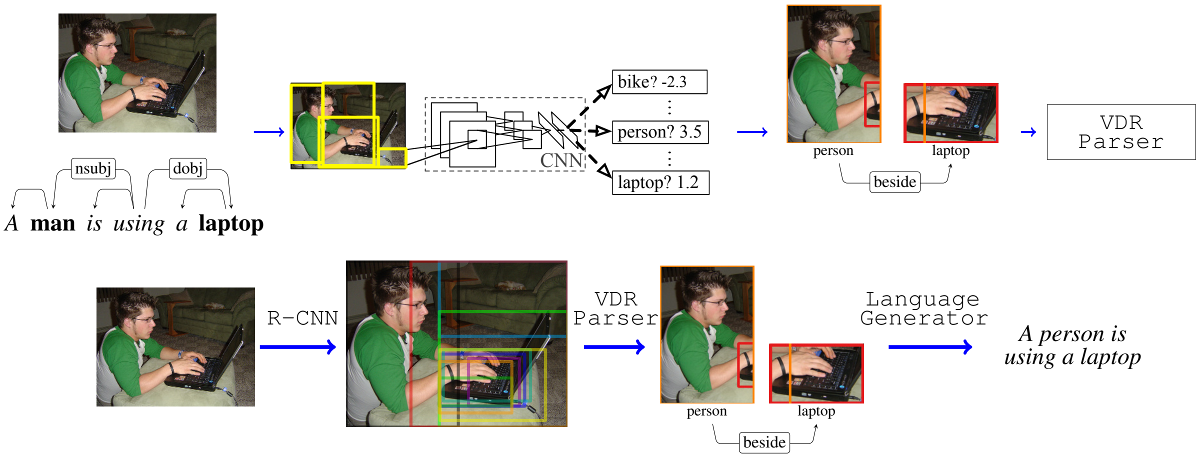

Figure 1: We present an approach to inferring VDR training data from images paired with descriptions (top), and for generating descriptions from VDR (bottom). Candidates for the subject and object in the image are extracted from the description. An object detector[1] searches for the objects and deterministically produces a training instance, which is used to train a VDR Parser to predict the relationships between objects in unseen images. When an unseen image is presented to the model, we first extract N-candidate objects for the image. The detected objects are then parsed into a VDR structure, which is passed into a template-based language generator to produce a description of the image.

alised as a "using", "typing", or "working" relationship between the objects.

The main limitation of previous research on VDR has been the reliance on gold-standard training annotations, which requires trained annotators. We present the first approach to automatically inferring VDR training examples from natural scenes using only an object detector and an image description. Ortiz et al. (2015) have recently presented an alternative treatment of VDR within the context of abstract scenes and phrase-based machine translation. Figure 1 shows a detailed overview of our approach. At training time, we learn a VDR Parsing model from representations that are constructed by searching for the subject and object in the image. The description of an unseen image is generated using a template-based generation model that leverages the VDR predicted over the top-N objects extracted from an object detector.

We evaluate our method for inferring VDRs in an image description experiment on the Pascal1K (Rashtchian et al., 2010) and VL2K data sets (Elliott and Keller, 2013) against two models: the bi-directional recurrent neural network (Karpathy and Fei-Fei, 2015, BRNN) and MIDGE (Mitchell et al., 2012). The main finding is that the quality of the descriptions generated by our method depends on whether the images depict an action. In the VLT2K data set of people performing actions, the performance of our approach is comparable to the BRNN; in the more diverse Pascal1K dataset, the BRNN is substantially better than our method. In a second experiment, we transfer the VDR-based model from the VLT2K data set to the Pascal1K data set without re-training, which improves the descriptions generated in the Pascal1K data set. This suggests that refining how we extract training data may yield further improvements to VDR-based image description.

The code and generated descriptions are available at `http://github.com/elliottd/vdr/`.

2 Automatically Inferring VDRs

The Visual Dependency Representation is a structured representation of an image that explicitly models the spatial relationships between objects. In this representation, the spatial relationship between a pair of objects is encoded with one of the following eight options: above, below, beside, opposite, on, surrounds, infront, and behind. Previous work on VDR-based image description has relied on training data from expert human annotators, which is expensive and difficult to scale to other data sets. In this paper, we describe an approach to automatically inferring VDRs using only an object detector and the description of an image. Our aim is to define an automated version

[1] The image of the R-CNN object detector was modified with permission from Girshick et al. (2014).

Relation	Definition
Beside	The angle between the subject and the object is either between 315° and 45° or 135° and 225°.
Above	The angle between the subject and object is between 225° and 315°.
Below	The angle between the subject and object is between 45° and 135°.
On	More than 50% of the subject overlaps with the object.
Surrounds	More than 90% of the subject overlaps with the object.

Table 1: The cascade of spatial relationships between objects in VDR. We always use the last relationship that matches. These definitions are mostly taken from (Elliott and Keller, 2013), except that we remove the 3D relationships. Angles are defined with respect to the unit circle, which has 0° on the right. All relations are specific with respect to the centroid of the bounding boxes.

of the human process used to create gold-standard data (Elliott and Keller, 2013).

An inferred VDR is constructed by searching for the subject and object referred to in the description of an image using an object detector. If both the subject and object can be found in the image, a VDR is created by attaching the detected subject to the detected object, given the spatial relationship between the object bounding boxes. The spatial relationships that can be applied between subjects and objects are defined in the cascade defined in Table 1. The set of relationships was reduced from eight to six due to the difficulty in predicting the 3D relationships in 2D images (Eigen et al., 2014). The spatial relation selected for a pair of objects is determined by applying each template defined in Table 1 to the object pair. We use only the final matching relationship, although future work may consider applying multiple matching relationships between objects.

Given a set of inferred VDR training examples, we train a VDR Parsing Model with the VDR+IMG feature set using only the inferred examples (Elliott et al., 2014). We tried training a model by combining the inferred and gold-standard VDRs but this lead to an erratic parsing model that would regularly predict flat structures instead of object–object relationships. One possibility for this behaviour is the mismatch caused by removing the infront and behind relationships in the inferred training data. Another possible explanation is the gold-standard data contains deeper and more complex structures than the simple object–object structures we infer.

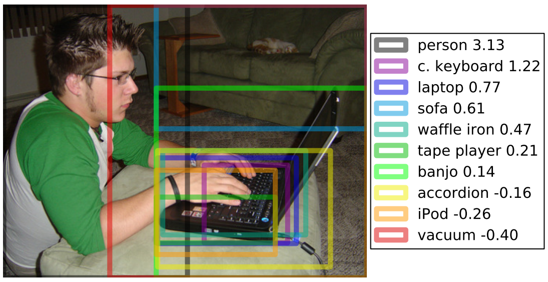

Figure 2: An example of the most confident object detections from the R-CNN object detector.

2.1 Linguistic Processing

The description of an image is processed to extract candidates for the mentioned objects. We extract candidates from the `nsubj` and `dobj` tokens in the dependency parsed description[2]. If the parsed description does not contain both a subject and an object, as defined here, the example is discarded.

2.2 Visual Processing

If the dependency parsed description contains candidates for the subject and object of an image, we attempt to find these objects in the image. We use the Regions with Convolutional Neural Network features object detector (Girshick et al., 2014, R-CNN) with the pre-trained `bvlc_reference_ilsvrc13` detection model implemented in Caffe (Jia et al., 2014). This object detection model is able to detect 200 different types of objects, with a mean average precision of 31.4% in the ImageNet Large-Scale Visual Recognition Challenge[3] (Russakovsky et al., 2014). The output of the object detector is a bounding box with real-valued confidence scores, as shown in

[2] The descriptions are Part-of-Speech tagged using the Stanford POS Tagger v3.1.0 (Toutanova et al., 2003) with the `english-bidirectional-distsim` pre-trained model. The tagged descriptions are then Dependency Parsed using Malt Parser v 1.7.2 (Nivre et al., 2007) with the `engmalt.poly-1.7` pre-trained model.

[3] The state-of-the-art result for this task is 37.2% using a Network in Network architecture (Lin et al., 2014a); a pre-trained detection model was not available in the Caffe Model Zoo at the time of writing.

Figure 3: Examples of the object detections and automatically inferred VDR. In each example, the object detector candidates were extracted from the description and the VDR relationships were determined by the cascade in Table 1. Automatically inferring VDR allows us to learn differences in spatial relationships from different camera viewpoints, such as people riding bicycles.

Figure 2. The confidence scores are not probabilities and can vary widely across images.

The words in a description that refer to objects in an image are not always within the constrained vocabulary of the object labels in the object detection model. We increase the chance of finding objects with two simple back-offs: by lemmatising the token, and transforming the token into its WordNet hypernym parent. If the subject and the object can be found in the image, we create an inferred VDR from the detections, otherwise we discard this training example.

Figure 3 shows a collection of automatically inferred VDRs. One of the immediate benefits of VDR, as a representation, is that we can easily interpret the structures extracted from images. An example of helpful object orientation invariance can be seen in 3 (b) and (c), where VDR captures the two different types of spatial relationships between people and bicycles that are grounded in the verb “riding”. This type of invariance is useful and it suggests VDR can model interacting objects from various viewpoints. We note here the similarities between automatically inferred VDR and Visual Phrases (Sadeghi and Farhadi, 2011). The main difference between these models is that VDR is primarily concerned with object–object interactions for generation and retrieval tasks, whereas Visual Phrases were intended to model person–object interactions for *activity recognition*.

2.3 Building a Language Model

We build a language model using the subjects, verbs, objects, and spatial relationships from the successfully constructed training examples. The subjects and objects take the form of the object detector labels to reduce the effects of sparsity. The verbs are found as the direct common verb parent of the subject and object in the dependency parsed sentence. We stem the verbs using *morpha*, to reduce sparsity, and inflect them in a generated description with +ing using *morphg* (Minnen et al., 2001). The spatial relationship between the subject and object region is used to help constrain language generation to produce descriptions, given observed spatial contexts in a VDR.

Figure 4: An overview of VDR-constrained language generation. We extract the top-N objects from an image using an object detector and predict the spatial relationships between the objects using a VDR Parser trained over the inferred training data. Descriptions are generated for all parent–child subtrees in the VDR, and the final text has the highest combined corpus and visual confidence. †: only generated is there are no verbs between the objects in the language model; ⋆: only generated if there are no verbs between any pairs of objects in the image.

3 Generating Descriptions

The description of an image is generated using a template-based language generation model designed to exploit the structure encoded in VDR. The language generation model extends Elliott and Keller (2013) with the visual confidence scores from the object detector. Figure 4 shows an overview of the generation process.

The top-N objects are extracted from an image using the pre-trained R-CNN object detector (see Section 2.2 for more details). We remove non-maximal detections with the same class label that overlap by more than 30%. The objects are then parsed into a VDR structure using the VDR Parser trained on the automatically inferred training data. Given the VDR over the set of detected objects, we generate all possible descriptions of the image that can be produced in a depth-first traversal of the VDR. A description is assigned a score that combines the corpus-based evidence and visual confidence of the objects selected for the description. The descriptions are generated using the following template:

DT **head** is V DT **child**.

In this template, **head** and **child** are the labels of the objects that appear in the head and child positions of a specific VDR subtree. V is a verb determined from a subject-verb-object-spatial relation model derived from the training data descriptions. This model captures statistics about nouns that appear as subjects and objects, the verbs between them, and spatial relationships observed in the inferred training VDRs. The verb v that satisfies the V field is determined as follows:

$$v = \arg\max_{v} p(v|head, child, spatial) \qquad (1)$$

$$\begin{aligned} p(v|head{,}child, spatial) = \\ p(v|head) \cdot p(child|v, head) \cdot \\ p(spatial|child, v, head) \end{aligned} \qquad (2)$$

If no verbs were observed between a particular object–object pair in the training corpus, V is filled using a back-off that uses the spatial relationship label between the objects in the VDR.

The object detection confidence values, which are not probabilities and can vary substantially between images, are transformed into the range [0,1] using $sgm(conf) = \frac{1}{1+e^{-conf}}$. The final score assigned to a description is then used to rank all of the candidate descriptions, and the highest-scoring description is assigned to an image:

$$\begin{aligned} score(head, v{,}child, spatial) = \\ p(v|head, child, spatial) \cdot \\ sgm(head) \cdot sgm(child) \end{aligned} \qquad (3)$$

If the VDR Parser does not predict any relationships between objects in an image, which may happen if all of the objects have never been observed in the training data, we use a back-off template to generate the description. In this case, the most confidently detected object in the image is used with the following template:

A/An **object** is in the image.

The number of objects N objects extracted from an unseen image is optimised by maximising the sentence-level Meteor score of the generated descriptions in the development data.

4 Experiments

We evaluate our approach to automatically inferring VDR training data in an automatic image description experiment. The aim in this task is to generate a natural language description of an image, which is evaluated directly against multiple reference descriptions.

4.1 Models

We compare our approach against two state-of-the-art image description models. MIDGE generates text based on tree-substitution grammar and relies on discrete object detections (Mitchell et al., 2012) for visual input. We make a small modification to MIDGE so it uses all of the top-N detected objects, regardless of the confidence of the detections[4]. BRNN is a multimodal deep neural network that generates descriptions directly from vector representations of the image and the description (Karpathy and Fei-Fei, 2015). The images are represented by the visual feature vector extracted from the FC_7 layer of the VGG 16-layer convolutional neural network (Simonyan and Zisserman, 2015) and the descriptions are represented as a word-embedding vector.

4.2 Evaluation Measures

We evaluate the generated descriptions using sentence-level Meteor (Denkowski and Lavie, 2011) and BLEU4 (Papineni et al., 2002), which have been shown to have moderate correlation with humans (Elliott and Keller, 2014). We adopt a jack-knifing evaluation methodology, which enables us to report human–human results (Lin and Och, 2004), using MultEval (Clark et al., 2011).

4.3 Data Sets

We perform our experiments on two data sets: Pascal1K and VLT2K. The Pascal1K data set contains 1,000 images sampled from the PASCAL Object Detection Challenge data set (Everingham et al., 2010); each image is paired with five reference descriptions collected from Mechanical Turk. It contains a wide variety of subject matter drawn from the original 20 PASCAL Detection classes. The VLT2K data set contains 2,424 images taken from the trainval 2011 portion of the PASCAL Action Recognition Challenge; each image is paired with three reference descriptions, also collected from Mechanical Turk. We randomly split the images into 80% training, 10% validation, and 10% test.

	VLT2K		Pascal1K	
	Meteor	BLEU	Meteor	BLEU
VDR	16.0	14.8	7.4	9.0
BRNN	18.6	23.7	12.6	16.0
-genders	16.6	17.4	12.1	15.1
MIDGE	5.5	8.2	3.6	9.1
Human	26.4	23.3	21.7	20.6

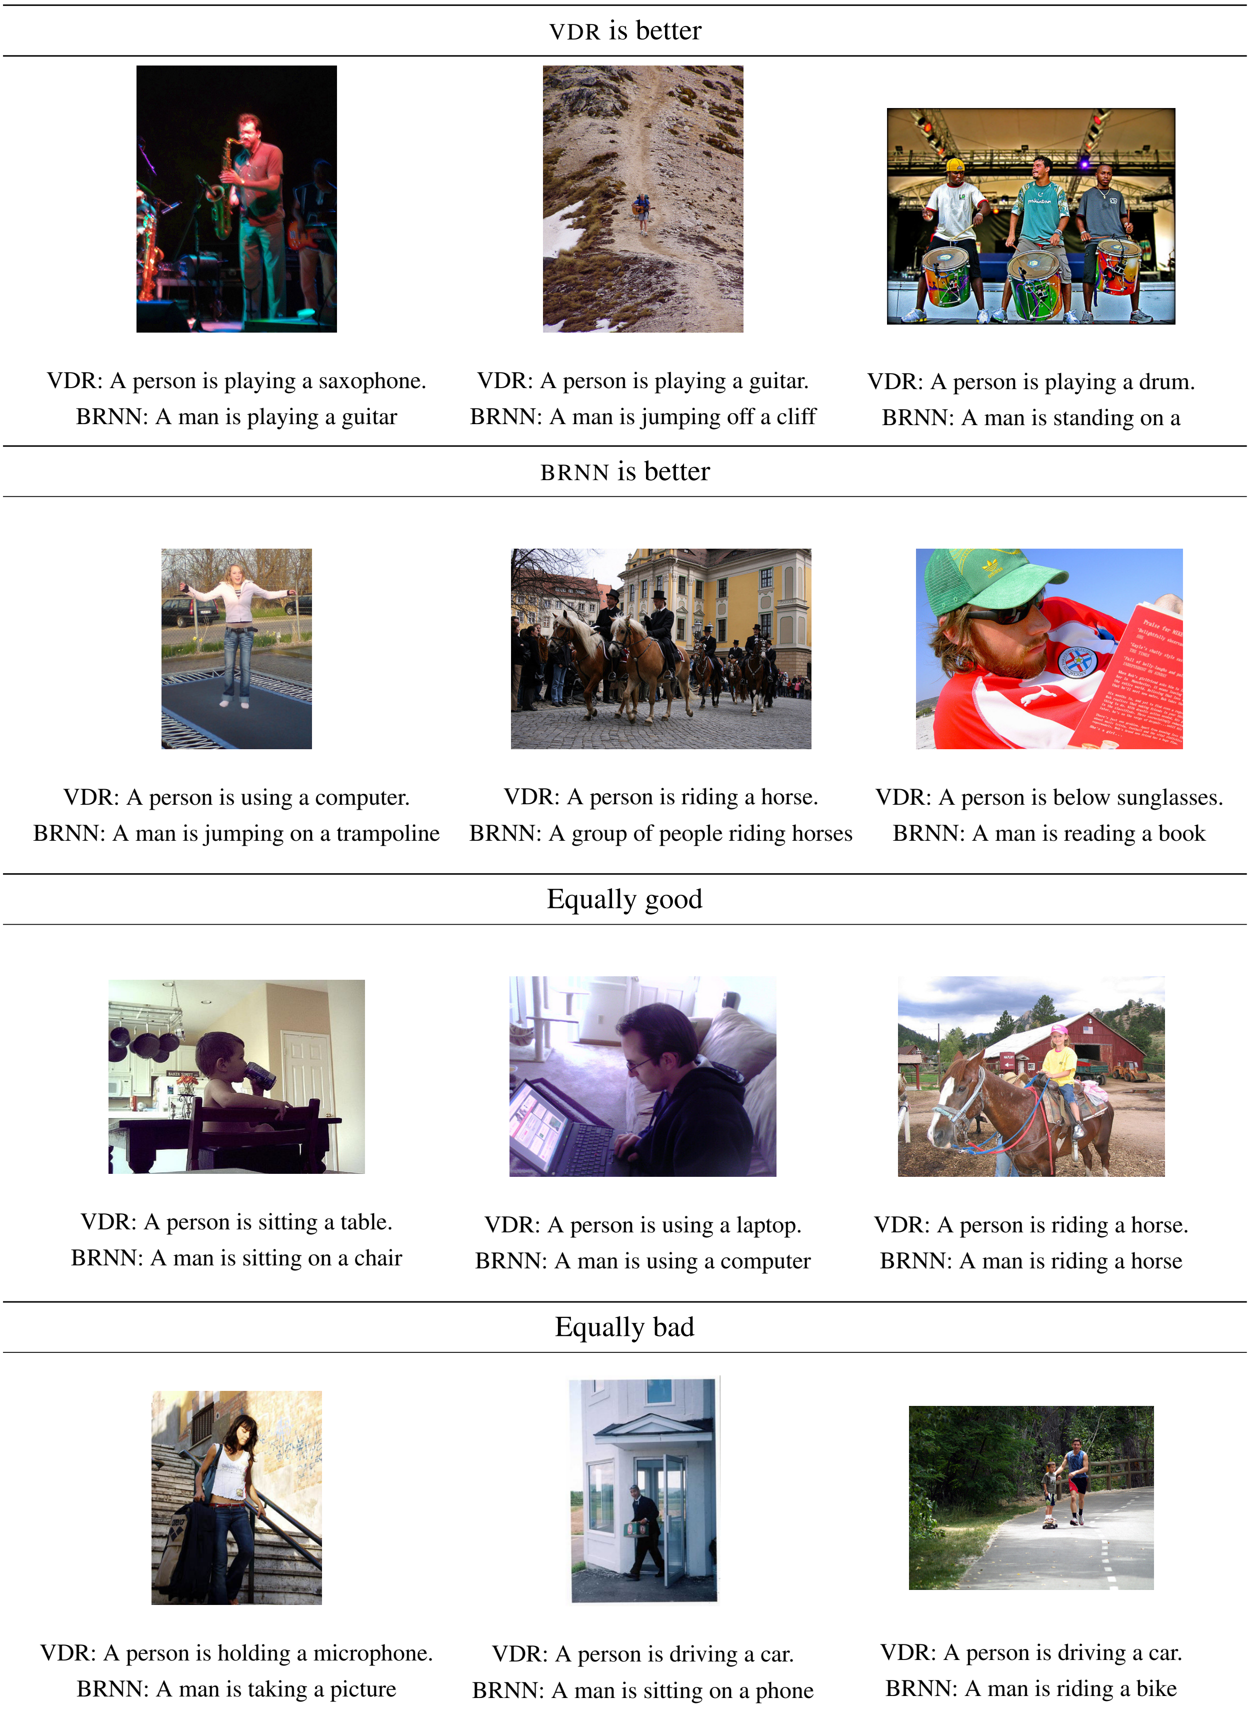
Table 2: Sentence-level evaluation of the generated descriptions. VDR is comparable to BRNN when the images exclusively depict actions (VLT2K). In a more diverse data set, BRNN generates better descriptions (Pascal1K).

4.4 Results

Table 2 shows the results of the image description experiment. The main finding of our experiments is that the performance of our proposed approach VDR depends on the type of images. We found that VDR is comparable to the deep neural network BRNN on the VLT2K data set of people performing actions. This is consistent with the hypothesis underlying VDR: it is useful to encode the spatial relationships between objects in images. The difference between the models is increased by the inability of the object detector used by VDR to predict bounding boxes for three objects (cameras, books, and phones) crucial to describing 30% of the images in this data set. In the more diverse Pascal1K data set, which does not necessarily depict people performing actions, the deep neural network generates substantially better descriptions than VDR and MIDGE. The tree-substitution grammar approach to generating descriptions used by MIDGE does not perform well on either data set.

There is an obvious discrepancy between the BLEU4 and Meteor scores for the models. BLEU4 relies on lexical matching between sentences and thus penalises semantically equivalent descriptions. For example, identifying the gender of a person is important for generating a good description. However, object recognizers are not (yet) able to reliably achieve this distinction, and we only have a single recogniser for "persons". The BRNN generates descriptions with "man" and "woman", which leads to higher BLEU scores than our VDR model, but this is based on corpus statistics than the observed visual information. Me-

[4] In personal communication with Margaret Mitchell, she explained that the object confidence thresholds for MIDGE were determined by visual inspection on held-out data, which we decided was not feasible for 200 new detectors.



VDR is better

VDR: A person is playing a saxophone.

Figure 5: Examples of descriptions generated using VDR and the BRNN in the VLT2K data set. Keen readers are encouraged to inspect the second image with a magnifying glass or an object detector.

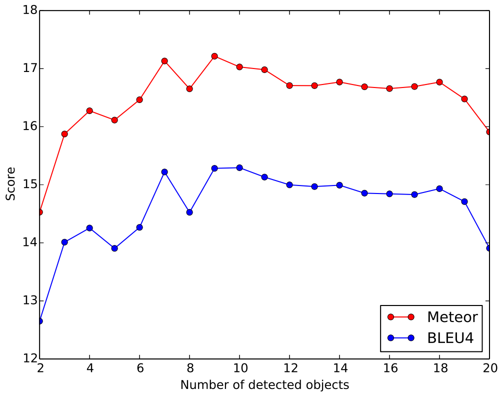

Figure 6: Optimising the number of detected objects against generated description Meteor scores for our model. Improvements are seen until eight objects, which suggests good descriptions do not always need the most confident detections.

teor is able to back-off from "man" or "woman" to "person" and still give partial credit to the description. If we replace the gendered referents in the descriptions generated by the BRNN, its performance on the VLT2K data set drops by 2.0 Meteor points and 6.3 BLEU points.

Figure 6 shows the effect of optimising the number of objects extracted from an image against the eventual Meteor score of a generated description in the validation data. It can be seen that the most confidently predicted objects are not always the most useful objects for generating descriptions. Interestingly, the quality of the descriptions does not significantly decrease with an increased number of detected objects, suggesting our model formulation is appropriately discarding unsuitable detections.

Figure 5 shows examples of the descriptions generated by VDR and BRNN on the VLT2K validation set. The examples where VDR generates better descriptions than BRNN are because the VDR Parser makes good decisions about which objects are interacting in an image. In the examples where the BRNN is better than VDR, we see that the multimodal RNN language model succeeds at describing intransitive verbs, group events, and objects not present in the R-CNN object detector. Both models generate bad descriptions when the visual input pushes them in the wrong direction, seen at the bottom of the figure.

	VLT → Pascal	
	Meteor	BLEU
VDR	7.4 → 8.2	9.1 → 9.2
BRNN	12.6 → 8.1	16.0 → 10.2

Table 3: Sentence-level scores when transferring models directly between data sets with no retraining. The VDR-based approach generates better descriptions in the Pascal1K data set if we transfer the model from the VLT2K data set.

4.5 Transferring Models

The main reason for the low performance of VDR on the Pascal1K data set is that the linguistic and visual processing steps (Section 2) discard too many training examples. We found that only 190 of the 4,000 description in the training data were used to infer VDRs. This was because most of the descriptions did not contain both a subject and an object, as required by our method. This observation led us to perform a second experiment where we transferred the VDR Parsing and Language Generation models between data sets. The aim of this experiment was to determine whether VDR simply cannot work on more widely diverse data sets, or whether the process we defined to replicate human VDR annotation was too strict.

Table 3 shows the results of the model transfer experiment. In general, neither model is particularly good at transferring between data sets. This could be attributed to the shift in the types of scenes depicted in each data set. However, transferring VDR from the VLT2K to the Pascal1K data set *improves* the generated descriptions from 7.4 → 8.2 Meteor points. The performance of BRNN substantially decreases when transferring between data sets, suggesting that the model may be overfitting its training domain.

4.6 Discussion

Notwithstanding the conceptual differences between multi-modal deep learning and learning an explicit spatial model of object–object relationships, two key differences between the BRNN and our approach are the nature visual input and the language generation models.

The neural network model can readily use the pre-softmax visual feature vector from any of the pre-trained models available in the Caffe Model

Zoo, whereas VDR is currently restricted to discrete object detector outputs from those models. The implication of this is that the VDR-based approach is unable to describe 30% of the data in the VLT2K data set. This is due to the object detection model not recognising crucial objects for three of the action classes: cameras, books, and telephones. We considered using the VGG-16 pretrained model from the ImageNet Recognition and Localization task in the RCNN object detector, thus mirroring the detection model used by the neural network. Frustratingly, this does not seem possible because none of the 1,000 types of objects in the recognition task correspond to a person-type of entity. One approach to alleviating this problem could be to use weakly-supervised object localisation (Oquab et al., 2014).

The template-based language generation model used by VDR lacks the flexibility to describe interesting prepositional phrases or variety within its current template. An n-gram language generator, such as the phrase-based approaches of (Ortiz et al., 2015; Lebret et al., 2015), that works within the constraints imposed by VDR structure may generate better descriptions of images than the current template.

5 Conclusions

In this paper we showed how to infer useful and reliable Visual Dependency Representations of images without expensive human supervision. Our approach was based on searching for objects in images, given a collection of co-occurring descriptions. We evaluated the utility of the representations on a downstream automatic image description task on two data sets, where the quality of the generated text largely depended on the data set. In a large data set of people performing actions, the descriptions generated by our model were comparable to a state-of-the-art multimodal deep neural network. In a smaller and more diverse data set, our approach produced poor descriptions because it was unable to extract enough useful training examples for the model. In a follow-up experiment that transferred the VDR Parsing and Language Generation model between data, we found improvements in the diverse data set. Our experiments demonstrated that explicitly encoding the spatial relationships between objects is a useful way of learning how to describe actions.

There are several fruitful opportunities for future work. The most immediate improvement may be found with broader coverage object detectors. It would be useful to search for objects using multiple pre-trained visual detection models, such as a 200-class ImageNet Detection model and a 1,000-class ImageNet Recognition and Localisation model. A second strand of further work would be to relax the strict mirroring of human annotator behaviour when searching for subjects and objects in an image. It may be possible to learn good representations using only the nouns in the POS tagged description. Our current approach strictly limits the inferred VDRs to transitive verbs; images with descriptions such as "A large cow in a field" or "A man is walking" are also a focus for future relaxations of the process for creating training data. Another direction for future work would be to use a n-gram based language model constrained by the structured predicted in VDR. The current template based method is limiting the generation of objects that are being correctly realised in images.

Tackling the aforementioned future work opens up opportunities to working with larger and more diverse data sets such as the Flickr8K (Hodosh et al., 2013), Flickr30K (Young et al., 2014), and MS COCO (Lin et al., 2014b) or larger action recognition data sets such as TUHOI (Le et al., 2014) or MPII Human Poses (Andriluka et al., 2014).

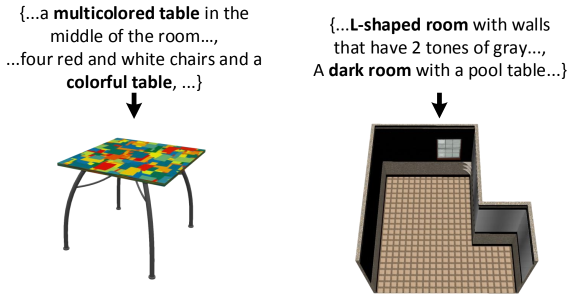
Abstract

The ability to map descriptions of scenes to 3D geometric representations has many applications in areas such as art, education, and robotics. However, prior work on the *text to 3D scene generation* task has used manually specified object categories and language that identifies them. We introduce a dataset of 3D scenes annotated with natural language descriptions and learn from this data how to ground textual descriptions to physical objects. Our method successfully grounds a variety of lexical terms to concrete referents, and we show quantitatively that our method improves 3D scene generation over previous work using purely rule-based methods. We evaluate the fidelity and plausibility of 3D scenes generated with our grounding approach through human judgments. To ease evaluation on this task, we also introduce an automated metric that strongly correlates with human judgments.

1 Introduction

We examine the task of *text to 3D scene generation*. The ability to map descriptions of scenes to 3D geometric representations has a wide variety of applications; many creative industries use 3D scenes. Robotics applications need to interpret commands referring to real-world environments, and the ability to visualize scenarios given high-level descriptions is of great practical use in educational tools. Unfortunately, 3D scene design user interfaces are prohibitively complex for novice users. Prior work has shown the task remains challenging and time intensive for non-experts, even with simplified interfaces (Savva et al., 2014).



{...a multicolored table in the middle of the room..., ...four red and white chairs and a colorful table, ...}
{...L-shaped room with walls that have 2 tones of gray..., A dark room with a pool table...}

Figure 1: We learn how to ground references such as "L-shaped room" to 3D models in a paired corpus of 3D scenes and natural language descriptions. Sentence fragments in bold were identified as high-weighted references to the shown objects.

Language offers a convenient way for designers to express their creative goals. Systems that can interpret natural descriptions to build a visual representation allow non-experts to visually express their thoughts with language, as was demonstrated by WordsEye, a pioneering work in text to 3D scene generation (Coyne and Sproat, 2001).

WordsEye and other prior work in this area (Seversky and Yin, 2006; Chang et al., 2014) used manually chosen mappings between language and objects in scenes. To our knowledge, we present the first 3D scene generation approach that learns from data how to map textual terms to objects. First, we collect a dataset of 3D scenes along with textual descriptions by people, which we contribute to the community. We then train a classifier on a scene discrimination task and extract high-weight features that ground lexical terms to 3D models. We integrate our learned lexical groundings with a rule-based scene generation approach, and we show through a human-judgment evaluation that the combination outperforms both approaches in isolation. Finally, we introduce a scene similarity metric that correlates with human judgments.

Figure 2: Illustration of the text to 3D scene generation pipeline. The input is text describing a scene (left), which we parse into an abstract scene template representation capturing objects and relations (middle). The scene template is then used to generate a concrete 3D scene visualizing the input description (right). The 3D scene is constructed by retrieving and arranging appropriate 3D models.

2 Task Description

In the text to 3D scene generation task, the input is a natural language description, and the output is a 3D representation of a plausible scene that fits the description and can be viewed and rendered from multiple perspectives. More precisely, given an utterance x as input, the output is a scene y: an arrangement of 3D models representing objects at specified positions and orientations in space.

In this paper, we focus on the subproblem of lexical grounding of textual terms to 3D model referents (i.e., choosing 3D models that represent objects referred to by terms in the input utterance x). We employ an intermediate *scene template* representation parsed from the input text to capture the physical objects present in a scene and constraints between them. This representation is then used to generate a 3D scene (Figure 2).

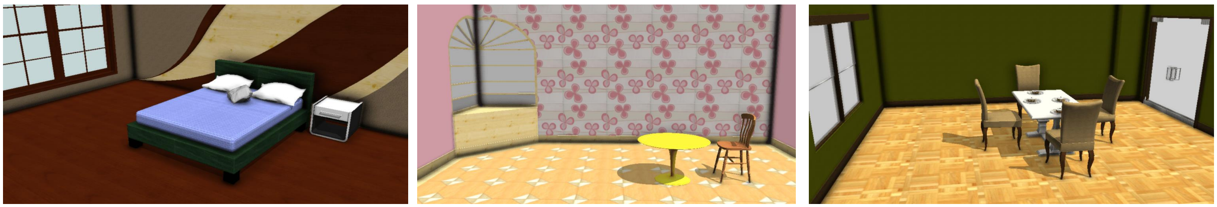
A naïve approach to scene generation might use keyword search to retrieve 3D models. However, such an approach is unlikely to generalize well in that it fails to capture important object attributes and spatial relations. In order for the generated scene to accurately reflect the input description, a deep understanding of language describing environments is necessary. Many challenging subproblems need to be tackled: physical object mention detection, estimation of object attributes such as size, extraction of spatial constraints, and placement of objects at appropriate relative positions and orientations. The subproblem of lexical grounding to 3D models has a larged impact on the quality of generated scenes, as later stages of scene generation rely on having a correctly chosen set of objects to arrange.

Another challenge is that much common knowledge about the physical properties of objects and the structure of environments is rarely mentioned in natural language (e.g., that most tables are supported on the floor and in an upright orientation). Unfortunately, common 3D representations of objects and scenes used in computer graphics specify only geometry and appearance, and rarely include such information. Prior work in text to 3D scene generation focused on collecting manual annotations of object properties and relations (Rouhizadeh et al., 2011; Coyne et al., 2012), which are used to drive rule-based generation systems. Regrettably, the task of scene generation has not yet benefited from recent related work in NLP.

3 Related Work

There is much prior work in image retrieval given textual queries; a recent overview is provided by Siddiquie et al. (2011). The image retrieval task bears some similarity to our task insofar as 3D scene retrieval is an approach that can approximate 3D scene generation.

However, there are fundamental differences between 2D images and 3D scenes. Generation in image space has predominantly focused on composition of simple 2D clip art elements, as exemplified recently by Zitnick et al. (2013). The task of composing 3D scenes presents a much higher-dimensional search space of scene configurations where finding plausible and desirable configurations is difficult. Unlike prior work in clip art generation which uses a small pre-specified set of objects, we ground to a large database of objects that can occur in various indoor environments: 12490 3D models from roughly 270 categories.



There is a bed and there is a nightstand next to the bed.

- There is a bed with three pillows and a bedside table next to it.
- The room appears to be a bedroom. A blue bed and white nightstand are pushed against the furthest wall. A window is on the left side.
- A dark bedroom with a queen bed with blue comforter and three pillows. There is a night stand. One wall is decorated with a large design and another wall has three large windows.

There is a chair and a table.

- There is a chair and a circular table in the middle of a floral print room.
- a corner widow room with a a table and chair sitting to the east side.
- There's a dresser in the corner of the room, and a yellow table with a brown wooden chair.

There is a table and there are four chairs. There are four plates and there are four sandwiches.

- dinning room with four plates, four chairs, and four sandwiches
- dark room with two small windows. A rectangular table seating four is in the middle of the room with plates set. There is a set of two gray double doors on another wall.
- i see a rectangular table in the center of the room. There are 4 chairs around the table and 4 plates on the table

Figure 3: Scenes created by participants from seed description sentences (**top**). Additional descriptions provided by other participants from the created scene (**bottom**). Our dataset contains around 19 scenes per seed sentence, for a total of 1129 scenes. Scenes exhibit variation in the specific objects chosen and their placement. Each scene is described by 3 or 4 other people, for a total of 4358 descriptions.

3.1 Text to Scene Systems

Pioneering work on the SHRDLU system (Winograd, 1972) demonstrated linguistic manipulation of objects in 3D scenes. However, the discourse domain was restricted to a micro-world with simple geometric shapes to simplify parsing and grounding of natural language input. More recently, prototype text to 3D scene generation systems have been built for broader domains, most notably the WordsEye system (Coyne and Sproat, 2001) and later work by Seversky and Yin (2006). Chang et al. (2014) showed it is possible to learn spatial priors for objects and relations directly from 3D scene data.

These systems use manually defined mappings between language and their representation of the physical world. This prevents generalization to more complex object descriptions, variations in word choice and spelling, and other languages. It also forces users to use unnatural language to express their intent (e.g., *the table is two feet to the south of the window*).

We propose reducing reliance on manual lexicons by learning to map descriptions to objects from a corpus of 3D scenes and associated textual descriptions. While we find that lexical knowledge alone is not sufficient to generate high-quality scenes, a learned approach to lexical grounding can be used in combination with a rule-based system for handling compositional knowledge, resulting in better scenes than either component alone.

3.2 Related Tasks

Prior work has generated sentences that describe 2D images (Farhadi et al., 2010; Kulkarni et al., 2011; Karpathy et al., 2014) and referring expressions for specific objects in images (FitzGerald et al., 2013; Kazemzadeh et al., 2014). However, generating scenes is currently out of reach for purely image-based approaches. 3D scene representations serve as an intermediate level of structure between raw image pixels and simpler microcosms (e.g., grid and block worlds). This level of structure is amenable to the generation task but still realistic enough to present a variety of challenges associated with natural scenes.

A related line of work focuses on grounding referring expressions to referents in 3D worlds with simple colored geometric shapes (Gorniak and Roy, 2004; Gorniak and Roy, 2005). More recent work grounds text to object attributes such as color and shape in images (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013). Golland et al. (2010) ground spatial relationship language in 3D scenes (e.g., *to the left of*, *behind*) by learning from pairwise object relations provided by crowdworkers. In contrast, we ground general descriptions to a wide variety of possible objects. The objects in our scenes represent a broader space of possible referents than the first two lines of work. Unlike the latter work, our descriptions are provided as unrestricted free-form text, rather than filling in specific templates of object references and fixed spatial relationships.

4 Dataset

We introduce a new dataset of 1128 scenes and 4284 free-form natural language descriptions of these scenes.[1] To create this training set, we used a simple online scene design interface that allows users to assemble scenes using available 3D models of common household objects (each model is annotated with a category label and has a unique ID). We used a set of 60 seed sentences describing simple configurations of interior scenes as prompts and asked workers on the Amazon Mechanical Turk crowdsourcing platform to create scenes corresponding to these seed descriptions. To obtain more varied descriptions for each scene, we asked other workers to describe each scene. Figure 3 shows examples of seed description sentences, 3D scenes created by people given those descriptions, and new descriptions provided by others viewing the created scenes.

We manually examined a random subset of the descriptions (approximately 10%) to eliminate spam and unacceptably poor descriptions. When we identified an unacceptable description, we also examined all other descriptions by the same worker, as most poor descriptions came from a small number of workers. From our sample, we estimate that less than 3% of descriptions were spam or unacceptably incoherent. To reflect natural use, we retained minor typographical and grammatical errors.

Despite the small set of seed sentences, the Turker-provided scenes exhibit much variety in the specific objects used and their placements within the scene. Over 600 distinct 3D models appear in at least one scene, and more than 40% of non-room objects are rotated from their default orientation, despite the fact that this requires an extra manipulation in the scene-building interface. The descriptions collected for these scenes are similarly diverse and usually differ substantially in length and content from the seed sentences.[2]

5 Model

To create a model for generating scene templates from text, we train a classifier to learn lexical groundings. We then combine our learned lexical groundings with a rule-based scene generation model. The learned groundings allow us to select better models, while the rule-based model offers simple compositionality for handling coreference and relationships between objects.

5.1 Learning lexical groundings

To learn lexical mappings from examples, we train a classifier on a related grounding task and extract the weights of lexical features for use in scene generation. This classifier learns from a "discrimination" version of our scene dataset, in which the scene in each scene–description pair is hidden among four other distractor scenes sampled uniformly at random. The training objective is to maximize the L_2-regularized log likelihood of this scene discrimination dataset under a one-vs.-all logistic regression model, using each true scene and each distractor scene as one example (with *true*/*distractor* as the output label).

The learned model uses binary-valued features indicating the co-occurrence of a unigram or bigram and an object category or model ID. For example, features extracted from the scene-description pair shown in Figure 2 would include the tuples (*desk*, `modelId:132`) and (*the notepad*, `category:notepad`).

To evaluate our learned model's performance at discriminating scenes, independently of its use in scene generation, we split our scene and description corpus (augmented with distractor scenes) randomly into train, development, and test portions 70%-15%-15% by scene. Using only model ID features, the classifier achieves a discrimination accuracy of 0.715 on the test set; adding features that use object categories as well as model IDs improves accuracy to 0.833.

5.2 Rule-based Model

We use the rule-based parsing component described in Chang et al. (2014). This system incorporates knowledge that is important for scene generation and not addressed by our learned model (e.g., spatial relationships and coreference). In Section 5.3, we describe how we use our learned model to augment this model.

This rule-based approach is a three-stage process using established NLP systems: 1) The input text is split into multiple sentences and parsed using the Stanford CoreNLP pipeline (Manning et

[1] Available at `http://nlp.stanford.edu/data/text2scene.shtml`.

[2] Mean 26.2 words, SD 17.4; versus mean 16.6, SD 7.2 for the seed sentences. If one considers seed sentences to be the "reference," the macro-averaged BLEU score (Papineni et al., 2002) of the Turker descriptions is 12.0.

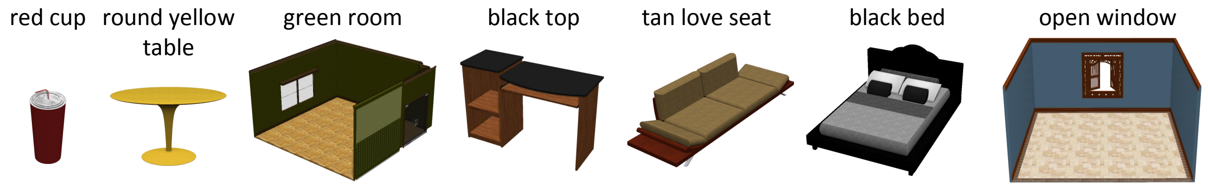


Figure 4: Some examples extracted from the top 20 highest-weight features in our learned model: lexical terms from the descriptions in our scene corpus are grounded to 3D models within the scene corpus.

al., 2014). Head words of noun phrases are identified as candidate object categories, filtered using WordNet (Miller, 1995) to only include physical objects. 2) References to the same object are collapsed using the Stanford coreference system. 3) Properties are attached to each object by extracting other adjectives and nouns in the noun phrase. These properties are later used to query the 3D model database.

We use the same model database as Chang et al. (2014) and also extract spatial relations between objects using the same set of dependency patterns.

5.3 Combined Model

The rule-based parsing model is limited in its ability to choose appropriate 3D models. We integrate our learned lexical groundings with this model to build an improved scene generation system.

Identifying object categories Using the rule-based model, we extract all noun phrases as potential objects. For each noun phrase p, we extract features $\{\phi_i\}$ and compute the score of a category c being described by the noun phrase as the sum of the feature weights from the learned model in Section 5.1:

$$\text{Score}(c \mid p) = \sum_{\phi_i \in \phi(p)} \theta_{(i,c)},$$

where $\theta_{(i,c)}$ is the weight for associating feature ϕ_i with category c. From categories with a score higher than $T_c = 0.5$, we select the best-scoring category as the representative for the noun phrase. If no category's score exceeds T_c, we use the head of the noun phrase for the object category.

3D model selection For each object mention detected in the description, we use the feature weights from the learned model to select a specific object to add to the scene. After using dependency rules to extract spatial relationships and descriptive terms associated with the object, we compute the score of a 3D model m given the category c and a set of descriptive terms d using a similar sum of feature weights. As the rule-based system may not accurately identify the correct set of terms d, we augment the score with a sum of feature weights over the entire input description x:

$$m = \operatorname*{arg\,max}_{m \in \{c\}} \lambda_d \sum_{\phi_i \in \phi(d)} \theta_{(i,m)} + \lambda_x \sum_{\phi_i \in \phi(x)} \theta_{(i,m)}$$

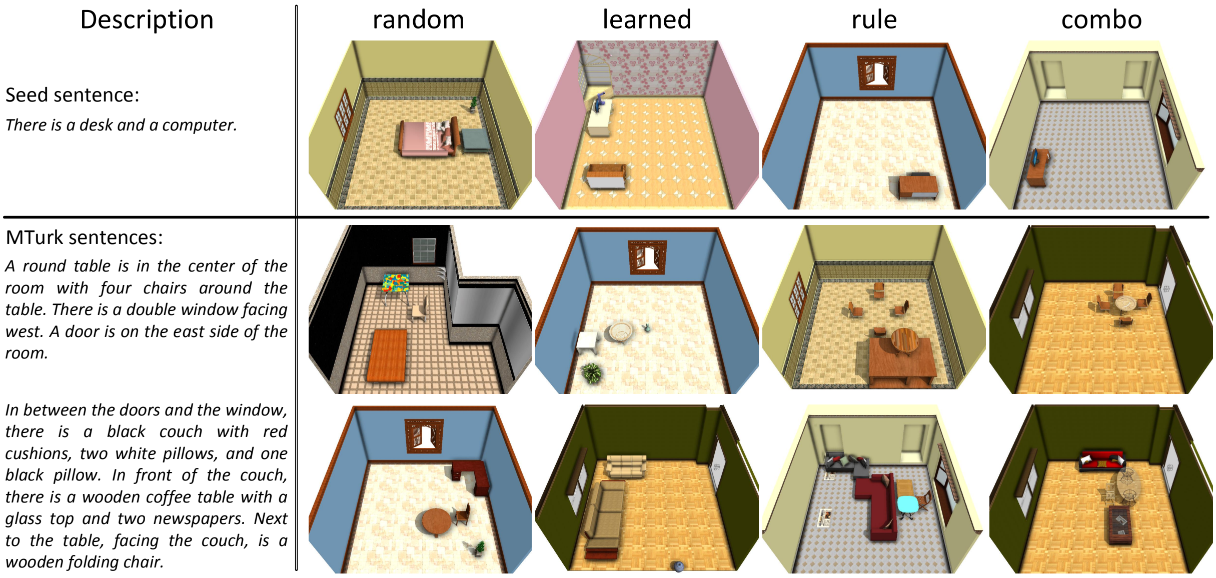
For the results shown here, $\lambda_d = 0.75$ and $\lambda_x = 0.25$. We select the best-scoring 3D model with positive score. If no model has positive score, we assume the object mention was spurious and omit the object.

text	category	text	category
chair	Chair	round	RoundTable
lamp	Lamp	laptop	Laptop
couch	Couch	fruit	Bowl
vase	Vase	round table	RoundTable
sofa	Couch	laptop	Computer
bed	Bed	bookshelf	Bookcase

Table 1: Top groundings of lexical terms in our dataset to categories of 3D models in the scenes.

6 Learned lexical groundings

By extracting high-weight features from our learned model, we can visualize specific models to which lexical terms are grounded (see Figure 4). These features correspond to high frequency text–3D model pairs within the scene corpus. Table 1 shows some of the top learned lexical groundings to model database categories. We are able to recover many simple identity mappings without using lexical similarity features, and we capture several lexical variants (e.g., *sofa* for Couch). A few erroneous mappings reflect common co-occurrences; for example, *fruit* is mapped to Bowl due to fruit typically being observed in bowls in our dataset.



Seed sentence:

There is a desk and a computer.

MTurk sentences:

A round table is in the center of the room with four chairs around the table. There is a double window facing west. A door is on the east side of the room.

In between the doors and the window, there is a black couch with red cushions, two white pillows, and one black pillow. In front of the couch, there is a wooden coffee table with a glass top and two newspapers. Next to the table, facing the couch, is a wooden folding chair.

Figure 5: Qualitative comparison of generated scenes for three input descriptions (one *Seed* and two *MTurk*), using the four different methods: *random*, *learned*, *rule*, *combo*.

7 Experimental Results

We conduct a human judgment experiment to compare the quality of generated scenes using the approaches we presented and baseline methods. To evaluate whether lexical grounding improves scene generation, we need a method to arrange the chosen models into 3D scenes. Since 3D scene layout is not a focus of our work, we use an approach based on prior work in 3D scene synthesis and text to scene generation (Fisher et al., 2012; Chang et al., 2014), simplified by using sampling rather than a hill climbing strategy.

Conditions We compare five conditions: {*random, learned, rule, combo, human*}. The *random* condition represents a baseline which synthesizes a scene with randomly-selected models, while *human* represents scenes created by people. The *learned* condition takes our learned lexical groundings, picks the four[3] most likely objects, and generates a scene based on them. The *rule* and *combo* conditions use scenes generated by the rule-based approach and the combined model, respectively.

Descriptions We consider two sets of input descriptions: {*Seeds, MTurk*}. The *Seeds* descriptions are 50 of the initial seed sentences from which workers were asked to create scenes. These seed sentences were simple (e.g., *There is a desk and a chair*, *There is a plate on a table*) and did not have modifiers describing the objects. The *MTurk* descriptions are much more descriptive and exhibit a wider variety in language (including misspellings and ungrammatical constructs). Our hypothesis was that the rule-based system would perform well on the simple *Seeds* descriptions, but it would be insufficient for handling the complexities of the more varied *MTurk* descriptions. For these more natural descriptions, we expected our combination model to perform better. Our experimental results confirm this hypothesis.

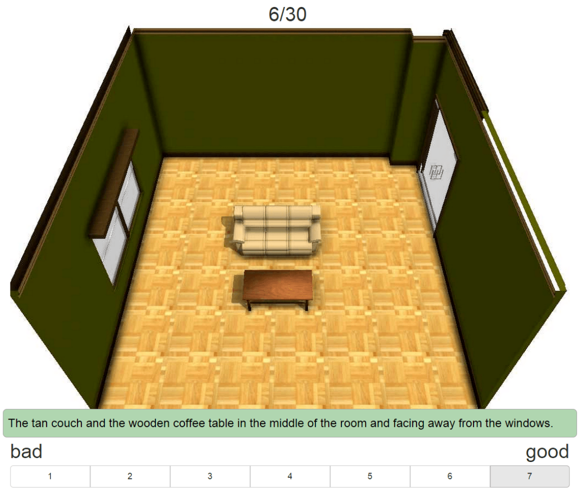
7.1 Qualitative Evaluation

Figure 5 shows a qualitative comparison of 3D scenes generated from example input descriptions using each of the four methods. In the top row, the *rule-based* approach selects a CPU chassis for *computer*, while *combo* and *learned* select a more iconic monitor. In the bottom row, the rule-based approach selects two newspapers and places them on the floor, while the combined approach correctly selects a coffee table with two newspapers on it. The learned model is limited to four objects and does not have a notion of object identity, so it often duplicates objects.

7.2 Human Evaluation

We performed an experiment in which people rated the degree to which scenes match the textual descriptions from which they were generated.

[3] The average number of objects in a scene in our human-built dataset was 3.9.



The tan couch and the wooden coffee table in the middle of the room and facing away from the windows.

Figure 6: Screenshot of the UI for rating scene-description match.

Such ratings are a natural way to evaluate how well our approach can generate scenes from text: in practical use, a person would provide an input description and then judge the suitability of the resulting scenes. For the *MTurk* descriptions, we randomly sampled 100 descriptions from the development split of our dataset.

Procedure During the experiment, each participant was shown 30 pairs of scene descriptions and generated 3D scenes drawn randomly from all five conditions. All participants provided 30 responses each for a total of 5040 scene-description ratings. Participants were asked to rate how well the generated scene matched the input description on a 7-point Likert scale, with 1 indicating a poor match and 7 a very good one (see Figure 6). In a separate task with the same experimental procedure, we asked other participants to rate the overall plausibility of each generated scene without a reference description. This plausibility rating measures whether a method can generate plausible scenes irrespective of the degree to which the input description is matched. We used Amazon Mechanical Turk to recruit 168 participants for rating the match of scenes to descriptions and 63 participants for rating scene plausibility.

Design The experiment followed a within-subjects factorial design. The dependent measure was the Likert rating. Since per-participant and per-scene variance on the rating is not accounted for by a standard ANOVA, we use a mixed effects model which can account for both fixed effects and random effects to determine the statistical significance of our results.[4] We treat the participant and the specific scene as random effects of varying intercept, and the method condition as the fixed effect.

method	Seeds		MTurk	
random	2.03	(1.88 – 2.18)	1.68	(1.57 – 1.79)
learned	3.51	(3.23 – 3.77)	2.61	(2.40 – 2.84)
rule	**5.44**	(5.26 – 5.61)	3.15	(2.91 – 3.40)
combo	5.23	(4.96 – 5.44)	**3.73**	(3.48 – 3.95)
human	6.06	(5.90 – 6.19)	5.87	(5.74 – 6.00)

Table 2: Average scene-description match ratings across sentence types and methods (95% C.I.).

Results There was a significant effect of the method condition on the scene-description match rating: $\chi^2(4, N = 5040) = 1378.2, p < 0.001$. Table 2 summarizes the average scene-description match ratings and 95% confidence intervals for all sentence type–condition pairs. All pairwise differences between ratings were significant under Wilcoxon rank-sum tests with the Bonferroni-Holm correction ($p < 0.05$). The scene plausibility ratings, which were obtained independent of descriptions, indicated that the only significant difference in plausibility was between scenes created by people (*human*) and all the other conditions. We see that for the simple seed sentences both the rule-based and combined model approach the quality of human-created scenes. However, all methods have significantly lower ratings for the more complex *MTurk* sentences. In this more challenging scenario, the combined model is closest to the manually created scenes and significantly outperforms both rule-based and learned models in isolation.

7.3 Error Analysis

Figure 7 shows some common error cases in our system. The top left scene was generated with the rule-based method, the top right with the learned method, and the bottom two with the combined approach. At the top left, there is an erroneous selection of concrete object category (wood logs) for the *four wood chairs* reference in the input description, due to an incorrect head identification. At top right, the learned model identifies the

[4] We used the `lme4` R package and optimized fit with maximum log-likelihood (Baayen et al., 2008). We report significance results using the likelihood-ratio (LR) test.

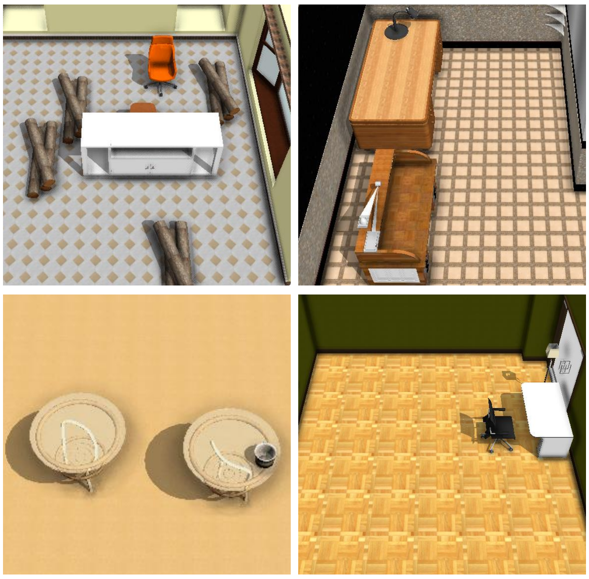


Figure 7: Common scene generation errors. From top left clockwise: *Wood table and four wood chairs in the center of the room*; *There is a black and brown desk with a table lamp and flowers*; *There is a white desk, a black chair, and a lamp in the corner of the room*; *There in the middle is a table, on the table is a cup*.

presence of brown desk and lamp but erroneously picks two desks and two lamps (since we always pick the top four objects). The scene on the bottom right does not obey the expressed spatial constraints (*in the corner of the room*) since our system does not understand the grounding of room corner and that the top right side is not a good fit due to the door. In the bottom left, incorrect coreference resolution results in two tables for *There in the middle is a table, on the table is a cup.*

7.4 Scene Similarity Metric

We introduce an automated metric for scoring scenes given a scene template representation, the *aligned scene template similarity* (ASTS). Given a one-to-one alignment A between the nodes of a scene template and the objects in a scene, let the alignment penalty $J(A)$ be the sum of the number of unaligned nodes in the scene template and the number of unaligned objects in the scene. For the aligned nodes, we compute a similarity score S per node pair (n, n') where $S(n, n') = 1$ if the model ID matches, $S(n, n') = 0.5$ if only the category matches and 0 otherwise.

We define the ASTS of a scene with respect to a scene template to be the maximum alignment score over all such alignments:

method	Human	ASTS
random	1.68	0.08
learned	2.61	0.23
rule	3.15	0.32
combo	**3.73**	**0.44**

Table 3: Average human ratings (out of 7) and aligned scene template similarity scores.

$$\text{ASTS}(s, z) = \max_A \frac{\sum_{(n,n') \in A} S(n, n')}{J(A) + |A|}.$$

With this definition, we compare average ASTS scores for each method against average human ratings (Table 3). We test the correlation of the ASTS metric against human ratings using Pearson's r and Kendall's rank correlation coefficient r_τ. We find that ASTS and human ratings are strongly correlated ($r = 0.70$, $r_\tau = 0.49$, $p < 0.001$). This suggests ASTS scores could be used to train and algorithmically evaluate scene generation systems that map descriptions to scene templates.

8 Future Work

Many error cases in our generated scenes resulted from not interpreting spatial relations. An obvious improvement would be to expand our learned lexical grounding approach to include spatial relations. This would help with spatial language that is not handled by the rule-based system's dependency patterns (e.g., *around*, *between*, *on the east side*). One approach would be to add spatial constraints to the definition of our scene similarity score and use this improved metric in training a semantic parser to generate scene templates.

To choose objects, our current system uses information obtained from language–object co-occurrences and sparse manually-annotated category labels; another promising avenue for achieving better lexical grounding is to propagate category labels using geometric and image features to learn the categories of unlabeled objects. Novel categories can also be extracted from Turker descriptions. These new labels could be used to improve the annotations in our 3D model database, enabling a wider range of object types to be used in scene generation.

Our approach learns object references without using lexical similarity features or a manually-assembled lexicon. Thus, we expect that our method for lexical grounding can facilitate development of text-to-scene systems in other languages. However, additional data collection and experiments are necessary to confirm this and identify challenges specific to other languages.

The necessity of handling omitted information suggests that a model incorporating a more sophisticated theory of pragmatic inference could be beneficial. Another important problem not addressed here is the role of context and discourse in interpreting scene descriptions. For example, several of our collected descriptions include language imagining embodied presence in the scene (e.g., *The wooden table is to your right, if you're entering the room from the doors*).

9 Conclusion

Prior work in 3D scene generation relies on purely rule-based methods to map object references to concrete 3D objects. We introduce a dataset of 3D scenes annotated with natural language descriptions which we believe will be of great interest to the research community. Using this corpus of scenes and descriptions, we present an approach that learns from data how to ground textual descriptions to objects.

To evaluate how our grounding approach impacts generated scene quality, we collect human judgments of generated scenes. In addition, we present a metric for automatically comparing generated scene templates to scenes, and we show that it correlates strongly with human judgments.

We demonstrate that rich lexical grounding can be learned directly from an unaligned corpus of 3D scenes and natural language descriptions, and that our model can successfully ground lexical terms to concrete referents, improving scene generation over baselines adapted from prior work.

MultiGranCNN: An Architecture for General Matching of Text Chunks on Multiple Levels of Granularity

Wenpeng Yin and **Hinrich Schütze**
Center for Information and Language Processing
University of Munich, Germany
wenpeng@cis.uni-muenchen.de

Abstract

We present MultiGranCNN, a general deep learning architecture for matching text chunks. MultiGranCNN supports *multigranular comparability* of representations: shorter sequences in one chunk can be directly compared to longer sequences in the other chunk. MultiGranCNN also contains a *flexible and modularized match feature component* that is easily adaptable to different types of chunk matching. We demonstrate state-of-the-art performance of MultiGranCNN on clause coherence and paraphrase identification tasks.

1 Introduction

Many natural language processing (NLP) tasks can be posed as classifying the relationship between two TEXTCHUNKS (cf. Li et al. (2012), Bordes et al. (2014b)) where a TEXTCHUNK can be a sentence, a clause, a paragraph or any other sequence of words that forms a unit.

Paraphrasing (Figure 1, top) is one task that we address in this paper and that can be formalized as classifying a TEXTCHUNK relation. The two classes correspond to the sentences being (e.g., the pair <$\mathbf{p}$, $\mathbf{q}^+$>) or not being (e.g., the pair <$\mathbf{p}$, $\mathbf{q}^-$>) paraphrases of each other. Another task we look at is clause coherence (Figure 1, bottom). Here the two TEXTCHUNK relation classes correspond to the second clause being (e.g., the pair <$\mathbf{x}$, $\mathbf{y}^+$>) or not being (e.g., the pair <$\mathbf{x}$, $\mathbf{y}^-$>) a discourse-coherent continuation of the first clause. Other tasks that can be formalized as TEXTCHUNK relations are question answering (QA) (is the second chunk an answer to the first?), textual inference (does the first chunk imply the second?) and machine translation (are the two chunks translations of each other?).

$\mathbf{p}$	PDC will also almost certainly *fan the flames of* speculation about *Longhorn's release*.
$\mathbf{q}^+$	PDC will also almost certainly *reignite* speculation about *release dates of Microsoft 's new products*.
$\mathbf{q}^-$	PDC is indifferent to the release of Longhorn.
$\mathbf{x}$	The dollar suffered its worst one-day loss in a month,
$\mathbf{y}^+$	falling to 1.7717 marks ... from 1.7925 marks yesterday.
$\mathbf{y}^-$	up from 112.78 yen in late New York trading yesterday.

Figure 1: Examples for paraphrasing and clause coherence tasks

In this paper, we present MultiGranCNN, a general architecture for TEXTCHUNK relation classification. MultiGranCNN can be applied to a broad range of different TEXTCHUNK relations. This is a challenge because natural language has a complex structure – both sequential and hierarchical – and because this structure is usually not parallel in the two chunks that must be matched, further increasing the difficulty of the task. A successful detection algorithm therefore needs to capture not only the internal structure of TEXTCHUNKS, but also the rich pattern of their interactions.

MultiGranCNN is based on two innovations that are critical for successful TEXTCHUNK relation classification. First, the architecture is designed to ensure *multigranular comparability*. For general matching, we need the ability to match short sequences in one chunk with long sequences in the other chunk. For example, what is expressed by a single word in one chunk ("reignite" in $\mathbf{q}^+$ in the figure) may be expressed by a sequence of several words in its paraphrase ("fan the flames of" in $\mathbf{p}$). To meet this objective, we learn representations for words, phrases and the entire sentence that are all mutually comparable; in particular, these representations all have the same dimensionality and live in the same space.

Most prior work (e.g., Blacoe and Lapata (2012; Hu et al. (2014)) has neglected the need for multigranular comparability and performed matching within fixed levels only, e.g., only words were

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 63–73,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

matched with words or only sentences with sentences. For a general solution to the problem of matching, we instead need the ability to match a unit on a lower level of granularity in one chunk with a unit on a higher level of granularity in the other chunk. Unlike (Socher et al., 2011), our model does not rely on parsing and it can more exhaustively search the hypothesis space of possible matchings, including matchings that correspond to conflicting segmentations of the input chunks (see Section 5).

Our second contribution is that MultiGranCNN contains a *flexible and modularized match feature component*. This component computes the basic features that measure how well phrases of the two chunks match. We investigate three different *match feature models* that demonstrate that a wide variety of different match feature models can be implemented. The match feature models can be swapped in and out of MultiGranCNN, depending on the characteristics of the task to be solved.

Prior work that has addressed matching tasks has usually focused on a single task like QA (Bordes et al., 2014a; Yu et al., 2014) or paraphrasing (Socher et al., 2011; Madnani et al., 2012; Ji and Eisenstein, 2013). The ARC architectures proposed by Hu et al. (2014) are intended to be more general, but seem to be somewhat limited in their flexibility to model different matching relations; e.g., they do not perform well for paraphrasing.

Different match feature models may also be required by factors other than the characteristics of the task. If the amount of labeled training data is small, then we may prefer a match feature model with few parameters that is robust against overfitting. If there is lots of training data, then a richer match feature model may be the right choice. This motivates the need for an architecture like MultiGranCNN that allows selection of the task-appropriate match feature model from a range of different models and its seamless integration into the architecture.

In remaining parts, Section 2 introduces some related work; Section 3 gives an overview of the proposed MultiGranCNN; Section 4 shows how to learn representations for generalized phrases (g-phrases); Section 5 describes the three matching models: DIRECTSIM, INDIRECTSIM and CONCAT; Section 6 describes the two 2D pooling methods: grid-based pooling and phrase-based pooling; Section 7 describes the match feature CNN; Section 8 summarizes the architecture of MultiGran CNN; and Section 9 presents experiments; finally, Section 10 concludes.

2 Related Work

Paraphrase identification (PI) is a typical task of sentence matching and it has been frequently studied (Qiu et al., 2006; Blacoe and Lapata, 2012; Madnani et al., 2012; Ji and Eisenstein, 2013). Socher et al. (2011) utilized parsing to model the hierarchical structure of sentences and uses unfolding recursive autoencoders to learn representations for single words and phrases acting as non-leaf nodes in the tree. The main difference to MultiGranCNN is that we stack multiple convolution layers to model flexible phrases and learn representations for them, and aim to address more general sentence correspondence. Bach et al. (2014) claimed that elementary discourse units obtained by segmenting sentences play an important role in paraphrasing. Their conclusion also endorses (Socher et al., 2011)'s and our work, for both take interactions between component phrases into account.

QA is another representative sentence matching problem. Yu et al. (2014) modeled sentence representations in a simplified CNN, finally finding the match score by projecting question and answer candidates into the same space. Other relevant QA work includes (Bordes et al., 2014c; Bordes et al., 2014a; Yang et al., 2014; Iyyer et al., 2014)

For more general matching, Chopra et al. (2005) and Liu (2013) used a Siamese architecture of shared-weight neural networks (NNs) to model two objects simultaneously, matching their representations and then learning a specific type of sentence relation. We adopt parts of their architecture, but we model phrase representations as well as sentence representations.

Li and Xu (2012) gave a comprehensive introduction to query-document matching and argued that query and document match at different levels: term, phrase, word sense, topic, structure etc. This also applies to sentence matching.

Lu and Li (2013) addressed matching of short texts. Interactions between the two texts were obtained via LDA (Blei et al., 2003) and were then the basis for computing a matching score. Compared to MultiGranCNN, drawbacks of this approach are that LDA parameters are not optimized for the specific task and that the interactions are formed on the level of single words only.

Gao et al. (2014) modeled interestingness between two documents with deep NNs. They mapped source-target document pairs to feature vectors in a latent space in such a way that the distance between the source document and its corresponding interesting target in that space was minimized. Interestingness is more like topic relevance, based mainly on the aggregated meaning of keywords, as opposed to more structural relationships as is the case for paraphrasing and clause coherence.

We briefly discussed (Hu et al., 2014)'s ARC in Section 1. MultiGranCNN is partially inspired by ARC, but introduces multigranular comparability (thus enabling crosslevel matching) and supports a wider range of match feature models.

Our unsupervised learning component (Section 4, last paragraph) resembles word2vec CBOW (Mikolov et al., 2013), but learns representations of TEXTCHUNKS as well as words. It also resembles PV-DM (Le and Mikolov, 2014), but our TEXTCHUNK representation is derived using a *hierarchical* architecture based on *convolution and pooling*.

3 Overview of MultiGranCNN

We use convolution-plus-pooling in two different components of MultiGranCNN. The first component, the *generalized phrase CNN* (gpCNN), will be introduced in Section 4. This component learns representations for *generalized phrases* (g-phrases) where a generalized phrase is a general term for subsequences of all granularities: words, short phrases, long phrases and the sentence itself. The gpCNN architecture has L layers of convolution, corresponding (for $L = 2$) to words, short phrases, long phrases and the sentence. We test different values of L in our experiments. We train gpCNN on large data in an unsupervised manner and then fine-tune it on labeled training data.

Using a *Siamese configuration*, two copies of gpCNN, one for each of the two input TEXTCHUNKS, are the input to the *match feature model*, presented in Section 5. This model produces $s_1 \times s_2$ matching features, one for each pair of g-phrases in the two chunks, where s_1, s_2 are the number of g-phrases in the two chunks, respectively.

The $s_1 \times s_2$ match feature matrix is first reduced to a fixed size by *dynamic 2D pooling*. The resulting fixed size matrix is then the input to the second convolution-plus-pooling component, the *match feature CNN* (mfCNN) whose output is fed to a *multilayer perceptron* (MLP) that produces the final match score. Section 6 will give details.

We use convolution-plus-pooling for both word sequences and match features because we want to compute increasingly abstract features at multiple levels of granularity. To ensure that g-phrases are mutually comparable when computing the $s_1 \times s_2$ match feature matrix, we impose the constraint that *all g-phrase representations live in the same space and have the same dimensionality*.

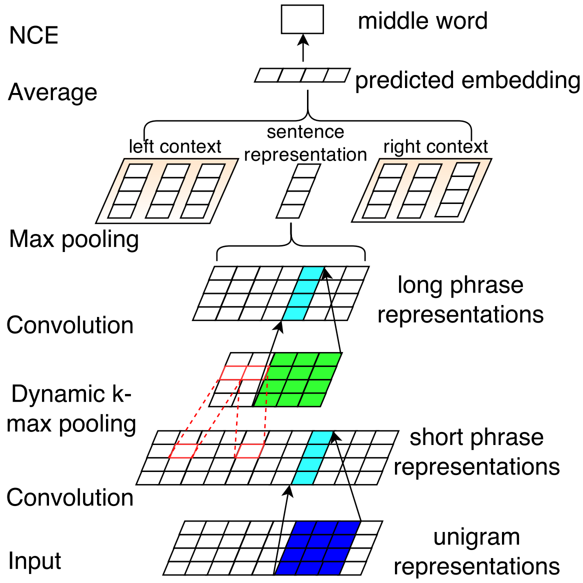

Figure 2: gpCNN: learning g-phrase representations. This figure only shows two convolution layers (i.e., $L = 2$) for saving space.

4 gpCNN: Learning Representations for g-Phrases

We use several stacked *blocks*, i.e., convolution-plus-pooling layers, to extract increasingly abstract features of the TEXTCHUNK. The input to the first block are the words of the TEXTCHUNK, represented by CW (Collobert and Weston, 2008) embeddings. Given a TEXTCHUNK of length $|S|$, let vector $\mathbf{c}_i \in \mathbb{R}^{wd}$ be the concatenated embeddings of words $v_{i-w+1}, \dots, v_i$ where $w = 5$ is the filter width, $d = 50$ is the dimensionality of CW embeddings and $0 < i < |S| + w$. Embeddings for words v_i, $i < 1$ and $i > |S|$, are set to zero. We then generate the representation $\mathbf{p}_i \in \mathbb{R}^d$ of the g-phrase $v_{i-w+1}, \dots, v_i$ using the convolution matrix $\mathbf{W}_l \in \mathbb{R}^{d\times wd}$:

$$\mathbf{p}_i = \tanh(\mathbf{W}_l\mathbf{c}_i + \mathbf{b}_l) \qquad (1)$$

where block index $l = 1$, bias $\mathbf{b}_l \in \mathbb{R}^d$. We use *wide convolution* (i.e., we apply the convolution matrix $\mathbf{W}_l$ to words v_i, $i < 1$ and $i > |S|$) because this makes sure that each word v_i, $1 \leq i \leq |S|$, can be detected by all weights of $\mathbf{W}_l$ – as opposed to only the rightmost (resp. leftmost) weights for initial (resp. final) words in narrow convolution.

The configuration of convolution layers in following blocks ($l > 1$) is exactly the same except that the input vectors $\mathbf{c}_i$ are not words, but the output of pooling from the previous layer of convolution – as we will explain presently. The configuration is the same (e.g., all $\mathbf{W}_l \in \mathbb{R}^{d\times wd}$) because, by design, all g-phrase representations have the same dimensionality d. This also ensures that each g-phrase representation can be directly compared with each other g-phrase representation.

We use *dynamic k-max pooling* to extract the k_l top values from each dimension after convolution in the l^{th} block and the k_L top values in the final block. We set

$$k_l = \max(\alpha, \lceil \frac{L-l}{L}|S|\rceil) \qquad (2)$$

where $l = 1, \cdots, L$ is the block index, and $\alpha = 4$ is a constant (cf. Kalchbrenner et al. (2014)) that makes sure a reasonable minimum number of values is passed on to the next layer. We set $k_L = 1$ (not 4, cf. Kalchbrenner et al. (2014)) because our design dictates that all g-phrase representations, including the representation of the TEXTCHUNK itself, have the same dimensionality. Example: for $L = 4, |S| = 20$, the k_i are $[15, 10, 5, 1]$.

Dynamic k-max pooling keeps the most important features and allows us to stack multiple blocks to extract hiearchical features: units on consecutive layers correspond to larger and larger parts of the TEXTCHUNK thanks to the subset selection property of pooling.

For many tasks, labeled data for training gpCNN is limited. We therefore employ *unsupervised training* to initialize gpCNN as shown in Figure 2. Similar to CBOW (Mikolov et al., 2013), we predict a sampled middle word v_i from the average of seven vectors: the TEXTCHUNK representation (the final output of gpCNN) and the three words to the left and to the right of v_i. We use noise-contrastive estimation (Mnih and Teh, 2012) for training: 10 noise words are sampled for each true example.

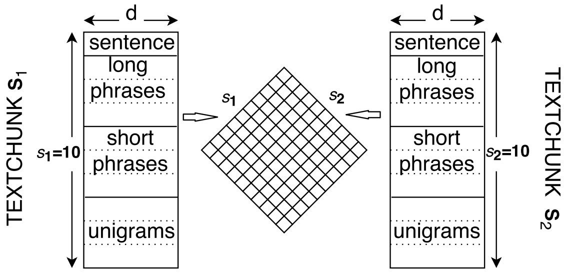

Figure 3: General illustration of match feature model. In this example, both S_1 and S_2 have 10 g-phrases, so the match feature matrix $\hat{\mathbf{F}} \in \mathbb{R}^{s_1\times s_2}$ has size 10×10.

5 Match Feature Models

Let $g_1, \ldots, g_{s_k}$ be an enumeration of the s_k g-phrases of TEXTCHUNK S_k. Let $\mathbf{S}_k \in \mathbb{R}^{s_k\times d}$ be the matrix, constructed by concatenating the four matrices of unigram, short phrase, long phrase and sentence representations shown in Figure 2 that contain the learned representations from Section 4 for these s_k g-phrases; i.e., row $\mathbf{S}_{ki}$ is the learned representation of g_i.

The basic design of a match feature model is that we produce an $s_1 \times s_2$ matrix $\hat{\mathbf{F}}$ for a pair of TEXTCHUNKS S_1 and S_2, shown in Figure 3. $\hat{\mathbf{F}}_{i,j}$ is a score that assesses the relationship between g-phrase g_i of S_1 and g-phrase g_j of S_2 *with respect to the* TEXTCHUNK *relation of interest* (paraphrasing, clause coherence etc). This score $\hat{\mathbf{F}}_{i,j}$ is computed based on the vector representations $\mathbf{S}_{1i}$ and $\mathbf{S}_{2j}$ of the two g-phrases.[1]

We experiment with three different feature models to compute the match score $\hat{\mathbf{F}}_{i,j}$ because we would like our architecture to address a wide variety of different TEXTCHUNK relations. We can model a TEXTCHUNK relation like paraphrasing as "for each meaning element in one sentence, there must be a similar meaning element in the other sentence"; thus, a good candidate for the match score $\hat{\mathbf{F}}_{i,j}$ is simply vector similarity. In contrast, similarity is a less promising match score for clause coherence; for clause coherence, we want a score that models how good a continuation one g-phrase is for the other. These considerations motivate us to define three different match feature models that we will introduce now.

The first match feature model is DIRECTSIM.

[1] In response to a reviewer question, recall that s_i is the total number of g-phrases of S_i, so there is only one $s_1 \times s_2$ matrix, not several on different levels of granularity.

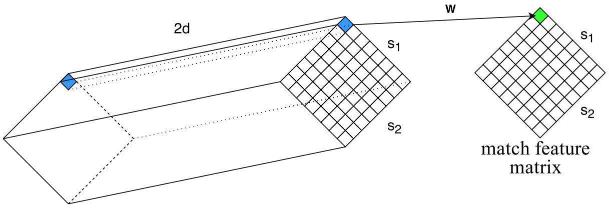

Figure 4: CONCAT match feature model

This model computes the match score of two g-phrases as their similarity using a radial basis function kernel:

$$\hat{\mathbf{F}}_{i,j} = \exp(\frac{-||\mathbf{S}_{1i} - \mathbf{S}_{2j}||^2}{2\beta}) \qquad (3)$$

where we set $\beta = 2$ (cf. Wu et al. (2013)). DIRECTSIM is an appropriate feature model for TEXTCHUNK relations like paraphrasing because in that case direct similarity features are helpful in assessing meaning equivalence.

The second match feature model is INDIRECTSIM. Instead of computing the similarity directly as we do for DIRECTSIM, we first transform the representation of the g-phrase in one TEXTCHUNK using a transformation matrix $\mathbf{M} \in \mathbb{R}^{d \times d}$, then compute the match score by inner product and sigmoid activation:

$$\hat{\mathbf{F}}_{i,j} = \sigma(\mathbf{S}_{1i}\mathbf{M}\mathbf{S}_{2j}^{\mathrm{T}} + b), \qquad (4)$$

Our motivation is that for a TEXTCHUNK relation like clause coherence, the two TEXTCHUNKS need not have any direct similarity. However, if we map the representations of TEXTCHUNK S_1 into an appropriate space then we can hope that similarity between these transformed representations of S_1 and the representations of TEXTCHUNK S_2 do yield useful features. We will see that this hope is borne out by our experiments.

The third match feature model is CONCAT. This is a general model that can learn any weighted combination of the values of the two vectors:

$$\hat{\mathbf{F}}_{i,j} = \sigma(\mathbf{w}^{\mathrm{T}}\mathbf{e}_{i,j} + b) \qquad (5)$$

where $\mathbf{e}_{i,j} \in \mathbb{R}^{2d}$ is the concatenation of $\mathbf{S}_{1i}$ and $\mathbf{S}_{2j}$. We can learn different combination weights $\mathbf{w}$ to solve different types of TEXTCHUNK matching.

We call this match feature model CONCAT because we implement it by concatenating g-phrase vectors to form a tensor as shown in Figure 4.

The match feature models implement multi-granular comparability: they match all units in one TEXTCHUNK with all units in the other TEXTCHUNK. This is necessary because a general solution to matching must match a low-level unit like "reignite" to a higher-level unit like "fan the flames of" (Figure 1). Unlike (Socher et al., 2011), our model does not rely on parsing; therefore, it can more exhaustively search the hypothesis space of possible matchings: mfCNN covers a wide variety of different, possibly overlapping units, not just those of a single parse tree.

6 Dynamic 2D Pooling

The match feature models generate an $s_1 \times s_2$ matrix. Since it has variable size, we apply two different dynamic 2D pooling methods, *grid-based pooling* and *phrase-focused pooling*, to transform it to a fixed size matrix.

6.1 Grid-based pooling

We need to map $\hat{\mathbf{F}} \in \mathbb{R}^{s_1 \times s_2}$ into a matrix $\mathbf{F}$ of fixed size $s^* \times s^*$ where s^* is a parameter. Grid-based pooling divides $\hat{\mathbf{F}}$ into $s^* \times s^*$ nonoverlapping *(dynamic) pools* and copies the maximum value in each dynamic pool to $\mathbf{F}$. This method is similar to (Socher et al., 2011), but preserves locality better.

$\hat{\mathbf{F}}$ can be split into equal regions only if both s_1 and s_2 are divisible by s^*. Otherwise, for $s_1 > s^*$ and if $s_1 \bmod s^* = b$, the dynamic pools in the first $s^* - b$ splits each have $\left\lfloor \frac{s_1}{s^*} \right\rfloor$ rows while the remaining b splits each have $\left\lfloor \frac{s_1}{s^*} \right\rfloor + 1$ rows. In Figure 5, a $s_1 \times s_2 = 4 \times 5$ matrix (left) is split into $s^* \times s^* = 3 \times 3$ dynamic pools (middle): each row is split into [1, 1, 2] and each column is split into [1, 2, 2].

If $s_1 < s^*$, we first repeat all rows in batch style with size s_1 until no fewer than s^* rows remain. Then the first s^* rows are kept and split into s^* dynamic pools. The same principle applies to the partitioning of columns. In Figure 5 (right), the areas with dashed lines and dotted lines are repeated parts for rows and columns, respectively; each cell is its own dynamic pool.

6.2 Phrase-focused pooling

In the match feature matrix $\hat{\mathbf{F}} \in \mathbb{R}^{s_1 \times s_2}$, row i (resp. column j) contains all feature values for g-phrase g_i of S_1 (resp. g_j of S_2). Phrase-focused pooling attempts to pick the largest match features

for a g-phrase g on the assumption that they are the best basis for assessing the relation of g with other g-phrases. To implement this, we sort the values of each row i (resp. each column j) in decreasing order giving us a matrix $\hat{\mathbf{F}}_r \in \mathbb{R}^{s_1 \times s_2}$ with sorted rows (resp. $\hat{\mathbf{F}}_c \in \mathbb{R}^{s_1 \times s_2}$ with sorted columns). Then we concatenate the columns of $\hat{\mathbf{F}}_r$ (resp. the rows of $\hat{\mathbf{F}}_c$) resulting in list $F_r = \{f^r_1, \ldots, f^r_{s_1 s_2}\}$ (resp. $F_c = \{f^c_1, \ldots, f^c_{s_1 s_2}\}$) where each f^r (f^c) is an element of $\hat{\mathbf{F}}_r$ ($\hat{\mathbf{F}}_c$). These two lists are merged into a list F by interleaving them so that members from F_r and F_c alternate. F is then used to fill the rows of $\mathbf{F}$ from top to bottom with each row being filled from left to right.[2]

7 mfCNN: Match feature CNN

The output of dynamic 2D pooling is further processed by the match feature CNN (mfCNN) as depicted in Figure 6. mfCNN extracts increasingly abstract interaction features from lower-level interaction features, using several layers of 2D wide convolution and fixed-size 2D pooling.

We call the combination of a 2D wide convolution layer and a fixed-size 2D pooling layer a *block*, denoted by index b ($b = 1, 2 \ldots$). In general, let tensor $\mathbf{T}^b \in \mathbb{R}^{c_b \times s_b \times s_b}$ denote the feature maps in block b; block b has c_b feature maps, each of size $s_b \times s_b$ ($\mathbf{T}^1 = \mathbf{F} \in \mathbb{R}^{1 \times s^* \times s^*}$). Let $\mathbf{W}^b \in \mathbb{R}^{c_{b+1} \times c_b \times f_b \times f_b}$ be the filter weights of 2D wide convolution in block b, $f_b \times f_b$ is then the size of sliding convolution regions. Then the convolution is performed as element-wise multiplication between $\mathbf{W}^b$ and $\mathbf{T}^b$ as follows:

$$\hat{\mathbf{T}}^{b+1}_{m,i-1,j-1} = \sigma\Big(\sum \mathbf{W}^b_{m,:,:,:} \mathbf{T}^b_{:,i-f_b:i,j-f_b:j} + \mathbf{b}^b_m\Big) \qquad (6)$$

where $0 \le m < c_{b+1}$, $1 \le i, j < s_b + f_b$, $\mathbf{b}^b \in \mathbb{R}^{c_{b+1}}$.

Subsequently, fixed-size 2D pooling selects dominant features from $k_b \times k_b$ non-overlapping windows of $\hat{\mathbf{T}}^{b+1}$ to form a tensor as input of block $b + 1$:

$$\mathbf{T}^{b+1}_{m,i,j} = \max(\hat{\mathbf{T}}^{b+1}_{m,ik_b:(i+1)k_b,jk_b:(j+1)k_b}) \qquad (7)$$

where $0 \le i, j < \lfloor \frac{s_b + f_b - 1}{k_b} \rfloor$.

Hu et al. (2014) used narrow convolution which would limit the number of blocks. 2D wide convolution in this work enables to stack multiple blocks of convolution and pooling to extract higher-level interaction features. We will study the influence of the number of blocks on performance below.

For the experiments, we set $s^* = 40$, $c_b = 50$, $f_b = 5$, $k_b = 2$ ($b = 1, 2, \cdots$).

8 MultiGranCNN

We can now describe the overall architecture of MultiGranCNN. First, using a Siamese configuration, two copies of gpCNN, one for each of the two input TEXTCHUNKS, produce g-phrase representations on different levels of abstraction (Figure 2). Then one of the three match feature models (DIRECTSIM, CONCAT or INDIRECTSIM) produces an $s_1 \times s_2$ match feature matrix, each cell of which assesses the match of a pair of g-phrases from the two chunks. This match feature matrix is reduced to a fixed size matrix by dynamic 2D pooling (Section 6). As shown in Figure 6, the resulting fixed size matrix is the input for mfCNN, which extracts interaction features of

[2] If $\hat{\mathbf{F}}$ has fewer cells than $\mathbf{F}$, then we simply repeat the filling procedure to fill all cells.

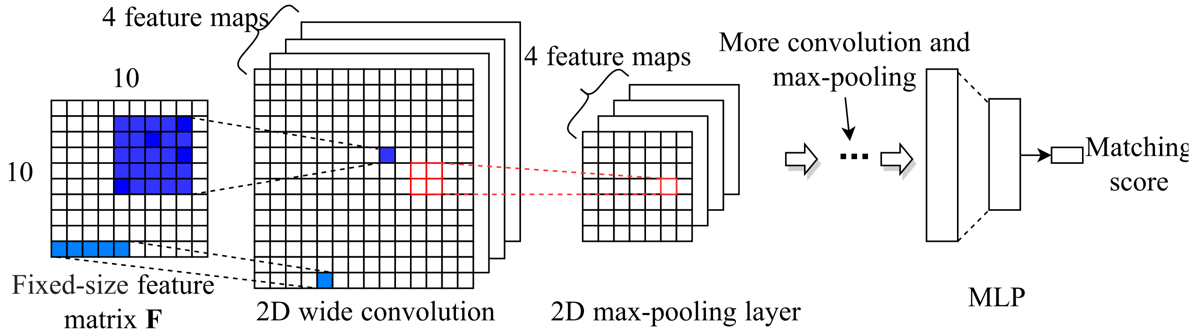

Figure 6: mfCNN & MLP for matching score learning. $s^* = 10$, $f_b = 5$, $k_b = 2$, $c_b = 4$ in this example.

increasing complexity from the basic interaction features computed by the match feature model. Finally, the output of the last block of mfCNN is the input to an MLP that computes the match score.

MultiGranCNN bears resemblance to previous work on clause and sentence matching (e.g., Hu et al. (2014), Socher et al. (2011)), but it is more general and more flexible. It learns representations of g-phrases, i.e., representations of parts of the TEXTCHUNK at multiple granularities, not just for a single level such as the sentence as ARC-I does (Hu et al., 2014). MultiGranCNN explores the space of interactions between the two chunks more exhaustively by considering interactions between every unit in one chunk with every other unit in the other chunk, at all levels of granularity. Finally, MultiGranCNN supports a number of different match feature models; the corresponding module can be instantiated in a way that ensures that match features are best suited to support accurate decisions on the TEXTCHUNK relation task that needs to be addressed.

9 Experimental Setup and Results

9.1 Training

Suppose the triple $(\mathbf{x}, \mathbf{y}^+, \mathbf{y}^-)$ is given and $\mathbf{x}$ matches $\mathbf{y}^+$ better than $\mathbf{y}^-$. Then our objective is the minimization of the following ranking loss:

$$l(\mathbf{x}, \mathbf{y}^+, \mathbf{y}^-) = \max(0, 1 + s(\mathbf{x}, \mathbf{y}^-) - s(\mathbf{x}, \mathbf{y}^+))$$

where $s(\mathbf{x}, \mathbf{y})$ is the predicted match score for $(\mathbf{x}, \mathbf{y})$. We use stochastic gradient descent with Adagrad (Duchi et al., 2011), L_2 regularization and minibatch training.

We set initial learning rate to 0.05, batch size to 70, L_2 weight to $5 \cdot 10^{-4}$.

Recall that we employ unsupervised pretraining of representations for g-phrases. We can either *freeze* these representations in subsequent supervised training; or we can *fine-tune* them. We study the performance of both regimes.

9.2 Clause Coherence Task

As introduced by Hu et al. (2014), the *clause coherence* task determines for a pair $(\mathbf{x}, \mathbf{y})$ of clauses if the sentence "**xy**" is a coherent sentence. We construct a clause coherence dataset as follows (the set used by Hu et al. (2014) is not yet available). We consider all sentences from English Gigaword (Parker et al., 2009) that consist of two comma-separated clauses $\mathbf{x}$ and $\mathbf{y}$, with each clause having between five and 30 words. For each $\mathbf{y}$, we choose four clauses $\mathbf{y}' \ldots \mathbf{y}''''$ randomly from the 1000 second clauses that have the highest similarity to $\mathbf{y}$, where similarity is cosine similarity of TF-IDF vectors of the clauses; restricting the alternatives to similar clauses ensures that the task is hard. The clause coherence task then is to select $\mathbf{y}$ from the set $\mathbf{y}, \mathbf{y}', \ldots, \mathbf{y}''''$ as the correct continuation of $\mathbf{x}$. We create 21 million examples, each consisting of a first clause $\mathbf{x}$ and five second clauses. This set is divided into a training set of 19 million and development and test sets of one million each. An example from the training set is given in Figure 1.

Then, we study the performance variance of different MultiGranCNN setups from three perspectives: a) layers of CNN in both unsupervised (gpCNN) and supervised (mfCNN) training phases; b) different approaches for clause relation feature modeling; c) dynamic pooling methods for generating same-sized feature matrices.

Figure 7 (top table) shows that (Hu et al., 2014)'s parameters are good choices for our setup as well. We get best result when both gpCNN and mfCNN have three blocks of convolution and pooling. This suggests that multiple layers of convolution succeed in extracting high-level features that are beneficial for clause coherence.

Figure 7 (2nd table) shows that INDIRECTSIM and CONCAT have comparable performance and both outperform DIRECTSIM. DIRECTSIM is expected to perform poorly because the contents in the two clauses usually have little or no overlapping meaning. In contrast, we can imagine that INDIRECTSIM first transforms the first clause $\mathbf{x}$ into a counterpart and then matches this counterpart with the second clause $\mathbf{y}$. In CONCAT, each of $s_1 \times s_2$ pairs of g-phrases is concatentated and supervised training can then learn an unrestricted function to assess the importance of this pair for clause coherence (cf. Eq. 5). Again, this is clearly a more promising TEXTCHUNK relation model for clause coherence than one that relies on DIRECTSIM.

Figure 7: Effect on dev acc (clause coherence) of different factors: # convolution blocks, match feature model, freeze vs. fine-tune, pooling method.

Figure 7 (3rd table) demonstrates that fine-tuning g-phrase representations gives better performance than freezing them. Also, grid-based and phrase-focused pooling outperform dynamic pooling (Socher et al., 2011) (4th table). Phrase-focused pooling performs best.

Table 1 compares MultiGranCNN to ARC-I and ARC-II, the architectures proposed by Hu et al. (2014). We also test the five baseline systems from their paper: DeepMatch, WordEmbed, SENMLP, SENNA+MLP, URAE+MLP. For MultiGranCNN, we use the best dev set settings: number of convolution layers in gpCNN and mfCNN is 3; INDIRECTSIM; phrase-focused pooling. Table 1 shows that MultiGranCNN outperforms all other approaches on clause coherence test set.

9.3 Paraphrase Identification Task

We evaluate paraphrase identification (PI) on the PAN corpus (http://bit.ly/mt-para, (Madnani et al., 2012)), consisting of training and test sets of 10,000 and 3000 sentence pairs, respectively. Sentences are about 40 words long on average.

Since PI is a binary classification task, we replace the MLP with a logistic regression layer. As phrase-focused pooling was proven to be optimal, we directly use phrase-focused pooling in PI task without comparison, assuming that the choice of dynamic pooling is task independent.

For parameter selection, we split the PAN training set into a core training set (core) of size 9000 and a development set (dev) of size 1000. We then train models on core and select parameters based on best performance on dev. The best results on dev are obtained for the following parameters: freezing g-phrase representations, DIRECTSIM, two convolution layers in gpCNN, no convolution layers in mfCNN. We use these parameter settings to train a model on the entire training set and report performance in Table 2.

We compare MultiGranCNN to ARC-I/II (Hu et al., 2014), and two previous papers reporting performance on PAN. Madnani et al. (2012) used a combination of three *basic MT metrics* (BLEU, NIST and TER) and five complex MT metrics (TERp, METEOR, BADGER, MAXISIM,

model	acc
Random Guess	20.00

SEPIA), computed on entire sentences. Bach et al. (2014) applied MT metrics to elementary discourse units. We integrate these eight MT metrics from prior work.

method	acc	F_1
ARC-I	61.4	60.3
ARC-II	64.9	63.5
basic MT metrics	88.6	87.8
+ TERp	91.5	91.2
+ METEOR	92.0	91.8
+ Others	92.3	92.1
(Bach et al., 2014)	93.4	93.3
8MT+MultiGranCNN (fine-tune)	94.1	94.0
8MT+MultiGranCNN (freeze)	**94.9**	**94.7**

Table 2: Results on PAN. “8MT” = 8 MT metrics

Table 2 shows that MultiGranCNN in combination with MT metrics obtains state-of-the-art performance on PAN. *Freezing* weights learned in unsupervised training (Figure 2) performs better than *fine-tuning* them; also, Table 3 shows that the best result is achieved if *no convolution* is used in mfCNN. Thus, the best configuration for paraphrase identification is to “forward” fixed-size interaction matrices as input to the logistic regression, without any intermediate convolution layers.

Freezing weights learned in unsupervised training and no convolution layers in mfCNN both protect against overfitting. Complex deep neural networks are in particular danger of overfitting when training sets are small as in the case of PAN (cf. Hu et al. (2014)). In contrast, fine-tuning weights and several convolution layers were the optimal setup for clause coherence. For clause coherence, we have a much larger training set and therefore can successfully train a much larger number of parameters.

Table 3 shows that CONCAT performs badly for PI while DIRECTSIM and INDIRECTSIM perform well. We can conceptualize PI as the task of determining if each meaning element in S_1 has a similar meaning element in S_2. The $s_1 \times s_2$ DIRECTSIM feature model directly models this task and the $s_1 \times s_2$ INDIRECTSIM feature model also models it, but learning a transformation of g-phrase representations before applying similarity. In contrast, CONCAT can learn arbitrary relations between parts of the two sentences, a model that seems to be too unconstrained for PI if insufficient training resources are available.

In contrast, for the clause coherence task, concatentation worked well and DIRECTSIM worked poorly and we provided an explanation based on the specific properties of clause coherence (see discussion of Figure 7). We conclude from these results that it is dependent on the task what the best feature model is for matching two linguistic objects. Interestingly, INDIRECTSIM performs well on both tasks. This suggests that INDIRECTSIM is a general feature model for matching, applicable to tasks with very different properties.

10 Conclusion

In this paper, we present MultiGranCNN, a general deep learning architecture for classifying the relation between two TEXTCHUNKS. MultiGranCNN supports *multigranular comparability* of representations: shorter sequences in one TEXTCHUNK can be directly compared to longer sequences in the other TEXTCHUNK. MultiGranCNN also contains a *flexible and modularized match feature component* that is easily adaptable to different TEXTCHUNK relations. We demonstrated state-of-the-art performance of MultiGranCNN on paraphrase identification and clause coherence tasks.

Abstract

Massive open online courses (MOOCs) are redefining the education system and transcending boundaries posed by traditional courses. With the increase in popularity of online courses, there is a corresponding increase in the need to understand and interpret the communications of the course participants. Identifying topics or *aspects* of conversation and inferring sentiment in online course forum posts can enable instructor interventions to meet the needs of the students, rapidly address course-related issues, and increase student retention. Labeled aspect-sentiment data for MOOCs are expensive to obtain and may not be transferable between courses, suggesting the need for approaches that do not require labeled data. We develop a weakly supervised joint model for aspect-sentiment in online courses, modeling the dependencies between various aspects and sentiment using a recently developed scalable class of statistical relational models called hinge-loss Markov random fields. We validate our models on posts sampled from twelve online courses, each containing an average of 10,000 posts, and demonstrate that jointly modeling aspect with sentiment improves the prediction accuracy for both aspect and sentiment.

1 Introduction

Massive Open Online Courses (MOOCs) have emerged as a powerful medium for imparting education to a wide geographical population. Discussion forums are the primary means of communication between MOOC participants (students, TAs, and instructors). Due to the open nature of these courses, they attract people from all over the world leading to large numbers of participants and hence, large numbers of posts in the discussion forums. In the courses we worked with, we found that over the course of the class there were typically over 10,000 posts.

Within this slew of posts, there are valuable *problem-reporting* posts that identify issues such as broken links, audio-visual glitches, and inaccuracies in the course materials. Automatically identifying these reported problems is important for several reasons: *i*) it is time-consuming for instructors to manually screen through all of the posts due to the highly skewed instructor-to-student ratio in MOOCs, *ii*) promptly addressing issues could help improve student retention, and *iii*) future iterations of the course could benefit from identifying technical and logistical issues currently faced by students. In this paper, we investigate the problem of determining the fine-grained topics of posts (which we refer to as “MOOC aspects”) and the sentiment toward them, which can potentially be used to improve the course.

While aspect-sentiment has been widely studied, the MOOC discussion forum scenario presents a unique set of challenges. Labeled data are expensive to obtain, and posts containing fine-grained aspects occur infrequently in courses and differ across courses, thereby making it expensive to get sufficient coverage of all labels. Few distinct aspects occur per course, and only 5-10% of posts in a course are relevant. Hence, getting labels for fine-grained labels involves mining and annotating posts from a large number of courses. Further, creating and sharing labeled data is difficult as data from online courses is governed by IRB regula-

tions. Privacy restrictions are another reason why unsupervised/weakly-supervised methods can be helpful. Lastly, to design a system capable of identifying all possible MOOC aspects across courses, we need to develop a system that is not fine-tuned to any particular course, but can adapt seamlessly across courses.

To this end, we develop a weakly supervised system for detecting aspect and sentiment in MOOC forum posts and validate its effectiveness on posts sampled from twelve MOOC courses. Our system can be applied to any MOOC discussion forum with no or minimal modifications.

Our contributions in this paper are as follows:

- We show how to encode weak supervision in the form of seed words to extract course-specific features in MOOCs using SeededLDA, a seeded variation of topic modeling (Jagarlamudi et al., 2012).

- Building upon our SeededLDA approach, we develop a joint model for aspects and sentiment using the *hinge-loss Markov random field (HL-MRF)* probabilistic modeling framework. This framework is especially well-suited for this problem because of its ability to combine information from multiple features and jointly reason about aspect and sentiment.

- To validate the effectiveness of our system, we construct a labeled evaluation dataset by sampling posts from twelve MOOC courses, and annotating these posts with fine-grained MOOC aspects and sentiment via *crowdsourcing*. The annotation captures fine-grained aspects of the course such as content, grading, deadlines, audio and video of lectures and sentiment (i.e., *positive, negative, and neutral*) toward the aspect in the post.

- We demonstrate that the proposed HL-MRF model can predict fine-grained aspects and sentiment and outperforms the model based only on SeededLDA.

2 Related Work

To the best of our knowledge, the problem of predicting aspect and sentiment in MOOC forums has not yet been addressed in the literature. We review prior work in related areas here.

Aspect-Sentiment in Online Reviews It is valuable to identify the sentiment of online reviews towards aspects such as hotel cleanliness and cellphone screen brightness, and sentiment analysis at the aspect-level has been studied extensively in this context (Liu and Zhang, 2012). Several of these methods use latent Dirichlet allocation topic models (Blei et al., 2003) and variants of it for detecting aspect and sentiment (Lu et al., 2011; Lin and He, 2009). Liu and Zhang (2012) provide a comprehensive survey of techniques for aspect and sentiment analysis. Here, we discuss works that are closely related to ours.

Titov and McDonald (2008) emphasize the importance of an unsupervised approach for aspect detection. However, the authors also indicate that standard LDA (Blei et al., 2003) methods capture global topics and not necessarily pertinent aspects — a challenge that we address in this work. Brody and Elhadad (2010), Titov and McDonald (2008), and Jo and Oh (2011) apply variations of LDA at the sentence level for online reviews. We find that around 90% of MOOC posts have only one aspect, which makes sentence-level aspect modeling inappropriate for our domain.

Most previous approaches for sentiment rely on manually constructed lexicons of strongly positive and negative words (Fahrni and Klenner, 2008; Brody and Elhadad, 2010). These methods are effective in an online review context, however sentiment in MOOC forum posts is often implicit, and not necessarily indicated by standard lexicons. For example, the post "Where is my certificate? Waiting over a month for it." expresses negative sentiment toward the *certificate* aspect, but does not include any typical negative sentiment words. In our work, we use a data-driven model-based approach to discover domain-specific lexicon information guided by small sets of seed words.

There has also been substantial work on joint models for aspect and sentiment (Kim et al., 2013; Diao et al., 2014; Zhao et al., 2010; Lin et al., 2012), and we adopt such an approach in this paper. Kim et al. (2013) use a hierarchical aspect-sentiment model and evaluate it for online reviews. Mukherjee and Liu (2012) use seed words for discovering aspect-based sentiment topics. Drawing on the ideas of Mukherjee and Liu (2012) and Kim et al. (2013), we propose a statistical relational learning approach that combines the advantages of seed words, aspect hierarchy, and flat

Table 1: Example posts from MOOC forums. Aspect words are highlighted in **bold**.

aspect-sentiment relationships. It is important to note that a broad majority of the previous work on aspect sentiment focuses on the specific challenges of online review data. As discussed in detail above, MOOC forum data have substantially different properties, and our approach is the first to be designed particularly for this domain.

Learning Analytics In another line of research, there is a growing body of work on the analysis of online courses. Regarding MOOC forum data, Stump et al. (2013) propose a framework for taxonomically categorizing forum posts, leveraging manual annotations. We differ from their approach in that we develop an automatic system to predict MOOC forum categories without using labeled training data. Ramesh et al. (2014b) categorize forum posts into three broad categories in order to predict student engagement. Unlike this method, our system is capable of fine-grained categorization and of identifying aspects in MOOCS. Chaturvedi et al. (2014) focus on predicting instructor intervention using lexicon features and thread features. In contrast, our system is capable of predicting fine MOOC aspects and sentiment of discussion forum posts and thus provides a more informed analysis of MOOC posts.

3 Problem Setting and Data

MOOC participants primarily communicate through discussion forums, consisting of posts, which are short pieces of text. Table 1 provides examples of posts in MOOC forums. Posts *1* and *2* report issues and feedback for the course, while post *3* is a social interaction message. Our goal is to distinguish *problem-reporting* posts such as *1* and *2* from *social* posts such as *3*, and to *identify the issues* that are being discussed.

We formalize this task as an *aspect-sentiment* prediction problem (Liu and Zhang, 2012). The issues reported in MOOC forums can be related to the different elements of the course such as *lectures* and *quizzes*, which are referred to as *aspects*. The aspects are selected based on MOOC domain expertise and inspiration from Stump et al. (2013), aiming to cover common concerns that could benefit from intervention. The task is to predict these aspects for each post, along with the *sentiment* polarity toward the aspect, which we code as *positive*, *negative*, or *neutral*. The negative-sentiment posts, along with their aspects, allow us to identify potentially correctable issues in the course. As labels are expensive in this scenario, we formulate the task as a *weakly supervised* prediction problem. In our work, we assume that a post has at most one fine-grained aspect, as we found that this was true for 90% of the posts in our data. This property is due in part to the brevity of forum posts, which are much shorter documents than those considered in other aspect-sentiment scenarios such as product reviews.

COARSE-ASPECT	FINE-ASPECT	Description	# of posts
LECTURE	LECTURE-CONTENT	Content of lectures.	559
	LECTURE-VIDEO	Video of lectures.	215
	LECTURE-SUBTITLES	Subtitles of lecture.	149
	LECTURE-AUDIO	Audio of lecture.	136
	LECTURE-LECTURER	Delivery of instructor.	69
QUIZ	QUIZ-CONTENT	Content in quizzes.	439
	QUIZ-GRADING	Grading of quizzes.	360
	QUIZ-SUBMISSION	Quiz submission.	329
	QUIZ-DEADLINE	Deadline of quizzes.	142
CERTIFICATE		Course certificates.	194
SOCIAL		Social interaction posts.	1187

Table 2: Descriptions of *coarse* and *fine* aspects.

3.1 Aspect Hierarchy

While we do not require labeled data, our approaches allow the analyst to instead relatively easily encode a small amount of domain knowledge by seeding the models with a few words relating to each aspect of interest. Hence, we refer to our approach as *weakly supervised*. Our models can further make use of hierarchical structure between the aspects. The proposed approach is flexible, allowing the aspect seeds and hierarchy to be selected for a given MOOC domain.

For the purposes of this study, we represent the MOOC aspects with a two-level hierarchy. We identify a list of *nine* fine-grained aspects, which are grouped into *four* coarse topics. The *coarse* aspects consist of LECTURE, QUIZ, CERTIFICATE, and SOCIAL topics. Table 2 provides a description of each of the aspects and also gives the number of posts in each aspect category after annotation.

As both LECTURE and QUIZ are key coarse-level aspects in online courses, and more nuanced aspect information for these is important to facilitate instructor interventions, we identify fine-grained aspects for these coarse aspects.

For LECTURE we identify LECTURE-CONTENT, LECTURE-VIDEO, LECTURE-AUDIO, LECTURE-SUBTITLES, and LECTURE-LECTURER as fine aspects. For QUIZ, we identify the fine aspects QUIZ-CONTENT, QUIZ-GRADING, QUIZ-DEADLINES, and QUIZ-SUBMISSION. We use the label SOCIAL to refer to social interaction posts that do not mention a problem-related aspect.

3.2 Dataset

We construct a dataset by sampling posts from MOOC courses to capture the variety of aspects discussed in online courses. We include courses from different disciplines (business, technology, history, and the sciences) to ensure broad coverage of aspects. Although we adopt an approach that does not require labeled data for training, which is important for most practical MOOC scenarios, in order to validate our methods we obtain labels for the sampled posts using *Crowdflower*,[1] an online crowd-sourcing annotation platform. Each post was annotated by at least 3 annotators. Crowdflower calculates *confidence* in labels by computing trust scores for annotators using test questions. Kolhatkar et al. (2013) provide a detailed analysis of Crowdflower trust calculations and the relationship to inter-annotator agreement. We follow their recommendations and retain only labels with *confidence* > 0.5.

4 Aspect-Sentiment Prediction Models

In this section, we develop models and feature-extraction techniques to address the challenges of aspect-sentiment prediction for MOOC forums. We present two weakly-supervised methods—first, using a seeded topic modeling approach (Jagarlamudi et al., 2012) to identify aspects and sentiment. Second, building upon this method, we then introduce a more powerful statistical relational model which reasons over the seeded LDA predictions as well as sentiment side-information to encode hierarchy information and correlations between sentiment and aspect.

4.1 Seeded LDA Model

Topic models (Blei et al., 2003), which identify latent semantic themes from text corpora, have previously been successfully used to discover aspects for sentiment analysis (Diao et al., 2014). By equating the topics, i.e. discrete distributions over words, with aspects and/or sentiment polarities, topic models can recover aspect-sentiment predictions. In the MOOC context we are specifically interested in problems with the courses, rather than general topics which may be identified by a topic model, such as the topics of the course material. To guide the topic model to identify aspects of interest, we use *SeededLDA* (Jagarlamudi et al., 2012), a variant of LDA which allows an analyst to "seed" topics by providing key words that should belong to the topics.

We construct SeededLDA models by providing a set of seed words for each of the coarse and fine aspects in the aspect hierarchy of Table 2. We also seed topics for *positive*, *negative* and *neutral* sentiment polarities. The seed words for coarse topics are provided in Table 3, and fine aspects in Table 4. For the sentiment topics (Table 5), the seed words for the topic *positive* are positive words often found in online courses such as *thank*, *congratulations*, *learn*, and *interest*. Similarly, the seed words for the *negative* topic are negative in the context of online courses, such as *difficult*, *error*, *issue*, *problem*, and *misunderstand*.

Additionally, we also use SeededLDA for isolating some common problems in online courses that are associated with sentiment, such as *difficulty*, *availability*, *correctness*, and course-specific seed words from the syllabus as described in Table 6. Finally, having inferred the SeededLDA model from the data set, for each post p we predict the most likely aspect and the most likely sentiment polarity according to the post's inferred distribution over topics $\theta^{(p)}$.

In our experiments, we tokenize and stem the posts using NLTK toolkit (Loper and Bird, 2002), and use a stop word list tuned to online course discussion forums. The topic model Dirichlet hyperparameters are set to $\alpha = 0.01$, $\beta = 0.01$ in our experiments. For SeededLDA models corresponding to the seed sets in Tables 3, 4, and 5, the number of topics is equal to the number of seeded topics. For SeededLDA models corresponding to the seed words in Tables 6 and 3, we use 10 topics, allowing for some *unseeded* topics that are not captured by the seed words.

4.2 Hinge-loss Markov Random Fields

The approach described in the previous section automatically identifies user-seeded aspects and sentiment, but it does not make further use of struc-

Table 6: Seed words for sentiment specific to online courses

ture or dependencies between these values, or any additional side-information. To address this, we propose a more powerful approach using hinge-loss Markov random fields (HL-MRFs), a scalable class of continuous, conditional graphical models (Bach et al., 2013). HL-MRFs have achieved state-of-the-art performance in many domains including knowledge graph identification (Pujara et al., 2013), understanding engagements in MOOCs (Ramesh et al., 2014a), biomedicine and multi-relational link prediction (Fakhraei et al., 2014), and modelling social trust (Huang et al., 2013). These models can be specified using *Probabilistic Soft Logic (PSL)* (Bach et al., 2015), a weighted first order logical templating language. An example of a PSL rule is

$$\lambda : P(a) \wedge Q(a,b) \rightarrow R(b),$$

where *P*, *Q*, and *R* are predicates, *a* and *b* are *variables*, and λ is the weight associated with the rule. The weight of the rule indicates its importance in the HL-MRF probabilistic model, which defines a probability density function of the form

$$P(\mathbf{Y}|\mathbf{X}) \propto \exp\Big(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y},\mathbf{X})\Big)$$
$$\phi_r(\mathbf{Y},\mathbf{X}) = (\max\{l_r(\mathbf{Y},\mathbf{X}),0\})^{\rho_r}\ , \qquad (1)$$

where $\phi_r(\mathbf{Y},\mathbf{X})$ is a *hinge-loss potential* corresponding to an instantiation of a rule, and is specified by a linear function l_r and optional exponent $\rho_r \in \{1,2\}$. For example, in our MOOC aspect-sentiment model, if *P* and *F* denote *post P* and *fine aspect F*, then we have predicates SEEDLDA-FINE(P, F) to denote the value corresponding to topic *F* in SeededLDA, and FINE-ASPECT(P, F) is the target variable denoting the fine aspect of the post *P*. A PSL rule to encode that the SeededLDA topic *F* suggests that aspect *F* is present is

$$\lambda : \text{SEEDLDA-FINE}(P,F) \rightarrow \text{FINE-ASPECT}(P,F).$$

We can generate more complex rules connecting the different features and target variables, e.g.

$$\lambda : \text{SEEDLDA-FINE}(P,F) \wedge \text{SENTIMENT}(P,S)$$
$$\rightarrow \text{FINE-ASPECT}(P,F).$$

This rule encodes a dependency between SENTIMENT and FINE-ASPECT, namely that the SeededLDA topic and a strong sentiment score increase the probability of the fine aspect. The HL-MRF model uses these rules to encode domain knowledge about dependencies among the predicates. The continuous value representation further helps in understanding the confidence of predictions.

4.3 Joint Aspect-Sentiment Prediction using Probabilistic Soft Logic (PSL-Joint)

In this section, we describe our joint approach to predicting aspect and sentiment in online discussion forums, leveraging the strong dependence between aspect and sentiment. We present a system designed using HL-MRFs which combines different features, accounting for their respective uncertainty, and encodes the dependencies between aspect and sentiment in the MOOC context.

Table 7 provides some representative rules from our model.[2] The rules can be classified into two broad categories—1) rules that combine multiple features, and 2) rules that encode the dependencies between aspect and sentiment.

4.3.1 Combining Features

The first set of rules in Table 7 combine different features extracted from the post. SEEDLDA-FINE, SEEDLDA-COARSE and SEEDLDA-SENTIMENT-COURSE predicates in rules refer to SeededLDA posterior distributions using *coarse*, *fine*, and course-specific *sentiment* seed words respectively. The strength of our model comes from its ability to encode different combinations of features and weight them according to their importance. The first rule in Table 7 combines the SeededLDA features from both SEEDLDA-FINE and SEEDLDA-COARSE to predict the fine aspect. Interpreting the rule, the fine aspect of the post is more likely to be LECTURE-LECTURER if the coarse SeededLDA score for the post is LECTURE, *and* the fine SeededLDA score for the post is LECTURE-LECTURER. Similarly, the second rule provides combinations of some of the other features used by the model—two different SeededLDA scores for sentiment, as indicated by seed words in Tables 5 and 6. The third rule states that certain fine aspects occur together with certain values of sentiment more than others. In online courses, posts that discuss grading usually talk about grievances and issues. The rule captures that QUIZ-GRADING occurs with negative sentiment in most cases.

4.3.2 Encoding Dependencies Between Aspect and Sentiment

In addition to combining features, we also encode rules to capture the taxonomic dependence between coarse and fine aspects, and the dependence between aspect and sentiment (Table 7, bottom). Rules 4 and 5 encode pair-wise dependency between FINE-ASPECT and SENTIMENT, and COARSE-ASPECT and FINE-ASPECT respectively. Rule 4 uses the SeededLDA value for QUIZ-DEADLINES to predict both SENTIMENT, and FINE-ASPECT jointly. This together with other rules for predicting SENTIMENT and FINE-ASPECT individually creates a constrained satisfaction problem, forcing aspect and sentiment to agree with each other. Rule 5 is similar to rule 4, capturing the taxonomic relationship between target variables COARSE-ASPECT and FINE-ASPECT.

Thus, by using conjunctions to combine features and appropriately weighting these rules, we account for the uncertainties in the underlying features and make them more robust. The combination of these two different types of weighted rules, referred to below as *PSL-Joint*, is able to reason collectively about aspect and sentiment.

5 Empirical Evaluation

In this section, we present the quantitative and qualitative results of our models on the annotated MOOC dataset. Our models do not require labeled data for training; we use the label annotations only for evaluation. Tables 8 – 11 show the results for the SeededLDA and PSL-Joint models. Statistically significant differences, evaluated using a paired t-test with a rejection threshold of *0.01*, are typed in bold.

5.1 SeededLDA for Aspect-Sentiment

For SeededLDA, we use the seed words for *coarse*, *fine*, and *sentiment* given in Tables 3 – 5. After training the model, we use the SeededLDA multinomial posterior distribution to predict the target variables. We use the maximum value in the posterior for the distribution over topics for each post to obtain predictions for coarse aspect, fine aspect, and sentiment. We then calculate precision, recall and F1 values comparing with our ground truth labels.

5.2 PSL for Joint Aspect-Sentiment (PSL-Joint)

Tables 8 and 9 give the results for the fine aspects under LECTURE and QUIZ. PSL-JOINT performs better than SEEDEDLDA in most cases, without suffering any statistically significant losses. Notable cases include the increase in scores for LECTURE-LECTURER, LECTURE-SUBTITLES, LECTURE-CONTENT, QUIZ-CONTENT, QUIZ-GRADING, and QUIZ-DEADLINES, for which the scores increase by a large margin over SeededLDA. We observe that for LECTURE-CONTENT and QUIZ-CONTENT, the increase in scores is more significant than others with SeededLDA performing very poorly. Since both lecture and quiz content have the same kind of words related to the course material, SeededLDA is not able to distinguish between these two aspects. We found that in 63% of these missed predictions, SeededLDA predicts LECTURE-CONTENT, instead of QUIZ-CONTENT, and vice versa. In contrast, PSL-Joint uses both coarse and fine SeededLDA scores and captures the dependency between a coarse aspect and its corresponding fine aspect. Therefore, PSL-Joint is able to distinguish between LECTURE-CONTENT and QUIZ-CONTENT. In the next section, we present some examples of posts that SEEDEDLDA misclassified but were predicted correctly by PSL-Joint.

Table 10 presents results for the *coarse-aspects*. We observe that PSL-Joint performs better than SeededLDA for all classes. In particular for CERTIFICATE and QUIZ, PSL-Joint exhibits a marked increase in scores when compared to SeededLDA. This is also true for sentiment, for which the scores for NEUTRAL and NEGATIVE sentiment show significant improvement (Table 11).

Correct Label	PSL	SeededLDA	Post
QUIZ-CONTENT	QUIZ-CONTENT	LECTURE-CONTENT	There is a typo or other mistake in the assignment instructions (e.g. essential information omitted) Type ID: programming-content Problem ID: programming-mistake Browser: Chrome 32 OS: Windows 7
QUIZ-CONTENT	QUIZ-CONTENT	LECTURE-CONTENT	There is a typo or other mistake on the page (e.g. factual error information omitted) Week 4 Quiz Question 6: Question 6 When a user clicks on a View that has registered to show a Context Menu which one of the following methods will be called?
LECTURE-AUDIO	LECTURE-AUDIO	LECTURE-SUBTITLES	Thanks for the suggestion about downloading the video and referring to the subtitles. I will give that a try but I would also like to point out that what the others are saying is true for me too: The audio is just barely audible even when the volume on my computer is set to 100%.
SOCIAL	SOCIAL	LECTURE-VIDEO	Let's start a group for discussing the lecture videos.

Table 12: Example posts that PSL-Joint predicted correctly, but were misclassified by SeededLDA

Correct Label	Predicted Label	Second Prediction	Post
LECTURE-CONTENT	QUIZ-CONTENT	LECTURE-CONTENT	I have a difference of opinion to the answer for Question 6 too. It differs from what is presented in lecture 1.
SOCIAL	LECTURE-SUBTITLES	SOCIAL	Hello guys!!! I am ... The course materials are extraordinary. The subtitles are really helpful! Thanks to instructors for giving us all a wonderful opportunity.
LECTURE-CONTENT	QUIZ-CONTENT	LECTURE-CONTENT	As the second lecture video told me I started windows telnet and connected to the virtual device. Then I typed the same command for sending an sms that the lecture video told me to. The phone received a message all right and I was able to open it but the message itself seems to be written with some strange characters.

Table 13: Example posts whose second-best prediction is correct

5.3 Interpreting PSL-Joint Predictions

Table 12 presents some examples of posts that PSL-Joint predicted correctly, and which SeededLDA misclassified. The first two examples illustrate that PSL can predict the subtle difference between LECTURE-CONTENT and QUIZ-CONTENT. Particularly notable is the third example, which contains mention of both *subtitles* and *audio*, but the negative sentiment is associated with *audio* rather than *subtitles*. PSL-Joint predicts the fine aspect as LECTURE-AUDIO, even though the underlying SeededLDA feature has a high score for LECTURE-SUBTITLES. This example illustrates the strength of the joint reasoning approach in PSL-Joint. Finally, in the last example, the post mentions starting a *group* to discuss videos. This is an ambiguous post containing the keyword *video*, while it is in reality a social post about starting a group. PSL-Joint is able to predict this because it uses both the sentiment scores associated with the post and the SeededLDA scores for fine aspect, and infers that social posts are generally positive. So, combining the feature values for social aspect and positive sentiment, it is able to predict the fine aspect as SOCIAL correctly.

The continuous valued output predictions produced by PSL-Joint allow us to rank the predicted variables by output prediction value. Analyzing the predictions for posts that PSL-Joint misclassified, we observe that for *four* out of *nine* fine aspects, more than 70% of the time the correct label is in the top three predictions. And, for all fine aspects, the correct label is found in the top 3 predictions around 40% of the time. Thus, using the top three predictions made by PSL-Joint, we can understand the fine aspect of the post to a great extent. Table 13 gives some examples of posts for which the second best prediction by PSL-Joint is the correct label. For these examples, we found that PSL-Joint misses the correct prediction by a small margin(< 0.2). Since our evaluation scheme only considers the maximum value to determine the scores, these examples were treated as misclassified.

5.4 Understanding Instructor Intervention using PSL-Joint Predictions

In our 3275 annotated posts, the instructor replied to 787 posts. Of these, 699 posts contain a mention of some MOOC aspect. PSL-Joint predicts 97.8% from those as having an aspect and 46.9% as the correct aspect. This indicates that PSL-Joint is capable of identifying the most important posts, i.e. those that the instructor replied to, with high accuracy. PSL-Joint's MOOC aspect predictions can potentially be used by the instructor to select a subset of posts to address in order to cover the main reported issues. We found in our data that some fine aspects, such as CERTIFICATE, have a higher percentage of instructor replies than others, such as QUIZ-GRADING. Using our system, instructors can sample from multiple aspect categories, thereby making sure that all categories of problems receive attention.

6 Conclusion

In this paper, we developed a weakly supervised joint probabilistic model (PSL-Joint) for predicting aspect-sentiment in online courses. Our model provides the ability to conveniently encode domain information in the form of seed words, and weighted logical rules capturing the dependencies between aspects and sentiment. We validated our approach on an annotated dataset of MOOC posts sampled from twelve courses. We compared our PSL-Joint probabilistic model to a simpler SeededLDA approach, and demonstrated that PSL-Joint produced statistically significantly better results, exhibiting a 3–5 times improvement in F1 score in most cases over a system using only SeededLDA. As further shown by our qualitative results and instructor reply information, our system can potentially be used for understanding student requirements and issues, identifying posts for instructor intervention, increasing student retention, and improving future iterations of the course.

Abstract

This paper considers the problem of embedding Knowledge Graphs (KGs) consisting of entities and relations into low-dimensional vector spaces. Most of the existing methods perform this task based solely on observed facts. The only requirement is that the learned embeddings should be compatible within each individual fact. In this paper, aiming at further discovering the intrinsic geometric structure of the embedding space, we propose *Semantically Smooth Embedding* (SSE). The key idea of SSE is to take full advantage of additional semantic information and enforce the embedding space to be semantically smooth, i.e., entities belonging to the same semantic category will lie close to each other in the embedding space. Two manifold learning algorithms Laplacian Eigenmaps and Locally Linear Embedding are used to model the smoothness assumption. Both are formulated as geometrically based regularization terms to constrain the embedding task. We empirically evaluate SSE in two benchmark tasks of link prediction and triple classification, and achieve significant and consistent improvements over state-of-the-art methods. Furthermore, SSE is a general framework. The smoothness assumption can be imposed to a wide variety of embedding models, and it can also be constructed using other information besides entities' semantic categories.

1 Introduction

Knowledge Graphs (KGs) like WordNet (Miller, 1995), Freebase (Bollacker et al., 2008), and DBpedia (Lehmann et al., 2014) have become extremely useful resources for many NLP related applications, such as word sense disambiguation (Agirre et al., 2014), named entity recognition (Magnini et al., 2002), and information extraction (Hoffmann et al., 2011). A KG is a multi-relational directed graph composed of entities as nodes and relations as edges. Each edge is represented as a triple of fact $\langle e_i, r_k, e_j \rangle$, indicating that head entity e_i and tail entity e_j are connected by relation r_k. Although powerful in representing structured data, the underlying symbolic nature makes KGs hard to manipulate.

Recently a new research direction called knowledge graph embedding has attracted much attention (Socher et al., 2013; Bordes et al., 2013; Bordes et al., 2014; Lin et al., 2015). It attempts to embed components of a KG into continuous vector spaces, so as to simplify the manipulation while preserving the inherent structure of the original graph. Specifically, given a KG, entities and relations are first represented in a low-dimensional vector space, and for each triple, a scoring function is defined to measure its plausibility in that space. Then the representations of entities and relations (i.e. embeddings) are learned by maximizing the total plausibility of observed triples. The learned embeddings can further be used to benefit all kinds of tasks, such as KG completion (Socher et al., 2013; Bordes et al., 2013), relation extraction (Riedel et al., 2013; Weston et al., 2013), and entity resolution (Bordes et al., 2014).

To our knowledge, most of existing KG embedding methods perform the embedding task based solely on observed facts. The only requirement is that the learned embeddings should be compatible within each individual fact. In this paper we propose *Semantically Smooth Embedding* (SSE), a new approach which further imposes constraints on the geometric structure of the embedding space. The key idea of SSE is to make ful-

l use of additional semantic information (i.e. semantic categories of entities) and enforce the embedding space to be semantically smooth—entities belonging to the same semantic category should lie close to each other in the embedding space. This smoothness assumption is closely related to the local invariance assumption exploited in manifold learning theory, which requires nearby points to have similar embeddings or labels (Belkin and Niyogi, 2001). Thus we employ two manifold learning algorithms Laplacian Eigenmaps (Belkin and Niyogi, 2001) and Locally Linear Embedding (Roweis and Saul, 2000) to model the smoothness assumption. The former requires an entity to lie close to every other entity in the same category, while the latter represents that entity as a linear combination of its nearest neighbors (i.e. entities within the same category). Both are formulated as manifold regularization terms to constrain the KG embedding objective function. As such, SSE obtains an embedding space which is semantically smooth and at the same time compatible with observed facts.

The advantages of SSE are two-fold: 1) By imposing the smoothness assumption, SSE successfully captures the semantic correlation between entities, which exists intrinsically but is overlooked in previous work on KG embedding. 2) KGs are typically very sparse, containing a relatively small number of facts compared to the large number of entities and relations. SSE can effectively deal with data sparsity by leveraging additional semantic information. Both aspects lead to more accurate embeddings in SSE. Moreover, our approach is quite general. The smoothness assumption can actually be imposed to a wide variety of KG embedding models. Besides semantic categories, other information (e.g. entity similarities specified by users or derived from auxiliary data sources) can also be used to construct the manifold regularization terms. And besides KG embedding, similar smoothness assumptions can also be applied in other embedding tasks (e.g. word embedding and sentence embedding).

Our main contributions can be summarized as follows. First, we devise a novel KG embedding framework that naturally requires the embedding space to be semantically smooth. As far as we know, it is the first work that imposes constraints on the geometric structure of the embedding space during KG embedding. By leveraging additional semantic information, our approach can also deal with the data sparsity issue that commonly exists in typical KGs. Second, we evaluate our approach in two benchmark tasks of link prediction and triple classification, and achieve significant and consistent improvements over state-of-the-art models.

In the remainder of this paper, we first provide a brief review of existing KG embedding models in Section 2, and then detail the proposed SSE framework in Section 3. Experiments and results are reported in Section 4. Then in Section 5 we discuss related work, followed by the conclusion and future work in Section 6.

2 A Brief Review of KG Embedding

KG embedding aims to embed entities and relations into a continuous vector space and model the plausibility of each fact in that space. In general, it consists of three steps: 1) representing entities and relations, 2) specifying a scoring function, and 3) learning the latent representations. In the first step, given a KG, entities are represented as points (i.e. vectors) in a continuous vector space, and relations as operators in that space, which can be characterized by vectors (Bordes et al., 2013; Bordes et al., 2014; Wang et al., 2014b), matrices (Bordes et al., 2011; Jenatton et al., 2012), or tensors (Socher et al., 2013). In the second step, for each candidate fact $\langle e_i, r_k, e_j \rangle$, an energy function $f(e_i, r_k, e_j)$ is further defined to measure its plausibility, with the corresponding entity and relation representations as variables. Plausible triples are assumed to have low energies. Then in the third step, to obtain the entity and relation representations, a margin-based ranking loss, i.e.,

$$\mathcal{L}=\sum_{t^+\in\mathcal{O}}\sum_{t^-\in\mathcal{N}_{t^+}}\left[\gamma+f(e_i,r_k,e_j)-f(e'_i,r_k,e'_j)\right]_+, \quad (1)$$

is minimized. Here, $\mathcal{O}$ is the set of observed (i.e. positive) triples, and $t^+ = \langle e_i, r_k, e_j \rangle \in \mathcal{O}$; $\mathcal{N}_{t^+}$ denotes the set of negative triples constructed by replacing entities in t^+, and $t^- = \langle e'_i, r_k, e'_j \rangle \in \mathcal{N}_{t^+}$; $\gamma > 0$ is a margin separating positive and negative triples; and $[x]_+ = \max(0, x)$. The ranking loss favors lower energies for positive triples than for negative ones. Stochastic gradient descent (in mini-batch mode) is adopted to solve the minimization problem. For details please refer to (Bordes et al., 2013) and references therein.

Different embedding models differ in the first two steps: entity/relation representation and energy

Method	Entity/Relation embeddings	Energy function
TransE (Bordes et al., 2013)	$\mathbf{e}, \mathbf{r} \in \mathbb{R}^d$	$f(e_i, r_k, e_j) = \|\mathbf{e}_i + \mathbf{r}_k - \mathbf{e}_j\|_{\ell_1/\ell_2}$
SME (lin) (Bordes et al., 2014)	$\mathbf{e}, \mathbf{r} \in \mathbb{R}^d$	$f(e_i, r_k, e_j) = (\mathbf{W}_{u1}\mathbf{r}_k + \mathbf{W}_{u2}\mathbf{e}_i + \mathbf{b}_u)^T \left(\mathbf{W}_{v1}\mathbf{r}_k + \mathbf{W}_{v2}\mathbf{e}_j + \mathbf{b}_v\right)$
SME (bilin) (Bordes et al., 2014)	$\mathbf{e}, \mathbf{r} \in \mathbb{R}^d$	$f(e_i, r_k, e_j) = \left(\left(\underline{\mathbf{W}}_u \bar{\times}_3 \mathbf{r}_k\right)\mathbf{e}_i + \mathbf{b}_u\right)^T \left(\left(\underline{\mathbf{W}}_v \bar{\times}_3 \mathbf{r}_k\right)\mathbf{e}_j + \mathbf{b}_v\right)$
SE (Bordes et al., 2011)	$\mathbf{e} \in \mathbb{R}^d$, $\mathbf{R}^u, \mathbf{R}^v \in \mathbb{R}^{d \times d}$	$f(e_i, r_k, e_j) = \|\mathbf{R}_k^u\mathbf{e}_i - \mathbf{R}_k^v\mathbf{e}_j\|_{\ell_1}$

Table 1: Existing KG embedding models.

function definition. Three state-of-the-art embedding models, namely TransE (Bordes et al., 2013), SME (Bordes et al., 2014), and SE (Bordes et al., 2011), are detailed below. Please refer to (Jenatton et al., 2012; Socher et al., 2013; Wang et al., 2014b; Lin et al., 2015) for other methods.

TransE (Bordes et al., 2013) represents both entities and relations as vectors in the embedding space. For a given triple $\langle e_i, r_k, e_j \rangle$, the relation is interpreted as a translation vector $\mathbf{r}_k$ so that the embedded entities $\mathbf{e}_i$ and $\mathbf{e}_j$ can be connected by $\mathbf{r}_k$ with low error. The energy function is defined as $f(e_i, r_k, e_j) = \|\mathbf{e}_i + \mathbf{r}_k - \mathbf{e}_j\|_{\ell_1/\ell_2}$, where $\|\cdot\|_{\ell_1/\ell_2}$ denotes the ℓ_1-norm or ℓ_2-norm.

SME (Bordes et al., 2014) also represents entities and relations as vectors, but models triples in a more expressive way. Given a triple $\langle e_i, r_k, e_j \rangle$, it first employs a function $g_u(\cdot, \cdot)$ to combine $\mathbf{r}_k$ and $\mathbf{e}_i$, and $g_v(\cdot, \cdot)$ to combine $\mathbf{r}_k$ and $\mathbf{e}_j$. Then, the energy function is defined as matching $g_u(\cdot, \cdot)$ and $g_v(\cdot, \cdot)$ by their dot product, i.e., $f(e_i, r_k, e_j) = g_u(\mathbf{r}_k, \mathbf{e}_i)^T g_v(\mathbf{r}_k, \mathbf{e}_j)$. There are two versions of SME, linear and bilinear (denoted as SME (lin) and SME (bilin) respectively), obtained by defining different $g_u(\cdot, \cdot)$ and $g_v(\cdot, \cdot)$.

SE (Bordes et al., 2011) represents entities as vectors but relations as matrices. Each relation is modeled by a left matrix $\mathbf{R}_k^u$ and a right matrix $\mathbf{R}_k^v$, acting as independent projections to head and tail entities respectively. If a triple $\langle e_i, r_k, e_j \rangle$ holds, $\mathbf{R}_k^u\mathbf{e}_i$ and $\mathbf{R}_k^v\mathbf{e}_j$ should be close to each other. The energy function is $f(e_i, r_k, e_j) = \|\mathbf{R}_k^u\mathbf{e}_i - \mathbf{R}_k^v\mathbf{e}_j\|_{\ell_1}$. Table 1 summarizes the entity/relation representations and energy functions used in these models.

3 Semantically Smooth Embedding

The methods introduced above perform the embedding task based solely on observed facts. The only requirement is that the learned embeddings should be compatible within each individual fact. However, they fail to discover the intrinsic geometric structure of the embedding space. To deal with this limitation, we introduce *Semantically Smooth Embedding* (SSE) which constrains the embedding task by incorporating geometrically based regularization terms, constructed by using additional semantic categories of entities.

3.1 Problem Formulation

Suppose we are given a KG consisting of n entities and m relations. The facts observed are stored as a set of triples $O = \left\{\langle e_i, r_k, e_j \rangle\right\}$. A triple $\langle e_i, r_k, e_j \rangle$ indicates that entity e_i and entity e_j are connected by relation r_k. In addition, the entities are classified into multiple semantic categories. Each entity e is associated with a label c_e indicating the category to which it belongs. SSE aims to embed the entities and relations into a continuous vector space which is compatible with the observed facts, and at the same time semantically smooth.

To make the embedding space compatible with the observed facts, we make use of the triple set O and follow the same strategy adopted in previous methods. That is, we define an energy function on each candidate triple (e.g. the energy functions listed in Table 1), and require observed triples to have lower energies than unobserved ones (i.e. the margin-based ranking loss defined in Eq. (1)).

To make the embedding space semantically smooth, we further leverage the entity category information $\{c_e\}$, and assume that entities within the same semantic category should lie close to each other in the embedding space. This smoothness assumption is similar to the local invariance assumption exploited in manifold learning theory (i.e. nearby points are likely to have similar embeddings or labels). So we employ two manifold learning algorithms Laplacian Eigenmaps (Belkin and Niyogi, 2001) and Locally Linear Embedding (Roweis and Saul, 2000) to model such semantic smoothness, termed as LE and LLE for short respectively.

3.2 Modeling Semantic Smoothness by LE

Laplacian Eigenmaps (LE) is a manifold learning algorithm that preserves local invariance between each two data points (Belkin and Niyogi, 2001). We borrow the idea of LE and enforce semantic smoothness by assuming:

Smoothness Assumption 1 *If two entities e_i and e_j belong to the same semantic category, they will have embeddings $\mathbf{e}_i$ and $\mathbf{e}_j$ close to each other.*

To encode the semantic information, we construct an adjacency matrix $\mathbf{W}_1 \in \mathbb{R}^{n \times n}$ among the entities, with the ij-th entry defined as:

$$w_{ij}^{(1)} = \begin{cases} 1, & \text{if } c_{e_i} = c_{e_j}, \\ 0, & \text{otherwise,} \end{cases}$$

where c_{e_i}/c_{e_j} is the category label of entity e_i/e_j. Then, we use the following term to measure the smoothness of the embedding space:

$$\mathcal{R}_1 = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} \|\mathbf{e}_i - \mathbf{e}_j\|_2^2 w_{ij}^{(1)},$$

where $\mathbf{e}_i$ and $\mathbf{e}_j$ are the embeddings of entities e_i and e_j respectively. By minimizing $\mathcal{R}_1$, we expect Smoothness Assumption 1: if two entities e_i and e_j belong to the same semantic category (i.e. $w_{ij}^{(1)} = 1$), the distance between $\mathbf{e}_i$ and $\mathbf{e}_j$ (i.e. $\|\mathbf{e}_i - \mathbf{e}_j\|_2^2$) should be small.

We further incorporate $\mathcal{R}_1$ as a regularization term into the margin-based ranking loss (i.e. Eq. (1)) adopted in previous KG embedding methods, and propose our first SSE model. The new model performs the embedding task by minimizing the following objective function:

$$\mathcal{L}_1 = \frac{1}{N} \sum_{t^+ \in \mathcal{O}} \sum_{t^- \in \mathcal{N}_{t^+}} \ell(t^+, t^-) + \frac{\lambda_1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} \|\mathbf{e}_i - \mathbf{e}_j\|_2^2 w_{ij}^{(1)},$$

where $\ell(t^+, t^-) = \left[\gamma + f(e_i, r_k, e_j) - f(e_i', r_k, e_j')\right]_+$ is the ranking loss on the positive-negative triple pair (t^+, t^-), and N is the total number of such triple pairs. The first term in $\mathcal{L}_1$ enforces the resultant embedding space compatible with all the observed triples, and the second term further requires that space to be semantically smooth. Hyperparameter λ_1 makes a trade-off between the two cases.

The minimization is carried out by stochastic gradient descent. Given a randomly sampled positive triple $t^+ = \langle e_i, r_k, e_j \rangle$ and the associated negative triple $t^- = \langle e_i', r_k, e_j' \rangle$,[1] the stochastic gradient w.r.t. $\mathbf{e}_s$ ($s \in \{i, j, i', j'\}$) can be calculated as:

$$\nabla_{\mathbf{e}_s} \mathcal{L}_1 = \nabla_{\mathbf{e}_s} \ell(t^+, t^-) + 2\lambda_1 \mathbf{E}(\mathbf{D} - \mathbf{W}_1) \mathbf{1}_s,$$

where $\mathbf{E} = [\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_n] \in \mathbb{R}^{d \times n}$ is a matrix consisting of entity embeddings; $\mathbf{D} \in \mathbb{R}^{n \times n}$ is a diagonal matrix with the i-th entry on the diagonal being $d_{ii} = \sum_{j=1}^{n} w_{ij}^{(1)}$; and $\mathbf{1}_s \in \mathbb{R}^n$ is a column vector where the s-th entry is 1 and the others are 0. Other parameters are not included in $\mathcal{R}_1$, and their gradients remain the same as defined in previous work.

3.3 Modeling Semantic Smoothness by LLE

As opposed to LE which preserves local invariance within data pairs, Locally Linear Embedding (LLE) expects each data point to be roughly reconstructed by a linear combination of its nearest neighbors (Roweis and Saul, 2000). We borrow the idea of LLE and enforce semantic smoothness by assuming:

Smoothness Assumption 2 *Each entity e_i can be roughly reconstructed by a linear combination of its nearest neighbors in the embedding space, i.e., $\mathbf{e}_i \approx \sum_{e_j \in \mathcal{N}(e_i)} \alpha_j \mathbf{e}_j$. Here nearest neighbors refer to entities belonging to the same semantic category with e_i.*

To model this assumption, for each entity e_i, we randomly sample K entities uniformly from the category to which e_i belongs, denoted as the nearest neighbor set $\mathcal{N}(e_i)$. We construct a weight matrix $\mathbf{W}_2 \in \mathbb{R}^{n \times n}$ by defining:

$$w_{ij}^{(2)} = \begin{cases} 1, & \text{if } e_j \in \mathcal{N}(e_i), \\ 0, & \text{otherwise,} \end{cases}$$

and normalize the rows so that $\sum_{j=1}^{n} w_{ij}^{(2)} = 1$ for each row i. Note that $\mathbf{W}_2$ is no longer a symmetric matrix. The smoothness of the embedding space can be measured by the reconstruction error:

$$\mathcal{R}_2 = \sum_{i=1}^{n} \left\| \mathbf{e}_i - \sum_{e_j \in \mathcal{N}(e_i)} w_{ij}^{(2)} \mathbf{e}_j \right\|_2^2.$$

Minimizing $\mathcal{R}_2$ results in Smoothness Assumption 2: each entity can be linearly reconstructed from its nearest neighbors with low error.

By incorporating $\mathcal{R}_2$ as a regularization term into the margin-based ranking loss defined in Eq. (1), we obtain our second SSE model, which performs the embedding task by minimizing:

$$\mathcal{L}_2 = \frac{1}{N} \sum_{t^+ \in \mathcal{O}} \sum_{t^- \in \mathcal{N}_{t^+}} \ell(t^+, t^-) + \lambda_2 \sum_{i=1}^{n} \left\| \mathbf{e}_i - \sum_{e_j \in \mathcal{N}(e_i)} w_{ij}^{(2)} \mathbf{e}_j \right\|_2^2.$$

[1] The negative triple is constructed by replacing one of the entities in the positive triple.

The resultant embedding space is also semantically smooth and compatible with the observed triples. Hyperparameter λ_2 makes a trade-off between the two cases.

Similar to the first model, stochastic gradient descent is used to solve the minimization problem. Given a positive triple $t^+ = \langle e_i, r_k, e_j \rangle$ and the associated negative triple $t^- = \langle e'_i, r_k, e'_j \rangle$, the gradient w.r.t. $\mathbf{e}_s$ ($s \in \{i, j, i', j'\}$) is calculated as:

$$\nabla_{\mathbf{e}_s}\mathcal{L}_2 = \nabla_{\mathbf{e}_s}\ell\left(t^+, t^-\right)+2\lambda_2\mathbf{E}\left(\mathbf{I}-\mathbf{W}_2\right)^T\left(\mathbf{I}-\mathbf{W}_2\right)\mathbf{1}_s,$$

where $\mathbf{I} \in \mathbb{R}^{n \times n}$ is the identity matrix. Other parameters are not included in $\mathcal{R}_2$, and their gradients remain the same as defined in previous work. To better capture the cohesion within each category, during each stochastic step we resample the nearest neighbors for each entity, uniformly from the category to which it belongs.

3.4 Advantages and Extensions

The advantages of our approach can be summarized as follows: 1) By incorporating geometrically based regularization terms, the SSE models are able to capture the semantic correlation between entities, which exists intrinsically but is overlooked in previous work. 2) By leveraging additional entity category information, the SSE models can deal with the data sparsity issue that commonly exists in most KGs. Both aspects lead to more accurate embeddings.

Entity category information has also been investigated in (Nickel et al., 2012; Chang et al., 2014; Wang et al., 2015), but in different manners. Nickel et al. (2012) take categories as pseudo entities and introduce a specific relation to link entities to categories. Chang et al. (2014) and Wang et al. (2015) use entity categories to specify relations' argument expectations, removing invalid triples during training and reasoning respectively. None of them considers the intrinsic geometric structure of the embedding space.

Actually, our approach is quite general. 1) The smoothness assumptions can be imposed to a wide variety of KG embedding models, not only the ones introduced in Section 2, but also those based on matrix/tensor factorization (Nickel et al., 2011; Chang et al., 2013). 2) Besides semantic categories, other information (e.g. entity similarities specified by users or derived from auxiliary data sources) can also be used to construct the manifold regularization terms. 3) Besides KG embedding, similar smoothness assumptions can also be applied in other embedding tasks (e.g. word embedding and sentence embedding).

4 Experiments

We empirically evaluate the proposed SSE models in two tasks: link prediction (Bordes et al., 2013) and triple classification (Socher et al., 2013).

4.1 Data Sets

We create three data sets with different sizes using NELL (Carlson et al., 2010): L , S , and N 186. L and S are two small-scale data sets, both containing 8 relations on the topics of "location" and "sport" respectively. The corresponding relations are listed in Table 2. N 186 is a larger data set containing the most frequent 186 relations. On all the data sets, entities appearing only once are removed. We extract the entity category information from a specific relation called `Generalization`, and keep non-overlapping categories.[2] Categories containing less than 5 entities on L and S as well as categories containing less than 50 entities on N 186 are further removed. Table 3 gives some statistics of the three data sets, where # Rel./# Ent./# Trip./# Cat. denotes the number of relations/entities/observed triples/categories respectively, and # c-Ent. denotes the number of entities that have category labels. Note that our SSE models do not require every entity to have a category label. From the statistics, we can see that all the three data sets suffer from the data sparsity issue, containing a relatively small number of observed triples compared to the number of entities.

On the two small-scale data sets L and S , triples are split into training/validation/test sets, with the ratio of 3:1:1. The first set is used for modeling training, the second for hyperparameter tuning, and the third for evaluation. All experiments are repeated 5 times by drawing new

[2] If two categories overlap, the smaller one is discarded.

training/validation/test splits, and results averaged over the 5 rounds are reported. On N 186 experiments are conducted only once, using a training/validation/test split with 31,134/5,000/5,000 triples respectively. We will release the data upon request.

4.2 Link Prediction

This task is to complete a triple $\langle e_i, r_k, e_j \rangle$ with e_i or e_j missing, i.e., predict e_i given (r_k, e_j) or predict e_j given (e_i, r_k).

Baseline methods. We take TransE, SME (lin), SME (bilin), and SE as our baselines. We then incorporate manifold regularization terms into these methods to obtain the SSE models. A model with the LE/LLE regularization term is denoted as TransE-LE/TransE-LLE for example. We further compare our SSE models with the setting proposed by Nickel et al. (2012), which also takes into account the entity category information, but in a more direct manner. That is, given an entity e with its category label c_e, we create a new triple $\langle e, \texttt{Generalization}, c_e \rangle$ and add it into the training set. Such a method is denoted as TransE-Cat for example.

Evaluation protocol. For evaluation, we adopt the same ranking procedure proposed by Bordes et al. (2013). For each test triple $\langle e_i, r_k, e_j \rangle$, the head entity e_i is replaced by every entity e'_i in the KG, and the energy is calculated for the corrupted triple $\langle e'_i, r_k, e_j \rangle$. Ranking the energies in ascending order, we get the rank of the correct entity e_i. Similarly, we can get another rank by corrupting the tail entity e_j. Aggregated over all test triples, we report three metrics: 1) the averaged rank, denoted as Mean (the smaller, the better); 2) the median of the ranks, denoted as Median (the smaller, the better); and 3) the proportion of ranks no larger than 10, denoted as Hits@10 (the higher, the better).

Implementation details. We implement the methods based on the code provided by Bordes et al. (2013)[3]. For all the methods, we create 100 mini-batches on each data set. On L and S, the dimension of the embedding space d is set in the range of $\{10, 20, 50, 100\}$, the margin γ is set in the range of $\{1, 2, 5, 10\}$, and the learning rate is fixed to 0.1. On N 186, the hyperparameters d and γ are fixed to 50 and 1 respectively, and the learning rate is fixed to 10. In LE and LLE, the regularization hyperparameters λ_1 and λ_2 are tuned in $\{10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}\}$. And the number of nearest neighbors K in LLE is tuned in $\{5, 10, 15, 20\}$. The best model is selected by early stopping on the validation sets (by monitoring Mean), with a total of at most 1000 iterations over the training sets.

Results. Table 4 reports the results on the test sets of L, S, and N 186. From the results, we can see that: 1) SSE (regularized via either LE or LLE) outperforms all the baselines on all the data sets and with all the metrics. The improvements are usually quite significant. The metric Mean drops by about 10% to 65%, Median drops by about 5% to 75%, and Hits@10 rises by about 5% to 190%. This observation demonstrates the superiority and generality of our approach. 2) Even if encoded in a direct way (e.g. TransE-Cat), the entity category information can still help the baseline methods in the link prediction task. This observation indicates that leveraging additional information is indeed useful in dealing with the data sparsity issue and hence leads to better performance. 3) Compared to the strategy which incorporates the entity category information directly, formulating such information as manifold regularization terms results in better and more stable results. The *-Cat models sometimes perform even worse than the baselines (e.g. TransE-Cat on S data), while the SSE models consistently achieve better results. This observation further demonstrates the superiority of constraining the geometric structure of the embedding space.

We further visualize and compare the geometric structures of the embedding spaces learned by traditional embedding and semantically smooth embedding. We select the 10 largest semantic categories in N 186 (specified in Figure 1) and the 5,740 entities therein. We take the embeddings of these entities learned by TransE, TransE-Cat, TransE-LE, and TransE-LLE, with the optimal hyperparameter settings determined in the link prediction task. Then we create 2D plots using t-SNE (Van der Maaten and Hinton, 2008)[4]. The results are shown in Figure 1, where a different

Figure 1: Embeddings of entities belonging to the 10 largest categories in N 186 (best viewed in color).

color is used for each category. It is easy to see that imposing the semantic smoothness assumptions helps in capturing the semantic correlation between entities in the embedding space. Entities within the same category lie closer to each other, while entities belonging to different categories are easily distinguished (see Figure 1(c) and Figure 1(d)). Incorporating the entity category information directly could also helps. But it fails on some "hard" entities (i.e., those belonging to different categories but mixed together in the center of Figure 1(b)). We have conducted the same experiments with the other methods and observed similar phenomena.

4.3 Triple Classification

This task is to verify whether a given triple $\langle e_i, r_k, e_j \rangle$ is correct or not. We test our SSE models in this task, with the same comparison settings as used in the link prediction task.

Evaluation protocol. We follow the same evaluation protocol used in (Socher et al., 2013; Wang et al., 2014b). To create labeled data for classification, for each triple in the test and validation sets, we construct a negative triple for it by randomly corrupting the entities. To corrupt a position (head or tail), only entities that have appeared in that position are allowed. During triple classification, a triple is predicted as positive if the energy is below a relation-specific threshold δ_r; otherwise as negative. We report two metrics on the test sets: micro-averaged accuracy and macro-averaged accuracy, denoted as Micro-ACC and Macro-ACC respectively. The former is a per-triple average, while the latter is a per-relation average.

Implementation details. We use the same hyperparameter settings as in the link prediction task. The relation-specific threshold δ_r is determined by maximizing Micro-ACC on the validation sets. Again, training is limited to at most 1000 iterations, and the best model is selected by early stopping on the validation sets (by monitoring Micro-ACC).

Results. Table 5 reports the results on the test sets of L , S , and N 186. The results indicate that: 1) SSE (regularized via either LE or LLE) performs consistently better than the base-

line methods on all the data sets in both metrics. The improvements are usually quite substantial. The metric Micro-ACC rises by about 1% to 25%, and Macro-ACC by about 2% to 30%. 2) Incorporating the entity category information directly can also improve the baselines in the triple classification task, again demonstrating the effectiveness of leveraging additional information to deal with the data sparsity issue. 3) It is a better choice to incorporate the entity category information as manifold regularization terms as opposed to encoding it directly. The *-Cat models sometimes perform even worse than the baselines (e.g. TransE-Cat on L data and SE-Cat on S data), while the SSE models consistently achieve better results. The observations are similar to those observed during the link prediction task, and further demonstrate the superiority and generality of our approach.

5 Related Work

This section reviews two lines of related work: KG embedding and manifold learning.

KG embedding aims to embed a KG composed of entities and relations into a low-dimensional vector space, and model the plausibility of each fact in that space. Yang et al. (2014) categorized the literature into three major groups: 1) methods based on neural networks, 2) methods based on matrix/tensor factorization, and 3) methods based on Bayesian clustering. The first group performs the embedding task using neural network architectures (Bordes et al., 2013; Bordes et al., 2014; Socher et al., 2013). Several state-of-the-art neural network-based embedding models have been introduced in Section 2. For other work please refer to (Jenatton et al., 2012; Wang et al., 2014b; Lin et al., 2015). In the second group, KGs are represented as tensors, and embedding is performed via tensor factorization or collective matrix factorization techniques (Singh and Gordon, 2008; Nickel et al., 2011; Chang et al., 2014). The third group embeds factorized representations of entities and relations into a nonparametric Bayesian clustering framework, so as to obtain more interpretable embeddings (Kemp et al., 2006; Sutskever et al., 2009). Our work falls into the first group, but differs in that it further imposes constraints on the geometric structure of the embedding space, which exists intrinsically but is overlooked in previous work. Although this paper focuses on incorporating geometrically based regularization terms into neural network architectures, it can be easily extended to matrix/tensor factorization techniques.

Manifold learning is a geometrically motivated framework for machine learning, enforcing the learning model to be smooth w.r.t. the geometric structure of data (Belkin et al., 2006). Within this framework, various manifold learning algorithms have been proposed, such as ISOMAP (Tenenbaum et al., 2000), Laplacian Eigenmaps (Belkin and Niyogi, 2001), and Locally Linear Embedding (Roweis and Saul, 2000). All these algorithms are based on the so-called local invariance assumption, i.e., nearby points are likely to have similar embeddings or labels. Manifold learning has been widely applied in many different areas, from dimensionality reduction (Belkin and Niyogi, 2001; Cai et al., 2008) and semi-supervised learning (Zhou et al., 2004; Zhu and Niyogi, 2005) to recommender systems (Ma et al., 2011) and community question answering (Wang et al., 2014a). This paper employs manifold learning algorithms to model the semantic smoothness assumptions in KG embedding.

6 Conclusion and Future Work

In this paper, we have proposed a novel approach to KG embedding, referred to as *Semantically Smooth Embedding* (SSE). The key idea of SSE is to impose constraints on the geometric structure of the embedding space and enforce it to be semantically smooth. The semantic smoothness assumptions are constructed by using entities' category information, and then formulated as geometrically based regularization terms to constrain the embedding task. The embeddings learned in this way are capable of capturing the semantic correlation between entities. By leveraging additional information besides observed triples, SSE can also deal with the data sparsity issue that commonly exists in most KGs. We empirically evaluate SSE in two benchmark tasks of link prediction and triple classification. Experimental results show that by incorporating the semantic smoothness assumptions, SSE significantly and consistently outperforms state-of-the-art embedding methods, demonstrating the superiority of our approach. In addition, our approach is quite general. The smoothness assumptions can actually be imposed to a wide variety of embedding models, and it can also be constructed using other information besides entities' semantic categories.

As future work, we would like to: 1) Construct the manifold regularization terms using other data sources. The only information required to construct the manifold regularization terms is the similarity between entities (used to define the adjacency matrix in LE and to select nearest neighbors for each entity in LLE). We would try entity similarities derived in different ways, e.g., specified by users or calculated from entities' textual descriptions. 2) Enhance the efficiency and scalability of SSE. Processing the manifold regularization terms can be time- and space-consuming (especially the one induced by the LE algorithm). We would investigate how to address this problem, e.g., via the efficient iterative algorithms introduced in (Saul and Roweis, 2003) or via parallel/distributed computing. 3) Impose the semantic smoothness assumptions on other KG embedding methods (e.g. those based on matrix/tensor factorization or Bayesian clustering), and even on other embedding tasks (e.g. word embedding or sentence embedding).

Department of Computer Science
Sapienza University of Rome
{iacobacci,pilehvar,navigli}@di.uniroma1.it

Abstract

Word embeddings have recently gained considerable popularity for modeling words in different Natural Language Processing (NLP) tasks including semantic similarity measurement. However, notwithstanding their success, word embeddings are by their very nature unable to capture polysemy, as different meanings of a word are conflated into a single representation. In addition, their learning process usually relies on massive corpora only, preventing them from taking advantage of structured knowledge. We address both issues by proposing a multifaceted approach that transforms word embeddings to the sense level and leverages knowledge from a large semantic network for effective semantic similarity measurement. We evaluate our approach on word similarity and relational similarity frameworks, reporting state-of-the-art performance on multiple datasets.

1 Introduction

The much celebrated word embeddings represent a new branch of corpus-based distributional semantic model which leverages neural networks to model the context in which a word is expected to appear. Thanks to their high coverage and their ability to capture both syntactic and semantic information, word embeddings have been successfully applied to a variety of NLP tasks, such as Word Sense Disambiguation (Chen et al., 2014), Machine Translation (Mikolov et al., 2013b), Relational Similarity (Mikolov et al., 2013c), Semantic Relatedness (Baroni et al., 2014) and Knowledge Representation (Bordes et al., 2013).

However, word embeddings inherit two important limitations from their antecedent corpus-based distributional models: (1) they are unable to model distinct meanings of a word as they conflate the contextual evidence of different meanings of a word into a single vector; and (2) they base their representations solely on the distributional statistics obtained from corpora, ignoring the wealth of information provided by existing semantic resources.

Several research works have tried to address these problems. For instance, basing their work on the original sense discrimination approach of Reisinger and Mooney (2010), Huang et al. (2012) applied K-means clustering to decompose word embeddings into multiple prototypes, each denoting a distinct meaning of the target word. However, the sense representations obtained are not linked to any sense inventory, a mapping that consequently has to be carried out either manually, or with the help of sense-annotated data. Another line of research investigates the possibility of taking advantage of existing semantic resources in word embeddings. A good example is the Relation Constrained Model (Yu and Dredze, 2014). When computing word embeddings, this model replaces the original co-occurrence clues from text corpora with the relationship information derived from the Paraphrase Database[1] (Ganitkevitch et al., 2013, PPDB), an automatically extracted dataset of paraphrase pairs.

However, none of these techniques have simultaneously solved both above-mentioned issues, i.e., inability to model polysemy and reliance on text corpora as the only source of knowledge. We propose a novel approach, called SensEmbed, which addresses both drawbacks by exploiting semantic knowledge for modeling arbitrary word senses in a large sense inventory. We evaluate our representation on multiple datasets in two standard tasks: word-level semantic similarity and relational similarity. Experimental results show that moving from words to senses, while making use

of lexical-semantic knowledge bases, makes embeddings significantly more powerful, resulting in consistent performance improvement across tasks.

Our contributions are twofold: (1) we propose a knowledge-based approach for obtaining continuous representations for individual word senses; and (2) by leveraging these representations and lexical-semantic knowledge, we put forward a semantic similarity measure with state-of-the-art performance on multiple datasets.

2 Sense Embeddings

Word embeddings are vector space models (VSM) that represent words as real-valued vectors in a low-dimensional (relative to the size of the vocabulary) semantic space, usually referred to as the continuous space language model. The conventional way to obtain such representations is to compute a term-document occurrence matrix on large corpora and then reduce the dimensionality of the matrix using techniques such as singular value decomposition (Deerwester et al., 1990; Bullinaria and Levy, 2012, SVD). Recent predictive techniques (Bengio et al., 2003; Collobert and Weston, 2008; Mnih and Hinton, 2007; Turian et al., 2010; Mikolov et al., 2013a) replace the conventional two-phase approach with a single supervised process, usually based on neural networks.

In contrast to word embeddings, which obtain a single model for potentially ambiguous words, sense embeddings are continuous representations of individual word senses. In order to be able to apply word embeddings techniques to obtain representations for individual word senses, large sense-annotated corpora have to be available. However, manual sense annotation is a difficult and time-consuming process, i.e., the so-called knowledge acquisition bottleneck. In fact, the largest existing manually sense annotated dataset is the SemCor corpus (Miller et al., 1993), whose creation dates back to more than two decades ago. In order to alleviate this issue, we leveraged a state-of-the-art Word Sense Disambiguation (WSD) algorithm to automatically generate large amounts of sense-annotated corpora.

In the rest of Section 2, first, in Section 2.1, we describe the sense inventory used for SENSEMBED. Section 2.2 introduces the corpus and the disambiguation procedure used to sense annotate this corpus. Finally in Section 2.3 we discuss how we leverage the automatically sense-tagged dataset for the training of sense embeddings.

2.1 Underlying sense inventory

We selected BabelNet[2] (Navigli and Ponzetto, 2012) as our underlying sense inventory. The resource is a merger of WordNet with multiple other lexical resources, the most prominent of which is Wikipedia. As a result, the manually-curated information in WordNet is augmented with the complementary knowledge from collaboratively-constructed resources, providing a high coverage of domain-specific terms and named entities and a rich set of relations. The usage of BabelNet as our underlying sense inventory provides us with the advantage of having our sense embeddings readily applicable to multiple sense inventories.

2.2 Generating a sense-annotated corpus

As our corpus we used the September-2014 dump of the English Wikipedia.[3] This corpus comprises texts from various domains and topics and provides a suitable word coverage. The unprocessed text of the corpus includes approximately three billion tokens and more than three million unique words. We only consider tokens with at least five occurrences.

As our WSD system, we opted for Babelfy[4] (Moro et al., 2014), a state-of-the-art WSD and Entity Linking algorithm based on BabelNet's semantic network. Babelfy first models each concept in the network through its corresponding "semantic signature" by leveraging a graph random walk algorithm. Given an input text, the algorithm uses the generated semantic signatures to construct a subgraph of the semantic network representing the input text. Babelfy then searches this subgraph for the intended sense of each content word using an iterative process and a dense subgraph heuristic. Thanks to its use of BabelNet, Babelfy inherently features multilinguality; hence, our representation approach is equally applicable to languages other than English. In order to guarantee high accuracy and to avoid bias towards more frequent senses, we do not consider those judgements made by Babelfy while backing off to the most frequent sense, a case that happens when a certain confidence threshold is not met by the algorithm. The disambiguated items with high confidence correspond to more than 50% of all the

Table 1: Closest senses to two senses of three ambiguous nouns: *bank*, *number*, and *hood*

content words. As a result of the disambiguation step, we obtain sense-annotated data comprising around one billion tagged words with at least five occurrences and 2.5 million unique word senses.

2.3 Learning sense embeddings

The disambiguated text is processed with the Word2vec (Mikolov et al., 2013a) toolkit[5]. We applied Word2vec to produce continuous representations of word senses based on the distributional information obtained from the annotated corpus. For each target word sense, a representation is computed by maximizing the log likelihood of the word sense with respect to its context. We opted for the Continuous Bag of Words (CBOW) architecture, the objective of which is to predict a single word (word sense in our case) given its context. The context is defined by a window, typically with the size of five words on each side with the paragraph ending barrier. We used hierarchical softmax as our training algorithm. The dimensionality of the vectors were set to 400 and the subsampling of frequent words to 10^{-3}.

As a result of the learning process, we obtain vector-based semantic representations for each of the word senses in the automatically-annotated corpus. We show in Table 1 some of the closest senses to six sample word senses: the geographical and financial senses of *river*, the performance and phone number senses of *number*, and the gang and car senses of *hood*.[6] As can be seen, sense embeddings can capture effectively the clear distinctions between different senses of a word. Additionally, the closest senses are not necessarily constrained to the same part of speech. For instance, the river sense of *bank* has the adverbs *upstream* and *downstream* and the "move along, of liquid" sense of the verb *run* among its closest senses.

hood$_{12}^n$	car with retractable top	convertible$_1^n$

Table 2: Sample initial senses of the noun *hood* (leftmost column) and their synonym expansion (rightmost column).

3 Similarity Measurement

This Section describes how we leverage the generated sense embeddings for the computation of word similarity and relational similarity. We start the Section by explaining how we associate a word with its set of corresponding senses and how we compare pairs of senses in Sections 3.1 and 3.2, respectively. We then illustrate our approach for measuring word similarity, together with its knowledge-based enhancement, in Section 3.3, and relational similarity in Section 3.4. Hereafter, we refer to our similarity measurement approach as SENSEMBED.

3.1 Associating senses with words

In order to be able to utilize our sense embeddings for a word-level task such as word similarity measurement, we need to associate each word with its set of relevant senses, each modeled by its corresponding vector. Let $\mathcal{S}_w$ be the set of senses associated with the word w. Our objective is to cover as many senses as can be associated with the word w. To this end we first initialize the set $\mathcal{S}_w$ by the word senses of the word w and all its synonymous word senses, as defined in the BabelNet sense inventory. We show in Table 2 some of the senses of the noun *hood* and the synonym expansion for these senses. We further expand the set $\mathcal{S}_w$ by repeating the same process for the lemma of word w (if not already in lemma form).

[5] `http://code.google.com/p/word2vec/`

[6] We follow Navigli (2009) and show the n^{th} sense of the *word* with part of speech x as *word*$_n^x$.

3.2 Vector comparison

For comparing vectors, we use the *Tanimoto* distance. The measure is a generalization of Jaccard similarity for real-valued vectors in [-1, 1]:

$$\mathcal{T}(\vec{w_1}, \vec{w_2}) = \frac{\vec{w_1} \cdot \vec{w_2}}{\|\vec{w_1}\|^2 + \|\vec{w_2}\|^2 - \vec{w_1} \cdot \vec{w_2}} \quad (1)$$

where $\vec{w_1} \cdot \vec{w_2}$ is the dot product of the vectors $\vec{w_1}$ and $\vec{w_2}$ and $\|\vec{w_1}\|$ is the Euclidean norm of $\vec{w_1}$. Rink and Harabagiu (2013) reported consistent improvements when using vector space metrics, in particular the Tanimoto distance, on the SemEval-2012 task on relational similarity (Jurgens et al., 2012) in comparison to several other measures that are designed for probability distributions, such as Jensen-Shannon divergence and Hellinger distance.

3.3 Word similarity

We show in Algorithm 1 our procedure for measuring the semantic similarity of a pair of input words w_1 and w_2. The algorithm also takes as its inputs the similarity strategy and the *weighted* similarity parameter α (Section 3.3.1) along with a *graph vicinity factor* flag (Section 3.3.2).

3.3.1 Similarity measurement strategy

We take two strategies for calculating the similarity of the given words w_1 and w_2. Let $\mathcal{S}_{w_1}$ and $\mathcal{S}_{w_2}$ be the sets of senses associated with the two respective input words w_1 and w_2, and let $\vec{s_i}$ be the sense embedding vector of the sense s$_i$. In the first strategy, which we refer to as *closest*, we follow the conventional approach (Budanitsky and Hirst, 2006) and measure the similarity of the two words as the similarity of their closest senses, i.e.:

$$Sim_{closest}(w_1, w_2) = \max_{\substack{s_1 \in \mathcal{S}_{w_1} \\ s_2 \in \mathcal{S}_{w_2}}} \mathcal{T}(\vec{s_1}, \vec{s_2}) \quad (2)$$

However, taking the similarity of the closest senses of two words as their overall similarity ignores the fact that the other senses can also contribute to the process of similarity judgement. In fact, psychological studies suggest that humans, while judging semantic similarity of a pair of words, consider different meanings of the two words and not only the closest ones (Tversky, 1977; Markman and Gentner, 1993). For instance, the WordSim-353 dataset (Finkelstein et al., 2002) contains the word pair *brother-monk*. Despite having the religious devotee sense in common, the two words are assigned the similarity judgement of 6.27, which is slightly above the middle point in the similarity scale [0,10] of the dataset. This clearly indicates that other non-synonymous, yet still related, senses of the two words have also played a role in the similarity judgement. Additionally, the relatively low score reflects the fact that the religious devotee sense is not a dominant meaning of the word *brother*.

Algorithm 1 Word Similarity

Input: Two words w_1 and w_2
Str, the similarity strategy
Vic, the *graph vicinity factor* flag
α parameter for the *weighted* strategy

Output: The similarity between w_1 and w_2

```
S_{w1} ← getSenses(w1), S_{w2} ← getSenses(w2)
if Str is closest then
    sim ← -1
else
    sim ← 0
end if
for each $s_1 \in \mathcal{S}_{w_1}$ and $s_2 \in \mathcal{S}_{w_2}$ do
    if Vic is true then
        tmp ← $\mathcal{T}^*(\vec{s_1},\vec{s_2})$
    else
        tmp ← $\mathcal{T}(\vec{s_1},\vec{s_2})$
    end if
    if Str is closest then
        sim ← max (sim, tmp)
    else
        sim ← sim + $tmp^{\alpha} \times d(s_1) \times d(s_2)$
    end if
end for
```

We therefore put forward another similarity measurement strategy, called *weighted*, in which different senses of the two words contribute to their similarity computation, but the contributions are scaled according to their relative importance. To this end, we first leverage sense occurrence frequencies in order to estimate the dominance of each specific word sense. For each word w, we first compute the dominance of its sense $s \in \mathcal{S}_w$ by dividing the frequency of s by the overall frequency of all senses associated with w, i.e., $\mathcal{S}_w$:

$$d(s) = \frac{freq(s)}{\sum_{s' \in \mathcal{S}_w} freq(s')} \quad (3)$$

We further recognize that the importance of a specific sense of a word can also be triggered by the word it is being compared with. We model this by biasing the similarity computation towards closer senses, by increasing the contribution of closer senses through a power function with parameter α. The similarity of a pair of words w_1 and w_2 according to the *weighted* strategy is computed as:

$$Sim_{\textit{weighted}}(w_1, w_2) = \sum_{s_1 \in \mathcal{S}_{w_1}} \sum_{s_2 \in \mathcal{S}_{w_2}} d(s_1)\, d(s_2)\, \mathcal{T}(\vec{s_1}, \vec{s_2})^{\alpha} \quad (4)$$

where the α parameter is a real-valued constant greater than one. We show in Section 4.1.3 how we tune the value of this parameter.

3.3.2 Enhancing similarity accuracy

Our similarity measurement approach takes advantage of lexical knowledge at two different levels. First, as we described in Sections 2.2 and 2.3, we use a knowledge-based disambiguation approach, i.e., Babelfy, which exploits BabelNet's semantic network. Second, we put forward a methodology that leverages the relations in BabelNet's graph for enhancing the accuracy of similarity judgements, to be discussed next.

As a distributional vector representation technique, our sense embeddings can potentially suffer from inaccurate modeling of less frequent word senses. In contrast, our underlying sense inventory provides a full coverage of all its concepts, with relations that are taken from WordNet and Wikipedia. In order to make use of the complementary information provided by our lexical knowledge base and to obtain more accurate similarity judgements, we introduce a *graph vicinity factor*, that combines the structural knowledge from BabelNet's semantic network and the distributional representation of sense embeddings. To this end, for a given sense pair, we scale the similarity judgement obtained by comparing their corresponding sense embeddings, based on their placement in the network. Let E be the set of all sense-to-sense relations provided by BabelNet's semantic network, i.e., $E = \{(s_i, s_j) : s_i - s_j\}$. Then, the similarity of a pair of words with the *graph vicinity factor* in formulas 2 and 4 is computed by replacing $\mathcal{T}$ with $\mathcal{T}^*$, defined as:

$$\mathcal{T}^*(\vec{s_1}, \vec{s_2}) = \begin{cases} \mathcal{T}(\vec{s_1}, \vec{s_2}) \times \beta, & \text{if } (s_1, s_2) \in E \\ \mathcal{T}(\vec{s_1}, \vec{s_2}) \times \beta^{-1}, & \text{otherwise} \end{cases} \quad (5)$$

We show in Section 4.1.3 how we tune the parameter β. This procedure is particularly helpful for the case of less frequent word senses that do not have enough contextual information to allow an effective representation. For instance, the SimLex-999 dataset (Hill et al., 2014), which we use as our tuning dataset (see Section 4.1.3), contains the highly-related pair *orthodontist-dentist*. We observed that the intended sense of the noun *orthodontist* occurs only 70 times in our annotated corpus. As a result, the obtained representation was not accurate, resulting in a low similarity score for the pair. The two respective senses are, however, directly connected in the BabelNet graph. Hence, the *graph vicinity factor* scales up the computed similarity value for the word pair.

3.4 Relational similarity

Relational similarity evaluates the correspondence between relations (Medin et al., 1990). The task can be viewed as an analogy problem in which, given two pairs of words (w_a, w_b) and (w_c, w_d), the goal is to compute the extent to which the relations of w_a to w_b and w_c to w_d are similar. Sense embeddings are suitable candidates for measuring this type of similarity, as they represent relations between senses as linear transformations. Given this property, the relation between a pair of words can be obtained by subtracting their corresponding normalized embeddings. Following Zhila et al. (2013), the relational similarity between two pairs of word (w_a, w_b) and (w_c, w_d) is accordingly calculated as:

$$\textsc{analogy}(\vec{w_a}, \vec{w_b}, \vec{w_c}, \vec{w_d}) = \mathcal{T}(\vec{w_b} - \vec{w_a}, \vec{w_d} - \vec{w_c}) \quad (6)$$

We show the procedure for measuring the relational similarity in Algorithm 2. The algorithm first finds the closest senses across the two word pairs: s_a^* and s_b^* for the first pair and s_c^* and s_d^* for the second. The analogy vector representations are accordingly computed as the difference between the sense embeddings of the corresponding closest senses. Finally, the relational similarity is computed as the similarity of the analogy vectors of the two pairs.

4 Experiments

We evaluate our sense-enhanced semantic representation on multiple word similarity and relatedness datasets (Section 4.1), as well as the relational similarity framework (Section 4.2).

Algorithm 2 Relational Similarity

```
Input: Two pairs of words $w_a$, $w_b$ and $w_c$, $w_d$
Output: The degree of analogy between the two pairs

$\mathcal{S}_{w_a} \leftarrow \mathit{getSenses}(w_a)$, $\mathcal{S}_{w_b} \leftarrow \mathit{getSenses}(w_b)$
$(s_a^*, s_b^*) \leftarrow \mathit{argmax}_{\substack{s_a \in \mathcal{S}_{w_a} \\ s_b \in \mathcal{S}_{w_b}}} \mathcal{T}(\vec{s_a}, \vec{s_b})$
$\mathcal{S}_{w_c} \leftarrow \mathit{getSenses}(w_c)$, $\mathcal{S}_{w_d} \leftarrow \mathit{getSenses}(w_d)$
$(s_c^*, s_d^*) \leftarrow \mathit{argmax}_{\substack{s_c \in \mathcal{S}_{w_c} \\ s_d \in \mathcal{S}_{w_d}}} \mathcal{T}(\vec{s_c}, \vec{s_d})$
return: $\mathcal{T}(\vec{s_b}^* - \vec{s_a}^*, \vec{s_d}^* - \vec{s_c}^*)$
```

4.1 Word similarity experiment

Word similarity measurement is one of the most popular evaluation methods in lexical semantics, and semantic similarity in particular, with numerous evaluation benchmarks and datasets. Given a set of word pairs, a system's task is to provide similarity judgments for each pair, and these judgements should ideally be as close as possible to those given by humans.

4.1.1 Datasets

We evaluate SENSEMBED on standard word similarity and relatedness datasets: the RG-65 (Rubenstein and Goodenough, 1965) and the WordSim-353 (Finkelstein et al., 2002, WS-353) datasets. Agirre et al. (2009) suggested that the original WS-353 dataset conflates similarity and relatedness and divided the dataset into two subsets, each containing pairs for just one type of association measure: similarity (the WS-Sim dataset) and relatedness (the WS-Rel dataset).

We also evaluate our approach on the YP-130 dataset, which was created by Yang and Powers (2005) specifically for measuring verb similarity, and also on the Stanford's Contextual Word Similarities (SCWS), a dataset for measuring word-in-context similarity (Huang et al., 2012). In the SCWS dataset each word is provided with the sentence containing it, which helps in pointing out the intended sense of the corresponding target word.

Finally, we also report results on the MEN dataset which was recently introduced by Bruni et al. (2014). MEN contains two sets of English word pairs, together with human-assigned similarity judgments, obtained by crowdsourcing using Amazon Mechanical Turk.

4.1.2 Comparison systems

We compare the performance of our similarity measure against twelve other approaches. As regards traditional distributional models, we report the best results computed by Baroni et al. (2014) for PMI-SVD, a system based on Pointwise Mutual Information (PMI) and SVD-based dimensionality reduction. For word embeddings, we report the results of Pennington et al. (2014, GloVe) and Collobert and Weston (2008). GloVe is an alternative way for learning embeddings, in which vector dimensions are made explicit, as opposed to the opaque meaning of the vector dimensions in Word2vec. The approach of Collobert and Weston (2008) is an embeddings model with a deeper architecture, designed to preserve more complex knowledge as distant relations. We also show results for the word embeddings trained by Baroni et al. (2014). The authors first constructed a massive corpus by combining several large corpora. Then, they trained dozens of different Word2vec models by varying the system's training parameters and reported the best performance obtained on each dataset.

As representatives for graph-based similarity techniques, we report results for the state-of-the-art approach of Pilehvar et al. (2013) which is based on random walks on WordNet's semantic network. Moreover, we present results for the graph-based approach of Zesch et al. (2008), which compares a pair of words based on the path lengths on Wiktionary's semantic network.

We also compare our word similarity measure against the multi-prototype models of Reisinger and Mooney (2010) and Huang et al. (2012), and against the approaches of Yu and Dredze (2014) and Chen et al. (2014), which enhance word embeddings with semantic knowledge derived from PPDB and WordNet, respectively. Finally, we report results for word embeddings, as our baseline, obtained using the Word2vec toolkit on the same corpus that was annotated and used for learning our sense embeddings (cf. Section 2.3).

4.1.3 Parameter tuning

Recall from Sections 3.3.1 and 3.3.2 that our algorithm has two parameters: the α parameter for the *weighted* strategy and the β parameter for the *graph vicinity factor*. We tuned these two parameters on the SimLex-999 dataset (Hill et al., 2014). We picked SimLex-999 since there are not many comparison systems in the literature that report re-

Measure	Dataset

SENSEMBED$_{weighted}$	0.871	**0.812**	**0.703**	0.639	**0.805**	**0.794**

Table 3: Spearman correlation performance on five word similarity and relatedness datasets.

sults on the dataset. We found the optimal values for α and β to be 8 and 1.6, respectively.

4.1.4 Results

Table 3 shows the experimental results on five different word similarity and relatedness datasets. We report the Spearman correlation performance for the two strategies of our approach as well as eight other comparison systems. SENSEMBED proves to be highly reliable on both similarity and relatedness measurement tasks, obtaining the best performance on most datasets. In addition, our approach shows itself to be equally suitable for verb similarity, as indicated by the results on YP-130.

The rightmost column in the Table shows the average performance weighted by dataset size. Between the two similarity measurement strategies, *weighted* proves to be the more suitable, achieving the best overall performance on three datasets and the best mean performance of 0.794 across the two strategies. This indicates that our assumption of considering all senses of a word in similarity computation was beneficial.

We report in Table 4 the Spearman correlation performance of four approaches that are similar to SENSEMBED: the multi-prototype models of Reisinger and Mooney (2010) and Huang et al. (2012), and the semantically enhanced models of Yu and Dredze (2014) and Chen et al. (2014). We provide results only on WS-353 and SCWS, since the above-mentioned approaches do not report their performance on other datasets. As we can see from the Table, SENSEMBED outperforms the other approaches on the WS-353 dataset. However, our approach lags behind on SCWS, highlighting the negative impact of taking the closest senses as the intended meanings. In fact, on this dataset, SENSEMBED$_{weighted}$ provides better performance owing to its taking into account other senses as well. The better performance of the multi-prototype systems can be attributed to their coarse-grained sense inventories which are automatically constructed by means of Word Sense Induction.

Measure	WS-353	SCWS

4.2 Relational similarity experiment

Dataset and evaluation. We take as our benchmark the SemEval-2012 task on Measuring Degrees of Relational Similarity (Jurgens et al., 2012). The task provides a dataset comprising 79 graded word relations, 10 of which are used for training and the rest for test. The task evaluated the participating systems in terms of the Spearman correlation and the MaxDiff score (Louviere, 1991).

Model	Setting			Dataset					
	Strategy	Vicinity	Expansion	RG-65	WS-Sim	WS-Rel	YP-130	MEN	Average
Word2vec	–	–		0.732	0.707	0.476	0.343	0.665	0.644

SENSEMBED$_{closest}$	**45.9**	**0.358**

Table 5: Spearman correlation performance of different systems on the SemEval-2012 Task on Relational Similarity.

Comparison systems. We compare our results against six other systems and the PMI baseline provided by the task organizers. As for systems that use word embeddings for measuring relational similarity, we report results for RNN-1600 (Mikolov et al., 2013c) and PairDirection (Levy and Goldberg, 2014). We also report results for UTD-NB and UTD-SVM (Rink and Harabagiu, 2012), which rely on lexical pattern classification based on Naïve Bayes and Support Vector Machine classifiers, respectively. UTD-LDA (Rink and Harabagiu, 2013) is another system presented by the same authors that casts the task as a selectional preferences one. Finally, we show the performance of Com (Zhila et al., 2013), a system that combines Word2vec, lexical patterns, and knowledge base information. Similarly to the word similarity experiments, we also report a baseline based on word embeddings (Word2vec) trained on the same corpus and with the same settings as SENSEMBED.

Results. Table 5 shows the performance of different systems in the task of relational similarity in terms of the Spearman correlation and MaxDiff score. A comparison of the results for Word2vec and SENSEMBED shows the advantage gained by moving from the word to the sense level. Among the comparison systems, Com attains the closest performance. However, we note that the system is a combination of several methods, whereas SENSEMBED is based on a single approach.

4.3 Analysis

In order to analyze the impact of the different components of our similarity measure, we carried out a series of experiments on our word similarity datasets. We show in Table 6 the experimental results in terms of Spearman correlation. Performance is reported for the two similarity measurement strategies, i.e., *closest* and *weighted*, and for different system settings with and without the expansion procedure (cf. Section 3.1) and *graph vicinity factor* (cf. Section 3.3.2). As our comparison baseline, we also report results for word embeddings, obtained using the Word2vec toolkit on the same corpus and with the same configuration (cf. Section 2.3) used for learning the sense embeddings (Word2vec in the Table). The rightmost column in the Table reports the mean performance weighted by dataset size. Word2vec$_{exp}$ is the word embeddings system in which the similarity of the two words is determined in terms of the closest word embeddings among all the corresponding synonyms obtained with the expansion procedure (cf. Section 3.1).

A comparison of word and sense embeddings in the vanilla setting (with neither the expansion procedure nor *graph vicinity factor*) indicates the consistent advantage gained by moving from word to sense level, irrespective of the dataset and the similarity measurement strategy. The consistent improvement shows that the semantic information provided more than compensates for the inherently imperfect disambiguation. Moreover, the results indicate the consistent benefit gained by introducing the *graph vicinity factor*, highlighting the fact that our combination of the complementary knowledge from sense embeddings and information derived from a semantic network is beneficial. Finally, note that the expansion procedure leads to performance improvement in most cases for sense embeddings. In direct contrast, the step proves harmful in the case of word embeddings, mainly due to their inability to distinguish individual word senses.

5 Related Work

Word embeddings were first introduced by Bengio et al. (2003) with the goal of statistical language modeling, i.e., learning the joint probability function of a sequence of words. The initial model was a Multilayer Perceptron (MLP) with two hidden layers: a shared non-linear and a regular hidden hyperbolic tangent one. Collobert and Weston (2008) deepened the original neural model by adding a convolutional layer and an extra layer for modeling long-distance dependencies. A significant contribution was later made by Mikolov et al. (2013a), who simplified the original model by removing the hyperbolic tangent layer and hence significantly speeding up the training process. Other related work includes GloVe (Pennington et al., 2014), which is an effort to make the vector dimensions in word embeddings explicit, and the approach of Bordes et al. (2013), which trains word embeddings on the basis of relationship information derived from WordNet.

Several techniques have been proposed for transforming word embeddings to the sense level. Chen et al. (2014) leveraged word embeddings in Word Sense Disambiguation and investigated the possibility of retrofitting embeddings with the resulting disambiguated words. Guo et al. (2014) exploited parallel data to automatically generate sense-annotated data, based on the fact that different senses of a word are usually translated to different words in another language (Chan and Ng, 2005). The automatically-generated sense-annotated data was later used for training sense-specific word embeddings. Huang et al. (2012) adopted a similar strategy by decomposing each word's single-prototype representation into multiple prototypes, denoting different senses of that word. To this end, they first gathered the context for all occurrences of a word and then used spherical K-means to cluster the contexts. Each cluster was taken as the context for a specific meaning of the word and hence used to train embeddings for that specific meaning (i.e., word sense). However, these techniques either suffer from low coverage as they can only model word senses that occur in the parallel data, or require manual intervention for linking the obtained representations to an existing sense inventory. In contrast, our approach enables high coverage and is readily applicable for the representation of word senses in widely-used lexical resources, such as WordNet, Wikipedia and Wiktionary, without needing to resort to additional manual effort.

6 Conclusions and Future Work

We proposed an approach for obtaining continuous representations of individual word senses, referred to as sense embeddings. Based on the proposed sense embeddings and the knowledge obtained from a large-scale lexical resource, i.e., BabelNet, we put forward an effective technique, called SENSEMBED, for measuring semantic similarity. We evaluated our approach on multiple datasets in the tasks of word and relational similarity. Two conclusions can be drawn on the basis of the experimental results: (1) moving from word to sense embeddings can significantly improve the effectiveness and accuracy of the representations; and (2) a meaningful combination of sense embeddings and knowledge from a semantic network can further enhance the similarity judgements. As future work, we intend to utilize our sense embeddings to perform WSD, as was proposed in Chen et al. (2014), in order to speed up the process and train sense embeddings on larger amounts of sense-annotated data.

Abstract

Contrasting meaning is a basic aspect of semantics. Recent word-embedding models based on *distributional semantics hypothesis* are known to be weak for modeling lexical contrast. We present in this paper the embedding models that achieve an F-score of 92% on the widely-used, publicly available dataset, the GRE “most contrasting word” questions (Mohammad et al., 2008). This is the highest performance seen so far on this dataset. Surprisingly at the first glance, unlike what was suggested in most previous work, where relatedness statistics learned from corpora is claimed to yield extra gains over lexicon-based models, we obtained our best result relying solely on lexical resources (Roget’s and WordNet)—corpora statistics did not lead to further improvement. However, this should not be simply taken as that distributional statistics is not useful. We examine several basic concerns in modeling contrasting meaning to provide detailed analysis, with the aim to shed some light on the future directions for this basic semantics modeling problem.

1 Introduction

Learning good representations of meaning for different granularities of texts is core to human language understanding, where a basic problem is representing the meanings of words. Distributed representations learned with neural networks have recently showed to result in significant improvement of performance on a number of language understanding problems (e.g., speech recognition and automatic machine translation) and on many non-language problems (e.g., image recognition). Distributed representations have been leveraged to represent words as in (Collobert et al., 2011; Mikolov et al., 2013).

Contrasting meaning is a basic aspect of semantics, but it is widely known that word embedding models based on *distributional semantics hypothesis* are weak in modeling this—contrasting meaning is often lost in the low-dimensional spaces based on such a hypothesis, and better models would be desirable.

Lexical contrast has been modeled in (Lin and Zhao, 2003; Mohammad et al., 2008; Mohammad et al., 2013). The recent literature has also included research efforts of modeling contrasting meaning in embedding spaces, leading to state-of-the-art performances. For example, Yih et al. (2012) proposed to use polarity-primed latent semantic analysis (LSA), called PILSA, to capture contrast, which was further used to initialize a neural network and achieved an F-score of 81% on the same GRE “most contrasting word” questions (Mohammad et al., 2008). More recently, Zhang et al. (2014) proposed a tensor factorization approach to solving the problem, resulting in a 82% F-score.

In this paper, we present embedding models that achieve an F-score of 92% on the GRE dataset, which outperforms the previous best result (82%) by a large margin. Unlike what was suggested in previous work, where relatedness statistics learned from corpora is often claimed to yield extra gains over lexicon-based models, we obtained this new state-of-the-art result relying solely on lexical resources (Roget’s and WordNet), and corpus statistics does not seem to bring further improvement. To provide a comprehensive understanding, we constructed our study in a framework that examines a number of basic concerns in modeling contrasting meaning. We hope our efforts would help shed some light on future directions for this basic semantic modeling problem.

2 Related Work

The terms *contrasting*, *opposite*, and *antonym* have different definitions in the literature, while sometimes they are used interchangeably. Following (Mohammad et al., 2013), in this paper we refer to *opposites* as word pairs that “have a strong binary incompatibility relation with each other or that are saliently different across a dimension of meaning”, e.g., *day* and *night*. *Antonyms* are a subset of opposites that are also gradable adjectives, with same definition as in (Cruse, 1986) as well. *Contrasting* word pairs have the broadest meaning among them, referring to word pairs having “some non-zero degree of binary incompatibility and/or have some non-zero difference across a dimension of meaning.” Therefore by definition, opposites are a subset of contrasting word pairs (refer to (Mohammad et al., 2013) for detailed discussions).

Word Embedding Word embedding models learn continuous representations for words in a low dimensional space (Turney and Pantel, 2010; Hinton and Roweis, 2002; Collobert et al., 2011; Mikolov et al., 2013; Liu et al., 2015), which is not new. Linear dimension reduction such as Latent Semantic Analysis (LSA) has been extensively used in lexical semantics (see (Turney and Pantel, 2010) for good discussions in vector space models.) Non-linear models such as those described in (Roweis and Saul, 2000) and (Tenenbaum et al., 2000), among many others, can also be applied to learn word embeddings. A particularly interesting model is stochastic neighbor embedding (SNE) (Hinton and Roweis, 2002), which explicitly enforces that in the embedding space, the distribution of neighbors of a given word to be similar to that in the original, uncompressed space. SNE can learn multiple senses of a word with a mixture component. Recently, neural-network based model such as those proposed by (Collobert et al., 2011) and (Mikolov et al., 2013) have attracted extensive attention; particularly the latter, which can scale up to handle large corpora efficiently.

Although word embeddings have recently showed to be superior in some NLP tasks, they are very weak in distinguishing contrasting meaning, as the models are often based on the well-known *distributional semantics hypothesis*—words in similar context have similar meanings. Contrasting words have similar context too, so contrasting meaning is not distinguished well in such representations. Better models for contrasting meaning is fundamentally interesting.

Modeling Contrasting Meaning Automatically detecting contrasting meaning has been studied in earlier work such as (Lin and Zhao, 2003; Mohammad et al., 2008; Mohammad et al., 2013). Specifically, as far as the embedding-based methods are concerned, PILSA (Yih et al., 2012) made a progress in achieving one of the best results, by priming LSA to encode contrasting meaning. In addition, PILSA was also used to initialize a neural network to get a further improvement on the GRE benchmark, where an F-score of 81% was obtained. Another recent method was proposed by (Zhang et al., 2014), called Bayesian probabilistic tensor factorization. It considered multidimensional semantic information, relations, unsupervised data structure information in tensor factorization, and achieved an F-score of 82% on the GRE questions. These methods employed both lexical resources and corpora statistics to achieve their best results. In this paper, we show that using only lexical resources to construct embedding systems can achieve significantly better results (an F-score of 92%). To provide a more comprehensive understanding, we constructed our study in a framework that examines a number of basic concerns in modeling contrasting meaning within embedding.

Note that sentiment contrast may be viewed as a specific case of more general semantic contrast or semantic differentials (Osgood et al., 1957). Tang et al. (2014) learned sentiment-specific embedding and applied it to sentiment analysis of tweets, which was often solved with more conventional methods (Zhu et al., 2014b; Kiritchenko et al., 2014a; Kiritchenko et al., 2014b).

3 The Models

We described in this section the framework in which we study word embedding for contrasting meaning. The general aim of the models is to enforce that in the embedding space, the word pairs with higher degrees of contrast will be put farther from each other than those of less contrast. How to learn this is critical. Figure 1 describes a very high-level view of the framework.

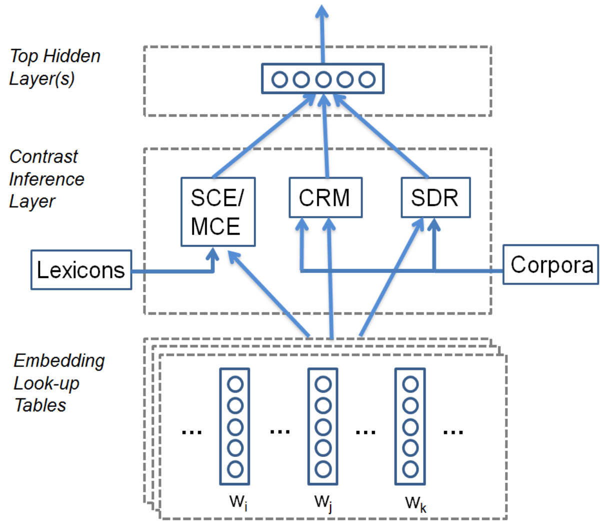

Figure 1: A high-level view of the contrasting embedding framework.

3.1 Top Hidden Layer(s)

It is widely recognized that contrasting words, e.g., *good* and *bad*, also intend to appear in similar context or co-occur with each other. For example, opposite pairs, special cases of contrasting words, tend to co-occur more often than chance (Charles and Miller, 1989; Fellbaum, 1995; Murphy and Andrew, 1993). Mohammad et al. (2013), in addition, proposed a *degree of contrast hypothesis*, stating that "if a pair of words, A and B, are contrasting, then their degree of contrast is proportional to their tendency to co-occur in a large corpus."

These suggest some non-linear interaction between distributional relatedness and the degree of contrast: the increase of relatedness correspond to the increase of both semantic contrast and semantic closeness; for example, they can form a U-shaped curve if one plots the word pairs on a two dimensional plane with y-axis denoting relatedness scores, while the most contrasting and (semantically) close pairs lie on the two side of the x-axis, respectively. In this paper, when combining word-pair distances learned by different components of the contrasting inference layer, we use some top hidden layer(s) to provide a non-linear combination. Specifically, we use two hidden layers, which is able to express complicated functions (Bishop, 2006). We use ten hidden units in each hidden layer.

3.2 Stochastic Contrast Embedding (SCE)

Hinton and Roweis (2002) proposed a stochastic neighbor embedding (SNE) framework. Informally, the objective is to explicitly enforce that in the learned embedding space, the distribution of neighbors of a given word w to be similar to the distribution of its neighbors in the original, uncompressed space.

In our study, we instead use the concept of "neighbors" to encode the contrasting pairs, and we call the model stochastic contrasting embedding (SCE), depicted by the left component of the *contrast inference layer* in Figure 1. The model is different from SNE in three respects. First, as mentioned above, "neighbors" here are actually contrasting pairs—we enforce that in the embedding space, the distribution of the contrasting "neighbors" to be close to the distribution of the "neighbors" in the original, higher-dimensional space. The probability of word w_k being contrasting neighbor of the given word w_i can be computed as:

$$p_1(w_k|w_i) = \frac{\exp(-d_{i,k}^2)}{\sum_{m \neq i}^{v} \exp(-d_{i,m}^2)} \qquad (1)$$

where d is some distance metric between w_i and w_k, and v is the size of a vocabulary.

Second, we train SCE using only lexical resources but not corpus statistics, so as to explore the behavior of lexical resources separately (we will use the relatedness modeling component below to model distributional semantics). Specifically, we use antonym pairs in lexical resources to learn *contrasting neighbors*. Hence in the original high-dimensional space, all antonyms of a given word w_i have the same probability to be its contrasting neighbors. That is, d in Equation (1) takes a binary score, with value *1* indicating an antonym pair and *0* not. In the embedding space, the corresponding probability of w_k to be the contrasting neighbor of w_i , denoted as $q_1(w_k|w_i)$, can be computed similarly with Equation (1). But since the embedding is in a continuous space, d is not binary but can be computed with regular distance metric such as euclidean and cosine. The objective is minimizing the KL divergence between $p(.)$ and $q(.)$.

Third, semantic closeness or contrast are not independent. For example, if a pair of words, A and B, are synonyms, and if the pair of words, A and C, are contrasting, then A and C is likely to be contrasting than a random chance. SCE considers both semantic contrast and closeness. That is, for a given word w_i, we jointly force that in the embedding space, its contrasting neighbors and semantically close neighbors to be similar to those in the original uncompressed space. These two objective functions are linearly combined with a parameter λ and are jointly optimized to learn one embedding. The value of λ is determined on the development questions of the GRE data. Later in Section 4, we will discuss how the training pairs of semantic contrast and closeness are obtained from lexical resources.

3.3 Marginal Contrast Embedding (MCE) [1]

In this paper, we use also another training criteria, motivated by the *pairwise ranking* approach (Cohen et al., 1998). The motivation is to explicitly enforce the distances between contrasting pairs to be larger than distances between unrelated word pairs by a margin, and enforce the distances between semantically close pairs to be smaller than unrelated word pairs by another margin. More specifically, we minimize the following objective functions:

$$Obj^{s}_{(mce)} = \sum_{(w_i,w_j)\in \mathbf{S}} \max\{0, \alpha - d_{i,r} + d_{i,j}\} \quad (2)$$

$$Obj^{a}_{(mce)} = \sum_{(w_i,w_k)\in \mathbf{A}} \max\{0, \beta - d_{i,k} + d_{i,r}\} \quad (3)$$

where $\mathbf{A}$ and $\mathbf{S}$ are the set of contrasting pairs and semantically close pairs in lexicons respectively; d denotes distance function between two words in the embedding space. The subscript r indicates a randomly sampled unrelated word. We call this model Marginal Contrasting Embedding (MCE).

Intuitively, if two words w_i and w_j are semantically close, the model maximizes Equation (2), which attempts to force the $d_{i,j}$ (distance between w_i and w_j) in the embedding space to be different from that of two unrelated words $d_{i,r}$ by a margin α. For each given word pair, we sample 100 random words during training. Similarly, if two words w_i and w_k are contrasting, the model maximizes Equation (3), which attempts to force the distance between w_i and w_k to be different from that of two unrelated words $d_{i,r}$ by a margin β. Same as in SCE, these two objective functions are linearly combined with a parameter λ and are jointly optimized to learn one embedding for each word. This joint objective function attempts to force the values of $d_{i,r}$ (distances of unrelated pairs) to be in between $d_{i,k}$ (distances of contrasting pairs) and $d_{i,j}$ (distances of semantically close pairs) by two margins.

3.4 Corpus Relatedness Modeling (CRM)

As discussed in previous work and above as well, relatedness obtained with corpora based on distributional hypothesis interplays with semantic closeness and contrast. Mohammad et al. (2013) proposed a *degree of contrast hypothesis*, stating that "if a pair of words, A and B, are contrasting, then their degree of contrast is proportional to their tendency to co-occur in a large corpus." In embedding, such dependency can be used to help measure the degree of contrast. Specifically, we use the skip-gram model (Mikolov et al., 2013) to learn the relatedness embedding.

As discussed above, through the top hidden layers, the word embedding and distances learned in SCE/MCE and CRM, together with that learned with SDR below, can be used to predict the GRE "most contrasting word"' questions. With enough GRE data, the prediction error may be backpropagated to directly adjust or learn embedding in the look-up tables. However, given the limited size of the GRE data, we only employed the top hidden layers to non-linearly merge the distances between a word pair that are obtained within each of the modules in the Contrast Inference Layer. We did not backpropagate the errors to fine-tune already learned word embeddings.

Note that embeddings in the look-up tables were learned independently in different modules in the contrast inference layer, e.g., in SCE, MCE and CRM, respectively. And in each module, given the corresponding objective functions, unconstrained optimization (e.g., in the paper SGD) was used to find embeddings that optimize the corresponding objectives. The embeddings were then used out-of-box and not further fine-tuned. Depending on experiment settings, embeddings learned in each module are either used separately or jointly (through the top hidden lay) to predict test cases.

[1] We made the code of MCE available at https://github.com/lukecq1231/mce, as MCE achieved the best performance according to the experimental results described later in this paper.

More details will be discussed in the experiment section below.

3.5 Semantic Differential Reconstruction (SDR)

Using factor analysis, Osgood et al. (1957) identified three dimensions of semantics that account for most of the variation in the connotative meaning of adjectives. These three dimensions are *evaluative* (good-bad), *potency* (strong-weak), and *activity*(active-passive). We hypothesize that such information should help reconstruct contrasting meaning.

The General Inquirer lexicon *(*Stone1966) represents these three factors but has a limited coverage. We used the algorithm of (Turney and Littman, 2003) to extend the labels to more words with Google one billion words corpus (refer to Section 4 for details). For example, to obtain the *evaluative* score for a candidate word w, the point-wise mutual information (PMI) between w and a set of seed words $eval^{+}$ and $eval^{-}$ are computed respectively, and the *evaluative* value for w is calculated with:

$$eval(w) = PMI(w, eval^{+}) - PMI(w, eval^{-}) \tag{4}$$

where $eval^{+}$ contains predefined positive *evaluative* words, e.g., *good, positive, fortunate*, and *superior*, while $eval^{-}$ includes negative *evaluative* words like *passive, slow, treble,* and *old*. The seed words were selected as described in (Turney and Littman, 2003) to have a good coverage and to avoid redundancy at the same time. Similarly, the *potency* and *activity* scores of a word can be obtained. The distances of a word pair on these three dimensions can therefore be obtained.

4 Experiment Set-Up

Data Our experiment uses the "most contrasting word" questions collected by Mohammad et al. (2008) from Graduate Record Examination (GRE), which was originally created by Educational Testing Service (ETS). Each GRE question has a target word and five candidate choices; the task is to identify among the choices the most contrasting word with regard to the given target word. The dataset consists of a development set and a test set, with 162 and 950 questions, respectively.

As an example from (Mohammad et al., 2013), one of the questions has the target word *adulterate* and the five candidate choices: (A) *renounce*, (B) *forbid*, (C) *purify*, (D) *criticize*, and (E) *correct*. While in this example the choice *correct* has a meaning that is contrasting with that of *adulterate*, the word *purify* is the gold answer as it has the greatest degree of contrast with *adulterate*.

Lexical Resources In our work, we use two publicly available lexical resources, *WordNet* (Miller, 1995) (version 3.0) and the *Roget's Thesaurus* (Kipfer, 2009). We utilized the labeled antonym relations to obtain more contrasting pairs under the contrast hypothesis (Mohammad et al., 2013), by assuming a contrasting pair is related to a pair of opposites (antonyms here). Specifically in WordNet, we consider the word pairs with relations other than antonym as semantically close. In this way, we obtained a thesaurus containing 83,118 words, 494,579 contrasting pairs, and 368,209 close pairs. Note that we did not only use synonyms to expand the contrasting pairs. We will discuss how this affects the performance in the experiment section.

In the Roget's Thesaurus, every word or entry has its synonyms and/or antonyms. We obtained 35,717 antonym pairs and 346,619 synonym pairs, which consist of 43,409 word types. The antonym and synonym pairs in Roget's were combined with contrasting pairs and semantically close pairs in WordNet, respectively. And in total, we have 92,339 word types, 520,734 antonym pairs, and 646,433 close pairs.

Google Billion-Word Corpus The corpus used in our experiment for modeling lexical relatedness in the CRM component was Google one billion word corpus (Chelba et al., 2013). Normalization and tokenization were performed using the scripts distributed from https://code.google.com/p/1-billion-word-language-modeling-benchmark/, and sentences were shuffled randomly. We computed embedding for a word if its count in the corpus is equal to or larger than five, with the method described in Section 3.4. Words with counts lower than five were discarded.

Evaluation Metric Same as in previous work, the evaluation metric is F-score, where *precision* is the percentage of the questions answered correctly over the questions the models attempt to answer, and *recall* is the percentage of the questions that are answered correctly among all questions.

5 Experiment Results

In training, we used stochastic gradient descent (SGD) to optimize the objective function, and the dimension of embedding was set to be 200. In MCE (Equation 2 and 3) the margins α and β are both set to be 0.4. During testing, when using SCE or MCE embedding to answer the GRE questions, we directly calculated distances for a pair between a question word and a candidate choice in these two corresponding embedding spaces to report their performances. We also combined SCE/MCE with other components in the contrast inference layer, for which we used ten-fold cross validation to tune the weights of the top hidden layers on nine fold and test on the rest and repeated this for ten times to report the results. As discussed above, errors were not backpropagated to modify word embedding.

5.1 General Performance of the Models

The performance of the models are showed in Table 1. For comparison, we list the results reported in (Yih et al., 2012) and (Zhang et al., 2014). The table shows that on the GRE dataset, both SCE (a 90% F-score) and MCE (92%) significantly outperform the previous best results reported in (Yih et al., 2012) (81%) and (Zhang et al., 2014) (82%). The F-score of MCE outperforms that of SCE by 2%, which suggests the ranking criterion fits the dataset better. In our experiment, we found that the MCE model achieved robust performances on different distance metrics, e.g., the cosine similarity and Euclidean distance. In the paper, we present the results with cosine similarity. SCE is slightly more sensitive to distance metrics, and the best performing metric on the development set is inner product, so we chose that for testing.

Unlike what was suggested in the previous work, where semantics learned from corpus is claimed to yield extra gains in performance, we obtained this result by using solely lexical resources (Roget's and WordNet) with SCE and MCE. Using corpus statistics that model *distributional hypothesis* (MCE+CRM) and utilize semantic differential categories (MCE+CRM+SDR) does not bring further improvement here (they are useful in the experiments discussed below in Section 5.3).

5.2 Roles of Lexical Resources

To provide a more detailed comparison, we also present lexicon lookup results, together with those reported in (Zhang et al., 2014) and (Yih et al., 2012). For our lookup results and those copied here from (Zhang et al., 2014), the methods do not randomly guess an answer if the target word is in the vocabulary but none of the choices are, while the results of (Yih et al., 2012) randomly guess an answer in this situation. The Encarta thesaurus used in (Yih et al., 2012) is not publicly available, so we did not use it in our experiments. We due the differences among the lookup results on WordNet (WordNet lookup) to the differences in preprocessing as well as the way we expanded indirect contrasting word pairs. As described in Section 4, we utilized all relations other than antonym pairs to expand our indirect antonym pairs. These also have impact on the W&R lookup results (WordNet and Roget's pairs are combined). For both settings, our expansion resulted in much better performances.

Whether the differences between the F-scores of MCE/SCE and that reported in (Zhang et al., 2014) and (Yih et al., 2012) are also due to the differences in expanding indirect pairs? To answer this, we downloaded the word pairs that Zhang et al. (2014) used to train their models,[2] but we used them to train our MCE. The result are presented in Table 1 and the F-score on test set is 91%, which is only slightly lower than MCE using our lexicon. So the extension is very helpful for lookup methods, but the MCE appears to be able to cover such information by itself.

SCE and MCE learn contrasting meaning that is not explicitly encoded in lexical resources. The experiment results show that such implicit contrast can be recovered by jointly learning the embedding by using contrasting words and other semantically close words.

To help better understand why corpus statistics does not further help SCE and MCE, we further demonstrate that most of the target-gold-answer pairs in the GRE test set are connected by short paths (with length between 1 to 3). More specifically, based on breadth-first search, we found the nearest paths that connect target-gold-answer pairs, in the graph formed by WordNet and Roget's—each word is a vertex, and contrasting words and semantically close words are

Table 1: Results on the GRE "most contrasting words" questions.

connected with these two types of edges respectively. Then we require the shortest path must have one and only one contrasting edge. Word pairs that cannot be connected by such paths are regarded to have an infinite length of distance.

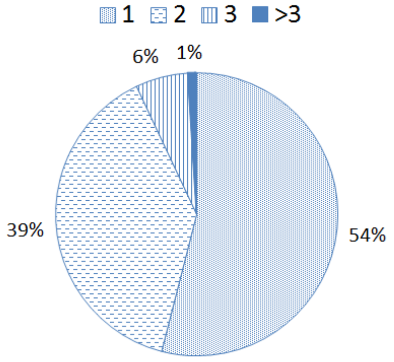

Figure 2: Percentages of target-gold-answer word pairs, categorized by the shortest lengths of paths connecting them.

The pie graph in Figure 2 shows the percentages of target-gold-answer word pairs, categorized by the lengths of shortest paths defined above. We can see that in the GRE data, the percentage of paths with a length larger than three is very small (1%). It seems that SCE and MCE can learn this very well. Again, they force semantically close pairs to be close in the embedding spaces which "share" similar contrasting pairs.

Figure 3 draws the envelope of histogram of cosine distance between all target-choice word pairs in the GRE test set, calculated in the embedding space learned with MCE. The figure intuitively shows how the target-gold-answer pairs (most contrasting pairs) are discriminated from the other target-choice pairs. We also plot the MCE results without using the random sampling depicted in Equation (2) and Equation (3), showing that discriminative power dramatically dropped. Without the sampling, the F-score achieved on the test data is 83%.

5.3 Roles of Corpus-based Embedding

However, the findings presented above should not be simply taken as that distributional hypothesis is not useful for learning lexical contrast. Our results and detailed analysis has showed it is due to the good coverage of the manually created lexical resources and the capability of the SCE and

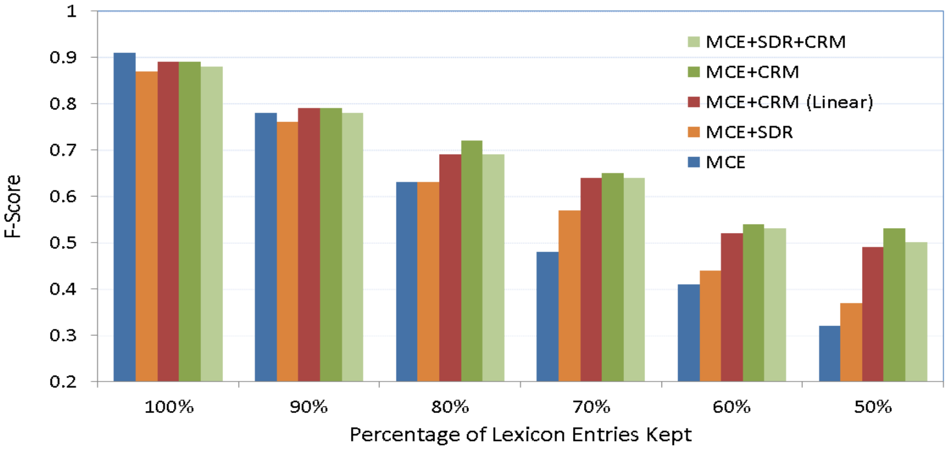

Figure 4: The effect of removing lexicon items.

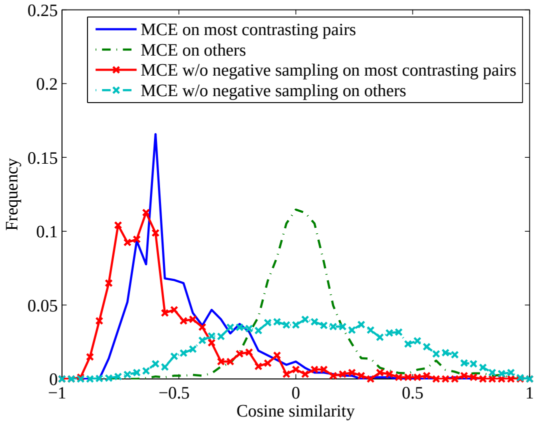

Figure 3: The envelope of histogram of cosine distance between word pair embeddings in GRE test set.

MCE models in capturing indirect semantic relations. There may exist circumstances where the coverage is be lower, e.g., for resource-poor languages or social media text where (indirect) out-of-vocabulary pairs may be frequent.

To simulate the situations, we randomly removed different percentages of words from the combined thesaurus used above in our experiments, and removed all the corresponding word pairs. The performances of different models are showed in Figure 4. It is observed that as the out of vocabulary (OOV) becomes more serious, the MCE suffered the most. Using the semantic differential (MCE+SDR) showed to be helpful as 50% to 70% lexicon entries are kept. Considering relatedness learned from corpus together with MCE (MCE+CRM), i.e., combining MCE distances with CRM distances for target-choice pairs, yielded robust performance—the F-score of MCE+CRM drops significantly slower than that of MCE, as we removed lexical entries. We also combined MCE distances and CRM distances linearly (MCE+CRM (linear)), with a coefficient determined with the development set. It showed a performance worse than that of MCE+CRM when 50%–80% entries kept, while as discussed above, MCE+CRM combines the two parts with the non-linear top layers. In general, using corpora statistics make the models more robust as OOV becomes more serious. It deserves to note that the use of corpora here is rather straightforward; more patterns may be learned from corpora to capture contrasting expressions as discussed in (Mohammad et al., 2013). Also, context such as negation may change contrasting meaning, e.g., sentiment contrast (Kiritchenko et al., 2014b; Zhu et al., 2014a), in a dramatic and complicated manner, which has been considered in learning sentiment contrast (Kiritchenko et al., 2014b).

6 Conclusions

Contrasting meaning is a basic aspect of semantics. In this paper, we present a new state-of-the-art result, a 92% F-score, on the GRE dataset created by (Mohammad et al., 2008), which is widely used as the benchmark for modeling lexical contrast. The result reported here outperforms the best reported in previous work (82%) by a large margin. Unlike what was suggested in most previous work, we show that this performance can be achieved without relying on corpora statistics. To provide a more comprehensive understanding, we constructed our study in a framework that examines a number of concerns in modeling contrasting meaning. We hope our work could help shed some light on future directions on this basic semantic problem.

From our own viewpoints, creating more evaluation data for measuring further progress in contrasting-meaning modeling, e.g., handling real OOV issues, is interesting to us. Also, the degree of contrast may be better formulated as a regression problem rather than a classification problem, in which finer or even real-valued annotation would be desirable.

Joint Models of Disagreement and Stance in Online Debate

Abstract

Online debate forums present a valuable opportunity for the understanding and modeling of dialogue. To understand these debates, a key challenge is inferring the stances of the participants, all of which are interrelated and dependent. While collectively modeling users' stances has been shown to be effective (Walker et al., 2012c; Hasan and Ng, 2013), there are many modeling decisions whose ramifications are not well understood. To investigate these choices and their effects, we introduce a scalable unified probabilistic modeling framework for stance classification models that 1) are collective, 2) reason about disagreement, and 3) can model stance at either the author level or at the post level. We comprehensively evaluate the possible modeling choices on eight topics across two online debate corpora, finding accuracy improvements of up to 11.5 percentage points over a local classifier. Our results highlight the importance of making the correct modeling choices for online dialogues, and having a unified probabilistic modeling framework that makes this possible.

1 Introduction

Understanding stance and opinion in dialogues can provide critical insight into the theoretical underpinnings of discourse, argumentation, and sentiment. Systems for predicting the stances of individuals can potentially have positive social impact and are of practical interest to non-profits, governmental organizations, and companies. For example, stance predictions may be used to target public awareness and advocacy campaigns, direct political fundraising and get-out-the vote efforts, and improve personalized recommendations.

Dialogue Turns	Stance
User 1: 18. That's the smoking age thats the shooting age. Why do you think they call it ATF?	ANTI
User 2: Shooting age? I know 7 year old shooters. 18 should be the gun purchasing age, but there is really no "shooting" age.	ANTI
User 1: I know. I was just pointing out that the logic used to propose a 21 year "shooting age" was inconsistent.	ANTI
User 2: I see. I dont think its really fair that you can join the army at 18 and use handguns and military weapons, but you cant purchase a handgun until 21.	ANTI

Figure 1: Example of a debate dialogue turn between two users on the *gun control* topic, from 4FORUMS.COM.

Online debate websites are a particularly rich source of argumentative dialogic data (Fig. 1). On these websites, users debate and share their opinions on a variety of social and political issues. Previous work (Somasundaran and Wiebe, 2010; Walker et al., 2012c) has shown that stance classification in online debates is a challenging problem. While collective approaches that jointly predict user stance seem promising (Walker et al., 2012c; Hasan and Ng, 2013), the rich structure of online debate forums necessitates many modeling choices. For example, users publish opinions and reply and respond to each others' posts. In so doing, they may agree or disagree with either all or a portion of another user's post, suggesting that collective classifiers for stance may benefit from text-based disagreement modeling. Furthermore, one can model stance either at the author level—assuming that an author's stance is based on all of their posts on a topic (Burfoot et al., 2011)—or at

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 116–125,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

the post level—assuming that an author's stance is post-specific and may vary across posts (Hasan and Ng, 2013). These decisions can drastically change the nature of stance models, so understanding their implications is critical.

In this paper, we develop a flexible modeling framework for stance classification using probabilistic soft logic (PSL) (Bach et al., 2013; Bach et al., 2015), a recently introduced probabilistic modeling framework.[1] PSL is a probabilistic programming system that allows models to be specified using a declarative, rule-like language. The resulting models are a special form of conditional random field, called a hinge-loss Markov random field, which admits highly scalable exact inference (Bach et al., 2013). Modeling stance in large, richly connected online debate forums requires a careful exploration of many modeling choices. This complex domain especially benefits from PSL's flexibility and scalability. PSL makes it easy to develop model variations and extensions, as one can readily incorporate new factors capturing additional intuitions about dependencies in a domain.

We evaluate our models on data from two debate sites, 4FORUMS and CREATEDEBATE (Walker et al., 2012b; Hasan and Ng, 2013), which we describe in detail in Section 2. Our experimental results show that there are important ramifications of several modeling decisions, including whether to use collective or non-collective models, to represent stance at the post level or the author level, and how to model disagreement. We find that with appropriate modeling choices, our approach leads to improvements of up to 11.5 percentage points of accuracy over simple classification approaches.

Our contributions include (1) a flexible, unified framework for modeling online debates, (2) extensive experimental study of many possible models on eight forum datasets, collected across two different debate websites, and (3) general modeling recommendations resulting from our empirical studies.

2 Online Debate Forums

Online debate forums represent richly structured argumentative dialogues. On these forums, users debate with each other in discussion threads on a variety of topics or issues, such as *gun control*, *gay marriage*, and *marijuana legalization*. Each discussion consists of a number of posts, which are short text documents authored by users of the forum. A post is either a reply to a previous post, or it is the start (root) of a thread. As users engage with each other, a thread branches out into a tree of argumentative interactions between the users. Forum users often post numerous times and across multiple discussions and topics, which creates a richly structured interaction graph. Online debates present different challenges than more controlled dialogic settings such as congressional debates. Posts are short and informal, there is limited external information about authors, and debate topics admit many modes of argumentation ranging from serious, to tangential, to sarcastic. The reply graph in online debates also has substantially different semantics to networks in other debate settings, such as the graph of speaker mentions in congressional debates. To illustrate this setting, Fig. 1 shows an example dialogue between two users who are debating their opinions on the topic of gun control.

In the context of online debate forums, *stance classification* (Thomas et al., 2006; Somasundaran and Wiebe, 2009) is the task of assigning stance labels with respect to a discussion topic, either at the level of the user or the level of the post. Stance is typically treated as a binary classification problem, with labels PRO and ANTI. In Fig. 1, both users' stances toward gun control are ANTI.

Previous work on stance in online debates has shown that contextual information given by reply links is important for stance classification (Walker et al., 2012a), and that collective classification often outperforms methods which treat each post independently. Hasan and Ng (2013) use conditional random fields (CRFs) to encourage opposite stances between sequences of posts, and Walker et al. (2012c) use MaxCut over explicitly given rebuttal links between posts to separate them into PRO and ANTI clusters. Sridhar et al. (2014) use hinge-loss Markov random fields (HL-MRFs) to encourage consistency between post level stance labels and observed post-level textual agreements and disagreements.

While the first two approaches leverage rebuttal or reply links, they model reply links as being indicative of opposite stances. However, as shown in Fig. 1, responses—even rebuttals—can occur be-

[1] PSL is an open-source Java toolkit, available here: http://psl.cs.umd.edu.

tween users with the same stance, which suggests the benefit of a more nuanced treatment of reply links. The approach of Sridhar et al. (2014) considers text-based agreement annotations between posts, though it requires that reply links are labeled. Accurate reply polarity labels are likely to be as expensive to obtain as the stance labels that we aim to predict. Noisy or sparse reply labels are cheaper, though likely to reduce performance. In this work, we show how to reason over uncertain reply label predictions to improve stance classification.

	4Forums	CreateDebate
Users per topic	336	311
Posts per user, per topic	19	4
Words per user, per topic	2511	476

%Post-level reply links have opposite-stance users	71.6	73.9
%Author-level reply links have opposite-stance users	52.0	68.9

Table 1: Structural statistics averages for 4Forums and CreateDebate.

Also in the online debate setting, Hasan and Ng (2014) show the benefits of joint modeling to classify post-level stance and the authors' reasons for their stances. In contrast, in this work we focus on the dependencies between stance and polarity of replies.

In the context of opinion subgroup discovery, Abu-Jbara and Radev (2013) demonstrate the effectiveness of clustering users by opinion-target similarity. In contrast, Murakami and Raymond (2010) use simple recurring patterns such as "*that's a good idea*" to categorize reply links as *agree*, *disagree* or *neutral*, prior to using MaxCut for subgroup clustering of comment streams on government websites. This approach improves over a MaxCut approach that casts all reply links as disagreements. Building on this work, Lu et al. (2012) model unsupervised discovery of supporting and opposing groups of users for topics in online military forums. They improve upon a MaxCut baseline by formulating a linear program (LP) to combine multiple textual and reply-link signals, suggesting the benefits of jointly modeling textual and reply-link features.

In a different line of work, while Somasundaran and Wiebe (2010) do not use relational information between users or posts, their approach shows the benefit of modeling opinions and their targets at a fine-grained level using relational sentiment analysis techniques. Similarly, Wang and Cardie (2014) demonstrate the effectiveness of using sentiment analysis to identify disputes on Wikipedia Talk pages. Boltužić and Šnajder (2014) and Ghosh et al. (2014) study various linguistic features to model stance and agreement interactions respectively.

In the congressional debate setting, approaches using CRFs and similar collective techniques such as minimum-cut have also leveraged reply link polarity for improvements in stance classification (Thomas et al., 2006; Bansal et al., 2008; Balahur et al., 2009; Burfoot et al., 2011). However, these methods rely heavily on features specific to the congressional setting in order to predict link polarity, and make little use of textual features. In contrast, Abbott et al. (2011) use a range of linguistic features from the text of posts and their parents to classify agreement or disagreement between posts on the online debate website 4Forums.com, without the goal of classifying stance.

In this work, we study datasets from two online debate websites: 4Forums.com, from the Internet Argument Corpus (Walker et al., 2012b), and CreateDebate.com (Hasan and Ng, 2013). Table 1 shows statistics about these datasets including the average number of users per discussion topic and average number of posts authored. The best stance classification accuracy to date for online debate forums ranges from 70.1% on ConvinceMe.net to 75.4% on CreateDebate.com (Walker et al., 2012c; Hasan and Ng, 2013). The web interface for ConvinceMe.net enforces opposite stances for reply posts, making this dataset inapplicable for text-based disagreement modeling, and so we do not consider it in our experiments. In the more typical online debate forum corpora that we study, the presence of a reply, or even a textual disagreement between posts, does not necessarily indicate opposite stance (e.g. in gun control debates on 4Forums, 23% of disagreements correspond with same stance).

For our unified framework, we specify a hinge-loss Markov random field to reason jointly about stance and reply-link polarity labels. A closely related line of work focuses on improving structured prediction with domain knowledge modeled as constraints in the objective function (Chang et al., 2012; Ganchev et al., 2010; Mann and McCallum, 2010). Though more often used in semi-supervised settings, constraint-based learning can be especially appropriate for supervised learning when commonly used feature functions for linear models do not capture the richness of the data. Our HL-MRF formulation admits highly expressive features while maintaining a convex objective, thereby enjoying both tractability and a fully probabilistic interpretation.

3 Modeling Choices

We face multiple modeling decisions that may impact predictive performance when classifying stance in online debates. A key contribution of this work is the exploration of the ramifications of these choices. We consider the following variations on modeling: collective (**C**) versus local (**L**) classifiers, whether to explicitly model disagreement (**D**), and author-level (**A**) versus post-level (**P**) models.

Collective versus Local. Both collective and non-collective methods for stance prediction require a strong local text classifier. The methods proposed in this paper build upon the state-of-the-art local classification approach of Walker et al. (2012a), which trains a supervised classifier using features including n-grams, lexical category counts, and text lengths. We use logistic regression for the local classifier. These models will be referred to as *local* (**L**). In *collective* (**C**) classification approaches for stance prediction, the stance labels are all predicted jointly, leveraging relationships along the graph of replies. The simplest way to make use of reply links is to encode that the stance of posts (or authors) that reply to each other is likely to be opposite (Walker et al., 2012c; Hasan and Ng, 2013). Collective approaches attempt to find the most likely joint stance labeling that is consistent with both the local classifier's predictions and the alternation of stance along response threads. The alternating stance assumption is not necessarily a hard constraint, and may potentially be overridden by the local predictions. **C** and **L** models can be constructed with **A** or **P**-level granularity as described below, resulting in four modeling combinations.

Modeling Disagreement. As seen in Fig. 1 and Table 1, the assumption that reply links correspond to opposite stance is not always correct. This suggests the potential benefit of more nuanced models of agreement and disagreement. A natural disagreement modeling approach is to predict the polarity of reply links jointly with stance.

There are two variants of reply link polarity to consider. In *textual disagreement*, replying posts are coded as expressing agreement or disagreement with the text of the parent post. This may not correspond to a disagreement in stance *relative to the thread topic*. Some forum interfaces support user self-labeling of post reply links as rebuttals or agreements, thereby explicitly providing textual disagreement labels for posts. Alternatively, in the *stance disagreement* variant, reply links denote either same or opposite *stance* between users (posts). In Fig. 1, User 1 and User 2 disagree in text but have the same stance. For collective modeling of stance and disagreement, it is useful to consider the stance disagreement variant which identifies opposite and same-stance reply links, and jointly encourage stance predictions to be consistent with the disagreement predictions.

As with the local classification of stance, we can construct local classifiers for stance disagreement. In this work, for each reply link instance, we use a copy of the local stance classification features for each author/post at the ends of the reply link. The linguistic features further include discourse markers such as "actually" and "because" from the disagreement classifier of Abbott et al. (2011). Additionally, we use textual disagreement as a feature for stance disagreementwhen available. When reply links are not explicitly labeled as rebuttals or agreements, or only rebuttals are known, we instead predict textual disagreement using the features given above, trained on a separate data set with textual-disagreement labels.

Finally, with a stance disagreement classifier in hand, we can build collective models that predict stance based on predicted stance disagreement polarity. We denote these models as *disagreement* (**D**). When applied at one of **A** or **P**-level modeling, this yields two more possible modeling configurations. These models are certainly more complex than others we consider, but their design is consistent with intuition about the nature of discourse, so the added complexity may yield better accuracy.

All models:		**Collective models only:**		**Disagreement models only:**	
localPro(X1)	→ *pro*(X1)	*disagree*(X1, X2) ∧ *pro*(X1)	→ ¬ *pro*(X2)	*localDisagree*(X1, X2)	→ *disagree*(X1, X2)
¬ *localPro*(X1)	→ ¬ *pro*(X1)	*disagree*(X1, X2) ∧ ¬ *pro*(X1)	→ *pro*(X2)	¬ *localDisagree*(X1, X2)	→ ¬ *disagree*(X1, X2)
		¬ *disagree*(X1, X2) ∧ *pro*(X1)	→ *pro*(X2)	*pro*(X1) ∧ ¬ *pro*(X2)	→ *disagree*(X1, X2)
		¬ *disagree*(X1, X2) ∧ ¬ *pro*(X1)	→ ¬ *pro*(X2)	*pro*(X1) ∧ *pro*(X2)	→ ¬ *disagree*(X1, X2)
		disagree(X1, X2)	= 1	¬ *pro*(X1) ∧ ¬ *pro*(X2)	→ ¬ *disagree*(X1, X2)

Figure 2: PSL rules to define the collective classification models, both for post-level and author-level models. Each X is an author or a post, depending on the level of granularity that the model is applied at. The *disagree*(X_1, X_2) predicates apply to post reply links, and to pairs of authors connected by reply links.

Author-Level versus Post-Level. When modeling debates, stance classifiers can predict either the stance of a debate participant (i.e. an *author* (**A**)) (Burfoot et al., 2011), or the stance expressed by a specific dialogue act (i.e. a *post* (**P**)) (Hasan and Ng, 2013). The choice of prediction target may depend on the downstream goal, such as user modeling or the study of the dialogic expression of disagreement. From a philosophical perspective, authors are individuals who hold opinions, while posts are not. A post is simply a piece of text which may or may not express the opinions of its author.

Nevertheless, given a prediction target, either author or post, it may be beneficial to consider modeling at a different level of granularity. For example, Hasan and Ng (2013) find that post-level prediction accuracy can be improved by "clamping" all posts by a given author to the same stance in order to smooth their labels. Alternatively, author-level predictions may potentially be improved by first treating each post separately, thereby effectively giving a classifier more training examples, i.e. the number of *posts* instead of the number of *authors*. With this procedure, a final author-level prediction can be obtained by averaging the predictions over the posts for the author, trading the noisiness of post-level instances against the smoothing afforded by the final aggregation. When designing a stance classifier, the modeler must decide the level of granularity for the prediction target and find the best model therein.

4 A Collective Classification Framework

To study these choices, we build a flexible stance classification framework that implements the above variations using probabilistic soft logic (PSL) (Bach et al., 2015; Bach et al., 2013), a recently introduced probabilistic programming system. Like other probabilistic modeling frameworks, notably Markov logic (Richardson and Domingos, 2006), PSL uses a logic-like language for defining the potential functions for a conditional random field. However, unlike Markov logic, PSL makes inference tractable, even in the loopy author-level networks and the very large post-level networks of online debates.

PSL's tractability arises from the use of a special class of conditional random field models referred to as hinge-loss MRFs (HL-MRFs), which admit efficient, scalable and exact maximum a posteriori (MAP) inference (Bach et al., 2013). These models are defined over continuous random variables, and MAP inference is a convex optimization problem over these variables. Formally, a hinge-loss MRF defines a probability density function of the form

$$P(\mathbf{Y}|\mathbf{X}) = \frac{1}{\mathcal{Z}} \exp\Big(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y}, \mathbf{X}) \Big)\,, \quad (1)$$

where the entries of $\mathbf{Y}$ and $\mathbf{X}$ are in $[0, 1]$, λ is a vector of weight parameters, $\mathcal{Z}$ is a normalization constant, and

$$\phi_r(\mathbf{Y}, \mathbf{X}) = (\max\{l_r(\mathbf{Y}, \mathbf{X}), 0\})^{\rho_r} \qquad (2)$$

is a *hinge-loss potential* specified by a linear function l_r and optional exponent $\rho_r \in \{1, 2\}$. Given a collection of first-order PSL rules, each instantiation of the rules maps to a hinge-loss potential function as in Equation 2, and the potential functions define an HL-MRF model. For example, $a \Rightarrow b \triangleq \max(a - b, 0)$, where a and b are ground variables, and $\max(a - b, 0)$ is a convex relaxation of logical implication, and which can be understood as its *distance to satisfaction*. For a full description of PSL, see (Bach et al., 2015).

The models we introduce are specified by the PSL rules in Fig. 2, with both post-level and author-level models following the same design. We denote the different modeling choices with the letters defined in Section 3. First, local logistic regression classifiers output stance probabilities based on textual features of posts or authors. All of the models begin with these real-valued stance predictions, encoded by the observed predicate *localPro*(X_i). The rules listed for all models encourage the inferred global predictions *pro*(X_i) to match these local predictions.

This defines the *local classification* models **L**, which are HL-MRFs with node potentials and no edge potentials, and which are equivalent to the local classifiers. The collective models extend the **L** models by adding edge potentials which encourage the stance labels to respect disagreement relationships along reply links. Specifically, every reply link between authors (for author-level models) or between posts (for post-level models) x_1 and x_2 is associated with a latent variable *disagree*$(x_1,\ x_2)$. The rules encourage the global stance variables to respect the polarity of the disagreement variables (same stance, or opposite stance) and while also trying to match the stance classifiers. For the models that do not explicitly model disagreement, it is assumed that every reply edge constitutes a disagreement, i.e. *disagree*$(x_1, x_2) = 1$. These models are denoted **C**.

Otherwise, the disagreement variables are encouraged to match binary-valued predictions from the local disagreement classifiers. We binarize the predictions of the disagreement classifiers to encourage propagation. The disagreement variables are modeled jointly with the stance variables, and label information propagates in both directions between stance and disagreement variables. The full joint stance/disagreement collective models are denoted **D**. In the following, the models are denoted by pairs of letters according to their collectivity level and modeling granularity. For example, **AC** denotes collective classification performed at the author level, without joint modeling of disagreement. To train these models and use them for prediction, weight learning and MAP inference are performed using the structured perceptron algorithm and ADMM algorithm of Bach et al. (2013).

5 Experimental Evaluation

The goals of our experiments were to validate the proposed collective modeling framework, and to make substantive conclusions about the merits of the different possible modeling options described in Section 3. To this end, we evaluated the models on eight topics from 4FORUMS.COM (Walker et al., 2012b) and CREATEDEBATE.COM (Hasan and Ng, 2013), for classification tasks at both the author level and the post level. With comparison to Hasan and Ng (2013), our collective models (**C**) are essentially equivalent to their CRF, up to the form of the CRF potential function, which is not explicitly specified in the paper. A further goal of our experiments was to determine whether the modeling options in our more general CRF could improve performance over models with this structure.

On average, each topic-wise data set contains hundreds of authors and thousands of posts. The 4FORUMS data sets are annotated for stance at the author level, while CREATEDEBATE has stance labels at the post level. To perform post-level evaluations on 4FORUMS we apply author labels to the posts of each author, and on CREATEDEBATE we computed author labels by selecting the majority label of their posts. For 4FORUMS, since post-level stance labels correspond directly to author-level stance labels, we use averages of post-level predictions as the local classifier output for authors. Section 2 includes an overview of these debate forum data sets.

In the experiments, classification accuracy was estimated via five repeats of 5-fold cross-validation. In each fold, we ran logistic regression using the scikit-learn software package,[2] using the default settings, except for the L1 regularization trade-off parameter C which was tuned on a within-fold hold-out set consisting of 20% of the discussions within the fold. For the collective models, weight learning was performed on the same in-fold tuning sets. We trained via 700 iterations of structured perceptron, and ran the ADMM MAP inference algorithm to convergence at test time. On average, weight learning and inference took around 1 minute per fold.

The full results for author-level and post-level predictions are given in Table 2 and Table 3, respectively. In the tables, entries in bold identify statistically significant differences from the local classifier baseline under a paired t-test with significance level $\alpha = 0.05$. These results are summarized in Fig. 3, which shows box plots for the six possible models, computed over the final cross-validated accuracy scores of each of the four data

[2] Available at `http://scikit-learn.org/`.

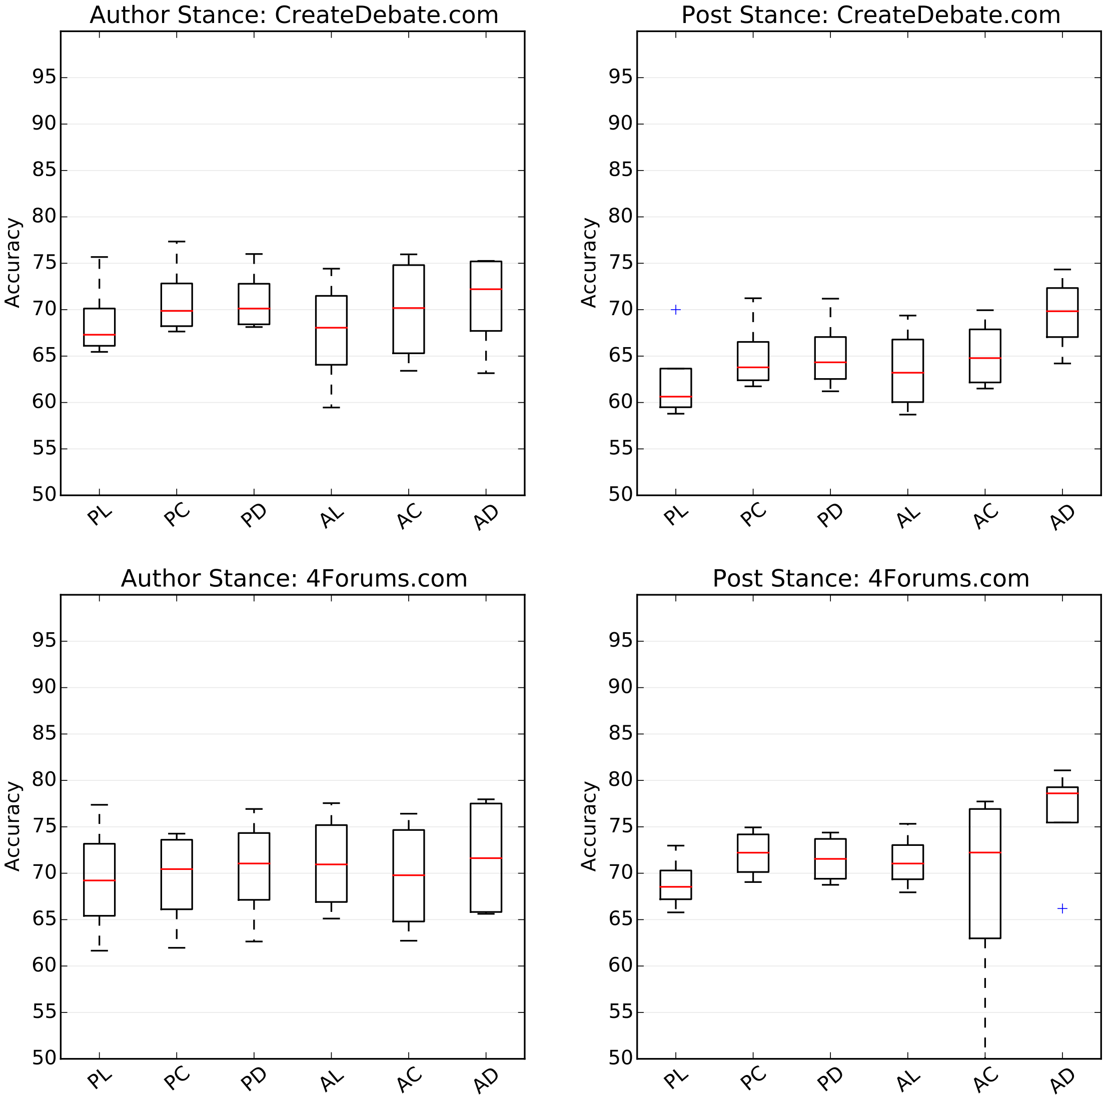

Figure 3: Overall accuracies per model for the author stance prediction task, computed over the final results for each of the four data sets per forum. Note that we expect significant variation in these plots, as the data sets are of varying degrees of difficulty.

sets from each forum. The overall trends can be seen by reading the box plots in each figure from left to right. In general, collective models outperform local models, and modeling disagreement further improves accuracy. Author-level modeling is typically better than post-level, even for the post-level prediction task. The improvements shown by collective models and author-level models are consistent with Hasan and Ng (2013)'s conclusion about the benefits of user-level constraints. This may suggest that posts only provide relatively noisy observations of the underlying author-level stance. Modeling at the author level results in more stable predictions, as noisy posts are pooled together. But here we also show that the full joint disagreement model at the author level, **AD**, performs the best overall, for both prediction tasks and for both forums, gaining up to 11.5 percentage points of post-level accuracy over the local post-level classifier.

A closer analysis reveals some subtleties. When comparing **D** models with **C** models in Fig. 3, disagreement modeling makes a much bigger difference at the author level than at the post level. This is likely impacted by the level of class imbalance for *disagreement* classification in the different levels of modeling. Disagreement, rather than agreement, between authors prompts many responses. Thus, reply links are more likely disagreements when measured at the post level, as seen in Ta-

ble 1. Therefore, enforcing disagreement may be a better assumption at the post level, and the nuanced disagreement model is not necessary in this case. The overall improvements in accuracy from disagreement modeling for post-level models were small.

On the other hand, the assumption that reply edges constitute disagreement is less accurate when modeling at the author level (see Table 1). In this case, the full joint disagreement model is necessary to obtain good performance. In an extreme example, the two datasets with the lowest disagreement rates at the author level are evolution (44.4%) and gun control (50.7%) from 4Forums. The **AC** classifier performed very poorly for these data sets, dropping to 46.9% accuracy in one instance, as the "opposite stance" assumption did not hold (Tables 2 and 3). The full joint disagreement model **AD** performed much better, in fact achieving an outstanding accuracy rates of 80.3% and 80.5% for posts on evolution and gay marriage respectively. To illustrate the benefits of author-level disagreement modeling, Fig. 4 shows a post for an author whose stance towards gun control is correctly predicted by **AD** but not the **AC** model, along with a subsequent reply. The authors largely agree with each other's views, which the joint disagreement model leverages, while the simpler collective model encourages opposite stance due to the presence of reply links between them.

Text	**Stance**
Post: I agree with everything except the last part. Safe gun storage is very important, and sensible storage requirements have two important factors.	ANTI
Reply: I can agree with this. And in case it seemed otherwise, I know full well how to store guns safely, and why it's necessary. My point was that I don't like the idea of such a law, especially when you consider the problem of enforcement.	ANTI

Figure 4: A post-reply pair by 4Forums.com authors whose gun control stance is correctly predicted by **AD**, but not by **AC**.

To summarize our conclusions from these experiments, the results suggest that author-level modeling is the preferred strategy, regardless of the prediction task. In this scenario, it is essential to explicitly model disagreement in the collective classifier. Our top performing **AD** model statistically significantly outperforms the respective prediction task baseline on 6 out of 8 topics for both tasks with p-values less than 0.001. Based on our experimental results, we recommend the full author-disagreement model **AD** as the classifier of choice.

6 Discussion and Future Work

The prediction of user stance in online debate forums is a valuable task, and modeling debate dialogue is complex and requires many decisions such collective or non-collective reasoning, nuanced or naive use of disagreement information, and post versus author-level modeling granularity. We systematically explore each choice, and in doing so build a unified joint framework that incorporates each salient decision. Our method uses a hinge-loss Markov random field to encourage consistency between local classifier predictions for stance and disagreement information. We find that modeling at the author level gives better predictive performance regardless of the granularity of the prediction task, and that nuanced disagreement modeling is of particular importance for author-level collective modeling. The resulting collective classifier gives improved predictive performance over both the simple non-collective and standard collective approaches, with a running time overhead of only a few minutes, thanks to the efficient nature of hinge-loss MRFs.

There are many directions for future work. Our results have found that collective reasoning can also be beneficial at the post level, as previously reported by Hasan and Ng (2013). It is likely that a multi-level model for a combination of post- and author-level collective modeling of both stance and disagreement could bring further improvements in performance. It would also be informative to explore dynamic models which elucidate trends of opinions over time. Another direction is to model influence between users in online debate forums, and to identify the most influential users who are able to convince other users to change their opinions. Finally, we note that stance and disagreement classification are both challenging and important problems, and going forward, there is likely to be much room for improvement in these prediction tasks.

Abstract

Entity classification, like many other important problems in NLP, involves learning classifiers over sparse high-dimensional feature spaces that result from the conjunction of elementary features of the entity mention and its context. In this paper we develop a low-rank regularization framework for training max-entropy models in such sparse conjunctive feature spaces. Our approach handles conjunctive feature spaces using matrices and induces an implicit low-dimensional representation via low-rank constraints. We show that when learning entity classifiers under minimal supervision, using a seed set, our approach is more effective in controlling model capacity than standard techniques for linear classifiers.

1 Introduction

Many important problems in NLP involve learning classifiers over sparse high-dimensional feature spaces that result from the conjunction of elementary features. For example, to classify an entity in a document, it is standard to exploit features of the left and right context in which the entity occurs as well as spelling features of the entity mention itself. These sets of features can be grouped into vectors which we call elementary feature vectors. In our example, there will be one elementary feature vector for the left context, one for the right context and one for the features of the mention. Observe that, when the elementary vectors consist of binary indicator features, the outer product of any pair of vectors represents all conjunctions of the corresponding elementary features.

Ideally, we would like to train a classifier that can leverage all conjunctions of elementary features, since among them there might be some that are discriminative for the classification task at hand. However, allowing for such expressive high dimensional feature space comes at a cost: data sparsity becomes a key challenge and controlling the capacity of the model is crucial to avoid overfitting the training data.

The problem of data sparsity is even more severe when the goal is to train classifiers with minimal supervision, i.e. small training sets. For example, in the entity classification setting we might be interested in training a classifier using only a small set of examples of each entity class. This is a typical scenario in an industrial setting, where developers are interested in classifying entities according to their own classification schema and can only provide a handful of examples of each class.

A standard approach to control the capacity of a linear classifier is to use ℓ_1 or ℓ_2 regularization on the parameter vector. However, this type of regularization does not seem to be effective when dealing with sparse conjunctive feature spaces. The main limitation is that ℓ_1 and ℓ_2 regularization can not let the model give weight to conjunctions that have not been observed at training. Without such ability it is unlikely that the model will generalize to novel examples, where most of the conjunctions will be unseen in the training set.

Of course, one could impose a strong prior on the weight vector so that it assigns weight to unseen conjunctions, but how can we build such a prior? What kind of reasonable constraints can we put on unseen conjunctions?

Another common approach to handle high dimensional conjunctive feature spaces is to manually design the feature function so that it includes

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 126–135,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

only a subset of "relevant" conjunctions. But designing such a feature function can be time consuming and one might need to design a new feature function for each classification task. Ideally, we would have a learning algorithm that does not require such feature engineering and that it can automatically leverage rich conjunctive feature spaces.

In this paper we present a solution to this problem by developing a regularization framework specifically designed for sparse conjunctive feature spaces. Our approach results in a more effective way of controlling model capacity and it does not require feature engineering.

Our strategy is based on:

- Employing tensors to define the scoring function of a max-entropy model as a multilinear form that computes weighted inner products between elementary vectors.
- Forcing the model to induce low-dimensional embeddings of elementary vectors via low-rank regularization on the tensor parameters.

The proposed regularization framework is based on a simple conceptual trick. The standard approach to handle conjunctive feature spaces in NLP is to regard the parameters of the linear model as long vectors computing an inner product with a high dimensional feature representation that lists explicitly all possible conjunctions. Instead, the parameters of our the model will be tensors and the compatibility score between an input pattern and a class will be defined as the sum of multilinear functions over elementary vectors.

We then show that the rank[1] of the tensor has a very natural interpretation. It can be seen as the intrinsic dimensionality of a latent embedding of the elementary feature vectors. Thus by imposing a low-rank penalty on the tensor parameters we are encouraging the model to induce a low-dimensional projection of the elementary feature vectors . Using the rank itself as a regularization constraint in the learning algorithm would result in a non-convex optimization. Instead, we follow a standard approach which is to use the nuclear norm as a convex relaxation of the rank.

In summary the main contributions of this paper are:

- We develop a new regularization framework for training max-entropy models in high-dimensional sparse conjunctive feature spaces. Since the proposed regularization implicitly induces a low dimensional embedding of feature vectors, our algorithm can also be seen as a way of implicitly learning a latent variable model.
- We present a simple convex learning algorithm for training the parameters of the model.
- We conduct experiments on learning entity classifiers with minimal supervision. Our results show that the proposed regularization framework is better for sparse conjunctive feature spaces than standard ℓ_2 and ℓ_1 regularization. These results make us conclude that encouraging the max-entropy model to operate on a low-dimensional space is an effective way of controlling the capacity of the model an ensure good generalization.

2 Entity Classification with Log-linear Models

The formulation we develop in this paper applies to any prediction task whose inputs are some form of tuple. We focus on classification of entity mentions, or entities in the context of a sentence. Formally, our input objects are tuples $x = \langle l, e, r \rangle$ consisting of an entity e, a left context l and a right context r. The goal is to classify x into one entity class in the set $\mathcal{Y}$.

We will use log-linear models of the form:

$$\Pr(y \mid x; \theta) = \frac{\exp\{s_\theta(x, y)\}}{\sum_{y'} \exp\{s_\theta(x, y')\}} \qquad (1)$$

where $s_\theta : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ is a scoring function of entity tuples with a candidate class, and θ are the parameters of this function, to be specified below.

In the literature it is common to employ a feature-based linear model. That is, one defines a feature function $\phi : \mathcal{X} \rightarrow \{0, 1\}^n$ that represents entity tuples in an n-dimensional binary feature space[2], and the model has a weight vector for each class, $\theta = \{\mathbf{w}_y\}_{y \in \mathcal{Y}}$. Then $s_\theta(x, y) = \phi(x) \cdot \mathbf{w}_y$.

[1] There are many ways of defining the rank of a tensor. In this paper we *matricize* tensors into matrices and use the rank of the resulting matrix. Matricization is also referred to as unfolding.

[2] In general, all models in this paper accept real-valued feature functions. But we focus on binary *indicator* features because in practice these are the standard type of features in NLP classifiers, and the ones we use here. In fact, in this paper we develop feature spaces based on *products* of elementary feature functions, in which case the resulting representations correspond to conjunctions of the elementary features.

3 Low-rank Entity Classification Models

In this section we propose a specific family of models for classifying entity tuples.

3.1 A Low-rank Model of Left-Right Contexts

We start from the observation that when representing tuple objects such as $x = \langle l, e, r \rangle$ with features, we often depart from a feature representation of each element of the tuple. Hence, let ϕ_{l} and ϕ_{r} be two feature functions representing left and right contexts, with binary dimensions d_1 and d_2 respectively. For now, we will define a model that ignores the entity mention e and makes predictions using context features. It is natural to define conjunctions of left and right features. Hence, in its most general form, one can define a matrix $\mathbf{W}_y \in \mathbb{R}^{d_1 \times d_2}$ for each class, such that $\theta = \{\mathbf{W}_y\}_{y \in \mathcal{Y}}$ and the score is:

$$s_\theta(\langle l, e, r \rangle, y) = \phi_{\mathrm{l}}(l)^\top \mathbf{W}_y \phi_{\mathrm{r}}(r) \quad . \tag{2}$$

Note that this corresponds to a feature-based linear model operating in the product space of ϕ_{l} and ϕ_{r}, that is, the score has one term for each pair of features: $\sum_{i,j} \phi_{\mathrm{l}}(l)[i]\ \phi_{\mathrm{r}}(r)[j]\ \mathbf{W}_y[i,j]$. Note also that it is trivial to include elementary features of ϕ_{l} and ϕ_{r}, in addition to conjunctions, by having a constant dimension in each of the two representations set to 1.

In all, the model in Eq. (2) is very expressive, with the caveat that it can easily overfit the data, specially when we work only with a handful of labeled examples. The standard way to control the capacity of a linear model is via ℓ_1 or ℓ_2 regularization.

Regarding our parameters as matrices allows us to control the capacity of the model via regularizers that favor parameter matrices with low rank. To see the effect of these regularizers, consider that $\mathbf{W}_y$ has rank k, and let $\mathbf{W}_y = \mathbf{U}_y \mathbf{\Sigma}_y \mathbf{V}_y^\top$ be the singular value decomposition, where $\mathbf{U}_y \in \mathbb{R}^{d_1 \times k}$ and $\mathbf{V}_y \in \mathbb{R}^{d_2 \times k}$ are orthonormal projections and $\mathbf{\Sigma}_y \in \mathbb{R}^{k \times k}$ is a diagonal matrix of singular values. We can rewrite the score function as

$$s_\theta(\langle l, e, r \rangle, y) = (\phi_{\mathrm{l}}(l)^\top \mathbf{U}_y)\ \mathbf{\Sigma}_y\ (\mathbf{V}_y^\top \phi_{\mathrm{r}}(r)) \quad . \tag{3}$$

In words, the rank k is the *intrinsic dimensionality* of the inner product behind the score function. A low-rank regularizer will favor parameter matrices that have low intrinsic dimensionality. Below we describe a convex optimization for low-rank models using *nuclear norm* regularization.

3.2 Adding Entity Features

The model above classifies entities based only on the context. Here we propose an extension to make use of features of the entity. Let $\mathcal{T}$ be a set of possible entity feature tags, i.e. tags that describe an entity, such as IsCapitalized, ContainsDigits, SingleToken, ... Let ϕ_{e} be a feature function representing entities. For this case, to simplify our expression, we will use a set notation and denote by $\phi_{\mathrm{e}}(e) \subseteq \mathcal{T}$ the set of feature tags that describe e. Our model will be defined with one parameter matrix per feature tag and class label, i.e. $\theta = \{\mathbf{W}_{t,y}\}_{t \in \mathcal{T}, y \in \mathcal{Y}}$. The model form is:

$$s_\theta(\langle l, e, r \rangle, y) = \sum_{t \in \phi_{\mathrm{e}}(e)} \phi_{\mathrm{l}}(l)^\top \mathbf{W}_{t,y} \quad .\phi_{\mathrm{r}}(r). \tag{4}$$

3.3 Learning with Low-rank Constraints

In this section we describe a convex procedure to learn models of the above form that have low rank. We will define an objective that combines a loss and a regularization term.

Our first observation is that our parameters are a tensor with up to four axes, namely left and right context representations, entity features, and entity classes. While a matrix has a clear definition of rank, it is not the case for general tensors, and there exist various definitions in the literature. The technique that we use is based on *matricization* of the tensor, that is, turning the tensor into a matrix that has the same parameters as the tensor but organized in two axes. This is done by partitioning the tensor axes into two sets, one for matrix rows and another for columns. Once the tensor has been turned into a matrix, we can use the standard definition of matrix rank. A main advantage of this approach is that we can make use of standard routines like singular value decomposition (SVD) to decompose the matricized tensor. This is the main reason behind our choice.

In general, different ways of partitioning the tensor axes will lead to different notions of intrinsic dimensions. In our case we choose the left context axes as the row dimension, and the rest of axes as the column dimension.[3] In this section, we will

[3] In preliminary experiments we tried variations, such as having right prefixes in the columns, and left prefixes, entity tags and classes in the rows. We only observer minor, non-significant variations in the results.

denote as $\mathbf{W}$ the matricized version of the parameters θ of our models.

The second observation is that minimizing the rank of a matrix is a non-convex problem. We make use of a convex relaxation based on the nuclear norm (Srebro and Shraibman, 2005). The *nuclear norm*[4] of a matrix $\mathbf{W}$, denoted $\|\mathbf{W}\|_\star$, is the sum of its singular values: $\|\mathbf{W}\|_\star = \sum_i \mathbf{\Sigma}_{i,i}$ where $\mathbf{W} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$ is the singular value decomposition of $\mathbf{W}$. This norm has been used in several applications in machine learning as a convex surrogate for imposing low rank, e.g. (Srebro et al., 2004).

Thus, the nuclear norm is used as a regularizer. With this, we define our objective as follows:

$$\operatorname*{argmin}_{\mathbf{W}} L(\mathbf{W}) + \tau R(\mathbf{W}) \quad , \tag{5}$$

where $L(\mathbf{W})$ is a convex loss function, $R(\mathbf{W})$ is a regularizer, and τ is a constant that trades off error and capacity. In experiments we will compare nuclear norm regularization with ℓ_1 and ℓ_2 regularizers. In all cases we use the negative log-likelihood as loss function, denoting the training data as $\mathcal{D}$:

$$L(\mathbf{W}) = \sum_{(\langle l,e,r\rangle,y)\in\mathcal{D}} -\log \Pr(y \mid \langle l,e,r\rangle; \mathbf{W}) \quad . \tag{6}$$

To solve the objective in Eq. (5) we use a simple optimization scheme known as *forward-backward splitting (FOBOS)* (Duchi and Singer, 2009). In a series of iterations, this algorithm performs a gradient update followed by a proximal projection of the parameters. Such projection depends on the regularizer used: for ℓ_1 it thresholds the parameters; for ℓ_2 it scales them; and for nuclear-norm regularization it thresholds the singular values. This means that, for nuclear norm regularization, each iteration requires to decompose $\mathbf{W}$ using SVD. See (Madhyastha et al., 2014) for details about this optimization for a related application.

4 Related Work

The main aspect of our approach is the use of a spectral penalty (i.e., the rank) to control the capacity of multilinear functions parameterized by matrices or tensors. Quattoni et al. (2014) used nuclear-norm regularization to learn latent-variable max-margin sequence taggers. Madhyastha et al. (2014) defined bilexical distributions parameterized by matrices which result lexical embeddings tailored for a particular linguistic relation. Like in our case, the low-dimensional latent projections in these papers are learned implicitly by imposing low-rank constraints on the predictions of the model.

Lei et al. (2014) also use low-rank tensor learning in the context of dependency parsing, where like in our case dependencies are represented by conjunctive feature spaces. While the motivation is similar, their technical solution is different. We use the technique of matricization of a tensor combined with a nuclear-norm relaxation to obtain a convex learning procedure. In their case they explicitly look for a low-dimensional factorization of the tensor using a greedy alternating optimization.

Also recently, Yao et al. (2013) have framed entity classification as a low-rank matrix completion problem. The idea is based on the fact that if two entities (in rows) have similar descriptions (in columns) they should have similar classes. The low-rank structure of the matrix defines intrinsic representations of entities and feature descriptions. The same idea was applied to relation extraction (Riedel et al., 2013), using a matrix of entity pairs times descriptions that corresponds to a matricization of an entity-entity-description tensor. Very recently Singh et al. (2015) explored alternative ways of applying low-rank constraints to tensor-based relation extraction.

Another aspect of this paper is training entity classification models using minimal supervision, which has been addressed by multiple works in the literature. A classical successful approach for this problem is to use co-training (Blum and Mitchell, 1998): learn two classifiers that use different views of the data by using each other's predictions. In the same line, Collins and Singer (1999) trained entity classifiers by bootstraping from an initial set of seeds, using a boosting version of co-training. Seed sets have also been exploited by graphical model approaches. Haghighi and Klein (2006) define a graphical model that is soft-constrained such that the prediction for an unlabeled example agrees with the labels of seeds that are distributionally similar. Li et al. (2010) present a Bayesian approach to expand an initial seed set, with the goal of creating a gazetteer.

Another approach to entity recognition that, like in our case, learns projections of contextual features is the method by Ando and Zhang (2005).

[4] Also known as the trace norm.

Class		Nb Mentions

Table 1: For each entity class, the seed of entities for the **10-30** set, together with the number of mentions in the training data that involve entities in the seed for various sizes of the seeds.

They define a set of auxiliary tasks, which can be supervised using unlabeled data, and find a projection of the data that works well as input representation for the auxiliary tasks. This representation is then used for the target task.

More recently Neelakantan and Collins (2014) presented another approach to gazetteer expansion using an initial seed. A novel aspect is the use of Canonical Correlation Analysis (CCA) to compute embeddings of entity contexts, that are used by the named entity classifier. Like in our case, their method learns a compressed representation of contexts that helps prediction.

5 Experiments

In this section we evaluate our regularization framework for training models in high-dimensional sparse conjunctive feature spaces. We run experiments on learning entity classifiers with minimal supervision. We focus on classification of unseen entities to highlight the ability of the regularizer to generalize over conjunctions that are not observed at training. We simulate minimal supervision using the CoNLL-2003 Shared Task data (Tjong Kim Sang and De Meulder, 2003), and compare the performance to ℓ_1 and ℓ_2 regularizers.

5.1 Minimal Supervision Task

We use a minimal supervision setting where we provide the algorithm a seed of entities for each class, that is, a list of entities that is representative for that class. The assumption is that any mention of an entity in the seed is a positive example for the corresponding class. Given unlabeled data and a seed of entities for each class, the goal is to learn a model that correctly classifies mentions of entities that are not in the seed. In addition to standard entity classes, we also consider a special non-entity class, which is part of the classification but is excluded from evaluation.

Note that named entity classification for *unseen* entities is a challenging problem. Even in the standard fully-supervised scenario, when we measure the performance of state-of-the-art methods on unseen entities, the F1 values are in the range of 60%. This represents a significant drop with respect to the standard metrics for named entity recognition, which consider all entity mentions of the test set irrespective of whether they appear in the training data or not, and where F1 values at 90% levels are obtained (e.g. (Ratinov and Roth, 2009)). This suggests that part of the success of state-of-the-art models is in storing known entities together with their type (in the form of gazetteers or directly in lexicalized parameters of the model).

5.2 Setting

We use the CoNLL-2003 English data, which is annotated with four types: person (PER), location (LOC), organization (ORG), and miscellaneous (MISC). In addition, the data is tagged with parts-of-speech (PoS), and we compute word clusters running the Brown clustering algorithm (Brown et al., 1992) on the words in the training set.

We consider annotated entity phrases as candidate entities, and all single nouns that are not part of an entity as candidate non-entities (O). Both candidate entities and non-entities will be referred to as candidates in the remaining of this section. We lowercase all candidates and remove the am-

Features	Window	Bag-of-words		N-grams	
		Lexical	Cluster	Lexical	Cluster
Elementary features of left and right contexts	1	13.63	**14.59**	13.63	**14.59**
	2	**15.49**	13.86	13.08	**13.54**
	3	12.18	**14.45**	12.14	**13.28**
Only full conjunctions of left and right contexts	1	12.90	**13.75**	12.90	**13.75**
	2	8.59	**8.85**	12.31	**12.43**
	3	8.57	**10.59**	10.15	**10.49**
Elementary features and all conjunctions of left and right contexts	1	15.30	**16.98**	15.30	**16.98**
	2	**13.26**	12.89	14.28	**15.33**
	3	**11.87**	11.54	**13.94**	**13.15**

Table 2: Average-F1 of classification of unseen entity candidates on development data, using the **10-30** training seed and ℓ_2 regularization, for different conjunctive spaces (elementary only, full conjunctions, all). **Bag-of-words** elementary features contain all clusters/PoS in separate windows to the left and to the right of the candidate. **N-grams** elementary features contain all n-grams of clusters/PoS in separate left and right windows (e.g. for size 3 it includes unigrams, bigrams and trigrams on each side).

biguous ones (i.e., those with more than one label in different mentions).[5]

To simulate a minimal supervision, we create supervision seeds by picking the n most frequent training candidates for entity types, and the m most frequent candidate non-entities. We create seeds of various sizes n-m, namely **10-30**, **40-120**, **640-1920**, as well as **all** of the candidates. For each seed, the training set consists of all training mentions that involve entities in the seed. Table 1 shows the smaller seed, as well as the number of mentions for each seed size.

For evaluation we use the development and test sections of the data, but we remove the instances of candidates in the training data (i.e., that are in the **all** seed). We do not remove instances that are ambiguous in the tests. [6] As evaluation metric we use the average F1 score computed over all entity types, excluding the non-entity type.

5.3 Context Representations

We refer to context as the sequence of tokens before (left context) and after (right context) a candidate mention in a sentence. Different classifiers can be built using different representations of the contexts. For example we can change the window size of the context sequence (i.e., for a window size of 1 we only use the last token before the mention and the first token after the mention). We can treat the left and right contexts independently of each other, we can treat them as a unique combination, or we can use both. We can also choose to use the word form of a token, its PoS tag, a word cluster, or a combination of these.

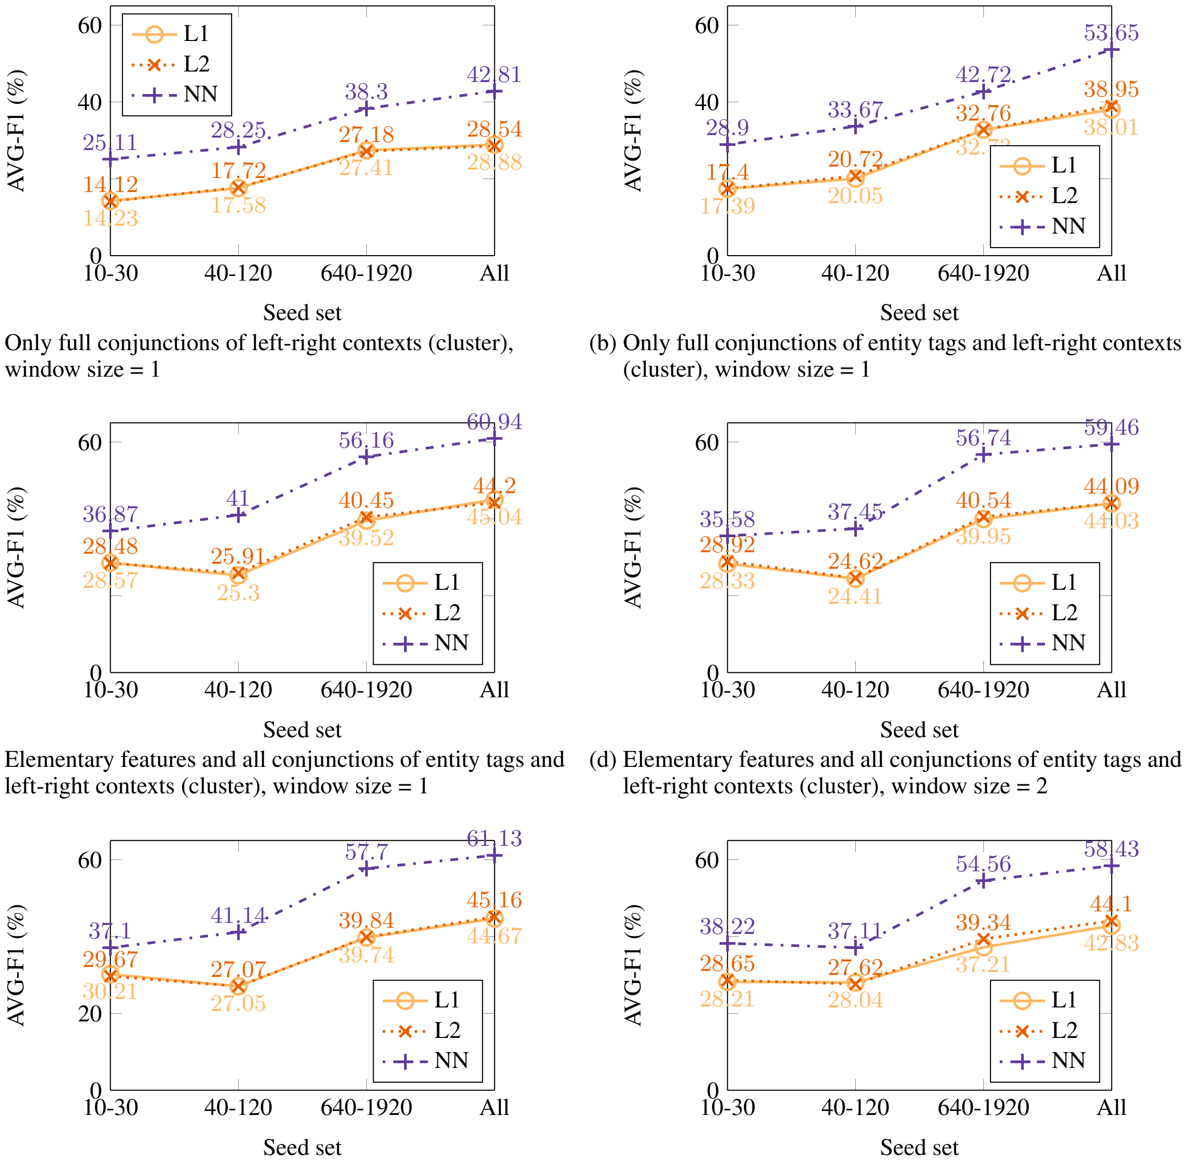
Table 2 compares different context representations and their performance in classifying unseen candidates using maximum-entropy classifiers trained with Mallet (McCallum, 2002) with ℓ_2 regularization, using the **10-30** seed. We use the lexical representation (the word itself) and a word cluster representation of the context tokens and use a window size of one to three. We use two types of features: bag-of-words features (1-grams of tokens in the specified window) and n-gram features (with n smaller or equal to the window size). The performance of using word clusters is comparable, and sometimes better, to using lexical representations. Moreover, using a longer window, in this case, does not necessarily result in better performance. [7] In the rest of the experiments

[5] In the CoNLL-2003 English training set, only 235 candidates are ambiguous out of 13,441 candidates, i.e. less than 2%. This suggests that in this data the difficulty behind the task is in recognizing and classifying unseen entities, and not in disambiguating known entities in a certain context.

[6] After removing the ambiguous candidates from the training data, and removing candidates seen in the training from the development and test sets, this is the number of mentions (and number of unique candidates in parenthesis) in the data used in our experiments:

	training	dev.	test
PER	6,516 (3,489)	1,040 (762)	1,342 (925)
LOC	6,159 (987)	176 (128)	246 (160)
ORG	5,271 (2,149)	400 (273)	638 (358)
MISC	3,205 (760)	177 (142)	213 (152)
O	36,673 (5,821)	951 (671)	995 (675)

[7] Our learner and feature configuration, using ℓ_2 regularization, obtains state-of-the-art results on the standard evalu-



(a) Only full conjunctions of left-right contexts (cluster), window size = 1

(b) Only full conjunctions of entity tags and left-right contexts (cluster), window size = 1

(c) Elementary features and all conjunctions of entity tags and left-right contexts (cluster), window size = 1

(d) Elementary features and all conjunctions of entity tags and left-right contexts (cluster), window size = 2

(e) Elementary features and all conjunctions of entity tags and left-right contexts (cluster & PoS), window size = 1

(f) Elementary features and all conjunctions of entity tags and left-right contexts (cluster & PoS), window size = 2

Figure 1: Average F1 of classification of unseen entity candidates on development data, with respect to the size of the seed. NN refers to models with nuclear norm regularization, L1 and L2 refer to ℓ_1 and ℓ_2 regularization. Each plot corresponds to a different conjunctive feature space with respect to window size (1 or 2), context representation (cluster with/out PoS), using entity features or not, and combining or not full conjunctions with lower-order conjunctions and elementary features.

- **cap=1**, **cap=0**: whether the first letter of the entity candidate is uppercase, or not
- **all-low=1**, **all-low=0**: whether all letters of the candidate are lowercase letters, or not
- **all-cap1=1**, **all-cap1=0**: whether all letters of the candidate are uppercase letters, or not
- **all-cap2=1**, **all-cap2=0**: whether all letters of the candidate are uppercase letters and periods, or not
- **num-tokens=1**, **num-tokens=2**, **num-tok>2**: whether the candidate consists of one token, two or more
- **dummy**: a tag that holds for any entity candidate, used to capture context features alone

Table 3: The 12 entity tags used to represent entity candidates. The tags **all-cap1** and **all-cap2** are from (Neelakantan and Collins, 2014).

we will use the elementary features that are more predictive and compact: clusters and PoS tags in windows of size at most 2.

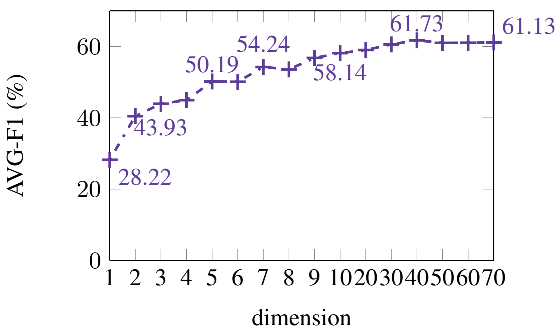

Figure 2: Avg. F1 on development for increasing dimensions, using the low-rank model in Figure 1e trained with **all** seeds.

5.4 Comparing Regularizers

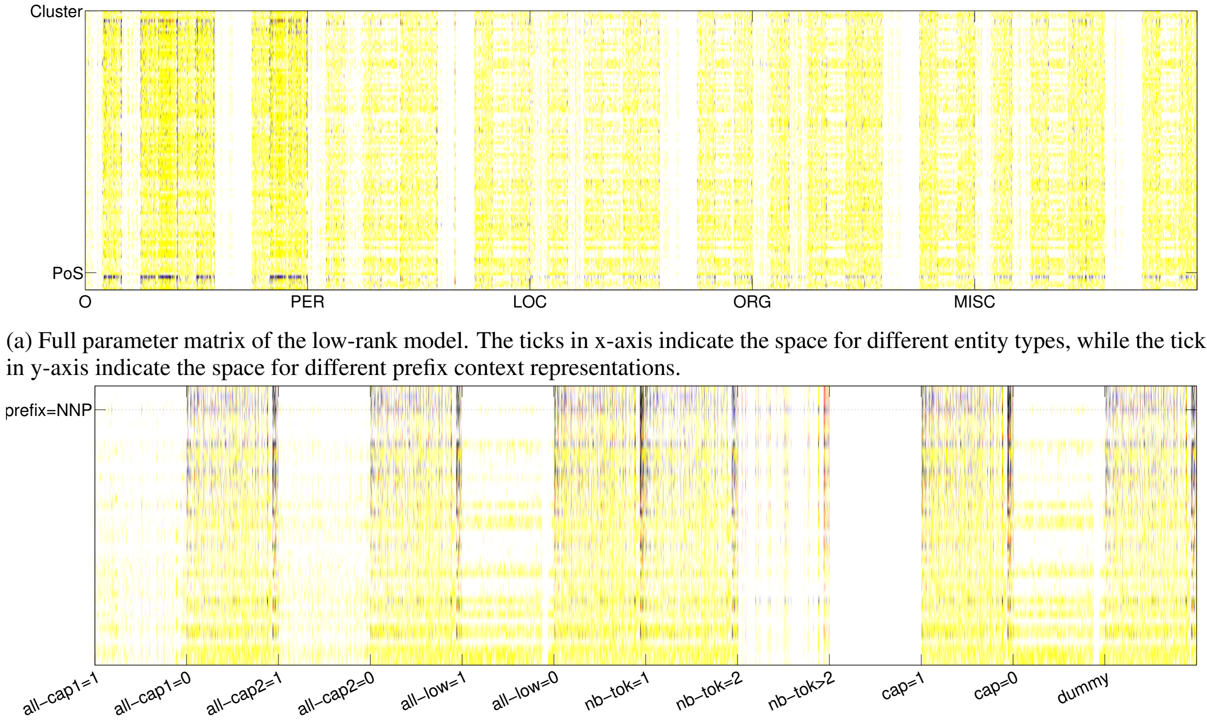
We compare the performance of models trained using the nuclear norm regularizer with models trained using ℓ_1 and ℓ_2 regularizers. To train each model, we validate the regularization parameter and the number of iterations on development data, trying a wide range of values. The best performing configuration is then used for the comparison.

Figure 1 shows results on the development set for different feature sets. We started representing context using cluster labels, as it is the most compact representation obtaining good results in preliminary experiments. We tried several conjunctions: a conjunction of the left and right context, as well as conjunctions of left and right contexts and features of the candidate entity. We also tried all different conjunction combinations of the contexts and the candidate entity features, as well as adding PoS tags to represent contexts. To represent an entity candidate we use standard traits of the spelling of the mention, such as capitalization, the existence of symbols, as well as the number of tokens in the candidate. See Table 3 for the definition of the features describing entity candidates.

We observe that for most conjunction settings our regularizer performs better than the ℓ_1 and ℓ_2 regularizers. Using the best model from each regularizer, we evaluated on the test set. Table 4 shows the test results. For all seed sets, the nuclear norm regularizer obtains the best average F1 performance. This shows that encouraging the max-entropy model to operate on a low-dimensional space is effective. Moreover, Figure 2 shows model performance as a function of the number of dimensions of the intrinsic projection. The model obtains a good performance even if only a few intrinsic dimensions are used.

Figure 3 shows the parameter matrix of the low-

ation. Using our richest feature set, the model obtains 76.76 of accuracy in the development, for the task of classifing entities with correct boundaries. If we add features capturing the full entity and its tokens, then the accuracy is 87.63, which is similar to state-of-the-art performance (the best results in literature typically exploit additional gazetteers). Since our evaluation focuses on unknown entities, our features do not include information about the word tokens of entites.



(a) Full parameter matrix of the low-rank model. The ticks in x-axis indicate the space for different entity types, while the ticks in y-axis indicate the space for different prefix context representations.

(b) The subblock for PER entity type and PoS representation of the prefixes. The ticks in x-axis indicate the space of the entity features used, while the tick in y-axis indicates an example of a frequently observed prefix for this entity type.

Figure 3: Parameter matrix of the low-rank model in Figure 1f trained with the **10-30** seed, with respect to observations of the associated features in training and development. Non-white conjunctions correspond to non-zero weights: black is for conjunctions seen in both the training and development sets; blue is for those seen in training but not in the development; red indicates that the conjunctions were observed only in the development; yellow is for those not observed in training nor development.

rank model in Figure 1f trained with the **10-30** seed, with respect to observed features in training and development data. Many of the conjunctions of the development set were never observed in the training set. Our regularizer framework is able to propagate weights from the conjunctive features seen in training to unseen conjunctive features that are close to each other in the projected space (these are the yellow and red cells in the matrix). In contrast, ℓ_1 and ℓ_2 regularization techniques can not put weight on unseen conjunctions.

6 Conclusion

We have developed a low-rank regularization framework for training max-entropy models in sparse conjunctive feature spaces. Our formulation is based on using tensors to parameterize classifiers. We control the capacity of the model using the nuclear-norm of a matricization of the tensor. Overall, our formulation results in a convex procedure for training model parameters.

We have experimented with these techniques in the context of learning entity classifiers. Compared to ℓ_1 and ℓ_2 penalties, the low-rank model obtains better performance, without the need to manually specify feature conjunctions. In our analysis, we have illustrated how the low-rank approach can assign non-zero weights to conjunctions that were unobserved at training, but are similar to observed conjunctions with respect to the low-dimensional projection of their elements.

We have used matricization of a tensor to define its rank, using a fixed transformation of the tensor into a matrix. Future work should explore how to combine efficiently different transformations.

Abstract

Vector space representation of words has been widely used to capture fine-grained linguistic regularities, and proven to be successful in various natural language processing tasks in recent years. However, existing models for learning word representations focus on either syntagmatic or paradigmatic relations alone. In this paper, we argue that it is beneficial to jointly modeling both relations so that we can not only encode different types of linguistic properties in a unified way, but also boost the representation learning due to the mutual enhancement between these two types of relations. We propose two novel distributional models for word representation using both syntagmatic and paradigmatic relations via a joint training objective. The proposed models are trained on a public Wikipedia corpus, and the learned representations are evaluated on word analogy and word similarity tasks. The results demonstrate that the proposed models can perform significantly better than all the state-of-the-art baseline methods on both tasks.

1 Introduction

Vector space models of language represent each word with a real-valued vector that captures both semantic and syntactic information of the word. The representations can be used as basic features in a variety of applications, such as information retrieval (Manning et al., 2008), named entity recognition (Collobert et al., 2011), question answering (Tellex et al., 2003), disambiguation (Schütze, 1998), and parsing (Socher et al., 2011).

A common paradigm for acquiring such representations is based on the *distributional hypothesis* (Harris, 1954; Firth, 1957), which states that words occurring in similar contexts tend to have similar meanings. Based on this hypothesis, various models on learning word representations have been proposed during the last two decades.

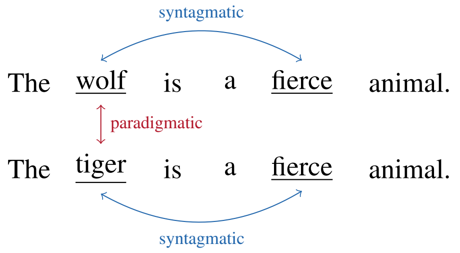

Figure 1: Example for syntagmatic and paradigmatic relations.

According to the leveraged distributional information, existing models can be grouped into two categories (Sahlgren, 2008). The first category mainly concerns the *syntagmatic relations* among the words, which relate the words that co-occur in the same text region. For example, “wolf” is close to “fierce” since they often co-occur in a sentence, as shown in Figure 1. This type of models learn the distributional representations of words based on the text region that the words occur in, as exemplified by Latent Semantic Analysis (LSA) model (Deerwester et al., 1990) and Non-negative Matrix Factorization (NMF) model (Lee and Seung, 1999). The second category mainly captures *paradigmatic relations*, which relate words that occur with similar contexts but may *not* co-occur in the text. For example, “wolf” is close to “tiger” since they often have similar context words. This type of models learn the word representations based on the surrounding words, as exemplified by the Hyperspace Analogue to Language (HAL) model (Lund et al., 1995), Continuous Bag-of-Words (CBOW) model and Skip-Gram (SG) model (Mikolov et al., 2013a).

In this work, we argue that it is important to

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 136–145,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

take both syntagmatic and paradigmatic relations into account to build a good distributional model. Firstly, in distributional meaning acquisition, it is expected that a good representation should be able to encode a bunch of linguistic properties. For example, it can put semantically related words close (*e.g.*, “microsoft” and “office”), and also be able to capture syntactic regularities like “big is to bigger as deep is to deeper”. Obviously, these linguistic properties are related to both syntagmatic and paradigmatic relations, and cannot be well modeled by either alone. Secondly, syntagmatic and paradigmatic relations are complimentary rather than conflicted in representation learning. That is relating the words that co-occur within the same text region (*e.g.*, “wolf” and “fierce” as well as “tiger” and “fierce”) can better relate words that occur with similar contexts (*e.g.*, “wolf” and “tiger”), and vice versa.

Based on the above analysis, we propose two new distributional models for word representation using both syntagmatic and paradigmatic relations. Specifically, we learn the distributional representations of words based on the text region (*i.e.*, the document) that the words occur in as well as the surrounding words (*i.e.*, word sequences within some window size). By combining these two types of relations either in a parallel or a hierarchical way, we obtain two different joint training objectives for word representation learning. We evaluate our new models in two tasks, *i.e.*, word analogy and word similarity. The experimental results demonstrate that the proposed models can perform significantly better than all of the state-of-the-art baseline methods in both of the tasks.

2 Related Work

The distributional hypothesis has provided the foundation for a class of statistical methods for word representation learning. According to the leveraged distributional information, existing models can be grouped into two categories, *i.e.*, syntagmatic models and paradigmatic models.

Syntagmatic models concern combinatorial relations between words (*i.e.*, syntagmatic relations), which relate words that co-occur within the same text region (*e.g.*, sentence, paragraph or document).

For example, sentences have been used as the text region to acquire co-occurrence information by (Rubenstein and Goodenough, 1965; Miller and Charles, 1991). However, as pointed our by Picard (1999), the smaller the context regions are that we use to collect syntagmatic information, the worse the sparse-data problem will be for the resulting representation. Therefore, syntagmatic models tend to favor the use of larger text regions as context. Specifically, a document is often taken as a natural context of a word following the literature of information retrieval. In these methods, a words-by-documents co-occurrence matrix is built to collect the distributional information, where the entry indicates the (normalized) frequency of a word in a document. A low-rank decomposition is then conducted to learn the distributional word representations. For example, LSA (Deerwester et al., 1990) employs singular value decomposition by assuming the decomposed matrices to be orthogonal. In (Lee and Seung, 1999), non-negative matrix factorization is conducted over the words-by-documents matrix to learn the word representations.

Paradigmatic models concern substitutional relations between words (*i.e.*, paradigmatic relations), which relate words that occur in the same context but may not at the same time. Unlike syntagmatic model, paradigmatic models typically collect distributional information in a words-by-words co-occurrence matrix, where entries indicate how many times words occur together within a context window of some size.

For example, the Hyperspace Analogue to Language (HAL) model (Lund et al., 1995) constructed a high-dimensional vector for words based on the word co-occurrence matrix from a large corpus of text. However, a major problem with HAL is that the similarity measure will be dominated by the most frequent words due to its weight scheme. Various methods have been proposed to address the drawback of HAL. For example, the Correlated Occurrence Analogue to Lexical Semantic (COALS) (Rohde et al., 2006) transformed the co-occurrence matrix by an entropy or correlation based normalization. Bullinaria and Levy (2007), and Levy and Goldberg (2014b) suggested that positive pointwise mutual information (PPMI) is a good transformation. More recently, Lebret and Collobert (2014) obtained the word representations through a Hellinger PCA (HPCA) of the words-by-words co-occurrence matrix. Pennington et al. (2014) explicitly factorizes the words-by-words co-occurrence matrix to obtain the Global Vectors (GloVe) for word representation.

Alternatively, neural probabilistic language models (NPLMs) (Bengio et al., 2003) learn word representations by predicting the next word given previously seen words. Unfortunately, the training of NPLMs is quite time consuming, since computing probabilities in such model requires normalizing over the entire vocabulary. Recently, Mnih and Teh (2012) applied Noise Contrastive Estimation (NCE) to approximately maximize the probability of the softmax in NPLM. Mikolov et al. (2013a) further proposed continuous bag-of-words (CBOW) and skip-gram (SG) models, which use a simple single-layer architecture based on inner product between two word vectors. Both models can be learned efficiently via a simple variant of Noise Contrastive Estimation, *i.e.*, Negative sampling (NS) (Mikolov et al., 2013b).

3 Our Models

In this paper, we argue that it is important to jointly model both syntagmatic and paradigmatic relations to learn good word representations. In this way, we not only encode different types of linguistic properties in a unified way, but also boost the representation learning due to the mutual enhancement between these two types of relations.

We propose two joint models that learn the distributional representations of words based on both the text region that the words occur in (*i.e.*, syntagmatic relations) and the surrounding words (*i.e.*, paradigmatic relations). To model syntagmatic relations, we follow the previous work (Deerwester et al., 1990; Lee and Seung, 1999) to take document as a nature text region of a word. To model paradigmatic relations, we are inspired by the recent work from Mikolov et al. (Mikolov et al., 2013a; Mikolov et al., 2013b), where simple models over word sequences are introduced for efficient and effective word representation learning.

In the following, we introduce the notations used in this paper, followed by detailed model descriptions, ending with some discussions of the proposed models.

3.1 Notation

Before presenting our models, we first list the notations used in this paper. Let $D=\{d_1,\ldots,d_N\}$ denote a corpus of N documents over the word vocabulary W. The contexts for word $w_i^n \in W$ (*i.e.* i-th word in document d_n) are the words surrounding it in an L-sized window $(c_{i-L}^n,\ldots,c_{i-1}^n,c_{i+1}^n,\ldots,c_{i+L}^n) \in H$, where $c_j^n \in W, j \in \{i-L,\ldots,i-1,i+1,\ldots,i+L\}$. Each document $d \in D$, each word $w \in W$ and each context $c \in W$ is associated with a vector $\vec{d} \in \mathbb{R}^K$, $\vec{w} \in \mathbb{R}^K$ and $\vec{c} \in \mathbb{R}^K$, respectively, where K is the embedding dimensionality. The entries in the vectors are treated as parameters to be learned.

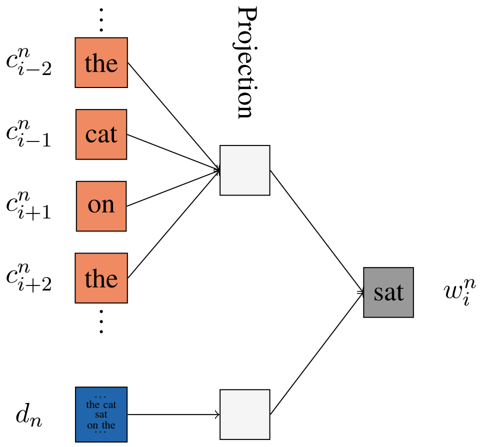

Figure 2: The framework for PDC model. Four words ("the", "cat", "on" and "the") are used to predict the center word ("sat"). Besides, the document in which the word sequence occurs is also used to predict the center word ("sat").

3.2 Parallel Document Context Model

The first proposed model architecture is shown in Figure 2. In this model, a target word is predicted by its surrounding context, as well as the document it occurs in. The former prediction task captures the paradigmatic relations, since words with similar context will tend to have similar representations. While the latter prediction task models the syntagmatic relations, since words co-occur in the same document will tend to have similar representations. More detailed analysis on this will be presented in Section 3.4. The model can be viewed as an extension of CBOW model (Mikolov et al., 2013a), by adding an extra document branch. Since both the context and document are parallel in predicting the target word, we call this model the Parallel Document Context (PDC) model.

More formally, the objective function of PDC model is the log likelihood of all words

$$\ell = \sum_{n=1}^{N} \sum_{w_i^n \in d_n} \big(\log p(w_i^n|h_i^n) + \log p(w_i^n|d_n)\big)$$

where h_i^n denotes the projection of w_i^n's contexts, defined as

$$h_i^n = f(c_{i-L}^n, \ldots, c_{i-1}^n, c_{i+1}^n, \ldots, c_{i+L}^n)$$

where $f(\cdot)$ can be sum, average, concatenate or max pooling of context vectors[1]. In this paper, we use average, as that of `word2vec` tool.

We use softmax function to define the probabilities $p(w_i^n|h_i^n)$ and $p(w_i^n|d_n)$ as follows:

$$p(w_i^n|h_i^n) = \frac{\exp(\vec{w_i^n} \cdot \vec{h_i^n})}{\sum_{w \in W} \exp(\vec{w} \cdot \vec{h_i^n})} \qquad (1)$$

$$p(w_i^n|d_n) = \frac{\exp(\vec{w_i^n} \cdot \vec{d_n})}{\sum_{w \in W} \exp(\vec{w} \cdot \vec{d_n})} \qquad (2)$$

where $\vec{h_i^n}$ denotes projected vector of w_i^n's contexts.

To learn the model, we adopt the negative sampling technique (Mikolov et al., 2013b) for efficient learning since the original objective is intractable for direct optimization. The negative sampling actually defines an alternate training objective function as follows

$$\begin{aligned}\ell = \sum_{n=1}^{N} \sum_{w_i^n \in d_n} \big(&\log \sigma(\vec{w_i^n} \cdot \vec{h_i^n}) + \log \sigma(\vec{w_i^n} \cdot \vec{d_n}) \\ &+ k \cdot \mathbb{E}_{w' \sim P_{\text{nw}}} \log \sigma(\vec{w'} \cdot \vec{h_i^n}) \\ &+ k \cdot \mathbb{E}_{w' \sim P_{\text{nw}}} \log \sigma(\vec{w'} \cdot \vec{d_n})\big)\end{aligned} \qquad (3)$$

where $\sigma(x) = 1/(1 + \exp(-x))$, k is the number of "negative" samples, w' denotes the sampled word, and P_{nw} denotes the distribution of negative word samples. We use stochastic gradient descent (SGD) for optimization, and the gradient is calculated via back-propagation algorithm.

3.3 Hierarchical Document Context Model

Since the above PDC model can be viewed as an extension of CBOW model, it is natural to introduce the same document-word prediction layer into the SG model. This becomes our second model architecture as shown in Figure 3. Specifically, the document is used to predict a target word, and the target word is further used to predict its surrounding context words. Since the prediction is conducted in a hierarchical manner, we name this model the Hierarchical Document Context (HDC) model. Similar as the PDC model, the syntagmatic relation in HDC is modeled by the document-word prediction layer and the word-context prediction layer models the paradigmatic relation.

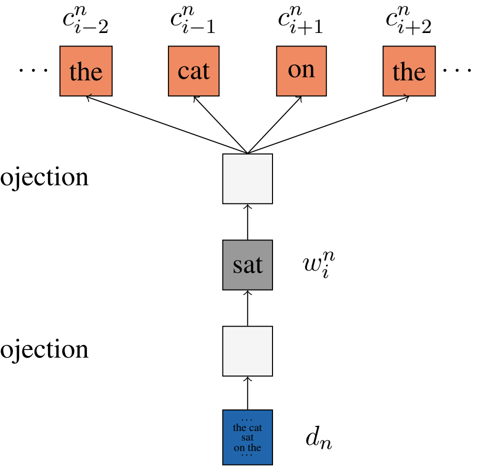

Figure 3: The framework for HDC model. The document is used to predict the target word ("sat"). Then, the word ("sat") is used to predict the surrounding words ("the", "cat", "on" and "the").

Formally, the objective function of HDC model is the log likelihood of all words:

$$\ell = \sum_{n=1}^{N} \sum_{w_i^n \in d_n} \Bigg(\sum_{\substack{j=i-L \\ j \neq i}}^{i+L} \log p(c_j^n|w_i^n) + \log p(w_i^n|d_n) \Bigg)$$

where $p(w_i^n|d_n)$ is defined the same as in Equation (2), and $p(c_j^n|w_i^n)$ is also defined by a softmax function as follows:

$$p(c_j^n|w_i^n) = \frac{\exp(\vec{c_j^n} \cdot \vec{w_i^n})}{\sum_{c \in W} \exp(\vec{c} \cdot \vec{w_i^n})}$$

Similarly, we adopt the negative sampling technique for learning, which defines the following

[1] Note that the context window size L can be a function of the target word w_i^n. In this paper, we use the same strategy as `word2vec` tools which uniformly samples from the set $\{1, 2, \cdots, L\}$.

training objective function

$$\ell = \sum_{n=1}^{N} \sum_{w_i^n \in d_n} \Bigg(\sum_{\substack{j=i-L \\ j \neq i}}^{i+L} \Big(\log \sigma(\vec{c_j^n} \cdot \vec{w_i^n}) + k \cdot \mathbb{E}_{c' \sim P_{\mathrm{nc}}} \log \sigma(\vec{c'} \cdot \vec{w_i^n}) \Big) + \log \sigma(\vec{w_i^n} \cdot \vec{d_n}) + k \cdot \mathbb{E}_{w' \sim P_{\mathrm{nw}}} \log \sigma(\vec{w'} \cdot \vec{d_n}) \Bigg)$$

where k is the number of the negative samples, c' and w' denotes the sampled context and word respectively, and P_{nc} and P_{nw} denotes the distribution of negative context and word samples respectively[2]. We also employ SGD for optimization, and calculate the gradient via back-propagation algorithm.

3.4 Discussions

In this section we first show how PDC and HDC models capture the syntagmatic and paradigmatic relations from the viewpoint of matrix factorization. We then talk about the relationship of our models with previous work.

As pointed out in (Sahlgren, 2008), to capture syntagmatic relations, the implementational basis is to collect text data in a words-by-documents co-occurrence matrix in which the entry indicates the (normalized) frequency of occurrence of a word in a document (or, some other type of text region, *e.g.*, a sentence). While the implementational basis for paradigmatic relations is to collect text data in a words-by-words co-occurrence matrix that is populated by counting how many times words occur together within the context window. We now take the proposed PDC model as an example to show how it achieves these goals, and similar results can be shown for HDC model.

The objective function of PDC with negative sampling in Equation (3) can be decomposed into the following two parts:

$$\ell_1 = \sum_{w \in W} \sum_{h \in H} \big(\#(w,h) \cdot \log \sigma(\vec{w} \cdot \vec{h}) + k \cdot \#(h) \cdot p_{\mathrm{nw}}(w) \log \sigma(-\vec{w} \cdot \vec{h}) \big) \tag{4}$$

$$\ell_2 = \sum_{d \in D} \sum_{w \in W} \big(\#(w,d) \cdot \log \sigma(\vec{w} \cdot \vec{d}) + k \cdot |d| \cdot p_{\mathrm{nw}}(w) \log \sigma(-\vec{w} \cdot \vec{d}) \big) \tag{5}$$

where $\#(\cdot,\cdot)$ denotes the number of times the pair $(\cdot,\cdot)$ appears in D, $\#(h) = \sum_{w \in W} \#(w,h)$, $|d|$ denotes the length of document d, the objective function ℓ_1 corresponds to the context-word prediction task and ℓ_2 corresponds to the document-word prediction task.

Following the idea introduced by (Levy and Goldberg, 2014a), it is easy to show that the solution of the objective function ℓ_1 follows that

$$\vec{w} \cdot \vec{h} = \log\Big(\frac{\#(w,h)}{\#(h) \cdot p_{\mathrm{nw}}(w)}\Big) - \log k$$

and the solution of the objective function ℓ_2 follows that

$$\vec{w} \cdot \vec{d} = \log\Big(\frac{\#(w,d)}{|d| \cdot p_{\mathrm{nw}}(w)}\Big) - \log k$$

It reveals that the PDC model with negative sampling is actually factorizing both a words-by-contexts co-occurrence matrix and a words-by-documents co-occurrence matrix simultaneously. In this way, we can see that the implementational basis of the PDC model is consistent with that of syntagmatic and paradigmatic models. In other words, PDC can indeed capture both syntagmatic and paradigmatic relations by processing the right distributional information. Please notice that the PDC model is not equivalent to direct combination of existing matrix factorization methods, due to the fact that the matrix entries defined in PDC model are more complicated than the simple co-occurrence frequency (Lee and Seung, 1999).

When considering existing models, one may connect our models to the Distributed Memory model of Paragraph Vectors (PV-DM) and the Distributed Bag of Words version of Paragraph Vectors (PV-DBOW) (Le and Mikolov, 2014). However, both of them are quite different from our models. In PV-DM, the paragraph vector and context vectors are averaged or concatenated to predict the next word. Therefore, the objective function of PV-DM can no longer decomposed as the PDC model as shown in Equation (4) and (5). In other words, although PV-DM leverages both paragraph and context information, it is unclear how these information is collected and used in this model. As for PV-DBOW, it simply leverages paragraph vector to predict words in the paragraph. It is easy to show that it only uses the words-by-documents co-occurrence matrix, and thus only captures syntagmatic relations.

Another close work is the Global Context-Aware Neural Language Model (GCANLM for

[2] P_{nc} is not necessary to be the same as P_{nw}.

short) (Huang et al., 2012). The model defines two scoring components that contribute to the final score of a (word sequence, document) pair. The architecture of GCANLM seems similar to our PDC model, but exhibits lots of differences as follows: (1) GCANLM employs neural networks as components while PDC resorts to simple model structure without non-linear hidden layers; (2) GCANLM uses weighted average of all word vectors to represent the document, which turns out to model words-by-words co-occurrence (*i.e.*, paradigmatic relations) again rather than words-by-documents co-occurrence (*i.e.*, syntagmatic relations); (3) GCANLM is a language model which predicts the next word given the preceding words, while PDC model leverages both preceding and succeeding contexts for prediction.

4 Experiments

In this section, we first describe our experimental settings including the corpus, hyper-parameter selections, and baseline methods. Then we compare our models with baseline methods on two tasks, *i.e.*, word analogy and word similarity. After that, we conduct some case studies to show that our model can better capture both syntagmatic and paradigmatic relations and how it improves the performances on semantic tasks.

4.1 Experimental Settings

We select Wikipedia, the largest online knowledge base, to train our models. We adopt the publicly available April 2010 dump[3] (Shaoul and Westbury, 2010), which is also used by (Huang et al., 2012; Luong et al., 2013; Neelakantan et al., 2014). The corpus in total has $3,035,070$ articles and about 1 billion tokens. In preprocessing, we lowercase the corpus, remove pure digit words and non-English characters[4].

Following the practice in (Pennington et al., 2014), we set context window size as 10 and use 10 negative samples. The noise distributions for context and words are set as the same as used in (Mikolov et al., 2013a), $p_{\mathrm{nw}}(w) \propto \#(w)^{0.75}$. We also adopt the same linear learning rate strategy described in (Mikolov et al., 2013a), where the initial learning rate of PDC model is 0.05, and HDC is 0.025. No additional regularization is used in our models[5].

Table 1: Corpora used in baseline models.

model	corpus	size
C&W	Wikipedia 2007 + Reuters RCV1	0.85B
HPCA	Wikipedia 2012	1.6B
GloVe	Wikipedia 2014+ Gigaword5	6B
GCANLM, CBOW, SG PV-DBOW, PV-DM	Wikipedia 2010	1B

We compare our models with various state-of-the-art models including C&W (Collobert et al., 2011), GCANLM (Huang et al., 2012), CBOW, SG (Mikolov et al., 2013a), GloVe (Pennington et al., 2014), PV-DM, PV-DBOW (Le and Mikolov, 2014) and HPCA (Lebret and Collobert, 2014). For C&W, GCANLM[6], GloVe and HPCA, we use the word embeddings they provided. For CBOW and SG model, we reimplement these two models since the original `word2vec` tool uses SGD but *cannot* shuffle the data. Besides, we also implement PV-DM and PV-DBOW models due to (Le and Mikolov, 2014) has not released source codes. We train these four models on the same dataset with the same hyper-parameter settings as our models for fair comparison. The statistics of the corpora used in baseline models are shown in Table 1. Moreover, since different papers report different dimensionality, to be fair, we conduct evaluations on three dimensions (*i.e.*, 50, 100, 300) to cover the publicly available results[7].

4.2 Word Analogy

The word analogy task is introduced by Mikolov et al. (2013a) to quantitatively evaluate the linguistic regularities between pairs of word representations. The task consists of questions like "*a* is to *b* as *c* is to __", where __ is missing and must be guessed from the entire vocabulary. To answer such questions, we need to find a word vector $\vec{x}$, which is the closest to $\vec{b} - \vec{a} + \vec{c}$ according to the cosine similarity:

$$\arg \max_{\substack{x \in W, x \neq a \\ x \neq b,\, x \neq c}} (\vec{b} + \vec{c} - \vec{a}) \cdot \vec{x}$$

The question is judged as correctly answered only if x is exactly the answer word in the evaluation

[3] http://www.psych.ualberta.ca/~westburylab/downloads/westburylab.wikicorp.download.html

[4] We ignore the words less than 20 occurrences during training.

[5] Codes avaiable at http://www.bigdatalab.ac.cn/benchmark/bm/bd?code=PDC, http://www.bigdatalab.ac.cn/benchmark/bm/bd?code=HDC.

[6] Here, we use GCANLM's single-prototype embedding.

[7] C&W and GCANLM only released the vectors with 50 dimensions, and HPCA released vectors with 50 and 100 dimensions.

Table 2: Results on the word analogy task. Underlined scores are the best within groups of the same dimensionality, while bold scores are the best overall.

model	size	dim	semantic	syntactic	total
C&W	0.85B	50	9.33	11.33	10.98
GCANLM	1B	50	2.6	10.7	7.34
HPCA	1.6B	50	3.36	9.89	7.2
GloVe	6B	50	48.46	45.24	46.22
CBOW	1B	50	54.38	49.64	52.01
SG	1B	50	53.73	46.12	49.04
PV-DBOW	1B	50	55.02	44.17	49.34
PV-DM	1B	50	45.08	43.22	44.25
PDC	1B	50	61.21	54.55	57.88
HDC	1B	50	57.8	49.74	53.41
HPCA	1.6B	100	4.16	15.73	10.79
GloVe	6B	100	65.34	61.51	63.11
CBOW	1B	100	70.73	63.01	66.87
SG	1B	100	67.66	59.72	63.45
PV-DBOW	1B	100	67.49	56.29	61.51
PV-DM	1B	100	57.72	58.81	58.45
PDC	1B	100	72.77	67.68	70.35
HDC	1B	100	69.57	63.75	66.67
GloVe	6B	300	77.44	67.75	71.7
CBOW	1B	300	76.2	68.44	72.39
SG	1B	300	78.9	65.72	71.88
PV-DBOW	1B	300	66.85	58.5	62.08
PV-DM	1B	300	56.88	68.35	63.39
PDC	1B	300	79.55	**69.71**	**74.76**
HDC	1B	300	**79.67**	67.1	73.13

set. The evaluation metric for this task is the percentage of questions answered correctly.

The dataset contains 5 types of semantic analogies and 9 types of syntactic analogies[8]. The semantic analogy contains $8,869$ questions, typically about people and place like "Beijing is to China as Paris is to France", while the syntactic analogy contains $10,675$ questions, mostly on forms of adjectives or verb tense, such as "good is to better as bad to worse".

Result Table 2 shows the results on word analogy task. As we can see that CBOW, SG and GloVe are much stronger baselines as compare with C&W, GCANLM and HPCA. Even so, our PDC model still performs significantly better than these state-of-the-art methods (p-value < 0.01), especially with smaller vector dimensionality. More interestingly, by only training on 1 billion words, our models can outperform the GloVe model which is trained on 6 billion words. The results demonstrate that by modeling both syntagmatic and paradigmatic relations, we can learn better word representations capturing linguistic regularities.

Besides, CBOW, SG and PV-DBOW can be viewed as sub-models of our proposed models, since they use either context (*i.e.*, paradigmatic relations) or document (*i.e.*, syntagmatic relations) alone to predict the target word. By comparing with these sub-models, we can see that the PDC and HDC models can perform significantly better on both syntactic and semantic subtasks. It shows that by jointly modeling the two relations, one can boost the representation learning and better capture both semantic and syntactic regularities.

4.3 Word Similarity

Besides the word analogy task, we also evaluate our models on three different word similarity tasks, including WordSim-353 (Finkelstein et al., 2002), Stanford's Contextual Word Similarities (SCWS) (Huang et al., 2012) and rare word (RW) (Luong et al., 2013). These datasets contain word paris together with human assigned similarity scores. We compute the Spearman rank correlation between similarity scores based on learned word representations and the human judgements. In all experiments, we removed the word pairs that cannot be found in the vocabulary.

Results Figure 4 shows results on three different word similarity datasets. First of all, our proposed PDC model always achieves the best performances on the three tasks. Besides, if we compare the PDC and HDC models with their corresponding sub-models (*i.e.*, CBOW and SG) respectively, we can see performance gain by adding syntagmatic information via document. This gain becomes even larger for rare words with low dimensionality as shown on RW dataset. Moreover, on the SCWS dataset, our PDC model using the single-prototype representations under dimensionality 50 can achieve a comparable result (65.63) to the state-of-the-art GCANLM (65.7 as the best performance reported in (Huang et al., 2012)) which uses multi-prototype vectors[9].

4.4 Case Study

Here we conduct some case studies to (1) gain some intuition on how these two relations affect

[8] http://code.google.com/p/word2vec/source/browse/trunk /questions-words.txt

[9] Note, in Figure 4, the performance of GCANLM is computed based on their released single-prototype vectors.

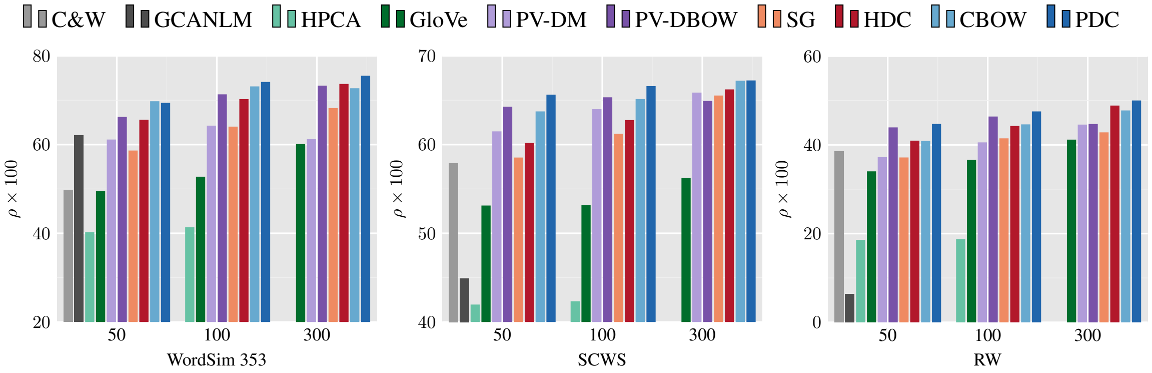

Figure 4: Spearman rank correlation on three datasets. Results are grouped by dimensionality.

Table 3: Target words and their 5 most similar words under different representations. Words in italic often co-occur with the target words, while words in bold are substitutable to the target words.

the representation learning, and (2) analyze why the joint model can perform better.

To show how syntagmatic and paradigmatic relations affect the learned representations, we present the 5 most similar words (by cosine similarity with 50-dimensional vectors) to a given target word under the PDC and HDC models, as well as three sub-models, *i.e.*, CBOW, SG, and PV-DBOW. The results are shown in table 3, where words in italic are those often co-occurred with the target word (*i.e.*, syntagmatic relations), while words in bold are whose substitutable to the target word (*i.e.*, paradigmatic relation).

Clearly, top words from CBOW and SG models are more under paradigmatic relations, while those from PV-DBOW model are more under syntagmatic relations, which is quite consistent with the model design. By modeling both relations, the top words from PDC and HDC models become more diverse, *i.e.*, more syntagmatic relations than CBOW and SG models, and more paradigmatic relations than PV-DBOW model. The results reveal that the word representations learned by PDC and HDC models are more balanced with respect to the two relations as compared with sub-models.

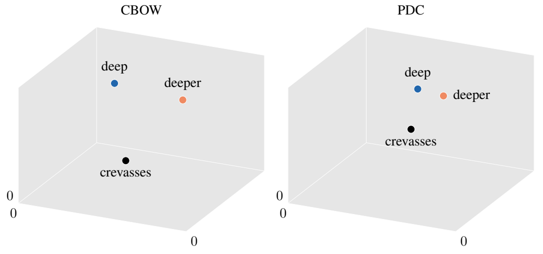

Figure 5: The 3-D embedding of learned word vectors of “deep”, “deeper” and “crevasses” under CBOW and PDC models.

The next question is why learning a joint model can work better on previous tasks? We first take one example from the word analogy task, which is the question “*big* is to *bigger* as *deep* is to __” with the correct answer as “deeper”. Our PDC model produce the right answer but the CBOW model fails with the answer “shallower”. We thus embedding the learned word vectors from the two models into a 3-D space to illustrate and analyze the reason.

As shown in Figure 5, we can see that by jointly modeling two relations, PDC model not only requires that “deep” to be close to “deeper” (in cosine similarity), but also requires that “deep” and “deeper” to be close to “crevasses”. The additional requirements further drag these three words closer as compared with those from the CBOW model, and this make our model outperform the CBOW model on this question. As for the word similarity tasks, we find that the word pairs are either syntagmatic (*e.g.*, "bank" and "money") or paradigmatic (*e.g.*, "left" and "abandon"). It is, therefore, not surprising to see that a more balanced representation can achieve much better performance than a biased representation.

5 Conclusion

Existing work on word representations models either syntagmatic or paradigmatic relations. In this paper, we propose two novel distributional models for word representation, using both syntagmatic and paradigmatic relations via a joint training objective. The experimental results on both word analogy and word similarity tasks show that the proposed joint models can learn much better word representations than the state-of-the-art methods.

Several directions remain to be explored. In this paper, the syntagmatic and paradigmatic relations are equivalently important in both PDC and HDC models. An interesting question would then be whether and how we can add different weights for syntagmatic and paradigmatic relations. Besides, we may also try to learn the multi-prototype word representations for polysemous words based on our proposed models.

Abstract

We present paired learning and inference algorithms for significantly reducing computation and increasing speed of the vector dot products in the classifiers that are at the heart of many NLP components. This is accomplished by partitioning the features into a sequence of templates which are ordered such that high confidence can often be reached using only a small fraction of all features. Parameter estimation is arranged to maximize accuracy and early confidence in this sequence. Our approach is simpler and better suited to NLP than other related cascade methods. We present experiments in left-to-right part-of-speech tagging, named entity recognition, and transition-based dependency parsing. On the typical benchmarking datasets we can preserve POS tagging accuracy above 97% and parsing LAS above 88.5% both with over a five-fold reduction in run-time, and NER F1 above 88 with more than 2x increase in speed.

1 Introduction

Many NLP tasks such as part-of-speech tagging, parsing and named entity recognition have become sufficiently accurate that they are no longer solely an object of research, but are also widely deployed in production systems. These systems can be run on billions of documents, making the efficiency of inference a significant concern—impacting not only wall-clock running time but also computer hardware budgets and the carbon footprint of data centers.

This paper describes a paired learning and inference approach for significantly reducing computation and increasing speed while preserving accuracy in the linear classifiers typically used in many NLP tasks. The heart of the prediction computation in these models is a dot-product between a dense parameter vector and a sparse feature vector. The bottleneck in these models is then often a combination of feature extraction and numerical operations, each of which scale linearly in the size of the feature vector. Feature extraction can be even more expensive than the dot products, involving, for example, walking sub-graphs, lexicon lookup, string concatenation and string hashing. We note, however, that in many cases not all of these features are necessary for accurate prediction. For example, in part-of-speech tagging if we see the word "the," there is no need to perform a large dot product or many string operations; we can accurately label the word a DETERMINER using the word identity feature alone. In other cases two features are sufficient: when we see the word "hits" preceded by a CARDINAL (e.g. "two hits") we can be confident that it is a NOUN.

We present a simple yet novel approach to improve processing speed by dynamically determining on a per-instance basis how many features are necessary for a high-confidence prediction. Our features are divided into a set of *feature templates*, such as current-token or previous-tag in the case of POS tagging. At training time, we determine an ordering on the templates such that we can approximate model scores at test time by incrementally calculating the dot product in template ordering. We then use a running confidence estimate for the label prediction to determine how many terms of the sum to compute for a given instance, and predict once confidence reaches a certain threshold.

In similar work, cascades of increasingly complex and high-recall models have been used for both structured and unstructured prediction. Viola and Jones (2001) use a cascade of boosted models to perform face detection. Weiss and Taskar (2010) add increasingly higher-order dependencies to a graphical model while filtering the out-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 146–155,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

put domain to maintain tractable inference. While most traditional cascades pass instances down to layers with increasingly higher recall, we use a single model and accumulate the scores from each additional template until a label is predicted with sufficient confidence, in a stagewise approximation of the full model score. Our technique applies to any linear classifier-based model over feature templates without changing the model structure or decreasing prediction speed.

Most similarly to our work, Weiss and Taskar (2013) improve performance for several structured vision tasks by dynamically selecting features at runtime. However, they use a reinforcement learning approach whose computational tradeoffs are better suited to vision problems with expensive features. Obtaining a speedup on tasks with comparatively cheap features, such as part-of-speech tagging or transition-based parsing, requires an approach with less overhead. In fact, the most attractive aspect of our approach is that it speeds up methods that are already among the fastest in NLP.

We apply our method to left-to-right part-of-speech tagging in which we achieve accuracy above 97% on the Penn Treebank WSJ corpus while running more than five times faster than our 97.2% baseline. We also achieve a five-fold increase in transition-based dependency parsing on the WSJ corpus while achieving an LAS just 1.5% lower than our 90.3% baseline. Named entity recognition also shows significant speed increases. We further demonstrate that our method can be tuned for $2.5 - 3.5$x multiplicative speedups with nearly no loss in accuracy.

2 Classification and Structured Prediction

Our algorithm speeds up prediction for multiclass classification problems where the label set can be tractably enumerated and scored, and the per-class scores of input features decompose as a sum over multiple feature templates. Frequently, classification problems in NLP are solved through the use of linear classifiers, which compute scores for input-label pairs using a dot product. These meet our additive scoring criteria, and our acceleration methods are directly applicable.

However, in this work we are interested in speeding up *structured prediction* problems, specifically part-of-speech (POS) tagging and dependency parsing. We apply our classification algorithms to these problems by reducing them to *sequential prediction* (Daumé III et al., 2009). For POS tagging, we describe a sentence's part of speech annotation by the left-to-right sequence of tagging decisions for individual tokens (Giménez and Màrquez, 2004). Similarly, we implement our parser with a classifier that generates a sequence of shift-reduce parsing transitions (Nivre, 2009).

The use of sequential prediction to solve these problems and others has a long history in practice as well as theory. Searn (Daumé III et al., 2009) and DAgger (Ross et al., 2011) are two popular principled frameworks for reducing sequential prediction to classification by learning a classifier on additional synthetic training data. However, as we do in our experiments, practitioners often see good results by training on the gold standard labels with an off-the-shelf classification algorithm, as though classifying IID data (Bengtson and Roth, 2008; Choi and Palmer, 2012).

Classifier-based approaches to structured prediction are faster than dynamic programming since they consider only a subset of candidate output structures in a greedy manner. For example, the Stanford CoreNLP classifier-based part-of-speech tagger provides a 6.5x speed advantage over their dynamic programming-based model, with little reduction in accuracy. Because our methods are designed for the greedy sequential prediction regime, we can provide further speed increases to the fastest inference methods in NLP.

3 Linear models

Our base classifier for sequential prediction tasks will be a *linear model*. Given an input $x \in \mathcal{X}$, a set of labels $\mathcal{Y}$, a feature map $\Phi(x, y)$, and a weight vector $\mathbf{w}$, a linear model predicts the highest-scoring label

$$y^* = \arg\max_{y \in \mathcal{Y}} \ \mathbf{w} \cdot \Phi(x, y). \qquad (1)$$

The parameter $\mathbf{w}$ is usually learned by minimizing a regularized (R) sum of loss functions (ℓ) over the training examples indexed by i

$$\mathbf{w}^* = \arg\min_{\mathbf{w}} \sum_i \ell(x_i, y_i, \mathbf{w}) + R(\mathbf{w}).$$

In this paper, we partition the features into a set of *feature templates*, so that the weights, feature function, and dot product factor as

$$\mathbf{w} \cdot \Phi(x, y) = \sum_j \mathbf{w}_j \cdot \Phi_j(x, y) \qquad (2)$$

for some set of *feature templates* $\{\Phi_j(x, y)\}$.

Our goal is to approximate the dot products in (1) sufficiently for purposes of prediction, while using as few terms of the sum in (2) as possible.

4 Method

We accomplish this goal by developing paired learning and inference procedures for feature-templated classifiers that optimize both accuracy and inference speed, using a process of *dynamic feature selection*. Since many decisions are easy to make in the presence of strongly predictive features, we would like our model to use fewer templates when it is more confident. For a fixed, learned ordering of feature templates, we build up a vector of class scores incrementally over each prefix of the sequence of templates, which we call the *prefix scores*. Once we reach a stopping criterion based on class confidence (margin), we stop computing prefix scores, and predict the current highest scoring class. Our aim is to train each prefix to be as good a classifier as possible without the following templates, minimizing the number of templates needed for accurate predictions.

Given this method for performing fast inference on an ordered set of feature templates, it remains to choose the ordering. In Section 4.5, we develop several methods for picking template orderings, based on ideas from group sparsity (Yuan and Lin, 2006; Swirszcz et al., 2009), and other techniques for feature subset-selection (Kohavi and John, 1997).

4.1 Definitions

Given a model that computes scores additively over template-specific scoring functions as in (2), parameters $\mathbf{w}$, and an observation $x \in X$, we can define the i'th *prefix score* for label $y \in \mathcal{Y}$ as:

$$P_{i,y}(x, \mathbf{w}) = \sum_{j=1}^{i} \mathbf{w}_j \cdot \Phi_j(x, y),$$

or $P_{i,y}$ when the choice of observations and weights is clear from context. Abusing notation we also refer to the vector containing all i'th prefix scores for observation x associated to each label in $\mathcal{Y}$ as $P_i(x, \mathbf{w})$, or P_i when this is unambiguous.

Given a parameter $m > 0$, called the *margin*, we define a function h on prefix scores:

$$h(P_i, y) = \max\{0, \max_{y' \neq y} P_{i,y'} - P_{i,y} + m\}$$

Algorithm 1 Inference

```
Input: template parameters $\{\mathbf{w}_i\}_{i=1}^{k}$, margin $m$
and optional (for train time) true label $y$
Initialize: $i = 1$
while $l > 0 \wedge i \leq k$ do
    $l = \max_{y'} h(P_i, y')$ (test) or $h(P_i, y)$ (train)
    $i \leftarrow i + 1$
end while
return $\{P_j\}_{j=1}^{i}$ (train) or $\max_{y'} P_{i,y'}$ (test)
```

Algorithm 2 Parameter Learning

```
Input: examples $\{(x_i, y_i)\}_i^N$, margin $m$
Initialize: parameters $\mathbf{w}_0 = 0$, $i = 1$
while $i \leq N$ do
    prefixes $\leftarrow$ Infer($x_i, y_i, \mathbf{w}_i, m$)
    $g_i \leftarrow$ ComputeGradient(prefixes)
    $\mathbf{w}_{i+1} \leftarrow$ UpdateParameters($\mathbf{w}_i, g_i$)
    $i \leftarrow i + 1$
end while
return $\mathbf{w}_N$
```

This is the familiar structured hinge loss function as in structured support vector machines (Tsochantaridis et al., 2004), which has a minimum at 0 if and only if class y is ranked ahead of all other classes by at least m.

Using this notation, the condition that some label y be ranked first by a margin can be written as $h(P_i, y) = 0$, and the condition that any class be ranked first by a margin can be written as $\max_{y'} h(P_i, y') = 0$.

4.2 Inference

As described in Algorithm 1, at test time we compute prefixes until some label is ranked ahead of all other labels with a margin m, then predict with that label. At train time, we predict until the correct label is ranked ahead with margin m, and return the whole set of prefixes for use by the learning algorithm. If no prefix scores have a margin, then we predict with the final prefix score involving all the feature templates.

4.3 Learning

We split learning into two subproblems: first, given an ordered sequence of feature templates and our inference procedure, we wish to learn parameters that optimize accuracy while using as few of those templates as possible. Second, given a method for training feature templated classifiers, we want to learn an ordering of templates that optimizes accuracy.

We wish to optimize several different objectives during learning: template parameters should have strong predictive power on their own, but also work well when combined with the scores from later templates. Additionally, we want to encourage well-calibrated confidence scores that allow us to stop prediction early without significant reduction in generalization ability.

4.4 Learning the parameters

To learn parameters that encourage the use of few feature templates, we look at the model as outputting not a single prediction but a sequence of prefix predictions $\{P_i\}$. For each training example, each feature template receives a number of hinge-loss gradients equal to its distance from the index where the margin requirement is finally reached. This is equivalent to treating each prefix as its own model for which we have a hinge loss function, and learning all models simultaneously. Our high-level approach is described in Algorithm 2.

Concretely, for k feature templates we optimize the following structured max-margin objective (with the dependence of P's on $\mathbf{w}$ written explicitly where helpful):

$$\begin{aligned}
\mathbf{w}^* &= \arg\min_{\mathbf{w}} \sum_{(x,y)} \ell(x,y,\mathbf{w}) \\
\ell(x,y,\mathbf{w}) &= \sum_{i=1}^{i_y^*} h(P_i(x,\mathbf{w}),y) \\
i_y^* &= \min_{i\in\{1..k\}} i \quad \text{s.t.} \quad h(P_i,y)=0
\end{aligned}$$

The per-example gradient of this objective for weights $\mathbf{w}_j$ corresponding to feature template Φ_j then corresponds to

$$\frac{\partial \ell}{\partial \mathbf{w}_j} = \sum_{i=j}^{i_y^*} \Phi_j(x, y_{\text{loss}}(P_i,y)) - \Phi_j(x,y).$$

where we define

$$y_{\text{loss}}(P_i,y) = \arg\max_{y'} P_{i,y'} - m \cdot I(y'=y),$$

where I is an indicator function of the label y, used to define loss-augmented inference.

We add an ℓ_2 regularization term to the objective, and tune the margin m and the regularization strength to tradeoff between speed and accuracy. In our experiments, we used a development set to choose a regularizer and margin that reduced test-time speed as much as possible without decreasing accuracy. We then varied the margin for that same model at test time to achieve larger speed gains at the cost of accuracy. In all experiments, the margin with which the model was trained corresponds to the largest margin reported, i.e. that with the highest accuracy.

4.5 Learning the template ordering

We examine three approaches to learning the template ordering.

4.5.1 Group Lasso and Group Orthogonal Matching Pursuit

The Group Lasso regularizer (Yuan and Lin, 2006) penalizes the sum of ℓ_2-norms of weights of feature templates (different from what is commonly called "ℓ_2" regularization, penalizing squared ℓ_2 norms), $\sum_i c_i \|w_i\|_2$, where c_i is a weight for each template. This regularizer encourages entire groups of weights to be set to 0, whose templates can then be discarded from the model. By varying the strength of the regularizer, we can learn an ordering of the importance of each template for a given model. The included groups for a given regularization strength are nearly always subsets of one another (technical conditions for this to be true are given in Hastie et al. (2007)). The sequence of solutions for varied regularization strength is called the *regularization path*, and by slight abuse of terminology we use this to refer to the induced template ordering.

An alternative and related approach to learning template orderings is based on the Group Orthogonal Matching Pursuit (GOMP) algorithm for generalized linear models (Swirszcz et al., 2009; Lozano et al., 2011), with a few modifications for the setting of high-dimensional, sparse NLP data (described in Appendix B). Orthogonal matching pursuit algorithms are a set of stagewise feature selection techniques similar to forward stagewise regression (Hastie et al., 2007) and LARS (Efron et al., 2004). At each stage, GOMP effectively uses each feature template to perform a linear regression to fit the gradient of the loss function. This attempts to find the correlation of each feature subset with the residual of the model. It then adds the feature template that best fits this gradient, and retrains the model. The main weakness of this method is that it fits the gradient of the training error which can rapidly overfit for sparse, high-dimensional data. Ultimately, we would prefer to use a development set for feature selection.

4.5.2 Wrapper Method

The *wrapper method* (Kohavi and John, 1997) is a meta-algorithm for feature selection, usually based on a validation set. We employ it in a stage-wise approach to learning a sequence of templates. Given an ordering of the initial sub-sequence and a learning procedure, we add each remaining template to our ordering and estimate parameters, selecting as the next template the one that gives the highest increase in development set performance. We begin the procedure with no templates, and repeat the procedure until we have a total ordering over the set of feature templates. When learning the ordering we use the same hyperparameters as will be used during final training.

While simpler than the Lasso and Matching Pursuit approaches, we empirically found this approach to outperform the others, due to the necessity of using a development set to select features for our high-dimensional application areas.

5 Related Work

Our work is primarily inspired by previous research on cascades of classifiers; however, it differs significantly by approximating the score of a single linear model—scoring as few of its features as possible to obtain sufficient confidence.

We pose and address the question of whether a single, interacting set of parameters can be learned such that they efficiently both (1) provide high accuracy and (2) good confidence estimates throughout their use in the lengthening prefixes of the feature template sequence. (These two requirements are both incorporated into our novel parameter estimation algorithm.) In contrast, other work (Weiss and Taskar, 2013; He et al., 2013) learns a separate classifier to determine when to add features. Such heavier-weight approaches are unsuitable for our setting, where the core classifier's features and scoring are already so cheap that adding complex decision-making would cause too much computational overhead.

Other previous work on cascades uses a series of increasingly complex models, such as the Viola-Jones face detection cascade of classifiers (2001), which applies boosted trees trained on subsets of features in increasing order of complexity as needed, aiming to reject many sub-image windows early in processing. We allow scores from each layer to directly affect the final prediction, avoiding duplicate incorporation of evidence.

Our work is also related to the field of learning and inference under test-time budget constraints (Grubb and Bagnell, 2012; Trapeznikov and Saligrama, 2013). However, common approaches to this problem also employ auxiliary models to rank which feature to add next, and are generally suited for problems where features are expensive to compute (*e.g* vision) and the extra computation of an auxiliary pruning-decision model is offset by substantial reduction in feature computations (Weiss and Taskar, 2013). Our method uses confidence scores directly from the model, and so requires no additional computation, making it suitable for speeding up classifier-based NLP methods that are already very fast and have relatively cheap features.

Some cascaded approaches strive at each stage to prune the number of possible output structures under consideration, whereas in our case we focus on pruning the input features. For example, Xu et al. (2013) learn a tree of classifiers that subdivides the set of classes to minimize average test-time cost. Chen et al. (2012) similarly use a linear cascade instead of a tree. Weiss and Taskar (2010) prune output labels in the context of structured prediction through a cascade of increasingly complex models, and Rush and Petrov (2012) successfully apply these structured prediction cascades to the task of graph-based dependency parsing.

In the context of NLP, He et al. (2013) describe a method for dynamic feature template selection at test time in graph-based dependency parsing. Their technique is particular to the parsing task—making a binary decision about whether to lock in edges in the dependency graph at each stage, and enforcing parsing-specific, hard-coded constraints on valid subsequent edges. Furthermore, as described above, they employ an auxiliary model to select features.

He and Eisner (2012) share our goal to speed test time prediction by dynamically selecting features, but they also learn an additional model on top of a fixed base model, rather than using the training objective of the model itself.

While our comparisons above focus on other methods of *dynamic* feature selection, there also exists related work in the field of general (static) feature selection. The most relevant results come from the applications of *group sparsity*, such as the work of Martins et al. (2011) in *Group Lasso* for NLP problems. The Group Lasso regularizer (Yuan and Lin, 2006) sparsifies groups of feature weights (e.g. feature templates), and has been used to speed up test-time prediction by removing entire templates from the model. The key difference between this work and ours is that we select our templates based on the test-time difficulty of the inference problem, while the Group Lasso must do so at train time. In Appendix A, we compare against Group Lasso and show improvements in accuracy and speed.

Note that non-grouped approaches to selecting sparse feature subsets, such as boosting and ℓ_1 regularization, do not achieve our goal of fast test-time prediction in NLP models, as they would not zero-out entire templates, and still require the computation of a feature for every template for every test instance.

6 Experimental Results

We present experiments on three NLP tasks for which greedy sequence labeling has been a successful solution: part-of-speech tagging, transition-based dependency parsing and named entity recognition. In all cases our method achieves multiplicative speedups at test time with little loss in accuracy.

6.1 Part-of-speech tagging

We conduct our experiments on classifier-based greedy part-of-speech tagging. Our baseline tagger uses the same features described in Choi and Palmer (2012). We evaluate our models on the Penn Treebank WSJ corpus (Marcus et al., 1993), employing the typical split of sections used for part-of-speech tagging: 0-18 train, 19-21 development, 22-24 test. The parameters of our models are learned using AdaGrad (Duchi et al., 2011) with ℓ_2 regularization via regularized dual averaging (Xiao, 2009), and we used random search on the development set to select hyperparameters.

This baseline model (**baseline**) tags at a rate of approximately 23,000 tokens per second on a 2010 2.1GHz AMD Opteron machine with accuracy comparable to similar taggers (Giménez and Màrquez, 2004; Choi and Palmer, 2012; Toutanova et al., 2003). On the same machine the greedy Stanford CoreNLP left3words part-of-speech tagger also tags at approximately 23,000 tokens per second. Significantly higher absolute speeds for all methods can be attained on more modern machines.

Model/m	**Tok.**	**Unk.**	**Feat.**	**Speed**
Baseline	97.22	88.63	46	1x
Stagewise	96.54	83.63	9.50	2.74
Fixed	89.88	56.25	1	16.16x
Fixed	94.66	60.59	3	9.54x
Fixed	96.16	87.09	5	7.02x
Fixed	96.88	88.81	10	3.82x
Dynamic/15	96.09	83.12	1.92	**10.36x**
Dynamic/35	97.02	88.26	4.33	**5.22x**
Dynamic/45	97.16	88.84	5.87	3.97x
Dynamic/50	**97.21**	88.95	6.89	3.41x

Table 1: Comparison of our models using different margins m, with speeds measured relative to the baseline. We train a model as accurate as the baseline while tagging 3.4x tokens/sec, and in another model maintain $> 97\%$ accuracy while tagging 5.2x, and $> 96\%$ accuracy with a speedup of 10.3x.

We include additional baselines that divide the features into templates, but train the templates' parameters more simply than our algorithm. The **stagewise** baseline learns the model parameters for each of the templates in order, starting with only one template—once each template has been trained for a fixed number of iterations, that template's parameters are fixed and we add the next one. We also create a separately-trained baseline model for each fixed prefix of the feature templates (**fixed**). This shows that our speedups are not simply due to superfluous features in the later templates.

Our main results are shown in Table 1. We increase the speed of our baseline POS tagger by a factor of 5.2x without falling below 97% test accuracy. By tuning our training method to more aggressively prune templates, we achieve speedups of over 10x while providing accuracy higher than 96%. It is worth noting that the results for our method (**dynamic**) are all obtained from a single trained model (with hyperparameters optimized for $m = 50$, which we observed gave a good speedup with nearly no lossin accuracy on the development set), the only difference being

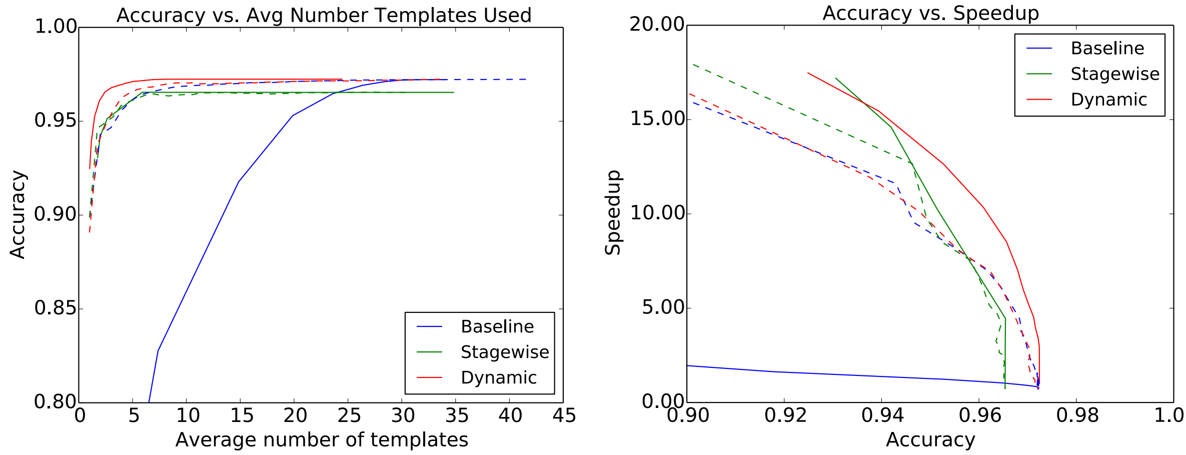

Figure 1: Left-hand plot depicts test accuracy as a function of the average number of templates used to predict. Right-hand plot shows speedup as a function of accuracy. Our model consistently achieves higher accuracy while using fewer templates resulting in the best ratio of speed to accuracy.

that we varied the margin at test time. Superior results for $m \neq 50$ could likely be obtained by optimizing hyperparameters for the desired margin.

Results show our method (**dynamic**) learns to dynamically select the number of templates, often using only a small fraction. The majority of test tokens can be tagged using only the first few templates: just over 40% use one template, and 75% require at most four templates, while maintaining 97.17% accuracy. On average 6.71 out of 46 templates are used, though a small set of complicated instances never surpass the margin and use all 46 templates. The right hand plot of Figure 1 shows speedup vs. accuracy for various settings of the confidence margin m.

The left plot in Figure 1 depicts accuracy as a function of the number of templates used at test time. We present results for both varying the number of templates directly (dashed) and margin (solid). The baseline model trained on all templates performs very poorly when using margin-based inference, since its training objective does not learn to predict with only prefixes. When predicting using a fixed subset of templates, we use a different baseline model for each one of the 46 total template prefixes, learned with only those features; we then compare the test accuracy of our dynamic model using template prefix i to the baseline model trained on the fixed prefix i. Our model performs just as well as these separately trained models, demonstrating that our objective learns weights that allow each prefix to act as its own high-quality classifier.

6.1.1 Learning the template ordering

As described in Section 4.5, we experimented on part-of-speech tagging with three different algorithms for learning an ordering of feature templates: Group Lasso, Group Orthogonal Matching Pursuit (GOMP), and the wrapper method. For the case of Group Lasso, this corresponds to the experimental setup used when evaluating Group Lasso for NLP in Martins et al. (2011). As detailed in the part-of-speech tagging experiments of Appendix A, we found the wrapper method to work best in our dynamic prediction setting. Therefore, we use it in our remaining experiments in parsing and named entity recognition. Essentially, the Group Lasso picks small templates too early in the ordering by penalizing template norms, and GOMP picks large templates too early by overfitting the train error.

6.2 Transition-based dependency parsing

We base our parsing experiments on the greedy, non-projective transition-based dependency parser described in Choi and Palmer (2011). Our model uses a total of 60 feature templates based mainly on the word form, POS tag, lemma and assigned head label of current and previous input and stack tokens, and parses about 300 sentences/second on a modest 2.1GHz AMD Opteron machine.

We train our parser on the English Penn TreeBank, learning the parameters using AdaGrad and the parsing split, training on sections 2–21, testing on section 23 and using section 22 for development and the Stanford dependency framework (de

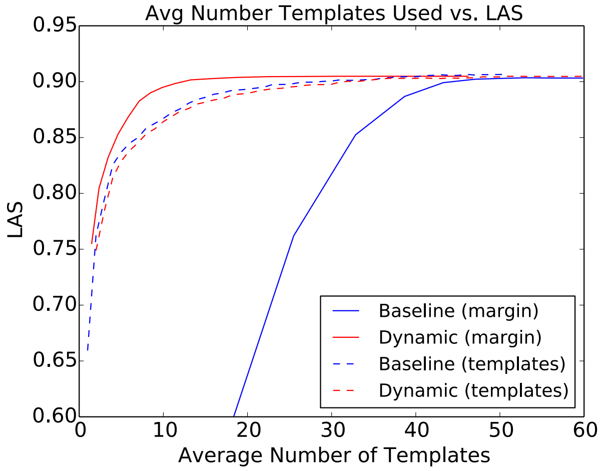

Figure 2: Parsing speedup as a function of accuracy. Our model achieves the highest accuracy while using the fewest feature templates.

Marneffe and Manning, 2008). POS tags were automatically generated via 10-way jackknifing using the baseline POS model described in the previous section, trained with AdaGrad using ℓ_2 regularization, with parameters tuned on the development set to achieve 97.22 accuracy on WSJ sections 22-24. Lemmas were automatically generated using the ClearNLP morphological analyzer. We measure accuracy using labeled and unlabeled attachment scores excluding punctuation, achieving a labeled score of 90.31 and unlabeled score of 91.83, which are comparable to similar greedy parsers (Choi and Palmer, 2011; Honnibal and Goldberg, 2013).

Our experimental setup is the same as for part-of-speech tagging. We compare our model (**dynamic**) to both a single **baseline** model trained on all features, and a set of 60 models each trained on a prefix of feature templates. Our experiments vary the margin used during prediction (solid) as well as the number of templates used (dashed).

As in part-of-speech tagging, we observe significant test-time speedups when applying our method of dynamic feature selection to dependency parsing. With a loss of only 0.04 labeled attachment score (LAS), our model produces parses 2.7 times faster than the baseline. As listed in Table 2, with a more aggressive margin our model can parse more than 3 times faster while remaining above 90% LAS, and more than 5 times faster while maintaining accuracy above 88.5%.

In Figure 2 we see not only that our **dynamic** model consistently achieves higher accuracy while using fewer templates, but also that our model (**dynamic**, dashed) performs exactly as well as separate models trained on each prefix of templates (**baseline**, dashed), demonstrating again that our training objective is successful in learning a single model that can predict as well as possible using any prefix of feature templates while successfully selecting which of these prefixes to use on a per-example basis.

Model/m	**LAS**	**UAS**	**Feat.**	**Speed**
Baseline	90.31	91.83	60	1x
Fixed	65.99	70.78	1	27.5x

Dynamic/11	90.27	91.80	15.83	2.71x

Table 2: Comparison of our baseline and templated models using varying margins m and numbers of templates.

6.3 Named entity recognition

We implement a greedy left-to-right named entity recognizer based on Ratinov and Roth (2009) using a total of 46 feature templates, including surface features such as lemma and capitalization, gazetteer look-ups, and each token's *extended prediction history*, as described in (Ratinov and Roth, 2009). Training, tuning, and evaluation are performed on the CoNLL 2003 English data set with the BILOU encoding to denote label spans.

Our baseline model achieves F1 scores of 88.35 and 93.37 on the test and development sets, respectively, and tags at a rate of approximately 5300 tokens per second on the hardware described in the experiments above. We achieve a 2.3x speedup while maintaining F1 score above 88 on the test set.

7 Conclusions and Future Work

By learning to dynamically select the most predictive features at test time, our algorithm provides significant speed improvements to classifier-based structured prediction algorithms, which themselves already comprise the fastest methods in NLP. Further, these speed gains come at very lit-

Model/m	Test F1	Feat.	Speed

Table 3: Comparison of our baseline and templated NER models using varying margin m and number of templates.

tle extra implementation cost and can easily be combined with existing state-of-the-art systems. Future work will remove the fixed ordering for feature templates, and dynamically add additional features based on the current scores of different labels.

Abstract

Knowledge base (KB) completion adds new facts to a KB by making inferences from existing facts, for example by inferring with high likelihood *nationality(X,Y)* from *bornIn(X,Y)*. Most previous methods infer simple one-hop relational synonyms like this, or use as evidence a multi-hop relational path treated as an atomic feature, like *bornIn(X,Z)* → *containedIn(Z,Y)*. This paper presents an approach that reasons about conjunctions of multi-hop relations *non-atomically*, composing the implications of a path using a recurrent neural network (RNN) that takes as inputs vector embeddings of the binary relation in the path. Not only does this allow us to generalize to paths unseen at training time, but also, with a single high-capacity RNN, to predict new relation types not seen when the compositional model was trained (zero-shot learning). We assemble a new dataset of over 52M relational triples, and show that our method improves over a traditional classifier by 11%, and a method leveraging pre-trained embeddings by 7%.

1 Introduction

Constructing large knowledge bases (KBs) supports downstream reasoning about resolved entities and their relations, rather than the noisy textual evidence surrounding their natural language mentions. For this reason KBs have been of increasing interest in both industry and academia (Bollacker et al., 2008; Suchanek et al., 2007; Carlson et al., 2010). Such KBs typically contain many millions of facts, most of them (entity1,relation,entity2) "triples" (also known as binary relations) such as *(Barack Obama, presidentOf, USA)* and *(Brad Pitt, marriedTo, Angelina Jolie)*.

However, even the largest KBs are woefully incomplete (Min et al., 2013), missing many important facts, and therefore damaging their usefulness in downstream tasks. Ironically, these missing facts can frequently be inferred from other facts already in the KB, thus representing a sort of inconsistency that can be repaired by the application of an automated process. The addition of new triples by leveraging existing triples is typically known as *KB completion*.

Early work on this problem focused on learning symbolic rules. For example, Schoenmackers et al. (2010) learns Horn clauses predictive of new binary relations by exhausitively exploring relational paths of increasing length, and selecting those surpassing an accuracy threshold. (A "path" is a sequence of triples in which the second entity of each triple matches the first entity of the next triple.) Lao et al. (2011) introduced the Path Ranking Algorithm (PRA), which greatly improves efficiency and robustness by replacing exhaustive search with random walks, and using unique paths as features in a per-target-relation binary classifier. A typical predictive feature learned by PRA is that *CountryOfHeadquarters(X, Y)* is implied by *IsBasedIn(X,A)* and *StateLocatedIn(A, B)* and *CountryLocatedIn(B, Y)*. Given *IsBasedIn(Microsoft, Seattle)*, *StateLocatedIn(Seattle, Washington)* and *CountryLocatedIn(Washington, USA)*, we can infer the fact *CountryOfHeadquarters(Microsoft, USA)* using the predictive feature. In later work, Lao et al. (2012) greatly increase available raw material for paths by augmenting KB-schema relations with relations defined by the text connecting mentions of entities in a large corpus (also known as OpenIE relations (Banko et al., 2007)).

However, these symbolic methods can produce many millions of distinct paths, each of which is categorically distinct, treated by PRA as a dis-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 156–166,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

tinct feature. (See Figure 1.) Even putting aside the OpenIE relations, this limits the applicability of these methods to modern KBs that have thousands of relation types, since the number of distinct paths increases rapidly with the number of relation types. If textually-defined OpenIE relations are included, the problem is obviously far more severe.

Better generalization can be gained by operating on embedded vector representations of relations, in which vector similarity can be interpreted as semantic similarity. For example, Bordes et al. (2013) learn low-dimensional vector representations of entities and KB relations, such that vector differences between two entities should be close to the vectors associated with their relations. This approach can find relation synonyms, and thus perform a kind of one-to-one, non-path-based relation prediction for KB completion. Similarly Nickel et al. (2011) and Socher et al. (2013a) perform KB completion by learning embeddings of relations, but based on matrices or tensors. Universal schema (Riedel et al., 2013) learns to perform relation prediction cast as matrix completion (likewise using vector embeddings), but predicts textually-defined OpenIE relations as well as KB relations, and embeds entity-pairs in addition to individual entities. Like all of the above, it also reasons about individual relations, not the evidence of a connected path of relations.

This paper proposes an approach combining the advantages of (a) reasoning about conjunctions of relations connected in a path, and (b) generalization through vector embeddings, and (c) reasoning non-atomically and compositionally about the elements of the path, for further generalization.

Our method uses recurrent neural networks (RNNs) (Werbos, 1990) to compose the semantics of relations in an arbitrary-length path. At each path-step it consumes both the vector embedding of the next relation, and the vector representing the path-so-far, then outputs a composed vector (representing the extended path-so-far), which will be the input to the next step. After consuming a path, the RNN should output a vector in the semantic neighborhood of the relation between the first and last entity of the path. For example, after consuming the relation vectors along the path *Melinda Gates → Bill Gates → Microsoft → Seattle*, our method produces a vector very close to the relation *livesIn*.

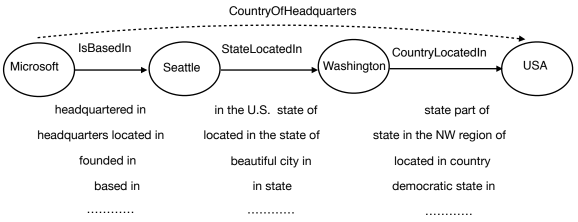

Figure 1: Semantically similar paths connecting entity pair (Microsoft, USA).

Our compositional approach allow us at test time to make predictions from paths that were unseen during training, because of the generalization provided by vector neighborhoods, and because they are composed in non-atomic fashion. This allows our model to seamlessly perform inference on many millions of paths in the KB graph. In most of our experiments, we learn a separate RNN for predicting each relation type, but alternatively, by learning a single high-capacity composition function for all relation types, our method can perform zero-shot learning—predicting new relation types for which the composition function was never explicitly trained.

Related to our work, new versions of PRA (Gardner et al., 2013; Gardner et al., 2014) use pre-trained vector representations of relations to alleviate its feature explosion problem—but the core mechanism continues to be a classifier based on atomic-path features. In the 2013 work many paths are collapsed by clustering paths according to their relations' embeddings, and substituting cluster ids for the original relation types. In the 2014 work unseen paths are mapped to nearby paths seen at training time, where nearness is measured using the embeddings. Neither is able to perform zero-shot learning since there must be a classifer for each predicted relation type. Furthermore their pre-trained vectors do not have the opportunity to be tuned to the KB completion task because the two sub-tasks are completely disentangled.

An additional contribution of our work is a new large-scale data set of over 52 million triples, and its preprocessing for purposes of path-based KB completion (can be downloaded from `http://iesl.cs.umass.edu/downloads/inferencerules/release.tar.gz`). The dataset is build from the combination of Freebase (Bollacker et al., 2008) and Google's entity linking in ClueWeb (Orr et al., 2013). Rather than Gardner's 1000 distinct paths per relation type, we have over 2 million. Rather than Gardner's 200

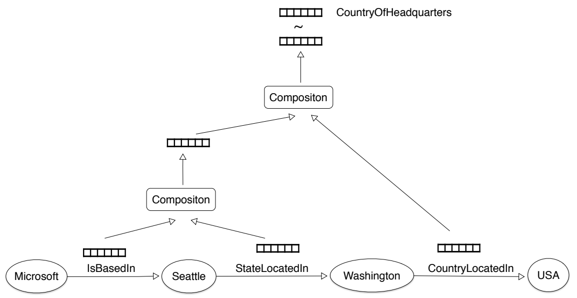

Figure 2: Vector Representations of the paths are computed by applying the composition function recursively.

entity pairs, we use over 10k. All experimental comparisons below are performed on this new data set.

On this challenging large-scale dataset our compositional method outperforms PRA (Lao et al., 2012), and Cluster PRA (Gardner et al., 2013) by 11% and 7% respectively. A further contribution of our work is a new, surprisingly strong baseline method using classifiers of path bigram features, which beats PRA and Cluster PRA, and statistically ties our compositional method. Our analysis shows that our method has substantially different strengths than the new baseline, and the combination of the two yields a 15% improvement over Gardner et al. (2013). We also show that our zero-shot model is indeed capable of predicting new unseen relation types.

2 Background

We give background on PRA which we use to obtain a set of paths connecting the entity pairs and the RNN model which we employ to model the composition function.

2.1 Path Ranking Algorithm

Since it is impractical to exhaustively obtain the set of all paths connecting an entity pair in the large KB graph, we use PRA (Lao et al., 2011) to obtain a set of paths connecting the entity pairs. Given a training set of entity pairs for a relation, PRA heuristically finds a set of paths by performing random walks from the source and target nodes keeping the most common paths. We use PRA to find millions of distinct paths per relation type. We do not use the random walk probabilities given by PRA since using it did not yield improvements in our experiments.

2.2 Recurrent Neural Networks

Recurrent neural network (RNN) (Werbos, 1990) is a neural network that constructs vector representation for sequences (of any length). For example, a RNN model can be used to construct vector representations for phrases or sentences (of any length) in natural language by applying a composition function (Mikolov et al., 2010; Sutskever et al., 2014; Vinyals et al., 2014). The vector representation of a phrase (w_1, w_2) consisting of words w_1 and w_2 is given by $f(W[v(w_1); v(w_2)])$ where $v(w) \in \mathbb{R}^d$ is the vector representation of w, f is an element-wise non linearity function, $[a; b]$ represents the concatenation two vectors a and b along with a bias term, and $W \in \mathbb{R}^{d \times 2*d+1}$ is the composition matrix. This operation can be repeated to construct vector representations of longer phrases.

3 Recurrent Neural Networks for KB Completion

This paper proposes a RNN model for KB completion that reasons on the paths connecting an entity pair to predict missing relation types. The vector representations of the paths (of any length) in the KB graph are computed by applying the composition function recursively as shown in Figure 2. To compute the vector representations for the higher nodes in the tree, the composition function consumes the vector representation of the node's two children nodes and outputs a new vector of the same dimension. Predictions about missing relation types are made by comparing the vector representation of the path with the vector representation of the relation using the sigmoid function.

We represent each binary relation using a d-dimensional real valued vector. We model composition using recurrent neural networks (Werbos, 1990). We learn a separate composition matrix for every relation that is predicted.

Let $v_r(\delta) \in \mathbb{R}^d$ be the vector representation of relation δ and $v_p(\pi) \in \mathbb{R}^d$ be the vector representation of path π. $v_p(\pi)$ denotes the relation vector if path π is of length one. To predict relation $\delta = \textit{CountryOfHeadquarters}$, the vector representation of the path $\pi = \textit{IsBasedIn} \rightarrow \textit{StateLocatedIn}$ containing two relations *IsBasedIn* and *StateLocatedIn* is computed by (Figure 2),

$$v_p(\pi) = \\ f(W_\delta[v_r(\textit{IsBasedIn}); v_r(\textit{StateLocatedIn})])$$

where $f = sigmoid$ is the element-wise non-linearity function, $W_\delta \in \mathbb{R}^{d*2d+1}$ is the composition matrix for $\delta =$ *CountryOfHeadquarters* and $[a; b]$ represents the concatenation of two vectors $a \in \mathbb{R}^d, b \in \mathbb{R}^d$ along with a bias feature to get a new vector $[a; b] \in \mathbb{R}^{2d+1}$.

The vector representation of the path $\Pi =$ *IsBasedIn* → *StateLocatedIn* → *CountryLocatedIn* in Figure 2 is computed similarly by,

$$v_p(\Pi) = \\ f(W_\delta[v_p(\pi); v_r(\textit{ CountryLocatedIn})])$$

where $v_p(\pi)$ is the vector representation of path *IsBasedIn* → *StateLocatedIn*. While computing the vector representation of a path we always traverse left to right, composing the relation vector in the right with the accumulated path vector in the left[1]. This makes our model a recurrent neural network (Werbos, 1990).

Finally, we make a prediction regarding *CountryOfHeadquarters(Microsoft, USA)* using the path $\Pi =$ *IsBasedIn* → *StateLocatedIn* → *CountryLocatedIn* by comparing the vector representation of the path ($v_p(\Pi)$) with the vector representation of the relation *CountryOfHeadquarters* (v_r(*CountryOfHeadquarters*)) using the sigmoid function.

3.1 Model Training

We train the model with the existing facts in a KB using them as positive examples and negative examples are obtained by treating the unobserved instances as negative examples (Mintz et al., 2009; Lao et al., 2011; Riedel et al., 2013; Bordes et al., 2013). Unlike in previous work that use RNNs(Socher et al., 2011; Iyyer et al., 2014; Irsoy and Cardie, 2014), a challenge with using them for our task is that among the set of paths connecting an entity pair, we do not observe which of the path(s) is predictive of a relation. We select the path that is closest to the relation type to be predicted in the vector space. This not only allows for faster training (compared to marginalization) but also gives improved performance. This technique has been successfully used in models other than RNNs previously (Weston et al., 2013; Neelakantan et al., 2014).

Algorithm 1 Training Algorithm of RNN model for relation δ

```
Input: $\Lambda_\delta = \Lambda_\delta^+ \cup \Lambda_\delta^-$, $\Phi_\delta$, number of iterations $T$, mini-batch size $B$
Initialize $v_r, W_\delta$ randomly
for $t = 1, 2, \ldots, T$ do
    $\nabla v_r = 0$, $\nabla W_\delta = 0$ and $b = 0$
    for $\lambda = (\gamma, \delta) \in \Lambda_\delta$ do
        $\mu_\lambda = \arg\max_{\pi \in \Phi_\delta(\gamma)} v_p(\pi).v_r(\delta)$
        Accumulate gradients to $\nabla v_r$, $\nabla W_\delta$
    using path $\mu_\lambda$.
        $b = b + 1$
        if $b = B$ then
            Gradient Update for $v_r, W_\delta$
            $\nabla v_r = 0$, $\nabla W_\delta = 0$ and $b = 0$
        end if
    end for
    if $b > 0$ then
        Gradient Update for $v_r, W_\delta$
    end if
end for
Output: $v_r, W_\delta$
```

We assume that we are given a KB (for example, Freebase enriched with SVO triples) containing a set of entity pairs Γ, set of relations Δ and a set of observed facts Λ^+ where $\forall \lambda = (\gamma, \delta) \in \Lambda^+ (\gamma \in \Gamma, \delta \in \Delta)$ indicates a positive fact that entity pair γ is in relation δ. Let $\Phi_\delta(\gamma)$ denote the set of paths connecting entity pair γ given by PRA for predicting relation δ.

In our task, we only observe the set of paths connecting an entity pair but we do not observe which of the path(s) is predictive of the fact. We treat this as a latent variable (μ_λ for the fact λ) and we assign μ_λ the path whose vector representation has maximum dot product with the vector representation of the relation to be predicted. For example, μ_λ for the fact $\lambda = (\gamma, \delta) \in \Lambda^+$ is given by,

$$\mu_\lambda = \underset{\pi \in \Phi_\delta(\gamma)}{\arg\max}\, v_p(\pi).v_r(\delta)$$

During training, we assign μ_λ using the current parameter estimates. We use the same procedure to assign μ_λ for unobserved facts that are used as negative examples during training.

We train a separate RNN model for predicting each relation and the parameters of the model for predicting relation $\delta \in \Delta$ are $\Theta = \{v_r(\omega) \forall \omega \in \Delta,\ W_\delta\}$. Given a training set consisting of posi-

[1] we did not get significant improvements when we tried more sophisticated ordering schemes for computing the path representations.

tive (Λ_δ^+) and negative (Λ_δ^-) instances[2] for relation δ, the parameters are trained to maximize the log likelihood of the training set with L-2 regularization.

$$\Theta^* = \arg\max_{\Theta} \sum_{\lambda=(\gamma,\delta)\in\Lambda_\delta^+} P(y_\lambda = 1;\Theta) + \sum_{\lambda=(\gamma,\delta)\in\Lambda_\delta^-} P(y_\lambda = 0;\Theta) - \rho\|\Theta\|^2$$

where y_λ is a binary random variable which takes the value 1 if the fact λ is true and 0 otherwise, and the probability of a fact $P(y_\lambda = 1;\Theta)$ is given by,

$$P(y_\lambda = 1;\Theta) = sigmoid(v_p(\mu_\lambda).v_r(\delta))$$
$$where\ \ \mu_\lambda = \arg\max_{\pi\in\Phi_\delta(\gamma)} v_p(\pi).v_r(\delta)$$

and $P(y_\lambda = 0;\Theta) = 1 - P(y_\lambda = 1;\Theta)$. The relation vectors and the composition matrix are initialized randomly. We train the network using backpropagation through structure (Goller and Küchler, 1996).

4 Zero-shot KB Completion

The KB completion task involves predicting facts on thousands of relations types and it is highly desirable that a method can infer facts about relation types without directly training for them. Given the vector representation of the relations, we show that our model described in the previous section is capable of predicting relational facts without explicitly training for the target (or test) relation types (zero-shot learning).

In zero-shot or zero-data learning (Larochelle et al., 2008; Palatucci et al., 2009), some labels or classes are not available during training the model and only a description of those classes are given at prediction time. We make two modifications to the model described in the previous section, (1) learn a general composition matrix, and (2) fix relation vectors with pre-trained vectors, so that we can predict relations that are unseen during training. This ability of the model to generalize to unseen relations is beyond the capabilities of all previous methods for KB inference (Schoenmackers et al., 2010; Lao et al., 2011; Gardner et al., 2013; Gardner et al., 2014).

We learn a general composition matrix for all relations instead of learning a separate composition matrix for every relation to be predicted. So, for example, the vector representation of the path π = *IsBasedIn* → *StateLocatedIn* containing two relations *IsBasedIn* and *StateLocatedIn* is computed by (Figure 2),

$$v_p(\pi) = f(W[v_r(\textit{IsBasedIn}); v_r(\textit{StateLocatedIn})])$$

where $W \in \mathbb{R}^{d*2d+1}$ is the general composition matrix.

We initialize the vector representations of the binary relations (v_r) using the representations learned in Riedel et al. (2013) and do not update them during training. The relation vectors are not updated because at prediction time we would be predicting relation types which are never seen during training and hence their vectors would never get updated. We learn only the general composition matrix in this model. We train a single model for a set of relation types by replacing the sigmoid function with a softmax function while computing probabilities and the parameters of the composition matrix are learned using the available training data containing instances of few relations. The other aspects of the model remain unchanged.

To predict facts whose relation types are unseen during training, we compute the vector representation of the path using the general composition matrix and compute the probability of the fact using the pre-trained relation vector. For example, using the vector representation of the path Π = *IsBasedIn* → *StateLocatedIn* → *CountryLocatedIn* in Figure 2, we can predict any relation irrespective of whether they are seen at training by comparing it with the pre-trained relation vectors.

5 Experiments

The hyperparameters of all the models were tuned on the same held-out development data. All the neural network models are trained for 150 iterations using 50 dimensional relation vectors, and we set the L2-regularizer and learning rate to 0.0001 and 0.1 respectively. We halved the learning rate after every 60 iterations and use mini-batches of size 20. The neural networks and the classifiers were optimized using AdaGrad (Duchi et al., 2011).

5.1 Data

We ran experiments on Freebase (Bollacker et al., 2008) enriched with information from ClueWeb.

[2] we sub-sample a portion of the set of all unobserved instances.

Entities	18M
Freebase triples	40M
ClueWeb triples	12M
Relations	25,994
Relation types tested	46
Avg. paths/relation	2.3M
Avg. training facts/relation	6638
Avg. positive test instances/relation	3492
Avg. negative test instances/relation	43,160

Table 1: Statistics of our dataset.

We use the publicly available entity links to Freebase in the ClueWeb dataset (Orr et al., 2013). Hence, we create nodes only for Freebase entities in our KB graph. We remove facts containing /type/object/type as they do not give useful predictive information for our task. We get triples from ClueWeb by considering sentences that contain two entities linked to Freebase. We extract the phrase between the two entities and treat them as the relation types. For phrases that are of length greater than four we keep only the first and last two words. This helps us to avoid the time consuming step of dependency parsing the sentence to get the relation type. These triples are similar to facts obtained by OpenIE (Banko et al., 2007). To reduce noise, we select relation types that occur at least 50 times. We evaluate on 46 relation types in Freebase that have the most number of instances. The methods are evaluated on a subset of facts in Freebase that were hidden during training. Table 1 shows important statistics of our dataset.

5.2 Predictive Paths

Table 2 shows predictive paths for 4 relations learned by the RNN model. The high quality of unseen paths is indicative of the fact that the RNN model is able to generalize to paths that are never seen during training.

5.3 Results

Using our dataset, we compare the performance of the following methods:

PRA Classifier is the method in Lao et al. (2012) which trains a logistic regression classifier by creating a feature for every path type.

Cluster PRA Classifier is the method in Gardner et al. (2013) which replaces relation types from ClueWeb triples with their cluster membership in the KB graph before the path finding step. After this step, their method proceeds in exactly the same manner as Lao et al. (2012) training a logistic regression classifier by creating a feature for every path type. We use pre-trained relation vectors from Riedel et al. (2013) and use k-means clustering to cluster the relation types to 25 clusters as done in Gardner et al. (2013).

Composition-Add uses a simple element-wise addition followed by sigmoid non-linearity as the composition function similar to Yang et al. (2014).

RNN-random is the supervised RNN model described in section 3 with the relation vectors initialized randomly.

RNN is the supervised RNN model described in section 3 with the relation vectors initialized using the method in Riedel et al. (2013).

PRA Classifier-b is our simple extension to the method in Lao et al. (2012) which additionally uses bigrams in the path as features. We add a special *start* and *stop* symbol to the path before computing the bigram features.

Cluster PRA Classifier-b is our simple extension to the method in Gardner et al. (2013) which additionally uses bigram features computed as previously described.

RNN + PRA Classifier combines the predictions of *RNN* and *PRA Classifier*. We combine the predictions by assigning the score of a fact as the sum of their rank in the two models after sorting them in ascending order.

RNN + PRA Classifier-b combines the predictions of *RNN* and *PRA Classifier-b* using the technique described previously.

Table 3 shows the results of our experiments. The method described in Gardner et al. (2014) is not included in the table since the publicly available implementation does not scale to our large dataset. First, we show that it is better to train the models using all the path types instead of using only the top $1,000$ path types as done in previous work (Gardner et al., 2013; Gardner et al., 2014). We can see that the RNN model performs significantly better than the baseline methods of Lao et al. (2012) and Gardner et al. (2013). The performance of the RNN model is not affected by initialization since using random vectors and pre-trained vectors results in similar performance.

A surprising result is the impressive performance of our simple extension to the classifier approach. After the addition of bigram features, the naive PRA method is as effective as the Clus-

The zero-shot model without explicitly training for the target relation types achieves impressive results by performing significantly ($p < 0.05$) better than a random baseline.

seen paths that are very different from the paths seen is training. Empirically, combining the predictions of *RNN* and *PRA Classifier-b* achieves a statistically significant gain over *PRA Classifier-b*.

5.3.1 Zero-shot

Table 4 shows the results of the zero-shot model described in section 4 compared with the fully supervised RNN model (section 3) and a baseline that produces a random ordering of the test facts. We evaluate on randomly selected 10 (out of 46) relation types, hence for the fully supervised version we train 10 RNNs, one for each relation type. For evaluating the zero-shot model, we randomly split the relations into two sets of equal size and train a zero-shot model on one set and test on the other set. So, in this case we have two RNNs making predictions on relation types that they have never seen during training. As expected, the fully supervised RNN outperforms the zero-shot model by a large margin but the zero-shot model without using any direct supervision clearly performs much better than a random baseline.

5.3.2 Discussion

To investigate whether the performance of the RNNs were affected by multiple local optima issues, we combined the predictions of five different RNNs trained using all the paths. Apart from *RNN* and *RNN-random*, we trained three more RNNs with different random initialization and the performance of the three RNNs individually are 57.09, 57.11 and 56.91. The performance of the ensemble is 59.16 and their performance stopped improving after using three RNNs. So, this indicates that even though multiple local optima affects the performance, it is likely not the only issue since the performance of the ensemble is still less than the performance of *RNN + PRA Classifier-b*.

We suspect the RNN model does not capture some of the important local structure as well as the classifier using bigram features. To overcome this drawback, in future work, we plan to explore compositional models that have a longer memory (Hochreiter and Schmidhuber, 1997; Cho et al., 2014; Mikolov et al., 2014). We also plan to include vector representations for the entities and develop models that address the issue of polysemy in verb phrases (Cheng et al., 2014).

6 Related Work

KB Completion includes methods such as Lin and Pantel (2001), Yates and Etzioni (2007) and Berant et al. (2011) that learn inference rules of length one. Schoenmackers et al. (2010) learn general inference rules by considering the set of all paths in the KB and selecting paths that satisfy a certain precision threshold. Their method does not scale well to modern KBs and also depends on carefully tuned thresholds. Lao et al. (2011) train a simple logistic regression classifier with NELL KB paths as features to perform KB completion while Gardner et al. (2013) and Gardner et al. (2014) extend it by using pre-trained relation vectors to overcome feature sparsity. Recently, Yang et al. (2014) learn inference rules using simple element-wise addition or multiplication as the composition function.

Compositional Vector Space Models have been developed to represent phrases and sentences in natural language as vectors (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Yessenalina and Cardie, 2011). Neural networks have been successfully used to learn vector representations of phrases using the vector representations of the words in that phrase. Recurrent neural networks have been used for many tasks such as language modeling (Mikolov et al., 2010), machine translation (Sutskever et al., 2014) and parsing (Vinyals et al., 2014). Recursive neural networks, a more general version of the recurrent neural networks have been used for many tasks like parsing (Socher et al., 2011), sentiment classification (Socher et al., 2012; Socher et al., 2013c; Irsoy and Cardie, 2014), question answering (Iyyer et al., 2014) and natural language logical semantics (Bowman et al., 2014). Our overall approach is similar to RNNs with attention (Bahdanau et al., 2014; Graves, 2013) since we select a path among the set of paths connecting the entity pair to make the final prediction.

Zero-shot or zero-data learning was introduced in Larochelle et al. (2008) for character recognition and drug discovery. Palatucci et al. (2009) perform zero-shot learning for neural decoding while there has been plenty of work in this direction for image recognition (Socher et al., 2013b; Frome et al., 2013; Norouzi et al., 2014).

7 Conclusion

We develop a compositional vector space model for knowledge base completion using recurrent neural networks. In our challenging large-scale dataset available at `http://iesl.cs.umass.edu/downloads/inferencerules/release.tar.gz`, our method outperforms two baseline methods and performs competitively with a modified stronger baseline. The best results are obtained by combining the predictions of our model with the predictions of the modified baseline which achieves a 15% improvement over Gardner et al. (2013). We also show that our model has the ability to perform zero-shot inference.

Abstract

Traditional approaches to the task of ACE event extraction primarily rely on elaborately designed features and complicated natural language processing (NLP) tools. These traditional approaches lack generalization, take a large amount of human effort and are prone to error propagation and data sparsity problems. This paper proposes a novel event-extraction method, which aims to automatically extract lexical-level and sentence-level features without using complicated NLP tools. We introduce a word-representation model to capture meaningful semantic regularities for words and adopt a framework based on a convolutional neural network (CNN) to capture sentence-level clues. However, CNN can only capture the most important information in a sentence and may miss valuable facts when considering multiple-event sentences. We propose a dynamic multi-pooling convolutional neural network (DMCNN), which uses a dynamic multi-pooling layer according to event triggers and arguments, to reserve more crucial information. The experimental results show that our approach significantly outperforms other state-of-the-art methods.

1 Introduction

Event extraction is an important and challenging task in Information Extraction (IE), which aims to discover event triggers with specific types and their arguments. Current state-of-the-art methods (Li et al., 2014; Li et al., 2013; Hong et al., 2011; Liao and Grishman, 2010; Ji and Grishman, 2008) often use a set of elaborately designed features that are extracted by textual analysis and linguistic knowledge. In general, we can divide the features into two categories: lexical features and contextual features.

Lexical features contain part-of-speech tags (POS), entity information, and morphology features (e.g., token, lemma, etc.), which aim to capture semantics or the background knowledge of words. For example, consider the following sentence with an ambiguous word *beats*:

S1: *Obama* ***beats*** *McCain.*

S2: *Tyson* ***beats*** *his opponent .*

In S1, *beats* is a trigger of type *Elect*. However, in S2, *beats* is a trigger of type *Attack*, which is more common than type *Elect*. Because of the ambiguity, a traditional approach may mislabel *beats* in S1 as a trigger of *Attack*. However, if we have the priori knowledge that *Obama* and *McCain* are presidential contenders, we have ample evidence to predict that *beats* is a trigger of type *Elect*. We call these knowledge **lexical-level clues**. To represent such features, the existing methods (Hong et al., 2011) often rely on human ingenuity, which is a time-consuming process and lacks generalization. Furthermore, traditional lexical features in previous methods are a one-hot representation, which may suffer from the data sparsity problem and may not be able to adequately capture the semantics of the words (Turian et al., 2010).

To identify events and arguments more precisely, previous methods often captured contextual features, such as syntactic features, which aim to understand how facts are tied together from a larger field of view. For example, in S3, there are two events that share three arguments as shown in Figure 1. From the dependency relation of *nsubj* between the argument *cameraman* and trigger *died*, we can induce a *Victim* role to *cameraman* in the *Die* event. We call such information **sentence-level clues**. However, the argument word *cameraman* and its trigger word *fired* are in different clauses, and there is no direct de-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 167–176,
Beijing, China, July 26-31, 2015.

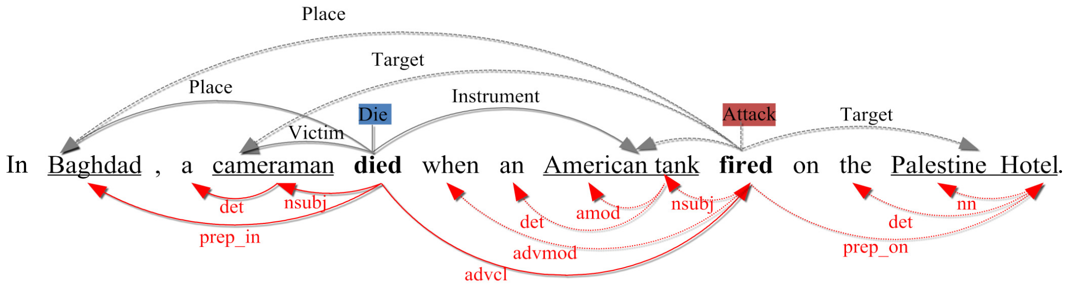

Figure 1: Event mentions and syntactic parser results of S3. The upper side shows two event mentions that share three arguments: the *Die* event mention, triggered by "died", and the *Attack* event mention, triggered by "fired". The lower side shows the collapsed dependency results.

pendency path between them. Thus it is difficult to find the *Target* role between them using traditional dependency features. In addition, extracting such features depends heavily on the performance of pre-existing NLP systems, which could suffer from error propagation.

S3: *In Baghdad, a cameraman* ***died*** *when an American tank* ***fired*** *on the Palestine Hotel.*

To correctly attach *cameraman* to *fired* as a *Target* argument, we must exploit internal semantics over the entire sentence such that the *Attack* event results in *Die* event. Recent improvements of convolutional neural networks (CNNs) have been proven to be efficient for capturing syntactic and semantics between words within a sentence (Collobert et al., 2011; Kalchbrenner and Blunsom, 2013; Zeng et al., 2014) for NLP tasks. CNNs typically use a max-pooling layer, which applies a max operation over the representation of an entire sentence to capture the most useful information. However, in event extraction, one sentence may contain two or more events, and these events may share the argument with different roles. For example, there are two events in S3, namely, the *Die* event and *Attack* event. If we use a traditional max-pooling layer and only keep the most important information to represent the sentence, we may obtain the information that depicts "a cameraman died" but miss the information about "American tank fired on the Palestine Hotel", which is important for predicting the *Attack* event and valuable for attaching *cameraman* to *fired* as an *Target* argument. In our experiments, we found that such multiple-event sentences comprise 27.3% of our dataset, which is a phenomenon we cannot ignore.

In this paper, we propose a dynamic multi-pooling convolutional neural network (**DMCNN**) to address the problems stated above. To capture lexical-level clues and reduce human effort, we introduce a word-representation model (Mikolov et al., 2013b), which has been shown to be able to capture the meaningful semantic regularities of words (Bengio et al., 2003; Erhan et al., 2010; Mikolov et al., 2013a). To capture sentence-level clues without using complicated NLP tools, and to reserve information more comprehensively, we devise a dynamic multi-pooling layer for CNN, which returns the maximum value in each part of the sentence according to event triggers and arguments. In summary, the contributions of this paper are as follows:

- We present a novel framework for event extraction, which can automatically induce lexical-level and sentence-level features from plain texts without complicated NLP preprocessing.
- We devise a dynamic multi-pooling convolutional neural network (DMCNN), which aims to capture more valuable information within a sentence for event extraction.
- We conduct experiments on a widely used ACE2005 event extraction dataset, and the experimental results show that our approach outperforms other state-of-the-art methods.

2 Event Extraction Task

In this paper, we focus on the event extraction task defined in Automatic Content Extraction[1] (ACE) evaluation, where an event is defined as a specific occurrence involving participants. First, we introduce some ACE terminology to understand this task more easily:

[1] http://projects.ldc.upenn.edu/ace/

- **Event mention**: a phrase or sentence within which an event is described, including a trigger and arguments.
- **Event trigger**: the main word that most clearly expresses the occurrence of an event (An ACE event trigger is typically a verb or a noun).
- **Event argument**: an entity mention, temporal expression or value (e.g. Job-Title) that is involved in an event (viz., participants).
- **Argument role**: the relationship between an argument to the event in which it participates.

Given an English text document, an event extraction system should predict event triggers with specific subtypes and their arguments for each sentence. The upper side of figure 1 depicts the event triggers and their arguments for S3 in Section 1. ACE defines 8 event types and 33 subtypes, such as *Attack* or *Elect*.

Although event extraction depends on name identification and entity mention co-reference, it is another difficult task in ACE evaluation and not the focus in the event extraction task. Thus, in this paper, we directly leverage the entity label provided by the ACE, following most previous works (Hong et al., 2011; Liao and Grishman, 2010; Ji and Grishman, 2008).

3 Methodology

In this paper, event extraction is formulated as a two-stage, multi-class classification via dynamic multi-pooling convolutional neural networks with the automatically learned features. The first stage is called *trigger classification*, in which we use a DMCNN to classify each word in a sentence to identify trigger words. If one sentence has triggers, the second stage is conducted, which applies a similar DMCNN to assign arguments to triggers and align the roles of the arguments. We call this *argument classification*. Because the second stage is more complicated, we first describe the methodology of argument classification in Section 3.1∼3.4 and then illustrate the difference between the DMCNNs that are used for trigger classification and those used for argument classification in Section 3.5.

Figure 2 describes the architecture of argument classification, which primarily involves the following four components: (i) word-embedding learning, which reveals the embedding vectors of words in an unsupervised manner; (ii) lexical-level feature representation, which directly uses embedding vectors of words to capture lexical clues; (iii) sentence-level feature extraction, which proposes a DMCNN to learn the compositional semantic features of sentences; and (iv) argument classifier output, which calculates a confidence score for each argument role candidate.

3.1 Word Embedding Learning and Lexical-Level Feature Representation

Lexical-level features serve as important clues for event extraction (Hong et al., 2011; Li et al., 2013). Traditional lexical-level features primarily include *lemma, synonyms* and *POS tag of the candidate words*. The quality of such features depends strongly on the results of existing NLP tools and human ingenuity. Additionally, the traditional features remain unsatisfactory for capturing the semantics of words, which are important in event extraction, as showed in S1 and S2. As Erhan et al. (2010) reported, word embeddings learned from a significant amount of unlabeled data are more powerful for capturing the meaningful semantic regularities of words. This paper uses unsupervised pre-trained word embedding as the source of base features. We select the word embeddings of candidate words (candidate trigger, candidate argument) and the context tokens (left and right tokens of the candidate words). Then, all of these word embeddings are concatenated into the lexical-level features vector L to represent the lexical-level features in argument classification.

In this work, we use the Skip-gram model to pre-train the word embedding. This model is the state-of-the-art model in many NLP tasks (Baroni et al., 2014). The Skip-gram model trains the embeddings of words $w_1, w_2...w_m$ by maximizing the average log probability,

$$\frac{1}{m}\sum_{t=1}^{m}\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t) \qquad (1)$$

where c is the size of the training window. Basically, $p(w_{t+j}|w_t)$ is defined as,

$$p(w_{t+j}|w_t) = \frac{\exp(e_{t+j}^{'T} e_t)}{\sum_{w=1}^{m}\exp(e_w^{'T} e_t)} \qquad (2)$$

where m is the vocabulary of the unlabeled text. $e_i^{'}$ is another embedding for e_i, see Morin and Bengio (2005) for details.

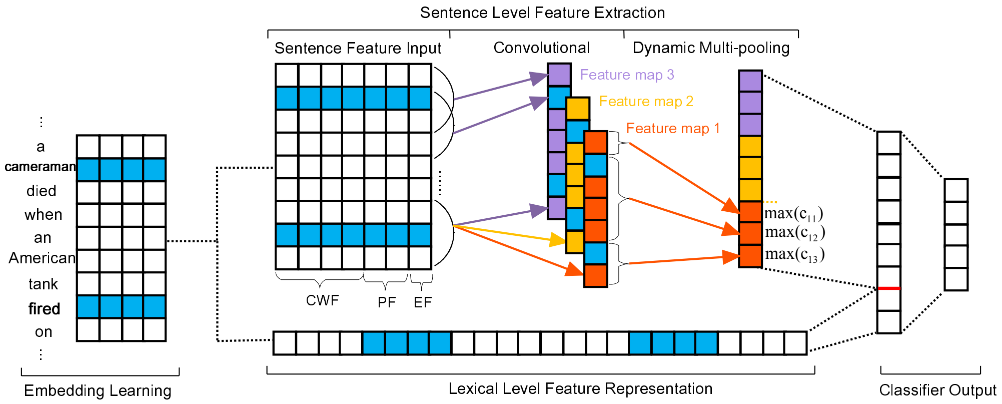

Figure 2: The architecture for the stage of argument classification in the event extraction. It illustrates the processing of one instance with the predict trigger *fired* and the candidate argument *cameraman*.

3.2 Extracting Sentence-Level Features Using a DMCNN

The CNN, with max-pooling layers, is a good choice to capture the semantics of long-distance words within a sentence (Collobert et al., 2011). However, as noted in the section 1, traditional CNN is incapable of addressing the event extraction problem. Because a sentence may contain more than one event, using only the most important information to represent a sentence, as in the traditional CNN, will miss valuable clues. To resolve this problem, we propose a DMCNN to extract the sentence-level features. The DMCNN uses a dynamic multi-pooling layer to obtain a maximum value for each part of a sentence, which is split by event triggers and event arguments. Thus, the DMCNN is expected to capture more valuable clues compared to traditional CNN methods.

3.2.1 Input

This subsection illustrates the input needed for a DMCNN to extract sentence-level features. The semantic interactions between the predicted trigger words and argument candidates are crucial for argument classification. Therefore, we propose three types of input that the DMCNN uses to capture these important clues:

- Context-word feature (CWF): Similar to Kalchbrenner et al. (2014) and Collobert et al. (2011), we take all the words of the whole sentence as the context. CWF is the vector of each word token transformed by looking up word embeddings.

- Position feature (PF): It is necessary to specify which words are the predicted trigger or candidate argument in the argument classification. Thus, we proposed the PF, which is defined as the relative distance of the current word to the predicted trigger or candidate argument. For example, in S3, the relative distances of *tank* to the candidate argument *cameraman* is 5. To encode the position feature, each distance value is also represented by an embedding vector. Similar to word embedding, Distance Values are randomly initialized and optimized through back propagation.

- Event-type feature (EF): The event type of a current trigger is valuable for argument classification (Ahn, 2006; Hong et al., 2011; Liao and Grishman, 2010; Li et al., 2013), so we encode event type predicted in the trigger classification stage as an important clue for the DMCNN, as in the PF.

Figure 2 assumes that word embedding has size $d_w = 4$, position embedding has size $d_p = 1$ and event-type embedding has size $d_e = 1$. Let $x_i \in \mathbb{R}^d$ be the d-dimensional vector representation corresponding to the i-th word in the sentence, where $d = d_w + d_p * 2 + d_e$. A sentence of length n is represented as follows:

$$x_{1:n} = x_1 \oplus x_2 \oplus ... \oplus x_n \qquad (3)$$

where $\oplus$ is the concatenation operator. Thus, combined word embedding, position embedding and event-type embedding transform an instance as a matrix $X \in \mathbb{R}^{n \times d}$. Then, X is fed into the convolution part.

3.2.2 Convolution

The convolution layer aims to capture the compositional semantics of a entire sentence and compress these valuable semantics into feature maps. In general, let $x_{i:i+j}$ refer to the concatenation of words $x_i, x_{i+1}, ..., x_{i+j}$. A convolution operation involves a filter $w \in \mathbb{R}^{h \times d}$, which is applied to a window of h words to produce a new feature. For example, a feature c_i is generated from a window of words $x_{i:i+h-1}$ by the following operator,

$$c_i = f(w \cdot x_{i:i+h-1} + b) \quad (4)$$

where $b \in R$ is a bias term and f is a non-linear function such as the hyperbolic tangent. This filter is applied to each possible window of words in the sentence $x_{1:h}, x_{2:h+1}, ..., x_{n-h+1:n}$ to produce a feature map c_i where the index i ranges from 1 to $n - h + 1$.

We have described the process of how one feature map is extracted from one filter. To capture different features, it usually use multiple filters in the convolution. Assuming that we use m filters $W = w_1, w_2, ..., w_m$, the convolution operation can be expressed as:

$$c_{ji} = f(w_j \cdot x_{i:i+h-1} + b_j) \quad (5)$$

where j ranges from 1 to m. The convolution result is a matrix $C \in \mathbb{R}^{m \times (n-h+1)}$.

3.2.3 Dynamic Multi-Pooling

To extract the most important features (max value) within each feature map, traditional CNNs (Collobert et al., 2011; Kim, 2014; Zeng et al., 2014) take one feature map as a pool and only get one max value for each feature map. However, single max-pooling is not sufficient for event extraction. Because in the task of this paper, one sentence may contain two or more events, and one argument candidate may play a different role with a different trigger. To make an accurate prediction, it is necessary to capture the most valuable information with regard to the change of the candidate words. Thus, we split each feature map into three parts according to the candidate argument and predicted trigger in the argument classification stage. Instead of using one max value for an entire feature map to represent the sentence, we keep the max value of each split part and call it dynamic multi-pooling. Compared to traditional max-pooling, dynamic multi-pooling can reserve more valuable information without missing the max-pooling value.

As shown in Figure 2, the feature map output c_j is divided into three sections c_{j1}, c_{j2}, c_{j3} by "cameraman" and "fired". The dynamic multi-pooling can be expressed as formula 6,where $1 \leq j \leq m$ and $1 \leq i \leq 3$.

$$p_{ji} = \max(c_{ji}) \quad (6)$$

Through the dynamic multi-pooling layer, we obtain the p_{ji} for each feature map. Then, we concatenate all p_{ji} to form a vector $P \in \mathbb{R}^{3m}$, which can be considered as higher-level features (sentence-level features).

3.3 Output

The automatically learned lexical and sentence-level features mentioned above are concatenated into a single vector $F = [L, P]$. To compute the confidence of each argument role, the feature vector $F \in \mathbb{R}^{3m+d_l}$, where m is the number of the feature map and d_l is the dimension of the lexical-level features, is fed into a classifier.

$$O = W_s F + b_s \quad (7)$$

$W_s \in \mathbb{R}^{n_1 \times (3m+d_l)}$ is the transformation matrix and $O \in \mathbb{R}^{n_1}$ is the final output of the network, where n_1 is equal to the number of the argument role including the "None role" label for the candidate argument which don't play any role in the event. For regularization, we also employ dropout(Hinton et al., 2012) on the penultimate layer, which can prevent the co-adaptation of hidden units by randomly dropping out a proportion p of the hidden units during forward and backpropagation.

3.4 Training

We define all of the parameters for the stage of argument classification to be trained as $\theta = (E, PF_1, PF_2, EF, W, b, W_S, b_s)$. Specifically, E is the word embedding, PF_1 and PF_2 are the position embedding, EF is the embedding of the event type, W and b are the parameter of the filter, W_s and b_s are all of the parameters of the output layer.

Given an input example s, the network with parameter θ outputs the vector O, where the i-th component O_i contains the score for argument role i. To obtain the conditional probability $p(i|x, \theta)$, we apply a softmax operation over all argument role types:

$$p(i|x,\theta) = \frac{e^{o_i}}{\sum\limits_{k=1}^{n_1} e^{o_k}} \quad (8)$$

Given all of our (suppose T) training examples $(x_i; y_i)$, we can then define the objective function as follows:

$$J(\theta) = \sum_{i=1}^{T} \log p(y^{(i)}|x^{(i)},\theta) \quad (9)$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ through stochastic gradient descent over shuffled mini-batches with the Adadelta (Zeiler, 2012) update rule.

3.5 Model for Trigger Classification

In the above sections, we presented our model and features for argument classification. The method proposed above is also suitable for trigger classification, but the task only need to find triggers in the sentence, which is less complicated than argument classification. Thus we can used a simplified version of DMCNN.

In the trigger classification, we only use the candidate trigger and its left and right tokens in the lexical-level feature representation. In the feature representation of the sentence level, we use the same CWF as does in argument classification, but we only use the position of the candidate trigger to embed the position feature. Furthermore, instead of splitting the sentence into three parts, the sentence is split into two parts by a candidate trigger. Except for the above change in the features and model, we classify a trigger as the classification of an argument. Both stages form the framework of the event extraction.

4 Experiments

4.1 Dataset and Evaluation Metric

We utilized the ACE 2005 corpus as our dataset. For comparison, as the same as Li et al. (2013), Hong et al. (2011) and Liao and Grishman (2010), we used the same test set with 40 newswire articles and the same development set with 30 other documents randomly selected from different genres and the rest 529 documents are used for training. Similar to previous work (Li et al., 2013; Hong et al., 2011; Liao and Grishman, 2010; Ji and Grishman, 2008), we use the following criteria to judge the correctness of each predicted event mention:

- A trigger is correct if its event subtype and offsets match those of a reference trigger.

- An argument is correctly identified if its event subtype and offsets match those of any of the reference argument mentions.

- An argument is correctly classified if its event subtype, offsets and argument role match those of any of the reference argument mentions.

Finally we use *Precision (P)*, *Recall (R)* and *F measure (F_1)* as the evaluation metrics.

4.2 Our Method vs. State-of-the-art Methods

We select the following state-of-the-art methods for comparison.
1) **Li's baseline** is the feature-based system proposed by Li et al. (2013), which only employs human-designed lexical features, basic features and syntactic features.
2) **Liao's cross-event** is the method proposed by Liao and Grishman (2010), which uses document-level information to improve the performance of ACE event extraction.
3) **Hong's cross-entity** is the method proposed by Hong et al. (2011), which extracts event by using cross-entity inference. To the best of our knowledge, it is the best-reported feature-based system in the literature based on gold standards argument candidates.
4) **Li's structure** is the method proposed by Li et al. (2013), which extracts events based on structure prediction. It is the best-reported structure-based system.

Following Li et al. (2013), we tuned the model parameters on the development through grid search. Moreover, in different stages of event extraction, we adopted different parameters in the DMCNN. Specifically, in the trigger classification, we set the window size as 3, the number of the feature map as 200, the batch size as 170 and the dimension of the PF as 5. In the argument classification, we set the window size as 3, the number of the feature map as 300, the batch size as 20 and the dimension of the PF and EF as 5. Stochastic gradient descent over shuffled mini-batches with the Adadelta update rule(Zeiler, 2012) is used for training and testing processes. It mainly contains two parameters p and ε. We set $p = 0.95$ and $\varepsilon = 1e^{-6}$. For the dropout operation, we set the

Methods	Trigger Identification(%)			Trigger Identification + Classification(%)			Argument Identification(%)			Argument Role(%)		
	P	R	F	P	R	F	P	R	F	P	R	F
Li's baseline	76.2	60.5	67.4	74.5	59.1	65.9	74.1	37.4	49.7	65.4	33.1	43.9
Liao's cross-event	N/A			68.7	68.9	68.8	50.9	49.7	50.3	45.1	44.1	44.6
Hong's cross-entity	N/A			72.9	64.3	68.3	53.4	52.9	53.1	51.6	45.5	48.3
Li's structure	76.9	65.0	70.4	73.7	62.3	67.5	69.8	47.9	56.8	64.7	44.4	52.7
DMCNN model	80.4	67.7	**73.5**	75.6	63.6	**69.1**	68.8	51.9	**59.1**	62.2	46.9	**53.5**

Table 1: Overall performance on blind test data

$rate = 0.5$. We train the word embedding using the Skip-gram algorithm [2] on the NYT corpus [3].

Table 1 shows the overall performance on the blind test dataset. From the results, we can see that the DMCNN model we proposed with the automatically learned features achieves the best performance among all of the compared methods. DMCNN can improve the best F_1 (Li et al., 2013) in the state-of-the-arts for trigger classification by 1.6% and argument role classification by 0.8%. This demonstrates the effectiveness of the proposed method. Moreover, a comparison of *Liao's cross-event* with *Li's baseline* illustrates that *Liao's cross-event* achieves a better performance. We can also make the same observation when comparing *Hong's cross-entity* with *Liao's cross-event* and comparing *Li's structure* with *Hong's cross-entity*. It proves that richer feature sets lead to better performance when using traditional human-designed features. However, our method could obtain further better results on the condition of only using automatically learned features from original words. Specifically, compared to *Hong's cross-entity*, it gains 0.8% improvement on trigger classification F_1 and 5.2% improvement on argument classification F_1. We believe the reason is that the features we automatically learned can capture more meaningful semantic regularities of words. Remarkably, compared to *Li's structure*, our approach with sentence and lexical features achieves comparable performance even though we do not use complicated NLP tools.

4.3 Effect of The DMCNN on Extracting Sentence-Level Features

In this subsection, we prove the effectiveness of the proposed DMCNN for sentence-level feature extraction. We specifically select two methods as baselines for comparison with our DMCNN: Embeddings+T and CNN. Embeddings+T uses word embeddings as lexical-level features and traditional sentence-level features based on human design (Li et al., 2013). A CNN is similar to a DMCNN, except that it uses a standard convolutional neural network with max-pooling to capture sentence-level features. By contrast, a DMCNN uses the dynamic multi-pooling layer in the network instead of the max-pooling layer in a CNN. Moreover, to prove that a DMCNN could capture more precise sentence-level features, especially for those sentences with multiple events, we divide the testing data into two parts according the event number in a sentence (single event and multiple events) and perform evaluations separately. Table 2 shows the proportion of sentences with multiple events or a single event and the proportion of arguments that attend one event or more events within one sentence in our dataset. Table 3 shows the results.

Stage	**1/1 (%)**	**1/N (%)**
Trigger	72.7	**27.3**
Argument	76.8	**23.2**

Table 2: The proportion of multiple events within one sentence. 1/1 means that one sentence only has one trigger or one argument plays a role in one sentence; otherwise, 1/N is used.

Table 3 illustrates that the methods based on convolutional neural networks (CNN and DMCNN) outperform Embeddings+T. It proves that convolutional neural networks could be more effective than traditional human-design strategies for sentence-level feature extraction. In table 3, for all sentences, our method achieves improvements of approximately 2.8% and 4.6% over the CNN. The results prove the effectiveness of the dynamic multi-pooling layer. Interestingly, the DMCNN yields a 7.8% improvement for trigger classification on the sentences with multiple events. This improvement is larger than in sentences with a single event. Similar observations can be made for

[2] https://code.google.com/p/word2vec/

[3] https://catalog.ldc.upenn.edu/LDC2008T19

the argument classification results. This demonstrates that the proposed DMCNN can effectively capture more valuable clues than the CNN with max-pooling, especially when one sentence contains more than one event.

Stage	Method	1/1	1/N	all
		F_1	F_1	F_1
Trigger	Embedding+T	68.1	25.5	59.8
	CNN	72.5	43.1	66.3
	DMCNN	**74.3**	**50.9**	**69.1**
Argument	Embedding+T	37.4	15.5	32.6
	CNN	51.6	36.6	48.9
	DMCNN	**54.6**	**48.7**	**53.5**

Table 3: Comparison of the event extraction scores obtained for the Traditional, CNN and DMCNN models

4.4 Effect of Word Embedding on Extracting Lexical-Level Features

This subsection studies the effectiveness of our word embedding for lexical features. For comparison purposes, we select the baseline described by Li et al. (2013) as the traditional method, which uses traditional lexical features, such as n-grams, POS tags and some entity information. In contrast, we only use word embedding as our lexical feature. Moreover, to prove that word embedding could capture more valuable semantics, especially for those words in the test data that never appear to be the same event type or argument role in the training data, we divide the triggers and arguments in the testing data into two parts (1: appearing in testing data only, or 2: appearing in both testing and training data with the same event type or argument role) and perform evaluations separately. For triggers, 34.9% of the trigger words in the test data never appear to be the same event type in the training data. This proportion is 83.1% for arguments. The experimental results are shown in Table 4.

Table 4 illustrates that for all situations, our method makes significant improvements compared with the traditional lexical features in the classification of both the trigger and argument. For situation B, the lexical-level features extracted from word embedding yield a 18.8% improvement for trigger classification and an 8.5% improvement for argument classification. This occurs because the baseline only uses discrete features, so they suffer from data sparsity and could not adequately handle a situation in which a trigger or argument does not appear in the training data.

Stage	Method	A	B	All
		F_1	F_1	F_1
Trigger	Traditional	68.8	14.3	61.2
	Ours	**70.7**	**33.1**	**64.9**
Argument	Traditional	58.5	22.2	34.6
	Ours	**59.5**	**30.7**	**40.2**

Table 4: Comparison of the results for the traditional lexical feature and our lexical feature. A denotes the triggers or arguments appearing in both training and test datasets, and B indicates all other cases.

4.5 Lexical features vs. Sentence Features

To compare the effectiveness of different levels of features, we extract events by using lexical features and sentence features separately. The results obtained using the DMCNN are shown in table 5. Interestingly, in the trigger-classification stage, the lexical features play an effective role, whereas the sentence features play a more important role in the argument-classification stage. The best results are achieved when we combine lexical-level and sentence-level features. This observation demonstrates that both of the two-level features are important for event extraction.

Feature	Trigger	Argument
	F_1	F_1
Lexical	**64.9**	40.2
Sentence	63.8	**50.7**
Combine	**69.1**	**53.5**

Table 5: Comparison of the trigger-classification score and argument-classification score obtained by lexical-level features, sentence-level features and a combination of both

5 Related Work

Event extraction is one of important topics in NLP. Many approaches have been explored for event extraction. Nearly all of the ACE event extraction use supervised paradigm. We further divide supervised approaches into feature-based methods and structure-based methods.

In feature-based methods, a diverse set of strategies has been exploited to convert classification clues (such as sequences and parse trees) into feature vectors. Ahn (2006) uses the lexical features(e.g., full word, pos tag), syntactic features (e.g., dependency features) and external-knowledge features(WordNet) to extract the event. Inspired by the hypothesis of “One Sense Per Discourse"(Yarowsky, 1995), Ji and Grishman (2008) combined global evidence from related documents with local decisions for the event extraction. To capture more clues from the texts, Gupta and Ji (2009), Liao and Grishman (2010) and Hong et al. (2011) proposed the cross-event and cross-entity inference for the ACE event task. Although these approaches achieve high performance, feature-based methods suffer from the problem of selecting a suitable feature set when converting the classification clues into feature vectors.

In structure-based methods, researchers treat event extraction as the task of predicting the structure of the event in a sentence. McClosky et al. (2011) casted the problem of biomedical event extraction as a dependency parsing problem. Li et al. (2013) presented a joint framework for ACE event extraction based on structured perceptron with beam search. To use more information from the sentence, Li et al. (2014) proposed to extract entity mentions, relations and events in ACE task based on the unified structure. These methods yield relatively high performance. However, the performance of these methods depend strongly on the quality of the designed features and endure the errors in the existing NLP tools.

6 Conclusion

This paper proposes a novel event extraction method, which can automatically extract lexical-level and sentence-level features from plain texts without complicated NLP preprocessing. A word-representation model is introduced to capture lexical semantic clues and a dynamic multi-pooling convolutional neural network (DMCNN) is devised to encode sentence semantic clues. The experimental results prove the effectiveness of the proposed method.

Abstract

We present results on using stacking to ensemble multiple systems for the Knowledge Base Population English Slot Filling (KBP-ESF) task. In addition to using the output and confidence of each system as input to the stacked classifier, we also use features capturing how well the systems agree about the provenance of the information they extract. We demonstrate that our stacking approach outperforms the best system from the 2014 KBP-ESF competition as well as alternative ensembling methods employed in the 2014 KBP Slot Filler Validation task and several other ensembling baselines. Additionally, we demonstrate that including provenance information further increases the performance of stacking.

1 Introduction

Using *ensembles* of multiple systems is a standard approach to improving accuracy in machine learning (Dietterich, 2000). Ensembles have been applied to a wide variety of problems in natural language processing, including parsing (Henderson and Brill, 1999), word sense disambiguation (Pedersen, 2000), and sentiment analysis (Whitehead and Yaeger, 2010). This paper presents a detailed study of ensembling methods for the TAC *Knowledge Base Population* (KBP) *English Slot Filling* (ESF) task (Surdeanu, 2013; Surdeanu and Ji, 2014).

We demonstrate new state-of-the-art results on this KBP task using *stacking* (Wolpert, 1992), which trains a final classifier to optimally combine the results of multiple systems. We present results for stacking all systems that competed in both the 2013 and 2014 KBP-ESF tracks, training on 2013 data and testing on 2014 data. The resulting stacked ensemble outperforms all systems in the 2014 competition, obtaining an F1 of 48.6% compared to 39.5% for the best performing system in the most recent competition.

Although the associated KBP Slot Filler Validation (SFV) Track (Wang et al., 2013; Yu et al., 2014; Sammons et al., 2014) is officially focused on improving the precision of individual existing systems by filtering their results, frequently participants in this track also combine the results of multiple systems and also report increased recall through this use of ensembling. However, SFV participants have not employed stacking, and we demonstrate that our stacking approach outperforms existing published SFV ensembling systems.

KBP ESF systems must also provide *provenance* information, i.e. each extracted slot-filler must include a pointer to a document passage that supports it (Surdeanu and Ji, 2014). Some SFV systems have used this provenance information to help filter and combine extractions (Sammons et al., 2014). Therefore, we also explored enhancing our stacking approach by including additional input features that capture provenance information. By including features that quantify how much the ensembled systems agree on provenance, we further improved our F1 score for the 2014 ESF task to 50.1%.

The remainder of the paper is organized as follows. Section 2 provides background information on existing KBP-ESF systems and stacking. Section 3 provides general background on the KBP-ESF task. Section 4 describes our stacking approach, including how provenance information is used. Section 5 presents comprehensive experiments comparing this approach to existing results and several additional baselines, demonstrating new state-of-the-art results on KBP-ESF. Section 6 reviews prior related work on ensembling

for information extraction. Section 7 presents our final conclusions and proposed directions for future research.

2 Background

For the past few years, NIST has been conducting the English Slot Filling (ESF) Task in the Knowledge Base Population (KBP) track among various other tasks as a part of the Text Analysis Conference(TAC)(Surdeanu, 2013; Surdeanu and Ji, 2014). In the ESF task, the goal is to fill specific slots of information for a given set of query entities (people or organizations) based on a supplied text corpus. The participating systems employ a variety of techniques in different stages of the slot filling pipeline, such as entity search, relevant document extraction, relation modeling and inference. In 2014, the top performing system, *DeepDive with Expert Advice* from Stanford University (Wazalwar et al., 2014), employed distant supervision (Mintz et al., 2009) and Markov Logic Networks (Domingos et al., 2008) in their learning and inferencing system. Another system, *RPI_BLENDER* (Hong et al., 2014), used a restricted fuzzy matching technique in a framework that learned event triggers and employed them to extract relations from documents.

Given the diverse set of slot-filling systems available, it is interesting to explore methods for ensembling these systems. In this regard, TAC also conducts a Slot Filler Validation (SFV) task who goal is to improve the slot-filling performance using the output of existing systems. The input for this task is the set of outputs from all slot-filling systems and the expected output is a filtered set of slot fills. As with the ESF task, participating systems employ a variety of techniques to perform validation. For instance, *RPI_BLENDER* used a Multi-dimensional Truth Finding model (Yu et al., 2014) which is an unsupervised validation approach based on computing multidimensional credibility scores. The *UI_CCG* system (Sammons et al., 2014) developed two different validation systems using entailment and majority voting.

However, *stacking* (Sigletos et al., 2005; Wolpert, 1992) has not previously been employed for ensembling KBP-ESF systems. In stacking, a meta-classifier is learned from the output of multiple underlying systems. In our work, we translate this to the context of ensembling slot filling systems and build a *stacked meta-classifier* that learns to combine the results from individual slot filling systems. We detail our stacking approach for ensembling existing slot filling systems in Section 4.

3 Overview of KBP Slot Filling Task

The goal of the TAC KBP-ESF task (Surdeanu, 2013; Surdeanu and Ji, 2014) is to collect information (fills) about specific attributes (slots) for a set of entities (queries) from a given corpus. The queries vary in each year of the task and can be either a person (PER) or an organization (ORG) entity. The slots are fixed and are listed in Table 1 by entity type. Some slots (like per:age) are *single-valued* while others (like per:children) are *list-valued* i.e., they can take multiple slot fillers.

3.1 Input and Output

The input for the task is a set of queries and the corpus in which to look for information. The queries are provided in an XML format containing basic information including an ID for the query, the name of the entity, and the type of entity (PER or ORG). The corpus consists of documents format from discussion forums, newswire and the Internet. Each document is identified by a unique document ID.

The output for the task is a set of slot fills for each input query. Depending on the type, each query should have a *NIL* or one or more lines of output for each of the corresponding slots. The output line for each slot fill contains the fields shown in Table 2. The query ID in Column 1 should match the ID of the query given as input. The slot name (Column 2) is one of the slots listed in Table 1 based on entity type. Run ID (Column 3) is a unique identifier for each system. Column 4 contains a *NIL* filler if the system could not find any relevant slot filler. Otherwise, it contains the *relation provenance*. Provenance is of the form *docid:startoffset-endoffset*, where *docid* specifies a source document from the corpus and the offsets demarcate the text in this document supporting the relation. The offsets correspond to the spans of the candidate document that describe the relation between the query entity and the extracted slot filler. Column 5 contains the extracted slot filler. Column 6 is a filler provenance that is similar in format to relation provenance but in this case the offset corresponds to the portion of the document containing the extracted filler. Column 7 is a confi-

dence score which systems can provide to indicate their certainty in the extracted information.

3.2 Scoring

The scoring for the ESF task is carried out as follows. The responses from all slot-filling systems are pooled and a *key file* is generated by having human assessors judge the correctness of these responses. In addition, LDC includes a manual key of fillers that were determined by human judges. Using the union of these keys as the gold standard, precision, recall, and F1 scores are computed.

4 Ensembling Slot-Filling Systems

Given a set of query entities and a fixed set of slots, the goal of ensembling is to effectively combine the output of different slot-filling systems. The input to the ensembling system is the output of individual systems (in the format described in previous section) containing slot fillers and additional information such as provenance and confidence scores. The output of the ensembling system is similar to the output of an individual system, but it productively aggregates the slot fillers from different systems.

4.1 Algorithm

This section describes our ensembling approach which trains a final binary classifier using features that help judge the reliability and thus correctness of individual slot fills. In a final *post-processing* step, the slot fills that get classified as "correct" by the classifier are kept while the others are set to NIL.

4.1.1 Stacking

Stacking is a popular ensembling method in machine learning (Wolpert, 1992) and has been successfully used in many applications including the top performing systems in the Netflix competition (Sill et al., 2009). The idea is to employ multiple learners and combine their predictions by training a "meta-classifier" to weight and combine multiple models using their confidence scores as features. By training on a set of supervised data that is disjoint from that used to train the individual models, it learns how to combine their results into an improved ensemble model. We employ a single classifier to train and test on all slot types using an L1-regularized SVM with a linear kernel (Fan et al., 2008).

4.1.2 Using Provenance

As discussed above, each system provides provenance information for every non-NIL slot filler. There are two kinds of provenance provided: the relation provenance and the filler provenance. In our algorithm, we only use the filler provenance for a given slot fill. This is because of the changes in the output formats for the ESF task from 2013 to 2014. Specifically, the 2013 specification requires separate entity and justification provenance fields, but the 2014 collapses these into a single relation provenance field. An additional filler provenance field is common to both specifications. Hence, we use the filler provenance that is common between 2013 and 2014 formats. As described earlier, every provenance has a *docid* and *startoffset-endoffset* that gives information about the document and offset in the document from where the slot fill has been extracted. The UI-CCG SFV system Sammons et al. (2014) effectively used this provenance information to help validate and filter slot fillers. This motivated us to use provenance in our stacking approach as additional features as input to the meta-classifier.

We use provenance in two ways, first using the *docid* information, and second using the *offset* information. We use the *docids* to define a document-based provenance score in the following way: for a given query and slot, if N systems provide answers and a maximum of n of those systems give the same *docid* in their filler provenance, then the document provenance score for those n slot fills is n/N. Similarly, other slot fills are given lower scores based on the fraction of systems whose provenance document agree with theirs. Since this provenance score is weighted by the number of systems that refer to the same provenance, it measures the reliability of a slot fill based on the document from where it was extracted.

Our second provenance measure uses *offsets*. The degree of overlap among the various systems' offsets can also be a good indicator of the reliability of the slot fill. The Jaccard similarity coefficient is a statistical measure of similarity between sets and is thus useful in measuring the degree of overlap among the offsets of systems. Slot fills have variable lengths and thus the provenance offset ranges are variable too. A metric such as the Jaccard coefficient captures the overlapping offsets along with normalizing based on the union and thus resolving the problem with variable offset ranges. For a given query and slot, if N systems that attempt to fill it have the same *docid* in their document provenance, then the offset provenance (OP) score for a slot fill by a system x is calculated as follows:

$$OP(x) = \frac{1}{|N|} \times \sum_{i \in N, i \neq x} \frac{|\mathsf{offsets(i)} \cap \mathsf{offsets(x)}|}{|\mathsf{offsets(i)} \cup \mathsf{offsets(x)}|}$$

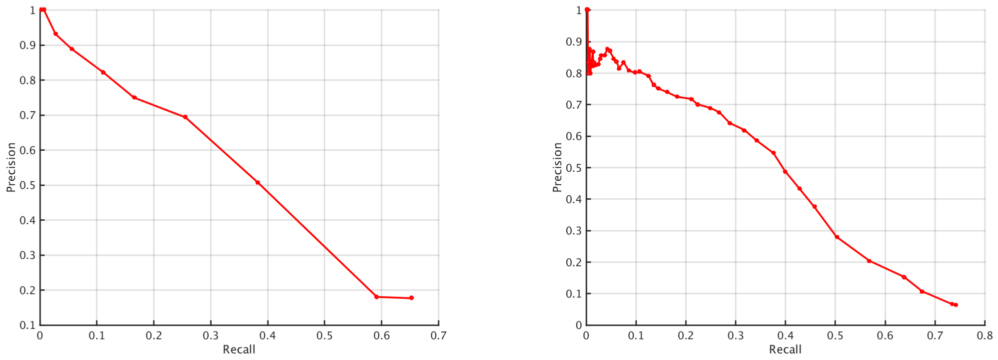
Per our definition, systems that extract slot fills from *different* documents for the same query slot have zero overlap among offsets. We note that the offset provenance is always used along with the document provenance and thus useful in discriminating slot fills extracted from a different document for the same query slot. Like the document provenance score, the offset provenance score is also a weighted feature and is a measure of reliability of a slot fill based on the offsets in the document from where it is extracted. Unlike past SFV systems that use provenance for validation, our approach does not need access to the large corpus of documents from where the slot fills are extracted and is thus very computationally inexpensive.

4.2 Eliminating Slot-Filler Aliases

When combining the output of different ESF systems, it is possible that some slot-filler entities might overlap with each other. An ESF system could extract a filler F_1 for a slot *S* while another ESF system extracts another filler F_2 for the same slot *S*. If the extracted fillers F_1 and F_2 are *aliases* (i.e. different names for the same entity), the scoring system for the TAC KBP SF task considers them redundant and penalizes the precision of the system.

In order to eliminate aliases from the output of ensembled system, we employ a technique derived by inverting the scheme used by the LSV ESF system (Roth et al., 2013) for query expansion. LSV ESF uses a Wikipedia anchor-text model (Roth and Klakow, 2010) to generate aliases for given query entities. By including aliases for query names, the ESF system increase the number of candidate sentences fetched for the query.

To eliminate filler aliases, we apply the same technique to generate aliases for all slot fillers of a given query and slot type. Given a slot filler, we obtain the Wikipedia page that is most likely linked to the filler text. Then, we obtain the anchor texts and their respective counts from all other Wikipedia pages that link to this page. Using these counts, we choose top N (we use N=10 as in LSV) and pick the corresponding anchor texts as aliases for the given slot filler. Using the generated aliases, we then verify if any of the slot fillers are redundant with respect to these aliases. This scheme is not applicable to slot types whose fillers are not entities (like date or age). Therefore, simpler matching schemes are used to eliminate redundancies for these slot types.



Common systems dataset

All 2014 SFV systems dataset

Figure 1: Precision-Recall curves for identifying the best voting performance on the two datasets

5 Experimental Evaluation

This section describes a comprehensive set of experiments evaluating ensembling for the KBP ESF task. Our experiments are divided into two subsets based on the datasets they employ. Since our stacking approach relies on 2013 SFV data for training, we build a dataset of one run for every team that participated in *both* the 2013 and 2014 competitions and call it the *common systems dataset*. There are 10 common teams of the 17 teams that participated in ESF 2014. The other dataset comprises of all 2014 SFV systems (including all runs of all 17 teams that participated in 2014). There are 10 systems in the common systems dataset, while there are 65 systems in the all 2014 SFV dataset. Table 3 gives a list of the common systems for 2013 and 2014 ESF task. ESF systems do change from year to year and it's not a perfect comparison, but systems generally get better every year and thus we are probably only underperforming.

5.1 Methodology and Results

For our unsupervised ensembling baselines, we evaluate on both the common systems dataset as well as the entire 2014 SFV dataset. We compare our stacking approach to three unsupervised baselines. The first is *Union* which takes the combination of values for all systems to maximize recall. If the slot type is list-valued, it classifies all slot fillers as correct and always includes them. If the slot type is single-valued, if only one systems attempts to answer it, then it includes that system's slot fill. Otherwise if multiple systems produce a response, it only includes the slot fill with the highest confidence value as correct and discards the rest.

The second baseline is *Voting*. For this approach, we vary the threshold on the number of systems that must agree on a slot fill from one to all. This gradually changes the system from the union to intersection of the slot fills, and we identify the threshold that results in the highest F1 score. We learn a threshold on the 2013 SFV dataset (containing 52 systems) that results in the best F1 score. We use this threshold for the voting baseline on 2014 SFV dataset. As we did for the 2013 common systems dataset, we learn a threshold on the 2013 common systems that results in the best F1 score and use this threshold for the voting baseline on 2014 common systems.

The third baseline is an "oracle threshold" version of *Voting*. Since the best threshold for 2013 may not necessarily be the best threshold for 2014, we identify the best threshold for 2014 by plotting a Precision-Recall curve and finding the best F1 score for the voting baseline on both the SFV and common systems datasets. Figure 1 shows the

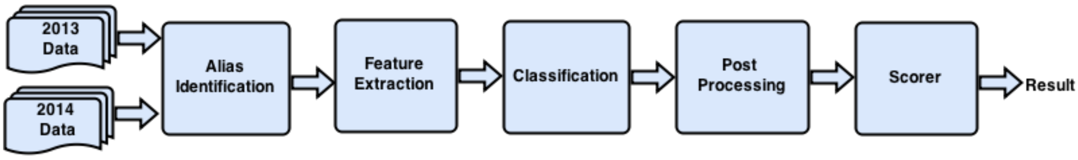

Figure 2: Our system pipeline for evaluating supervised ensembling approaches

Baseline	Precision	Recall	F1
Union	0.067	**0.762**	0.122

Table 5: Performance on the common systems dataset (10 systems) for various configurations. All approaches except the Stanford system are our implementations.

Precision-Recall curve for two datasets for finding the best possible F1 score using the voting baseline. We find that for the common systems dataset, a threshold of 3 (of 10) systems gives the best F1 score, while for the entire 2014 SFV dataset, a threshold of 10 (of 65) systems gives the highest F1. Note that this gives an upper bound on the best results that can be achieved with voting, assuming an optimal threshold is chosen. Since the upper bound can not be predicted without using the 2014 dataset, this baseline has an unfair advantage. Table 4 shows the performance of all 3 baselines on the all 2014 SFV systems dataset.

For all our supervised ensembling approaches, we train on the 2013 SFV data and test on the 2014 data for the common systems. We have 5 different supervised approaches. Our first approach is stacking the common systems using their confidence scores to learn a classifier. As discussed earlier, in stacking we train a meta-classifier that combines the systems using their confidence scores as features. Since the common systems dataset has 10 systems, this classifier uses 10 features. The second approach also provides stacking with a nominal feature giving the relation name (as listed in Table 1) for the given slot instance. This allows the system to learn different evidence-combining functions for different slot types if the classifier finds this useful. For our third approach, we also provide the document provenance feature described in Section 4.1. Altogether this approach has 11 features (10 confidence score + 1 document provenance score). The fourth approach uses confidences, the document provenance feature, and a one-hot encoding of the relation name for the slot instance. Our final approach also includes the offset provenance (OP) feature discussed in Section 4.1. There are altogether 13 features in this approach. All our supervised approaches use the Weka package (Hall et al., 2009) for training the meta-classifier, using an L1-regularized SVM with a linear kernel (other classifiers gave similar results). Figure 2 shows our system pipeline for evaluating supervised ensembling approaches. Table 5 gives the performance of all our supervised approaches as well as our unsupervised baselines for the common systems dataset.

Analysis by Surdeanu and Ji (2014) suggests that 2014 ESF queries are more difficult than those for 2013. They compare two systems by running both on 2013 and 2014 data and find there is a considerable drop in the performance of both the systems. We note that they run the same exact system on 2013 and 2014 data. Thus, in order to have a better understanding of our results, we plot a learning curve by training on different sizes of the 2013 SFV data and using the scorer to measure the F1 score on the 2014 SFV data for the 10 common systems. Figure 3 shows the learning curve thus obtained. Although there are certain parts of the dataset when the F1 score drops which we suspect is due to overfitting the 2013 data, there is still a strong correlation between the 2013 training data size and F1 score on the 2014 dataset. Thus we can infer that training on 2013 data is useful even though the 2013 and 2014 data are fairly different. Although the queries change, the common systems remain more-or-less the same and stacking enables a meta-classifier to weigh those common systems based on their 2013 performance.

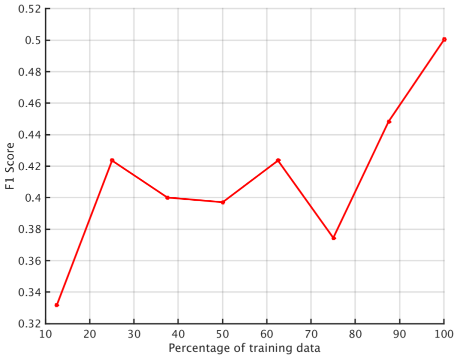

Figure 3: Learning curve for training on 2013 and testing on 2014 common systems dataset

To further validate our approach, we divide the 2013 SFV data based on the systems that extracted those slot fills. Then we sort the systems, from higher to lower, based on the number of false positives produced by them in the ensembling approach. Next we train a classifier in an incremental fashion adding one system's slot fills for training at each step and analyzing the performance on 2014 data. This allows us to analyze the results at the system level. Figure 4 shows the plot of F1 score vs. the number of systems at each step. The figure shows huge improvement in F1 score at steps 6 and 7. At step 6 the Stanford system is added to the pool of systems which is the best performing ESF system in 2014 and fourth best in 2013. At step 7, the UMass system is added to the pool and, although the system on it own is weak, it boosts the performance of our ensembling approach. This is because the UMass system alone contributes approximately 24% of the 2013 training data (Singh et al., 2013). Thus adding this one system significantly improves the training step leading to better performance. We also notice that our system becomes less conservative at this step and has higher recall. The reason for this is that the systems from 1 to 5 had very high precision and low recall whereas from system 6 onwards the systems have high recall. Thus adding the UMass system enables our meta-classifier to have a higher recall for small decrease in precision and thus boosting the overall F1 measure. Without it, the classifier produces high precision but low recall and decreases the overall F1 score by approximately 6 points.

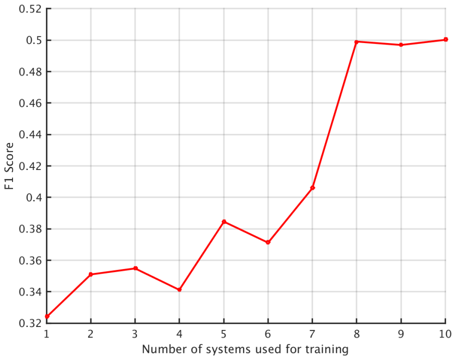

Figure 4: Incrementally training on 2013 by adding a system at each step and testing on 2014 common systems dataset

We also experimented with cross validation within the 2014 dataset. Since we used only 2014 data for this experiment, we also included the relation provenance as discussed in Section 4.1.2. Table 6 shows the results on 10-fold cross-validation on 2014 data with only the filler provenance and with both the filler and relation provenance. The performance of using only the filler provenance is slightly worse than training on 2013 because the 2014 SFV data has many fewer instances but uses more systems for learning compared to the 2013

Table 8: Performance on the common systems dataset (10 systems) for various configurations using the unofficial scorer. All approaches except the UIUC system are our implementations.

SFV data.

The TAC KBP official scoring key for the ESF task includes human annotated slot fills along with the pooled slot fills obtained by all participating systems. However, Sammons et al. (2014) use an unofficial scoring key in their paper that does not include human annotated slot fills. In order to compare to their results, we also present results using the same unofficial key. Table 7 gives the performance of our baseline systems on the 2014 SFV dataset using the unofficial key for scoring. We note that our *Union* does not produce a recall of 1.0 on the unofficial scorer due to our single-valued slot selection strategy for multiple systems. As discussed earlier for the single-valued slot, we include the slot fill with highest confidence (which may not necessarily be correct) and thus may not match the unofficial scorer.

Table 8 gives the performance of all our supervised approaches along with the baselines on the common systems dataset using the unofficial key for scoring. UIUC is one of the two teams participating in the SFV 2014 task and the only team to report results, but they report 6 different system configurations and we show their best performance.

5.2 Discussion

Our results indicate that stacking with provenance information and relation type gives the best performance using both the official ESF scorer as well as the unofficial scorer that excludes the human-generated slot fills. Our stacking approach that uses the 10 systems common between 2013 and 2014 also outperforms the ensembling baselines that have the advantage of using *all 65* of the 2014 systems. Our stacking approach would presumably perform even better if we had access to 2013 training data for all 2014 systems.

Of course, the best-performing ESF system for 2014 did not have access to the pooled slot fills of all participating systems. Although pooling the results has an advantage, naive pooling methods such as the ensembling baselines, in particular the voting approach, do not perform as well as our stacked ensembles. Our best approach outperforms the best baseline for both the datasets by at least 6 F1 points using both the official and unofficial scorer.

As expected the *Union* baseline has the highest recall. Among the supervised approaches, stacking with document provenance produces the highest precision and is significantly higher (approximately 5%) than the approach that produces the second highest precision. As discussed earlier, we also scored our approaches on the unofficial scorer so that we can compare our results to the UIUC system that was the best performer in the 2014 SFV task. Our best approach beats their best system configuration by a F1 score of 12 points. Our stacking approach also outperforms them on precision and recall by a large margin.

6 Related Work

Our system is part of a body of work on increasing the performance of relation extraction through ensemble methods.

The use of *stacked generalization* for information extraction has been demonstrated to outperform both majority voting and weighted voting methods (Sigletos et al., 2005). In relation extraction, a stacked classifier effectively combines a supervised, closed-domain Conditional Random Field-based relation extractor with an open-domain CRF Open IE system, yielding a 10% increase in precision without harming recall (Banko et al., 2008). To our knowledge, we are the first to apply stacking to KBP and the first to use provenance as a feature in a stacking approach.

Many KBP SFV systems cast validation as a single-document problem and apply a variety of techniques, such as rule-based consistency checks (Angeli et al., 2013), and techniques from the well-known Recognizing Textual Entailment (RTE) task (Cheng et al., 2013; Sammons et al., 2014). In contrast, the 2013 *JHUAPL* system aggregates the results of many different extractors using a constraint optimization framework, exploiting confidence values reported by each input system (Wang et al., 2013). A second approach in the *UI_CCG* system (Sammons et al., 2014) aggregates results of multiple systems by using majority voting.

In the database, web-search, and data-mining communities, a line of research into "truth-finding" or "truth-discovery" methods addresses the related problem of combining evidence for facts from multiple sources, each with a latent credibility (Yin et al., 2008). The *RPI_BLENDER* KBP system (Yu et al., 2014) casts SFV in this framework, using a graph propagation method that modeled the credibility of systems, sources, and response values. However they only report scores on the 2013 SFV data which contain less complicated and easier queries compared to the 2014 data. Therefore, we cannot directly compare our system's performance to theirs.

Google's Knowledge Vault system (Dong et al., 2014) combines the output of four diverse extraction methods by building a boosted decision stump classifier (Reyzin and Schapire, 2006). For each proposed fact, the classifier considers both the confidence value of each extractor and the number of responsive documents found by the extractor. A separate classifier is trained for each predicate, and Platt Scaling (Platt, 1999) is used to calibrate confidence scores.

7 Conclusion

This paper has presented experimental results showing that *stacking* is a very promising approach to ensembling KBP systems. From our literature survey, we observe that we are the first to employ stacking and combine it with provenance information to ensemble KBP systems. Our stacked meta-classifier provides an F1 score of 50.1% on 2014 KBP ESF, outperforming the best ESF and SFV systems from the 2014 competition, and thereby achieving a new state-of-the-art for this task. We found that provenance features increased accuracy, highlighting the importance of provenance information (even without accessing the source corpus) in addition to confidence scores for ensembling information extraction systems.

Abstract

This paper presents a generative model to event schema induction. Previous methods in the literature only use head words to represent entities. However, elements other than head words contain useful information. For instance, *an armed man* is more discriminative than *man*. Our model takes into account this information and precisely represents it using probabilistic topic distributions. We illustrate that such information plays an important role in parameter estimation. Mostly, it makes topic distributions more coherent and more discriminative. Experimental results on benchmark dataset empirically confirm this enhancement.

1 Introduction

Information Extraction was initially defined (and is still defined) by the MUC evaluations (Grishman and Sundheim, 1996) and more specifically by the task of template filling. The objective of this task is to assign event roles to individual textual mentions. A template defines a specific type of events (*e.g.* earthquakes), associated with semantic roles (or slots) hold by entities (for earthquakes, their location, date, magnitude and the damages they caused (Jean-Louis et al., 2011)).

Schema induction is the task of learning these templates with no supervision from unlabeled text. We focus here on *event* schema induction and continue the trend of generative models proposed earlier for this task. The idea is to group together entities corresponding to the same role in an event template based on the similarity of the relations that these entities hold with predicates. For example, in a corpus about terrorist attacks, entities that are objects of verbs *to kill*, *to attack* can be grouped together and characterized by a role named VICTIM. The output of this identification operation is a set of clusters of which members are both words and relations, associated with their probability (see an example later in Figure 4). These clusters are not labeled but each of them represents an event slot.

Our approach here is to improve this initial idea by entity disambiguation. Some ambiguous entities, such as *man* or *soldier*, can match two different slots (victim or perpetrator). An entity such as *terrorist* can be mixed up with victims when articles relate that a terrorist has been killed by police (and thus is object of *to kill*). Our hypothesis is that the immediate context of entities is helpful for disambiguating them. For example, the fact that *man* is associated with *armed*, *dangerous*, *heroic* or *innocent* can lead to a better attribution and definition of roles. We then introduce relations between entities and their attributes in the model by means of syntactic relations.

The document level, which is generally a center notion in topic modeling, is not used in our generative model. This results in a simpler, more intuitive model, where observations are generated from slots, that are defined by probabilistic distributions on entities, predicates and syntactic attributes. This model offers room for further extensions since multiple observations on an entity can be represented in the same manner.

Model parameters are estimated by Gibbs sampling. We evaluate the performance of this approach by an automatic and empiric mapping between slots from the system and slots from the reference in a way similar to previous work in the domain.

The rest of this paper is organized as follows: Section 2 briefly presents previous work; in Section 3, we detail our entity and relation representation; we describe our generative model in Section 4, before presenting our experiments and evaluations in Section 5.

2 Related Work

Despite efforts made for making template filling as generic as possible, it still depends heavily on the type of events. Mixing generic processes with a restrictive number of domain-specific rules (Freedman et al., 2011) or examples (Grishman and He, 2014) is a way to reduce the amount of effort needed for adapting a system to another domain. The approaches of *On-demand information extraction* (Hasegawa et al., 2004; Sekine, 2006) and *Preemptive Information Extraction* (Shinyama and Sekine, 2006) tried to overcome this difficulty in another way by exploiting templates induced from representative documents selected by queries.

Event schema induction takes root in work on the acquisition from text of knowledge structures, such as the Memory Organization Packets (Schank, 1980), used by early text understanding systems (DeJong, 1982) and more recently by Ferret and Grau (1997). First attempts for applying such processes to schema induction have been made in the fields of Information Extraction (Collier, 1998), Automatic Summarization (Harabagiu, 2004) and event Question-Answering (Filatova et al., 2006; Filatova, 2008).

More recently, work after (Hasegawa et al., 2004) has developed weakly supervised forms of Information Extraction including schema induction in their objectives. However, they have been mainly applied to binary relation extraction in practice (Eichler et al., 2008; Rosenfeld and Feldman, 2007; Min et al., 2012). In parallel, several approaches were proposed for performing specifically schema induction in already existing frameworks: clause graph clustering (Qiu et al., 2008), event sequence alignment (Regneri et al., 2010) or LDA-based approach relying on FrameNet-like semantic frames (Bejan, 2008). More event-specific generative models were proposed by Chambers (2013) and Cheung et al. (2013). Finally, Chambers and Jurafsky (2008), Chambers and Jurafsky (2009), Chambers and Jurafsky (2011), improved by Balasubramanian et al. (2013), and Chambers (2013) focused specifically on the induction of event roles and the identification of chains of events for building representations from texts by exploiting coreference resolution or the temporal ordering of events. All this work is also linked to work about the induction of scripts from texts, more or less closely linked to events, such as (Frermann et al., 2014), (Pichotta and Mooney, 2014) or (Modi and Titov, 2014).

	Attributes	**Head**	**Triggers**
#1	[armed:amod]	man	[attack:nsubj, kill:nsubj]
#2	[police:nn]	station	[attack:dobj]
#3	[]	policeman	[kill:dobj]
#4	[innocent:amod, young:amod]	man	[wound:dobj]

Figure 1: Entity representation as tuples of ([attributes], head, [triggers]).

The work we present in this article is in line with Chambers (2013), which will be described in more details in Section 5, together with a quantitative and qualitative comparison.

3 Entity Representation

An entity is represented as a triple containing: a head word h, a list A of attribute relations and a list T of trigger relations. Consider the following example:

(1) Two armed men attacked the police station and killed a policeman. An innocent young man was also wounded.

As illustrated in Figure 1, four entities, equivalent to four separated triples, are generated from the text above. Head words are extracted from noun phrases. A trigger relation is composed of a predicate (*attack*, *kill*, *wound*) and a dependency type (subject, object). An attribute relation is composed of an argument (*armed*, *police*, *young*) and a dependency type (adjectival, nominal or verbal modifier). In the relationship to triggers, a head word is argument, but in the relationship to attributes, it is predicate. We use Stanford NLP toolkit (Manning et al., 2014) for parsing and coreference resolution.

A head word is extracted if it is a nominal or proper noun and it is related to at least one trigger; pronouns are omitted. A trigger of an head word is extracted if it is a verb or an eventive noun and the head word serves as its subject, object, or preposition. We use the categories *noun.EVENT* and *noun.ACT* in WordNet as a list of eventive nouns. A head word can have more than one trigger. These multiple relations can come from a syntactic coordination inside a single sentence, as it is the case in the first sentence of the illustrating example. They can also represent a coreference

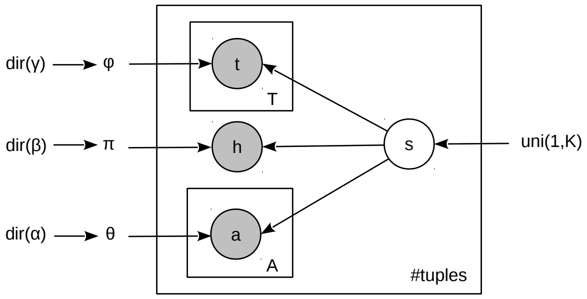

Figure 2: Generative model for event induction.

chain across sentences, as we use coreference resolution to merge the triggers of mentions corefering to the same entity in a document. Coreferences are useful sources for event induction (Chambers and Jurafsky, 2011; Chambers, 2013). Finally, an attribute is extracted if it is an adjective, a noun or a verb and serves as an adjective, verbal or nominal modifier of a head word. If there are several modifiers, only the closest to the head word is selected. This "best selection" heuristic allows to omit non-discriminative attributes for the entity.

4 Generative Model

4.1 Model Description

Figure 2 shows the plate notation of our model. For each triple representing an entity e, the model first assigns a slot s for the entity from an uniform distribution $uni(1, K)$. Its head word h is then generated from a multinominal distribution π_s. Each t_i of event trigger relations T_e is generated from a multinominal distribution ϕ_s. Each a_j of attribute relations A_e is similarly generated from a multinominal distribution θ_s. The distributions θ, π, and ϕ are generated from Dirichlet priors $dir(\alpha)$, $dir(\beta)$ and $dir(\gamma)$ respectively.

Given a set of entities E, our model (π, ϕ, θ) is defined by

$$P_{\pi,\phi,\theta}(E) = \prod_{e \in E} P_{\pi,\phi,\theta}(e) \qquad (2)$$

where the probability of each entity e is defined by

$$\begin{aligned} P_{\pi,\phi,\theta}(e) &= P(s) \\ &\times P(h|s) \\ &\times \prod_{t \in T_e} P(t|s) \\ &\times \prod_{a \in A_e} P(a|s) \qquad (3) \end{aligned}$$

The generative story is as follows:

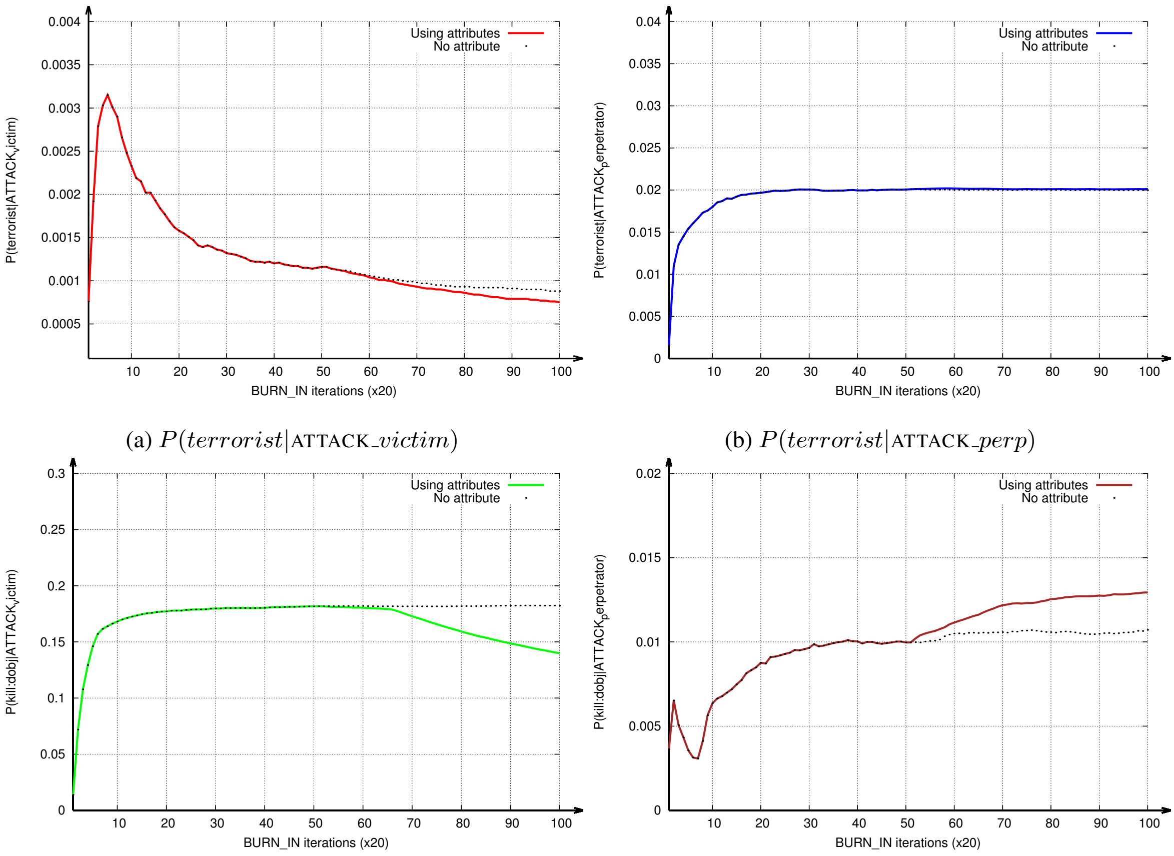
```
for slot $s \leftarrow 1$ to $K$ do
    Generate an attribute distribution $\theta_s$ from a Dirichlet prior $dir(\alpha)$;
    Generate a head distribution $\pi_s$ from a Dirichlet prior $dir(\beta)$;
    Generate a trigger distribution $\phi_s$ from a Dirichlet prior $dir(\gamma)$;
end
for entity $e \in E$ do
    Generate a slot $s$ from a uniform distribution $uni(1, K)$;
    Generate a head $h$ from a multinominal distribution $\pi_s$;
    for $i \leftarrow 1$ to $|T_e|$ do
        Generate a trigger $t_i$ from a multinominal distribution $\phi_s$;
    end
    for $j \leftarrow 1$ to $|A_e|$ do
        Generate an attribute $a_j$ from a multinominal distribution $\phi_s$;
    end
end
```

4.2 Parameter Estimation

For parameter estimation, we use the Gibbs sampling method (Griffiths, 2002). The slot variable s is sampled by integrating out all the other variables.

Previous models (Cheung et al., 2013; Chambers, 2013) are based on document-level topic modeling, which originated from models such as Latent Dirichlet Allocation (Blei et al., 2003). Our model is, instead, independent from document contexts. Its input is a sequence of entity triples. Document boundary is only used in a post-processing step of filtering (see Section 5.3 for more details). There is a universal slot distribution instead of each slot distribution for one document. Furthermore, slot prior is ignored by using a uniform distribution as a particular case of categorical probability. Sampling-based slot assignment could depend on initial states and random seeds. In our implementation of Gibbs sampling, we use 2,000 *burn-in* of overall 10,000 iterations. The purpose of *burn-in* is to assure that parameters converge to a stable state before estimating the probability distributions. Moreover, an interval step of 100 is applied between consecutive samples in order to avoid too strong coherence.

Particularly, for tracking changes in probabilities resulting from attribute relations, we ran in the first stage a specific burn-in with only heads and trigger relations. This stable state was then used as initialization for the second burn-in in



(a) $P(terrorist|\text{ATTACK\_}victim)$

(b) $P(terrorist|\text{ATTACK\_}perp)$

(c) $P(kill : dobj|\text{ATTACK\_}victim)$

(d) $P(kill : dobj|\text{ATTACK\_}perp)$

Figure 3: Probability convergence when using attributes in sampling. The use of attributes is started at point 50 (*i.e.*, 50% of burn-in phase). The dotted line shows convergence without attributes; the continuous line shows convergence with attributes.

which attributes, heads, and triggers were used altogether. This specific experimental setting made us understand how the attributes modified distributions. We observed that non-ambiguous words or relations (*i.e. explode*, *murder:nsubj*) were only slightly modified whereas probabilities of ambiguous words such as *man*, *soldier* or triggers such as *kill:dobj* or *attack:nsubj* converged smoothly to a different stable state that was semantically more coherent. For instance, the model interestingly realized that even if a *terrorist* was killed (*e.g.* by police), he was not actually a real victim of an attack. Figure 3 shows probability convergences of *terrorist* and *kill:dobj* given ATTACK_victim and ATTACK_perpetrator.

5 Evaluations

In order to compare with related work, we evaluated our method on the Message Understanding Conference (MUC-4) corpus (Sundheim, 1991) using precision, recall and F-score as conventional metrics for template extraction.

In what follows, we first introduce the MUC-4 corpus (Section 5.1.1), we detail the mapping technique between learned slots and reference slots (5.1.2) as well as the hyper-parameters of our model (5.1.3). Next, we present a first experiment (Section 5.2) showing how using attribute relations improves overall results. The second experiment (Section 5.3) studies the impact of document classification. We then compare our results with previous approaches, more particularly with Chambers (2013), from both quantitative and qualitative points of view (Section 5.4). Finally, Section 5.5 is dedicated to error analysis, with a special emphasis on sources of false positives.

5.1 Experimental Setups

5.1.1 Datasets

The MUC-4 corpus contains 1,700 news articles about terrorist incidents happening in Latin America. The corpus is divided into 1,300 documents for the development set and four test sets, each containing 100 documents.

We follow the rules in the literature to guarantee comparable results (Patwardhan and Riloff, 2007; Chambers and Jurafsky, 2011). The evaluation focuses on four template types – ARSON, ATTACK, BOMBING, KIDNAPPING – and four slots – Perpetrator, Instrument, Target, and Victim. Perpetrator is merged from Perpetrator_Individual and Perpetrator_Organization. The matching between system answers and references is based on head word matching. A head word is defined as the right-most word of the phrase or as the right-most word of the first 'of' if the phrase contains any. Optional templates and slots are ignored when calculating recall. Template types are ignored in evaluation: this means that a perpetrator of BOMBING in the answers could be compared to a perpetrator of ARSON, ATTACK, BOMBING or KIDNAPPING in the reference.

5.1.2 Slot Mapping

The model learns K slots and assigns each entity in a document to one of the learned slots. Slot mapping consists in matching each reference slot to an equivalent learned slot.

Note that among the K learned slots, some are irrelevant while others, sometimes of high quality, contain entities that are not part of the reference (spatio-temporal information, protagonist context, etc.). For this reason, it makes sense to have much more learned slots than expected event slots.

Similarly to previous work in the literature, we implemented an automatic empirical-driven slot mapping. Each reference slot was mapped to the learned slot that performed the best on the task of template extraction according to the F-score metric. Here, two identical slots of two different templates, such as ATTACK_victim and KIDNAPPING_victim, must to be mapped separately. Figure 4 shows the most common words of two learned slots which were mapped to BOMBING_instrument and KIDNAPPING_victim. This mapping is then kept for testing.

5.1.3 Parameter Tuning

We first tuned hyper-parameters of the models on the development set. The number of slots was set to $K = 35$. Dirichlet priors were set to $\alpha = 0.1$, $\beta = 1$ and $\gamma = 0.1$. The model was learned from the whole dataset. Slot mapping was done on tst1 and tst2. Outputs from tst3 and tst4 were evaluated using references and were averaged across ten runs.

BOMBING_instrument

Attributes	Heads	Triggers
car:nn	bomb	explode:nsubj
powerful:amod	fire	hear:dobj
explosive:amod	explosion	place:dobj
dynamite:nn	blow	cause:nsubj
heavy:amod	charge	set:dobj

KIDNAPPING_victim

Attributes	Heads	Triggers
several:amod	people	arrest:dobj
other:amod	person	kidnap:dobj
responsible:amod	man	release:dobj
military:amod	member	kill:dobj
young:amod	leader	identify:prep_as

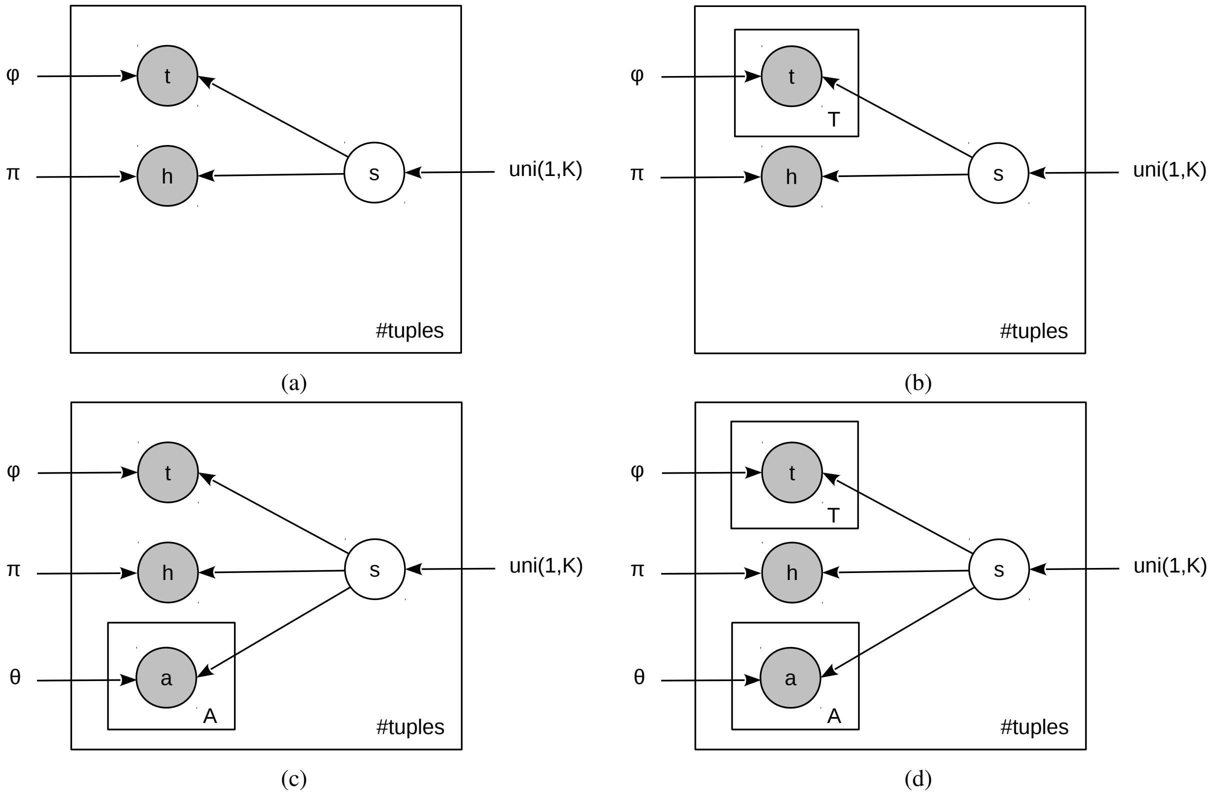
Figure 4: Attribute, head and trigger distributions learned by the model *HT+A* for learned slots that were mapped to BOMBING_instrument and KIDNAPPING_victim.

5.2 Experiment 1: Using Entity Attributes

In this experiment, two versions of our model are compared: *HT+A* uses entity heads, event trigger relations and entity attribute relations. *HT* uses only entity heads and event triggers and omits attributes.

We studied the gain brought by attribute relations with a focus on their effect when coreference information was available or was missing. The variations on the model input are named *single*, *multi* and *coref*. *Single* input has only one event trigger for each entity. A text like *an armed man attacked the police station and killed a policeman* results in two triples for the entity *man*: *(armed:amod, man, attack:nsubj)* and *(armed:amod, man, kill:nsubj)*. In *multi* input, one entity can have several event triggers, leading for the text above to the triple *(armed:amod, man, [attack:nsubj, kill:nsubj])*. The *coref* input is richer than *multi* in that, in addition to triggers from the same sentence, triggers linked to the same corefered entity are merged together. For instance, if *man* in the above example corefers with *he* in *He was arrested three hours later*, the merged triple becomes *(armed:amod, man, [attack:nsubj, kill:nsubj, arrest:dobj])*. The plate notations of these model+data combinations are given in Figure 5.

Table 1 shows a consistent improvement when using attributes, both with and without coreferences. The best performance of 40.62 F-score is obtained by the full model on inputs with coref-



(a)

(b)

(c)

(d)

Figure 5: Model variants (Dirichlet priors are omitted for simplicity): 5a) HT model ran on single data. This model is equivalent to 5b) with T=1; 5b) HT model ran on multi data; 5c) HT+A model ran on single data; 5d) HT+A model ran on multi data.

Data	HT			HT+A		
	P	R	F	P	R	F
Single	29.59	51.17	37.48	30.22	52.41	38.33

Coref	39.99	53.53	40.01	32.42	54.59	40.62

Table 1: Improvement from using attributes.

erences. Using both attributes in the model and coreference to generate input data results in a gain of 3 F-score points.

5.3 Experiment 2: Document Classification

In the second experiment, we evaluated our model with a post-processing step of document classification.

The MUC-4 corpus contains many “irrelevant” documents. A document is irrelevant if it contains no template. Among 1,300 documents in the development set, 567 are irrelevant. The most challenging part is that there are many terrorist entities, *e.g. bomb*, *force*, *guerrilla*, occurring in irrelevant documents. That makes filtering out those documents important, but difficult. As document classification is not explicitly performed by our model, a post-processing step is needed. Document classification is expected to reduce false positives in irrelevant documents while not dramatically reducing recall.

Given a document d with slot-assigned entities and a set of mapped slots S_m resulting from slot mapping, we have to decide whether this document is relevant or not. We define the relevance score of a document as:

$$relevance(d) = \frac{\sum_{e\in d: s_e\in S_m}\sum_{t\in T_e} P(t|s_e)}{\sum_{e\in d}\sum_{t\in T_e} P(t|s_e)} \quad (4)$$

where e is an entity in the document d; s_e is the slot value assigned to e; and t is an event trigger in the list of triggers T_e.

The equation (4) defines the score of an entity as the sum of the conditional probabilities of triggers given a slot. The relevance score of the document is proportional to the score of the entities assigned to mapped slots. If this relevance score is higher than a threshold λ, then the document is considered as relevant. The value of $\lambda = 0.02$ was tuned

System	P	R	F
HT+A	32.42	54.59	40.62
HT+A + doc. classification	35.57	53.89	42.79
HT+A + oracle classification	44.58	54.59	49.08

Table 2: Improvement from document classification as post-processing.

on the development set by maximizing the F-score of document classification.

Table 2 shows the improvement when applying document classification. The precision increases as false positives from irrelevant documents are filtered out. The loss of recall comes from relevant documents that are mistakenly filtered out. However, this loss is not significant and the overall F-score finally increases by 5%. We also compare our results to an "oracle" classifier that would remove all irrelevant documents while preserving all relevant ones. The performance of this oracle classification shows that there are some room for further improvement from document classification.

Irrelevant document filtering is a technique applied by most supervised and unsupervised approaches. Supervised methods prefer relevance detection at sentence or phrase-level (Patwardhan and Riloff, 2009; Patwardhan and Riloff, 2007). As for several unsupervised methods, Chambers (2013) includes document classification in his topic model. Chambers and Jurafsky (2011) and Cheung et al. (2013) use the learned clusters to classify documents by estimating the relevance of a document with respect to a template from *post-hoc* statistics about event triggers.

5.4 Comparison to State-of-the-Art

For comparing in more depth our results to the state-of-the-art in the literature. we reimplemented the method proposed in Chambers (2013) and integrated our attribute distributions into his model (as shown in Figure 6).

The main differences between this model and ours are the following:

1. The *full template model* of Chambers (2013) adds a distribution ψ linking events to documents. This makes the model more complex and maybe less intuitive since there is no reason to connect documents and slots (a document may contain references to several templates and slot mapping does not depend on document level). A benefit of this document distribution is that it leads to a free classification of irrelevant documents, thus avoiding a pre- or post-processing for classification. However, this issue of document relevance is very specific to the MUC corpus and the evaluation method; In a more general use case, there would be no "irrelevant" documents, only documents on various topics.

System	P	R	F
Cheung et al. (2013)	32	37	34
Chambers and Jurafsky (2011)	**48**	25	33
Chambers (2013) (paper values)	41	41	41
HT+A + doc. classification	36	**54**	**43**

Table 3: Comparison to state-of-the-art unsupervised systems.

2. Each entity is linked to an event variable e. This event generates a predicate for each entity mention (recall that mentions of an entity are all occurrences of this entity in the documents, for example in a coreference chain). Our work instead focus on the fact that a probabilistic model could have multiple observations at the same position. Multiple triggers and multiple attributes are treated equally. The sources of multiple attributes and multiple triggers are not only from document-level coreferences but also from dependency relations (or even from domain-level entity coreferences if available). Hence, our model arguably generalizes better in terms of both modeling and input data.

3. Chambers (2013) applies a heuristic constraint during the sampling process, imposing that subject and object of the same predicate (*e.g. kill:nsubj* and *kill:dobj*) are not distributed into the same slot. Our model does not require this heuristic.

Some details concerning data preprocessing and model parameters are not fully specified by Chambers (2013); for this reason, our implementation of the model (applied on the same data) leads to slightly different results than those published. That is why we present the two results here (paper values in Table 3, reimplementation values in Table 4).

Table 3 shows that our model outperforms the others on recall by a large margin. It achieves the

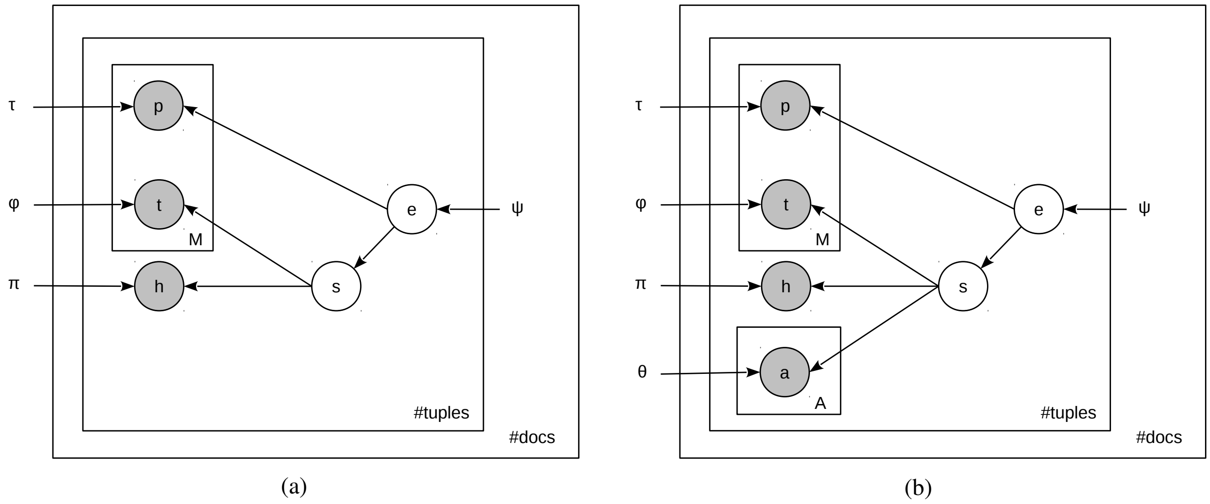

Figure 6: Variation of Chambers (2013) model: 6a) Original model; 6b) Original model + attribute distributions.

Chambers (2013)	P	R	F
Original reimpl.	38.65	42.68	40.56
Original reimpl. + Attribute	39.25	43.68	41.31

Table 4: Performance on reimplementation of Chambers (2013).

best overall F-score. In addition, as stated by our experiments, precision could be further improved by more sophisticated document classification. Interestingly, using attributes also proves to be useful in the model proposed by Chambers (2013) (as shown in Table 4).

5.5 Error Analysis

We performed an error analysis on the output of *HT+A + doc. classification* to detect the origin of false positives (FPs). 38% of FPs are mentions that never occur in the reference. Within this 38%, *attacker* and *killer* are among the most frequent errors. These words could refer to a perpetrator of an attack. These mentions, however, do not occur in the reference, possibly because human annotators consider them as too generic terms. Apart from such generic terms, other assignments are obvious errors of the system, *e.g. window*, *door* or *wall* as physical target; *action* or *massacre* as perpetrator; *explosion* or *shooting* as instrument. These kinds of errors are due to the fact that in our model, as in the one of Chambers (2013), the number of slots is fixed and is not equivalent to the real number of reference slots.

On the other hand, 62% of FPs are mentions of entities that occur at least once in the reference. On top of the list are perpetrators such as *guerrilla*, *group* and *rebel*. The model is capable of assigning *guerrilla* to *attribution* slot if it is accompanied by a trigger like *announce:nsubj*. However, triggers that describe quasi-terrorism events (*e.g.* menace, threatening, military conflict) are also grouped into *perpetrator* slots. Similarly, mentions of frequent words such as *bomb* (*instrument*), *building*, *house*, *office* (*targets*) tend to be systematically grouped into these slots, regardless of their relations. Increasing the number of slots (to sharpen their content) does not help overall. This is due to the fact that the MUC corpus is very small and is biased towards terrorism events. Adding a higher level of template type as in Chambers (2013) partially solves the problem but makes recall decrease (as shown in Table 3).

6 Conclusions and Perspectives

We presented a generative model for representing the roles played by the entities in an event template. We focused on using immediate contexts of entities and proposed a simpler and more effective model than those proposed in previous work. We evaluated this model on the MUC-4 corpus.

Even if our results outperform other unsupervised approaches, we are still far from results obtained by supervised systems. Improvements can be obtained by several ways. First, the characteristics of the MUC-4 corpus are a limiting factor. The corpus is small and roles are similar from a template to another, which does not reflect reality.

A bigger corpus, even partially annotated but presenting a better variety of templates, could lead to very different approaches.

As we showed, our model comes with a unified representation of all types of relations. This opens the way to the use of multiple types of relations (syntactic, semantic, thematic, etc.) to refine the clusters.

Last but not least, the evaluation protocol, that became a kind of *de facto* standard, is very much imperfect. Most notably, the way of finally mapping with reference slots can have a great influence on the results.

Abstract

Simultaneous translation is a method to reduce the latency of communication through machine translation (MT) by dividing the input into short segments before performing translation. However, short segments pose problems for syntax-based translation methods, as it is difficult to generate accurate parse trees for sub-sentential segments. In this paper, we perform the first experiments applying syntax-based SMT to simultaneous translation, and propose two methods to prevent degradations in accuracy: a method to predict unseen syntactic constituents that help generate complete parse trees, and a method that waits for more input when the current utterance is not enough to generate a fluent translation. Experiments on English-Japanese translation show that the proposed methods allow for improvements in accuracy, particularly with regards to word order of the target sentences.

1 Introduction

Speech translation is an application of machine translation (MT) that converts utterances from the speaker's language into the listener's language. One of the most identifying features of speech translation is the fact that it must be performed in real time while the speaker is speaking, and thus it is necessary to split a constant stream of words into translatable segments before starting the translation process. Traditionally, speech translation assumes that each segment corresponds to a sentence, and thus performs sentence boundary detection before translation (Matusov et al., 2006). However, full sentences can be long, particularly in formal speech such as lectures, and if translation does not start until explicit ends of sentences, listeners may be forced to wait a considerable time until receiving the result of translation. For example, when the speaker continues to talk for 10 seconds, listeners must wait at least 10 seconds to obtain the result of translation. This is the major factor limiting simultaneity in traditional speech translation systems.

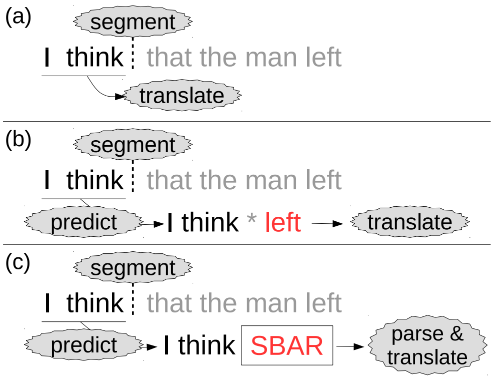

Figure 1: Simultaneous translation where the source sentence is segmented after "I think" and translated according to (a) the standard method, (b) Grissom II et al. (2014)'s method of final verb prediction, and (c) our method of predicting syntactic constituents.

Simultaneous translation (Section 2) avoids this problem by starting to translate before observing the whole sentence, as shown in Figure 1 (a). However, as translation starts before the whole sentence is observed, translation units are often not syntactically or semantically complete, and the performance may suffer accordingly. The deleterious effect of this missing information is less worrying in largely monotonic language pairs (e.g. English-French), but cannot be discounted in syntactically distant language pairs (e.g. English-Japanese) that often require long-distance reordering beyond translation units.

One way to avoid this problem of missing information is to explicitly predict information needed

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 198–207,
Beijing, China, July 26-31, 2015.

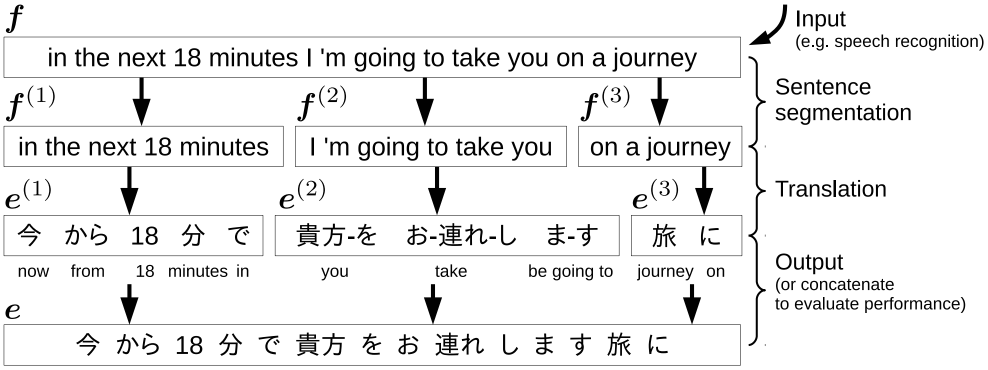

Figure 2: Process of English-Japanese simultaneous translation with sentence segmentation.

to translate the content accurately. An ambitious first step in this direction was recently proposed by Grissom II et al. (2014), who describe a method that predicts sentence-final verbs using reinforcement learning (e.g. Figure 1 (b)). This approach has the potential to greatly decrease the delay in translation from verb-final languages to verb-initial languages (such as German-English), but is also limited to only this particular case.

In this paper, we propose a more general method that focuses on a different variety of information: *unseen syntactic constituents*. This method is motivated by our desire to apply translation models that use source-side parsing, such as tree-to-string (T2S) translation (Huang et al., 2006) or syntactic pre-ordering (Xia and McCord, 2004), which have been shown to greatly improve translation accuracy over syntactically divergent language pairs. However, conventional methods for parsing are not directly applicable to the partial sentences that arise in simultaneous MT. The reason for this, as explained in detail in Section 3, is that parsing methods generally assume that they are given input that forms a complete syntactic phrase. Looking at the example in Figure 1, after the speaker has spoken the words "I think" we have a partial sentence that will only be complete once we observe the following SBAR. Our method attempts to predict exactly this information, as shown in Figure 1 (c), guessing the remaining syntactic constituents that will allow us to acquire a proper parse tree.

Specifically the method consists of two parts: First, we propose a method that trains a statistical model to predict future syntactic constituents based on features of the input segment (Section 4). Second, we demonstrate how to apply this syntactic prediction to MT, including the proposal of a heuristic method that examines whether a future constituent has the potential to cause a reordering problem during translation, and wait for more input in these cases (Section 5).

Based on the proposed method, we perform experiments in simultaneous translation of English-Japanese talks (Section 6). As this is the first work applying T2S translation to simultaneous MT, we first compare T2S to more traditional phrase-based techniques. We find that T2S translation is effective with longer segments, but drops off quickly with shorter segments, justifying the need for techniques to handle translation when full context is not available. We then compare the proposed method of predicting syntactic constituents, and find that it improves translation results, particularly with respect to word ordering in the output sentences.

2 Simultaneous Translation

In simultaneous translation, we assume that we are given an incoming stream of words f, which we are expected to translate. As the f is long, we would like to begin translating before we reach the end of the stream. Previous methods to do so can generally be categorized into *incremental decoding* methods, and *sentence segmentation* methods.

In incremental decoding, each incoming word is fed into the decoder one-by-one, and the decoder updates the search graph with the new words and decides whether it should begin translation. Incremental decoding methods have been proposed for phrase-based (Sankaran et al., 2010; Yarmohammadi et al., 2013; Finch et al., 2014) and hierarchical phrase-based (Siahbani et al., 2014) SMT models.[1] Incremental decoding has the advantage of using information about the decoding graph in the choice of translation timing, but also requires significant changes to the internal workings of the decoder, precluding the use of standard decoding tools or techniques.

Sentence segmentation methods (Figure 2) provide a simpler alternative by first dividing $\boldsymbol{f}$ into subsequences of 1 or more words $[\boldsymbol{f}^{(1)}, \ldots, \boldsymbol{f}^{(N)}]$. These segments are then translated with a traditional decoder into output sequences $[\boldsymbol{e}^{(1)}, \ldots, \boldsymbol{e}^{(N)}]$, which each are output as soon as translation finishes. Many methods have been proposed to perform segmentation, including the use of prosodic boundaries (Fügen et al., 2007; Bangalore et al., 2012), predicting punctuation marks (Rangarajan Sridhar et al., 2013), reordering probabilities of phrases (Fujita et al., 2013), or models to explicitly optimize translation accuracy (Oda et al., 2014). Previous work often assumes that $\boldsymbol{f}$ is a single sentence, and focus on sub-sentential segmentation, an approach we follow in this work.

Sentence segmentation methods have the obvious advantage of allowing for translation as soon as a segment is decided. However, the use of the shorter segments also makes it necessary to translate while part of the utterance is still unknown. As a result, segmenting sentences more aggressively often results in a decrease translation accuracy. This is a problem in phrase-based MT, the framework used in the majority of previous research on simultaneous translation. However, it is an even larger problem when performing translation that relies on parsing the input sentence. We describe the problems caused by parsing a segment $\boldsymbol{f}^{(n)}$, and solutions, in the following section.

3 Parsing Incomplete Sentences

3.1 Difficulties in Incomplete Parsing

In standard phrase structure parsing, the parser assumes that each input string is a complete sentence, or at least a complete phrase. For example, Figure 3 (a) shows the phrase structure of the complete sentence "this is a pen." However, in the case of simultaneous translation, each translation unit is not necessarily segmented in a way that guarantees that the translation unit is a complete sentence, so each translation unit should be treated not as a whole, but as a part of a spoken sentence. As a result, the parser input may be an incomplete sequence of words (e.g. "this is," "is a"), and a standard parser will generate an incorrect parse as shown in Figures 3(b) and 3(c).

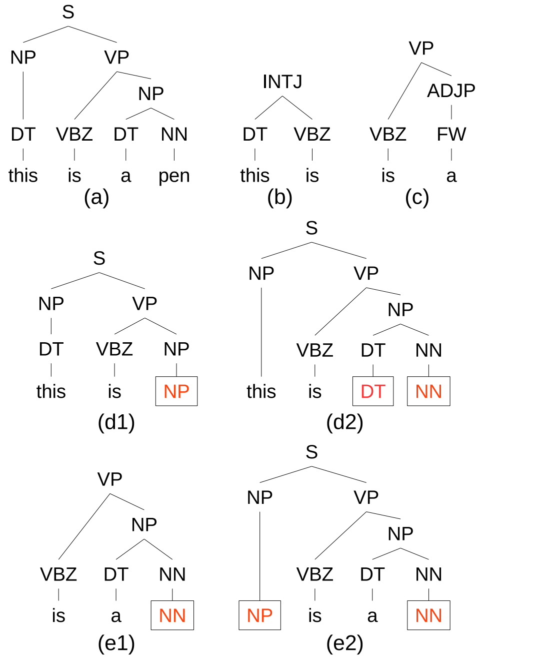

Figure 3: Phrase structures with surrounding syntactic constituents.

The proposed method solves this problem by supplementing unseen syntactic constituents before and after the translation unit. For example, considering parse trees for the complete sentence in Figure 3(a), we see that a noun phrase (NP) can be placed after the translation unit "this is." If we append the syntactic constituent $\boxed{\text{NP}}$ as a "black box" before parsing, we can create a syntactically desirable parse tree as shown in Figure 3(d1) We also can construct another tree as shown in Figure 3(d2) by appending two constituents $\boxed{\text{DT}}$ and $\boxed{\text{NN}}$. For the other example "is a," we can create the parse tree in Figure 3(e1) by appending $\boxed{\text{NP}}$ before the unit and $\boxed{\text{NN}}$ after the unit, or can create the tree in Figure 3(e2) by appending only $\boxed{\text{NN}}$ after the unit.

3.2 Formulation of Incomplete Parsing

A typical model for phrase structure parsing is the probabilistic context-free grammar (PCFG). Parsing is performed by finding the parse tree T that

[1] There is also one previous rule-based system that uses syntax in incremental translation, but it is language specific and limited domain (Ryu et al., 2006), and thus difficult to compare with our SMT-based system. It also does not predict unseen constituents, relying only on the observed segment.

maximizes the PCFG probability given a sequence of words $\boldsymbol{w} \equiv [w_1, w_2, \cdots, w_n]$ as shown by Eq. (2):

$$\begin{aligned} T^* &\equiv \arg\max_T \Pr(T|\boldsymbol{w}) & (1) \\ &\simeq \arg\max_T [\\ & \quad \sum_{(X\to[Y,\cdots])\in T} \log \Pr(X \to [Y, \cdots]) + \\ & \quad \sum_{(X\to w_i)\in T} \log \Pr(X \to w_i) \;], & (2) \end{aligned}$$

where $\Pr(X \to [Y, \cdots])$ represents the generative probabilities of the sequence of constituents $[Y, \cdots]$ given a parent constituent X, and $\Pr(X \to w_i)$ represents the generative probabilities of each word w_i $(1 \le i \le n)$ given a parent constituent X.

To consider parsing of incomplete sentences with appended syntactic constituents, We define $\boldsymbol{L} \equiv [L_{|\boldsymbol{L}|}, \cdots, L_2, L_1]$ as the sequence of preceding syntactic constituents of the translation unit and $\boldsymbol{R} \equiv [R_1, R_2, \cdots, R_{|\boldsymbol{R}|}]$ as the sequence of following syntactic constituents of the translation unit. For the example Figure 3(d1), we assume that $\boldsymbol{L} = [\,]$ and $\boldsymbol{R} = [\,\boxed{\text{NP}}\,]$.

We assume that both sequences of syntactic constituents $\boldsymbol{L}$ and $\boldsymbol{R}$ are predicted based on the sequence of words $\boldsymbol{w}$ before the main parsing step. Thus, the whole process of parsing incomplete sentences can be described as the combination of predicting both sequences of syntactic constituents represented by Eq. (3) and (4) and parsing with predicted syntactic constituents represented by Eq. (5):

$$\begin{aligned} \boldsymbol{L}^* &\equiv \arg\max_{\boldsymbol{L}} \Pr(\boldsymbol{L}|\boldsymbol{w}), & (3) \\ \boldsymbol{R}^* &\equiv \arg\max_{\boldsymbol{R}} \Pr(\boldsymbol{R}|\boldsymbol{w}), & (4) \\ T^* &\equiv \arg\max_T \Pr(T|\boldsymbol{L}^*, \boldsymbol{w}, \boldsymbol{R}^*). & (5) \end{aligned}$$

Algorithmically, parsing with predicted syntactic constituents can be achieved by simply treating each syntactic constituent as another word in the input sequence and using a standard parsing algorithm such as the CKY algorithm. In this process, the only difference between syntactic constituents and normal words is the probability, which we define as follows:

$$\Pr(X \to \boxed{Y}) \equiv \begin{cases} 1, & \text{if } Y = X \\ 0, & \text{otherwise.} \end{cases} \qquad (6)$$

It should be noted that here $\boldsymbol{L}$ refers to syntactic constituents that have already been seen in the past. Thus, it is theoretically possible to store past parse trees as history and generate $\boldsymbol{L}$ based on this history, or condition Eq. 3 based on this information. However, deciding which part of trees to use as $\boldsymbol{L}$ is not trivial, and applying this approach requires that we predict $\boldsymbol{L}$ and $\boldsymbol{R}$ using different methods. Thus, in this study, we use the same method to predict both sequences of constituents for simplicity.

In the next section, we describe the actual method used to create a predictive model for these strings of syntactic constituents.

4 Predicting Syntactic Constituents

In order to define which syntactic constituents should be predicted by our model, we assume that each final parse tree generated by $\boldsymbol{w}$, $\boldsymbol{L}$ and $\boldsymbol{R}$ must satisfy the following conditions:

1. The parse tree generated by $\boldsymbol{w}$, $\boldsymbol{L}$ and $\boldsymbol{R}$ must be "complete." Defining this formally, this means that the root node of the parse tree for the segment must correspond to a node in the parse tree for the original complete sentence.

2. Each parse tree contains only $\boldsymbol{L}$, $\boldsymbol{w}$ and $\boldsymbol{R}$ as terminal symbols.

3. The number of nodes is the minimum necessary to satisfy these conditions.

As shown in the Figure 3, there is ambiguity regarding syntactic constituents to be predicted (e.g. we can choose either $[\,\boxed{\text{NP}}\,]$ or $[\,\boxed{\text{DT}}, \boxed{\text{NN}}\,]$ as $\boldsymbol{R}$ for $\boldsymbol{w} = [$ "this", "is" $]$). These conditions avoid ambiguity of which syntactic constituents should predicted for partial sentences in the training data. Looking at the example, Figures 3(d1) and 3(e1) satisfy these conditions, but 3(d2) and 3(e2) do not.

Figure 4 shows the statistics of the lengths of $\boldsymbol{L}$ and $\boldsymbol{R}$ sequences extracted according to these criteria for all substrings of the WSJ datasets 2 to 23 of the Penn Treebank (Marcus et al., 1993), a standard training set for English syntactic parsers. From the figure we can see that lengths of up to 2 constituents cover the majority of cases for both $\boldsymbol{L}$ and $\boldsymbol{R}$, but a significant number of cases require longer strings. Thus methods that predict a fixed number of constituents are not appropriate here. In Algorithm 1, we show the method we propose to

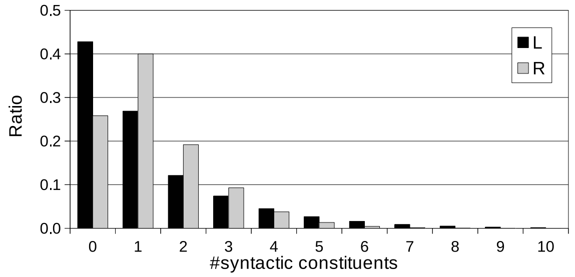

Figure 4: Statistics of numbers of syntactic constituents to be predicted.

predict $\boldsymbol{R}$ for constituent sequences of an arbitrary length. Here $+\!\!+$ represents the concatenation of two sequences.

First, our method forcibly parses the input sequence $\boldsymbol{w}$ and retrieves a potentially incorrect parse tree T', which is used to calculate features for the prediction model. The next syntactic constituent R^{+} is then predicted using features extracted from $\boldsymbol{w}$, T', and the predicted sequence history $\boldsymbol{R}^{*}$. This prediction is repeated recurrently until the end-of-sentence symbol ("nil" in Algorithm 1) is predicted as the next symbol.

In this study, we use a multi-label classifier based on linear SVMs (Fan et al., 2008) to predict new syntactic constituents with features shown in Table 1. We treat the input sequence $\boldsymbol{w}$ and predicted syntactic constituents $\boldsymbol{R}^{*}$ as a concatenated sequence $\boldsymbol{w} +\!\!+ \boldsymbol{R}^{*}$. For example, if we have $\boldsymbol{w} = [\ \text{this},\ \text{is},\ \text{a}\ ]$ and $\boldsymbol{R}^{*} = [\ \boxed{\text{NN}}\ ]$, then the word features "3 rightmost 1-grams" will take the values "is," "a," and $\boxed{\text{NN}}$. Tags of semi-terminal nodes in T' are used as part-of-speech (POS) tags for corresponding words and the POS of each predicted syntactic constituent is simply its tag. "nil" is used when some information is not available. For example, if we have $\boldsymbol{w} = [\ \text{this},\ \text{is}\ ]$ and $\boldsymbol{R}^{*} = [\,]$ then "3 rightmost 1-grams" will take the values "nil," "this," and "is." Algorithm 1 and Table 1 shows the method used to predict $\boldsymbol{R}^{*}$ but $\boldsymbol{L}^{*}$ can be predicted by performing the prediction process in the reverse order.

Algorithm 1 Prediction algorithm for following constituents $\boldsymbol{R}^{*}$

```
$T' \leftarrow \arg\max_{T} \Pr(T|\boldsymbol{w})$
$\boldsymbol{R}^{*} \leftarrow [\,]$
**loop**
    $R^{+} \leftarrow \arg\max_{R} \Pr(R|T', \boldsymbol{R}^{*})$
    **if** $R^{+} = \text{nil}$ **then**
        **return** $\boldsymbol{R}^{*}$
    **end if**
    $\boldsymbol{R}^{*} \leftarrow \boldsymbol{R}^{*} +\!\!+ [R^{+}]$
**end loop**
```

Table 1: Features used in predicting syntactic constituents.

Type	Feature
Words	3 leftmost 1,2-grams in $\boldsymbol{w} +\!\!+ \boldsymbol{R}^{*}$
	3 rightmost 1,2-grams in $\boldsymbol{w} +\!\!+ \boldsymbol{R}^{*}$
	Left/rightmost pair in $\boldsymbol{w} +\!\!+ \boldsymbol{R}^{*}$
POS	Same as "Words"
Parse	Tag of the root node
	Tags of children of the root node
	Pairs of root and children nodes
Length	$\|\boldsymbol{w}\|$
	$\|\boldsymbol{R}^{*}\|$

5 Tree-to-string SMT with Syntactic Constituents

Once we have created a tree from the sequence $\boldsymbol{L}^{*} +\!\!+ \boldsymbol{w} +\!\!+ \boldsymbol{R}^{*}$ by performing PCFG parsing with predicted syntactic constituents according to Eqs. (2), (5), and (6), the next step is to use this tree in translation. In this section, we focus specifically on T2S translation, which we use in our experiments, but it is likely that similar methods are applicable to other uses of source-side syntax such as pre-ordering as well.

It should be noted that using these trees in T2S translation models is not trivial because each estimated syntactic constituent should be treated as an aggregated entity representing all possibilities of subtrees rooted in such a constituent. Specifically, there are two problems: the possibility of *reordering* an as-of-yet unseen syntactic constituent into the middle of the translated sentence, and the calculation of *language model probabilities* considering syntactic constituent tags.

With regards to the first problem of reordering, consider the example of English-Japanese translation in Figure 5(b), where a syntactic constituent $\boxed{\text{PP}}$ is placed at the end of the English sequence ($\boldsymbol{R}^{*}$), but the corresponding entity in the Japanese translation result should be placed in the middle of the sentence. In this case, if we attempt to translate immediately, we will have to omit the as-of-yet unknown $\boxed{\text{PP}}$ from our translation and translate it later, resulting in an unnatural word ordering in the

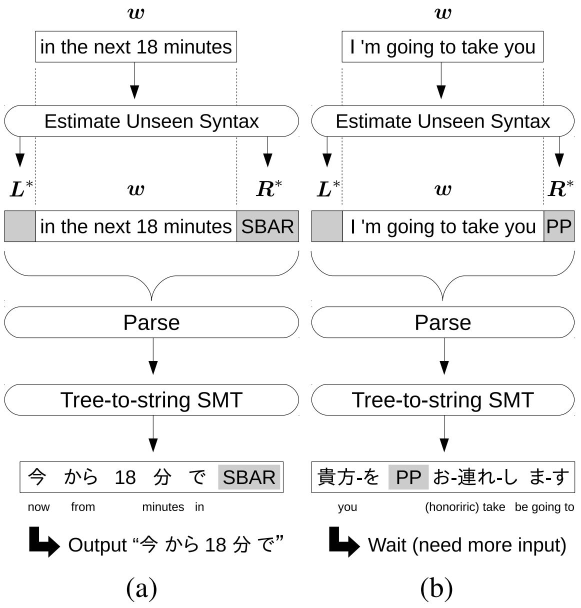

Figure 5: Waiting for the next translation unit.

target sentence.[2]

Thus, if any of the syntactic constituents in $\boldsymbol{R}$ are placed anywhere other than the end of the translation result, we can assume that this is a hint that the current segmentation boundary is not appropriate. Based on this intuition, we propose a heuristic method that ignores segmentation boundaries that result in a translation of this type, and instead wait for the next translation unit, helping to avoid problems due to inappropriate segmentation boundaries. Algorithm 2 formally describes this *waiting* method.

The second problem of language model probabilities arises because we are attempting to generate a string of words, some of which are not actual words but tags representing syntactic constituents. Creating a language model that contains probabilities for these tags in the appropriate places is not trivial, so for simplicity, we simply assume that every syntactic constituent tag is an unknown word, and that the output of translation consists of both translated normal words and non-translated tags as shown in Figure 5. We relegate a more complete handling of these tags to future work.

Algorithm 2 Waiting algorithm for T2S SMT

```
$\boldsymbol{w} \leftarrow [\,]$
loop
    $\boldsymbol{w} \leftarrow \boldsymbol{w} +\!\!+ \mathrm{NextSegment}()$
    $\boldsymbol{L}^* \leftarrow \arg\max_{\boldsymbol{L}} \Pr(\boldsymbol{L}|\boldsymbol{w})$
    $\boldsymbol{R}^* \leftarrow \arg\max_{\boldsymbol{R}} \Pr(\boldsymbol{R}|\boldsymbol{w})$
    $T^* \leftarrow \arg\max_{T} \Pr(T|\boldsymbol{L}^*, \boldsymbol{w}, \boldsymbol{R}^*)$
    $\boldsymbol{e}^* \leftarrow \arg\max_{\boldsymbol{e}} \Pr(\boldsymbol{e}|T^*)$

6 Experiments

6.1 Experiment Settings

We perform 2 types of experiments to evaluate the effectiveness of the proposed methods.

6.1.1 Predicting Syntactic Constituents

In the first experiment, we evaluate prediction accuracies of unseen syntactic constituents $\boldsymbol{L}$ and $\boldsymbol{R}$. To do so, we train a predictive model as described in Section 4 using an English treebank and evaluate its performance. To create training and testing data, we extract all substrings $\boldsymbol{w}$ s.t. $|\boldsymbol{w}| \geq 2$ in the Penn Treebank and calculate the corresponding syntactic constituents $\boldsymbol{L}$ and $\boldsymbol{R}$ by according to the original trees and substring $\boldsymbol{w}$. We use the 90% of the extracted data for training a classifier and the remaining 10% for testing estimation recall, precision and F-measure. We use the Ckylark parser(Oda et al., 2015) to generate T' from $\boldsymbol{w}$.

6.1.2 Simultaneous Translation

Next, we evaluate the performance of T2S simultaneous translation adopting the two proposed methods. We use data of TED talks from the English-Japanese section of WIT3 (Cettolo et al., 2012), and also append dictionary entries and examples in Eijiro[3] to the training data to increase the vocabulary of the translation model. The total number of sentences/entries is 2.49M (WIT3, Eijiro), 998 (WIT3), and 468 (WIT3) sentences for training, development, and testing respectively.

We use the Stanford Tokenizer[4] for English tokenization, KyTea (Neubig et al., 2011) for

[2] It is also potentially possible to create a predictive model for the actual content of the $\boxed{\text{PP}}$ as done for sentence-final verbs by Grissom II et al. (2014), but the space of potential prepositional phrases is huge, and we leave this non-trivial task for future work.

[3] http://eijiro.jp/

[4] http://nlp.stanford.edu/software/tokenizer.shtml

Japanese tokenization, GIZA++ (Och and Ney, 2003) to construct word alignment, and KenLM (Heafield et al., 2013) to generate a 5-gram target language model. We use the Ckylark parser, which we modified to implement the parsing method of Section 3.2, to generate T^* from $\boldsymbol{L}^*$, $\boldsymbol{w}$ and $\boldsymbol{R}^*$.

We use Travatar (Neubig, 2013) to train the T2S translation model used in the proposed method, and also Moses (Koehn et al., 2007) to train phrase-based translation models that serve as a baseline. Each translation model is tuned using MERT (Och, 2003) to maximize BLEU (Papineni et al., 2002). We evaluate translation accuracies by BLEU and also RIBES (Isozaki et al., 2010), a reordering-focused metric which has achieved high correlation with human evaluation on English-Japanese translation tasks.

We perform tests using two different sentence segmentation methods. The first is n-words segmentation (Rangarajan Sridhar et al., 2013), a simple heuristic that simply segments the input every n words. This method disregards syntactic and semantic units in the original sentence, allowing us to evaluate the robustness of translation against poor segmentation boundaries. The second method is the state-of-the-art segmentation strategy proposed by Oda et al. (2014), which finds segmentation boundaries that optimize the accuracy of the translation output. We use BLEU+1 (Lin and Och, 2004) as the objective of this segmentation strategy.

We evaluate the following baseline and proposed methods:

PBMT is a baseline using phrase-based SMT.

T2S uses T2S SMT with parse trees generated from only $\boldsymbol{w}$.

T2S-Tag further predicts unseen syntactic constituents according to Section 4. Before evaluation, all constituent tags are simply deleted from the output.

T2S-Wait uses *T2S-Tag* and adds the waiting strategy described in Section 5.

We also show *PBMT-Sent* and *T2S-Sent* which are full sentence-based *PBMT* and *T2S* systems.

6.2 Results

6.2.1 Predicting Syntactic Constituents

Table 2 shows the recall, precision, and F-measure of the estimated $\boldsymbol{L}$ and $\boldsymbol{R}$ sequences. The table shows results of two evaluation settings, where the order of generated constituents is considered or not.

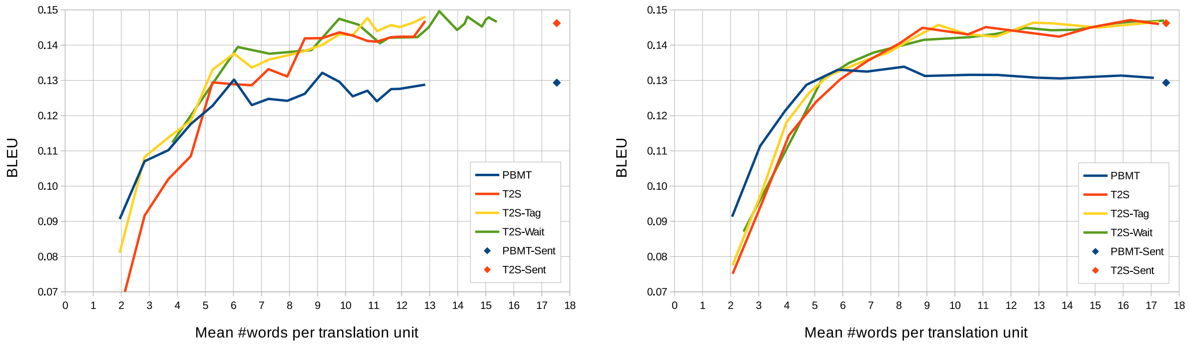
Table 2: Performance of syntactic constituent prediction.

Target		**P** %	**R** %	**F** %
$\boldsymbol{L}$	(ordered)	31.93	7.27	11.85
	(unordered)	51.21	11.66	19.00
$\boldsymbol{R}$	(ordered)	51.12	33.78	40.68
	(unordered)	52.77	34.87	42.00

We can see that in each case recall is lower than the corresponding precision and the performance of $\boldsymbol{L}$ differs between ordered and unordered results. These trends result from the fact that the model generates fewer constituents than exist in the test data. However, this trend is not entirely unexpected because it is not possible to completely accurately guess syntactic constituents from every substring $\boldsymbol{w}$. For example, parts of the sentence "in the next 18 minutes" can generate the sequence "in the next $\boxed{\text{CD}}$ $\boxed{\text{NN}}$" and "$\boxed{\text{IN}}$ $\boxed{\text{DT}}$ $\boxed{\text{JJ}}$ 18 minutes," but the constituents $\boxed{\text{CD}}$ in the former case and $\boxed{\text{DT}}$ and $\boxed{\text{JJ}}$ in the latter case are not necessary in all situations. In contrast, $\boxed{\text{NN}}$ and $\boxed{\text{IN}}$ will probably be inserted most cases. As a result, the appearance of such ambiguous constituents in the training data is less consistent than that of necessary syntactic constituents, and thus the prediction model avoids generating such ambiguous constituents.

6.2.2 Simultaneous Translation

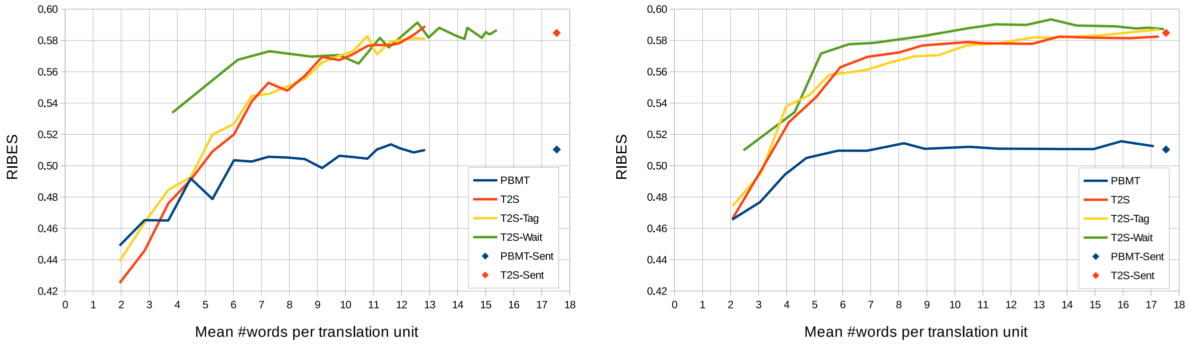
Next, we evaluate the translation results achieved by the proposed method. Figures 6 and 7 show the relationship between the mean number of words in the translation segments and translation accuracy of BLEU and RIBES respectively. Each horizontal axis of these graphs indicates the mean number of words in translation units that are used to generate the actual translation output, and these can be assumed to be proportional to the mean waiting time for listeners. In cases except *T2S-Wait*, these values are equal to the mean length of translation unit generated by the segmentation strategies, and in the case of *T2S-Wait*, this value shows the length of the translation units concatenated by the waiting strategy. First looking at the full sentence results (rightmost points in each graph), we can see that *T2S* greatly outperforms *PBMT* on full sentences,



(a) n-words segmentation

(b) optimized segmentation

Figure 6: Mean #words and BLEU scores of each method.



(a) n-words segmentation

(b) optimized segmentation

Figure 7: Mean #words and RIBES scores of each method.

underlining the importance of considering syntax for this language pair.

Turning to simultaneous translation, we first consider the case of n-words segmentation, which will demonstrate robustness of each method to poorly formed translation segments. When we compare *PBMT* and *T2S*, we can see that *T2S* is superior for longer segments, but on shorter segments performance is greatly reduced, dropping below that of *PBMT* in BLEU at an average of 6 words, and RIBES at an average of 4 words. This trend is reasonable, considering that shorter translation units will result in syntactically inconsistent units and thus incorrect parse trees. Next looking at the results for *T2S-Tag*, we can see that in the case of the n-words segmentation, it is able to maintain the same translation performance of *PBMT*, even at the shorter settings. Furthermore, *T2S-Wait* also maintains the same performance of *T2S-Tag* in BLEU and achieves much higher performance than any of the other methods in RIBES, particularly with regards to shorter translation units. This result shows that the method of waiting for more input in the face of potential reordering problems is highly effective in maintaining the correct ordering of the output.

In the case of the optimized segmentation, all three T2S methods maintain approximately the same performance, consistently outperforming *PBMT* in RIBES, and crossing in BLEU around 5-6 words. From this, we can hypothesize that the optimized segmentation strategy learns features that maintain some syntactic consistency, which plays a similar role to the proposed method. However, RIBES scores for *T2S-Wait* is still generally higher than the other methods, demonstrating that waiting maintains its reordering advantage even in the optimized segmentation case.

7 Conclusion and Future Work

In this paper, we proposed the first method to apply SMT using source syntax to simultaneous translation. Especially, we proposed methods to maintain the syntactic consistency of translation units by predicting unseen syntactic constituents, and waiting until more input is available when it is necessary to achieve good translation results. Experiments on an English-Japanese TED talk translation task demonstrate that our methods are more robust to short, inconsistent translation segments.

As future work, we are planning to devise more sophisticated methods for language modeling using constituent tags, and ways to incorporate previously translated segments into the estimation process for left-hand constituents. Next, our method to predict additional constituents does not target the grammatically correct translation units for which $\boldsymbol{L} = [\,]$ and $\boldsymbol{R} = [\,]$, although there is still room for improvement in this assumption. In addition, we hope to expand the methods proposed here to a more incremental setting, where both parsing and decoding are performed incrementally, and the information from these processes can be reflected in the decision of segmentation boundaries.

Efficient Top-Down BTG Parsing for Machine Translation Preordering

Tetsuji Nakagawa
Google Japan Inc.
tnaka@google.com

Abstract

We present an efficient incremental top-down parsing method for preordering based on Bracketing Transduction Grammar (BTG). The BTG-based preordering framework (Neubig et al., 2012) can be applied to any language using only parallel text, but has the problem of computational efficiency. Our top-down parsing algorithm allows us to use the early update technique easily for the latent variable structured Perceptron algorithm with beam search, and solves the problem.

Experimental results showed that the top-down method is more than 10 times faster than a method using the CYK algorithm. A phrase-based machine translation system with the top-down method had statistically significantly higher BLEU scores for 7 language pairs without relying on supervised syntactic parsers, compared to baseline systems using existing preordering methods.

1 Introduction

The difference of the word order between source and target languages is one of major problems in phrase-based statistical machine translation. In order to cope with the issue, many approaches have been studied. Distortion models consider word reordering in decoding time using such as distance (Koehn et al., 2003) and lexical information (Tillman, 2004). Another direction is to use more complex translation models such as hierarchical models (Chiang, 2007). However, these approaches suffer from the long-distance reordering issue and computational complexity.

Preordering (reordering-as-preprocessing) (Xia and McCord, 2004; Collins et al., 2005) is another approach for tackling the problem, which modifies the word order of an input sentence in a source language to have the word order in a target language (Figure 1(a)).

Various methods for preordering have been studied, and a method based on Bracketing Transduction Grammar (BTG) was proposed by Neubig et al. (2012). It reorders source sentences by handling sentence structures as latent variables. The method can be applied to any language using only parallel text. However, the method has the problem of computational efficiency.

In this paper, we propose an efficient incremental top-down BTG parsing method which can be applied to preordering. Model parameters can be learned using latent variable Perceptron with the early update technique (Collins and Roark, 2004), since the parsing method provides an easy way for checking the reachability of each parser state to valid final states. We also try to use forced-decoding instead of word alignment based on Expectation Maximization (EM) algorithms in order to create better training data for preordering. In experiments, preordering using the top-down parsing algorithm was faster and gave higher BLEU scores than BTG-based preordering using the CYK algorithm. Compared to existing preordering methods, our method had better or comparable BLEU scores without using supervised parsers.

2 Previous Work

2.1 Preordering for Machine Translation

Many preordering methods which use syntactic parse trees have been proposed, because syntactic information is useful for determining the word order in a target language, and it can be used to restrict the search space against all the possible permutations. Preordering methods using manually created rules on parse trees have been studied (Collins et al., 2005; Xu et al., 2009), but

Figure 1: An example of preordering.

linguistic knowledge for a language pair is necessary to create such rules. Preordering methods which automatically create reordering rules or utilize statistical classifiers have also been studied (Xia and McCord, 2004; Li et al., 2007; Genzel, 2010; Visweswariah et al., 2010; Yang et al., 2012; Miceli Barone and Attardi, 2013; Lerner and Petrov, 2013; Jehl et al., 2014). These methods rely on source-side parse trees and cannot be applied to languages where no syntactic parsers are available.

There are preordering methods that do not need parse trees. They are usually trained only on automatically word-aligned parallel text. It is possible to mine parallel text from the Web (Uszkoreit et al., 2010; Antonova and Misyurev, 2011), and the preordering systems can be trained without manually annotated language resources. Tromble and Eisner (2009) studied preordering based on a Linear Ordering Problem by defining a pairwise preference matrix. Khalilov and Sima'an (2010) proposed a method which swaps adjacent two words using a maximum entropy model. Visweswariah et al. (2011) regarded the preordering problem as a Traveling Salesman Problem (TSP) and applied TSP solvers for obtaining reordered words. These methods do not consider sentence structures.

DeNero and Uszkoreit (2011) presented a preordering method which builds a monolingual parsing model and a tree reordering model from parallel text. Neubig et al. (2012) proposed to train a discriminative BTG parser for preordering directly from word-aligned parallel text by handling underlying parse trees with latent variables. This method is explained in detail in the next subsection. These two methods can use sentence structures for designing feature functions to score permutations.

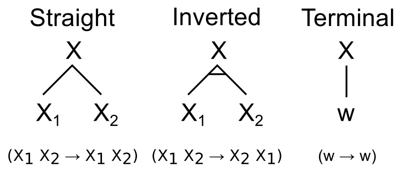

Figure 2: Bracketing transduction grammar.

2.2 BTG-based Preordering

Neubig et al. (2012) proposed a BTG-based preordering method. Bracketing Transduction Grammar (BTG) (Wu, 1997) is a binary synchronous context-free grammar with only one non-terminal symbol, and has three types of rules (Figure 2): *Straight* which keeps the order of child nodes, *Inverted* which reverses the order, and *Terminal* which generates a terminal symbol.[1]

BTG can express word reordering. For example, the word reordering in Figure 1(a) can be represented with the BTG parse tree in Figure 1(b).[2] Therefore, the task to reorder an input source sentence can be solved as a BTG parsing task to find an appropriate BTG tree.

In order to find the best BTG tree among all the possible ones, a score function is defined. Let $\Phi(m)$ denote the vector of feature functions for the BTG tree node m, and Λ denote the vector of feature weights. Then, for a given source sentence x, the best BTG tree $\hat{z}$ and the reordered sentence x' can be obtained as follows:

$$\hat{z} = \operatorname*{argmax}_{z \in Z(x)} \sum_{m \in Nodes(z)} \Lambda \cdot \Phi(m), \quad (1)$$

$$x' = Proj(\hat{z}), \quad (2)$$

where $Z(x)$ is the set of all the possible BTG trees for x, $Nodes(z)$ is the set of all the nodes in the tree z, and $Proj(z)$ is the function which generates a reordered sentence from the BTG tree z.

The method was shown to improve translation performance. However, it has a problem of processing speed. The CYK algorithm, whose computational complexity is $O(n^3)$ for a sen-

[1] Although *Terminal* produces a pair of source and target words in the original BTG (Wu, 1997), the target-side words are ignored here because both the input and the output of preordering systems are in the source language. In (Wu, 1997), (DeNero and Uszkoreit, 2011) and (Neubig et al., 2012), *Terminal* can produce multiple words. Here, we produce only one word.

[2] There may be more than one BTG tree which represents the same word reordering (e.g., the word reordering $C_3B_2A_1$ to $A_1B_2C_3$ has two possible BTG trees), and there are permutations which cannot be represented with BTG (e.g., $B_2D_4A_1C_3$ to $A_1B_2C_3D_4$, which is called the 2413 pattern).

tence of length n, is used to find the best parse tree. Furthermore, due to the use of a complex loss function, the complexity at training time is $O(n^5)$ (Neubig et al., 2012). Since the computational cost is prohibitive, some techniques like cube pruning and cube growing have been applied (Neubig et al., 2012; Na and Lee, 2013). In this study, we propose a top-down parsing algorithm in order to achieve fast BTG-based preordering.

3 Preordering with Incremental Top-Down BTG Parsing

3.1 Parsing Algorithm

We explain an incremental top-down BTG parsing algorithm using Figure 3, which illustrates how a parse tree is built for the example sentence in Figure 1. At the beginning, a tree (span) which covers all the words in the sentence is considered. Then, a span which covers more than one word is split in each step, and the node type (*Straight* or *Inverted*) for the splitting point is determined. The algorithm terminates after $(n-1)$ iterations for a sentence with n words, because there are $(n-1)$ positions which can be split.

We consider that the incremental parser has a *parser state* in each step, and define the state as a triple $\langle P, C, v\rangle$. P is a stack of unresolved spans. A span denoted by $[p,q)$ covers the words $x_p \cdots x_{q-1}$ for an input word sequence $x = x_0 \cdots x_{|x|-1}$. C is a list of past parser actions. A parser action denoted by (r,o) represents the action to split a span at the position between x_{r-1} and x_r with the node type $o \in \{\mathrm{S}, \mathrm{I}\}$, where S and I indicate *Straight* and *Inverted* respectively. v is the score of the state, which is the sum of the scores for the nodes constructed so far. Parsing starts with the initial state $\langle[[0,|x|)],[],0\rangle$, because there is one span covering all the words at the beginning. In each step, a span is popped from the top of the stack, and a splitting point in the span and its node type are determined. The new spans generated by the split are pushed onto the stack if their lengths are greater than 1, and the action is added to the list. On termination, the parser has the final state $\langle[],[c_0,\cdots,c_{|x|-2}],v\rangle$, because the stack is empty and there are $(|x|-1)$ actions in total. The parse tree can be obtained from the list of actions. Table 1 shows the parser state for each step in Figure 3.

```

    return $S$
```

Figure 4: Top-down BTG parsing with beam search.

The top-down parsing method can be used with beam search as shown in Figure 4. $\tau_{x,\Lambda}(s)$ is a function which returns the set of all the possible next states for the state s. $Top_k(S)$ returns the top k states from S in terms of their scores, $Score(s)$ returns the score of the state s, and $Tree(s)$ returns the BTG parse tree constructed from s. $\Phi(x,C,p,q,r,o)$ is the feature vector for the node created by splitting the span $[p,q)$ at r with the node type o, and is explained in Section 3.3.

3.2 Learning Algorithm

Model parameters Λ are estimated from training examples. We assume that each training example consists of a sentence x and its word order in a target language $y = y_0 \cdots y_{|x|-1}$, where y_i is the position of x_i in the target language. For example, the example sentence in Figure 1(a) will have $y = 0, 1, 4, 3, 2$. y can have ambiguities. Multiple words can be reordered to the same position on the target side. The words whose target positions are unknown are indicated by position -1, and we consider such words can appear at any position.[3] For example, the word alignment in Figure 5 gives the target side word positions $y = -1, 2, 1, 0, 0$.

Statistical syntactic parsers are usually trained on tree-annotated corpora. However, corpora annotated with BTG parse trees are unavailable, and only the gold standard permutation y is available. Neubig et al. (2012) proposed to train BTG parsers for preordering by regarding BTG trees behind word reordering as latent variables, and we use latent variable Perceptron (Sun et al., 2009) together with beam search. In latent variable Perceptron, among the examples whose latent variables are compatible with a gold standard label, the one with the highest score is picked up as a positive example. Such an approach was used for parsing with multiple correct actions (Goldberg and Elhadad, 2010; Sartorio et al., 2013).

Figure 6 describes the training algorithm.[4] $\Phi(x, s)$ is the feature vector for all the nodes in the partial parse tree at the state s, and $\tau_{x,\Lambda,y}(s)$ is the set of all the next states for the state s. The algorithm adopts the early update technique (Collins and Roark, 2004) which terminates incremental parsing if a correct state falls off the beam, and there is no possibility to obtain a correct output. Huang et al. (2012) proposed the violation-fixing Perceptron framework which is guaranteed to converge even if inexact search is used, and also showed that early update is a special case of the framework. We define that a parser state is *valid* if the state can reach a final state whose BTG parse tree is compatible with y. Since this is a latent variable setting in which multiple states can reach correct final states, early update occurs when all the valid states fall off the beam (Ma et al., 2013; Yu et al., 2013). In order to use early update, we need to check the validity of each parser state. We extend the parser state to the four tuple $\langle P, A, v, w\rangle$, where $w \in \{\text{true}, \text{false}\}$ is the validity of the state. We remove training examples which cannot be represented with BTG beforehand and set w of the initial state to true. The function $Valid(s)$ in Figure 6 returns the validity of state s. One advantage of the top-down parsing algorithm is that it is easy to track the validity of each state. The validity of a state can be calculated using the following property, and we can implement the function $\tau_{x,\Lambda,y}(s)$ by modifying the function $\tau_{x,\Lambda}(s)$ in Figure 4.

Lemma 1. *When a valid state s, which has $[p, q)$ in the top of the stack, transitions to a state s' by the action (r, o), s' is also valid if and only if the following condition holds:*

$$\begin{aligned} \forall i \in \{p, \cdots, r-1\}\, y_i = -1 \quad &\lor \\ \forall i \in \{r, \cdots, q-1\}\, y_i = -1 \quad &\lor \\ \Bigl(o = \mathrm{S} \land \max_{\substack{i=p,\cdots,r-1\\ y_i \neq -1}} y_i \le \min_{\substack{i=r,\cdots,q-1\\ y_i \neq -1}} y_i\Bigr) \quad &\lor \\ \Bigl(o = \mathrm{I} \land \max_{\substack{i=r,\cdots,q-1\\ y_i \neq -1}} y_i \le \min_{\substack{i=p,\cdots,r-1\\ y_i \neq -1}} y_i\Bigr). \quad & \end{aligned} \tag{3}$$

Proof. Let π_i denote the position of x_i after reordering by BTG parsing. If Condition (3) does not hold, there are i and j which satisfy $\pi_i < \pi_j \land y_i > y_j \land y_i \neq -1 \land y_j \neq -1$, and π_i and π_j are not compatible with y. Therefore, s' is valid only if Condition (3) holds.

When Condition (3) holds, a valid permutation can be obtained if the spans $[p, r)$ and $[r, q)$ are BTG-parsable. They are BTG-parsable as shown below. Let us assume that y does not have ambiguities. The class of the permutations which can be represented by BTG is known as *separable permutations* in combinatorics. It can be proven (Bose et al., 1998) that a permutation is a separable permutation if and only if it contains neither the 2413 nor the 3142 patterns. Since s is valid, y is a separable permutation. y does not contain the 2413 nor the 3142 patterns, and any subsequence of y also does not contain the patterns. Thus, $[p, r)$ and $[r, q)$ are separable permutations. The above argument holds even if y has ambiguities (duplicated positions or unaligned words). In such a case, we can always make a word order y' which specializes y and has no ambiguities (e.g., $y' = 2, 1.0, 0.0, 0.1, 1.1$ for $y = -1, 1, 0, 0, 1$), because s is valid, and there is at least one BTG parse tree which licenses y. Any subsequence in

[3] In (Neubig et al., 2012), the positions of such words were fixed by heuristics. In this study, the positions are not fixed, and all the possibilities are considered by latent variables.

[4] Although the simple Perceptron algorithm is used for explanation, we actually used the Passive Aggressive algorithm (Crammer et al., 2006) with the parameter averaging technique (Freund and Schapire, 1999).

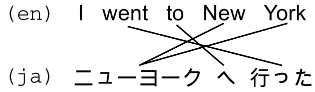

Figure 5: An example of word reordering with ambiguities.

y' is a separable permutation, and $[p, r)$ and $[r, q)$ are separable permutations. Therefore, s' is valid if Condition (3) holds. □

For dependency parsing and constituent parsing, incremental bottom-up parsing methods have been studied (Yamada and Matsumoto, 2003; Nivre, 2004; Goldberg and Elhadad, 2010; Sagae and Lavie, 2005). Our top-down approach is contrastive to the bottom-up approaches. In the bottom-up approaches, spans which cover individual words are considered at the beginning, then they are merged into larger spans in each step, and a span which covers all the words is obtained at the end. In the top-down approach, a span which covers all the words is considered at the beginning, then spans are split into smaller spans in each step, and spans which cover individual words are obtained at the end. The top-down BTG parsing method has the advantage that the validity of parser states can be easily tracked.

The computational complexity of the top-down parsing algorithm is $O(kn^2)$ for sentence length n and beam width k, because in Line 5 of Figure 4, which is repeated at most $k(n-1)$ times, at most $2(n-1)$ parser states are generated, and their scores are calculated. The learning algorithm uses the same decoding algorithm as in the parsing phase, and has the same time complexity. Note that the validity of a parser state can be calculated in $O(1)$ by pre-calculating $\min_{i=p,\cdots,r \wedge y_i \neq -1} y_i$, $\max_{i=p,\cdots,r \wedge y_i \neq -1} y_i$, $\min_{i=r,\cdots,q-1 \wedge y_i \neq -1} y_i$, and $\max_{i=r,\cdots,q-1 \wedge y_i \neq -1} y_i$ for all r for the span $[p, q)$ when it is popped from the stack.

3.3 Features

We assume that each word x_i in a sentence has three attributes: word surface form x_i^{w}, part-of-speech (POS) tag x_i^{p} and word class x_i^{c} (Section 4.1 explains how x_i^{p} and x_i^{c} are obtained).

Table 2 lists the features generated for the node which is created by splitting the span $[p, q)$ with the action (r, o). o' is the node type of the parent node, $d \in \{\text{left}, \text{right}\}$ indicates whether this node is the left-hand-side or the right-hand-side child of the parent node, and $Balance(p, q, r)$ returns a value among $\{$'<', '=', '>'$\}$ according to the relation of the lengths of $[p, r)$ and $[r, q)$. The baseline feature templates are those used by Neubig et al. (2012), and the additional feature templates are extended features that we introduce in this study. The top-down parser is fast, and allows us to use a larger number of features.

```
Input: Training data $\{\langle x^l, y^l \rangle\}_{l=0}^{L-1}$,
       number of iterations $T$, beam width $k$.
Output: Feature weights $\Lambda$.
$\Lambda \leftarrow \mathbf{0}$
for $t := 0, \cdots, T-1$ do
  for $l := 0, \cdots, L-1$ do
    $S_0 \leftarrow \{\langle [[0, |x^l|)], [], 0, \mathrm{true} \rangle\}$
    for $i := 1, \cdots, |x^l| - 1$ do
      $S \leftarrow \{\}$
      foreach $s \in S_{i-1}$ do
        $S \leftarrow S \cup \tau_{x^l, \Lambda, y^l}(s)$
      $S_i \leftarrow Top_k(S)$
      $\hat{s} \leftarrow \mathrm{argmax}_{s \in S}\, Score(s)$
      $s^* \leftarrow \mathrm{argmax}_{s \in S \wedge Valid(s)}\, Score(s)$
      if $s^* \notin S_i$ then
        break                              // Early update.
    if $\hat{s} \neq s^*$ then
      $\Lambda \leftarrow \Lambda + \Phi(x^l, s^*) - \Phi(x^l, \hat{s})$
return $\Lambda$
```

Figure 6: A training algorithm for latent variable Perceptron with beam search.

In order to make the feature generation efficient, the attributes of all the words are converted to their 64-bit hash values beforehand, and concatenating the attributes is executed not as string manipulation but as faster integer calculation to generate a hash value by merging two hash values. The hash values are used as feature names. Therefore, when accessing feature weights stored in a hash table using the feature names as keys, the keys can be used as their hash values. This technique is different from the hashing trick (Ganchev and Dredze, 2008) which directly uses hash values as indices, and no noticeable differences in accuracy were observed by using this technique.

3.4 Training Data for Preordering

As described in Section 3.2, each training example has y which represents correct word positions after reordering. However, only word alignment data is generally available, and we need to convert it to y. Let A_i denote the set of indices of the target-side words which are aligned to the source-side word x_i. We define an order relation between two words:

$$x_i \leq x_j \quad \Leftrightarrow \quad \forall a \in A_i \setminus A_j, \forall b \in A_j \; a \leq b \wedge \forall a \in A_i, \forall b \in A_j \setminus A_i \; a \leq b. \quad (4)$$

Baseline Feature Template
$o(q-p), oBalance(p,q,r),$
$ox^{\mathrm{w}}_{p-1}, ox^{\mathrm{w}}_{p}, ox^{\mathrm{w}}_{r-1}, ox^{\mathrm{w}}_{r}, ox^{\mathrm{w}}_{q-1}, ox^{\mathrm{w}}_{q}, ox^{\mathrm{w}}_{p}x^{\mathrm{w}}_{q-1}, ox^{\mathrm{w}}_{r-1}x^{\mathrm{w}}_{r},$
$ox^{\mathrm{p}}_{p-1}, ox^{\mathrm{p}}_{p}, ox^{\mathrm{p}}_{r-1}, ox^{\mathrm{p}}_{r}, ox^{\mathrm{p}}_{q-1}, ox^{\mathrm{p}}_{q}, ox^{\mathrm{p}}_{p}x^{\mathrm{p}}_{q-1}, ox^{\mathrm{p}}_{r-1}x^{\mathrm{p}}_{r},$
$ox^{\mathrm{c}}_{p-1}, ox^{\mathrm{c}}_{p}, ox^{\mathrm{c}}_{r-1}, ox^{\mathrm{c}}_{r}, ox^{\mathrm{c}}_{q-1}, ox^{\mathrm{c}}_{q}, ox^{\mathrm{c}}_{p}x^{\mathrm{c}}_{q-1}, ox^{\mathrm{c}}_{r-1}x^{\mathrm{c}}_{r}.$

Additional Feature Template
$o \min(r-p,5) \min(q-r,5), oo', oo'd,$
$ox^{\mathrm{w}}_{p-1}x^{\mathrm{w}}_{p}, ox^{\mathrm{w}}_{p}x^{\mathrm{w}}_{r-1}, ox^{\mathrm{w}}_{p}x^{\mathrm{w}}_{r}, ox^{\mathrm{w}}_{r-1}x^{\mathrm{w}}_{q-1}, ox^{\mathrm{w}}_{r}x^{\mathrm{w}}_{q-1}, ox^{\mathrm{w}}_{q-1}x^{\mathrm{w}}_{q},$

$ox^{\mathrm{c}}_{p}x^{\mathrm{c}}_{r-1}x^{\mathrm{c}}_{r}x^{\mathrm{c}}_{q-1},$
$oo'dx^{\mathrm{c}}_{p}, oo'dx^{\mathrm{c}}_{r-1}, oo'dx^{\mathrm{c}}_{r}, oo'dx^{\mathrm{c}}_{q-1}, oo'dx^{\mathrm{c}}_{p}x^{\mathrm{c}}_{q-1}.$

Table 2: Feature templates.

Then, we sort x using the order relation and assign the position of x_i in the sorted result to y_i. If there are two words x_i and x_j in x which satisfy neither $x_i \leq x_j$ nor $x_j \leq x_i$ (that is, x does not make a totally ordered set with the order relation), then x cannot be sorted, and the example is removed from the training data. -1 is assigned to the words which do not have aligned target words. Two words x_i and x_j are regarded to have the same position if $x_i \leq x_j$ and $x_j \leq x_i$.

The quality of training data is important to make accurate preordering systems, but automatically word-aligned data by EM algorithms tend to have many wrong alignments. We use forced-decoding in order to make training data for preordering. Given a parallel sentence pair and a phrase table, forced-decoding tries to translate the source sentence to the target sentence, and produces phrase alignments. We train the parameters for forced-decoding using the same parallel data used for training the final translation system. Infrequent phrase translations are pruned when the phrase table is created, and forced-decoding does not always succeed for the parallel sentences in the training data. Forced-decoding tends to succeed for shorter sentences, and the phrase-alignment data obtained by forced-decoding is biased to contain more shorter sentences. Therefore, we apply the following processing for the output of forced-decoding to make training data for preordering:

1. Remove sentences which contain less than 3 or more than 50 words.
2. Remove sentences which contain less than 3 phrase alignments.
3. Remove sentences if they contain word 5-grams which appear in other sentences in order to drop boilerplates.
4. Lastly, randomly resample sentences from the pool of filtered sentences to make the distribution of the sentence lengths follow a normal distribution with the mean of 20 and the standard deviation of 8. The parameters were determined from randomly sampled sentences from the Web.

4 Experiments

4.1 Experimental Settings

We conduct experiments for 12 language pairs: Dutch (nl)-English (en), en-nl, en-French (fr), en-Japanese (ja), en-Spanish (es), fr-en, Hindi (hi)-en, ja-en, Korean (ko)-en, Turkish (tr)-en, Urdu (ur)-en and Welsh (cy)-en.

We use a phrase-based statistical machine translation system which is similar to (Och and Ney, 2004). The decoder adopts the regular distance distortion model, and also incorporates a maximum entropy based lexicalized phrase reordering model (Zens and Ney, 2006). The distortion limit is set to 5 words. Word alignments are learned using 3 iterations of IBM Model-1 (Brown et al., 1993) and 3 iterations of the HMM alignment model (Vogel et al., 1996). Lattice-based minimum error rate training (MERT) (Macherey et al., 2008) is applied to optimize feature weights. 5-gram language models trained on sentences collected from various sources are used.

The translation system is trained with parallel sentences automatically collected from the Web. The parallel data for each language pair consists of around 400 million source and target words. In order to make the development data for MERT and test data (3,000 and 5,000 sentences respectively for each language), we created parallel sentences by randomly collecting English sentences from the Web, and translating them by humans into each language.

As an evaluation metric for translation quality, BLEU (Papineni et al., 2002) is used. As intrinsic evaluation metrics for preordering, Fuzzy Reordering Score (FRS) (Talbot et al., 2011) and Kendall's τ (Kendall, 1938; Birch et al., 2010; Isozaki et al., 2010) are used. Let ρ_i denote the position in the input sentence of the $(i+1)$-th token in a preordered word sequence excluding unaligned words in the gold-standard evaluation data. For

Classifier	80.89	90.61	**18.53**	74.24	82.83	13.90

Table 4: Performance of preordering for various training data. Bold BLEU scores indicate no statistically significant difference at $p < 0.05$ from the best system (Koehn, 2004).

example, the preordering result "New York I to went" for the gold-standard data in Figure 5 has $\rho = 3, 4, 2, 1$. Then FRS and τ are calculated as follows:

$$FRS = \frac{B}{|\rho| + 1}, \qquad (5)$$

$$B = \sum_{i=0}^{|\rho|-2} \delta(y_{\rho_i}{=}y_{\rho_{i+1}} \vee y_{\rho_i}{+}1{=}y_{\rho_{i+1}}) + \delta(y_{\rho_0}{=}0) + \delta(y_{\rho_{|\rho|-1}}{=}\max_i y_i), \qquad (6)$$

$$\tau = \frac{\sum_{i=0}^{|\rho|-2} \sum_{j=i+1}^{|\rho|-1} \delta(y_{\rho_i} \leq y_{\rho_j})}{\frac{1}{2}|\rho|(|\rho| - 1)}, \qquad (7)$$

where $\delta(X)$ is the Kronecker's delta function which returns 1 if X is true or 0 otherwise. These scores are calculated for each sentence, and are averaged over all sentences in test data. As above, FRS can be calculated as the precision of word bigrams (B is the number of the word bigrams which exist both in the system output and the gold standard data). This formulation is equivalent to the original formulation based on chunk fragmentation by Talbot et al. (2011). Equation (6) takes into account the positions of the beginning and the ending words (Neubig et al., 2012). Kendall's τ is equivalent to the (normalized) crossing alignment link score used by Genzel (2010).

We prepared three types of training data for learning model parameters of BTG-based preordering:

Manual-8k Manually word-aligned 8,000 sentence pairs.

EM-10k, EM-100k These are the data obtained with the EM-based word alignment learning. From the word alignment result for phrase translation extraction described above, 10,000 and 100,000 sentence pairs were randomly sampled. Before the sampling, the data filtering procedure 1 and 3 in Section 3.4 were applied, and also sentences were removed if more than half of source words do not have aligned target words. Word alignment was obtained by symmetrizing source-to-target and target-to-source word alignment with the INTERSECTION heuristic.[5]

Forced-10k, Forced-100k These are 10,000 and 100,000 word-aligned sentence pairs obtained with forced-decoding as described in Section 3.4.

As test data for intrinsic evaluation of preordering, we manually word-aligned 2,000 sentence pairs for en-ja and ja-en.

Several preordering systems were prepared in order to compare the following six systems:

No-Preordering This is a system without preordering.

Manual-Rules This system uses the preordering method based on manually created rules (Xu

[5] In our preliminary experiments, the UNION and GROW-DIAG-FINAL heuristics were also applied to generate the training data for preordering, but INTERSECTION performed the best.

	No- Preordering	Manual- Rules	Auto- Rules	Classifier	Lader (EM-100k)	Top-Down (EM-100k)	Top-Down (Forced-100k)

Table 6: BLEU scores for different distortion limits.

et al., 2009). We made 43 precedence rules for en-ja, and 24 for ja-en.

Auto-Rules This system uses the rule-based preordering method which automatically learns the rules from word-aligned data using the Variant 1 learning algorithm described in (Genzel, 2010). 27 to 36 rules were automatically learned for each language pair.

Classifier This system uses the preordering method based on statistical classifiers (Lerner and Petrov, 2013), and the 2-step algorithm was implemented.

Lader This system uses Latent Derivation Reorderer (Neubig et al., 2012), which is a BTG-based preordering system using the CYK algorithm.[6] The basic feature templates in Table 2 are used as features.

Top-Down This system uses the preordering system described in Section 3.

Among the six systems, Manual-Rules, Auto-Rules and Classifier need dependency parsers for source languages. A dependency parser based on the shift-reduce algorithm with beam search (Zhang and Nivre, 2011) is used. The dependency parser and all the preordering systems need POS taggers. A supervised POS tagger based on conditional random fields (Lafferty et al., 2001) trained with manually POS annotated data is used for nl, en, fr, ja and ko. For other languages, we use a POS tagger based on POS projection (Täckström et al., 2013) which does not need POS annotated data. Word classes in Table 2 are obtained by using Brown clusters (Koo et al., 2008) (the number of classes is set to 256). For both Lader and Top-Down, the beam width is set to 20, and the number of training iterations of online learning is set to 20.

The CPU time shown in this paper is measured using Intel Xeon 3.20GHz with 32GB RAM.

4.2 Results

4.2.1 Training and Preordering Speed

Table 3 shows the training time and preordering speed together with the intrinsic evaluation metrics. In this experiment, both Top-Down and Lader were trained using the EM-100k data. Compared to Lader, Top-Down was faster: more than 20 times in training, and more than 10 times in preordering. Top-down had higher preordering accuracy in FRS and τ for en-ja. Although Lader uses sophisticated loss functions, Top-Down uses a larger number of features.

Top-Down (Basic feats.) is the top-down method using only the basic feature templates in Table 2. It was much faster but less accurate than Top-Down using the additional features. Top-Down (Basic feats.) and Lader use exactly the same features. However, there are differences in the two systems, and they had different accuracies. Top-Down uses the beam search-based top-down method for parsing and the Passive-Aggressive algorithm for parameter estimation, and Lader uses the CYK algorithm with cube pruning and an on-

[6] lader 0.1.4. http://www.phontron.com/lader/

line SVM algorithm. Especially, Lader optimizes FRS in the default setting, and it may be the reason that Lader had higher FRS.

4.2.2 Performance of Preordering for Various Training Data

Table 4 shows the preordering accuracy and BLEU scores when Top-Down was trained with various data. The best BLEU score for Top-Down was obtained by using manually annotated data for en-ja and 100k forced-decoding data for ja-en. The performance was improved by increasing the data size.

4.2.3 End-to-End Evaluation for Various Language Pairs

Table 5 shows the BLEU score of each system for 12 language pairs. Some blank fields mean that the results are unavailable due to the lack of rules or dependency parsers. For all the language pairs, Top-Down had higher BLEU scores than Lader. For ja-en and ur-en, using Forced-100k instead of EM-100k for Top-Down improved the BLEU scores by more than 0.6, but it did not always improved.

Manual-Rules performed the best for en-ja, but it needs manually created rules and is difficult to be applied to many language pairs. Auto-Rules and Classifier had higher scores than No-Preordering except for fr-en, but cannot be applied to the languages with no available dependency parsers. Top-Down (Forced-100k) can be applied to any language, and had statistically significantly better BLEU scores than No-Preordering, Manual-Rules, Auto-Rules, Classifier and Lader for 7 language pairs (en-fr, fr-en, hi-en, ja-en, ko-en, tr-en and ur-en), and similar performance for other language pairs except for en-ja, without dependency parsers trained with manually annotated data.

In all the experiments so far, the decoder was allowed to reorder even after preordering was carried out. In order to see the performance without reordering after preordering, we conducted experiments by setting the distortion limit to 0. Table 6 shows the results. The effect of the distortion limits varies for language pairs and preordering methods. The BLEU scores of Top-Down were not affected largely even when relying only on preordering.

5 Conclusion

In this paper, we proposed a top-down BTG parsing method for preordering. The method incrementally builds parse trees by splitting larger spans into smaller ones. The method provides an easy way to check the validity of each parser state, which allows us to use early update for latent variable Perceptron with beam search. In the experiments, it was shown that the top-down parsing method is more than 10 times faster than a CYK-based method. The top-down method had better BLEU scores for 7 language pairs without relying on supervised syntactic parsers compared to other preordering methods. Future work includes developing a bottom-up BTG parser with latent variables, and comparing the results to the top-down parser.

Abstract

We present a method for predicting machine translation output quality geared to the needs of computer-assisted translation. These include the capability to: *i)* continuously learn and self-adapt to a stream of data coming from multiple translation jobs, *ii)* react to data diversity by exploiting human feedback, and *iii)* leverage data similarity by learning and transferring knowledge across domains. To achieve these goals, we combine two supervised machine learning paradigms, online and multitask learning, adapting and unifying them in a single framework. We show the effectiveness of our approach in a regression task (HTER prediction), in which online multitask learning outperforms the competitive online single-task and pooling methods used for comparison. This indicates the feasibility of integrating in a CAT tool a single QE component capable to simultaneously serve (and continuously learn from) multiple translation jobs involving different domains and users.

1 Introduction

Even if not perfect, machine translation (MT) is now getting reliable enough to support and speed-up human translation. Thanks to this progress, the work of professional translators is gradually shifting from full translation from scratch to MT post-editing. Advanced computer-assisted translation (CAT) tools[1] provide a natural framework for this activity by proposing, for each segment in a source document, one or more suggestions obtained either from a translation memory (TM) or from an MT engine. In both cases, accurate mechanisms to indicate the reliability of a suggestion are extremely useful to let the user decide whether to post-edit a given suggestion or ignore it and translate the source segment from scratch. However, while scoring TM matches relies on standard methods based on fuzzy matching, predicting the quality of MT suggestions at run-time and without references is still an open issue.

This is the goal of MT quality estimation (QE), which aims to predict the quality of an automatic translation as a function of the estimated number of editing operations or the time required for manual correction (Specia et al., 2009; Soricut and Echihabi, 2010; Bach et al., 2011; Mehdad et al., 2012). So far, QE has been mainly approached in controlled settings where homogeneous training and test data is used to learn and evaluate static predictors. Cast in this way, however, it does not fully reflect (nor exploit) the working conditions posed by the CAT framework, in which:

1. The QE module is exposed to a continuous stream of data. The amount of such data and the tight schedule of multiple, simultaneous translation jobs prevents from (theoretically feasible but impractical) complete re-training procedures in a batch fashion and advocate for continuous learning methods.

2. The input data can be diverse in nature. Continuous learning should be sensitive to such differences, in a way that each translation job and user is supported by a reactive model that is robust to variable working conditions.

3. The input data can show similarities with previous observations. Continuous learning should leverage such similarities, so that QE can capitalize from all the previously processed segments even if they come from different domains, genres or users.

While previous QE research disregarded these challenges or addressed them in isolation, our

[1] See for instance the open source MateCat tool (Federico et al., 2014).

and the 7th International Joint Conference on Natural Language Processing, pages 219–228,
Beijing, China, July 26-31, 2015.

work tackles them in a single unifying framework based on the combination of two paradigms: *online* and *multitask* learning. The former provides continuous learning capabilities that allow the QE model to be robust and self-adapt to a stream of potentially diverse data. The latter provides the model with the capability to exploit the similarities between data coming from different sources. Along this direction our contributions are:

- The first application of online multitask learning to QE, geared to the challenges posed by CAT technology. In this framework, our models are trained to predict MT quality in terms of HTER (Snover et al., 2006).[2]

- The extension of current online multitask learning methods to regression. Prior works in the machine learning field applied this paradigm to classification problems, but its use for HTER estimation requires real-valued predictions. To this aim, we propose a new regression algorithm that, at the same time, handles positive and negative transfer and performs online weight updates.

- A comparison between online multitask and alternative, state-of-the-art online learning strategies. Our experiments, carried out in a realistic scenario involving a stream of data from four domains, lead to consistent results that prove the effectiveness of our approach.

2 Related Work

In recent years, sentence-level QE has been mainly investigated in controlled evaluation scenarios such as those proposed by the shared tasks organized within the WMT workshop on SMT (Callison-Burch et al., 2012; Bojar et al., 2013; Bojar et al., 2014). In this framework, systems trained from a collection of (*source*, *target*, *label*) instances are evaluated based on their capability to predict the correct label[3] for new, unseen test items. Compared to our application scenario, the shared tasks setting differs in two main aspects. First, the data used are substantially homogeneous (usually they come from the same domain, and target translations are produced by the same MT system). Second, training and test are carried out as distinct, sequential phases. Instead, in the CAT environment, a QE component should ideally serve, adapt to and continuously learn from simultaneous translation jobs involving different MT engines, domains, genres and users (Turchi et al., 2013).

These challenges have been separately addressed from different perspectives in few recent works. Huang et al. (2014) proposed a method to adaptively train a QE model for document-specific MT post-editing. Adaptability, however, is achieved in a batch fashion, by re-training an *ad hoc* QE component for each document to be translated. The adaptive approach proposed by Turchi et al. (2014) overcomes the limitations of batch methods by applying an online learning protocol to continuously learn from a stream of (potentially heterogeneous) data. Experimental results suggest the effectiveness of online learning as a way to exploit user feedback to tailor QE predictions to their quality standards and to cope with the heterogeneity of data coming from different domains. However, though robust to user and domain changes, the method is solely driven by the distance computed between predicted and true labels, and it does not exploit any notion of similarity between tasks (*e.g.* domains, users, MT engines).

On the other way round, task relatedness is successfully exploited by Cohn and Specia (2013), who apply multitask learning to jointly learn from data obtained from several annotators with different levels of expertise and reliability. A similar approach is adopted by de Souza et al. (2014a), who apply multitask learning to cope with situations in which a QE model has to be trained with scarce data from multiple domains/genres, different from the actual test domain. The two methods significantly outperform both individual single-task (in-domain) models and single pooled models. However, operating in batch learning mode, none of them provides the continuous learning capabilities desirable in the CAT framework.

The idea that online and multitask learning can complement each other if combined is suggested by (de Souza et al., 2014b), who compared the two learning paradigms in the same experimental setting. So far, however, empirical evidence of this complementarity is still lacking.

[2] The HTER is the minimum edit distance between a translation suggestion and its manually post-edited version in the [0,1] interval. Edit distance is calculated as the number of edits (word insertions, deletions, substitutions, and shifts) divided by the number of words in the reference.

[3] Possible label types include *post-editing effort* scores (*e.g.* 1-5 Likert scores indicating the estimated percentage of MT output that has to be corrected), *HTER* values, and post-editing *time* (*e.g.* seconds per word).

3 Online Multitask Learning for QE

Online learning takes place in a stepwise fashion. At each step, the learner processes an instance (in our case a feature vector extracted from source and target sentences) and predicts a label for it (in our case an HTER value). After the prediction, the learner receives the "true" label (in our case the actual HTER computed from a human post-edition) and computes a *loss* that indicates the distance between the predicted and the true label. Before going to the next step, the weights are updated according to the suffered loss.

Multitask learning (MTL) aims to simultaneously learn models for a set of possibly related tasks by exploiting their relationships. By doing this, improved generalization capabilities are obtained over models trained on the different tasks in isolation (single-task learning – STL). The relationships among tasks are provided by a shared structure, which can encode three types of relationships based on their correlation (Zhang and Yeung, 2010). Positive correlation indicates that the tasks are related and knowledge transfer should lead to similar model parameters. Negative correlation indicates that the tasks are likely to be unrelated and knowledge transfer should force an increase in the distance between model parameters. No correlation indicates that the tasks are independent and no knowledge transfer should take place. In our case, a task is a set of (instance, label) pairs obtained from source sentences coming from different translation jobs, together with their translations produced by several MT systems and the relative post-editions from various translators. In this paper the terms task and domain are used interchangeably.

Early MTL methods model only positive correlation (Caruana, 1997; Argyriou et al., 2008), which results in a positive knowledge transfer between all the tasks, with the risk of impairing each other's performance when they are unrelated or negatively correlated. Other methods (Jacob et al., 2009; Zhong and Kwok, 2012; Yan et al., 2014) cluster tasks into different groups and share knowledge only among those in the same cluster, thus implicitly identifying outlier tasks. A third class of algorithms considers all the three types of relationships by learning task interaction via the covariance of task-specific weights (Bonilla et al., 2008; Zhang and Yeung, 2010). All these methods, however, learn the task relationships in batch mode. To overcome this limitation, recent works propose the "lifelong learning" paradigm (Eaton and Ruvolo, 2013; Ruvolo and Eaton, 2014), in which all the instances of a task are given to the learner sequentially and the previously learned tasks are leveraged to improve generalization for future tasks. This approach, however, is not applicable to our scenario as it assumes that all the instances of each task are processed as separate blocks.

In this paper we propose a novel MTL algorithm for QE that learns the structure shared by different tasks in an online fashion and from an input stream of instances from all the tasks. To this aim, we extend the online passive aggressive (PA) algorithm (Crammer et al., 2006) to the multitask scenario, learning a set of task-specific regression models. The multitask component of our method is given by an "interaction matrix" that defines to which extent each encoded task can "borrow" and "lend" knowledge from and to the other tasks. Opposite to previous methods (Cavallanti et al., 2010) that assume fixed dependencies among tasks, we propose to learn the interaction matrix instance-by-instance from the data. To this aim we follow the recent work of Saha et al. (2011), extending it to a regression setting. The choice of PA is motivated by practical reasons. Indeed, by providing the best trade-off between accuracy and computational time (He and Wang, 2012) compared to other algorithms such as OnlineSVR (Parrella, 2007), it represents a good solution to meet the demand of efficiency posed by the CAT framework.

3.1 Passive Aggressive Algorithm

PA follows the typical online learning protocol. At each round t the learner receives an instance, $\mathbf{x}_t \in \mathbb{R}^d$ (d is the number of features), and predicts the label $\hat{y}_t$ according to a function parametrized by a set weights $\mathbf{w}_t \in \mathbb{R}^d$. Next, the learner receives the true label y_t, computes the ϵ-insensitive loss, ℓ_ϵ, measuring the deviation between the prediction $\hat{y}_t$ and the true label y_t and updates the weights. The weights are updated by solving the optimization problem:

$$\begin{aligned} \mathbf{w}_t = \arg\min_{\mathbf{w}} \quad & \mathcal{C}_{PA}(\mathbf{w}) + C\xi \\ \text{s.t.} \quad & \ell_\epsilon(\mathbf{w}, (\mathbf{x}_t, y_t)) \leq \xi \text{ and } \xi \geq 0 \end{aligned} \tag{1}$$

where $\mathcal{C}_{PA}(\mathbf{w}) = \frac{1}{2}||\mathbf{w} - \mathbf{w}_{t-1}||^2$ and ℓ_ϵ is the ϵ-insensitive hinge loss defined as:

$$\ell_\epsilon(\mathbf{w},(\mathbf{x},y)) = \begin{cases} 0, & \text{if } |y - \mathbf{w}\cdot\mathbf{x}| \leq \epsilon \\ |y - \mathbf{w}\cdot\mathbf{x}| - \epsilon, & \text{otherwise} \end{cases} \quad (2)$$

The loss is zero when the absolute difference between the prediction and the true label is smaller or equal to ϵ, and grows linearly with this difference otherwise. The ϵ parameter is given as input and regulates the sensitivity to mistakes. The slack variable ξ acts as an upper-bound to the loss, while the C parameter is introduced to control the aggressiveness of the weights update. High C values lead to more aggressive weight updates. However, when the labels present some degree of noise (a common situation in MT QE), they might cause the learner to drastically change the weight vector in a wrong direction. In these situations, setting C to small values is desirable. As shown in (Crammer et al., 2006), a closed form solution for the weights update in Eq.1 can be derived as:

$$\mathbf{w}_t = \mathbf{w}_{t-1} + \text{sgn}(y_t - \hat{y}_t)\tau_t\mathbf{x}_t \quad (3)$$

with $\tau_t = \min(C, \frac{\ell_t}{||\mathbf{x}_t||^2})$ and $\ell_t = \ell_\epsilon(\mathbf{w},(\mathbf{x}_t, y_t))$.

3.2 Passive Aggressive MTL Algorithm

Our Passive Aggressive Multitask Learning (PAMTL) algorithm extends the traditional PA for regression to multitask learning. Our approach is inspired by the Online Task Relationship Learning algorithm proposed by Saha et al. (2011) which, however, is only defined for classification.

The learning process considers one instance at each round t. The random sequence of instances belongs to a fixed set of K tasks and the goal of the algorithm is to learn K linear models, one for each task, parametrized by weight vectors $\widetilde{\mathbf{w}}_{t,k}$, $k \in \{1,\ldots,K\}$. Moreover, the algorithm also learns a positive semidefinite matrix $\mathbf{\Omega} \in \mathbb{R}^{K\times K}$, modeling the relationship among tasks. Algorithm 1 summarizes our approach. At each round t, the learner receives a pair $(\mathbf{x}_t, i_t)$ where $\mathbf{x}_t \in \mathbb{R}^d$ is an instance and $i_t \in \{1,\ldots,K\}$ is the task identifier. Each incoming instance is transformed to a compound vector $\boldsymbol{\phi}_t = [0,\ldots,0,\mathbf{x}_t,0,\ldots,0] \in \mathbb{R}^{Kd}$. Then, the algorithm predicts the HTER score corresponding to the label $\hat{y}$ by using the weight vector $\widetilde{\mathbf{w}}_t$. The weight vector is a compound vector $\widetilde{\mathbf{w}}_t = [\widetilde{\mathbf{w}}_{t,1},\ldots,\widetilde{\mathbf{w}}_{t,K}] \in \mathbb{R}^{Kd}$, where $\widetilde{\mathbf{w}}_{t,k} \in \mathbb{R}^d$, $k \in \{1,\ldots,K\}$. Next, the learner receives the true HTER label y and computes the loss ℓ_ϵ (Eq. 2) for round t.

Algorithm 1 PA Multitask Learning (PAMTL)

```
Input: instances from $K$ tasks, number of rounds $R > 0$,
$\epsilon > 0, C > 0$
Output: $\mathbf{w}$ and $\mathbf{\Omega}$, learned after $T$ rounds

Initialization: $\mathbf{\Omega} = \frac{1}{K} \times \mathbf{I}_k$, $\mathbf{w} = \mathbf{0}$
for t = 1 to T do
    receive instance $(\mathbf{x}_t, i_t)$
    compute $\boldsymbol{\phi}_t$ from $\mathbf{x}_t$
    predict HTER $\hat{y}_t = (\widetilde{\mathbf{w}}_t^T \cdot \boldsymbol{\phi}_t)$
    receive true HTER label $y_t$
    compute $\ell_t$ (Eq. 2)
    compute $\tau_t = \min(C, \frac{\ell_t}{||\boldsymbol{\phi}_t||^2})$
    /* update weights */
    $\widetilde{\mathbf{w}}_t = \widetilde{\mathbf{w}}_{t-1} + \text{sgn}(y_t - \hat{y}_t)\tau_t(\mathbf{\Omega}_{t-1} \otimes \mathbf{I}_d)^{-1}\boldsymbol{\phi}_t$
    /* update task matrix */
    if $t > R$ then
        update $\mathbf{\Omega}_t$ with Eq. 6 or Eq. 7
    end if
end for
```

We propose to update the weights by solving:

$$\begin{aligned} \widetilde{\mathbf{w}}_t, \mathbf{\Omega}_t = \underset{\mathbf{w},\mathbf{\Omega}\succ 0}{\text{argmin}} \quad & \mathcal{C}_{MTL}(\mathbf{w},\mathbf{\Omega}) + C\xi + \mathcal{D}(\mathbf{\Omega},\mathbf{\Omega}_{t-1}) \\ \text{s.t.} \quad & \ell_\epsilon(\mathbf{w},(\mathbf{x}_t,y_t)) \leq \xi, \xi \geq 0 \end{aligned} \quad (4)$$

The first term models the joint dependencies between the task weights and the interaction matrix and it is defined as $\mathcal{C}_{MTL}(\mathbf{w},\mathbf{\Omega}) = \frac{1}{2}(\mathbf{w} - \widetilde{\mathbf{w}}_t)^T\mathbf{\Omega}_\otimes(\mathbf{w} - \widetilde{\mathbf{w}}_t)$, where $\mathbf{\Omega}_\otimes = \mathbf{\Omega} \otimes \mathbf{I}_d$. The function $\mathcal{D}(\cdot)$ represents the divergence between a pair of positive definite matrices. Similar to (Saha et al., 2011), to define $\mathcal{D}(\cdot)$ we also consider the family of Bregman divergences and specifically the LogDet and the Von Neumann divergences. Given two matrices $\mathbf{X},\mathbf{Y} \in \mathbb{R}^{n\times n}$, the LogDet divergence is $\mathcal{D}_{LD}(\mathbf{X},\mathbf{Y}) = \text{tr}(\mathbf{X}\mathbf{Y}^{-1}) - \log|\mathbf{X}\mathbf{Y}^{-1}| - n$, while the Von Neumann divergence is computed as $\mathcal{D}_{VN}(\mathbf{X},\mathbf{Y}) = \text{tr}(\mathbf{X}\log\mathbf{X} - \mathbf{Y}\log\mathbf{Y} - \mathbf{X} + \mathbf{Y})$.

The optimization process to solve Eq.4 is performed with an alternate scheme: first, with a fixed $\mathbf{\Omega}$, we compute $\mathbf{w}$; then, given $\mathbf{w}$ we optimize for $\mathbf{\Omega}$. The closed-form solution for updating $\mathbf{w}$, which we derived similarly to the PA update (Crammer et al., 2006), becomes:

$$\widetilde{\mathbf{w}}_t = \widetilde{\mathbf{w}}_{t-1} + \text{sgn}(y_t - \hat{y}_t)\tau_t(\mathbf{\Omega}_{t-1} \otimes \mathbf{I}_d)^{-1}\boldsymbol{\phi}_t \quad (5)$$

In practice, the interaction matrix works as a learning rate when updating the weights of each task. Similarly, following previous works (Tsuda et al., 2005), the update steps for the interaction matrix $\mathbf{\Omega}$ can be easily derived. For the Log-Det divergence we have:

$$\mathbf{\Omega}_t = (\mathbf{\Omega}_{t-1} + \eta\,\text{sym}(\widetilde{\mathbf{W}}_{t-1}^T\widetilde{\mathbf{W}}_{t-1}))^{-1} \quad (6)$$

while for the Von Neumann we obtain:

$$\mathbf{\Omega}_t = \exp(\log \mathbf{\Omega}_{t-1} - \eta \, \mathrm{sym}(\widetilde{\mathbf{W}}_{t-1}^T \widetilde{\mathbf{W}}_{t-1})) \qquad (7)$$

where $\widetilde{\mathbf{W}}_t \in \mathbb{R}^{d \times K}$ is a matrix obtained by column-wise reshaping the weight vector $\widetilde{\mathbf{w}}_t$, $\mathrm{sym}(\mathbf{X}) = (\mathbf{X} + \mathbf{X}^T)/2$ and η is the learning rate parameter. The sequence of steps to compute $\mathbf{\Omega}_t$ and $\widetilde{\mathbf{w}}_t$ is summarized in Algorithm 1. Importantly, the weight vector is updated at each round t, while $\mathbf{\Omega}_t$ is initialized to a diagonal matrix and it is only computed after R iterations. In this way, at the beginning, the tasks are assumed to be independent and the task-specific regression models are learned in isolation. Then, after R rounds, the interaction matrix is updated and the weights are refined considering tasks dependencies. This leads to a progressive increase in the correlation of weight vectors of related tasks. In the following, PAMTL$_{vn}$ refers to PAMTL with the Von Neumann updates and PAMTL$_{ld}$ to PAMTL with LogDet updates.

4 Experimental Setting

In this section, we describe the data used in our experiments, the features extracted from the source and target sentences, the evaluation metric and the baselines used for comparison.

Data. We experiment with English-French datasets coming from Technology Entertainment Design talks (TED), Information Technology manuals (IT) and Education Material (EM). All datasets provide a set of tuples composed by (source, translation and post-edited translation).

The TED dataset is distributed in the Trace corpus[4] and includes, as source sentences, the subtitles of several talks spanning a range of topics presented in the TED conferences. Translations were generated by two different MT systems: a phrase-based statistical MT system and a commercial rule-based system. Post-editions were collected from four different translators, as described by Wisniewski et al. (2013).

The IT manuals data come from two language service providers, henceforth $LSP1$ and $LSP2$. The IT_{LSP1} tuples belong to a software manual translated by an SMT system trained using the Moses toolkit (Koehn et al., 2007). The post-editions were produced by one professional translator. The IT_{LSP2} data includes a software manual from the automotive industry; its source sentences are translated with an adaptive proprietary MT system and post-edited by several professional translators. The EM corpus is also provided by $LSP2$ and regards educational material (*e.g.* courseware and assessments) of various text styles. The translations and post-editions are produced in the same way as for IT_{LSP2}. The IT_{LSP2} and the EM datasets are derived from the Autodesk Post-Editing Data corpus.[5]

Domain	**No. tokens**	**Vocab. Size**	**Avg. Snt. Length**
TED src	20,048	3,452	20
TED tgt	21,565	3,940	22
IT$_{LSP1}$ src	12,791	2,013	13
IT$_{LSP1}$ tgt	13,626	2,321	13
EM src	15,327	3,200	15
EM tgt	17,857	3,149	17
IT$_{LSP2}$ src	15,128	2,105	13
IT$_{LSP2}$ tgt	17,109	2,104	14

Table 1: Data statistics for each domain.

In total, we end up with four domains (TED, IT$_{LSP1}$, EM and IT$_{LSP2}$), which allows us to evaluate the PAMTL algorithm in realistic conditions where the QE component is exposed to a continuous stream of heterogeneous data. Each domain is composed by 1,000 tuples formed by: *i)* the English source sentence, *ii)* its automatic translation in French, and *iii)* a real-valued quality label obtained by computing the HTER between the translation and the post-edition with the TERCpp open source tool.[6]

Table 1 reports some macro-indicators (number of tokens, vocabulary size, average sentence length) that give an idea about the similarities and differences between domains. Although they contain data from different software manuals, similar vocabulary size and sentence lengths for the two IT domains seem to reflect some commonalities in their technical style and jargon. Larger values for TED and EM evidence a higher lexical variability in the topics that compose these domains and the expected stylistic differences featured by speech transcriptions and non-technical writing. Overall, these numbers suggest a possible dissimilar-

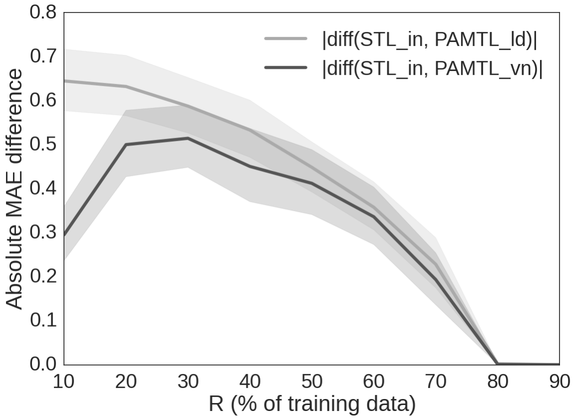

Figure 1: Validation curves for the R parameter.

ity between IT$_{LSP1}$ and IT$_{LSP2}$ and the other two domains, which might make knowledge transfer across them more difficult and QE model reactivity to domain changes particularly important.

Features. Our models are trained using the 17 baseline features proposed in (Specia et al., 2009), extracted with the online version of the QuEst feature extractor (Shah et al., 2014). These features take into account the complexity of the source sentence (*e.g.* number of tokens, number of translations per source word) and the fluency of the translation (*e.g.* language model probabilities). Their description is available in (Callison-Burch et al., 2012). The results of previous WMT QE shared tasks have shown that these features are particularly competitive in the HTER prediction task.

Baselines. We compare the performance of PAMTL against three baselines: *i)* pooling mean, *ii)* pooling online single task learning (STL$_{pool}$) and *iii)* in-domain online single task learning (STL$_{in}$). The pooling mean is obtained by assigning a fixed prediction value to each test point. This value is the average HTER computed on the entire pool of training data. Although assigning the same prediction to each test instance would be useless in real applications, we compare against the mean baseline since it is often hard to beat in regression tasks, especially when dealing with heterogeneous data distributions (Rubino et al., 2013).

The two online single task baselines implement the PA algorithm described in Section 3.1. The choice of PA is to make them comparable to our method, so that we can isolate more precisely the contribution of multitask learning. STL$_{pool}$ results are obtained by a single model trained on the entire pool of available training data presented in random order. STL$_{in}$ results are obtained by separately training one model for each domain. These represent two alternative strategies for the integration of QE in the CAT framework. The former would allow a single model to simultaneously support multiple translation jobs in different domains, without any notion about their relations. The latter would lead to a more complex architecture, organized as a pool of independent, specialized QE modules.

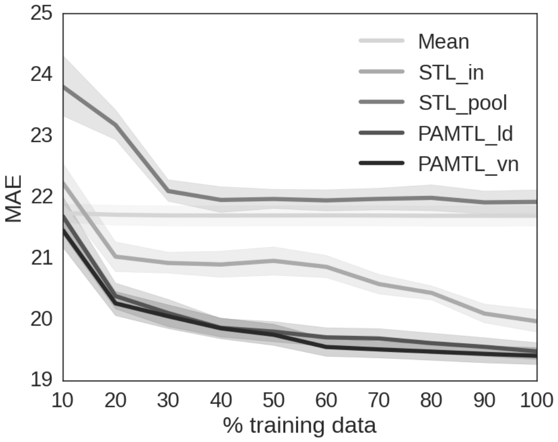

Figure 2: Learning curves for all the domains, computed by calculating the mean MAE (↓) of the four domains.

Evaluation metric. The performance of our regression models is evaluated in terms of mean absolute error (MAE), a standard error measure for regression problems commonly used also for QE (Callison-Burch et al., 2012). The MAE is the average of the absolute errors $e_i = |\hat{y}_i - y_i|$, where $\hat{y}_i$ is the prediction of the model and y_i is the true value for the i^{th} instance. As it is an error measure, lower values indicate better performance (↓).

5 Results and Discussion

In this Section we evaluate the proposed PAMTL algorithm. First, by analyzing how the number of rounds R impacts on the performance of our approach, we empirically find the value that will be used to train the model. Then, the learned model is run on test data and compared against the baselines. Performance is analyzed both by averaging the MAE results computed on all the domains, and by separately discussing in-domain behavior. Finally, the capability of the algorithm to learn task correlations and, in turn, transfer knowledge across them, is analysed by presenting the correla-

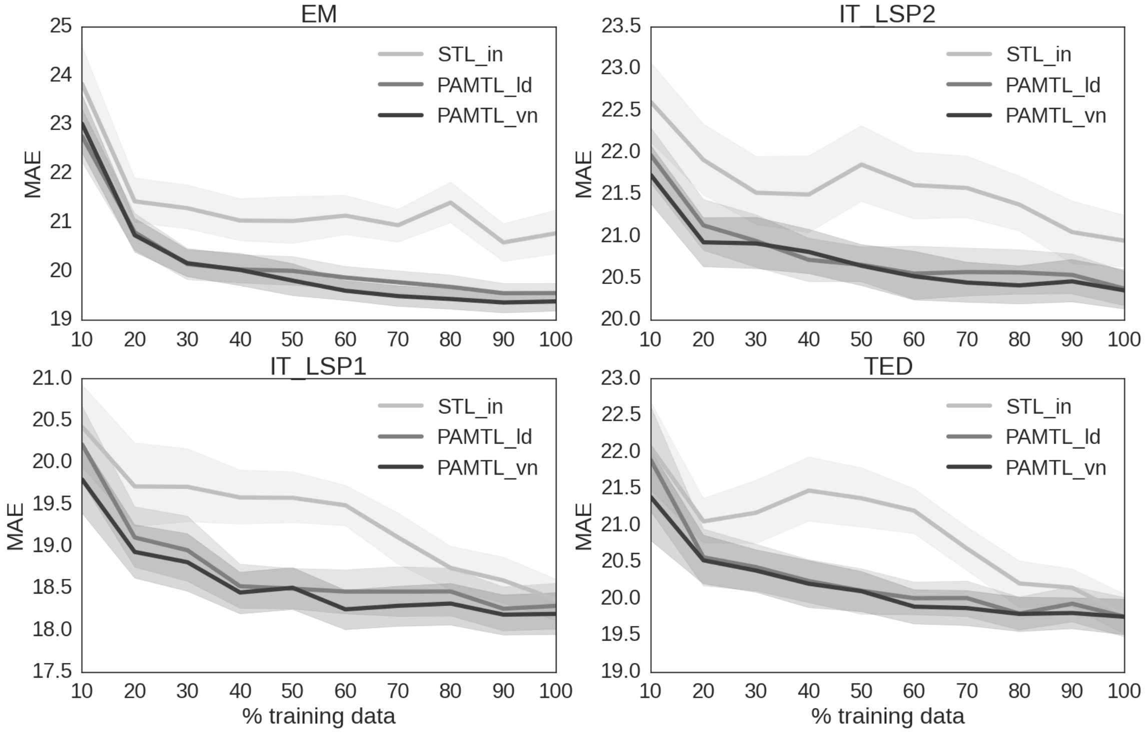

Figure 3: Learning curves showing MAE (↓) variations for each domain.

tion matrix of the task weights.

For the evaluation, we uniformly sample 700 instances from each domain for training, leaving the remaining 300 instances for test. The training sets of all the domains are concatenated and shuffled to create a random sequence of points. To investigate the impact of different amounts of data on the learning process, we create ten subsets of 10 to 100% of the training data. We optimize the parameters of all the models with a grid search procedure using 5-fold cross-validation. This process is repeated for 30 different train/test splits over the whole data. Results are presented with 95% confidence bands.[7]

Analysis of the R parameter. We empirically study the influence of the number of instances required to start updating the interaction matrix (the R parameter in Algorithm 1). For that, we perform a set of experiments where R is initialized with nine different values (expressed as percentage of training data). Figure 1 shows the validation curves obtained in cross-validation over the training data using the LogDet and Von Neumann updates. The curves report the performance (MAE) difference between STL$_{in}$ and PAMTL$_{ld}$ (black curve) and STL$_{in}$ and PAMTL$_{vn}$ (grey curve). The higher the difference, the better. The PAMTL$_{vn}$ curve differs from PAMTL$_{ld}$ one only for small values of R (< 20), showing that the two divergences are substantially equivalent. It is interesting to note that with only 20% of the training data ($R = 20$), PAMTL is able to find a stable set of weights and to effectively update the interaction matrix. Larger values of R harm the performance, indicating that the interaction matrix updates require a reasonable amount of points to reliably transfer knowledge across tasks. We use this observation to set R for our final experiment, in which we evaluate the methods over the test data.

Evaluation on test data. Global evaluation results are summarized in Figure 2, which shows five curves: one for each baseline (Mean, STL$_{in}$, STL$_{pool}$) and two for the proposed online multitask method (PAMTL$_{vn}$ and PAMTL$_{ld}$). The curves are computed by calculating the average MAE achieved with different amounts of data on each domain's test set.

The results show that PAMTL$_{ld}$ and PAMTL$_{vn}$ have similar trends (confirming the substantial equivalence previously observed), and that both outperform all the baselines in a statistically significant manner. This holds for all the training set

[7] Confidence bands are used to show whether performance differences between the models are statistically significant.

sizes we experimented with. The maximum improvement over the baselines (+1.3 MAE) is observed with 60% of the training data when comparing PAMTL$_{vn}$ with STL$_{in}$. Even if this is the best baseline, also with 100% of the data its results are not competitive and of limited interest with respect to our application scenario (the integration of effective QE models in the CAT framework). Indeed, despite the STL$_{in}$ downward error trend, it's worth remarking that an increased competitiveness would come at the cost of: *i)* collecting large amounts of annotated data and *ii)* integrating the model in a complex CAT architecture organized as a pool of independent QE components. Under the tested conditions, it is also evident that the alternative strategy of using a single QE component to simultaneously serve multiple translation jobs is not viable. Indeed, STL$_{pool}$ is the worst performing baseline, with a constant distance of around 2 MAE points from the best PAMTL model for almost all the training set sizes. The fact that, with increasing amounts of data, the STL$_{pool}$ predictions get close to those of the simple mean baseline indicates its limitations to cope with the noise introduced by a continuous stream of diverse data. The capability to handle such stream by exploiting task relationships makes PAMTL a much better solution for our purposes.

Per-domain analysis. Figure 3 shows the MAE results achieved on each target domain by the most competitive baseline (STL$_{in}$) and the proposed online multitask method (PAMTL$_{vn}$, PAMTL$_{ld}$).

For all the domains, the behavior of PAMTL$_{ld}$ and PAMTL$_{vn}$ is consistent and almost identical. With both divergences, the improvement of PAMTL over online single task learning becomes statistically significant when using more than 30% of the training data (210 instances). Interestingly, in all the plots, with 20% of the training data (140 instances for each domain, *i.e.* a total of 560 instances adding data from all the domains), PATML results are comparable to those achieved by STL$_{in}$ with 80% of the training data (*i.e.* 560 in-domain instances). This confirms that PATML can effectively leverage data heterogeneity, and that a limited amount of in-domain data is sufficient to make it competitive. Nevertheless, for all domains except EM, the PATML and STL$_{in}$ curves converge to comparable performance when trained with 100% of the data. This is not surprising if we consider that EM has a varied vocabulary (see Table 1), which may be evidence of the presence of different topics, increasing its similarity with other domains. The same assumption should also hold for TED, given that its source sentences belong to talks about different topics. The results for the TED domain, however, do not present the same degree of improvement as for EM.

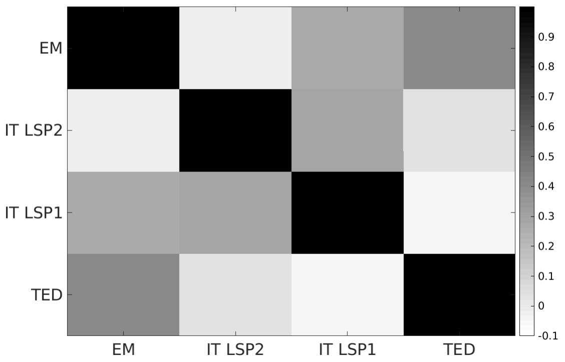

Figure 4: Correlation among the weights predicted by PATML$_{vn}$ using all the training data.

To better understand the relationships learned by the PAMTL models, we compute the correlation between the weights inferred for each domain (as performed by Saha et al. (2011)). Figure 4 shows the correlations computed on the task weights learned by PATML$_{vn}$ with all the training data. In the matrix, EM is the domain that presents the highest correlation with all the others. Instead, TED and IT$_{LSP2}$ are the less correlated with the other domains (even though, being close to the other IT domain, IT$_{LSP2}$ can share knowledge with it). This explains why the improvement measured on TED is smaller compared to EM. Although there is no canonical way to measure correlation among domains, the weights correlation matrix and the improvements achieved by PAMTL show the capability of the method to identify task relationships and exploit them to improve the generalization properties of the model.

6 Conclusion

We addressed the problem of developing quality estimation models suitable for integration in computer-assisted translation technology. In this framework, on-the-fly MT quality prediction for a stream of heterogeneous data coming from different domains/users/MT systems represents a major challenge. On one side, processing such stream calls for supervised solutions that avoid the bottleneck of periodically retraining the QE models in a batch fashion. On the other side, handling data heterogeneity requires the capability to leverage data similarities and dissimilarities. While previous works addressed these two problems in isolation, by proposing approaches respectively based on online and multitask learning, our solution unifies the two paradigms in a single online multitask approach. To this aim, we developed a novel regression algorithm, filling a gap left by current online multitask learning methods that only operate in classification mode. Our approach, which is based on the passive aggressive algorithm, has been successfully evaluated against strong online single-task competitors in a scenario involving four domains. Our future objective is to extend our evaluation to streams of data coming from a larger number of domains. Finding reasonably-sized datasets for this purpose is currently difficult. However, we are confident that the gradual shift of the translation industry towards human MT post-editing will not only push for further research on these problems, but also provide data for larger scale evaluations in a short time.

To allow for replicability of our results and promote further research on QE, the features extracted from our data, the computed labels and the source code of the method are available at `https://github.com/jsouza/pamtl`.

Abstract

Lexical selection is crucial for statistical machine translation. Previous studies separately exploit sentence-level contexts and document-level topics for lexical selection, neglecting their correlations. In this paper, we propose a context-aware topic model for lexical selection, which not only models local contexts and global topics but also captures their correlations. The model uses target-side translations as hidden variables to connect document topics and source-side local contextual words. In order to learn hidden variables and distributions from data, we introduce a Gibbs sampling algorithm for statistical estimation and inference. A new translation probability based on distributions learned by the model is integrated into a translation system for lexical selection. Experiment results on NIST Chinese-English test sets demonstrate that 1) our model significantly outperforms previous lexical selection methods and 2) modeling correlations between local words and global topics can further improve translation quality.

1 Introduction

Lexical selection is a very important task in statistical machine translation (SMT). Given a sentence in the source language, lexical selection statistically predicts translations for source words, based on various translation knowledge. Most conventional SMT systems (Koehn et al., 2003; Galley et al., 2006; Chiang, 2007) exploit very limited context information contained in bilingual rules for lexical selection.

Figure 1: A Chinese-English translation example to illustrate the effect of local contexts and global topics as well as their correlations on lexical selection. Each black line indicates a set of translation candidates for a Chinese content word (within a dotted box). Green lines point to translations that are favored by local contexts while blue lines show bidirectional associations between global topics and their consistent target-side translations.

Previous studies that explore richer information for lexical selection can be divided into two categories: 1) incorporating sentence-level contexts (Chan et al., 2007; Carpuat and Wu, 2007; Hasan et al., 2008; Mauser et al., 2009; He et al., 2008; Shen et al., 2009) or 2) integrating document-level topics (Xiao et al., 2011; Ture et al., 2012; Xiao et al., 2012; Eidelman et al., 2012; Hewavitharana et al., 2013; Xiong et al., 2013; Hasler et al., 2014a; Hasler et al., 2014b) into SMT. The methods in these two strands have shown their effectiveness on lexical selection.

However, correlations between sentence- and document-level contexts have never been explored before. It is clear that local contexts and global topics are often highly correlated. Consider a Chinese-English translation example presented in Figure 1. On the one hand, if local contexts suggest that the source word "立场/*lìchǎng*" should be translated in-

to “*stance*”, they will also indicate that the topic of the document where the example sentence occurs is about *politics*. The *politics* topic can be further used to enable the decoder to select a correct translation “*issue*” for another source word “问题/*wèntǐ*”, which is consistent with this topic. On the other hand, if we know that this document mainly focuses on the *politics* topic, the candiate translation “*stance*” will be more compatible with the context of “立场/*lìchǎng*” than the candiate translation “*attitude*”. This is because neighboring source-side words “中国/*zhōnguó*” and “中立/*zhōnglì*” often occur in documents that are about international politics. We believe that such correlations between local contextual words and global topics can be used to further improve lexical selection.

In this paper, we propose a unified framework to jointly model local contexts, global topics as well as their correlations for lexical selection. Specifically,

- First, we present a context-aware topic model (CATM) to exploit the features mentioned above for lexical selection in SMT. To the best of our knowledge, this is the first work to jointly model both local and global contexts for lexical selection in a topic model.

- Second, we present a Gibbs sampling algorithm to learn various distributions that are related to topics and translations from data. The translation probabilities derived from our model are integrated into SMT to allow collective lexical selection with both local and global informtion.

We validate the effectiveness of our model on a state-of-the-art phrase-based translation system. Experiment results on the NIST Chinese-English translation task show that our model significantly outperforms previous lexical selection methods.

2 Context-Aware Topic Model

In this section, we describe basic assumptions and elaborate the proposed context-aware topic model.

2.1 Basic Assumptions

In CATM, we assume that each source document d consists of two types of words: *topical words* which are related to topics of the document and *contextual words* which affect translation selections of topical words.

As topics of a document are usually represented by content words in it, we choose source-side *nouns*, *verbs*, *adjectives* and *adverbs* as topical words. For contextual words, we use all words in a source sentence as contextual words. We assume that they are generated by target-side translations of other words than themselves. Note that a source word may be both topical and contextual. For each topical word, we identify its candidate translations from training corpus according to word alignments between the source and target language. We allow a target translation to be a phrase of length no more than 3 words. We refer to these translations of source topical words as *target-side topical items*, which can be either words or phrases. In the example shown in Figure 1, all source words within dotted boxes are topical words. Topical word “立场/*lìchǎng*” is supposed to be translated into a target-side topical item “*stance*”, which is collectively suggested by neighboring contextual words “中国/*zhōngguó*”, “中立/*zhōnglì*” and the topic of the corresponding document.

In our model, all target-side topical items in a document are generated according to the following two assumptions:

- *Topic consistency assumption*: All target-side topical items in a document should be consistent with the topic distribution of the document. For example, the translations “*issue*”, “*stance*” tend to occur in documents about *politics* topic.

- *Context compatibility assumption*: For a topical word, its translation (i.e., the counterpart target-side topical item) should be compatible with its neighboring contextual words. For instance, the translation “*stance*” of “立场/*lìchǎng*” is closely related to contextual words “中国/*zhōnguó*” and “中立/*zhōnglì*”.

2.2 Model

The graphical representation of CATM, which visualizes the generative process of training data $\boldsymbol{D}$, is shown in Figure 2. Notations of CATM are presented in Table 1. In CATM, each document d can be generated in the following three steps[1]:

[1] In the following description, $Dir(.)$, $Mult(.)$ and $Unif(.)$ denote *Dirichlet*, *Multinomial* and *Uniform* distributions, re-

Symbol	Meaning
α	hyperparameter for θ
β	hyperparameter for ϕ
γ	hyperparameter for ψ
δ	hyperparameter for ξ
f	topical word
c	contextual word
$\tilde{e}$	target-side topical item
$\tilde{e}'$	a sampled target-side topical item used to generate a source-side contextual word
θ	the topic distribution of document
ϕ	the distribution of a topic over target-side topical items
ψ	the translation probability distribution of a target-side topical item over source-side topical words
ξ	the generation probability distribution of a target-side topical item over source-side contextual words
N_z	topic number
N_d	document number
N_f	the number of topical words
N_c	the number of contextual words
$N_{\tilde{e}}$	the number of target-side topical items
$N_{f,d}$	the number of topical words in d
$N_{c,d}$	the number of contextual words in d

Table 1: Notations in CATM.

1. Sample a topic distribution $\theta_d \sim Dir(\alpha)$.

2. For each position i that corresponds to a topical word f_i in the document:

- **(a)** Sample a topic $z_i \sim Mult(\theta_d)$.
- **(b)** Conditioned on the topic z_i, sample a target-side topical item $\tilde{e}_i \sim Mult(\phi_{z_i})$.
- **(c)** Conditioned on the target-side topical item $\tilde{e}_i$, sample the topical word $f_i \sim Mult(\psi_{\tilde{e}_i})$.

3. For each position j that corresponds to a contextual word c_j in the document:

- **(a)** Collect all target-side topical items $\tilde{\boldsymbol{e}}_s$ that are translations of neighboring topical words within a window centered at c_j (window size w_s).
- **(b)** Randomly sample an item from $\tilde{\boldsymbol{e}}_s$, $\tilde{e}'_j \sim Unif(\tilde{\boldsymbol{e}}_s)$.
- **(c)** Conditioned on the sampled target-side topical item $\tilde{e}'_j$, sample the contextual word $c_j \sim Mult(\xi_{\tilde{e}'_j})$.

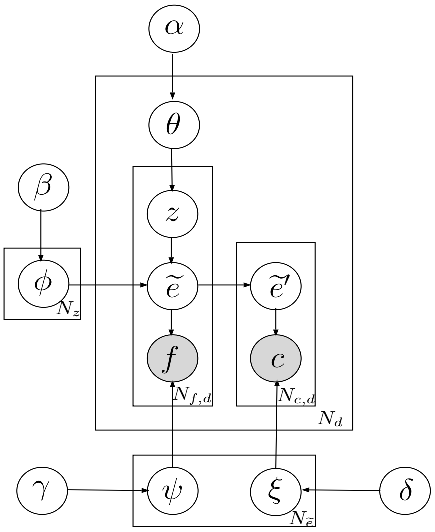

Figure 2: Graphical representation of our model.

To better illustrate CATM, let us revisit the example in Figure 1. We describe how CATM generates topical words “问题/*wèntí*”, “立场/*lìchǎng*”, and contextual word “中立/*zhōnglì*” in the following steps:

Step 1: The model generates a topic distribution for the corresponding document as $\{economy^{0.25}, politics^{0.75}\}$.

Step 2: Based on the topic distribution, we choose “*economy*” and “*politics*” as topic assignments for “问题/*wèntí*” and “立场/*lìchǎng*” respectively; Then, according to the distributions of the two topics over target-side topical items, we generate target-side topical items “*issue*” and “*stance*”; Finally, according to the translation probability distributions of these two topical items over source-side topical words, we generate source-side topical words “问题/*wèntí*” and “立场/*lìchǎng*” for them respectively.

Step 3: For the contextual word “中立/*zhōnglì*”, we first collect target-side topical items of its neighboring topical words such as “问题/*wèntí*”, “保持/*bǎochí*” and “立场/*lìchǎng*” to form a target-side topical item set $\{“issue”, “keep”, “stance”\}$, from which we randomly sample one item “*stance*”. Next, according to the generation probability distribution of “*stance*” over source contextual words, we finally generate the source contextual word “中立/*zhōnglì*”.

In the above generative process, all target-side topical items are generated from the underlying topics of a source document, which guarantees that selected target translations are topic-consistent. Ad-

spectively.

ditionally, each source contextual word is derived from a target-side topical item given its generation probability distribution. This makes selected target translations also compatible with source-side local contextual words. In this way, global topics, topical words, local contextual words and target-side topical items are highly correlated in CATM that exactly captures such correlations for lexical selection.

3 Parameter Estimation and Inference

We propose a Gibbs sampling algorithm to learn various distributions described in the previous section. Details of the learning and inference process are presented in this section.

3.1 The Probability of Training Corpus

According to CATM, the total probability of training data $\boldsymbol{D}$ given hyperparameters α, β, γ and δ is computed as follows:

$$\begin{aligned} P(\boldsymbol{D};\alpha,\beta,\gamma,\delta) &= \prod_{d} P(\boldsymbol{f}_d,\boldsymbol{c}_d;\alpha,\beta,\gamma,\delta) \\ &= \prod_{d}\sum_{\tilde{\boldsymbol{e}}_d} P(\tilde{\boldsymbol{e}}_d|\alpha,\beta)P(\boldsymbol{f}_d|\tilde{\boldsymbol{e}}_d,\gamma)P(\boldsymbol{c}_d|\tilde{\boldsymbol{e}}_d,\delta) \\ &= \int_{\phi} P(\phi|\beta)\int_{\psi} P(\psi|\gamma)\prod_{d}\sum_{\tilde{\boldsymbol{e}}_d} P(\boldsymbol{f}_d|\tilde{\boldsymbol{e}}_d,\psi) \\ &\quad \times \int_{\xi} P(\xi|\delta)\sum_{\tilde{\boldsymbol{e}}'_d} P(\tilde{\boldsymbol{e}}'_d|\tilde{\boldsymbol{e}}_d)p(\boldsymbol{c}_d|\tilde{\boldsymbol{e}}'_d,\xi) \\ &\quad \times \int_{\theta} P(\theta|\alpha)P(\tilde{\boldsymbol{e}}_d|\theta,\phi)d\theta d\xi d\psi d\phi \end{aligned} \tag{1}$$

where $\boldsymbol{f}_d$ and $\tilde{\boldsymbol{e}}_d$ denote the sets of topical words and their target-side topical item assignments in document d, $\boldsymbol{c}_d$ and $\tilde{\boldsymbol{e}}'_d$ are the sets of contextual words and their target-side topical item assignments in document d.

3.2 Parameter Estimation via Gibbs Sampling

The joint distribution in Eq. (1) is intractable to compute because of coupled hyperparameters and hidden variables. Following Han et al, (2012), we adapt the well-known Gibbs sampling algorithm (Griffiths and Steyvers, 2004) to our model. We compute the joint posterior distribution of hidden variables, denoted by $P(\boldsymbol{z},\tilde{\boldsymbol{e}},\tilde{\boldsymbol{e}}'|\boldsymbol{D})$, and then use this distribution to 1) estimate θ, ϕ, ψ and ξ, and 2) predict translations and topics of all documents in $\boldsymbol{D}$.

Specifically, we derive the joint posterior distribution from Eq. (1) as:

$$P(\boldsymbol{z},\tilde{\boldsymbol{e}},\tilde{\boldsymbol{e}}'|\boldsymbol{D}) \propto P(\boldsymbol{z})P(\tilde{\boldsymbol{e}}|\boldsymbol{z})P(\boldsymbol{f}|\tilde{\boldsymbol{e}})P(\tilde{\boldsymbol{e}}'|\tilde{\boldsymbol{e}})P(\boldsymbol{c}|\tilde{\boldsymbol{e}}') \tag{2}$$

Based on the equation above, we construct a Markov chain that converges to $P(\boldsymbol{z},\tilde{\boldsymbol{e}},\tilde{\boldsymbol{e}}'|\boldsymbol{D})$, where each state is an assignment of a hidden variable (including topic assignment to a topical word, target-side topical item assignment to a source topical or contextual word.). Then, we sequentially sample each assignment according to the following three conditional assignment distributions:

1. $P(z_i = z|\boldsymbol{z}_{-i},\tilde{\boldsymbol{e}},\tilde{\boldsymbol{e}}',\boldsymbol{D})$: topic assignment distribution of a topical word given $\boldsymbol{z}_{-i}$ that denotes all topic assignments but z_i, $\tilde{\boldsymbol{e}}$ and $\tilde{\boldsymbol{e}}'$ that are target-side topical item assignments. It is updated as follows:

$$\begin{gathered} P(z_i = z|\boldsymbol{z}_{-i},\tilde{\boldsymbol{e}},\tilde{\boldsymbol{e}}',\boldsymbol{D}) \propto \\ \frac{C^{DZ}_{(-i)dz}+\alpha}{C^{DZ}_{(-i)d*}+N_z\alpha} \times \frac{C^{Z\tilde{E}}_{(-i)z\tilde{e}}+\beta}{C^{Z\tilde{E}}_{(-i)z*}+N_{\tilde{e}}\beta} \end{gathered} \tag{3}$$

where the topic assignment to a topical word is determined by the probability that this topic appears in document d (the 1st term) and the probability that the selected item $\tilde{e}$ occurs in this topic (the 2nd term).

2. $P(\tilde{e}_i = \tilde{e}|\boldsymbol{z},\tilde{\boldsymbol{e}}_{-i},\tilde{\boldsymbol{e}}',\boldsymbol{D})$: target-side topical item assignment distribution of a source topical word given the current topic assignments $\boldsymbol{z}$, the current item assignments of all other topical words $\tilde{\boldsymbol{e}}_{-i}$, and the current item assignments of contextual words $\tilde{\boldsymbol{e}}'$. It is updated as follows:

$$\begin{aligned} P(\tilde{e}_i = \tilde{e}|\boldsymbol{z},\tilde{\boldsymbol{e}}_{-i},\tilde{\boldsymbol{e}}',\boldsymbol{D}) &\propto \frac{C^{Z\tilde{E}}_{(-i)z\tilde{e}}+\beta}{C^{Z\tilde{E}}_{(-i)z*}+N_{\tilde{e}}\beta} \\ \times \frac{C^{\tilde{E}F}_{(-i)\tilde{e}f}+\gamma}{C^{\tilde{E}F}_{(-i)\tilde{e}*}+N_f\gamma} &\times (\frac{C^{W\tilde{E}}_{(-i)w\tilde{e}}+1}{C^{W\tilde{E}}_{(-i)w\tilde{e}}})^{C^{W\tilde{E}'}_{w\tilde{e}}} \end{aligned} \tag{4}$$

where the target-side topical item assignment to a topical word is determined by the probability that this item is from the topic z (the 1st term), the probability that this item is translated into the topical word f (the 2nd term) and the probability of contextual words within a w_s word window centered at the topical word f, which influence the selection of the target-side topical item $\tilde{e}$ (the 3rd term). It is very important to note that we use a parallel corpus to train the model. Therefore we directly identify target-side topical items for source topical words via word alignments rather than sampling.

3. $P(\tilde{e}'_i = \tilde{e} | \boldsymbol{z}, \tilde{\boldsymbol{e}}, \tilde{\boldsymbol{e}}'_{-i}, \boldsymbol{D})$: target-side topical item assignment distribution for a contextual word given the current topic assignments $\boldsymbol{z}$, the current item assignments of topical words $\tilde{\boldsymbol{e}}$, and the current item assignments of all other contextual words $\tilde{\boldsymbol{e}}'_{-i}$. It is updated as follows:

$$P(\tilde{e}'_i = \tilde{e} | \boldsymbol{z}, \tilde{\boldsymbol{e}}, \tilde{\boldsymbol{e}}'_{-i}, \boldsymbol{D}) \propto \frac{C^{W\tilde{E}}_{w\tilde{e}}}{C^{W\tilde{E}}_{w*}} \times \frac{C^{\tilde{E}C}_{(-i)\tilde{e}c} + \delta}{C^{\tilde{E}C}_{(-i)\tilde{e}*} + N_c\,\delta} \tag{5}$$

where the target-side topical item assignment used to generate a contextual word is determined by the probability of this item being assigned to generate contextual words within a surface window of size w_s (the 1st term) and the probability that contextual words occur in the context of this item (the 2nd term).

In all above formulas, C^{DZ}_{dz} is the number of times that topic z has been assigned for all topical words in document d, C^{DZ}_{d*}=$\sum_z C^{DZ}_{dz}$ is the topic number in document d, and $C^{Z\tilde{E}}_{z\tilde{e}}$, $C^{\tilde{E}F}_{\tilde{e}f}$, $C^{W\tilde{E}}_{w\tilde{e}}$, $C^{W\tilde{E}'}_{w\tilde{e}}$ and $C^{\tilde{E}C}_{\tilde{e}c}$ have similar explanations. Based on the above marginal distributions, we iteratively update all assignments of corpus $\boldsymbol{D}$ until the constructed Markov chain converges. Model parameters are estimated using these final assignments.

3.3 Inference on Unseen Documents

For a new document, we first predict its topics and target-side topical items using the incremental Gibbs sampling algorithm described in (Kataria et al., 2011). In this algorithm, we iteratively update topic assignments and translation assignments of an unseen document following the same process described in Section 3.2, but with estimated model parameters.

Once we obtain these assignments, we estimate lexical translation probabilities based on the sampled counts of target-side topical items. Formally, for the position i in the document corresponding to the content word f, we collect the sampled count that translation $\tilde{e}$ generates f, denoted by $C_{sam}(\tilde{e}, f)$. This count can be normalized to form a new translation probability in the following way:

$$p(\tilde{e}|f) = \frac{C_{sam}(\tilde{e}, f) + k}{C_{sam} + k \cdot N_{\tilde{e},f}} \tag{6}$$

where C_{sam} is the total number of samples during inference and $N_{\tilde{e},f}$ is the number of candidate translations of f. Here we apply *add-k* smoothing to refine this translation probability, where k is a tunable global smoothing constant. Under the framework of log-linear model (Och and Ney, 2002), we use this translation probability as a new feature to improve lexical selection in SMT.

4 Experiments

In order to examine the effectiveness of our model, we carried out several groups of experiments on Chinese-to-English translation.

4.1 Setup

Our bilingual training corpus is from the FBIS corpus and the Hansards part of LDC2004T07 corpus ($1M$ parallel sentences, $54.6K$ documents, with $25.2M$ Chinese words and $29M$ English words). We first used *ZPar* toolkit[2] and Stanford toolkit[3] to preprocess (i.e., word segmenting, PoS tagging) the Chinese and English parts of training corpus, and then word-aligned them using *GIZA++* (Och and Ney, 2003) with the option "*grow-diag-final-and*". We chose the NIST evaluation set of MT05 as the development set, and the sets of MT06/MT08 as test sets. On average, these three sets contain 17.2, 13.9 and 14.1 content words per sentence, respectively. We trained a 5-gram language model on the Xinhua portion of Gigaword corpus using the *SRILM* Toolkit (Stolcke, 2002).

Our baseline system is a state-of-the-art SMT system, which adapts bracketing transduction grammars (Wu, 1997) to phrasal translation and equips itself with a maximum entropy based reordering model (MEBTG) (Xiong et al., 2006). We used the toolkit[4] developed by Zhang (2004) to train the reordering model with the following parameters: iteration number $iter$=200 and Gaussian prior g=1.0. During decoding, we set the *ttable-limit* as 20, the *stack-size* as 100. The translation quality is evaluated by case-insensitive BLEU-4 (Papineni et al., 2002) metric. Finally, we conducted *paired bootstrap sampling* (Koehn, 2004) to test the significance in BLEU score differences.

Model	**MT05**
CATM (± 6w)	33.35
CATM (± 8w)	33.43
CATM (± 10w)	33.42
CATM (± 12w)	33.49
CATM (± 14w)	33.30

Table 2: Experiment results on the development set using different window sizes w_s.

To train CATM, we set the topic number N_z as 25.[5] For hyperparameters α and β, we empirically set α=$50/N_z$ and β=0.1, as implemented in (Griffiths and Steyvers, 2004). Following Han et al. (2012), we set γ and δ as $1.0/N_f$ and $2000/N_c$, respectively. During the training process, we ran 400 iterations of the Gibbs sampling algorithm. For documents to be translated, we first ran 300 rounds in a *burn-in* step to let the probability distributions converge, and then ran 1500 rounds where we collected independent samples every 5 rounds. The longest training time of CATM is less than four days on our server using 4GB RAM and one core of 3.2GHz CPU. As for the smoothing constant k in Eq. (6), we set its values to 0.5 according to the performance on the development set in additional experiments.

4.2 Impact of Window Size w_s

Our first group of experiments were conducted on the development set to investigate the impact of the window size w_s. We gradually varied window size from 6 to 14 with an increment of 2.

Experiment results are shown in Table 2. We achieve the best performance when w_s=12. This suggests that a $\pm$12-word window context is sufficient for predicting target-side translations for ambiguous source-side topical words. We therefore set w_s=12 for all experiments thereafter.

4.3 Overall Performance

In the second group of experiments, in addition to the conventional MEBTG system, we also compared CATM with the following two models:

Word Sense Disambiguation Model (**WSDM**) (Chan et al., 2007). This model improves lexical selection in SMT by exploiting local contexts. For each content word, we construct a MaxEnt-based classifier incorporating local collocation and surrounding word features, which are also adopted by Chan et al. (2007). For each candidate translation $\tilde{e}$ of topical word f, we use WSDM to estimate the context-specific translation probability $P(\tilde{e}|f)$, which is used as a new feature in SMT system.

Topic-specific Lexicon Translation Model (**TLTM**) (Zhao and Xing, 2007). This model focuses on the utilization of document-level context. We adapted it to estimate a lexicon translation probability as follows:

$$\begin{aligned} p(f|\tilde{e},d) &\propto p(\tilde{e}|f,d)\cdot p(f|d) \\ &= \sum_z p(\tilde{e}|f,z)\cdot p(f|z)\cdot p(z|d) \end{aligned} \quad (7)$$

where $p(\tilde{e}|f,z)$ is the lexical translation probability conditioned on topic z, which can be calculated according to the principle of maximal likelihood, $p(f|z)$ is the generation probability of word f from topic z, and $p(z|d)$ denotes the posterior topic distribution of document d.

Note that our CATM is proposed for lexical selection on content words. To show the strong effectiveness of our model, we also compared it against the full-fledged variants of the above-mentioned two models that are built for all source words. We refer to them as **WSDM (All)** and **TLTM (All)**, respectively.

Table 3 displays BLEU scores of different lexical selection models. All models outperform the baseline. Although we only use CATM to predict translations for content words, CATM achieves an average BLEU score of **26.77** on the two test sets, which is higher than that of the baseline by **1.18** BLEU points. This improvement is statistically significant at p<0.01. Furthermore, we also find that our model performs better than WSDM and TLTM with significant improvements. Finally, even if WSDM (All) and TLTM (all) are built for all source words, they are still no better than than CATM that selects desirable translations for content words. These experiment results strongly demonstrate the advantage of CATM over previous lexical selection models.

5 Analysis

In order to investigate why CATM is able to outperform previous models that explore only local contex-

[5] We try different topic numbers from 25 to 100 with an increment of 25 each time. We find that N_z=25 produces a slightly better performance than other values on the development set.

Model	Local Context	Global Topic	MT06	MT08	Avg
Baseline	×	×	$29.66^{\downarrow\downarrow}$	$21.52^{\downarrow\downarrow}$	25.59
WSDM	√	×	$30.62^{\downarrow}$	$22.05^{\downarrow\downarrow}$	26.34
WSDM (All)	√	×	30.92	22.27	26.60
TLTM	×	√	$30.27^{\downarrow\downarrow}$	$21.70^{\downarrow\downarrow}$	25.99
TLTM (All)	×	√	$30.33^{\downarrow\downarrow}$	$21.58^{\downarrow\downarrow}$	25.96
CATM	√	√	**30.97**	**22.56**	**26.77**

Table 3: Experiment results on the test sets. **Avg** = average BLEU scores. **WSDM (All)** and **TLTM (All)** are models built for all source words. ↓: significantly worse than CATM (p<0.05), ↓↓: significantly worse than CATM (p<0.01)
.

tual words or global topics, we take a deep look into topics, topical items and contextual words learned by CATM and empirically analyze the effect of modeling correlations between local contextual words and global topics on lexical selection.

5.1 Outputs of CATM

We present some examples of topics learned by CATM in Table 4. We also list five target-side topical items with the highest probabilities for each topic, and the most probable five contextual words for each target-side topical item. These examples clearly show that target-side topical items tightly connect global topics and local contextual words by capturing their correlations.

5.2 Effect of Correlation Modeling

Compared to previous lexical selection models, CATM jointly models both local contextual words and global topics. Such a joint modeling also enables CATM to capture their inner correlations at the model level. In order to examine the effect of correlation modeling on lexical selection, we compared CATM with its three variants: ① **CATM (Context)** that only uses local context information. We determined target-side topical items for content words in this variant by setting the probability distribution that a topic generates a target-side topical item to be uniform; ② **CATM (Topic)** that explores only global topic information. We identified target-side topical items for content words in the model by setting w_s as 0, i.e., no local contextual words being used at all. ③ **CATM (Log-linear)** is the combination of the above-mentioned two variants (① and ②) in a log-linear manner, which does not capture correlations between local contextual words and global topics at the model level.

Model	MT06	MT08	Avg
CATM (Context)	$30.46^{\downarrow\downarrow}$	$22.02^{\downarrow\downarrow}$	26.24
CATM (Topic)	$30.20^{\downarrow\downarrow}$	$21.90^{\downarrow\downarrow}$	26.05
CATM (Log-linear)	$30.59^{\downarrow}$	$22.24^{\downarrow}$	26.42
CATM	**30.97**	**22.56**	**26.77**

Table 5: Experiment results on the test sets. CATM (Log-linear) is the combination of CATM (Context) and CATM (Topic) in a log-linear manner.

Results in Table 5 show that CATM performs significantlly better than both CATM (Topic) and CATM (Context). Even compared with CATM (Log-linear), CATM still achieves a significant improvement of 0.35 BLEU points (p<0.05). This validates the effectiveness of capturing correlations for lexical selection at the model level.

6 Related Work

Our work is partially inspired by (Han and Sun, 2012), where an entity-topic model is presented for entity linking. We successfully adapt this work to lexical selection in SMT. The related work mainly includes the following two strands.

(1) *Lexical Selection in SMT*. In order to explore rich context information for lexical selection, some researchers propose *trigger-based lexicon models* to capture long-distance dependencies (Hasan et al., 2008; Mauser et al., 2009), and many more researchers build classifiers to select desirable translations during decoding (Chan et al., 2007; Carpuat and Wu, 2007; He et al., 2008; Liu et al., 2008). Along this line, Shen et al. (2009) introduce four new linguistic and contextual features for translation selection in SMT. Recently, we have witnessed an increasing efforts in exploiting document-level context information to improve lexical selection. Xiao et al. (2011) impose a hard constraint to guarantee

Table 4: Examples of topics, topical items and contextual words learned by CATM with N_z=25 and W_s=12. Chinese words that do not have direct English translations are denoted with ”*”. Here “枚” and “场” are Chinese quantifiers for *missile* and *war*, respectively; “两” and “岸” together means *cross-starit*.

the document-level translation consistency. Ture et al. (2012) soften this consistency constraint by integrating three counting features into decoder. Also relevant is the work of Xiong et al.(2013), who use three different models to capture lexical cohesion for document-level SMT.

(2) *SMT with Topic Models*. In this strand, Zhao and Xing (2006, 2007) first present a bilingual topical admixture formalism for word alignment in SMT. Tam et al. (2007) and Ruiz et al. (2012) apply topic model into language model adaptation. Su et al. (2012) conduct translation model adaptation with monolingual topic information. Gong et al. (2010) and Xiao et al. (2012) introduce topic-based similarity models to improve SMT system. Axelrod et al. (2012) build topic-specific translation models from the TED corpus and select topic-relevant data from the UN corpus to improve coverage. Eidelman et al. (2012) incorporate topic-specific lexical weights into translation model. Hewavitharana et al. (2013) propose an incremental topic based translation model adaptation approach that satisfies the causality constraint imposed by spoken conversations. Hasler et al. (2014) present a new bilingual variant of LDA to compute topic-adapted, probabilistic phrase translation features. They also use a topic model to learn latent distributional representations of different context levels of a phrase pair (Hasler et al., 2014b).

In the studies mentioned above, those by Zhao and Xing (2006), Zhao and Xing (2007), Hasler et al. (2014a), and Hasler et al. (2014b) are most related to our work. However, they all perform dynamic translation model adaptation with topic models. Significantly different from them, we propose a new topic model that exploits both local contextual words and global topics for lexical selection. To the best of our knowledge, this is first attempt to capture correlations between local words and global topics for better lexical selection at the model level.

7 Conclusion and Future Work

This paper has presented a novel context-aware topic model for lexical selection in SMT. Jointly modeling local contexts, global topics and their correlations in a unified framework, our model provides an effective way to capture context information at different levels for better lexical selection in SMT. Experiment results not only demonstrate the effectiveness of the proposed topic model, but also show that lexical selection benefits from correlation modeling.

In the future, we want to extend our model from the word level to the phrase level. We also plan to improve our model with monolingual corpora.

Abstract

Understanding open-domain text is one of the primary challenges in NLP. Machine comprehension evaluates the system's ability to understand text through a series of question-answering tasks on short pieces of text such that the correct answer can be found only in the given text. For this task, we posit that there is a hidden (latent) structure that explains the relation between the question, correct answer, and text. We call this the *answer-entailing structure*; given the structure, the correctness of the answer is evident. Since the structure is latent, it must be inferred. We present a unified max-margin framework that learns to find these hidden structures (given a corpus of question-answer pairs), and uses what it learns to answer machine comprehension questions on novel texts. We extend this framework to incorporate multi-task learning on the different subtasks that are required to perform machine comprehension. Evaluation on a publicly available dataset shows that our framework outperforms various IR and neural-network baselines, achieving an overall accuracy of 67.8% (vs. 59.9%, the best previously-published result.)

1 Introduction

Developing an ability to understand natural language is a long-standing goal in NLP and holds the promise of revolutionizing the way in which people interact with machines and retrieve information (e.g., for scientific endeavor). To evaluate this ability, Richardson et al. (2013) proposed the task of machine comprehension (MCTest), along with a dataset for evaluation. Machine comprehension evaluates a machine's understanding by posing a series of reading comprehension questions and associated texts, where the answer to each question can be found only in its associated text. Solutions typically focus on some semantic interpretation of the text, possibly with some form of probabilistic or logical inference, in order to answer the questions. Despite significant recent interest (Burges, 2013; Weston et al., 2014; Weston et al., 2015), the problem remains unsolved.

In this paper, we propose an approach for machine comprehension. Our approach learns latent *answer-entailing structures* that can help us answer questions about a text. The answer-entailing structures in our model are closely related to the inference procedure often used in various models for MT (Blunsom and Cohn, 2006), RTE (MacCartney et al., 2008), paraphrase (Yao et al., 2013b), QA (Yih et al., 2013), etc. and correspond to the best (latent) alignment between a hypothesis (formed from the question and a candidate answer) with appropriate snippets in the text that are required to answer the question. An example of such an answer-entailing structure is given in Figure 1. The key difference between the answer-entailing structures considered here and the alignment structures considered in previous works is that we can align multiple sentences in the text to the hypothesis. The sentences in the text considered for alignment are not restricted to occur contiguously in the text. To allow such a discontiguous alignment, we make use of the document structure; in particular, we take help from rhetorical structure theory (Mann and Thompson, 1988) and event and entity coreference links across sentences. Modelling the inference procedure via answer-entailing structures is a crude yet effective and computationally inexpensive proxy to model the semantics needed for the problem. Learning these latent structures can also be bene-

elaboration
Text: … The restaurant had a special on catfish … Alyssa enjoyed the restaurant's special …
Hypothesis: Alyssa ate Catfish at the restaurant.
(Question: What did Alyssa eat at the restaurant? Answer Candidate: Catfish)

Figure 1: The *answer-entailing structure* for an example from MCTest500 dataset. The question and answer candidate are combined to generate a hypothesis sentence. Then latent alignments are found between the hypothesis and the appropriate snippets in the text. The solid red lines show the word alignments from the hypothesis words to the passage words, the dashed black lines show auxiliary co-reference links in the text and the labelled dotted black arrows show the RST relation (elaboration) between the two sentences. Note that the two sentences do not have to be contiguous sentences in the text. We provide some more examples of *answer-entailing structures* in the supplementary.

ficial as they can assist a human in verifying the correctness of the answer, eliminating the need to read a lengthy document.

The overall model is trained in a max-margin fashion using a latent structural SVM (LSSVM) where the answer-entailing structures are latent. We also extend our LSSVM to multi-task settings using a top-level question-type classification. Many QA systems include a question classification component (Li and Roth, 2002; Zhang and Lee, 2003), which typically divides the questions into semantic categories based on the type of the question or answers expected. This helps the system impose some constraints on the plausible answers. Machine comprehension can benefit from such a pre-classification step, not only to constrain plausible answers, but also to allow the system to use different processing strategies for each category. Recently, Weston et al. (2015) defined a set of 20 sub-tasks in the machine comprehension setting, each referring to a specific aspect of language understanding and reasoning required to build a machine comprehension system. They include fact chaining, negation, temporal and spatial reasoning, simple induction, deduction and many more. We use this set to learn to classify questions into the various machine comprehension subtasks, and show that this task classification further improves our performance on MCTest. By using the multi-task setting, our learner is able to exploit the commonality among tasks where possible, while having the flexibility to learn task-specific parameters where needed. To the best of our knowledge, this is the first use of multi-task learning in a structured prediction model for QA.

We provide experimental validation for our model on a real-world dataset (Richardson et al., 2013) and achieve superior performance vs. a number of IR and neural network baselines.

2 The Problem

Machine comprehension requires us to answer questions based on unstructured text. We treat this as selecting the best answer from a set of candidate answers. The candidate answers may be pre-defined, as is the case in multiple-choice question answering, or may be undefined but restricted (e.g., to yes, no, or any noun phrase in the text).

Machine Comprehension as Textual Entailment: Let for each question $q_i \in Q$, $\mathbf{t}_i$ be the unstructured text and $A_i = \{a_{i1}, \ldots, a_{im}\}$ be the set of candidate answers to the question. We cast the machine comprehension task as a textual entailment task by converting each question-answer candidate pair $(q_i, a_{i,j})$ into a hypothesis statement h_{ij}. For example, the question "What did Alyssa eat at the restaurant?" and answer candidate "Catfish" in Figure 1 can be combined to achieve a hypothesis "Alyssa ate Catfish at the restaurant". We use the question matching/rewriting rules described in Cucerzan and Agichtein (2005) to achieve this transformation. For each question q_i, the machine comprehension task reduces to picking the hypothesis $\hat{h}_i$ that has the highest likelihood of being entailed by the text among the set of hypotheses $\mathbf{h}_i = \{h_{i1}, \ldots, h_{im}\}$ generated for that question. Let $h_i^* \in \mathbf{h}_i$ be the correct hypothesis. Now let us define the latent answer-entailing structures.

3 Latent Answer-Entailing Structures

The latent answer-entailing structures help the model in providing evidence for the correct hypothesis. We consider the quality of a one-to-one word alignment from a hypothesis to snippets in the text as a proxy for the evidence. Hypothesis words are aligned to a unique text word in the text or an empty word. For example, in Figure 1, all words but "at" are aligned to a word in the text. The word "at" can be assumed to be aligned to an empty word and it has no effect on the model. Learning these alignment edges typically helps a model decompose the input and output structures into semantic constituents and determine which constituents should be compared to each other. These alignments can then be used to generate more effective features.

The alignment depends on two things: (a) snippets in the text to be aligned to the hypothesis and (b) word alignment from the hypothesis to the snippets. We explore three variants of the snippets in the text to be aligned to the hypothesis. The choice of these snippets composed with the word alignment is the resulting hidden structure called an answer-entailing structure.

1. Sentence Alignment: The simplest variant is to find a single sentence in the text that best aligns to the hypothesis. This is the structure considered in a majority of previous works in RTE (MacCartney et al., 2008) and QA (Yih et al., 2013) as they only reason on single sentence length texts.

2. Subset Alignment: Here we find a subset of sentences from the text (instead of just one sentence) that best aligns with the hypothesis.

3. Subset+ Alignment: This is the same as above except that the best subset is an ordered set.

4 Method

A natural solution is to treat MCTest as a structured prediction problem of ranking the hypotheses $\mathbf{h}_i$ such that the correct hypothesis is at the top of this ranking. This induces a constraint on the ranking structure that the correct hypothesis is ranked above the other competing hypotheses. For each text $\mathbf{t}_i$ and hypotheses set $\mathbf{h}_i$, let $\mathcal{Y}_i$ be the set of possible orderings of the hypotheses. Let $\mathbf{y}_i^* \in \mathcal{Y}_i$ be a correct ranking (such that the correct hypothesis is at the top of this ranking). Let the set of possible answer-entailing structures for each text hypothesis pair $(\mathbf{t}_i, \mathbf{h}_i)$ be denoted by $\mathcal{Z}_i$. For each text $\mathbf{t}_i$, with hypotheses set $\mathbf{h}_i$, an ordering of the hypotheses $\mathbf{y} \in \mathcal{Y}_i$, and hidden structure $\mathbf{z} \in \mathcal{Z}_i.$ we define a scoring function $Score_{\mathbf{w}}(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})$ parameterized by a weight vector $\mathbf{w}$ such that we have the prediction rule: $(\widehat{\mathbf{y}}_i, \widehat{\mathbf{z}}_i) = \arg\max_{\mathbf{y}\in\mathcal{Y}_i, \mathbf{z}\in\mathcal{Z}_i} Score_{\mathbf{w}}(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})$. The learning task is to find $\mathbf{w}$ such that the predicted ordering $\widehat{\mathbf{y}}_i$ is close to the optimal ordering $\mathbf{y}_i^*$. Mathematically this can be written as $\min_{\mathbf{w}} \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_i \Delta(\mathbf{y}_i^*, \mathbf{z}_i^*, \widehat{\mathbf{y}}_i, \widehat{\mathbf{z}}_i)$ where $\mathbf{z}_i^* = \arg\max_{\mathbf{z}\in\mathcal{Z}_i} Score_{\mathbf{w}}(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}_i^*)$ and Δ is the loss function between the predicted and the actual ranking and latent structure. We simplify the loss function and assume it to be independent of the hidden structure $(\Delta(\mathbf{y}_i^*, \mathbf{z}_i^*, \widehat{\mathbf{y}}_i, \widehat{\mathbf{z}}_i) = \Delta(\mathbf{y}_i^*, \widehat{\mathbf{y}}_i))$ and use a linear scoring function: $Score_{\mathbf{w}}(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) = \mathbf{w}^T\phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})$ where ϕ is a feature map dependent on the text $\mathbf{t}_i$, the hypothesis set $\mathbf{h}_i$, an ordering of answers $\mathbf{y}$ and a hidden structure $\mathbf{z}$. We use a convex upper bound of the loss function (Yu and Joachims, 2009) to rewrite the objective:

$$\min_{\mathbf{w}} \frac{1}{2}\|\mathbf{w}\|^2 - C\sum_i \mathbf{w}^T\phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}_i^*, \mathbf{y}_i^*) \quad (1)$$

$$+C\sum_{i=1}^{n} \max_{\mathbf{y}\in\mathcal{Y}_i, \mathbf{z}\in\mathcal{Z}_i} \{\mathbf{w}^T\phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) + \Delta(\mathbf{y}_i^*, \mathbf{y})\}$$

This problem can be solved using Concave-Convex Programming (Yuille and Rangarajan, 2003) with the cutting plane algorithm for structural SVM (Finley and Joachims, 2008). We use phi partial order (Joachims, 2006; Dubey et al., 2009) which has been used in previous structural ranking literature to incorporate ranking structure in the feature vector ϕ:

$$\phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) = \sum_{j:h_{ij}\neq h_i^*} c_j(\mathbf{y})(\psi(\mathbf{t}_i, h_i^*, z_i^*) - \psi(\mathbf{t}_i, h_{ij}, z_j)) \quad (2)$$

where, $c_j(\mathbf{y}) = 1$ if h_i^* is above $\mathbf{h}_{ij}$ in the ranking $\mathbf{y}$ else -1. We use pair preference (Chakrabarti et al., 2008) as the ranking loss $\Delta(\mathbf{y}_i^*, \mathbf{y})$. Here, ψ is the feature vector defined for a text, hypothesis and answer-entailing structure.

Solution: We substitute the feature map definition (2) into Equation 1, leading to our LSSVM formulation. We consider the optimization as an alternating minimization problem where we alternate between getting the best z_{ij} and ψ for each text-hypothesis pair given $\mathbf{w}$ (inference) and then solving for the weights $\mathbf{w}$ given ψ to obtain an optimal ordering of the hypothesis (learning). The step for solving for the weights is similar to rankSVM

(Joachims, 2002). Algorithm 1 describes our overall procedure Here, we use beam search for inferring the latent structure z_{ij} in step 3. Also, note that in step 3, when the answer-entailing structures are "Subset" or "Subset+", we can always get a higher score by considering a larger subset of sentences. To discourage this, we add a penalty on the score proportional to the size of the subset.

Algorithm 1 Alternate Minimization for LSSVM

```
1: Initialize $\mathbf{w}$
2: repeat
3:     $z_{ij} = \arg\max_z \mathbf{w}^T \psi(\mathbf{t}_i, h_{ij}, z)\ \forall i, j$
4:     Compute $\psi$ for each $i, j$
5:     $\mathcal{C}_i = \emptyset\ \forall i$
6:     repeat
7:         for $i = 1, \ldots, n$ do
8:             $r(\mathbf{y}) = \mathbf{w}^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) + \Delta(\mathbf{y}_i^*, \mathbf{y}) - \mathbf{w}^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}_i^*, \mathbf{y}_i^*)$
9:             $\widehat{\mathbf{y}}_i = \arg\max_{\mathbf{y} \in \mathcal{Y}_i} r(\mathbf{y})$
10:            $\xi_i = \max\{0, \max_{\mathbf{y} \in \mathcal{U}_i} r(\mathbf{y})\}$
11:            if $r(\widehat{\mathbf{y}}_i) > \xi_i + \epsilon$ then
12:                $\mathcal{C}_i = \mathcal{C}_i \cup \widehat{\mathbf{y}}_i$

               $Solve: \quad \min_{\mathbf{w}, \xi} \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_i \xi_i$
               $\forall i, \forall \mathbf{y} \in \mathcal{C}_i : \mathbf{w}^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}_i^*, \mathbf{y}_i^*)$
               $\geq \mathbf{w}^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) + \Delta(\mathbf{y}_i^*, \mathbf{y}) - \xi_i$

13:    until no change in any $\mathcal{C}_i$
14: until Convergence
```

Multi-task Latent Structured Learning: Machine comprehension is a complex task which often requires us to interpret questions, the kind of answers they seek as well as the kinds of inference required to solve them. Many approaches in QA (Moldovan et al., 2003; Ferrucci, 2012) solve this by having a top-level classifier that categorizes the complex task into a variety of sub-tasks. The subtasks can correspond to various categories of questions that can be asked or various facets of text understanding that are required to do well at machine comprehension in its entirety.It is well known that learning a sub-task together with other related subtasks leads to a better solution for each sub-task. Hence, we consider learning classifications of the sub-tasks and then using multi-task learning.

We extend our LSSVM to multi-task settings. Let S be the number of sub-tasks. We assume that the predictor $\mathbf{w}$ for each subtask s is partitioned into two parts: a parameter $\mathbf{w}_0$ that is globally shared across each subtasks and a parameter $\mathbf{v}_s$ that is locally used to provide for the variations within the particular subtask: $\mathbf{w} = \mathbf{w}_0 + \mathbf{v}_s$. Mathematically we define the scoring function for text $\mathbf{t}_i$, hypothesis set $\mathbf{h}_i$ of the subtask s to be $Score_{\mathbf{w}_0, \mathbf{v}, s}(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) = (\mathbf{w}_0 + \mathbf{v}_s)^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})$. The objective in this case is

$$\min_{\mathbf{w}_0, \mathbf{v}} \lambda_2 \|\mathbf{w}_0\|^2 + \frac{\lambda_1}{S} \sum_{s=1}^{S} \|\mathbf{v}_s\|^2 \tag{3}$$
$$\sum_{s=1}^{S} \sum_{i=1}^{n} \max_{\mathbf{y} \in \mathcal{Y}_i, \mathbf{z} \in \mathcal{Z}_i} \{(\mathbf{w}_0 + \mathbf{v}_s)^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})$$
$$+ \Delta(\mathbf{y}_i^*, \mathbf{y})\} - C \sum_i (\mathbf{w}_0 + \mathbf{v}_s)^T \phi(\mathbf{t}, \mathbf{h}_i, \mathbf{z}_i^*, \mathbf{y}_i^*)$$

Now, we extend a trick that Evgeniou and Pontil (2004) used on linear SVM to reformulate this problem into an objective that looks like (1). Such reformulation will help in using algorithm 1 to solve the multi-task problem as well. Lets define a new feature map Φ_s, one for each sub-task s using the old feature map ϕ as:

$$\Phi_s(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) = (\frac{\phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})}{\mu}, \underbrace{\mathbf{0}, \ldots, \mathbf{0}}_{s-1},$$
$$\phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}), \underbrace{\mathbf{0}, \ldots, \mathbf{0}}_{S-s})$$

where $\mu = \frac{S\lambda_2}{\lambda_1}$ and the $\mathbf{0}$ denotes the zero vector of the same size as ϕ. Also define our new predictor as $\mathbf{w} = (\sqrt{\mu}\mathbf{w}_0, \mathbf{v}_1, \ldots, \mathbf{v}_S)$. Using this formulation we can show that $\mathbf{w}^T \Phi_s(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y}) = (\mathbf{w}_0 + \mathbf{v}_s)^T \phi(\mathbf{t}_i, \mathbf{h}_i, \mathbf{z}, \mathbf{y})$ and $\|\mathbf{w}\|^2 = \sum_s \|\mathbf{v}_s\|^2 + \mu \|\mathbf{w}_0\|^2$. Hence, if we now define the objective (1) but use the new feature map and $\mathbf{w}$ then we will get back our multi-task objective (3). Thus we can use the same setup as before for multi-task learning after appropriately changing the feature map. We will explore a few definitions of sub-tasks in our experiments.

Features: Recall that our features had the form $\psi(\mathbf{t}, h, z)$ where the hypothesis h was itself formed from a question q and answer candidate a. Given an answer-entailing structure z, we induce the following features based on word level similarity of aligned words: (a) Limited word-level surface-form matching and (b) Semantic word form matching: Word similarity for synonymy using SENNA word vectors (Collobert et al., 2011), "Antonymy" 'Class-Inclusion' or 'Is-A' relations using Wordnet (Fellbaum, 1998). We compute additional features of the aforementioned kinds to match named entities and events. We also add features for matching local neighborhood in the aligned structure: features for matching bigrams, trigrams, dependencies, semantic roles, predicate-argument structure as well as features for matching global structure: a tree kernel for matching syntactic representations of entire sentences using Srivastava and Hovy (2013). The local and global features can use the RST and coreference links enabling inference across sentences. For instance, in the example shown in figure 1, the coreference link connecting the two "restaurant" words brings the snippets "Alyssa enjoyed the" and "had a special on catfish" closer making these features more effective. The answer-entailing structures should be intuitively similar to the question but also the answer. Hence, we add features that are the product of features for the text-question match and text-answer match.

String edit Features: In addition to looking for features on exact word/phrase match, we also add features using two paraphrase databases ParaPara (Chan et al., 2011) and DIRT (Lin and Pantel, 2001). The ParaPara database contains strings of the form $\text{string}_1 \rightarrow \text{string}_2$ like "total lack of" → "lack of", "is one of" → "among", etc. Similarly, the DIRT database contains paraphrases of the form "If **X** decreases **Y** then **X** reduces **Y**", "If **X** causes **Y** then **X** affects **Y**", etc. Whenever we have a substring in the text can be transformed into another using these two databases, we keep match features for the substring with a higher score (according to $\mathbf{w}$) and ignore the other substring.

The sentences with discourse relations are related to each other by means of substitution, ellipsis, conjunction and lexical cohesion, etc (Mann and Thompson, 1988) and can help us answer certain kinds of questions (Jansen et al., 2014). As an example, the "cause" relation between sentences in the text can often give cues that can help us answer "why" or "how" questions. Hence, we add additional features - conjunction of the RST label and the question word - to our feature vector. Similarly, the entity and event co-reference relations can allows the system to reason about repeating entities or events through all the sentences they get mentioned in. Thus, we add additional features of the aforementioned types by replacing entity mentions with their first mentions.

Subset+ Features: We add an additional set of features which match the first sentence in the ordered set to the question and the last sentence in the ordered set to the answer. This helps in the case when a certain portion of the text is targeted by the question but then it must be used in combination with another sentence to answer the question. For instance, in Figure 1, sentence 2 mentions the target of the question but the answer can only be given when in combination with sentence 1.

Negation We empirically found that one key limitation in our formulation is its inability to handle negation (both in questions and text). Negation is especially hurtful to our model as it not only results in poor performance on questions that require us to reason with negated facts, it provides our model with a wrong signal (facts usually align well with their negated versions). We use a simple heuristic to overcome the negation problem. We detect negation (either in the hypothesis or a sentence in the text snippet aligned to it) using a small set of manually defined rules that test for presence of words such as "not", "n't", etc. Then, we flip the partial order - i.e. the correct hypothesis is now ranked below the other competing hypotheses. For inference at test time, we also invert the prediction rule i.e. we predict the hypothesis (answer) that has the least score under the model.

5 Experiments

Datasets: We use two datasets for our evaluation. **(1)** First is the MCTest-500 dataset [1], a freely available set of 500 stories (split into 300 train, 50 dev and 150 test) and associated questions (Richardson et al., 2013). The stories are fictional so the answers can be found only in the story itself. The stories and questions are carefully limited, thereby minimizing the world knowledge required for this task. Yet, the task is challenging for most modern NLP systems. Each story in MCTest has four multiple choice questions, each with four answer choices. Each question has only one correct answer. Furthermore, questions are also annotated with 'single' and 'multiple' labels. The questions annotated 'single' only require one sentence in the story to answer them. For 'multiple' questions it should not be possible to find the answer to the question in any individual sentence of the passage. In a sense, the 'multiple' questions are

[1] http://research.microsoft.com/mct

harder than the 'single' questions as they typically require complex lexical analysis, some inference and some form of limited reasoning. Cucerzan-converted questions can also be downloaded from the MCTest website.

(2) The second dataset is a synthetic dataset released under the *bAbI project*[2] (Weston et al., 2015). The dataset presents a set of 20 'tasks', each testing a different aspect of text understanding and reasoning in the QA setting, and hence can be used to test and compare capabilities of learning models in a fine-grained manner. For each 'task', 1000 questions are used for training and 1000 for testing. The 'tasks' refer to question categories such as questions requiring reasoning over single/two/three supporting facts or two/three arg. relations, yes/no questions, counting questions, etc. Candidate answers are not provided but the answers are typically constrained to a small set: either yes or no or entities already appearing in the text, etc. We write simple rules to convert the question and answer candidate pairs to hypotheses. [3]

Baselines: We have five baselines. (1) The first three baselines are inspired from Richardson et al. (2013). The first baseline (called *SW*) uses a sliding window and matches a bag of words constructed from the question and hypothesized answer to the text. (2) Since this ignores long range dependencies, the second baseline (called *SW+D*) accounts for intra-word distances as well. As far as we know, *SW+D* is the best previously published result on this task.[4] (3) The third baseline (called *RTE*) uses textual entailment to answer MCTest questions. For this baseline, MCTest is again re-casted as an RTE task by converting each question-answer pair into a statement (using Cucerzan and Agichtein (2005)) and then selecting the answer whose statement has the highest likelihood of being entailed by the story. [5] (4) The fourth baseline (called *LSTM*) is taken from Weston et al. (2015). The baseline uses LSTMs (Hochreiter and Schmidhuber, 1997) to accomplish the task. LSTMs have recently achieved state-of-the-art results in a variety of tasks due to their ability to model long-term context information as opposed to other neural networks based techniques. (5) The fifth baseline (called *QANTA*)[6] is taken from Iyyer et al. (2014). *QANTA* too uses a recursive neural network for question answering.

Task Classification for MultiTask Learning: We consider three alternative task classifications for our experiments. First, we look at question classification. We use a simple question classification based on the question word (what, why, what, etc.). We call this QClassification. Next, we also use a question/answer classification[7] from Li and Roth (2002). This classifies questions into different semantic classes based on the possible semantic types of the answers sought. We call this QAClassification. Finally, we also learn a classifier for the 20 tasks in the Machine Comprehension gamut described in Weston et al. (2015). The classification algorithm (called TaskClassification) was built on the *bAbI* training set. It is essentially a Naive-Bayes classifier and uses only simple unigram and bigram features for the question and answer. The tasks typically correspond to different strategies when looking for an answer in the machine comprehension setting. In our experiments we will see that learning these strategies is better than learning the question answer classification which is in turn better than learning the question classification.

Results: We compare multiple variants of our LSSVM[8] where we consider a variety of answer-entailing structures and our modification for negation and multi-task LSSVM, where we consider three kinds of task classification strategies against the baselines on the *MCTest* dataset. We consider two evaluation metrics: accuracy (proportion of questions correctly answered) and NDCG$_4$

[2] https://research.facebook.com/researchers/1543934539189348

[3] Note that the *bAbI* dataset is artificial and not meant for open-domain machine comprehension. It is a toy dataset generated from a simulated world. Due to its restrictive nature, we do not use it directly in evaluating our method vs. other open-domain machine comprehension methods. However, it provides benefit in identifying interesting subtasks of machine comprehension. As will be seen, we are able to leverage the dataset both to improve our multi-task learning algorithm, as well as to analyze the strengths and weaknesses of our model.

[4] We also construct two additional baselines (*LSTM* and *QUANTA*) for comparison in this paper both of which achieve superior performance to *SW+D*.

[5] The BIUTEE system (Stern and Dagan, 2012) available under the Excitement Open Platform http://hltfbk.github.io/Excitement-Open-Platform/ was used for recognizing textual entailment.

[6] http://cs.umd.edu/ miyyer/qblearn/

[7] http://cogcomp.cs.illinois.edu/Data/QA/QC/

[8] We tune the SVM regularization parameter C and the penalty factor on the subset size on the development set. We use a beam of size 5 in our experiments. We use Stanford CoreNLP and the HILDA parser (Feng and Hirst, 2014) for linguistic preprocessing.

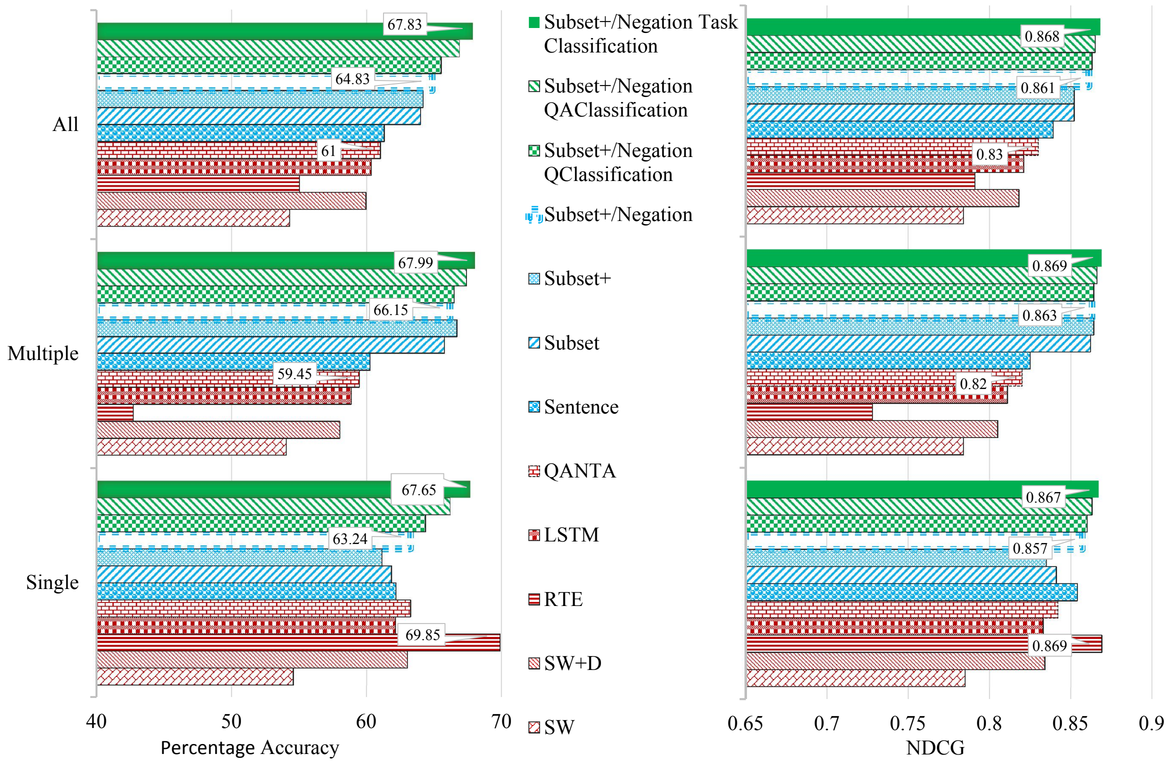

Figure 2: Comparison of variations of our method against several baselines on the MCTest-500 dataset. The figure shows two statistics, accuracy (on the left) and NDCG$_4$ (on the right) on the test set of MCTest-500. All differences between the baselines and LSSVMs, the improvement due to negation and the improvements due to multi-task learning are significant ($p < 0.01$) using the two-tailed paired T-test. The exact numbers are available in the supplementary.

(Järvelin and Kekäläinen, 2002). Unlike classification accuracy which evaluates if the prediction is correct or not, NDCG$_4$, being a measure of ranking quality, evaluates the position of the correct answer in our predicted ranking.

Figure 2 describes the comparison on *MCTest*. We can observe that all the LSSVM models have a better performance than all the five baselines (including LSTMs and RNNs which are state-of-the-art for many other NLP tasks) on both metrics. Very interestingly, LSSVMs have a considerable improvement over the baselines for "multiple" questions. We posit that this is because of our answer-entailing structure alignment strategy which is a weak proxy to the deep semantic inference procedure required for machine comprehension. The RTE baseline achieves the best performance on the "single" questions. This is perhaps because the RTE community has almost entirely focused on single sentence text hypothesis pairs for a long time. However, RTE fares pretty poorly on the "multiple" questions indicating that of-the-shelf RTE systems cannot perform inference across large texts.

Figure 2 also compares the performance of LSSVM variants when various answer-entailing structures are considered. Here we observe a clear benefit of using the alignment to the best subset structure over alignment to best sentence structure. We furthermore see improvements when the best subset alignment structure is augmented with the subset+ features. We can observe that the negation heuristic also helps, especially for "single" questions (majority of negation cases in the *MCTest* dataset are for the "single" questions).

It is also interesting to see that the multi-task learners show a substantial boost over the single task SSVM. Also, it can be observed that the multi-task learner greatly benefits if we can learn a separation between the various strategies needed to learn an overarching list of subtasks required to solve the machine comprehension task. [9] The multi-task method (TaskClassification) which uses the Weston style categorization does better

[9] Note that this is despite the fact that the classifier in not learned on the *MCTest* dataset but the *bAbI* dataset! This hints at the fact that the task classification proposed in Weston et al. (2015) is more general and broadly also makes sense for other machine comprehension settings such as *MCTest*.

than the multi-task method (QAClassification) that learns the question answer classification. QAClassification in turn performs better than multi-task method (QClassification) that learns the question classification only.

6 Strengths and Weaknesses

A good question to be asked is how good is structure alignment as a proxy to the semantics of the problem? In this section, we attempt to tease out the strengths and limitations of such a structure alignment approach for machine comprehension. To do so, we evaluate our methods on various tasks in the *bAbl* dataset.For the *bAbI* dataset, we add additional features inspired from the "task" distinction to handle specific "tasks".

In our experiments, we observed a similar general pattern of improvement of LSSVM over the baselines as well as the improvement due to multi-task learning. Again task classification helped the multi-task learner the most and the QA classification helped more than the QClassification. It is interesting here to look at the performance within the sub-tasks. Negation improved the performance for three sub-tasks, namely, the tasks of modelling "yes/no questions", "simple negations" and "indefinite knowledge" (the "Indefinite Knowledge" sub-task tests the ability to model statements that describe possibilities rather than certainties). Each of these sub-tasks contain a significant number of negation cases. Our models do especially well on questions requiring reasoning over one and two supporting facts, two arg. relations, indefinite knowledge, basic and compound coreference and conjunction. Our models achieve lower accuracy better than the baselines on two sub-tasks, namely "path finding" and "agent motivations". Our model along with the baselines do not do too well on the "counting" sub-task, although we get slightly better scores. The "counting" sub-task (which asks about the number of objects with a certain property) requires the inference to have an ability to perform simple counting operations. The "path finding" sub-task requires the inference to reason about the spatial path between locations (e.g. Pittsburgh is located on the west of New York). The "agents motivations" sub-task asks questions such as 'why an agent performs a certain action'. As inference is cheaply modelled via alignment structure, we lack the ability to deeply reason about facts or numbers. This is an important challenge for future work.

7 Related Work

The field of QA is quite rich. Most QA evaluations such as TREC have typically focused on short factoid questions. The solutions proposed have ranged from various IR based approaches (Mittal and Mittal, 2011) that treat this as a problem of retrieval from existing knowledge bases and perform some shallow inference to NLP approaches that learn a similarity between the question and a set of candidate answers (Yih et al., 2013). A majority of these approaches do not focus on doing any deeper inference. However, the task of machine comprehension requires an ability to perform inference over paragraph length texts to seek the answer. This is challenging for most IR and NLP techniques. In this paper, we presented a strategy for learning answer-entailing structures that helped us perform inference over much longer texts by treating this as a structured input-output problem.

The approach of treating a problem as one of mapping structured inputs to structured outputs is common across many NLP applications. Examples include word or phrase alignment for bitexts in MT (Blunsom and Cohn, 2006), text-hypothesis alignment in RTE (Sammons et al., 2009; MacCartney et al., 2008; Yao et al., 2013a; Sultan et al., 2014), question-answer alignment in QA (Berant et al., 2013; Yih et al., 2013; Yao and Van Durme, 2014), etc. Again all of these approaches align local parts of the input to local parts of the output. In this work, we extended the word alignment formalism to align multiple sentences in the text to the hypothesis. We also incorporated the document structure (rhetorical structures (Mann and Thompson, 1988)) and co-reference to help us perform inference over longer documents.

QA has had a long history of using pipeline models that extract a limited number of high-level features from induced representations of question-answer pairs, and then built a classifier using some labelled corpora. On the other hand we learnt these structures and performed machine comprehension jointly through a unified max-margin framework. We note that there exist some recent models such as Yih et al. (2013) that do model QA by automatically defining some kind of alignment between the question and answer snippets and use a similar structured input-output model. However, they are limited to single sentence answers.

Another advantage of our approach is its simple and elegant extension to multi-task settings. There has been a rich vein of work in multi-task learning for SVMs in the ML community. Evgeniou and Pontil (2004) proposed a multi-task SVM formulation assuming that the multi-task predictor $\mathbf{w}$ factorizes as the sum of a shared and a task-specific component. We used the same idea to propose a multi-task variant of Latent Structured SVMs. This allows us to use the single task SVM in the multi-task setting with a different feature mapping. This is much simpler than other competing approaches such as Zhu et al. (2011) proposed in the literature for multi-task LSSVM.

8 Conclusion

In this paper, we addressed the problem of machine comprehension which tests language understanding through multiple choice question answering tasks. We posed the task as an extension to RTE. Then, we proposed a solution by learning latent alignment structures between texts and the hypotheses in the equivalent RTE setting. The task requires solving a variety of sub-tasks so we extended our technique to a multi-task setting. Our technique showed empirical improvements over various IR and neural network baselines. The latent structures while effective are cheap proxies to the reasoning and language understanding required for this task and have their own limitations. We also discuss strengths and limitations of our model in a more fine-grained analysis. In the future, we plan to use logic-like semantic representations of texts, questions and answers and explore approaches to perform structured inference over richer semantic representations.

Learning Continuous Word Embedding with Metadata for Question Retrieval in Community Question Answering

Abstract

Community question answering (cQA) has become an important issue due to the popularity of cQA archives on the web. This paper is concerned with the problem of question retrieval. Question retrieval in cQA archives aims to find the existing questions that are semantically equivalent or relevant to the queried questions. However, the lexical gap problem brings about new challenge for question retrieval in cQA. In this paper, we propose to learn continuous word embeddings with metadata of category information within cQA pages for question retrieval. To deal with the variable size of word embedding vectors, we employ the framework of fisher kernel to aggregated them into the fixed-length vectors. Experimental results on large-scale real world cQA data set show that our approach can significantly outperform state-of-the-art translation models and topic-based models for question retrieval in cQA.

1 Introduction

Over the past few years, a large amount of user-generated content have become an important information resource on the web. These include the traditional Frequently Asked Questions (FAQ) archives and the emerging community question answering (cQA) services, such as Yahoo! Answers[1], Live QnA[2], and Baidu Zhidao[3]. The content in these web sites is usually organized as questions and lists of answers associated with metadata like user chosen categories to questions and askers' awards to the best answers. This data made cQA archives valuable resources for various tasks like question-answering (Jeon et al., 2005; Xue et al., 2008) and knowledge mining (Adamic et al., 2008), etc.

One fundamental task for reusing content in cQA is finding similar questions for queried questions, as questions are the keys to accessing the knowledge in cQA. Then the best answers of these similar questions will be used to answer the queried questions. Many studies have been done along this line (Jeon et al., 2005; Xue et al., 2008; Duan et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009; Cao et al., 2010; Zhou et al., 2011; Singh, 2012; Zhang et al., 2014a). One big challenge for question retrieval in cQA is the lexical gap between the queried questions and the existing questions in the archives. Lexical gap means that the queried questions may contain words that are different from, but related to, the words in the existing questions. For example shown in (Zhang et al., 2014a), we find that for a queried question "how do I get knots out of my cats fur?", there are good answers under an existing question "how can I remove a tangle in my cat's fur?" in Yahoo! Answers. Although the two questions share few words in common, they have very similar meanings, it is hard for traditional retrieval models (e.g., BM25 (Robertson et al., 1994)) to determine their similarity. This lexical gap has become a major barricade preventing traditional IR models (e.g., BM25) from retrieving similar questions in cQA.

To address the lexical gap problem in cQA, previous work in the literature can be divided into two groups. The first group is the translation models, which leverage the question-answer pairs to learn the semantically related words to improve traditional IR models (Jeon et al., 2005; Xue et al., 2008; Zhou et al., 2011). The basic assumption is that question-answer pairs are "parallel texts" and relationship of words (or phrases) can be established through word-to-word (or phrase-to-phrase)

translation probabilities (Jeon et al., 2005; Xue et al., 2008; Zhou et al., 2011). Experimental results show that translation models obtain state-of-the-art performance for question retrieval in cQA. However, questions and answers are far from "parallel" in practice, questions and answers are highly asymmetric on the information they contain (Zhang et al., 2014a). The second group is the topic-based models (Cai et al., 2011; Ji et al., 2012), which learn the latent topics aligned across the question-answer pairs to alleviate the lexical gap problem, with the assumption that a question and its paired answers share the same topic distribution. However, questions and answers are heterogeneous in many aspects, they do not share the same topic distribution in practice.

Inspired by the recent success of continuous space word representations in capturing the semantic similarities in various natural language processing tasks, we propose to incorporate an embedding of words in a continuous space for question representations. Due to the ability of word embeddings, we firstly transform words in a question into continuous vector representations by looking up tables. These word embeddings are learned in advance using a continuous skip-gram model (Mikolov et al., 2013), or other continuous word representation learning methods. Once the words are embedded in a continuous space, one can view a question as a Bag-of-Embedded-Words (BoEW). Then, the variable-cardinality BoEW will be aggregated into a fixed-length vector by using the Fisher kernel (FK) framework of (Clinchant and Perronnin, 2013; Sanchez et al., 2013). Through the two steps, the proposed approach can map a question into a length invariable compact vector, which can be efficiently and effectively for large-scale question retrieval task in cQA.

We test the proposed approach on large-scale Yahoo! Answers data and Baidu Zhidao data. Yahoo! Answers and Baidu Zhidao represent the largest and most popular cQA archives in English and Chinese, respectively. We conduct both quantitative and qualitative evaluations. Experimental results show that our approach can significantly outperform state-of-the-art translation models and topic-based models for question retrieval in cQA.

Our contribution in this paper are three-fold: (1) we represent a question as a bag-of-embedded-words (BoEW) in a continuous space; (2) we introduce a novel method to aggregate the variable-cardinality BoEW into a fixed-length vector by using the FK. The FK is just one possible way to subsequently transform this bag representation into a fixed-length vector which is more amenable to large-scale processing; (3) an empirical verification of the efficacy of the proposed framework on large-scale English and Chinese cQA data.

The rest of this paper is organized as follows. Section 2 summarizes the related work. Section 3 describes our proposed framework for question retrieval. Section 4 reports the experimental results. Finally, we conclude the paper in Section 5.

2 Related Work

2.1 Question Retrieval in cQA

Significant research efforts have been conducted over the years in attempt to improve question retrieval in cQA (Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Duan et al., 2008; Bernhard and Gurevych, 2009; Cao et al., 2010; Zhou et al., 2011; Singh, 2012; Zhang et al., 2014a). Most of these works focus on finding similar questions for the user queried questions. The major challenge for question retrieval in cQA is the lexical gap problem. Jeon et al. (2005) proposed a word-based translation model for automatically fixing the lexical gap problem. Xue et al. (2008) proposed a word-based translation language model for question retrieval. Lee et al. (2008) tried to further improve the translation probabilities based on question-answer pairs by selecting the most important terms to build compact translation models. Bernhard and Gurevych (2009) proposed to use as a parallel training data set the definitions and glosses provided for the same term by different lexical semantic resources. In order to improve the word-based translation model with some contextual information, Riezler et al. (2007) and Zhou et al. (2011) proposed a phrase-based translation model for question and answer retrieval. The phrase-based translation model can capture some contextual information in modeling the translation of phrases as a whole, thus the more accurate translations can better improve the retrieval performance. Singh (2012) addressed the lexical gap issues by extending the lexical word-based translation model to incorporate semantic information (entities).

In contrast to the works described above that assume question-answer pairs are "parallel text", our paper deals with the lexical gap by learning continuous word embeddings in capturing the similarities without any assumptions, which is much more reasonable in practice.

Besides, some other studies model the semantic relationship between questions and answers with deep linguistic analysis (Duan et al., 2008; Wang et al., 2009; Wang et al., 2010; Ji et al., 2012; Zhang et al., 2014a) or a learning to rank strategy (Surdeanu et al., 2008; Carmel et al., 2014). Recently, Cao et al. (2010) and Zhou et al. (2013) exploited the category metadata within cQA pages to further improve the performance. On the contrary, we focus on the representation learning for questions, with a different solution with those previous works.

2.2 Word Embedding Learning

Representation of words as continuous vectors has attracted increasing attention in the area of natural language processing (NLP). Recently, a series of works applied deep learning techniques to learn high-quality word representations. Bengio et al. (2003) proposed a probabilistic neural network language model (NNLM) for word representations. Furthermore, Mikolov et al. (2013) proposed efficient neural network models for learning word representations, including the continuous *skip-gram* model and the continuous bag-of-word model (CBOW), both of which are unsupervised models learned from large-scale text corpora. Besides, there are also a large number of works addressing the task of learning word representations (Huang et al., 2012; Maas et al., 2011; Turian et al., 2010).

Nevertheless, since most the existing works learned word representations mainly based on the word co-occurrence information, the obtained word embeddings cannot capture the relationship between two syntactically or semantically similar words if either of them yields very little context information. On the other hand, even though amount of context could be noisy or biased such that they cannot reflect the inherent relationship between words and further mislead the training process. Most recently, Yu et al. (2014) used semantic prior knowledge to improve word representations. Xu et al. (2014) used the knowledge graph to advance the learning of word embeddings. In contrast to all the aforementioned works, in this paper, we present a general method to leverage the metadata of category information within cQA pages to further improve the word embedding representations. To our knowledge, it is the first work to learn word embeddings with metadata on cQA data set.

3 Our Approach

In this Section, we describe the proposed approach: learning continuous word embedding with metadata for question retrieval in cQA. The proposed framework consists of two steps: (1) *word embedding learning* step: given a cQA data collection, questions are treated as the basic units. For each word in a question, we firstly transform it to a continuous word vector through the looking up tables. Once the word embeddings are learned, each question is represented by a variable-cardinality word embedding vector (also called BoEW); (2) *fisher vector generation* step: which uses a generative model in the FK framework to generate fisher vectors (FVs) by aggregating the BoEWs for all the questions. Question retrieval can be performed through calculating the similarity between the FVs of a queried question and an existing question in the archive.

From the framework, we can see that although the word embedding learning computations and generative model estimation are time consuming, they can run only once in advance. Meanwhile, the computational requirements of FV generation and similarity calculation are limited. Hence, the proposed framework can efficiently achieve the large-scale question retrieval task.

3.1 Word Embedding Learning

In this paper, we consider a context-aware predicting model, more specifically, the *Skip-gram* model (Mikolov et al., 2013) for learning word embeddings, since it is much more efficient as well as memory-saving than other approaches.[4] *Skip-gram* is recently proposed for learning word representations using a neural network model, whose underlying idea is that similar words should have similar contexts. In the *Skip-gram* model (see Figure 1), a sliding window is employed on the input text stream to generate the training data, and l indicates the context window size to be $2l + 1$. In each slide window, the model aims to use the central word w_k as input to predict the context words. Let $M_{d \times N}$ denote the learned embedding matrix,

[4] Note that although we use the skip-gram model as an example to illustrate our approach, the similar framework can be developed on the basis of any other word embedding models.

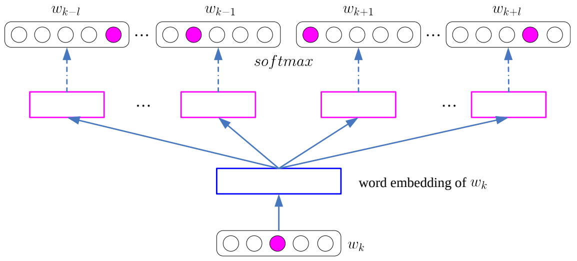

Figure 1: The continuous skip-gram model.

where N is the vocabulary size and d is the dimension of word embeddings. Each column of M represents the embedding of a word. Let w_k is first mapped to its embedding e_{w_k} by selecting the corresponding column vector of M. The probability of its context word w_{k+j} is then computed using a log-linear *softmax* function:

$$p(w_{k+j}|w_k;\theta) = \frac{\exp(e^T_{w_{k+j}} e_{w_k})}{\sum_{w=1}^{N} \exp(e^T_{w} e_{w_k})} \quad (1)$$

where θ are the parameters we should learned, $k = 1 \cdots d$, and $j \in [-l, l]$. Then, the log-likelihood over the entire training data can be computed as:

$$J(\theta) = \sum_{(w_k, w_{k+j})} \log p(w_{k+j}|w_k;\theta) \quad (2)$$

To calculate the prediction errors for back propagation, we need to compute the derivative of $p(w_{k+j}|w_k;\theta)$, whose computation cost is proportional to the vocabulary size N. As N is often very large, it is difficult to directly compute the derivative. To deal this problem, Mikolov et al. (2013) proposed a simple negative sampling method, which generates r noise samples for each input word to estimate the target word, in which r is a very small number compared with N. Therefore, the training time yields linear scale to the number of noise samples and it becomes independent of the vocabulary size. Suppose the frequency of word w is $u(w)$, then the probability of sampling w is usually set to $p(w) \propto u(w)^{3/4}$ (Mikolov et al., 2013).

3.2 Metadata Powered Model

After briefing the *skip-gram* model, we introduce how we equip it with the metadata information. In cQA sites, there are several metadata, such as "category","voting" and so on. In this paper, we only consider the metadata of category information for word embedding learning. All questions in cQA are usually organized into a hierarchy of categories. When an user asks a question, the user typically required to choose a category label for the question from a predefined hierarchy of categories (Cao et al., 2010; Zhou et al., 2013). Previous work in the literature has demonstrated the effectiveness of the category information for question retrieval (Cao et al., 2010; Zhou et al., 2013). On the contrary, we argue that the category information benefits the word embedding learning in this work. The basic idea is that category information encodes the attributes or properties of words, from which we can group similar words according to their categories. Here, a word's category is assigned based on the questions it appeared in. For example, a question "What are the security issues with *java*?" is under the category of "Computers & Internet → Security", we simply put the category of a word *java* as "Computers & Internet → Security". Then, we may require the representations of words that belong to the same category to be close to each other.

Let $s(w_k, w_i)$ be the similarity score between w_k and w_i. Under the above assumption, we use the following heuristic to constrain the similar scores:

$$s(w_k, w_i) = \begin{cases} 1 & \text{if } c(w_k) = c(w_i) \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where $c(w_k)$ denotes the category of w_k. If the central word w_k shares the same category with the word w_i, their similarity score will become 1, otherwise, we set to 0. Then we encode the category information using a regularization function E_c:

$$E_c = \sum_{k=1}^{N} \sum_{i=1}^{N} s(w_k, w_i) d(w_k, w_i) \quad (4)$$

where $d(w_k, w_i)$ is the distance for the words in the embedding space and $s(w_k, w_i)$ serves as a weighting function. Again, for simplicity, we define $d(w_k, w_i)$ as the Euclidean distance between w_k and w_i.

We combine the *skip-gram* objective function and the regularization function derived from the metadata of category information, we get the following combined objective J_c that incorporates category information into the word representation learning process:

$$J_c = J(\theta) + \beta E_c \quad (5)$$

where β is the combination coefficient. Our goal is to maximize the combined objective J_c, which

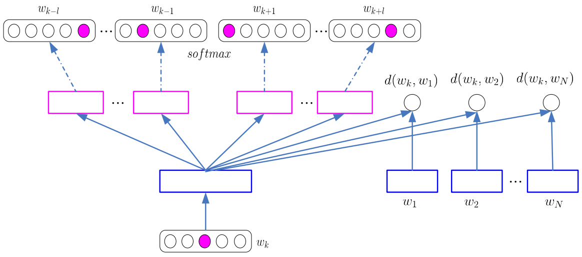

Figure 2: The continuous skip-gram model with metadata of category information, called M-NET.

can be optimized using back propagation neural networks. We call this model as metadata powered model (see Figure 2), and denote it by M-NET for easy of reference.

In the implementation, we optimize the regularization function derived from the metadata of category information along with the training process of the *skip-gram* model. During the procedure of learning word representations from the context words in the sliding window, if the central word w_k hits the category information, the corresponding optimization process of the metadata powered regularization function will be activated. Therefore, we maximize the weighted Euclidean distance between the representation of the central word and that of its similar words according to the objective function in Equation (5).

3.3 Fisher Vector Generation

Once the word embeddings are learned, questions can be represented by variable length sets of word embedding vectors, which can be viewed as BoEWs. Semantic level similarities between queried questions and the existing questions represented by BoEWs can be captured more accurately than previous bag-of-words (BoW) methods. However, since BoEWs are variable-size sets of word embeddings and most of the index methods in information retrieval field are not suitable for this kinds of issues, BoEWs cannot be directly used for large-scale question retrieval task.

Given a cQA data collection $\mathcal{Q} = \{q_i, 1 \leq i \leq |\mathcal{Q}|\}$, where q_i is the ith question and $|\mathcal{Q}|$ is the number of questions in the data collection. The ith question q_i is composed by a sequence of words $w_i = \{w_{ij}, 1 \leq j \leq N_i\}$, where N_i denotes the length of q_i. Through looking up table (word embedding matrix) of M, the ith question q_i can be represented by $E_{w_i} = \{e_{w_{ij}}, 1 \leq j \leq N_i\}$, where $e_{w_{ij}}$ is the word embedding of w_{ij}. According to the framework of FK (Clinchant and Perronnin, 2013; Sanchez et al., 2013; Zhang et al., 2014b), questions are modeled by a probability density function. In this work, we use Gaussian mixture model (GMM) to do it. We assume that the continuous word embedding E_{w_i} for question q_i have been generated by a "universal" (e.g., question-independent) probability density function (pdf). As is a common practice, we choose this pdf to be a GMM since any continuous distribution can be approximated with arbitrary precision by a mixture of Gaussian. In what follows, the pdf is denoted u_λ where $\lambda = \{\theta_i, \mu_i, \Sigma_i, i = 1 \cdots K\}$ is the set of parameters of the GMM. θ_i, μ_i and Σ_i denote respectively the mixture weight, mean vector and covariance matrix of Gaussian i. For computational reasons, we assume that the covariance matrices are diagonal and denote σ_i^2 the variance vector of Gaussian i, e.g., $\sigma_i^2 = \text{diag}(\sum_i)$. In real applications, the GMM is estimated offline with a set of continuous word embeddings extracted from a representative set of questions. The parameters λ are estimated through the optimization of a Maximum Likelihood (ML) criterion using the Expectation-Maximization (EM) algorithm. In the following, we follow the notations used in (Sanchez et al., 2013).

Given u_λ, one can characterize the question q_i using the following score function:

$$G_\lambda^{q_i} = \nabla_\lambda^{N_i} \log u_\lambda(q_i) \tag{6}$$

where $G_\lambda^{q_i}$ is a vector whose size depends only on the number of parameters in λ. Assuming that the word embedding $e_{w_{ij}}$ is iid (a simplifying assumption), we get:

$$G_\lambda^{q_i} = \sum_{j=1}^{N_i} \nabla_\lambda \log u_\lambda(e_{w_{ij}}) \tag{7}$$

Following the literature (Sanchez et al., 2013), we propose to measure the similarity between two questions q_i and q_j using the FK:

$$K(q_i, q_j) = G_\lambda^{q_i^T} F_\lambda^{-1} G_\lambda^{q_j} \tag{8}$$

where F_λ is the Fisher Information Matrix (FIM) of u_λ:

$$F_\lambda = E_{q_i \sim u_\lambda}\left[G_\lambda^{q_i} G_\lambda^{q_i^T}\right] \tag{9}$$

Since F_λ is symmetric and positive definite, F_λ^{-1} can be transformed to $L_\lambda^T L_\lambda$ based on the Cholesky decomposition. Hence, $K_{FK}(q_i, q_j)$ can rewritten as follows:

$$K_{FK}(q_i, q_j) = \mathcal{G}_\lambda^{q_i^T} \mathcal{G}_\lambda^{q_j} \tag{10}$$

where

$$\mathcal{G}_{\lambda}^{q_i} = L_{\lambda} G_{\lambda}^{q_i} = L_{\lambda} \bigtriangledown_{\lambda} \log u_{\lambda}(q_i) \tag{11}$$

In (Sanchez et al., 2013), $\mathcal{G}_{\lambda}^{q_i}$ refers to as the *Fisher Vector* (FV) of q_i. The dot product between FVs can be used to calculate the semantic similarities. Based on the specific probability density function, GMM, FV of q_i is respect to the mean μ and standard deviation σ of all the mixed Gaussian distributions. Let $\gamma_j(k)$ be the soft assignment of the jth word embedding $e_{w_{ij}}$ in q_i to Guassian k (u_k):

$$\gamma_j(k) = p(k|e_{w_{ij}}) \frac{\theta_i u_k(e_{w_{ij}})}{\sum_{j=1}^{K} \theta_k u_k(e_{w_{ij}})} \tag{12}$$

Mathematical derivations lead to:

$$\mathcal{G}_{\mu,k}^{q_i} = \frac{1}{N_i\sqrt{\theta_i}} \sum_{j=1}^{N_i} \gamma_j(k) \left[\frac{e_{w_{ij}} - \mu_k}{\sigma_k}\right] \tag{13}$$

$$\mathcal{G}_{\sigma,k}^{q_i} = \frac{1}{N_i\sqrt{2\theta_i}} \sum_{j=1}^{N_i} \gamma_j(k) \left[\frac{(e_{w_{ij}} - \mu_k)^2}{\sigma_k^2} - 1\right]$$

The division by the vector σ_k should be understood as a term-by-term operation. The final gradient vector $\mathcal{G}_{\lambda}^{q_i}$is the concatenation of the $\mathcal{G}_{\mu,k}^{q_i}$ and $\mathcal{G}_{\sigma,k}^{q_i}$ vectors for $k = 1 \cdots K$. Let d denote the dimensionality of the continuous word embeddings and K be the number of Gaussians. The final fisher vector $\mathcal{G}_{\lambda}^{q_i}$ is therefore $2Kd$-dimensional.

4 Experiments

In this section, we present the experiments to evaluate the performance of the proposed method for question retrieval.

4.1 Data Set and Evaluation Metrics

We collect the data sets from Yahoo! Answers and Baidu Zhidao. Yahoo! Answers and Baidu Zhidao represent the largest and the most popular cQA archives in English and Chinese, respectively. More specifically, we utilized the *resolved* questions at Yahoo! Answers and Baidu Zhidao. The questions include 10 million items from Yahoo! Answers and 8 million items from Baidu Zhidao (also called retrieval data). Each resolved question consists of three fields: "title", "description" and "answers", as well as some metadata, such as "category". For question retrieval, we use only the "title" field and "category" metadata. It is assumed that the titles of questions already provide enough semantic information for understanding users' information needs (Duan et al., 2008). We develop two test sets, one for "Yahoo data", and the other for "Baidu data". In order to create the test sets, we collect some extra questions that have been posted more recently than the retrieval data, and randomly sample $1,000$ questions for Yahoo! Answers and Baidu Zhidao, respectively. We take those questions as queries. All questions are lowercased and stemmed. Stopwords[5] are also removed.

	#queries	#candidate	#relevant
Yahoo data	1,000	13,000	2,671
Baidu data	1,000	8,000	2,104

Table 1: Statistics on the manually labeled data.

We separately index all data from Yahoo! Answers and Baidu Zhidao using an open source *Lucene* with the BM25 scoring function[6]. For each query from Yahoo! Answers and Baidu Zhidao, we retrieve the several candidate questions from the corresponding indexed data by using the BM25 ranking algorithm in *Lucene*. On average, each query from Yahoo! Answers has 13 candidate questions and the average number of candidate questions for Baidu Zhidao is 8.

We recruit students to label the relevance of the candidate questions regarding to the queries. Specifically, for each type of language, we let three native students. Given a candidate question, a student is asked to label it with "relevant" or "irrelevant". If a candidate question is considered semantically similar to the query, the student will label it as "relevant"; otherwise, the student will label it as "irrelevant". As a result, each candidate question gets three labels and the majority of the label is taken as the final decision for a query-candidate pair. We randomly split each of the two labeled data sets into a validation set and a test set with a ration $1 : 3$. The validation set is used for tuning parameters of different models, while the test set is used for evaluating how well the models ranked relevant candidates in contrast to irrelevant candidates. Table 1 presents the manually labeled data.

Please note that rather than evaluate both retrieval and ranking capability of different meth-

[6] We use the BM25 implementation provided by Apache Lucene (http://lucene.apache.org/), using the default parameter setting ($k_1 = 1.2$, $b = 0.75$)

ods like the existing work (Cao et al., 2010), we compare them in a ranking task. This may lose recall for some methods, but it can enable large-scale evaluation.

In order to evaluate the performance of different models, we employ Mean Average Precision (MAP), Mean Reciprocal Rank (MRR), R-Precision (R-Prec), and Precision at K (P@5) as evaluation measures. These measures are widely used in the literature for question retrieval in cQA (Cao et al., 2010).

4.2 Parameter Setting

In our experiments, we train the word embeddings on another large-scale data set from cQA sites. For English, we train the word embeddings on the Yahoo! Webscope dataset[7]. For Chinese, we train the word embeddings on a data set with 1 billion web pages from Baidu Zhidao. These two data sets do not intersect with the above mentioned retrieval data. Little pre-processing is conducted for the training of word embeddings. The resulting text is tokenized using the Stanford tokenizer,[8], and every word is converted to lowercase. Since the proposed framework has no limits in using which of the word embedding learning methods, we only consider the following two representative methods: *Skip-gram* (baseline) and *M-NET*. To train the word embedding using these two methods, we apply the same setting for their common parameters. Specifically, the count of negative samples r is set to 3; the context window size l is set to 5; each model is trained through 1 epoch; the learning rate is initialized as 0.025 and is set to decrease linearly so that it approached zero at the end of training.

Besides, the combination weight β used in *M-NET* also plays an important role in producing high quality word embedding. Overemphasizing the weight of the original objective of *Skip-gram* may result in weakened influence of metadata, while putting too large weight on metadata powered objective may hurt the generality of learned word embedding. Based on our experience, it is a better way to decode the objective combination weight of the *Skip-gram* model and metadata information based on the scale of their respective derivatives during optimization. Finally, we set $\beta = 0.001$ empirically. Note that if the parameter is optimized on the validation set, the final performance can be further improved.

For parameter K used in FV, we do an experiment on the validation data set to determine the best value among 1, 2, 4, $\cdots$, 64 in terms of MAP. As a result, we set $K = 16$ in the experiments empirically as this setting yields the best performance.

4.3 Main Results

In this subsection, we present the experimental results on the test sets of Yahoo data and Baidu data. We compare the baseline word embedding trained by *Skip-gram* against this trained by *M-NET*. The dimension of word embedding is set as 50,100 and 300. Since the motivation of this paper attempts to tackle the lexical gap problem for queried questions and questions in the archive, we also compare them with the two groups of methods which also address the lexical gap in the literature. The first group is the translation models: word-based translation model (Jeon et al., 2005), word-based translation language model (Xue et al., 2008), and phrase-based translation model (Zhou et al., 2011). We implement those three translation models based on the original papers and train those models with (question, best answer) pairs from the Yahoo! Webscope dataset Yahoo answers and the 1 billion web pages of Baidu Zhidao for English and Chinese, respectively. Training the translation models with different pairs (e.g., question-best answer, question-description, question-answer) may achieve inconsistent performance on Yahoo data and Baidu data, but its comparison and analysis are beyond the scope of this paper. The second group is the topic-based methods: unsupervised question-answer topic model (Ji et al., 2012) and supervised question-answer topic model (Zhang et al., 2014a). We re-implement these two topic-based models and tune the parameter settings on our data set. Besides, we also introduce a baseline language model (LM) (Zhai and Lafferty, 2001) for comparison.

Table 2 shows the question retrieval performance by using different evaluation metrics. From this table, we can see that learning continuous word embedding representations (Skip-gram + FV, M-NET + FV) for question retrieval can outperform the translation-based approaches and topic-based approaches on all evaluation metrics. We conduct a statistical test (t-test), the results

	300	**0.571**‡	**0.643**‡	**0.455**‡	**0.374**‡	**0.475**‡	**0.477**‡	**0.385**‡	**0.283**‡

Table 2: Evaluation results on Yahoo data and Baidu data, where dim denotes the dimension of the word embeddings. The bold formate indicates the best results for question retrieval. † indicates that the difference between the results of our proposed approach (Skip-gram + FV, M-NET + FV) and other methods are mildly significant with $p < 0.08$ under a t-test; ‡ indicates the comparisons are statistically significant with $p < 0.05$.

show that the improvements between the proposed M-NET + FV and the two groups of compared methods (translation-based approaches and topic-based approaches) are statistically significant ($p < 0.05$), while the improvements between Skip-gram + FV and the translation-based approaches are mildly significant ($p < 0.08$). Moreover, the metadata of category information powered model (M-NET + FV) outperforms the baseline skip-gram model (Skip-gram + FV) and yields the largest improvements. These results can imply that the metadata powered word embedding is of higher quality than the baseline model with no metadata information regularization. Besides, we also note that setting higher dimension brings more improvements for question retrieval task.

Translation-based methods significantly outperform LM, which demonstrate that matching questions with the semantically related translation words or phrases from question-answer pairs can effectively address the word lexical gap problem. Besides, we also note that phrase-based translation model is more effective because it captures some contextual information in modeling the translation of phrases as a whole. More precise translation can be determined for phrases than for words. Similar observation has also been found in the previous work (Zhou et al., 2011).

On both data sets, topic-based models achieve comparable performance with the translation-based models and but they perform better than LM. The results demonstrate that learning the latent topics aligned across the question-answer pairs can be an alternative for bridging lexical gap problem for question retrieval.

5 Conclusion

This paper proposes to learn continuous vector representations for question retrieval in cQA. We firstly introduce a new metadata powered word embedding method, called M-NET, to leverage the category information within cQA pages to obtain word representations. Once the words are embeded in a continuous space, we treat each question as a BoEW. Then, the variable size BoEWs are aggregated into fixed-length vectors by using FK. Finally, the dot product between FVs are used to calculate the semantic similarities for question retrieval. Experiments on large-scale real world cQA data demonstrate that the efficacy of the proposed approach. For the future work, we will explore how to incorporate more types of metadata information, such as the *user ratings*, *like signals* and *Poll and Survey signals*, into the learning process to obtain more powerful word representations.

Abstract

Answering natural language questions over a knowledge base is an important and challenging task. Most of existing systems typically rely on hand-crafted features and rules to conduct question understanding and/or answer ranking. In this paper, we introduce multi-column convolutional neural networks (MCCNNs) to understand questions from three different aspects (namely, answer path, answer context, and answer type) and learn their distributed representations. Meanwhile, we jointly learn low-dimensional embeddings of entities and relations in the knowledge base. Question-answer pairs are used to train the model to rank candidate answers. We also leverage question paraphrases to train the column networks in a multi-task learning manner. We use FREEBASE as the knowledge base and conduct extensive experiments on the WEBQUESTIONS dataset. Experimental results show that our method achieves better or comparable performance compared with baseline systems. In addition, we develop a method to compute the salience scores of question words in different column networks. The results help us intuitively understand what MCCNNs learn.

1 Introduction

Automatic question answering systems return the direct and exact answers to natural language questions. In recent years, the development of large-scale knowledge bases, such as FREEBASE (Bollacker et al., 2008), provides a rich resource to answer open-domain questions. However, how to understand questions and bridge the gap between natural languages and structured semantics of knowledge bases is still very challenging.

Up to now, there are two mainstream methods for this task. The first one is based on semantic parsing (Berant et al., 2013; Berant and Liang, 2014) and the other relies on information extraction over the structured knowledge base (Yao and Van Durme, 2014; Bordes et al., 2014a; Bordes et al., 2014b). The semantic parsers learn to understand natural language questions by converting them into logical forms. Then, the parse results are used to generate structured queries to search knowledge bases and obtain the answers. Recent works mainly focus on using question-answer pairs, instead of annotated logical forms of questions, as weak training signals (Liang et al., 2011; Krishnamurthy and Mitchell, 2012) to reduce annotation costs. However, some of them still assume a fixed and pre-defined set of lexical triggers which limit their domains and scalability capability. In addition, they need to manually design features for semantic parsers. The second approach uses information extraction techniques for open question answering. These methods retrieve a set of candidate answers from the knowledge base, and the extract features for the question and these candidates to rank them. However, the method proposed by Yao and Van Durme (2014) relies on rules and dependency parse results to extract hand-crafted features for questions. Moreover, some methods (Bordes et al., 2014a; Bordes et al., 2014b) use the summation of question word embeddings to represent questions, which ignores word order information and cannot process complicated questions.

In this paper, we introduce the multi-column convolutional neural networks (MCCNNs) to automatically analyze questions from multiple aspects. Specifically, the model shares the same word embeddings to represent question words.

MCCNNs use different column networks to extract answer types, relations, and context information from the input questions. The entities and relations in the knowledge base (namely FREEBASE in our experiments) are also represented as low-dimensional vectors. Then, a score layer is employed to rank candidate answers according to the representations of questions and candidate answers. The proposed information extraction based method utilizes question-answer pairs to automatically learn the model without relying on manually annotated logical forms and hand-crafted features. We also do not use any pre-defined lexical triggers and rules. In addition, the question paraphrases are also used to train networks and generalize for the unseen words in a multi-task learning manner. We have conducted extensive experiments on WEBQUESTIONS. Experimental results illustrate that our method outperforms several baseline systems.

The contributions of this paper are three-fold:

- We introduce multi-column convolutional neural networks for question understanding without relying on hand-crafted features and rules, and use question paraphrases to train the column networks and word vectors in a multi-task learning manner;

- We jointly learn low-dimensional embeddings for the entities and relations in FREEBASE with question-answer pairs as supervision signals;

- We conduct extensive experiments on the WEBQUESTIONS dataset, and provide some intuitive interpretations for MCCNNs by developing a method to detect salient question words in the different column networks.

2 Related Work

The state-of-the-art methods for question answering over a knowledge base can be classified into two classes, i.e., semantic parsing based and information retrieval based.

Semantic parsing based approaches aim at learning semantic parsers which parse natural language questions into logical forms and then query knowledge base to lookup answers. The most important step is mapping questions into predefined logical forms, such as combinatory categorial grammar (Cai and Yates, 2013) and dependency-based compositional semantics (Liang et al., 2011). Some semantic parsing based systems required manually annotated logical forms to train the parsers (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010). These annotations are relatively expensive. So recent works (Liang et al., 2011; Kwiatkowski et al., 2013; Berant et al., 2013; Berant and Liang, 2014; Bao et al., 2014; Reddy et al., 2014) mainly aimed at using weak supervision (question-answer pairs) to effectively train semantic parsers. These methods achieved comparable results without using logical forms annotated by experts. However, some methods relied on lexical triggers or manually defined features.

On the other hand, information retrieval based systems retrieve a set of candidate answers and then conduct further analysis to obtain answers. Their main difference is how to select correct answers from the candidate set. Yao and Van Durme (2014) used rules to extract question features from dependency parse of questions, and used relations and properties in the retrieved topic graph as knowledge base features. Then, the production of these two kinds of features was fed into a logistic regression model to classify the question's candidate answers into correct/wrong. In contrast, we do not use rules, dependency parse results, or hand-crafted features for question understanding. Some other works (Bordes et al., 2014a; Bordes et al., 2014b) learned low-dimensional vectors for question words and knowledge base constitutes, and used the sum of vectors to represent questions and candidate answers. However, simple vector addition ignores word order information and high-order n-grams. For example, the question representations of *who killed A* and *who A killed* are same in the vector addition model. We instead use multi-column convolutional neural networks which are more powerful to process complicated question patterns. Moreover, our multi-column network architecture distinguishes between information of answer type, answer path and answer context by learning multiple column networks, while the addition model mixes them together.

Another line of related work is applying deep learning techniques for the question answering task. Grefenstette et al. (2014) proposed a deep architecture to learn a semantic parser from annotated logic forms of questions. Iyyer et al. (2014) introduced dependency-tree recursive neural networks for the quiz bowl game which asked players to answer an entity for a given paragraph. Yu et al. (2014) proposed a bigram model based on convolutional neural networks to select answer sentences from text data. The model learned a similarity function between questions and answer sentences. Yih et al. (2014) used convolutional neural networks to answer single-relation questions on REVERB (Fader et al., 2011). However, the system worked on relation-entity triples instead of more structured knowledge bases. For instance, the question shown in Figure 1 is answered by using several triples in FREEBASE. Also, we can utilize richer information (such as entity types) in structured knowledge bases.

3 Setup

Given a natural language question $q = w_1 \dots w_n$, we retrieve related entities and properties from FREEBASE and use them as the candidate answers C_q. Our goal is to score these candidates and predict answers. For instance, the correct output of the question *when did Avatar release in UK* is *2009-12-17*. It should be noted that there may be several correct answers for a question. In order to train the model, we use question-answer pairs without annotated logic forms. We further describe the datasets used in our work as follows:

WebQuestions This dataset (Berant et al., 2013) contains 3,778 training instances and 2,032 test instances. We further split the training instances into the training set and the development set by 80%/20%. The questions were collected by querying the Google Suggest API. A breadth-first search beginning with *wh-* was conducted. Then, answers were annotated in Amazon Mechanical Turk. All the answers can be found in FREEBASE.

Freebase It is a large-scale knowledge base that consists of general facts (Bollacker et al., 2008). These facts are organized as subject-property-object triples. For example, the fact *Avatar is directed by James Cameron* is represented by (/m/0bth54, film.film.directed_by, /m/03_gd) in RDF format. The preprocess method presented in (Bordes et al., 2014a) was used to make FREEBASE fit in memory. Specifically, we kept the triples where one of the entities appeared in the training/development set of WEBQUESTIONS or CLUEWEB extractions provided in (Lin et al., 2012), and removed the entities appearing less than five times. Then, we obtained 18M triples that contained 2.9M entities and 7k relation types. As described in (Bordes et al., 2014a), this preprocess method does not ease the task because WEBQUESTIONS only contains about 2k entities.

WikiAnswers Fader et al. (2013) extracted the similar questions on WIKIANSWERS and used them as question paraphrases. There are 350,000 paraphrase clusters which contain about two million questions. They are used to generalize for unseen words and question patterns.

4 Methods

The overview of our framework is shown in Figure 1. For instance, for the question *when did Avatar release in UK*, the related nodes of the entity *Avatar* are queried from FREEBASE. These related nodes are regarded as candidate answers (C_q). Then, for every candidate answer a, the model predicts a score $S(q,a)$ to determine whether it is a correct answer or not.

We use multi-column convolutional neural networks (MCCNNs) to learn representations of questions. The models share the same word embeddings, and have multiple columns of convolutional neural networks. The number of columns is set to three in our QA task. These columns are used to analyze different aspects of a question, i.e., answer path, answer context, and answer type. The vector representations learned by these columns are denoted as $\mathbf{f}_1(q), \mathbf{f}_2(q), \mathbf{f}_3(q)$. We also learn embeddings for the candidate answers appeared in FREEBASE. For every candidate answer a, we compute its vector representations and denote them as $\mathbf{g}_1(a), \mathbf{g}_2(a), \mathbf{g}_3(a)$. These three vectors correspond to the three aspects used in question understanding. Using these vector representations defined for questions and answers, we can compute the score for the question-answer pair (q,a). Specifically, the scoring function $S(q,a)$ is defined as:

$$S(q,a) = \underbrace{\mathbf{f}_1(q)^{\mathsf{T}}\mathbf{g}_1(a)}_{answer\ path} + \underbrace{\mathbf{f}_2(q)^{\mathsf{T}}\mathbf{g}_2(a)}_{answer\ context} + \underbrace{\mathbf{f}_3(q)^{\mathsf{T}}\mathbf{g}_3(a)}_{answer\ type} \quad (1)$$

where $\mathbf{f}_i(q)$ and $\mathbf{g}_i(a)$ have the same dimension. As shown in Figure 1, the score layer computes scores and adds them together.

4.1 Candidate Generation

The first step is to retrieve candidate answers from FREEBASE for a question. Questions should contain an identified entity that can be linked to the

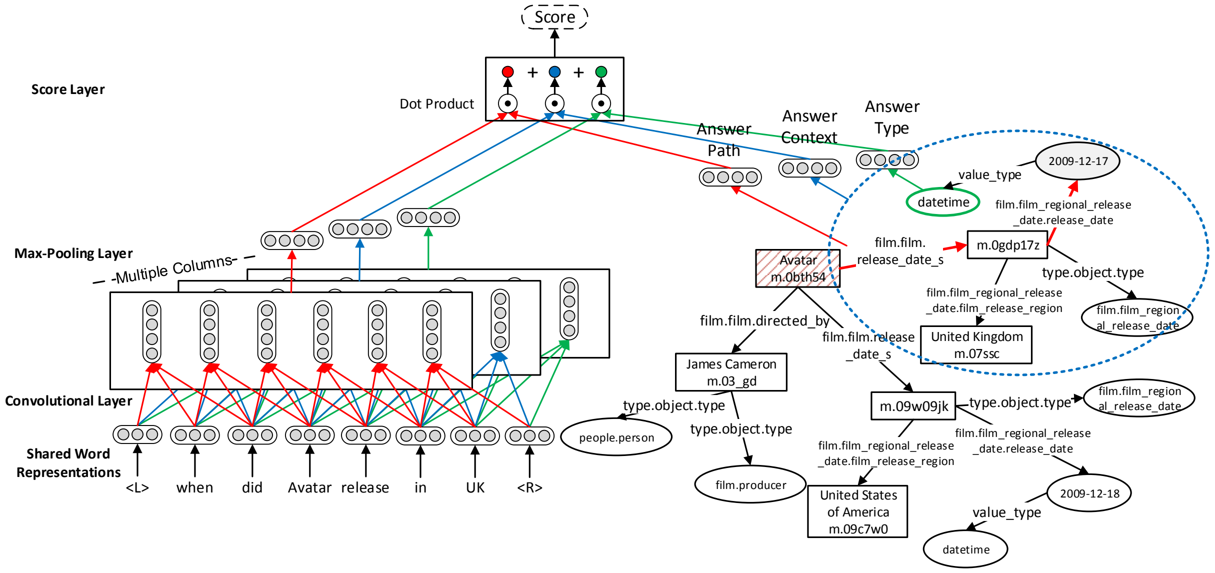

Figure 1: Overview for the question-answer pair *(when did Avatar release in UK, 2009-12-17)*. Left: network architecture for question understanding. Right: embedding candidate answers.

knowledge base. We use the Freebase Search API (Bollacker et al., 2008) to query named entities in a question. If there is not any named entity, noun phrases are queried. We use the top one entity in the ranked list returned by the API. This entity resolution method was also used in (Yao and Van Durme, 2014). Better methods can be developed, while it is not the focus of this paper. Then, all the 2-hops nodes of the linked entity are regarded as the candidate answers. We denote the candidate set for the question q as C_q.

4.2 MCCNNs for Question Understanding

MCCNNs use multiple convolutional neural networks to learn different aspects of questions from shared input word embeddings. For every single column, the network structure presented in (Collobert et al., 2011) is used to tackle the variable-length questions.

We present the model in the left part of Figure 1. Specifically, for the question $q = w_1 \dots w_n$, the lookup layer transforms every word into a vector $\mathbf{w}_j = \mathbf{W}_v \mathbf{u}(w_j)$, where $\mathbf{W}_v \in \mathbb{R}^{d_v \times |V|}$ is the word embedding matrix, $\mathbf{u}(w_j) \in \{0,1\}^{|V|}$ is the one-hot representation of w_j, and $|V|$ is the vocabulary size. The word embeddings are parameters, and are updated in the training process.

Then, the convolutional layer computes representations of the words in sliding windows. For the i-th column of MCCNNs, the convolutional layer computes n vectors for question q. The j-th vector is:

$$\mathbf{x}_j^{(i)} = \mathbf{h}\left(\mathbf{W}^{(i)} \left[\mathbf{w}_{j-s}^{\mathsf{T}} \dots \mathbf{w}_j^{\mathsf{T}} \dots \mathbf{w}_{j+s}^{\mathsf{T}}\right]^{\mathsf{T}} + \mathbf{b}^{(i)}\right) \tag{2}$$

where $(2s+1)$ is the window size, $\mathbf{W}^{(i)} \in \mathbb{R}^{d_q \times (2s+1)d_v}$ is the weight matrix of convolutional layer, $\mathbf{b}^{(i)} \in \mathbb{R}^{d_q \times 1}$ is the bias vector, and $\mathbf{h}(\cdot)$ is the nonlinearity function (such as softsign, tanh, and sigmoid). Paddings are used for left and right absent words.

Finally, a max-pooling layer is followed to obtain the fixed-size vector representations of questions. The max-pooling layer in the i-th column of MCCNNs computes the representation of the question q via:

$$\mathbf{f}_i(q) = \max_{j=1,\dots,n} \{\mathbf{x}_j^{(i)}\} \tag{3}$$

where $\max\{\cdot\}$ is an element-wise operator over vectors.

4.3 Embedding Candidate Answers

Vector representations $\mathbf{g}_1(a), \mathbf{g}_2(a), \mathbf{g}_3(a)$ are learned for the candidate answer a. The vectors are employed to represent different aspects of a. The embedding methods are described as follows:

Answer Path The answer path is the set of relations between the answer node and the entity asked in question. As shown in Figure 1, the 2-hops path between the entity *Avatar* and the correct answer is (film.film.release_date_s, film.film_regional_release_date.release_date). The vector representation $\mathbf{g}_1(a)$ is computed via $\mathbf{g}_1(a) = \frac{1}{\|\mathbf{u}_p(a)\|_1}\mathbf{W}_p\mathbf{u}_p(a)$, where $\|\cdot\|_1$ is 1-norm, $\mathbf{u}_p(a) \in \mathbb{R}^{|R|\times 1}$ is a binary vector which represents the presence or absence of every relation in the answer path, $\mathbf{W}_p \in \mathbb{R}^{d_q\times |R|}$ is the parameter matrix, and $|R|$ is the number of relations. In other words, the embeddings of relations that appear on the answer path are averaged.

Answer Context The 1-hop entities and relations connected to the answer path are regarded as the answer context. It is used to deal with constraints in questions. For instance, as shown in Figure 1, the release date of Avatar in UK is asked, so it is not enough that only the triples on answer path are considered. With the help of context information, the release date in UK has a higher score than in USA. The context representation is $\mathbf{g}_2(a) = \frac{1}{\|\mathbf{u}_c(a)\|_1}\mathbf{W}_c\mathbf{u}_c(a)$, where $\mathbf{W}_c \in \mathbb{R}^{d_q\times |C|}$ is the parameter matrix, $\mathbf{u}_c(a) \in \mathbb{R}^{|C|\times 1}$ is a binary vector expressing the presence or absence of context nodes, and $|C|$ is the number of entities and relations which appear in answer context.

Answer Type Type information in FREEBASE is an important clue to score candidate answers. As illustrated in Figure 1, the type of *2009-12-17* is datetime, and the type of *James Cameron* is people.person and film.producer. For the example question *when did Avatar release in UK*, the candidate answers whose types are datetime should be assigned with higher scores than others. The vector representation is defined as $\mathbf{g}_3(a) = \frac{1}{\|\mathbf{u}_t(a)\|_1}\mathbf{W}_t\mathbf{u}_t(a)$, where $\mathbf{W}_t \in \mathbb{R}^{d_q\times |T|}$ is the matrix of type embeddings, $\mathbf{u}_t(a) \in \mathbb{R}^{|T|\times 1}$ is a binary vector which indicates the presence or absence of answer types, and $|T|$ is the number of types. In our implementation, we use the relation common.topic.notable_types to query types. If a candidate answer is a property value, we instead use its value type (e.g., float, string, datetime).

4.4 Model Training

For every correct answer $a \in A_q$ of the question q, we randomly sample k wrong answers a' from the set of candidate answers C_q, and use them as negative instances to estimate parameters. To be more specific, the hinge loss is considered for pairs (q, a) and (q, a'):

$$l\left(q, a, a'\right) = \left(m - S(q, a) + S(q, a')\right)_+ \quad (4)$$

where $S(\cdot, \cdot)$ is the scoring function defined in Equation (1), m is the margin parameter employed to regularize the gap between two scores, and $(z)_+ = \max\{0, z\}$. The objective function is:

$$\min \sum_q \frac{1}{|A_q|} \sum_{a\in A_q} \sum_{a'\in R_q} l\left(q, a, a'\right) \quad (5)$$

where $|A_q|$ is the number of correct answers, and $R_q \subseteq C_q \setminus A_q$ is the set of k wrong answers.

The back-propagation algorithm (Rumelhart et al., 1986) is used to train the model. It back-propagates errors from top to the other layers. Derivatives are calculated and gathered to update parameters. The AdaGrad algorithm (Duchi et al., 2011) is then employed to solve this non-convex optimization problem. Moreover, the max-norm regularization (Srebro and Shraibman, 2005; Srivastava et al., 2014) is used for the column vectors of parameter matrices.

4.5 Inference

During the test, we retrieve all the candidate answers C_q for the question q. For every candidate $\hat{a}$, we compute its score $S(q, \hat{a})$. Then, the candidate answers with the highest scores are regarded as predicted results.

Because there may be more than one correct answers for some questions, we need a criterion to determine the score threshold. Specifically, the following equation is used to determine outputs:

$$\hat{A}_q = \{\hat{a} \mid \hat{a} \in C_q \;\; and \;\; \max_{a'\in C_q}\{S(q, a')\} - S(q, \hat{a}) < m\} \quad (6)$$

where m is the margin defined in Equation (4). The candidates whose scores are not far from the best answer are regarded as predicted results.

Some questions may have a large set of candidate answers. So we use a heuristic method to prune their candidate sets. To be more specific, if the number of candidates on the same answer path is greater than 200, we randomly keep 200 candidates for this path. Then, we score and rank all these generated candidate answers together. If one of the candidates on the pruned path is regarded as a predicted answer, we further score the other candidates that are pruned on this path and determine the final results.

4.6 Question Paraphrases for Multi-Task Learning

We use the question paraphrases dataset WIKIANSWERS to generalize for words and question patterns which are unseen in the training set of question-answer pairs. The question understanding results of paraphrases should be same. Consequently, the representations of two paraphrases computed by the same column of MCCNNs should be similar. We use dot similarity to define the hinge loss $l_p(q_1, q_2, q_3)$ as:

$$l_p(q_1, q_2, q_3) = \sum_{i=1}^{3} \left(m_p - \mathbf{f}_i(q_1)^{\mathsf{T}} \mathbf{f}_i(q_2) + \mathbf{f}_i(q_1)^{\mathsf{T}} \mathbf{f}_i(q_3) \right)_+ \tag{7}$$

where q_1, q_2 are questions in the same paraphrase cluster P, q_3 is randomly sampled from another cluster, and m_p is the margin. The objective function is defined as:

$$\min \sum_{P} \sum_{q_1, q_2 \in P} \sum_{q_3 \in R_P} l_p(q_1, q_2, q_3) \tag{8}$$

where R_P contains k_p questions which are randomly sampled from other clusters. The same optimization algorithm described in Section 4.4 is used to update parameters.

5 Experiments

In order to evaluate the model, we use the dataset WEBQUESTIONS (Section 3) to conduct experiments.

Settings The development set is used to select hyper-parameters in the experiments. The nonlinearity function $f = \tanh$ is employed. The dimension of word vectors is set to 25. They are initialized by the pre-trained word embeddings provided in (Turian et al., 2010). The window size of MCCNNs is 5. The dimension of the pooling layers and the dimension of answer embeddings are set to 64. The parameters are initialized by the techniques described in (Bengio, 2012). The max value used for max-norm regularization is 3. The initial learning rate used in AdaGrad is set to 0.01. A mini-batch consists of 10 question-answer pairs, and every question-answer pair has k negative samples that are randomly sampled from its candidate set. The margin values in Equation (4) and Equation (7) is set to $m = 0.5$ and $m_p = 0.1$.

Table 1: Evaluation results on the test split of WEBQUESTIONS.

5.1 Experimental Results

The evaluation metrics macro F1 score (Berant et al., 2013) and precision @ 1 (Bordes et al., 2014a) are reported. We use the official evaluation script provided by Berant et al. (2013) to compute the F1 score. Notably, the F1 score defined in (Yao and Van Durme, 2014) is slightly different from others (how to compute scores for the questions without predicted results). We instead use the original definition in experiments.

As shown in Table 1, our method achieves better or comparable results than baseline methods on WEBQUESTIONS. To be more specific, the first three rows are semantic parsing based methods, and the other baselines are information extraction based methods. These approaches except (Bordes et al., 2014a; Bordes et al., 2014b) rely on handcrafted features and predefined rules. The results show that automatically question understanding can be as good as the models using manually designed features. Besides, our multi-column convolutional neural networks based model outperforms the methods that use the sum of word embeddings as question representations (Bordes et al., 2014a; Bordes et al., 2014b).

5.2 Model Analysis

We also conduct ablation experiments to compare the results using different experiment settings. As shown in Table 2, the abbreviation *w/o* means removing a particular part from the model. We find that answer path information is most important among these three columns, and answer type information is more important than answer context information. The reason is that answer path and answer type are more direct clues for questions, but answer context is used to handle additional constraints in questions which are less common in the dataset. Moreover, we compare to the

Setting	F1	P@1
all	**40.8**	**45.1**
w/o path	32.5	37.1
w/o type	37.7	40.9
w/o context	39.1	41.0
w/o multi-column	38.4	41.8
w/o paraphrase	40.0	43.9
1-hop	29.3	32.2

Table 2: Evaluation results of different settings on the test split of WEBQUESTIONS. w/o path/type/context: without using the specific column. w/o multi-column: tying parameters of multiple columns. w/o paraphrase: without using question paraphrases for training. 1-hop: using 1-hop paths to generate candidate answers.

model using single-column networks (w/o multi-column), i.e., tying the parameters of different columns. The results indicate that using multiple columns to understand questions from different aspects improves the performance. Besides, we find that using question paraphrases in a multi-task learning manner contributes to the performance. In addition, we evaluate the results only using 1-hop paths to generate candidate answers. Compared to using 2-hops paths, we find that the performance drops significantly. This indicates only using the nodes directly connected to the queried entity in FREEBASE cannot handle many questions.

5.3 Salient Words Detection

In order to analyze the model, we detect salient words in questions. The salience score of a question word depends on how much the word affects the computation of question representation. In other words, if a word plays more important role in the model, its salience score should be larger.

We compute several salience scores for a same word to illustrate its importance in different columns of networks. For the i-th column, the salience score of word w_j in the question $q = w_1^n$ is defined as:

$$e_i(w_j) = \left\| \mathbf{f}_i\left(w_1^n\right) - \mathbf{f}_i\left(w_1^{j-1} w_j' w_{j+1}^n\right) \right\|_2 \quad (9)$$

where the word w_j is replaced with w_j', and $\|\cdot\|_2$ denotes Euclidean norm. In practice, we replace w_j with several stop words (such as *is*, *to*, and *a*), and then compute their average score.

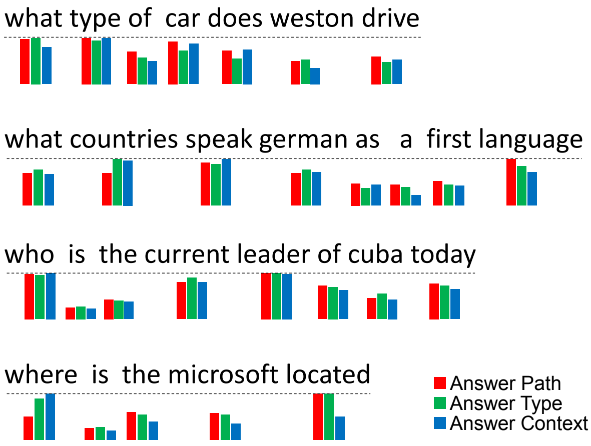

Figure 2: Salient words detection results for questions. From left to right, the three bars of every word correspond to salience scores in answer path column, answer type column, and answer context column, respectively. The salience scores are normalized by the max values of different columns.

As shown in Figure 2, we compute salience scores for several questions, and normalize them by the max values in different columns. We clearly see that these words play different roles in a question. The overall conclusion is that the *wh-* words (such as *what*, *who* and *where*) tend to be important for question understanding. Moreover, nouns dependent of the *wh-* words and verbs are important clues to obtain question representations. For instance, the figure demonstrates that the nouns *type/country/leader* and the verbs *speak/located* are salient in the columns of networks. These observations agree with previous works (Li and Roth, 2002). Some manually defined rules (Yao and Van Durme, 2014) used in the question answering task are also based on them.

5.4 Examples

Question representations computed by different columns of MCCNNs are used to query their most similar neighbors. We use cosine similarity in experiments. This experiment demonstrates whether the model learns different aspects of questions. For example, if a column of networks is employed to analyze answer types, the answer types of nearest questions should be same as the query.

As shown in Table 3, these three columns of table correspond to different columns of networks. To be more specific, the first column is used to process answer path. We find that the model learns different question patterns for the same

Column 1 (Answer Path)	Column 2 (Answer Type)	Column 3 (Answer Context)
what to do in hollywood can this weekend	**where be george washington originally from**	**where do charle draw go to college**
what to do in midland tx this weekend	where be george washington carver from	where do kevin love go to college

what money do japanese use	what be the official language of brazil now	what be the time zone in france

Table 3: Using question representations obtained by different column networks to query the nearest neighbors. From left to right, the three columns are used to analyze information about answer path, answer type, and answer context, respectively. Lemmatization is used to better show question patterns.

path. For instance, the vector representations of "*who found/own/start **" and "*who be the owner of **" obtained by the first column are similar. The second column is employed to extract answer type information from questions. The answer types of example questions in Table 3 are same, while they may ask different relations. The third column learns to embed question information into answer context. We find that the similar questions are clustered together by this column.

5.5 Error Analysis

We investigate the predicted results on the development set, and show several error causes as follows.

Candidate Generation Some entity mentions in questions are linked incorrectly, hence we cannot obtain the desired candidate answers. As described in (Yao and Van Durme, 2014), the Freebase Search API returned correct entities for 86.4% of questions in top one results. Because some questions use the abbreviation or a part of its mention to express an entity. For example, it is not trivial to link *jfk* to *John F. Kennedy* in the question "*where did jfk and his wife live*". A better entity retrieval step should be developed for the open question answering scenario.

Time-Aware Questions We need to compare date values for some time-aware questions. For instance, to answer the question "*who is johnny cash's **first** wife*", we have to know the order of several marriages by comparing the marriage date. Its correct response should contain only one entity (*vivian liberto*). However, our system additionally outputs *june carter cash* who is his second wife, because both the candidate answers are connected to *johnny cash* by the relation people.person.spouse_s. In order to solve this issue, we need to define some ad-hoc operators used for comparisons or develop more advanced semantic representations.

Ambiguous Questions Some questions are ambiguous to obtain their correct representations. For example, the question *what has anna kendrick been in* is used to ask what movies she has played in. This question does not have explicit clue words to indicate the meanings, so it is difficult to rank the candidates. Moreover, the question *who is aidan quinn* is employed to ask what his occupation is. It also lacks sufficient clues for question understanding, and using *who is* to ask occupation is rare in the training data.

6 Conclusion and Future Work

This paper presents a method for question answering over FREEBASE using multi-column convolutional neural networks (MCCNNs). MCCNNs share the same word embeddings, and use multiple columns of convolutional neural networks to learn the representations of different aspects of questions. Accordingly, we use low-dimensional embeddings to represent multiple aspects of candidate answers, i.e., answer path, answer type, and answer context. We estimate the parameters from question-answer pairs, and use question paraphrases to train the columns of MCCNNs in a multi-task learning manner. Experimental results on WEBQUESTIONS show that our approach achieves better or comparable performance comparing with baselines. There are several interesting directions that are worth exploring in the future. For instance, we are integrating more external knowledge source, such as CLUEWEB (Lin et al., 2012), to train MCCNNs in a multi-task learning manner. Furthermore, as our model is capable of detecting the most important words in a question, it would be interesting to use the results to mine effective question patterns.

Hubness and Pollution: Delving into Cross-Space Mapping for Zero-Shot Learning

Angeliki Lazaridou Georgiana Dinu Marco Baroni

University of Trento
{angeliki.lazaridou|georgiana.dinu|marco.baroni}@unitn.it

Abstract

Zero-shot methods in language, vision and other domains rely on a *cross-space mapping* function that projects vectors from the relevant feature space (e.g., visual-feature-based image representations) to a large semantic word space (induced in an unsupervised way from corpus data), where the entities of interest (e.g., objects images depict) are labeled with the words associated to the nearest neighbours of the mapped vectors. Zero-shot cross-space mapping methods hold great promise as a way to scale up annotation tasks well beyond the labels in the training data (e.g., recognizing objects that were never seen in training). However, the current performance of cross-space mapping functions is still quite low, so that the strategy is not yet usable in practical applications. In this paper, we explore some general properties, both theoretical and empirical, of the cross-space mapping function, and we build on them to propose better methods to estimate it. In this way, we attain large improvements over the state of the art, both in cross-linguistic (word translation) and cross-modal (image labeling) zero-shot experiments.

1 Introduction

In many supervised problems, the parameters of a classification function are estimated on $(\mathbf{x}, \mathrm{y})$ pairs, where $\mathbf{x}$ is a vector representing a training instance in some feature space, and y is the label assigned to the instance. For example, in image labeling $\mathbf{x}$ contains visual features extracted from a picture and y is the name of the object depicted in the picture (Grauman and Leibe, 2011). Since each label is treated as an unanalyzed primitive, this approach requires *ad-hoc* annotation for each label of interest, and it will not scale up to challenges where the potential label set is vast (for example, bilingual dictionary induction, where the label set corresponds to the full vocabulary of the target language).

Zero-shot methods (Palatucci et al., 2009) address the scalability problem by building on the observation that the labels of interest are often words (or longer linguistic expressions), which stand in a semantic similarity relation to each other. Moreover, distributional approaches allow us to estimate very large *semantic word spaces* in an efficient and unsupervised manner, using just unannotated text corpora as input (Turney and Pantel, 2010). Extensive evidence has shown that the similarity estimates obtained by representing words as vectors in such corpus-induced semantic spaces are extremely accurate (Baroni et al., 2014). Under the assumption that the domain of interest (e.g., objects in pictures, words in a source language) exhibits comparable similarity structure to that manifested in language, we can rephrase the learning task, from inducing multiple functions from the source feature space onto independent atomic labels, to that of estimating a single *cross-space mapping* function from vectors in the source feature space onto vectors for the corresponding word labels in distributional semantic space. The induced function can then also be applied to a data-point whose label was not used for training. The word corresponding to the nearest neighbour of the mapped vector in the latter space is used as the label of the data point. Zero-shot learning using distributional semantic spaces was originally proposed for brain signal decoding (Mitchell et al., 2008), but it has since been extensively applied in other domains, including image labeling (Frome et al., 2013; Lazaridou et al., 2014; Socher et al., 2013) and bilingual dictionary/phrase table induction (Dinu and Baroni, 2014; Mikolov et al.,

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 270–280,
Beijing, China, July 26-31, 2015.

2013a), the two applications we focus on here.

Effective zero-shot learning by cross-space mapping could get us through the manual annotation bottleneck that hampers many applications. However, in practice, the accuracy in label retrieval with current mapping methods is still too low for practical uses. In image labeling, when a search space of realistic size is considered, accuracy is just above 1% (which is still well above chance for large search spaces). In bilingual lexicon induction, accuracy reaches values around 30% (across words of varying frequency), which are definitely more encouraging, but still indicate that only 1 word in 3 will be translated correctly.

In this article, we look at some general properties of the linear cross-modal mapping function standardly used for zero-shot learning, in order to achieve a better understanding of its shortcomings, and improve its quality by devising methods to overcome them. First, when the mapping function is estimated with least-squares error techniques, we observe a systematic increase in *hubness* (Radovanović et al., 2010b), that is, in the tendency of some vectors ("hubs") to appear in the top neighbour lists of many test items. We connect hubness to least-squares estimation, and we show how it is greatly mitigated when the mapping function is estimated with a max-margin ranking loss instead. Still, switching to max-margin greatly improves accuracy in the cross-linguistic context, but not for vision-to-language mapping. In the cross-modal setting, we observe indeed a different problem, that we name (training instance) *pollution*: The neighbourhoods of mapped test items are "polluted" by the target vectors used in training. This suggests that cross-modal mapping suffers from overfitting issues, and consequently from poor generalization power. Taking inspiration from domain adaptation, which addresses similar generalization concerns, and self-learning, we propose a technique to augment the training data with automatically constructed examples that force the function to generalize better. Having shown the advantages of a ranking loss, our final contribution is the adaptation of some insights from the max-margin literature to our setting, in particular concerning the choice of negative examples. This leads to further accuracy improvements. We thus conclude the paper by reporting zero-shot performances in both cross-modal and cross-language settings that are well above the current state of the art. Table 1 provides a roadmap and summary of our results.

	cross-linguistic	cross-modal
former state of art	33.0	0.5
standard mapping	29.7	1.1
max-margin - §3	39.4	1.9
data augmentation - §4	NA	3.7
negative evidence - §5	40.2	5.6

Table 1: **Roadmap.** Proposed changes to cross-space mapping training and resulting percentage Precision @1 in our two experimental setups.

2 Experimental Setup

Cross-linguistic experiments In the cross-linguistic experiments, we learn a mapping from the semantic space of language A to the semantic space of language B, which can then be used for translating words outside the training set. Specifically, given the vector representation of a word in language A, we apply the mapping to obtain an estimate of the vector representation of its meaning in language B, returning the nearest neighbour of the mapped vector in the B space as candidate translation. We focus on translating from English to Italian and adopt the setup (word vectors, training and test data) of Dinu et al. (2015). For a set of 200K words, 300-dimensional vectors were built using the word2vec toolkit,[1] choosing the CBOW method.[2] CBOW, which learns to predict a target word from the ones surrounding it, produces state-of-the-art results in many linguistic tasks (Baroni et al., 2014). The word vectors were induced from corpora of 2.8 and 1.6 billion tokens, respectively, for English and Italian.[3] The train and test English-to-Italian translation pairs were extracted from a Europarl-derived dictionary (Tiedemann, 2012).[4] The 5K most frequent translation pairs were used for training, while the test set includes 1.5K English words equally split into 5 frequency bins. The search for the correct translation is performed in a semantic space of 200K

[1] `https://code.google.com/p/word2vec/`

[2] Other hyperparameters, which we adopted without further tuning, include a context window size of 5 words to either side of the target, setting the sub-sampling option to 1e-05 and estimating the probability of target words by negative sampling, drawing 10 samples from the noise distribution (Mikolov et al., 2013b).

[3] Corpus sources: `http://wacky.sslmit.unibo.it`, `http://www.natcorp.ox.ac.uk`

[4] `http://opus.lingfil.uu.se/`

Italian words.[5]

Cross-modal experiments In the cross-modal experiments, we induce a mapping from visual to linguistic space. Specifically, given an image, we apply the mapping to its visual vector representation to obtain an estimate of its representation in linguistic space, where the word associated to the nearest neighbour is retrieved as the image label. Similarly to translation pairs in the cross-linguistic setup, we create a list of "visual translation" pairs between images and their corresponding noun labels. Our starting point are the 5.1K labels in ImageNet (Deng et al., 2009) that occur at least 500 times in our English corpus and have concreteness score $\geq$5, according to Turney et al. (2011). For each label, we sample 100 pictures from its ImageNet entry, and associate each picture with the 4094-dimensional layer (fc7) at the top of the pre-trained convolutional neural network model of Krizhevsky et al. (2012), using the Caffe toolkit (Jia et al., 2014). The target word space is identical to the English space used in the cross-linguistic experiment. Finally, we use 75% of the labels (and the respective images) for training and the remaining 25% of the labels for testing.[6] From the 127.5K images corresponding to test labels, we sample 1K images as our test set. For zero-shot evaluation purposes, the search for the correct label is performed in the space of 5.1K possible labels, unless otherwise specified. However, when quantifying hubness and pollution, in order to have a setting comparable to that of cross-language mapping, we use the full set of 200K English words as search space.

Learning objectives We assume that we have cross-space "translation" pairs available for a set of $|Tr|$ items $(\mathbf{x}_i, \mathbf{y}_i) = \{\mathbf{x}_i \in \mathbb{R}^{d1}, \mathbf{y}_i \in \mathbb{R}^{d2}\}$. Moreover, following previous work, we assume that the mapping function is linear. For estimating its parameters $\mathbf{W} \in \mathbb{R}^{d1 \times d2}$, we consider two objectives. The first is L2-penalized least squares (**ridge**):

$$\hat{\mathbf{W}} = \underset{\mathbf{W} \in \mathbb{R}^{d1 \times d2}}{\operatorname{argmin}} \|\mathbf{XW} - \mathbf{Y}\| + \lambda \|\mathbf{W}\|,$$

which has an analytical solution.

The second objective is a margin-based ranking loss (**max-margin**) similar in spirit to the one used in similar cross-modal experiments with WSABIE (Weston et al., 2011) and DeViSE (Frome et al., 2013). The loss for a given pair of training items $(\mathbf{x}_i, \mathbf{y}_i)$ and the corresponding mapping-based prediction $\hat{\mathbf{y}}_i = \mathbf{W}\mathbf{x}_i$ is defined as

$$\sum_{j \neq i}^{k} \max\{0, \gamma + dist(\hat{\mathbf{y}}_i, \mathbf{y}_i) - dist(\hat{\mathbf{y}}_i, \mathbf{y}_j)\},$$

where $dist$ is a distance measure, in our case the inverse cosine, and γ and k are tunable hyperparameters denoting the margin and the number of negative examples, respectively. Intuitively, the goal of the max-margin objective is to rank the correct translation $\mathbf{y}_i$ of $\mathbf{x}_i$ higher than any other possible translation $\mathbf{y}_j$. In theory, the summation in the equation could range over all possible labels, but in practice this is too expensive (e.g., in the cross-linguistic experiments the search space contains 200K candidate labels!), and it is usually computed over just a portion of the label space. In Weston et al. (2011), the authors propose an efficient way of selecting negative examples, in which they randomly sample, for each training item, labels from the complete set, and pick as negative sample the first label violating the margin. This guarantees that there will be exactly as many weight updates as training items. Another possibility is proposed in Mikolov et al. (2013b), where negative samples are picked from a non-item specific distribution (e.g., the uniform distribution).[7] For the experiments in Sections 3 and 4, we follow a more general setup in which the size of the margin and number of negative samples is tuned for each task. In this way, for a sufficiently large margin and number of negative samples, we increase the probability of performing a weight update per training item. We estimate the mapping parameters $\mathbf{W}$ with stochastic gradient descent and per-parameter learning rates tuned with Adagrad (Duchi et al., 2011). The tuning of hyperparameters γ and k is performed on a random 25% subset of the training data.

[5] Faithful to the zero-shot setup, in our experiments there is never any overlap between train and test words; however, to make the task more challenging, we include the train words in the search space, except where expressly indicated.

[6] At training time, we average the 100 vectors associated to a label into a single representation, to reduce training set size while minimizing information loss. At test time, as normally done, we present the model with single image visual vectors.

[7] The notion of negative samples is not unique to margin-based learning; in Mikolov et al. (2013b), the authors used it to efficiently estimate a word probability distribution.

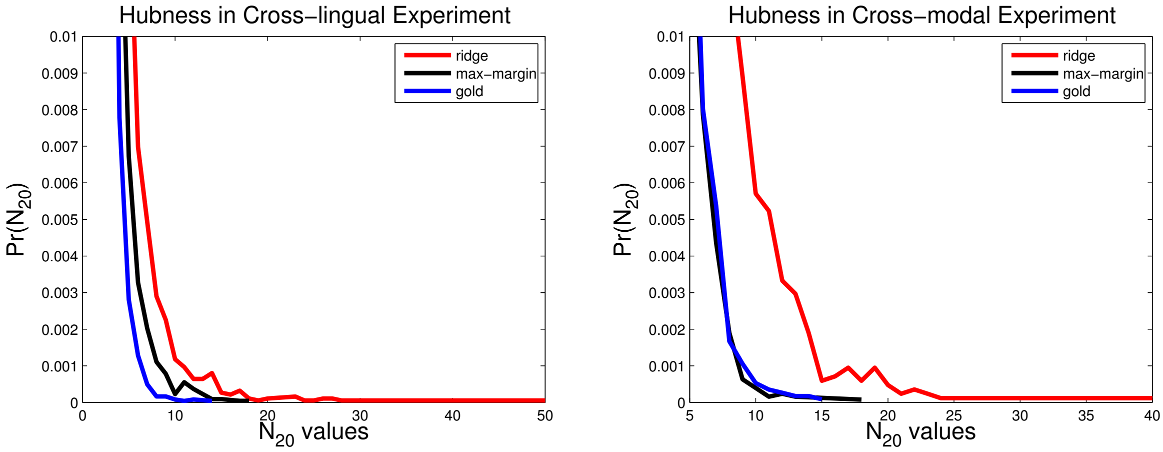

Figure 1: **Hubness distribution in cross-linguistic (left) and cross-modal (right) search spaces.** The hubness score (N_{20}) is computed on the top-20 neighbour lists of the test items, using their original (gold), ridge- or max-margin-mapped vectors as query terms.

3 Hubness

High-dimensional spaces are often affected by *hubness* (Radovanović et al., 2010b; Radovanović et al., 2010a), that is, they contain certain elements – *hubs* – that are near many other points in space without being similar to the latter in any meaningful way. As recently noted by Dinu et al. (2015), the hubness problem is greatly exacerbated when one looks at the nearest neighbours of vectors that have been mapped across spaces with **ridge**.[8] Given a set of query vectors with the corresponding top-k nearest neighbour lists, we can quantify the degree of hubness of an item in the search space (parameterized by k) by the number of lists in which it occurs. $N_k(y)$, the *hubness* at k of an item y, is computed as follows:

$$N_k(y) = |\{x \in T | y \in NN_k(x, S)\}|,$$

where S denotes the search space, T denotes the set of query items and $NN_k(x, S)$ denotes the k nearest neighbors of x in S.

Figure 1 reports N_{20} distributions across the cross-linguistic and cross-modal search spaces, using the respective test items as query vectors. The blue line shows the distributions for the "gold" vectors (that is, the vectors in the target space we would like to approximate). The red line shows the same distributions when neighbours are queried for the ridge-mapped test vectors (ignore black lines for now). In both spaces, when the query vectors are mapped, hubness increases dramatically. The largest hubs for the original test items occur in 15 neighbour lists or less. With the mapped vectors, we find hubs occurring in 40 lists or more. The figure also shows that, in both spaces, we observe more points with smaller but non-negligible N_{20} (e.g., around 10) when mapped vectors are queried. In both spaces, the difference in hubness is very significant according to a cross-tab test ($p<10^{-30}$). Finally, as Table 2 shows, the largest hubs are by no means terms that we might expect to occur as neighbours of many other items on semantic grounds (e.g., very general terms), but rather very specific and rare words whose high hubness cannot possibly be a genuine semantic property.

Cross-linguistic	Cross-modal
blockmonthon (50)	smilodon (40)
hashim (28)	pintle (33)
akayev (27)	knurled (27)
autogiustificazione (27)	handwheel (24)
limassol (26)	circlip (23)
regulars (26)	black-footed (23)
18 (25)	flatbread (22)

Table 2: **Top ridge hubs**, together with N_{20} scores. Note that cross-linguistic hubs are supposed to be *Italian* words.

Causes of hubness Why should the mapping function lead to an increase in hubness? We conjecture that this is due to an intrinsic property of least-squares estimation. Given the training ma-

[8] Dinu et al. (2015) observe, but do not attempt to understand hubness, as we do here. They propose to address it with methods to re-rank neighbour lists, which are less general and should be largely complementary to our effort to improve estimation of the cross-mapping function.

trices $\mathbf{X}$ and $\mathbf{Y}$, and the projection matrix $\mathbf{W}$ obtained by minimizing squared error, each column $\hat{\mathbf{y}}_{*,i}$ of $\hat{\mathbf{Y}} = \mathbf{XW}$ is the orthogonal projection of $\mathbf{y}_{*,i}$, the corresponding $\mathbf{Y}$ column onto the column space of $\mathbf{X}$ (Strang, 2003, Ch. 4). Consequently, $\mathbf{y}_{*,i} = \boldsymbol{\epsilon}_i + \hat{\mathbf{y}}_{*,i}$, where the $\boldsymbol{\epsilon}_i$ error vector is orthogonal to $\hat{\mathbf{y}}_{*,i}$. It follows that $||\mathbf{y}_{*,i}||^2 \geq= ||\hat{\mathbf{y}}_{*,i}||^2$. Since $\mathbf{y}_{*,i}$ and $\hat{\mathbf{y}}_{*,i}$ have equal means (because the error terms in $\boldsymbol{\epsilon}_i$ must sum to 0), it immediately follows from the squared length inequality that $\hat{\mathbf{y}}_{*,i}$ has lower or equal variance to $\mathbf{y}_{*,i}$. Since this holds for all columns of $\hat{\mathbf{Y}}$, it follows in turn that the set of mapped vectors in $\hat{\mathbf{Y}}$ has lower or equal variance to the corresponding set of original vectors in $\mathbf{Y}$. Coming back to hubness, a set of lower variance points (such as the mapped vectors) will result in higher hubness since the points will on average be closer to each other. The problem is likely to be further exacerbated by the property of least-squares to ignore relative distances between points (the objective only aims at making predicted and observed vectors look like each other),

Strictly, the theoretical result only holds for the training points. However, to the extent that the training set is representative of what will be encountered in the test set, it should also extend to test data (and if training and testing data are very different, the mapping function will generalize very poorly anyway). Moreover, the result holds for a pure least-squares solution, without the ridge L2 regularization term. Whether it also applies to ridge-based estimates will depend on the relative impact of the least-squares and L2 terms on the final solution (and it is not excluded that the L2 term might also independently reduce variance, of course). Empirically, we find that, indeed, lower variance also characterizes test vectors mapped with a ridge-estimated function.

Interestingly, in the literature on cross-space mapping we find that authors choose a different cost function than ridge, without motivating the choice. Socher et al. (2014) mention in passing that max-margin outperforms a least-squared-error cost for cross-modal mapping.

Max-margin as a solution to hubness Referring back to Figure 1, we see that when ridge estimation is replaced by max-margin (black line), there is a considerable decrease in hubness in both settings. This is directly reflected in a large increase in performance in our cross-linguistic (English-to-Italian) zero-shot task (left two columns of Table 3), with the largest improvement for the all important P@1 measure (equivalent to accuracy).[9] These results are well above the current best cross-language accuracy for cross-modal mapping without added orthographic cues (33%), attained by Mikolov et al. (2013a).[10] The absolute performance figures are low in the challenging cross-modal setting, but here too we observe a considerable improvement in accuracy when max-margin is applied. Indeed, we are already above the cross-modal zero-shot mapping state of the art for a search space of similar size (0.5% accuracy in Frome et al. (2013)). Still, the improvement over ridge (while present) is not as large for the less strict (higher ranks) performance scores.

Table 4 confirms that the improvement brought about by max-margin is indeed (at least partially) due to hubness reduction. A large proportion of vectors retrieved as top-1 predictions (translations/labels) are hubs when mapping is trained with ridge, but the proportion drops dramatically with max-margin. Still, more than 1/5 top predictions for cross-modal mapping with max-margin are hubs (vs. less than 1/10 for the original vectors). Now, the mathematical properties we reviewed above suggest that, for least-squares estimation, hubness is caused by general reduced variance of the space after mapping. Thus, hubs should be vectors that are near the mean of the space. The first row of Table 5 confirms that the hubs found in the neighbourhoods of ridge-mapped query terms are items that tend to be closer to the search space mean vector, and that this effect is radically reduced with max-margin estimation. However, the second row of the table shows another factor at play, that has a major role in the cross-modal setting, and it is only partially addressed by max-margin estimation: Namely, in vision-to-language mapping, there is a strong tendency for hubs (that, recall, have an important effect on performance, as they enter many nearest neighbour lists) to be close to a training data point.

[9] We have no realistic upper-bound estimate, but due to different word senses, synonymy, etc., it is certainly not 100%.

[10] Although the numbers are not fully comparable because of different language pairs and various methodological details, their method is essentially equivalent to our **ridge** approach we are clearly outperforming.

	Cross-linguistic		Cross-modal	
	ridge	**max-margin**	**ridge**	**max-margin**

4 Pollution

The quantitative results and post-hoc analysis of hubs in Section 3 suggest that cross-modal mapping is facing a serious generalization problem. To get a better grasp of the phenomenon, we define a binary measure of *(training data) pollution* for a queried item x and parameterized by k, such that pollution is 1 if x has a (target) training item y among its k nearest neighbours, 0 otherwise. Formally:

$$\mathrm{N}^{\mathrm{pol}}_{\mathrm{k,S}}(\mathrm{x}) = [\![\exists \mathrm{y} \in \mathbf{Y}^{Tr} : y \in \mathrm{NN}_{\mathrm{k,S}}(\mathrm{x})]\!],$$

where $\mathbf{Y}^{Tr}$ is the matrix of target vectors used in training, $\mathrm{NN}_{\mathrm{k,S}}(\mathrm{y})$ denotes the top k neighbors of y in search space S, and $[\![\mathrm{z}]\!]$ is an indicator function.[11]

The average pollution $\mathrm{N}^{\mathrm{pol}}_{1,\mathrm{S}}$ of all test items in the cross-modal experiment, when $|\mathrm{S}|=200K$ is 18%, which indicates that in 1/5 of cases the returned label is that of a training point. The equivalent statistic in the cross-linguistic experiment drops to 8.7% (words tend to be more varied than the set of concrete, imageable concepts used for image annotation tasks, and so the cross-linguistic training set is probably less uniform than the one used in the vision-to-language setting).

The real extent of the generalization problem in the cross-modal setup becomes more obvious if we restrict the search space to labels effectively associated to an image in our data set ($|\mathrm{S}|=5.1K$). In this case, the average pollution $\mathrm{N}^{\mathrm{pol}}_{1,\mathrm{S}}$ across all test items jumps to 88%, that is, the vast majority of test images are annotated with a label coming from the training data. Clearly, there is a serious problem of overfitting to the training subspace. While we came to this observation by inspecting the properties of hubs, other work in zero-shot for image labeling has indirectly noted the same. Frome et al. (2013) empirically showed that the performance of the system is higher when removing training labels from the search space, while Norouzi et al. (2014) proposed a zero-shot method that avoids explicit cross-modal mapping.

Adapting to the full search space by data augmentation High training-data pollution indicates that cross-modal mapping does not generalize well beyond the kind of data points it encountered in learning. This is a special case of the *dataset bias* problem (Torralba and Efros, 2011) and, given that the latter has been addressed as a domain adaptation problem (Gong et al., 2012; Donahue et al., 2013), we adopt here a similar view. Self-training has been successfully used for domain adaptation in NLP, e.g., in syntactic parsing. Given the limited amount of syntactically annotated data coming from monotonous sources (e.g., the Wall Street Journal), parsers show a big drop in performance when applied to different domains (e.g., reviews), since training and test domains differ dramatically, thus affecting their generalization performance. In a nutshell, the idea behind self-training (McClosky et al., 2006; Reichart and Rappoport, 2007) is to use manually annotated data $(\mathrm{x}^{\mathrm{A}}_{\mathrm{i}}, .., \mathrm{x}^{\mathrm{A}}_{\mathrm{N}}, \mathrm{y}^{\mathrm{A}}_{\mathrm{i}}, .., \mathrm{y}^{\mathrm{A}}_{\mathrm{N}})$ from domain A to train a parser, feed the trained parser with data $\mathrm{x}^{\mathrm{B}}_{\mathrm{i}}, .., \mathrm{x}^{\mathrm{B}}_{\mathrm{K}}$ from domain B in order to obtain their automated annotations $\hat{\mathrm{y}}^{\mathrm{B}}_{\mathrm{i}}, .., \hat{\mathrm{y}}^{\mathrm{B}}_{\mathrm{K}}$ and then retrain the parser

[11] Pollution is of course an effect of overfitting, but we use this more specific term to refer to the tendency of training vectors to "pollute" nearest neighbour lists of mapped vectors.

dolphin	tarantula	highland
whale	anteater	whisky
orca	arachnid	lowland

P@10	9.0	15.8	15.9

Table 7: **Cross-modal zero-shot experiment with data augmentation.** Labeling precision @N with no data augmentation (**none**) and when using top 5 (**chimera-5**) and top 10 (**chimera-10**) nearest neighbors from training set of each item in the search space to build the corresponding chimeras (1K test items, 5.1K search space).

with a combination of "clean" data from domain A and "noisy" data from domain B.

In our setup, self-training would be applied by labeling a larger set of images with a cross-modal mapping function estimated on the initial training data, and then using both sources of labeled data to retrain the function. Although the idea of self-training for inducing cross-modal mapping functions is appealing, especially given the vast amount of unlabeled data available out there, the very low performance of current cross-modal mapping functions makes the effort questionable. We would like to exploit unannotated data representative of the search space, *without* relying on the output of cross-modal mapping for their annotation. One way to achieve this is to use *data augmentation* techniques that are representative of the search space. Data augmentation is popular in computer vision, where it is performed (among others) by data jittering, visual sampling or image perturbations. It has proven beneficial for both "deep" (Krizhevsky et al., 2012; Zeiler and Fergus, 2014) and "shallow" (Chatfield et al., 2014) systems, and it was recently introduced to NLP tasks (Zhang and LeCun, 2015).

Specifically, in order to train the mapping function using both annotated data and points that are representative of the full search space, we rely on a form of data augmentation that we call *visual chimera* creation. For every item $y_i \notin \mathbf{Y}^{Tr}$ in the search space S, we use linguistic similarity as a proxy of visual similarity, and create its *visual vector* $\hat{x}_i$ by averaging the visual vectors corresponding to the nearest words in language space that do occur as labels in the training set. Table 6 presents some examples of visual chimeras. For y_i=*dolphin*, the visual vectors of other cetacean mammals are averaged to create the chimera $\hat{x}_i$. Since linguistic similarity is not always determined by visual factors, the method also produces noisy data points. For y_i=*tarantula*, *opossums* enter the picture, while for y_i=*highland* images of "topically" similar concepts are used (e.g., *bagpipe*).

Table 7 reports cross-modal zero-shot labeling when training with **max-margin** and data augmentation. We experiment with visual chimeras constructed using 5 vs. 10 nearest neighbours. While the examples above suggest that the process injects some noise in the training data, we also observe a decrease of pollution $N^{pol}_{1,S}$ from 88% when using the "clean" training data, to 71% and 73% when expanding them with chimeras (for **chimera-5** and **chimera-10**, respectively). Reflecting this drop in pollution, we see large improvements in precision at all levels, when chimeras are used (no big differences between 5 or 10 neighbours).

The improvements brought about by the chimera method are robust. First, Table 8 reports performance when the search space excludes the training labels, showing that data augmentation is beneficial beyond mitigating the bias in favor of the latter. In this setup, **chimera-5** is clearly outperforming **chimera-10** (longer neighbour lists will include more noise), and we focus on it from here on.

All experiments up to here follow the standard cross-modal zero-shot protocol, in which the search space is given by the union of the test and training labels, or a subset thereof. Next, we make the task more challenging by increasing it with 1K extra elements acting as distractors. The distractors are either randomly sampled from our usual 200K English word space, or, in the most challenging scenario, picked among those words, in the same space, that are among the top-5 near-

	none	chimera-5	chimera-10

P@10	29.9	34.3	29.7

Table 8: **Cross-modal zero-shot experiment with data augmentation, disjoint train/search spaces.** Same setup as Table 8, but search space excludes training elements (1K test items, 1K search space).

	random		related	
	none	**chimera-5**	**none**	**chimera-5**
P@1	0.8	3.3	1.9	2.8
P@5	5.3	9.0	4.8	8.8
P@10	8.8	13.3	7.9	12.6

Table 9: **Cross-modal zero-shot experiment with data augmentation, enlarged search space.** Labeling precision @N with no data augmentation (**none**) and when using top 5 (**chimera-5**) nearest neighbors from training set of each item in the search space to build the corresponding chimeras. Test items: 1K. Search space: 5.1K+1K extra distractors from a 200K word space, either randomly picked (*random*), or *related* to the training items.

est neighbours of a training element. Again, we create one visual chimera for each label in the search space. Results are presented in Table 9. As expected, performance is negatively affected with both plain and data-augmented models, but the latter is still better in absolute terms. While **chimera-5** undergoes a larger drop when the search contains many elements similar to the training data ("related" column), which is explained by the fact that visual chimeras will often include the distractor items of this setup, it appears to be more resistant against random labels, which in many cases are words that bear no resemblance to the training data (e.g., *naushad*, *yamato*, *13-14*). The picture when using no data augmentation is exactly the opposite, with the model being more harmed, at P@1, by the random labels.

Finally, Table 10 presents results in the cross-linguistic setup, when applying the same data augmentation technique. In this case, we augment the 5K training elements with 11.5K chimeras, for the 1.5K test elements and 10K randomly sampled distractors. For these 11.5K elements, we associate their Italian (target space) label $\mathrm{y_i}$ with a "pseudo-translation" vector $\hat{\mathrm{x}}_\mathrm{i}$ obtained by averaging the vectors of the English (source space) translations of the nearest Italian words to $\mathrm{y_i}$ included in the training set. Results, in Table 10, show that in this case our data augmentation method is actually hampering performance. We saw that pollution affects the cross-linguistic setup much less than it affects the cross-modal one, and we conjecture that, consequently, in the translation task, there is not a large-enough generalization gain to make up for the extra noise introduced by augmentation.

	none	chimera-5

P@5	54.2	46.1
P@10	60.4	51.3

Table 10: **Cross-linguistic zero-shot experiment with data augmentation**. Translation precision @N when learning with **max-margin** and no data augmentation (**none**) or data augmentation using the top 5 (**chimera-5**) nearest neighbors of 11.5K items in the 200K-word search space (1.5K test items).

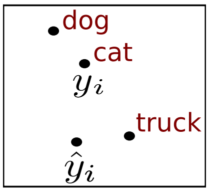

Figure 2: **Looking for intruders.** We pick *truck* rather than *dog* as negative example for *cat*.

5 Picking informative negative examples

An interesting feature of the ranking max-margin objective lies in its active use of negative examples. While previous work in cross-space mapping has paid little attention to the properties that negative samples should possess, this has not gone unnoticed in the NLP literature on structured prediction tasks. Smith and Eisner (2005) propose a contrastive estimation framework in the context of POS-tagging, in which positive evidence derived from gold sentence annotations is extended with negative evidence derived by various *neighbourhood functions* that corrupt the data in particular ways (e.g., by deleting 1 word).

Having shown the effectiveness of max-margin estimation in the previous sections, we now take

	Cross-linguistic		Cross-modal	
	random	**intruder**	**random**	**intruder**
P@1	38.4	40.2	3.7	5.6
P@5	54.2	55.5	10.9	12.4
P@10	60.4	61.8	15.8	17.8

Table 11: **Random vs. intruding negative examples.** Zero-shot precision @N results when cross-space function is estimated using **max-margin** with random or "intruder" negative examples, cross-linguistically (test items: 1.5K, search space: 200K) and cross-modally (test items: 1K, search space: 5.1K).

a first step towards engineering the negative evidence exploited by this method, in the context of inducing cross-space mapping functions. In particular, our idea is that, given a training instance $\mathrm{x_i}$, an informative negative example would be *near* the mapped vector $\mathrm{\hat{y}_i}$, but *far* from the actual gold target space vector $\mathrm{y_i}$. Intuitively, such "intruders" correspond to cases where the mapping function is getting the predictions seriously wrong, and thus they should be very informative in "correcting" the function mapping trajectories. This can seen as a vector-space interpretation of the *max-loss* update protocol (Crammer et al., 2006) that picks negative samples expected to harm performance more. Figure 2 illustrates the idea with a cartoon example. If *cat* is the gold target vector $\mathrm{y_i}$ and $\mathrm{\hat{y}_i}$ the corresponding mapped vector, then we are going to pick *truck* as negative example, since it is an intruder (near the mapped vector, far from the gold one).

More formally, at each step of stochastic gradient descent, given a source space vector $\mathrm{x_i}$, its target gold label/translation $\mathrm{y_i}$ in $\mathbf{Y}^{Tr}$ and the mapped vector $\mathrm{\hat{y}_i}$, we compute $\mathrm{s_j} = \cos(\mathrm{\hat{y}_i}, \mathrm{y_j}) - \cos(\mathrm{y_i}, \mathrm{y_j})$, for all vectors $\mathrm{y_j}$ in $\mathbf{Y}^{Tr}$ s.t. $j \neq i$, and pick as negative example for $\mathrm{x_i}$ the vector with the largest $\mathrm{s_j}$.

Table 11 presents zero-shot mapping results when intruding negative examples are used for max-margin estimation. For cross-modal mapping, we apply data augmentation as described in the previous section. While the absolute performance increase is relatively small (less than 2% in both setups), it is consistent. Furthermore, the proposed protocol results in lower $\mathrm{N}^{\mathrm{pol}}_{1,\mathrm{S}}$ pollution in the cross-modal setup (from 71% to 63%). Finally, we observe that the learning behaviour of the two protocols (intruders vs. random) is different; the **intruder** approach is already achieving good performance after just few training epochs, since it can rely on more informative negative samples (see Figure 3).

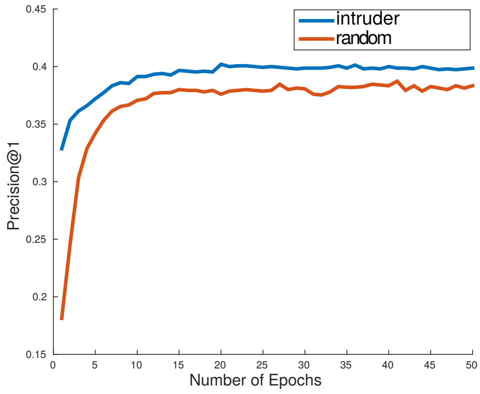

Figure 3: **Learning curve with random or intruding negative samples** in the cross-linguistic experiment.

6 Conclusion

We have considered some general mathematical and empirical properties of linear cross-space mapping functions, suggesting one well-known (max-margin estimation) and two new (chimera augmentation and "intruder" negative sample adjustment) methods to improve their performance. With them, we achieve results well above the state of the art in both the cross-linguistic and the cross-modal setting. Both chimera and the intruder methods are flexible, and we plan to explore them further in future research. In particular, we want to devise more semantically-motivated methods to select chimera components and negative samples.

Abstract

Over the last two decades, numerous algorithms have been developed that successfully capture something of the semantics of single words by looking at their distribution in text and comparing these distributions in a vector space model. However, it is not straightforward to construct meaning representations beyond the level of individual words – i.e. the combination of words into larger units – using distributional methods. Our contribution is twofold. First of all, we carry out a large-scale evaluation, comparing different composition methods within the distributional framework for the cases of both adjective-noun and noun-noun composition, making use of a newly developed dataset. Secondly, we propose a novel method for composition, which generalises the approach by Baroni and Zamparelli (2010). The performance of our novel method is also evaluated on our new dataset and proves competitive with the best methods.

1 Introduction

In the course of the last two decades, there has been a growing interest in distributional methods for lexical semantics (Landauer and Dumais, 1997; Lin, 1998; Turney and Pantel, 2010). These methods are based on the distributional hypothesis (Harris, 1954), according to which words that appear in the same contexts tend to be similar in meaning. Inspired by Harris' hypothesis, numerous researchers have developed algorithms that try to capture the semantics of individual words by looking at their distribution in a large corpus.

Compared to manual studies common to formal semantics, distributional semantics offers substantially larger coverage since it is able to analyze massive amounts of empirical data. However, it is not trivial to combine the algebraic objects created by distributional semantics to get a sensible distributional representation for more complex expressions, consisting of several words. On the other hand, the formalism of the λ-calculus provides us with general, advanced and efficient methods for composition that can model meaning composition not only of simple phrases, but also more complex phenomena such as coercion or composition with fine-grained types (Asher, 2011; Luo, 2010; Bassac et al., 2010). Despite continued efforts to find a general method for composition and various approaches for the composition of specific syntactic structures (e.g. adjective-noun composition, or the composition of transitive verbs and direct objects (Mitchell and Lapata, 2008; Coecke et al., 2010; Baroni and Zamparelli, 2010)), the modeling of compositionality is still an important challenge for distributional semantics. Moreover, the validation of proposed methods for composition has used relatively small datasets of human similarity judgements (Mitchell and Lapata, 2008).[1] Although such studies comparing similarity judgements have their merits, it would be interesting to have studies that evaluate methods for composition on a larger scale, using a larger test set of different specific compositions. Such an evaluation would allow us to evaluate more thoroughly the different methods of composition that have been proposed. This is one of the goals of this paper.

To achieve this goal, we make use of two different resources. We have constructed a dataset for French containing a large number of pairs of a compositional expression (adjective-noun) and a single noun that is semantically close or identical to the composed expression. These pairs have been extracted semi-automatically from

[1] A notable exception is (Marelli et al., 2014), who propose a large-scale evaluation dataset for composition at the sentence level.

and the 7th International Joint Conference on Natural Language Processing*, pages 281–291,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

the French Wiktionary. We have also used the Semeval 2013 dataset of phrasal similarity judgements for English with similar pairs extracted semi-automatically from the English Wiktionary to construct a dataset for English for both adjective-noun and noun-noun composition. This affords us a cross-linguistic comparison of the methods.

These data sets provide a substantial evaluation of the performance of different compositional methods. We have tested three different methods of composition proposed in the literature, viz. the additive and multiplicative model (Mitchell and Lapata, 2008), as well as the lexical function approach (Baroni and Zamparelli, 2010).

The two first methods are entirely general, and take as input automatically constructed vectors for adjectives and nouns. The method by Baroni and Zamparelli, on the other hand, requires the acquisition of a particular function for each adjective, represented by a matrix. The second goal of our paper is to generalise the functional approach in order to eliminate the need for an individual function for each adjective. To this goal, we automatically learn a generalised lexical function, based on Baroni and Zamparelli's approach. This generalised function combines with an adjective vector and a noun vector in a generalised way. The performance of our novel generalised lexical function approach is evaluated on our test sets and proves competitive with the best, extant methods.

Our paper is organized as follows. First, we discuss the different compositional models that we have evaluated in our study, briefly revisiting the different existing methods for composition, followed by a description of our generalisation of the lexical function approach. Next, we report on our evaluation method and its results. The results section is followed by a section that discusses work related to ours. Lastly, we draw conclusions and lay out some avenues for future work.

2 Composition methods

2.1 Simple Models of Composition

In this section, we describe the composition models for the adjective-noun case. The extension of these models to the noun-noun case is straightforward; one just needs to replace the adjective by the subordinate noun. Admittedly, choosing which noun is subordinate in noun-noun composition may be an interesting problem but it is outside the scope of this paper. We tested three simple models of composition: a baseline method that discounts the contribution of the adjective completely, and the additive and multiplicative models of composition. The baseline method is defined as follows:

$$\text{Comp}_{\text{baseline}}(\text{adj}, \text{noun}) = \mathbf{noun}$$

The additive model adds the point-wise values of the adjective vector **adj** and noun vector **noun** using independent coefficients to provide a result for the composition:

$$\text{Comp}_{\text{additive}}(\text{adj}, \text{noun}) = \alpha\,\mathbf{noun} + \beta\,\mathbf{adj}$$

The multiplicative model consists in a point-wise multiplication of the vectors **adj** and **noun**:

$$\text{Comp}_{\text{multiplicative}}(\text{adj}, \text{noun}) = \mathbf{noun} \otimes \mathbf{adj}$$
$$\text{with} \quad (\mathbf{noun} \otimes \mathbf{adj})_i = \mathbf{noun}_i \times \mathbf{adj}_i$$

2.2 The lexical function model

Baroni and Zamparelli's (2010) lexical function model (LF) is somewhat more complex. Adjective-noun composition is modeled as the functional application of an adjective meaning (represented as a matrix) to a noun meaning (represented as a vector). Thus, the combination of an adjective and noun is the product of the matrix **ADJ** and the vector **noun** as shown in Figure 1.

Baroni and Zamparelli propose learning an adjective's matrix from examples of the vectors for **adj_noun** obtained directly from the corpus. These vectors **adj_noun** are obtained in the same way as vectors representing a single word: when the adjective-noun combination occurs, we observe its context and construct the vector from those observations. As an illustration, consider the example in 2. The word *name* appears three times modified by an adjective in the following excerpt from Oscar Wilde's *The Importance of Being Earnest*. This informs us about the cooccurrence frequencies of three vectors: one for **divine_name**, another for **nice_name**, and one for **charming_name**.

Once the **adj_noun** vectors have been created for a given adjective, we are able to calculate the **ADJ** matrix using a least squares regression that minimizes the equation **ADJ**×**adj_noun** − **noun**. More formally, the problem is the following:

Find **ADJ** s.t.
$\sum_{\text{noun}}(\mathbf{ADJ} \times \mathbf{noun} - \mathbf{adj\_noun})^2$
is minimal

$$\text{Composition}_{\text{LF}}(\text{adjective, noun}) = \boxed{\textbf{ADJECTIVE}} \times \boxed{\begin{matrix}\mathbf{n}\\ \mathbf{o}\\ \mathbf{u}\\ \mathbf{n}\end{matrix}}$$

Figure 1: Lexical Function Composition

Jack: Personally, darling, to speak quite candidly, I don't much care about the name of Ernest . . . I don't think the name suits me at all.
Gwendolen: It suits you perfectly. It is a divine [name]. It has a music of its own. It produces vibrations.
Jack: Well, really, Gwendolen, I must say that I think there are lots of other much nicer [names]. I think Jack, for instance, is a charming [name].

Figure 2: Excerpt from Oscar Wilde's *The Importance of Being Earnest*

For our example, we would minimize, among others DIVINE×**divine_name** – **name** to get the matrix for DIVINE.

LF requires a large corpus, because we have to observe a sufficient number of examples of the adjective and noun combined, which are perforce less exemplified than the presence of the noun or adjective in isolation. In Figure 2, each of the occurrences of 'name' can contribute to the information in the vector **name** but none can contribute to the vector **evanescent_name**.

Baroni and Zamparelli (2010) offer an explanation of how to cope with the potential sparse data problem for learning matrices for adjectives. Moreover, recent evaluations of LF show that existent corpora have enough data for it to provide a semantics for the most frequent adjectives and obtain better results than other methods (Dinu et al., 2013b).

Nevertheless, LF has limitations in treating relatively rare adjectives. For example, the adjective 'evanescent' appears 359 times in the UKWaC corpus (Baroni et al., 2009). This is enough to generate a vector for **evanescent**, but may not be sufficient to generate a sufficient number of vectors **evanescent_noun** to build the matrix EVANESCENT. More importantly, for noun-noun combinations, one may need to have a LF for a combination. To get the meaning of *blood donation campaign* in the LF approach, the matrix BLOOD_DONATION must be combined to the vector **campaign**. Learning this matrix would require to build vectors **blood_donation_noun** for many nouns. Even if it were possible, the issue would arise again for *blood donation campaign plan*, then for *blood donation campaign plan meeting* and so forth.

In addition, LF's approach to adjectival meaning and composition has a theoretical drawback. Like Montague Grammar, it supposes that the effect of an adjective on a noun meaning is specific to the adjective (Kamp, 1975). However, recent studies suggest that the Montague approach overgeneralises from the worst case, and that the vast majority of adjectives in the world's languages are subsective, suggesting that the modification of nominal meaning that results from their composition with a noun follows general principles (Partee, 2010; Asher, 2011) that are independent of the presence or absence of examples of association.

2.3 Generalised LF

To solve these problems, we generalise LF and replace individual matrices for adjectival meanings by a single lexical function: a tensor for adjectival composition $\mathscr{A}$.[2] Our proposal is that adjective-noun composition is carried out by multiplying the tensor $\mathscr{A}$ with the vector for the adjective **adj**, followed by a multiplication with the vector **noun**, *c.f.* Figure 3.

The product of the tensor $\mathscr{A}$ and the vector **adj** yields a matrix dependent of the adjective that is multiplied with the vector **noun**. This matrix corresponds to the LF matrix ADJ. As indicated in Figure 4, we obtain $\mathscr{A}$ with the help of matrices obtained from the LF approach, and from vectors for single words easily obtained in distributional semantics; we perform a least square regression minimizing the norm of the matrices generated by the equations in Figure 4. Formally, the problem is

[2] A tensor generalises a matrix to several dimensions. We use a tensor in three modes. For an introduction to tensors, see (Kolda and Bader, 2009).

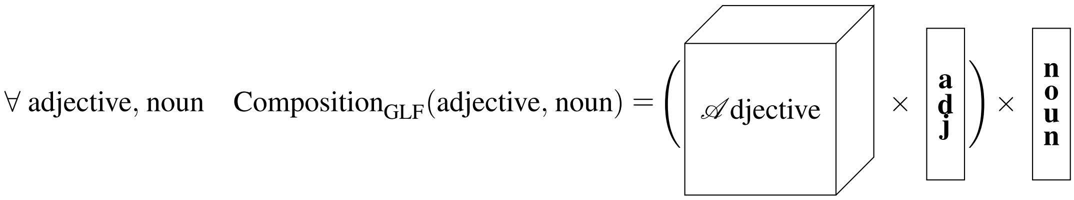

Figure 3: Composition in the generalised lexical function model

Find $\mathscr{A}$ s.t.
$\sum_{\text{adj}}(\mathscr{A} \times \mathbf{adj} - \textbf{ADJ})^2$
is minimal

Note that our tensor is not just the compilation of the information found in the LF matrices: the adjective mode of our tensor has a limited number of dimensions, whereas the LF approach creates a separate matrix for each individual adjective. This reduction forces the model to generalise, and we hypothesise that this generalisation allows us to make proper noun modifications even in the light of sparse data.

Our approach requires learning a significant number of matrices **ADJ**. This is not a problem, since FRWaC and UKWaC provide sufficient data for the LF approach to generate matrices for a significant number of adjectives. For example, the 2000th most frequent adjective in FRWaC ('fasciste') has more than 4000 occurrences.

To return to our example of *blood donation campaign*, once the tensor $\mathscr{N}$ for noun-noun composition is learned, our approach requires only the knowledge of the vectors **blood**, **donation** and **campaign**. We would then perform the following computations:

$$\mathbf{blood\_donation} = (\mathscr{N} \times \mathbf{blood}) \times \mathbf{donation}$$
$$\mathbf{blood\_donation\_campaign} = (\mathscr{N} \times \mathbf{blood\_donation}) \times \mathbf{campaign}$$

and this allows us to avoid the sparse data problem for the LF approach in generating the matrix **BLOOD_DONATION**.

Once we have obtained the tensor $\mathscr{A}$, we verify experimentally its relevance to composition, in order to check whether a tensor optimising the equations in Figure 4 would be semantically interesting.

3 Evaluation

3.1 Tasks description

In order to evaluate the different composition methods, we constructed test sets for French and English, inspired by the work of Zanzotto et al. (2010) and the SEMEVAL-2013 task *evaluating phrasal semantics* (Korkontzelos et al., 2013). The task is to make a judgement about the semantic similarity of a short word sequence (an adjective-noun combination) and a single noun. This is important, as composition models need to be able to treat word sequences of arbitrary length. Formally, the task is presented as:

With	$\mathbf{comp} = \text{composition}(\text{adj}, \text{noun}_1)$
Evaluate	$\text{similarity}(\mathbf{comp}, \mathbf{noun_2})$

where the 'composition' function is carried out by the different composition models. 'Similarity' needs to be a binary function, with return values 'similar' and 'non-similar'. Note, however, that the distributional approach yields a continuous similarity value (such as the cosine similarity between two vectors). In order to determine which cosine values correspond to 'similar' and which cosine values correspond to 'non-similar', we looked at a number of examples from a development set. More precisely, we carried out a logistic regression on 50 positive and 50 negative examples (separate from our test set) in order to automatically learn the threshold at which a pair is considered to be similar. Finally, we decided to use balanced test sets containing as many positive instances as negative ones.

The test set is constructed in a semi-automatic way, making use of the canonical phrasing of dictionary definitions. Take for example the definition of *bassoon* in the English Wiktionary[3], presented in Figure 5. It is quite straightforward to extract the pair (*musical_instrument*, *bassoon*) from this definition. Using a large dictionary (such as Wiktionary), it is then possible to extract a large number of positive – i.e. similar – (`adjective_noun`, `noun`) pairs.

For the construction of our test set for French, we downloaded all entries of the French Wiktionary (*Wiktionnaire*) and annotated them with

[3] `http://en.wiktionary.org/wiki/bassoon`, accessed on 26 February 2015.

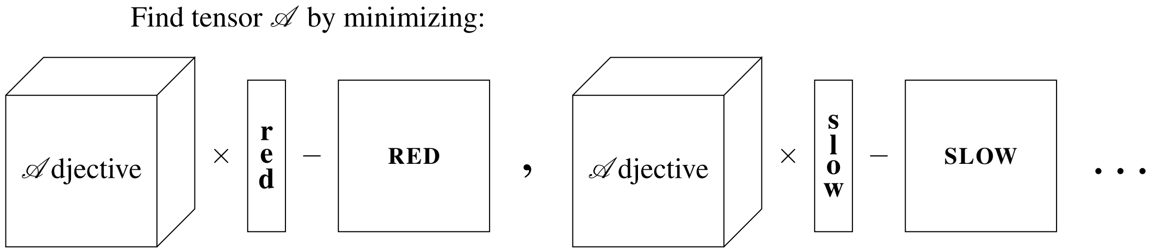

Figure 4: Learning the $\mathscr{A}$djective tensor

bassoon /bəˈsuːn/ (plural bassoons)

1. A musical instrument in the woodwind family, having a double reed and, playing in the tenor and bass ranges.

Figure 5: Definition of *bassoon*, extracted from the English Wiktionary

part of speech tags, using the French part of speech tagger MElt (Denis et al., 2010). Next, we extracted all definitions that start with an adjective-noun combination. As a final step, we filtered all instances containing words that appear too infrequently in our FRWaC corpus.[4]

The automatically extracted instances were then checked manually, and all instances that were considered incorrect were rejected. This gave us a final test set of 714 positive examples.

We also created an initial set of negative examples, where we combined an existing combination of `adjective_noun1` (extracted from the French Wiktionary), with a randomly selected noun `noun2`. Again, we verified manually that the resulting (`adjective_noun1`, `noun2`) pairs constituted actual negative examples. We then created a second set of negative examples by randomly selecting two nouns (`noun1`,`noun2`) and one adjective `adjective`. The resulting pairs (`adjective_noun1`, `noun2`) were verified manually.

In addition to our new test set for French, we also experimented with the original test set of the SEMEVAL-2013 task *evaluation phrasal semantics* for English. However, the original test set lacked human oversight as ‘manly behavior’ was considered similar to ‘testosterone’ for example. We thus hand-checked the test set ourselves and extracted 652 positive pairs.

The negative pairs from the original SEMEVAL-2013 are a combination of a random noun and a random adjective-noun compositon found in the English Wiktionary. We used it as our first set of English negative examples as it is similar in construction to our first set of negative examples in French. In addition, we created a completely random negative test set for English in the same fashion we did for the second negative test set for French.

Finally, the original test set also contains noun-noun compounds so we also created a test set for that. This gave us 226 positive and negative pairs for the noun-noun composition.

3.2 Semantic space construction

In this section, we describe the construction of our semantic space. Our semantic space for French was built using the FRWaC corpus (Baroni et al., 2009) – about 1,6 billion words of web texts – which has been tagged with MElt tagger (Denis et al., 2010) and parsed with MaltParser (Nivre et al., 2006a), trained on a dependency-based version of the French treebank (Candito et al., 2010). Our semantic space for English has been built using the UKWaC corpus (Baroni et al., 2009), which consists of about 2 billion words extracted from the web. The corpus has been part of speech tagged and lemmatized with Stanford Part-Of-Speech Tagger (Toutanova and Manning, 2000; Toutanova et al., 2003), and parsed with MaltParser (Nivre et al., 2006b) trained on sections 2-21 of the Wall Street Journal section of the Penn Treebank extended with about 4000 ques-

[4] *i.e.* less than 200 times for adjectives and less than 1500 times for nouns

positive examples	random negative examples	Wiktionary-based negative examples
(*mot_court*, *abréviation*)	(*importance_fortuit*, *gamme*)	(*jugement_favorable*, *discorde*)
‘short word’, ‘abbreviation’	‘accidental importance’, ‘range’	‘favorable judgement’, ‘discord’
(*ouvrage_littéraire*, *essai*)	(*penchant_autoritaire*, *ile*)	(*circonscription_administratif*, *fumier*)

(*compagnie_honorifique*, *ordre*)	(*auspice_aviaire*, *ponton*)	(*mention_honorable*, *renne*)
‘honorary company’, ‘order’	‘avian omen’, ‘pontoon’	‘honorable mention’, ‘reindeer’

Table 1: A number of examples from our test set for French

tions from the QuestionBank[5].

For both corpora, we extracted the lemmas of all nouns, adjectives and (bag of words) context words. We only kept those lemmas that consist of alphabetic characters.[6] We then selected the 10K most frequent lemmas for each category (nouns, adjectives, context words), making sure to include all the words from the test set. As a final step, we created our semantic space vectors using adjectives and nouns as instances, and bag of words context words as features. The resulting vectors were weighted using *positive point-wise mutual information* (*ppmi*, (Church and Hanks, 1990)), and all vectors were normalized to unit length.

We then compared the different composition methods on different versions of the same semantic space (both for French and English): the full semantic space, a reduced version of the space to 300 dimensions using singular value decomposition (*svd*, (Golub and Van Loan, 1996)), and a reduced version of the space to 300 dimensions using non-negative matrix factorization (*nmf*, (Lee and Seung, 2000)). We did so in order to test each method in its optimal conditions. In fact:

- A non-reduced space contains more information. This might be beneficial for methods that are able to take advantage of the full semantic space (viz. the additive et multiplicative model). On the other hand, to be able to use the non-reduced space for the lexical function approach, one would have to learn matrices of size 10K ×10K for each adjective. This would be problematic in terms of computing time and data sparseness, as we previously noted. The same goes for our generalised approach.
- Previous research has indicated that the lexical function approach is able to achieve better results using a reduced space with *svd*. On the other hand, the negative values that result from *svd* are detrimental for the multiplicative approach.
- An *nmf*-reduced semantic space is not detrimental for the multiplicative approach.

In order to determine the best parameters for the additive model, we tested this model for different values of α and β where $\alpha + \beta = 1$[7] on a development set and kept the values with the best results: $\alpha = 0.4$, $\beta = 0.6$.

3.3 Data used for regression

The LF approach and its generalisation need data in order to perform the least square regression. We thus created a semantic space for **adjective_noun** and **noun_noun** vectors using the most frequent ones in a similar way to how we created them in 3.2. Then we solved the equations in 2.2 and forth. Even though the regression data were disjoint from the test sets, for each pair, we removed some of the data that may cause overfitting.

For the lexical function tests, we remove the **adjective_noun** vector corresponding to the test pair from the regression data. For example, we do not use **short_word** to learn **SHORT** for the (short_word, abbrevation) pair.

For the generalised lexical function tests, we use the full regression data to learn the lexical functions used to train the tensor. However, we remove the **ADJECTIVE** matrix corresponding to the test pair from the (tensor) regression data. For example, we do not use **SHORT** to learn $\mathscr{A}$ for the (short_word, abbreviation) pair.

[5] http://maltparser.org/mco/english_parser/engmalt.html

[6] This step generally filters out dates, numbers and punctuation, which have little interest for the distributional approach.

[7] Since the vectors are normalized (*cf.* 3.2), this condition does not affect the generality of our test.

Table 2: Percentage of correctly classified pairs for $(\text{adjective\_noun1}, \text{noun2})$ for both French and English spaces.

	baseline		multiplicative		additive		LF		generalised LF	
	fr	**en**	**fr**	**en**	**fr**	**en**	**fr**	**en**	**fr**	**en**
non-reduced	0.83	0.81	0.86	0.86	0.88	0.86	N/A		N/A

svd	0.78	0.49	**0.86**	0.83	0.82
nmf	0.79	0.82	**0.86**	**0.85**	0.83

3.4 Results

In this section, we present how the various models perform on our test sets.

3.4.1 General results

Tables 2 & 3 give an overview of the results. Note first that the baseline approach, which compares only the two nouns and ignores the subordinate adjective or noun, does relatively well on the task ($\sim$ 80% accuracy). This reflects the fact that the head noun in our pairs extracted from definitions is close to (and usually a super type of) the noun to be defined.

In addition, we observe that the multiplicative method performs badly, as expected, on the semantic space reduced with *svd*. This confirms the incompatibility of this method with the negative values generated by *svd*. Indeed, multiplying two vectors with negative values term by term may yield a third vector very far away from the other two. Such a combination does not support the subsectivity of most our test pairs. Apart from that, *svd* and *nmf* reductions do not affect the methods much.

Moreover, we observe that the multiplicative model performs better than the baseline but is bested by the additive model. We also see that additive and lexical functions often yield similar performance.

Finally, the generalised lexical function is slightly less accurate than the lexical functions. This is an expected consequence of generalisation. Nevertheless, the generalised lexical function yields sound results confirming our intuition that we can represent adjective-noun (or noun-noun) combinations by one function.

3.4.2 Adjective-noun

With random negative pairs (Table 2a), we observe that the lexical function model obtains the best results for the *svd* space. This result is significantly better than any other method on any of the spaces—e.g.,for French space, $\chi^2 = 33.49$, $p < 0.01$ when compared to the additive model for the non-reduced space which performs second.

However, with non-random negative pairs (Table 2b), LF and the additive model obtain scores that are globally equivalent for their best respective conditions — in French 0.85 for the additive non-reduced model vs. 0.84 for the LF *svd* model, a difference that is not significant ($\chi^2 = 0.20$, $p < 0.05$).

This seems to indicate that LF is especially efficient at separating out nonsense combinations. This may be caused by the fact that lexical functions learn from actual pairs. Thus, when an adjective_noun combination is bizarre, the ADJECTIVE matrix has not been optimized to interact with the **noun** vector and may lead to complete non-sense — Which is a good thing because humans would analyze the combination as such.

Finally, similar results in French and English confirm the intuition that distributional methods (and its composition models) are independent of the idiosyncrasies of a particular language; in particular they are as efficient for French as for English.

3.4.3 Noun-noun

The noun-noun tests (Table 3) yields similar results to the adjective-noun tests. This is not so surprising since noun noun compounds in English also obey a roughly subsective property: a baseball field is still a field (though a cricket pitch is perhaps not so obviously a pitch). We can see that the accuracy increase from the baseline is higher compared to adjective-noun test on the same exact spaces (Table 2b, right values). This may be due to the fact that the subordinate noun in noun-noun combinations is more important than the adjective subordinate in adjective-noun combination.

4 Related work

Many researchers have already studied and evaluated different composition models within a distributional approach. One of the first studies evaluating compositional phenomena in a systematic way is Mitchell and Lapata's (2008) approach. They explore a number of different models for vector composition, of which vector addition (the sum of each feature) and vector multiplication (the element-wise multiplication of each feature) are the most important. They evaluate their models on a noun-verb phrase similarity task. Human annotators were asked to judge the similarity of two composed pairs (by attributing a certain score). The model's task is then to reproduce the human judgements. Their results show that the multiplicative model yields the best results, along with a weighted combination of the additive and multiplicative model. The authors redid their study using a larger test set in Mitchell and Lapata (2010) (adjective-noun composition was also included), and they confirmed their initial results.

Baroni and Zamparelli (2010) evaluate their lexical function model within a somewhat different context. They evaluated their model by looking at its capacity of reconstructing the **adjective_noun** vectors that have not been seen during training. Their results show that their lexical function model obtains the best results for the reconstruction of the original co-occurrence vectors, followed by the additive model. We observe the same tendency in our evaluation results for French, although our results for English show a different picture. We would like to explore this discordance further in future work.

Grefenstette et al. (2013) equally propose a generalisation of the lexical function model that uses tensors. Their goal is to model transitive verbs, and the way we acquire our tensor is similar to theirs. In fact, they use the LF approach in order to learn **VERB_OBJECT** matrices that may be multiplied by a **subject** vector to obtain the **subject_verb_object** vector. In a second step, they learn a tensor for each individual verb, which is similar to how we learn our adjective tensor $\mathscr{A}$.

Coecke et al. (2010) present an abstract theoretical framework in which a sentence vector is a function of the Kronecker product of its word vectors, which allows for greater interaction between the different word features. A number of instantiations of the framework – where the key idea is that relational words (e.g. adjectives or verbs) have a rich (multi-dimensional) structure that acts as a filter on their arguments – are tested experimentally in Grefenstette and Sadrzadeh (2011a) and Grefenstette and Sadrzadeh (2011b). The authors evaluated their models using a similarity task that is similar to the one used by Mitchell & Lapata. However, they use more complex compositional expressions: rather than using compositions of two words (such as a verb and an object), they use simple transitive phrases (subject-verb-object). They show that their instantiations of the categorical model reach better results than the additive and multiplicative models on their transitive similarity task.

Socher et al. (2012) present a compositional model based on a recursive neural network. Each node in a syntactic tree is assigned both a vector and a matrix; the vector captures the actual meaning of the constituent, while the matrix models the way it changes the meaning of neighbouring words and phrases. They use an extrinsic evaluation, using the model for a sentiment prediction task. They show that their model gets better results than the additive, multiplicative, and lexical function approach. Other researchers, however, have published different results. Blacoe and Lapata (2012) evaluated the additive and multiplicative model, as well as Socher et al.'s (2012) approach on two different tasks: Mitchell & Lapata's (2010) similarity task and a paraphrase detection task. They find that the additive and multiplicative models reach better scores than Socher et al.'s model.

Tensors have been used before to model different aspects of natural language. Giesbrecht (2010) describes a tensor factorization model for the construction of a distributional model that is sensitive to word order. And Van de Cruys (2010) uses a tensor factorization model in order to construct a three-way selectional preference model of verbs, subjects, and objects.

5 Conclusion

We have developed a new method of composition and tested it in comparison with different composition methods assuming a distributional approach. We developed a test set for French pairing nouns with adjective noun combinations very similar in meaning from the French Wiktionary. We also used an existing SEMEVAL-2013 set to create a similar test set for English both for adjective noun combination and noun noun combination. Our tests confirm that the lexical function approach by Baroni and Zamparelli performs well compared to other methods of composition, but only when the negative examples are constructed randomly. Our generalised lexical function approach fares almost equally well. It also has the advantage of being constructed from automatically acquired adjectival and noun vectors, and offers the additional advantage of countering data sparseness. However, the lexical function approach claims to perform well on more subtle cases — *e.g.* non-subsective combinations such as *stone lion*. Our test sets does not contain such cases, and so we cannot draw any conclusion on this claim.

In future work, we would like to test different sizes of dimensionality reduction, in order to optimize our generalised lexical function model. Moreover, it is possible that better results may be obtained by proposing multiple generalised lexical functions, rather than a single one. We could, e.g., try to separate the intersective adjectives from non-intersective adjectives. And finally, we would like to further explore the performance of the lexical function model and generalised lexical function model on different datasets, which involve more complex compositional phenomena.

6 Acknowledgments

We thank Dinu et al. (2013a) for their work on the DisSeCT toolkit[8], which provides plenty of helpful functions for composition in distributional semantics. We also thank the OSIRIM platform[9] for allowing us to do the computations we needed. Finally, we thank the reviewers of this paper for their insightful comments.

Abstract

An elementary way of using language is to *refer* to objects. Often, these objects are physically present in the shared environment and reference is done via mention of perceivable properties of the objects. This is a type of language use that is modelled well neither by logical semantics nor by distributional semantics, the former focusing on inferential relations between expressed propositions, the latter on similarity relations between words or phrases. We present an account of word and phrase meaning that is perceptually grounded, trainable, compositional, and 'dialogue-plausible' in that it computes meanings word-by-word. We show that the approach performs well (with an accuracy of 65% on a 1-out-of-32 reference resolution task) on direct descriptions and target/landmark descriptions, even when trained with less than 800 training examples and automatically transcribed utterances.

1 Introduction

The most basic, fundamental site of language use is co-located dialogue (Fillmore, 1975; Clark, 1996) and referring to objects, as in Example (1), is a common occurrence in such a co-located setting.

(1) *The green book on the left next to the mug.*

Logical semantics (Montague, 1973; Gamut, 1991; Partee et al., 1993) has little to say about this process – its focus is on the construction of syntactically manipulable objects that model inferential relations; here, e.g. the inference that there are (at least) two objects. Vector space approaches to distributional semantics (Turney and Pantel, 2010) similarly focuses on something else, namely semantic similarity relations between words or phrases (e.g. finding closeness for "coloured tome on the right of the cup"). Neither approach by itself says anything about processing; typically, the assumption in applications is that fully presented phrases are being processed.

Lacking in these approaches is a notion of *grounding* of symbols in features of the world (Harnad, 1990).[1] In this paper, we present an account of word and phrase meaning that is (a) perceptually grounded in that it provides a link between words and (computer) vision features of real images, (b) trainable, as that link is learned from examples of language use, (c) compositional in that the meaning of phrases is a function of that of its parts and composition is driven by structural analysis, and (d) 'dialogue-plausible' in that it computes meanings incrementally, word-by-word and can work with noisy input from an automatic speech recogniser (ASR). We show that the approach performs well (with an accuracy of 65% on a reference resolution task out of 32 objects) on direct descriptions as well as target/landmark descriptions, even when trained with little data (less than 800 training examples).

In the following section we will give a background on reference resolution, followed by a description of our model. We will then describe the data we used and explain our evaluations. We finish by giving results, providing some additional analysis, and discussion.

2 Background: Reference Resolution

Reference resolution (RR) is the task of resolving referring expressions (REs; as in Example (1)) to a *referent*, the entity to which they are intended to refer. Following Kennington et al. (2015a), this can be formalised as a function f_{rr} that, given a representation U of the RE and a representation W

[1] But see discussion below of recent extensions of these approaches taking this into account.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 292–301,
Beijing, China, July 26-31, 2015.

of the (relevant aspects of the) world, returns I^*, the identifier of one the objects in the world that is the referent of the RE. A number of recent papers have used stochastic models for f_{rr} where, given W and U, a distribution over a specified set of candidate entities in W is obtained and the probability assigned to each entity represents the strength of belief that it is the referent. The referent is then the argmax:

$$I^* = \operatorname*{argmax}_I P(I|U, W) \tag{1}$$

Recently, generative approaches, including our own, have been presented (Funakoshi et al., 2012; Kennington et al., 2013; Kennington et al., 2014; Kennington et al., 2015b; Engonopoulos et al., 2013) which model U as words or ngrams and the world W as a set of objects in a virtual game board, represented as a set properties or concepts (in some cases, extra-linguistic or discourse aspects were also modelled in W, such as deixis). In Matuszek et al. (2014), W was represented as a distribution over properties of tangible objects and U was a Combinatory Categorical Grammar parse. In all of these approaches, the objects are distinct and represented via symbolically specified *properties*, such as colour and shape. The set of properties is either read directly from the world if it is virtual, or computed (i.e., discretised) from the real world objects.

In this paper, we learn a mapping from W to U directly, without mediating symbolic properties; such a mapping is a kind of perceptual grounding of meaning between W and U. Situated RR is a convenient setting for learning perceptually-grounded meaning, as objects that are referred to are physically present, are described by the RE, and have visual features that can be computationally extracted and represented.

Further comparison to related work will be discussed in Section 5.

3 Modelling Reference to Visible Objects

Overview As a representative of the kind of model explained above with formula (1), we want our model to compute a probability distribution over candidate objects, given a RE (or rather, possibly just a prefix of it). We break this task down into components: The basis of our model is a model of word meaning as a function from perceptual features of a given object to a judgement about how well a word and that object "fit together". (See Section 5 for discussion of prior uses of this "words as classifiers"-approach.) This can (loosely) be seen as corresponding to the *intension* of a word, which for example in Montague's approach is similarly modelled as a function, but from possible worlds to extensions (Gamut, 1991). We model two different types of words / word meanings: those picking out properties of single objects (e.g., "green" in "the green book"), following Kennington et al. (2015a), and those picking out relations of two objects (e.g., "next to" in (1)), going beyond Kennington et al. (2015a). These word meanings are learned from instances of language use.

The second component then is the application of these word meanings in the context of an actual reference and within a phrase. This application gives the desired result of a probability distribution over candidate objects, where the probability expresses the strength of belief in the object falling in the *extension* of the expression. Here we model two different types of composition, of what we call *simple references* and *relational references*. These applications are strictly compositional in the sense that the meanings of the more complex constructions are a function of those of their parts.

Word Meanings The first type of word (or rather, word meaning) we model picks out a single object via its visual properties. (At least, this is what we use here; any type of feature could be used.) To model this, we train for each word w from our corpus of REs a binary logistic regression classifier that takes a representation of a candidate object via visual features ($\mathbf{x}$) and returns a probability p_w for it being a good fit to the word (where $\mathbf{w}$ is the weight vector that is learned and σ is the logistic function):

$$p_w(\mathbf{x}) = \sigma(\mathbf{w}^\intercal \mathbf{x} + b) \tag{2}$$

Formalising the correspondence mentioned above, the *intension* of a word can in this approach then be seen as the classifier itself, a function from a representation of an object to a probability:

$$[\![w]\!]_{obj} = \lambda \mathbf{x}.p_w(\mathbf{x}) \tag{3}$$

(Where $[\![w]\!]$ denotes the meaning of w, and $\mathbf{x}$ is of the type of feature given by f_{obj}, the function computing a feature representation for a given object.)

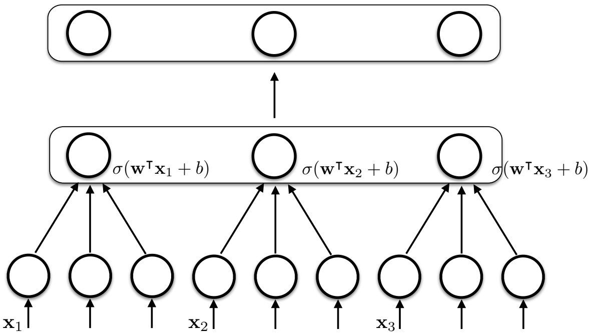
We train these classifiers using a corpus of REs (further described in Section 4), coupled with representations of the scenes in which they were used and an annotation of the referent of that scene. The setting was restricted to reference to single objects. To get positive training examples, we pair each word of a RE with the features of the referent. To get negative training examples, we pair the word with features of (randomly picked) other objects present in the same scene, but *not* referred to by it. This selection of negative examples makes the assumption that the words from the RE apply only to the referent. This is wrong as a strict rule, as other objects could have similar visual features as the referent; for this to work, however, this has to be the case only more often than it is not.

The second type of word that we model expresses a relation between objects. Its meaning is trained in a similar fashion, except that it is presented a vector of features of a *pair* of objects, such as their euclidean distance, vertical and horizontal differences, and binary features denoting higher than/lower than and left/right relationships.

Application and Composition The model just described gives us a prediction for a pair of word and object (or pair of objects). What we wanted, however, is a distribution over all candidate objects in a given utterance situation, and not only for individual words, but for (incrementally growing) REs. Again as mentioned above, we model two types of application and composition. First, what we call '**simple references**'—which roughly corresponds to simple NPs—that refer only by mentioning properties of the referent (e.g. "the red cross on the left"). To get a distribution for a single word, we apply the word classifier (the *intension*) to all candidate objects and normalise; this can then be seen as the *extension* of the word in a given (here, visual) discourse universe W, which provides the candidate objects ($\mathbf{x}_i$ is the feature vector for object i, $normalize()$ vectorized normalisation, and I a random variable ranging over the candidates):

$$[\![w]\!]^W_{obj} = normalize(([\![w]\!]_{obj}(\mathbf{x}_1), \dots, [\![w]\!]_{obj}(\mathbf{x}_k))) = normalize((p_w(\mathbf{x}_1), \dots, p_w(\mathbf{x}_k))) = P(I|w) \quad (4)$$

In effect, this combines the individual classifiers into something like a multi-class logistic regression / maximum entropy model—but, *nota bene*, only for application. The training regime did not need to make any assumptions about the number of objects present, as it trained classifiers for a 2-class problem (how well does this given object fit to the word?). The multi-class nature is also indicated in Figure 1, which shows multiple applications of the logistic regression network for a word, and a normalisation layer on top.



$\sigma(\mathbf{w}^\intercal\mathbf{x}_1 + b)$
$\sigma(\mathbf{w}^\intercal\mathbf{x}_2 + b)$
$\sigma(\mathbf{w}^\intercal\mathbf{x}_3 + b)$

$\mathbf{x}_2$
$\mathbf{x}_3$

Figure 1: Representation as network with normalisation layer.

To compose the evidence from individual words $w_1, \dots, w_k$ into a prediction for a 'simple' RE $[_{sr} w_1, \dots, w_k]$ (where the bracketing indicates the structural assumption that the words belong to one, possibly incomplete, 'simple reference'), we average the contributions of its constituent words. The averaging function $avg()$ over distributions then is the contribution of the construction 'simple reference (phrase)', sr, and the meaning of the whole phrase is the application of the meaning of the construction to the meaning of the words:

$$[\![[_{sr} w_1, \dots, w_k]]\!]^W = [\![sr]\!]^W [\![w_1, \dots, w_k]\!]^W = avg([\![w_1]\!]^W, \dots, [\![w_k]\!]^W) \quad (5)$$

where $avg()$ is defined as

$$avg([\![w_1]\!]^W, [\![w_2]\!]^W) = P_{avg}(I|w_1, w_2) \text{ with } P_{avg}(I = i|w_1, w_2) = \frac{1}{2}(P(I = i|w_1) + P(I = i|w_2)) \text{ for } i \in I \quad (6)$$

The averaging function is inherently incremental, in the sense that $avg(a, b, c) = avg(avg(a, b), c)$ and hence it can be extended "on the right". This represents an incremental model where new information from the current increment is added to what is already known, resulting in an intersective way of composing the meaning of the phrase. This cannot account for all constructions (such as negation or generally quantification), of course; we leave exploring other constructions that could occur even in our 'simple references' to future work.

Relational references such as in Example (1) from the introduction have a more complex structure, being a relation between a (simple) reference to a *landmark* and a (simple) reference to a *target*. This structure is indicated abstractly in the following 'parse': $[_{rel}[_{sr}w_1, \ldots, w_k][_r r_1, \ldots, r_n][_{sr}w'_1, \ldots, w'_m]]$, where the w are the target words, r the relational expression words, and w' the landmark words.

As mentioned above, the relational expression similarly is treated as a classifier (in fact, technically we contract expressions such as "to the left of" into a single token and learn one classifier for it), but expressing a judgement for pairs of objects. It can be applied to a specific scene with a set of candidate objects (and hence, candidate pairs) in a similar way by applying the classifier to all pairs and normalising, resulting in a distribution over pairs:

$$[\![r]\!]^W = P(R_1, R_2|r) \tag{7}$$

We expect the meaning of the phrase to be a function of the meaning of the constituent parts (the simple references, the relation expression, and the construction), that is:

$$\begin{aligned}&[\![[_{rel}[_{sr}w_1, \ldots, w_k][_r r][_{sr}w'_1, \ldots, w'_m]]]\!] = \\ &\qquad [\![rel]\!]([\![sr]\!][\![w_1 \ldots w_k]\!], [\![r]\!], [\![sr]\!][\![w'_1 \ldots w'_m]\!])\end{aligned} \tag{8}$$

(dropping the indicator for concrete application, ^{W} on $[\![\ ]\!]$, for reasons of space and readability).

What is the contribution of the relational construction, $[\![rel]\!]$? Intuitively, what we want to express here is that the belief in an object being the intended referent should combine the evidence from the simple reference to the landmark object (e.g., "the mug" in (1)), from the simple (but presumably deficient) reference to the target object ("the green book on the left"), and that for the relation between them ("next to"). Instead of averaging (that is, combining additively), as for sr, we combine this evidence multiplicatively here: If the target constituent contributes $P(I_t|w_1, \ldots, w_k)$, the landmark constituent $P(I_l|w'_1, \ldots, w'_m)$, and the relation expression $P(R_1, R_2|r)$, with I_l, I_t, R_1 and R_2 all having the same domain, the set of all candidate objects, then the combination is

$$\begin{aligned}&P(R_1|w_1, \ldots, w_k, r, w'_1, \ldots, w'_m) = \\ &\quad \sum_{R_2}\sum_{I_l}\sum_{I_t} P(R_1, R_2|r) * P(I_l|w'_1, \ldots, w'_m) * \\ &\qquad\qquad P(I_t|w_1, \ldots, w_k) * P(R_1|I_t) * P(R_2|I_l)\end{aligned} \tag{9}$$

The last two factors force identity on the elements of the pair and target and landmark, respectively (they are not learnt, but rather set to be 0 unless the values of R and I are equal), and so effectively reduce the summations so that all pairs need to be evaluated only once. The contribution of the construction then is this multiplication of the contributions of the parts, together with the factors enforcing that the pairs being evaluated by the relation expression consist of the objects evaluated by target and landmark expression, respectively.

In the following section, we will explain the data we collected and used to evaluate our model, the evaluation procedure, and the results.

4 Experiments

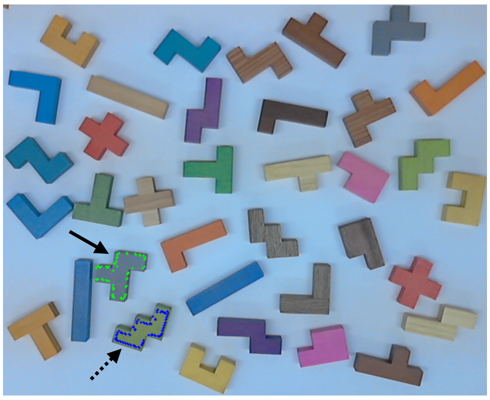

Figure 2: Example episode for *phase-2* where the target is outlined in green (solid arrow added here for presentation), the landmark outlined in blue (dashed arrow).

Data We evaluated our model using data we collected in a Wizard-of-Oz setting (that is, a human/computer interaction setting where parts of the functionality of the computer system were provided by a human experimentor). Participants were seated in front of a table with 36 Pentomino puzzle pieces that were randomly placed with some space between them, as shown in Figure 2. Above the table was a camera that recorded a video feed of the objects, processed using OpenCV (Pulli et al., 2012) to segment the objects (see below for details); of those, one (or one pair) was chosen randomly by the experiment software. The video image was presented to the participant on a display placed behind the table, but with the randomly selected piece (or pair of pieces) indicated by an overlay).

The task of the participant was to refer to that object using only speech, as if identifying it for a friend sitting next to the participant. The wizard (experimentor) had an identical screen depicting the scene but not the selected object. The wizard listened to the participant's RE and clicked on the object she thought was being referred on her screen. If it was the target object, a tone sounded and a new object was randomly chosen. This constituted a single *episode*. If a wrong object was clicked, a different tone sounded, the episode was flagged, and a new episode began. At varied intervals, the participant was instructed to "shuffle" the board between episodes by moving around the pieces.

The first half of the allotted time constituted phase-1. After phase-1 was complete, instructions for phase-2 were explained: the screen showed the target and also a landmark object, outlined in blue, near the target (again, see Figure 2). The participant was to refer to the target using the landmark. (In the instructions, the concepts of landmark and target were explained in general terms.) All other instructions remained the same as phase-1. The target's identifier, which was always known beforehand, was always recorded. For phase-2, the landmark's identifier was also recorded.

Nine participants (6 female, 3 male; avg. age of 22) took part in the study; the language of the study was German. Phase-1 for one participant and phase-2 for another participant were not used due to misunderstanding and a technical difficulty. This produced a corpus of 870 non-flagged episodes in total. Even though each episode had 36 objects in the scene, all objects were not always recognised by the computer vision processing. On average, 32 objects were recognized.

To obtain transcriptions, we used Google Web Speech (with a word error rate of 0.65, as determined by comparing to a hand transcribed sample) This resulted in 1587 distinct words, with 15.53 words on average per episode. The objects were not manipulated in any way during an episode, so the episode was guaranteed to remain static during a RE and a single image is sufficient to represent the layout of one episode's scene. Each scene was processed using computer vision techniques to obtain low-level features for each (detected) object in the scene which were used for the word classifiers.

We annotated each episode's RE with a simple tagging scheme that segmented the RE into words that directly referred to the target, words that directly referred to the landmark (or multiple landmarks, in some cases) and the relation words. For certain word types, additional information about the word was included in the tag if it described colour, shape, or spatial placement (denoted *contributing* REs in the evaluations below). The *direction* of certain relation words was normalised (e.g., *left-of* should always denote a landmark-target relation). This represents a minimal amount of "syntactic" information needed for the application of the classifiers and the composition of the phrase meanings. We leave applying a syntactic parser to future work. An example RE in the original German (as recognised by the ASR), English gloss, and tags for each word is given in (2).

(2) a. *grauer stein über dem grünen m unten links*
b. gray block above the green m bottom left
c. tc ts r l lc ls tf tf

To obtain visual features of each object, we used the same simple computer-vision pipeline of object segmentation and contour reconstruction as used by Kennington et al. (2015a), providing us with RGB representations for the colour and features such as skewness, number of edges etc. for the shapes.

Procedure We break down our data as follows: episodes where the target was referred directly via a 'simple reference' construction (DD; 410 episodes) and episodes where a target was referred via a landmark relation (RD; 460 episodes). We also test with either knowledge about structure (simple or relational reference) provided (ST) or not (WO, for "words-only"). All results shown are from 10-fold cross validations averaged over 10 runs; where for evaluations labelled RD the training data always includes all of DD plus 9 folds of RD, testing on RD. The sets address the following questions:

- how well does the sr model work on its own with just words? – DD.WO
- how well does the sr model work when it knows about REs? – DD.ST
- how well does the sr model work when it knows about REs, but not about relations? – RD.ST (sr)
- how well does the model learn relation words after it has learned about sr? RD.ST (r)
- how well does the rr model work (together with the sr)? RD.ST with DD.ST (rr)

Words were stemmed using the NLTK (Loper and Bird, 2002) Snowball Stemmer, reducing the vocabulary size to 1306. Due to sparsity, for relation words with a token count of less than 4 (found by ranging over values in a held-out set) relational features were piped into an UNK relation, which was used for unseen relations during evaluation (we assume the UNK relation would learn a general notion of 'nearness'). For the individual word classifiers, we always paired one negative example with one positive example.

For this evaluation, word classifiers for *sr* were given the following features: RGB values, HSV values, x and y coordinates of the centroids, euclidean distance of centroid from the center, and number of edges. The relation classifiers received information relating two objects, namely the euclidean distance between them, the vertical and horizontal distances, and two binary features that denoted if the landmark was higher than/lower than or left/right of the target.

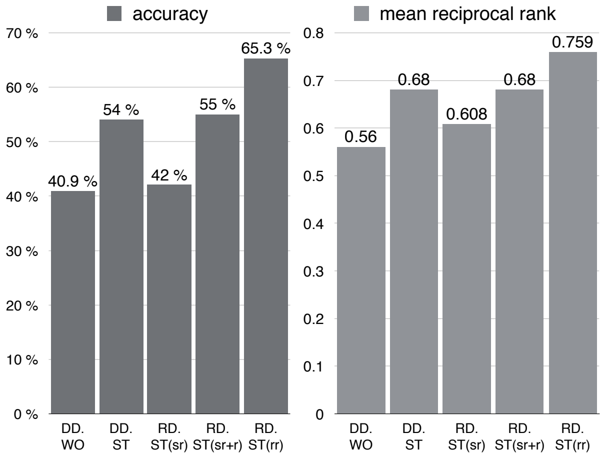

Figure 3: Results of our evaluation.

Metrics for Evaluation To give a picture of the overall performance of the model, we report **accuracy** (how often was the argmax the gold target) and **mean reciprocal rank** (MRR) of the gold target in the distribution over all the objects (like accuracy, higher MRR values are better; values range between 0 and 1). The use of MRR is motivated by the assumption that in general, a good rank for the correct object is desirable, even if it doesn't reach the first position, as when integrated in a dialogue system this information might still be useful to formulate clarification questions.

Results Figure 3 shows the results. (Random baseline of 1/32 or 3% not shown in plot.) DD.WO shows how well the *sr* model performs using the whole utterances and not just the REs. (Note that all evaluations are on noisy ASR transcriptions.) DD.ST adds structure by only considering words that are part of the actual RE, improving the results further. The remaining sets evaluate the contributions of the *rr* model. RD.ST (*sr*) does this indirectly, by including the target and landmark simple references, but not the model for the relations; the task here is to resolve target and landmark SRs as they are. This provides the baseline for the next two evaluations, which include the relation model. In RD.ST (*sr*+*r*), the model learns SRs from DD data and only relations from RD. The performance is substantially better than the baseline without the relation model. Performance is best finally for RD.ST (*rr*), where the landmark and target SRs in the training portion of RD also contribute to the word models.

The *mean reciprocal rank* scores follow a similar pattern and show that even though the target object was not the argmax of the distribution, on average it was high in the distribution. For all evaluations, the average standard deviation across the 10 runs was very small (0.01), meaning the model was fairly stable, despite the possibility of one run having randomly chosen more discriminating negative examples. Our conclusion from these experiments is that despite the small amount of training data and noise from ASR as well as the scene, the model is robust and yields respectable results.

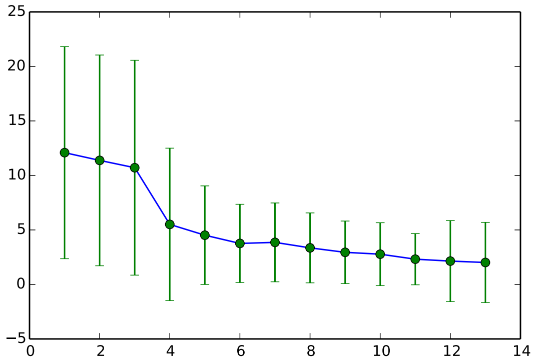

Figure 5: Incremental results: average rank improves over time

Incremental Results Figure 5 shows how our *rr* model processes incrementally, by giving the *average rank* of the (gold) target at each increment for the REs with the most common length in our data (13 words, of which there were 64 examples). A system that works incrementally would have a monotonically decreasing average rank as the utterance unfolds. The overall trend as shown in that

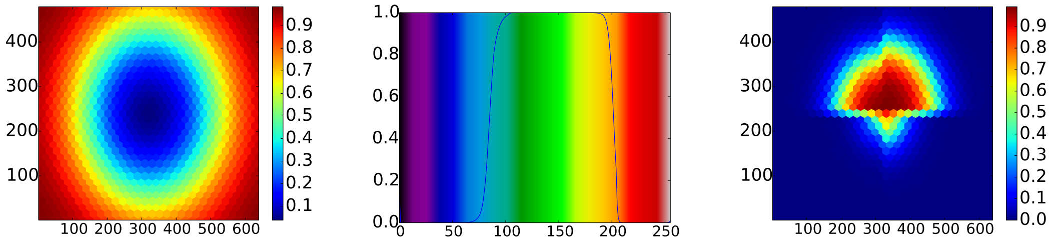

Figure 4: Each plot represents how well selected words fit assumptions about their lexical semantics: the leftmost plot *ecke* (*corner*) yields higher probabilities as objects are closer to the corner; the middle plot *grün* (*green*) yields higher probabilities when the colour spectrum values are nearer to green; the rightmost plot *über* (*above*) yields higher probabilities when targets are nearer to a landmark set in the middle.

Figure is as expected. There is a slight increase between 6-7, though very small (a difference of 0.09). Overall, these results seem to show that our model indeed works *intersectively* and "zooms in" on the intended referent.

4.1 Further Analysis

Analysis of Selected Words We analysed several individual word classifiers to determine how well their predictions match assumptions about their lexical semantics. For example, for the spatial word *Ecke* (*corner*), we would expect its classifier to return high probabilities if features related to an object's position (e.g., x and y coordinates, distance from the center) are near corners of the scene. The leftmost plot in Figure 4 shows that this is indeed the case; by holding all non-position features constant and ranging over all points on the screen, we can see that the classifier gives high probabilities around the edges, particularly in the four corners, and very low probabilities in the middle region. Similarly for the colour word *grün*, the centre plot in Figure 4 (overlaid with a colour spectrum) shows high probabilities are given when presented with the colour green, as expected. Similarly, for the relational word *über* (*above*), by treating the center point as the landmark and ranging over all other points on the plot for the target, the *über* classifier gives high probabilities when directly above the center point, with linear negative growth as the distance from the landmark increases.

Note that we selected the type of feature to vary here for presentation; all classifiers get the full feature set and learn automatically to "ignore" the irrelevant features (e.g., that for *grün* does not respond to variations in positional features). They do this wuite well, but we noticed some 'blurring', due to not all combinations of colours and shape being represented in the objects in the training set.

Analysis of Incremental Processing Figure 6 finally shows the interpretation of the RE in Example (2) in the scene from Figure 2. The top row depicts the distribution over objects (true target shown in red) after the relation word *unten* (bottom) is uttered; the second row that for landmark objects, after the landmark description begins (*dem grünen m* / *the green m*). The third row (target objects), ceases to change after the relational word is uttered, but continues again as additional target words are uttered (*unten links* / *bottom left*). While the true target is ranked highly already on the basis of the target SR alone, it is only when the relational information is added (top row) that it becomes argmax.

Discussion We did not explore how well our model could handle generalised quantifiers, such as *all* (e.g., *all the red objects*) or a specific number of objects (e.g., *the two green Ts*). We speculate that one could see as the contribution of words such as *all* or *two* a change to how the distribution is evaluated ("return the n top candidates"). Our model also doesn't yet directly handle more descriptive REs like *the cross in the top-right corner on the left*, as *left* is learned as a global term, or negation (*the cross that's not red*). We leave exploring such constructions to future work.

5 Related Work

Kelleher et al. (2005) approached RR using perceptually-grounded models, focusing on saliency and discourse context. In Gorniak and Roy (2004), descriptions of objects were used to learn a perceptually-grounded meaning with focus on spatial terms such as *on the left*. Steels and Belpaeme (2005) used neural networks to connect language with colour terms by interacting with humans. Larsson (2013) is closest in spirit to what we are attempting here; he provides a detailed

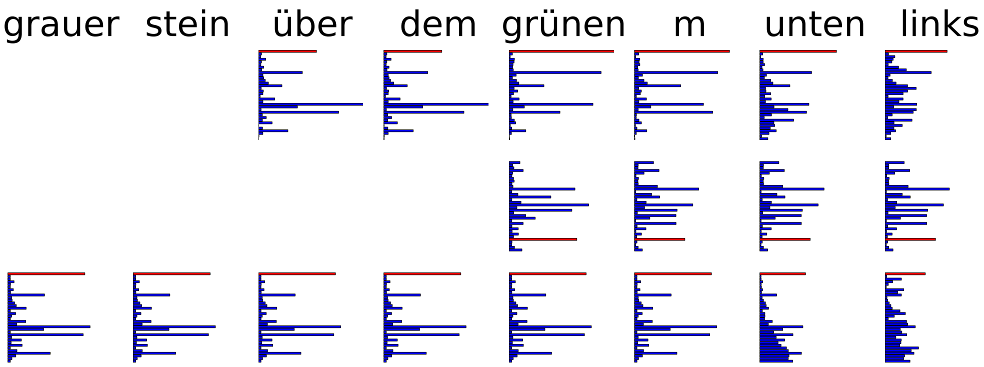

Figure 6: A depiction of the model working incrementally for the RE in Example (2): the distribution over objects for relation is row 1, landmark is row 2, target is row 3.

formal semantics for similarly descriptive terms, where parts of the semantics are modelled by a perceptual classifier. These approaches had limited lexicons (where we attempt to model all words in our corpus), and do not process incrementally, which we do here.

Recent efforts in multimodal distributional semantics have also looked at modelling word meaning based on visual context. Originally, vector space distributional semantics focused words in the context of other words (Turney and Pantel, 2010); recent multimodal approaches also consider low-level features from images. Bruni et al. (2012) and Bruni et al. (2014) for example model word meaning by word and visual context; each modality is represented by a vector, fused by concatenation. Socher et al. (2014) and Kiros et al. (2014) present approaches where words/phrases and images are mapped into the same high-dimensional space. While these approaches similarly provide a link between words and images, they are typically tailored towards a different setting (the words being descriptions of the whole image, and not utterance intended to perform a function within a visual situation). We leave more detailed exploration of similarities and differences to future work and only note for now that our approach, relying on much simpler classifiers (log-linear, basically), works with much smaller data sets and additionally seem to provide an easier interface to more traditional ways of composition (see Section 3 above).

The issue of semantic compositionality is also actively discussed in the distributional semantics literature (see, e.g., (Mitchell and Lapata, 2010; Erk, 2013; Lewis and Steedman, 2013; Paperno et al., 2014)), investigating how to combine vectors. This could be seen as composition on the level of intensions (if one sees distributional representations as intensions, as is variously hinted at, e.g. Erk (2013)). In our approach, composition is done on the extensional level (by interpolating distributions over candidate objects).

We do not see our approach as being in opposition to these attempts. Rather, we envision a system of semantics that combines traditional symbolic expressions (on which inferences can be modelled via syntactic calculi) with distributed representations (which model conceptual knowledge / semantic networks, as well as encyclopedic knowledge) and with our action-based (namely, identification in the environment via perceptual information) semantics. This line of approach is connected to a number of recent works (e.g., (Erk, 2013; Lewis and Steedman, 2013; Larsson, 2013)); for now, exploring its ramifications is left for future work.

6 Conclusion

In this paper, we presented a model of reference resolution that learns a perceptually-grounded meaning of words, including relational words. The model is simple, compositional, and robust despite low amounts of training data and noisy modalities. Our model is not without limitations; it so far only handles definite descriptions, yet there are other ways to refer to real-world objects, such as via pronouns and deixis. A unified model that can handle all of these, similar in spirit perhaps to Funakoshi et al. (2012), but with perceptual groundings, is left for future work. Our approach could also benefit from improved object segmentation and representation.

Our next steps with this model is to handle compositional structures without relying on our closed tag set (e.g., using a syntactic parser). We also plan to test our model in a natural, interactive dialogue system.

Acknowledgements We want to thank the anonymous reviewers for their comments. We also want to thank Spyros Kousidis for helping with data collection, Livia Dia for help with the computer vision processing, and Julian Hough for fruitful discussions on semantics, though we can't blame them for any problems of the work that may remain. Neural CRF Parsing

Greg Durrett and **Dan Klein**

Abstract

This paper describes a parsing model that combines the exact dynamic programming of CRF parsing with the rich nonlinear featurization of neural net approaches. Our model is structurally a CRF that factors over anchored rule productions, but instead of linear potential functions based on sparse features, we use nonlinear potentials computed via a feedforward neural network. Because potentials are still local to anchored rules, structured inference (CKY) is unchanged from the sparse case. Computing gradients during learning involves backpropagating an error signal formed from standard CRF sufficient statistics (expected rule counts). Using only dense features, our neural CRF already exceeds a strong baseline CRF model (Hall et al., 2014). In combination with sparse features, our system[1] achieves 91.1 F_1 on section 23 of the Penn Treebank, and more generally outperforms the best prior single parser results on a range of languages.

1 Introduction

Neural network-based approaches to structured NLP tasks have both strengths and weaknesses when compared to more conventional models, such conditional random fields (CRFs). A key strength of neural approaches is their ability to learn nonlinear interactions between underlying features. In the case of unstructured output spaces, this capability has led to gains in problems ranging from syntax (Chen and Manning, 2014; Belinkov et al., 2014) to lexical semantics (Kalchbrenner et al., 2014; Kim, 2014). Neural methods are also powerful tools in the case of structured output spaces. Here, past work has often relied on recurrent architectures (Henderson, 2003; Socher et al., 2013; İrsoy and Cardie, 2014), which can propagate information through structure via real-valued hidden state, but as a result do not admit efficient dynamic programming (Socher et al., 2013; Le and Zuidema, 2014). However, there is a natural marriage of nonlinear induced features and efficient structured inference, as explored by Collobert et al. (2011) for the case of sequence modeling: feedforward neural networks can be used to score local decisions which are then "reconciled" in a discrete structured modeling framework, allowing inference via dynamic programming.

In this work, we present a CRF constituency parser based on these principles, where individual anchored rule productions are scored based on nonlinear features computed with a feedforward neural network. A separate, identically-parameterized replicate of the network exists for each possible span and split point. As input, it takes vector representations of words at the split point and span boundaries; it then outputs scores for anchored rules applied to that span and split point. These scores can be thought of as nonlinear potentials analogous to linear potentials in conventional CRFs. Crucially, while the network replicates are connected in a unified model, their computations factor along the same substructures as in standard CRFs.

Prior work on parsing using neural network models has often sidestepped the problem of structured inference by making sequential decisions (Henderson, 2003; Chen and Manning, 2014; Tsuboi, 2014) or by doing reranking (Socher et al., 2013; Le and Zuidema, 2014); by contrast, our framework permits exact inference via CKY, since the model's structured interactions are purely discrete and do not involve continuous hidden state. Therefore, we can exploit a neural net's capacity to learn nonlinear features without modifying

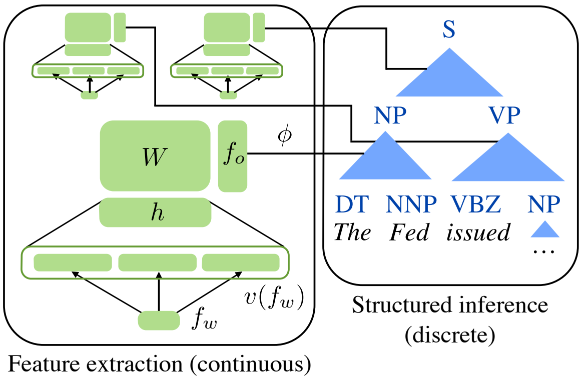

Figure 1: Neural CRF model. On the right, each anchored rule (r, s) in the tree is independently scored by a function ϕ, so we can perform inference with CKY to compute marginals or the Viterbi tree. On the left, we show the process for scoring an anchored rule with neural features: words in f_w (see Figure 2) are embedded, then fed through a neural network with one hidden layer to compute dense intermediate features, whose conjunctions with sparse rule indicator features f_o are scored according to parameters W.

our core inference mechanism, allowing us to use tricks like coarse pruning that make inference efficient in the purely sparse model. Our model can be trained by gradient descent exactly as in a conventional CRF, with the gradient of the network parameters naturally computed by backpropagating a difference of expected anchored rule counts through the network for each span and split point.

Using dense learned features alone, the neural CRF model obtains high performance, outperforming the CRF parser of Hall et al. (2014). When sparse indicators are used in addition, the resulting model gets 91.1 F_1 on section 23 of the Penn Treebank, outperforming the parser of Socher et al. (2013) as well as the Berkeley Parser (Petrov and Klein, 2007) and matching the discriminative parser of Carreras et al. (2008). The model also obtains the best single parser results on nine other languages, again outperforming the system of Hall et al. (2014).

2 Model

Figure 1 shows our neural CRF model. The model decomposes over anchored rules, and it scores each of these with a potential function; in a standard CRF, these potentials are typically linear functions of sparse indicator features, whereas

Figure 2: Example of an anchored rule production for the rule NP → NP PP. From the anchoring $s = (i, j, k)$, we extract either sparse surface features f_s or a sequence of word indicators f_w which are embedded to form a vector representation $v(f_w)$ of the anchoring's lexical properties.

in our approach they are nonlinear functions of word embeddings.[2] Section 2.1 describes our notation for anchored rules, and Section 2.2 talks about how they are scored. We then discuss specific choices of our featurization (Section 2.3) and the backbone grammar used for structured inference (Section 2.4).

2.1 Anchored Rules

The fundamental units that our parsing models consider are *anchored rules*. As shown in Figure 2, we define an anchored rule as a tuple (r, s), where r is an indicator of the rule's identity and $s = (i, j, k)$ indicates the span (i, k) and split point j of the rule.[3] A tree T is simply a collection of anchored rules subject to the constraint that those rules form a tree. All of our parsing models are CRFs that decompose over anchored rule productions and place a probability distribution over trees conditioned on a sentence $\mathbf{w}$ as follows:

$$P(T|\mathbf{w}) \propto \exp\left(\sum_{(r,s)\in T} \phi(\mathbf{w}, r, s)\right)$$

[2] Throughout this work, we will primarily consider two potential functions: linear functions of sparse indicators and nonlinear neural networks over dense, continuous features. Although other modeling choices are possible, these two points in the design space reflect common choices in NLP, and past work has suggested that nonlinear functions of indicators or linear functions of dense features may perform less well (Wang and Manning, 2013).

[3] For simplicity of exposition, we ignore unary rules; however, they are easily supported in this framework by simply specifying a null value for the split point.

where ϕ is a scoring function that considers the input sentence and the anchored rule in question. Figure 1 shows this scoring process schematically. As we will see, the module on the left can be be a neural net, a linear function of surface features, or a combination of the two, as long as it provides anchored rule scores, and the structured inference component is the same regardless (CKY).

A PCFG estimated with maximum likelihood has $\phi(\mathbf{w}, r, s) = \log P(r|\text{parent}(r))$, which is independent of the anchoring s and the words $\mathbf{w}$ except for preterminal productions; a basic discriminative parser might let this be a learned parameter but still disregard the surface information. However, surface features can capture useful syntactic cues (Finkel et al., 2008; Hall et al., 2014). Consider the example in Figure 2: the proposed parent NP is preceded by the word *reflected* and followed by a period, which is a surface context characteristic of NPs or PPs in object position. Beginning with *the* and ending with *personality* are typical properties of NPs as well, and the choice of the particular rule NP → NP PP is supported by the fact that the proposed child PP begins with *of*. This information can be captured with sparse features (f_s in Figure 2) or, as we describe below, with a neural network taking lexical context as input.

2.2 Scoring Anchored Rules

Following Hall et al. (2014), our baseline sparse scoring function takes the following bilinear form:

$$\phi_{\text{sparse}}(\mathbf{w}, r, s; W) = f_s(\mathbf{w}, s)^\top W f_o(r)$$

where $f_o(r) \in \{0,1\}^{n_o}$ is a sparse vector of features expressing properties of r (such as the rule's identity or its parent label) and $f_s(\mathbf{w}, s) \in \{0,1\}^{n_s}$ is a sparse vector of surface features associated with the words in the sentence and the anchoring, as shown in Figure 2. W is a $n_s \times n_o$ matrix of weights.[4] The scoring of a particular anchored rule is depicted in Figure 3a; note that surface features and rule indicators are conjoined in a systematic way.

The role of f_s can be equally well played by a vector of dense features learned via a neural network. We will now describe how to compute these features, which represent a transformation of surface lexical indicators f_w. Define $f_w(\mathbf{w}, s) \in \mathbb{N}^{n_w}$ to be a function that produces a fixed-length sequence of word indicators based on the input sentence and the anchoring. This vector of word identities is then passed to an embedding function $v : \mathbb{N} \to \mathbb{R}^{n_e}$ and the dense representations of the words are subsequently concatenated to form a vector we denote by $v(f_w)$.[5] Finally, we multiply this by a matrix $H \in \mathbb{R}^{n_h \times (n_w n_e)}$ of real-valued parameters and pass it through an elementwise nonlinearity $g(\cdot)$. We use rectified linear units $g(x) = \max(x, 0)$ and discuss this choice more in Section 6.

f_w

Figure 3: Our sparse (left) and neural (right) scoring functions for CRF parsing. f_s and f_w are raw surface feature vectors for the sparse and neural models (respectively) extracted over anchored spans with split points. (a) In the sparse case, we multiply f_s by a weight matrix W and then a sparse output vector f_o to score the rule production. (b) In the neural case, we first embed f_w and then transform it with a one-layer neural network in order to produce an intermediate feature representation h before combining with W and f_o.

Replacing f_s with the end result of this computation $h(\mathbf{w}, s; H) = g(Hv(f_w(\mathbf{w}, s)))$, our scoring function becomes

$$\phi_{\text{neural}}(\mathbf{w}, r, s; H, W) = h(\mathbf{w}, s; H)^\top W f_o(r)$$

as shown in Figure 3b. For a fixed H, this model can be viewed as a basic CRF with dense input features. By learning H, we learn intermediate feature representations that provide the model with

[4] A more conventional expression of the scoring function for a CRF is $\phi(\mathbf{w}, r, s) = \theta^\top f(\mathbf{w}, r, s)$, with a vector θ for the parameters and a single feature extractor f that jointly inspects the surface and the rule. However, when the feature representation conjoins each rule r with surface properties of the sentence in a systematic way (an assumption that holds in our case as well as for standard CRF models for POS tagging and NER), this is equivalent to our formalism.

[5] Embedding words allows us to use standard pre-trained vectors more easily and tying embeddings across word positions substantially reduces the number of model parameters. However, embedding features rather than words has also been shown to be effective (Chen et al., 2014).

more discriminating power. Also note that it is possible to use deeper networks or more sophisticated architectures here; we will return to this in Section 6.

Our two models can be easily combined:

$$\begin{aligned}\phi(\mathbf{w}, r, s; W_1, H, W_2) = \phi_{\text{sparse}}(\mathbf{w}, r, s; W_1) \\ + \phi_{\text{neural}}(\mathbf{w}, r, s; H, W_2)\end{aligned}$$

Weights for each component of the scoring function can be learned fully jointly and inference proceeds as before.

2.3 Features

We take f_s to be the set of features described in Hall et al. (2014). At the preterminal layer, the model considers prefixes and suffixes up to length 5 of the current word and neighboring words, as well as the words' identities. For nonterminal productions, we fire indicators on the words[6] before and after the start, end, and split point of the anchored rule (as shown in Figure 2) as well as on two other span properties, span length and span shape (an indicator of where capitalized words, numbers, and punctuation occur in the span).

For our neural model, we take f_w for all productions (preterminal and nonterminal) to be the words surrounding the beginning and end of a span and the split point, as shown in Figure 2; in particular, we look two words in either direction around each point of interest, meaning the neural net takes 12 words as input.[7] For our word embeddings v, we use pre-trained word vectors from Bansal et al. (2014). We compare with other sources of word vectors in Section 5. Contrary to standard practice, we do not update these vectors during training; we found that doing so did not provide an accuracy benefit and slowed down training considerably.

2.4 Grammar Refinements

A recurring issue in discriminative constituency parsing is the granularity of annotation in the base grammar (Finkel et al., 2008; Petrov and Klein, 2008; Hall et al., 2014). Using finer-grained symbols in our rules r gives the model greater capacity, but also introduces more parameters into W and increases the ability to overfit. Following Hall et al. (2014), we use grammars with very little annotation: we use no horizontal Markovization for any of experiments, and all of our English experiments with the neural CRF use no vertical Markovization ($V = 0$). This also has the benefit of making the system much faster, due to the smaller state space for dynamic programming. We do find that using parent annotation ($V = 1$) is useful on other languages (see Section 7.2), but this is the only grammar refinement we consider.

3 Learning

To learn weights for our neural model, we maximize the conditional log likelihood of our D training trees T^*:

$$\mathcal{L}(H, W) = \sum_{i=1}^{D} \log P(T_i^* | \mathbf{w}_i; H, W)$$

Because we are using rectified linear units as our nonlinearity, our objective is not everywhere differentiable. The interaction of the parameters and the nonlinearity also makes the objective nonconvex. However, in spite of this, we can still follow subgradients to optimize this objective, as is standard practice.

Recall that $h(\mathbf{w}, s; H)$ are the hidden layer activations. The gradient of W takes the standard form of log-linear models:

$$\frac{\partial \mathcal{L}}{\partial W} = \left(\sum_{(r,s) \in T^*} h(\mathbf{w}, s; H) f_o(r)^\top \right) - \left(\sum_T P(T|\mathbf{w}; H, W) \sum_{(r,s) \in T} h(\mathbf{w}, s; H) f_o(r)^\top \right)$$

Note that the outer products give matrices of feature counts isomorphic to W. The second expression can be simplified to be in terms of expected feature counts. To update H, we use standard backpropagation by first computing:

$$\frac{\partial \mathcal{L}}{\partial h} = \left(\sum_{(r,s) \in T^*} W f_o(r) \right) - \left(\sum_T P(T|\mathbf{w}; H, W) \sum_{(r,s) \in T} W f_o(r) \right)$$

Since h is the output of the neural network, we can then apply the chain rule to compute gradients for H and any other parameters in the neural network.

[6] The model actually uses the longest suffix of each word occurring at least 100 times in the training set, up to the entire word. Removing this abstraction of rare words harms performance.

[7] The sparse model did not benefit from using this larger neighborhood, so improvements from the neural net are not simply due to considering more lexical context.

Learning uses Adadelta (Zeiler, 2012), which has been employed in past work (Kim, 2014). We found that Adagrad (Duchi et al., 2011) performed equally well with tuned regularization and step size parameters, but Adadelta worked better out of the box. We set the momentum term $\rho = 0.95$ (as suggested by Zeiler (2012)) and did not regularize the weights at all. We used a minibatch size of 200 trees, although the system was not particularly sensitive to this. For each treebank, we trained for either 10 passes through the treebank or 1000 minibatches, whichever is shorter.

We initialized the output weight matrix W to zero. To break symmetry, the lower level neural network parameters H were initialized with each entry being independently sampled from a Gaussian with mean 0 and variance 0.01; Gaussian performed better than uniform initialization, but the variance was not important.

4 Inference

Our baseline and neural model both score anchored rule productions. We can use CKY in the standard fashion to compute either expected anchored rule counts $\mathbb{E}_{P(T|\mathbf{w})}[(r, s)]$ or the Viterbi tree $\arg\max_T P(T|\mathbf{w})$.

We speed up inference by using a coarse pruning pass. We follow Hall et al. (2014) and prune according to an X-bar grammar with head-outward binarization, ruling out any constituent whose max marginal probability is less than e^{-9}. With this pruning, the number of spans and split points to be considered is greatly reduced; however, we still need to compute the neural network activations for each remaining span and split point, of which there may be thousands for a given sentence.[8] We can improve efficiency further by noting that the same word will appear in the same position in a large number of span/split point combinations, and cache the contribution to the hidden layer caused by that word (Chen and Manning, 2014). Computing the hidden layer then simply requires adding n_w vectors together and applying the nonlinearity, instead of a more costly matrix multiply.

Because the number of rule indicators n_o is fairly large (approximately 4000 in the Penn Treebank), the multiplication by W in the model is also expensive. However, because only a small number of rules can apply to a given span and split point, f_o is sparse and we can selectively compute the terms necessary for the final bilinear product.

Our combined sparse and neural model trains on the Penn Treebank in 24 hours on a single machine with a parallelized CPU implementation. For reference, the purely sparse model with a parent-annotated grammar (necessary for the best results) takes around 15 hours on the same machine.

5 System Ablations

Table 1 shows results on section 22 (the development set) of the English Penn Treebank (Marcus et al., 1993), computed using `evalb`. Full test results and comparisons to other systems are shown in Table 4. We compare variants of our system along two axes: whether they use standard linear sparse features, nonlinear dense features from the neural net, or both, and whether any word representations (vectors or clusters) are used.

Sparse vs. neural The neural CRF (line (d) in Table 1) on its own outperforms the sparse CRF (a, b) even when the sparse CRF has a more heavily annotated grammar. This is a surprising result: the features in the sparse CRF have been carefully engineered to capture a range of linguistic phenomena (Hall et al., 2014), and there is no guarantee that word vectors will capture the same. For example, at the POS tagging layer, the sparse model looks at prefixes and suffixes of words, which give the model access to morphology for predicting tags of unknown words, which typically have regular inflection patterns. By contrast, the neural model must rely on the geometry of the vector space exposing useful regularities. At the same time, the strong performance of the combination of the two systems (g) indicates that not only are both featurization approaches high-performing on their own, but that they have complementary strengths.

Unlabeled data Much attention has been paid to the choice of word vectors for various NLP tasks, notably whether they capture more syntactic or semantic phenomena (Bansal et al., 2014; Levy and Goldberg, 2014). We primarily use vectors from Bansal et al. (2014), who train the skip-gram model of Mikolov et al. (2013) using contexts from dependency links; a similar approach was also suggested by Levy and Goldberg (2014).

[8] One reason we did not choose to include the rule identity f_o as an input to the network is that it requires computing an even larger number of network activations, since we cannot reuse them across rules over the same span and split point.

	Sparse	Neural	V	Word Reps	F_1 len ≤ 40	F_1 all
Hall et al. (2014), $V = 1$					90.5	
a	✓		0		89.89	89.22
b	✓		1		90.82	90.13
c	✓		1	Brown	90.80	90.17
d		✓	0	Bansal	90.97	90.44
e		✓	0	Collobert	90.25	89.63
f		✓	0	PTB	89.34	88.99
g	✓	✓	0	Bansal	**92.04**	**91.34**
h	✓	✓	0	PTB	91.39	90.91

Table 1: Results of our sparse CRF, neural CRF, and combined parsing models on section 22 of the Penn Treebank. Systems are broken down by whether local potentials come from sparse features and/or the neural network (the primary contribution of this work), their level of vertical Markovization, and what kind of word representations they use. The neural CRF (d) outperforms the sparse CRF (a, b) even when a more heavily annotated grammar is used, and the combined approach (g) is substantially better than either individual model. The contribution of the neural architecture cannot be replaced by Brown clusters (c), and even word representations learned just on the Penn Treebank are surprisingly effective (f, h).

		F_1 len ≤ 40	Δ

Embed output		88.81	-2.16

Table 2: Exploration of other implementation choices in the feedforward neural network on sentences of length ≤ 40 from section 22 of the Penn Treebank. Rectified linear units perform better than tanh or cubic units, a network with one hidden layer performs best, and embedding the output feature vector gives worse performance.

However, as these embeddings are trained on a relatively small corpus (BLLIP minus the Penn Treebank), it is natural to wonder whether less-syntactic embeddings trained on a larger corpus might be more useful. This is not the case: line (e) in Table 1 shows the performance of the neural CRF using the Wikipedia-trained word embeddings of Collobert et al. (2011), which do not perform better than the vectors of Bansal et al. (2014).

To isolate the contribution of continuous word representations themselves, we also experimented with vectors trained on just the text from the training set of the Penn Treebank using the skip-gram model with a window size of 1. While these vectors are somewhat lower performing on their own (f), they still provide a surprising and noticeable gain when stacked on top of sparse features (h), again suggesting that dense and sparse representations have complementary strengths. This result also reinforces the notion that the utility of word vectors does *not* come primarily from importing information about out-of-vocabulary words (Andreas and Klein, 2014).

Since the neural features incorporate information from unlabeled data, we should provide the sparse model with similar information for a true apples-to-apples comparison. Brown clusters have been shown to be effective vehicles in the past (Koo et al., 2008; Turian et al., 2010; Bansal et al., 2014). We can incorporate Brown clusters into the baseline CRF model in an analogous way to how embedding features are used in the dense model: surface features are fired on Brown cluster identities (we use prefixes of length 4 and 10) of key words. We use the Brown clusters from Koo et al. (2008), which are trained on the same data as the vectors of Bansal et al. (2014). However, Table 1 shows that these features provide no benefit to the baseline model, which suggests either that it is difficult to learn reliable weights for these as sparse features or that different regularities are being captured by the word embeddings.

6 Design Choices

The neural net design space is large, so we wish to analyze the particular design choices we made for this system by examining the performance of several variants of the neural net architecture used in our system. Table 2 shows development results from potential alternate architectural choices, which we now discuss.

Choice of nonlinearity The choice of nonlinearity g has been frequently discussed in the neural network literature. Our choice $g(x) = \max(x, 0)$, a rectified linear unit, is increasingly popular in computer vision (Krizhevsky et al., 2012). $g(x) = \tanh(x)$ is a traditional nonlinearity widely used throughout the history of neural nets (Bengio et al., 2003). $g(x) = x^3$ (cube) was found to be most successful by Chen and Manning (2014).

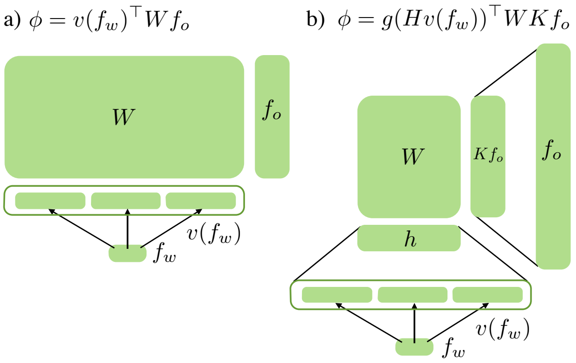
Table 2 compares the performance of these three nonlinearities. We see that rectified linear units perform the best, followed by $\tanh$ units, followed by cubic units.[9] One drawback of $\tanh$ as an activation function is that it is easily "saturated" if the input to the unit is too far away from zero, causing the backpropagation of derivatives through that unit to essentially cease; this is known to cause problems for training, requiring special purpose machinery for use in deep networks (Ioffe and Szegedy, 2015).

Depth Given that we are using rectified linear units, it bears asking whether or not our implementation is improving substantially over linear features of the continuous input. We can use the embedding vector of an anchored span $v(f_w)$ directly as input to a basic linear CRF, as shown in Figure 4a. Table 1 shows that the purely linear architecture (0 HL) performs surprisingly well, but is still less effective than the network with one hidden layer. This agrees with the results of Wang and Manning (2013), who noted that dense features typically benefit from nonlinear modeling. We also compare against a two-layer neural network, but find that this also performs worse than the one-layer architecture.

Densifying output features Overall, it appears beneficial to use dense representations of surface features; a natural question that one might ask is whether the same technique can be applied to the sparse output feature vector f_o. We can apply the approach of Srikumar and Manning (2014) and multiply the sparse output vector by a dense matrix K, giving the following scoring function (shown in Figure 4b):

$$\phi(\mathbf{w}, r, s; H, W, K) = g(Hv(f_w(\mathbf{w}, s)))^\top W K f_o(r)$$

where W is now $n_h \times n_{oe}$ and K is $n_{oe} \times n_o$. WK can be seen a low-rank approximation of the original W at the output layer, similar to low-rank factorizations of parameter matrices used in past work (Lei et al., 2014). This approach saves us from having to learn a separate row of W for every rule in the grammar; if rules are given similar embeddings, then they will behave similarly according to the model.



a) $\phi = v(f_w)^\top W f_o$
b) $\phi = g(Hv(f_w))^\top W K f_o$
W
f_o
$v(f_w)$

W
Kf_o
f_o
h
$v(f_w)$
f_w

Figure 4: Two additional forms of the scoring function. a) Linear version of the dense model, equivalent to a CRF with continuous-valued input features. b) Version of the dense model where outputs are also embedded according to a learned matrix K.

We experimented with $n_{oe} = 20$ and show the results in Table 2. Unfortunately, this approach does not seem to work well for parsing. Learning the output representation was empirically very unstable, and it also required careful initialization. We tried Gaussian initialization (as in the rest of our model) and initializing the model by clustering rules either randomly or according to their parent symbol. The latter is what is shown in the table, and gave substantially better performance. We hypothesize that blurring distinctions between output classes may harm the model's ability to differentiate between closely-related symbols, which is required for good parsing performance. Using pretrained rule embeddings at this layer might also improve performance of this method.

7 Test Results

We evaluate our system under two conditions: first, on the English Penn Treebank, and second, on the nine languages used in the SPMRL 2013 and 2014 shared tasks.

7.1 Penn Treebank

Table 4 reports results on section 23 of the Penn Treebank (PTB). We focus our comparison on single parser systems as opposed to rerankers, ensembles, or self-trained methods (though these are also mentioned for context). First, we compare against

[9] The performance of cube decreased substantially late in learning; it peaked at around 90.52. Dropout may be useful for alleviating this type of overfitting, but in our experiments we did not find dropout to be beneficial overall.

Table 3: Results for the nine treebanks in the SPMRL 2013/2014 Shared Tasks; all values are F-scores for sentences of all lengths using the version of `evalb` distributed with the shared task. Our parser substantially outperforms the strongest single parser results on this dataset (Hall et al., 2014; Crabbé and Seddah, 2014). Berkeley-Tags is an improved version of the Berkeley parser designed for the shared task (Seddah et al., 2013). 2014 Best is a reranked ensemble of modified Berkeley parsers and constitutes the best published numbers on this dataset (Björkelund et al., 2013; Björkelund et al., 2014).

Shindo et al. (2012) ensemble	92.4

Table 4: Test results on section 23 of the Penn Treebank. We compare to several categories of parsers from the literatures. We outperform strong baselines such as the Berkeley Parser (Petrov and Klein, 2007) and the CVG Stanford parser (Socher et al., 2013) and we match the performance of sophisticated generative (Shindo et al., 2012) and discriminative (Carreras et al., 2008) parsers.

four parsers trained only on the PTB with no auxiliary data: the CRF parser of Hall et al. (2014), the Berkeley parser (Petrov and Klein, 2007), the discriminative parser of Carreras et al. (2008), and the single TSG parser of Shindo et al. (2012). To our knowledge, the latter two systems are the highest performing in this PTB-only, single parser data condition; we match their performance at 91.1 F_1, though we also use word vectors computed from unlabeled data. We further compare to the shift-reduce parser of Zhu et al. (2013), which uses unlabeled data in the form of Brown clusters. Our method achieves performance close to that of their parser.

We also compare to the compositional vector grammar (CVG) parser of Socher et al. (2013) as well as the LSTM-based parser of Vinyals et al. (2014). The conditions these parsers are operating under are slightly different: the former is a reranker on top of the Stanford Parser (Klein and Manning, 2003) and the latter trains on much larger amounts of data parsed by a product of Berkeley parsers (Petrov, 2010). Regardless, we outperform the CVG parser as well as the single parser results from Vinyals et al. (2014).

7.2 SPMRL

We also examine the performance of our parser on other languages, specifically the nine morphologically-rich languages used in the SPMRL 2013/2014 shared tasks (Seddah et al., 2013; Seddah et al., 2014). We train word vectors on the monolingual data distributed with the SPMRL 2014 shared task (typically 100M-200M tokens per language) using the skip-gram approach of `word2vec` with a window size of 1

(Mikolov et al., 2013).[10] Here we use $V = 1$ in the backbone grammar, which we found to be beneficial overall. Table 3 shows that our system improves upon the performance of the parser from Hall et al. (2014) as well as the top single parser from the shared task (Crabbé and Seddah, 2014), with robust improvements on all languages.

8 Conclusion

In this work, we presented a CRF parser that scores anchored rule productions using dense input features computed from a feedforward neural net. Because the neural component is modularized, we can easily integrate it into a preexisting learning and inference framework based around dynamic programming of a discrete parse chart. Our combined neural and sparse model gives strong performance both on English and on other languages.

Our system is publicly available at http://nlp.cs.berkeley.edu.

Acknowledgments

This work was partially supported by BBN under DARPA contract HR0011-12-C-0014, by a Facebook fellowship for the first author, and by a Google Faculty Research Award to the second author. Thanks to David Hall for assistance with the Epic parsing framework and for a preliminary implementation of the neural architecture, to Kush Rastogi for training word vectors on the SPMRL data, to Dan Jurafsky for helpful discussions, and to the anonymous reviewers for their insightful comments.

Abstract

Most existing graph-based parsing models rely on millions of hand-crafted features, which limits their generalization ability and slows down the parsing speed. In this paper, we propose a general and effective Neural Network model for graph-based dependency parsing. Our model can automatically learn high-order feature combinations using only atomic features by exploiting a novel activation function *tanh-cube*. Moreover, we propose a simple yet effective way to utilize phrase-level information that is expensive to use in conventional graph-based parsers. Experiments on the English Penn Treebank show that parsers based on our model perform better than conventional graph-based parsers.

1 Introduction

Dependency parsing is essential for computers to understand natural languages, whose performance may have a direct effect on many NLP application. Due to its importance, dependency parsing, has been studied for tens of years. Among a variety of dependency parsing approaches (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Zhang and Nivre, 2011), graph-based models seem to be one of the most successful solutions to the challenge due to its ability of scoring the parsing decisions on whole-tree basis. Typical graph-based models factor the dependency tree into subgraphs, ranging from the smallest edge (first-order) to a controllable bigger subgraph consisting of more than one single edge (second-order and third order), and score the whole tree by summing scores of the subgraphs. In these models, subgraphs are usually represented as a high-dimensional feature vectors which are fed into a linear model to learn the feature weight for scoring the subgraphs.

In spite of their advantages, conventional graph-based models rely heavily on an enormous number of hand-crafted features, which brings about serious problems. First, a mass of features could put the models in the risk of overfitting and slow down the parsing speed, especially in the high-order models where combinational features capturing interactions between head, modifier, siblings and (or) grandparent could easily explode the feature space. In addition, feature design requires domain expertise, which means useful features are likely to be neglected due to a lack of domain knowledge. As a matter of fact, these two problems exist in most graph-based models, which have stuck the development of dependency parsing for a few years.

To ease the problem of feature engineering, we propose a general and effective Neural Network model for graph-based dependency parsing in this paper. The main advantages of our model are as follows:

- Instead of using large number of hand-crafted features, our model only uses atomic features (Chen et al., 2014) such as word unigrams and POS-tag unigrams. Feature combinations and high-order features are automatically learned with our novel activation function *tanh-cube*, thus alleviating the heavy burden of feature engineering in conventional graph-based models (McDonald et al., 2005; McDonald and Pereira, 2006; Koo and Collins, 2010). Not only does it avoid the risk of overfitting but also it discovers useful new features that have never been used in conventional parsers.

- We propose to exploit phrase-level information through distributed representation for phrases (phrase embeddings). It not only en-

(a) First-order (b) Second-order

Figure 1: First-order and Second-order factorization strategy. Here h stands for head word, m stands for modifier word and s stands for the sibling of m.

ables our model to exploit richer context information that previous work did not consider due to the curse of dimension but also captures inherent correlations between phrases.

- Unlike other neural network based models (Chen et al., 2014; Le and Zuidema, 2014) where an additional parser is needed for either extracting features (Chen et al., 2014) or generating k-best list for reranking (Le and Zuidema, 2014), both training and decoding in our model are performed based on our neural network architecture in an effective way.
- Our model does not impose any change to the decoding process of conventional graph-based parsing model. First-order, second-order and higher order models can be easily implemented using our model.

We implement three effective models with increasing expressive capabilities. The first model is a simple first-order model that uses only atomic features and does not use any combinational features. Despite its simpleness, it outperforms conventional first-order model (McDonald et al., 2005) and has a faster parsing speed. To further strengthen our parsing model, we incorporate phrase embeddings into the model, which significantly improves the parsing accuracy. Finally, we extend our first-order model to a second-order model that exploits interactions between two adjacent dependency edges as in McDonald and Pereira (2006) thus further improves the model performance.

We evaluate our models on the English Penn Treebank. Experiment results show that both our first-order and second-order models outperform the corresponding conventional models.

2 Neural Network Model

A dependency tree is a rooted, directed tree spanning the whole sentence. Given a sentence x, graph-based models formulates the parsing process as a searching problem:

$$y^*(x) = \operatorname*{arg\,max}_{\hat{y} \in Y(x)} Score(x, \hat{y}(x); \theta) \qquad (1)$$

where $y^*(x)$ is tree with highest score, $Y(x)$ is the set of all trees compatible with x, θ are model parameters and $Score(x, \hat{y}(x); \theta)$ represents how likely that a particular tree $\hat{y}(x)$ is the correct analysis for x. However, the size of $Y(x)$ is exponential large, which makes it impractical to solve equation (1) directly. Previous work (McDonald et al., 2005; McDonald and Pereira, 2006; Koo and Collins, 2010) assumes that the score of $\hat{y}(x)$ factors through the scores of subgraphs c of $\hat{y}(x)$ so that efficient algorithms can be designed for decoding:

$$Score(x, \hat{y}(x); \theta) = \sum_{c \in \hat{y}(x)} ScoreF(x, c; \theta) \quad (2)$$

Figure 1 gives two examples of commonly used factorization strategy proposed by Mcdonald et.al (2005) and Mcdonald and Pereira (2006). The simplest subgraph uses a first-order factorization (McDonald et al., 2005) which decomposes a dependency tree into single dependency arcs (Figure 1(a)). Based on the first-order model, second-order factorization (McDonald and Pereira, 2006) (Figure 1(b)) brings sibling information into decoding. Specifically, a sibling part consists of a triple of indices (h, m, s) where (h, m) and (h, s) are dependencies and s and m are successive modifiers to the same side of h.

The most common choice for $ScoreF(x, c; \theta)$, which is the score function for subgraph c in the tree, is a simple linear function:

$$ScoreF(x, c; \theta) = \boldsymbol{w} \cdot \boldsymbol{f}(x, c) \qquad (3)$$

where $\boldsymbol{f}(x, c)$ is the feature representation of subgraph c and $\boldsymbol{w}$ is the corresponding weight vector. However, the effectiveness of this function relies heavily on the design of feature vector $\boldsymbol{f}(x, c)$. In previous work (McDonald et al., 2005; McDonald and Pereira, 2006), millions of hand-crafted features were used to capture context and structure information in the subgraph which not only limits the model's ability to generalize well but only slows down the parsing speed.

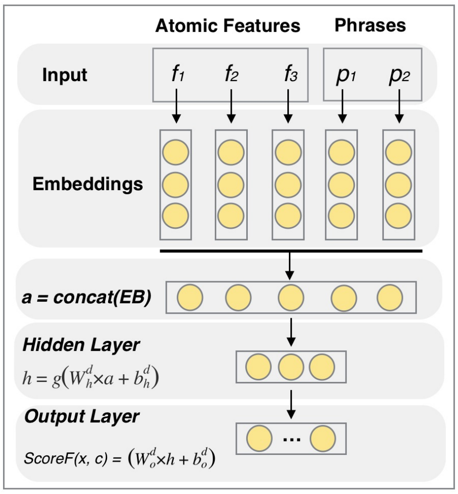

Figure 2: Architecture of the Neural Network

In our work, we propose a neural network model for scoring subgraph c in the tree:

$$ScoreF(x, c; \theta) = \boldsymbol{NN}(x, c) \tag{4}$$

where $\boldsymbol{NN}$ is our scoring function based on neural network (Figure 2). As we will show in the following sections, it alleviates the heavy burden of feature engineering in conventional graph-based models and achieves better performance by automatically learning useful information in the data.

The effectiveness of our neural network depends on five key components: *Feature Embeddings*, *Phrase Embeddings*, *Direction-specific transformation*, *Learning Feature Combinations* and *Max-Margin Training*.

2.1 Feature Embeddings

As shown in Figure 2, part of the input to the neural network is feature representation of the subgraph. Instead of using millions of features as in conventional models, we only use use atomic features (Chen et al., 2014) such as word unigrams and POS-tag unigrams, which are less likely to be sparse. The detailed atomic features we use will be described in Section 3. Unlike conventional models, the atomic features in our model are transformed into their corresponding distributed representations (feature embeddings).

The idea of distributed representation for symbolic data is one of the most important reasons why neural network works in NLP tasks. It is shown that similar features will have similar embeddings which capture the syntactic and semantic information behind features (Bengio et al., 2003; Collobert et al., 2011; Schwenk et al., 2012; Mikolov et al., 2013; Socher et al., 2013; Pei et al., 2014).

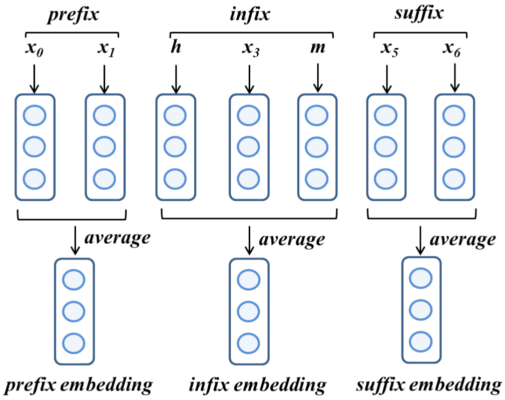

Figure 3: Illustration for phrase embeddings. h, m and x_0 to x_6 are words in the sentence.

Formally, we have a feature dictionary D of size $|D|$. Each feature $f \in D$ is represented as a real-valued vector (feature embedding) $Embed(f) \in \mathbb{R}^d$ where d is the dimensionality of the vector space. All feature embeddings stacking together forms the embedding matrix $M \in \mathbb{R}^{d \times |D|}$. The embedding matrix M is initialized randomly and trained by our model (Section 2.6).

2.2 Phrase Embeddings

Context information of word pairs[1] such as the dependency pair (h, m) has widely believed to be useful in graph-based models (McDonald et al., 2005; McDonald and Pereira, 2006). Given a sentence x, the context for $\boldsymbol{h}$ and $\boldsymbol{m}$ includes three context parts: *prefix*, *infix* and *suffix*, as illustrated in Figure 3. We call these parts *phrases* in our work.

Context representation in conventional models are limited: First, phrases cannot be used as features directly because of the data sparseness problem. Therefore, phrases are backed off to low-order representation such as bigrams and trigrams. For example, Mcdonald et.al (2005) used tri-gram features of *infix* between head-modifier pair (h, m). Sometimes even tri-grams are expensive to use, which is the reason why Mcdonald and Pereira (2006) chose to ignore features over triples of words in their second-order model to prevent from exploding the size of the feature space. Sec-

[1] A word pair is not limited to the dependency pair (h, m). It could be any pair with particular relation (e.g., sibling pair (s, m) in Figure 1). Figure 3 only uses (h, m) as an example.

ond, bigrams or tri-grams are lexical features thus cannot capture syntactic and semantic information behind phrases. For instance, "*hit the ball*" and "*kick the football*" should have similar representations because they share similar syntactic structures, but lexical tri-grams will fail to capture their similarity.

Unlike previous work, we propose to use distributed representation (phrase embedding) of phrases to capture phrase-level information. We use a simple yet effective way to calculate phrase embeddings from word (POS-tag) embeddings. As shown in Figure 3, we average the word embeddings in *prefix*, *infix* and *suffix* respectively and get three global word-phrase embeddings. For pairs where no prefix or suffix exists, the corresponding embedding is set to zero. We also get three global POS-phrase embeddings which are calculated in the same way as words. These embeddings are then concatenated with feature embeddings and fed to the following hidden layer.

Phrase embeddings provide panorama representation of the context, allowing our model to capture richer context information compared with the back-off tri-gram representation. Moreover, as a distributed representation, phrase embeddings perform generalization over specific phrases, thus better capture the syntactic and semantic information than back-off tri-grams.

2.3 Direction-specific Transformation

In dependency representation of sentence, the edge direction indicates which one of the words is the head h and which one is the modifier m. Unlike previous work (McDonald et al., 2005; McDonald and Pereira, 2006) that models the edge direction as feature to be conjoined with other features, we model the edge direction with direction-specific transformation.

As shown in Figure 2, the parameters in hidden layer (W_h^d, b_h^d) and the output layer (W_o^d, b_o^d) are bound with index $d \in \{0, 1\}$ which indicates the direction between head and modifier (0 for left arc and 1 for right arc). In this way, the model can learn direction-specific parameters and automatically capture the interactions between edge direction and other features.

2.4 Learning Feature Combination

The key to the success of graph-based dependency parsing is the design of features, especially combinational features. Effective as these features are, as we have said in Section 1, they are prone to overfitting and hard to design. In our work, we introduce a new activation function that can automatically learn these feature combinations.

As shown in Figure 2, we first concatenate the embeddings into a single vector a. Then a is fed into the next layer which performs linear transformation followed by an element-wise activation function g:

$$h = g(W_h^d a + b_h^d) \tag{5}$$

Our new activation function g is defined as follows:

$$g(l) = tanh(l^3 + l) \tag{6}$$

where l is the result of linear transformation and *tanh* is the *hyperbolic tangent* activation function widely used in neural networks. We call this new activation function *tanh-cube*.

As we can see, without the cube term, *tanh-cube* would be just the same as the conventional nonlinear transformation in most neural networks. The cube extension is added to enhance the ability to capture complex interactions between input features. Intuitively, the cube term in each hidden unit directly models feature combinations in a multiplicative way:

$$\begin{gathered}(w_1a_1 + w_2a_2 + ... + w_na_n + b)^3 = \\ \sum_{i,j,k}(w_iw_jw_k)a_ia_ja_k + \sum_{i,j} b(w_iw_j)a_ia_j...\end{gathered}$$

These feature combinations are hand-designed in conventional graph-based models but our model learns these combinations automatically and encodes them in the model parameters.

Similar ideas were also proposed in previous works (Socher et al., 2013; Pei et al., 2014; Chen and Manning, 2014). Socher et.al (2013) and Pei et.al (2014) used a tensor-based activation function to learn feature combinations. However, tensor-based transformation is quite slow even with tensor factorization (Pei et al., 2014). Chen and Manning (2014) proposed to use cube function $g(l) = l^3$ which inspires our *tanh-cube* function. Compared with cube function, *tanh-cube* has three advantages:

- The cube function is unbounded, making the activation output either too small or too big if the norm of input l is not properly controlled, especially in deep neural network. On the contrary, *tanh-cube* is bounded by the *tanh* function thus safer to use in deep neural network.

- Intuitively, the behavior of cube function resembles the "polynomial kernel" in SVM. In fact, SVM can be seen as a special one-hidden-layer neural network where the kernel function that performs non-linear transformation is seen as a hidden layer and support vectors as hidden units. Compared with cube function, *tanh-cube* combines the power of "kernel function" with the *tanh* non-linear transformation in neural network.
- Last but not least, as we will show in Section 4, *tanh-cube* converges faster than the cube function although the rigorous proof is still open to investigate.

2.5 Model Output

After the non-linear transformation of hidden layer, the score of the subgraph c is calculated in the output layer using a simple linear function:

$$ScoreF(x, c) = W_o^d h + b_o^d \tag{7}$$

The output score $ScoreF(x, c) \in \mathbb{R}^{|L|}$ is a score vector where $|L|$ is the number of dependency types and each dimension of $ScoreF(x, c)$ is the score for each kind of dependency type of head-modifier pair (i.e. (h, m) in Figure 1).

2.6 Max-Margin Training

The parameters of our model are $\theta = \{W_h^d, b_h^d, W_o^d, b_o^d, M\}$. All parameters are initialized with uniform distribution within (-0.01, 0.01).

For model training, we use the Max-Margin criterion. Given a training instance (x, y), we search for the dependency tree with the highest score computed as equation (1) in Section 2. The object of Max-Margin training is that the highest scoring tree is the correct one: $y^* = y$ and its score will be larger up to a margin to other possible tree $\hat{y} \in Y(x)$:

$$Score(x, y; \theta) \geq Score(x, \hat{y}; \theta) + \triangle(y, \hat{y})$$

The structured margin loss $\triangle(y, \hat{y})$ is defined as:

$$\triangle(y, \hat{y}) = \sum_{j}^{n} \kappa \mathbf{1}\{h(y, x_j) \neq h(\hat{y}, x_j)\}$$

where n is the length of sentence x, $h(y, x_j)$ is the head (with type) for the j-th word of x in tree y and κ is a discount parameter. The loss is proportional to the number of word with an incorrect head and edge type in the proposed tree. This leads to the regularized objective function for m training examples:

$$\begin{aligned} J(\theta) &= \frac{1}{m}\sum_{i=1}^{m} l_i(\theta) + \frac{\lambda}{2}||\theta||^2 \\ l_i(\theta) &= \max_{\hat{y} \in Y(x_i)} (Score(x_i, \hat{y}; \theta) + \triangle(y_i, \hat{y})) \\ &\quad -Score(x_i, y_i; \theta)) \end{aligned} \tag{8}$$

We use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs (batch size = 20) to minimize the object function. We also apply dropout (Hinton et al., 2012) with 0.5 rate to the hidden layer.

1-order-atomic	$h_{-2}.w$, $h_{-1}.w$, $h.w$, $h_1.w$, $h_2.w$ $h_{-2}.p$, $h_{-1}.p$, $h.p$, $h_1.p$, $h_2.p$ $m_{-2}.w$, $m_{-1}.w$, $m.w$, $m_1.w$, $m_2.w$ $m_{-2}.p$, $m_{-1}.p$, $m.p$, $m_1.p$, $m_2.p$ *dis(h, m)*

Table 1: Features in our three models. w is short for word and p for POS-tag. h indicates head and m indicates modifier. The subscript represents the relative position to the center word. $dis(h, m)$ is the distance between head and modifier. *hm_prefix*, *hm_infix* and *hm_suffix* are phrases for head-modifier pair (h, m). s indicates the sibling in second-order model. *sm_infix* is the *infix* phrase between sibling pair (s, m)

3 Model Implementation

Base on our Neural Network model, we present three model implementations with increasing expressive capabilities in this section.

3.1 First-order models

We first implement two first-order models: **1-order-atomic** and **1-order-phrase**. We use the Eisner (2000) algorithm for decoding. The first two rows of Table 1 list the features we use in these two models.

1-order-atomic only uses atomic features as shown in the first row of Table 1. Specifically, the

	Models	**Dev**		Test		Speed (sent/s)
		UAS	LAS	UAS	LAS	
First-order	MSTParser-1-order	92.01	90.77	91.60	90.39	20
	1-order-atomic-rand	92.00	90.71	91.62	90.41	**55**
	1-order-atomic	92.19	90.94	92.14	90.92	**55**
	1-order-phrase-rand	92.47	91.19	92.25	91.05	26
	1-order-phrase	**92.82**	**91.48**	**92.59**	**91.37**	26
Second-order	MSTParser-2-order	92.70	91.48	92.30	91.06	14
	2-order-phrase-rand	93.39	92.10	92.99	91.79	10
	2-order-phrase	**93.57**	**92.29**	**93.29**	**92.13**	10
Third-order	(Koo and Collins, 2010)	93.49	N/A	93.04	N/A	N/A

Table 2: Comparison with conventional graph-based models.

head word and its local neighbor words that are within the distance of 2 are selected as the head's word unigram features. The modifier's word unigram features is extracted in the same way. We also use the POS-tags of the corresponding word features and the distance between head and modifier as additional atomic features.

We then improved **1-order-atomic** to **1-order-phrase** by incorporating additional phrase embeddings. The three phrase embeddings of head-modifier pair (h, m): *hm_prefix*, *hm_infix* and *hm_suffix* are calculated as in Section 2.2.

3.2 Second-order model

Our model can be easily extended to a second-order model using the second-order decoding algorithm (Eisner, 1996; McDonald and Pereira, 2006). The third row of Table 1 shows the additional features we use in our second-order model.

Sibling node and its local context are used as additional atomic features. We also used the *infix embedding* for the *infix* between sibling pair (s, m), which we call *sm_infix*. It is calculated in the same way as *infix* between head-modifier pair (h, m) (i.e., *hm_infix*) in Section 2.2 except that the word pair is now s and m. For cases where no sibling information is available, the corresponding sibling-related embeddings are set to zero vector.

4 Experiments

4.1 Experiment Setup

We use the English Penn Treebank (PTB) to evaluate our model implementations and Yamada and Matsumoto (2003) head rules are used to extract dependency trees. We follow the standard splits of PTB3, using section 2-21 for training, section 22 as development set and 23 as test set. The Stanford POS Tagger (Toutanova et al., 2003) with ten-way jackknifing of the training data is used for assigning POS tags (accuracy ≈ 97.2%).

Hyper-parameters of our models are tuned on the development set and their final settings are as follows: embedding size d = 50, hidden layer (Layer 2) size = 200, regularization parameter λ = 10^{-4}, discount parameter for margin loss κ = 0.3, initial learning rate of AdaGrad alpha = 0.1.

4.2 Experiment Results

Table 2 compares our models with several conventional graph-based parsers. We use MSTParser[2] for conventional first-order model (McDonald et al., 2005) and second-order model (McDonald and Pereira, 2006). We also include the result of a third-order model of Koo and Collins (2010) for comparison[3]. For our models, we report the results with and without unsupervised pre-training. Pre-training only trains the word-based feature embeddings on Gigaword corpus (Graff et al., 2003) using *word2vec*[4] and all other parameters are still initialized randomly. In all experiments, we report unlabeled attachment scores (UAS) and labeled attachment scores (LAS) and punctuation[5] is excluded in all evaluation metrics. The parsing speeds are measured on a workstation with Intel Xeon 3.4GHz CPU and 32GB RAM.

As we can see, even with random initialization, **1-order-atomic-rand** performs as well as conventional first-order model and both **1-order-phrase-**

[2] `http://sourceforge.net/projects/mstparser`

[3] Note that Koo and Collins (2010)'s third-order model and our models are not strict comparable since their model is an unlabeled model.

[4] `https://code.google.com/p/word2vec/`

[5] Following previous work, a token is a punctuation if its POS tag is {“ ” : , .}

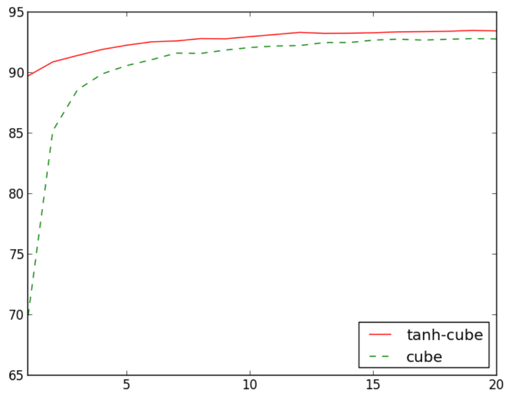

Figure 4: Convergence curve for *tanh-cube* and *cube* activation function.

rand and **2-order-phrase-rand** perform better than conventional models in MSTParser. Pretraining further improves the performance of all three models, which is consistent with the conclusion of previous work (Pei et al., 2014; Chen and Manning, 2014). Moreover, **1-order-phrase** performs better than **1-order-atomic**, which shows that phrase embeddings do improve the model. **2-order-phrase** further improves the performance because of the more expressive second-order factorization. All three models perform significantly better than their counterparts in MSTParser where millions of features are used and **1-order-phrase** works surprisingly well that it even beats the conventional second-order model.

With regard to parsing speed, **1-order-atomic** is the fastest while other two models have similar speeds as MSTParser. Further speed up could be achieved by using pre-computing strategy as mentioned in Chen and Manning (2014). We did not try this strategy since parsing speed is not the main focus of this paper.

Model	*tanh-cube*	*cube*	*tanh*
1-order-atomic	**92.19**	91.97	91.73
1-order-phrase	**92.82**	92.25	92.13
2-order-phrase	**93.57**	92.95	92.91

Table 3: Model Performance of different activation functions.

We also investigated the effect of different activation functions. We trained our models with the same configuration except for the activation function. Table 3 lists the UAS of three models on development set.

Feature Type	Instance	Neighboors

	which	where, who, whom, whose, though
POS-tags	NN	NNPS, NNS, EX, NNP, POS
	JJ	JJR, JJS, PDT, RBR, RBS

Table 4: Examples of similar words and POS-tags according to feature embeddings.

As we can see, *tanh-cube* function outperforms *cube* function because of advantages we mentioned in Section 2.4. Moreover, both *tanh-cube* function and *cube* function performs better than *tanh* function. The reason is that the cube term can capture more interactions between input features.

We also plot the UAS of **2-order-phrase** during each iteration of training. As shown in Figure 4, *tanh-cube* function converges faster than *cube* function.

4.3 Qualitative Analysis

In order to see why our models work, we made qualitative analysis on different aspects of our model.

Ability of Feature Abstraction

Feature embeddings give our model the ability of feature abstraction. They capture the inherent correlations between features so that syntactic similar features will have similar representations, which makes our model generalizes well on unseen data.

Table 4 shows the effect of different feature embeddings which are obtained from **2-order-phrase** after training. For each kind of feature type, we list several features as well as top 5 features that are nearest (measured by Euclidean distance) to the corresponding feature according to their embeddings.

We first analysis the effect of word embeddings after training. For comparison, we also list the initial word embeddings in word2vec. As we can see, in word2vec word embeddings, words that are similar to *in* and *which* tends to be those

Table 5: Examples of similar phrases according to phrase embeddings.

co-occuring with them and for word *his*, similar words are morphologies of *he*. On the contrary, similar words measured by our embeddings have similar syntactic functions. This is helpful for dependency parsing since parsing models care more about the syntactic functions of words rather than their collocations or morphologies.

POS-tag embeddings also show similar behavior with word embeddings. As shown in Table 4, our model captures similarities between POS-tags even though their embeddings are initialized randomly.

We also investigated the effect of phrase embeddings in the same way as feature embeddings. Table 5 lists the examples of similar phrases. Our phrase embeddings work pretty well given that only a simple averaging strategy is used. Phrases that are close to each other tend to share similar syntactic and semantic information. By using phrase embeddings, our model sees panorama of the context rather than limited word tri-grams and thus captures richer context information, which is the reason why phrase embeddings significantly improve the performance.

Ability of Feature Learning

Finally, we try to unveil the mysterious hidden layer and investigate what features it learns. For each hidden unit of **2-order-phrase**, we get its connections with embeddings (i.e., W_h^d in Figure 2) and pick the connections whose weights have absolute value > 0.1. We sampled several hidden units and invenstigated which features their highly weighted connections belong to:

- Hidden 1: $h.w$, $m.w$, $h_{-1}.w$, $m_1.w$
- Hidden 2: $h.p$, $m.p$, $s.p$
- Hidden 3: *hm_infix.p, hm_infix.w, hm_prefix.w*
- Hidden 4: *hm_infix.w, hm_prefix.w, sm_infix.w*
- Hidden 5: *hm_infix.p, hm_infix.w, hm_suffix.w*

The samples above give qualitative results of what features the hidden layer learns:

- Hidden unit 1 and 2 show that atomic features of *head*, *modifier*, *sibling* and their local context words are useful in our model, which is consistent with our expectations since these features are also very important features in conventional graph-based models (McDonald and Pereira, 2006).
- Features in the same hidden unit will "combine" with each other through our *tanh-cube* activation function. As we can see, feature combination in hidden unit 2 were also used in Mcdonald and Pereira (2006). However, these feature combinations are automatically captured by our model without the labor-intensive feature engineering.
- Hidden unit 3 to 5 show that phrase-level information like *hm_prefix*, *hm_suffix* and *sm_infix* are effective in our model. These features are not used in conventional second-order model (McDonald and Pereira, 2006) because they could explode the feature space. Through our tanh-cube activation function, our model further captures the interactions between phrases and other features without the concern of overfitting.

5 Related Work

Models for dependency parsing have been studied with considerable effort in the NLP community. Among them, we only focus on the graph-based models here. Most previous systems address this task by using linear statistical models with carefully designed context and structure features. The types of features available rely on tree factorization and decoding algorithm. Mcdonald et.al (2005) proposed the first-order model which is also know as arc-factored model. Efficient decoding can be performed with Eisner (2000) algorithm in $O(n^3)$ time and $O(n^2)$ space. Mcdonald and Pereira (2006) further extend the first-order model to second-order model where sibling information is available during decoding. Eisner (2000) algorithm can be modified trivially for second-order decoding. Carreras (2007) proposed a more powerful second-order model that can score both sibling and grandchild parts with the cost of $O(n^4)$ time and $O(n^3)$ space. To exploit more structure information, Koo and Collins (2010) proposed three third-order models with computational requirements of $O(n^4)$ time and $O(n^3)$ space.

Recently, neural network models have been increasingly focused on for their ability to minimize the effort in feature engineering. Chen et.al (2014) proposed an approach to automatically learning feature embeddings for graph-based dependency parsing. The learned feature embeddings are used as additional features in conventional graph-based model. Le and Zuidema (2014) proprosed an infinite-order model based on recursive neural network. However, their model can only be used as an reranking model since decoding is intractable.

Compared with these work, our model is a general and standalone neural network model. Both training and decoding in our model are performed based on our neural network architecture in an effective way. Although only first-order and second-order models are implemented in our work, higher-order graph-based models can be easily implemented using our model.

6 Conclusion

In this paper, we propose a general and effective neural network model that can automatically learn feature combinations with our novel activation function. Moreover, we introduce a simple yet effect way to utilize phrase-level information, which greatly improves the model performance. Experiments on the benchmark dataset show that our model achieves better results than conventional models.

Abstract

We present structured perceptron training for neural network transition-based dependency parsing. We learn the neural network representation using a gold corpus augmented by a large number of automatically parsed sentences. Given this fixed network representation, we learn a final layer using the structured perceptron with beam-search decoding. On the Penn Treebank, our parser reaches 94.26% unlabeled and 92.41% labeled attachment accuracy, which to our knowledge is the best accuracy on Stanford Dependencies to date. We also provide in-depth ablative analysis to determine which aspects of our model provide the largest gains in accuracy.

1 Introduction

Syntactic analysis is a central problem in language understanding that has received a tremendous amount of attention. Lately, dependency parsing has emerged as a popular approach to this problem due to the availability of dependency treebanks in many languages (Buchholz and Marsi, 2006; Nivre et al., 2007; McDonald et al., 2013) and the efficiency of dependency parsers.

Transition-based parsers (Nivre, 2008) have been shown to provide a good balance between efficiency and accuracy. In transition-based parsing, sentences are processed in a linear left to right pass; at each position, the parser needs to choose from a set of possible actions defined by the transition strategy. In greedy models, a classifier is used to independently decide which transition to take based on local features of the current parse configuration. This classifier typically uses hand-engineered features and is trained on individual transitions extracted from the gold transition sequence. While extremely fast, these greedy models typically suffer from search errors due to the inability to recover from incorrect decisions. Zhang and Clark (2008) showed that a beam-search decoding algorithm utilizing the structured perceptron training algorithm can greatly improve accuracy. Nonetheless, significant manual feature engineering was required before transition-based systems provided competitive accuracy with graph-based parsers (Zhang and Nivre, 2011), and only by incorporating graph-based scoring functions were Bohnet and Kuhn (2012) able to exceed the accuracy of graph-based approaches.

In contrast to these carefully hand-tuned approaches, Chen and Manning (2014) recently presented a neural network version of a greedy transition-based parser. In their model, a feed-forward neural network with a hidden layer is used to make the transition decisions. The hidden layer has the power to learn arbitrary combinations of the atomic inputs, thereby eliminating the need for hand-engineered features. Furthermore, because the neural network uses a distributed representation, it is able to model lexical, part-of-speech (POS) tag, and arc label similarities in a continuous space. However, although their model outperforms its greedy hand-engineered counterparts, it is not competitive with state-of-the-art dependency parsers that are trained for structured search.

In this work, we combine the representational power of neural networks with the superior search enabled by structured training and inference, making our parser one of the most accurate dependency parsers to date. Training and testing on the Penn Treebank (Marcus et al., 1993), our transition-based parser achieves 93.99% unlabeled (UAS) / 92.05% labeled (LAS) attachment accuracy, outperforming the 93.22% UAS / 91.02% LAS of Zhang and McDonald (2014) and 93.27 UAS / 91.19 LAS of Bohnet and Kuhn (2012). In addition, by incorporating unlabeled data into training, we further improve the accuracy of our model to 94.26% UAS / 92.41% LAS (93.46%

UAS / 91.49% LAS for our greedy model).

In our approach we start with the basic structure of Chen and Manning (2014), but with a deeper architecture and improvements to the optimization procedure. These modifications (Section 2) increase the performance of the greedy model by as much as 1%. As in prior work, we train the neural network to model the probability of individual parse actions. However, we do not use these probabilities directly for prediction. Instead, we use the activations from all layers of the neural network as the representation in a structured perceptron model that is trained with beam search and early updates (Section 3). On the Penn Treebank, this structured learning approach significantly improves parsing accuracy by 0.8%.

An additional contribution of this work is an effective way to leverage unlabeled data. Neural networks are known to perform very well in the presence of large amounts of training data; however, obtaining more expert-annotated parse trees is very expensive. To this end, we generate large quantities of high-confidence parse trees by parsing unlabeled data with two different parsers and selecting only the sentences for which the two parsers produced the same trees (Section 3.3). This approach is known as "tri-training" (Li et al., 2014) and we show that it benefits our neural network parser significantly more than other approaches. By adding 10 million automatically parsed tokens to the training data, we improve the accuracy of our parsers by almost ~1.0% on web domain data.

We provide an extensive exploration of our model in Section 5 through ablative analysis and other retrospective experiments. One of the goals of this work is to provide guidance for future refinements and improvements on the architecture and modeling choices we introduce in this paper.

Finally, we also note that neural network representations have a long history in syntactic parsing (Henderson, 2004; Titov and Henderson, 2007; Titov and Henderson, 2010); however, like Chen and Manning (2014), our network avoids any recurrent structure so as to keep inference fast and efficient and to allow the use of simple backpropagation to compute gradients. Our work is also not the first to apply structured training to neural networks (see e.g. Peng et al. (2009) and Do and Artires (2010) for Conditional Random Field (CRF) training of neural networks). Our paper extends this line of work to the setting of inexact search with beam decoding for dependency parsing; Zhou et al. (2015) concurrently explored a similar approach using a structured probabilistic ranking objective. Dyer et al. (2015) concurrently developed the Stack Long Short-Term Memory (S-LSTM) architecture, which does incorporate recurrent architecture and look-ahead, and which yields comparable accuracy on the Penn Treebank to our greedy model.

Figure 1: Schematic overview of our neural network model. Atomic features are extracted from the i'th elements on the stack (s_i) and the buffer (b_i); lc_i indicates the i'th leftmost child and rc_i the i'th rightmost child. We use the top two elements on the stack for the arc features and the top four tokens on stack and buffer for words, tags and arc labels.

2 Neural Network Model

In this section, we describe the architecture of our model, which is summarized in Figure 1. Note that we separate the embedding processing to a distinct "embedding layer" for clarity of presentation. Our model is based upon that of Chen and Manning (2014) and we discuss the differences between our model and theirs in detail at the end of this section. We use the *arc-standard* (Nivre, 2004) transition system.

2.1 Input layer

Given a parse configuration c (consisting of a stack s and a buffer b), we extract a rich set of discrete features which we feed into the neural network. Following Chen and Manning (2014), we group these features by their input source: words, POS tags, and arc labels. The features extracted for each group are represented as a sparse $F \times V$ matrix $\mathbf{X}$, where V is the size of the vocabulary of the feature group and F is the number of features. The value of element X_{fv} is 1 if the f'th feature takes on value v. We produce three input matrices: $\mathbf{X}_{\text{word}}$ for words features, $\mathbf{X}_{\text{tag}}$ for POS tag features, and $\mathbf{X}_{\text{label}}$ for arc labels, with $F_{\text{word}} = F_{\text{tag}} = 20$ and $F_{\text{label}} = 12$ (Figure 1).

For all feature groups, we add additional special values for "ROOT" (indicating the POS or word of the root token), "NULL" (indicating no valid feature value could be computed) or "UNK" (indicating an out-of-vocabulary item).

2.2 Embedding layer

The first learned layer h_0 in the network transforms the sparse, discrete features $\mathbf{X}$ into a dense, continuous embedded representation. For each feature group $\mathbf{X}_g$, we learn a $V_g \times D_g$ embedding matrix $\mathbf{E}_g$ that applies the conversion:

$$\mathbf{h}_0 = [\mathbf{X}_g \mathbf{E}_g \mid g \in \{\text{word}, \text{tag}, \text{label}\}], \qquad (1)$$

where we apply the computation separately for each group g and concatenate the results. Thus, the embedding layer has $E = \sum_g F_g D_g$ outputs, which we reshape to a vector $\mathbf{h}_0$. We can choose the embedding dimensionality D for each group freely. Since POS tags and arc labels have much smaller vocabularies, we show in our experiments (Section 5.1) that we can use smaller D_{tag} and D_{label}, without a loss in accuracy.

2.3 Hidden layers

We experimented with one and two hidden layers composed of M rectified linear (Relu) units (Nair and Hinton, 2010). Each unit in the hidden layers is fully connected to the previous layer:

$$\mathbf{h}_i = \max\{0, \mathbf{W}_i \mathbf{h}_{i-1} + \mathbf{b}_i\}, \qquad (2)$$

where $\mathbf{W}_1$ is a $M_1 \times E$ weight matrix for the first hidden layer and $\mathbf{W}_i$ are $M_i \times M_{i-1}$ matrices for all subsequent layers. The weights $\mathbf{b}_i$ are bias terms. Relu layers have been well studied in the neural network literature and have been shown to work well for a wide domain of problems (Krizhevsky et al., 2012; Zeiler et al., 2013). Through most of development, we kept $M_i = 200$, but we found that significantly increasing the number of hidden units improved our results for the final comparison.

2.4 Relationship to Chen and Manning (2014)

Our model is clearly inspired by and based on the work of Chen and Manning (2014). There are a few structural differences: (1) we allow for much smaller embeddings of POS tags and labels, (2) we use Relu units in our hidden layers, and (3) we use a deeper model with two hidden layers. Somewhat to our surprise, we found these changes combined with an SGD training scheme (Section 3.1) during the "pre-training" phase of the model to lead to an almost 1% accuracy gain over Chen and Manning (2014). This trend held despite carefully tuning hyperparameters for each method of training and structure combination.

Our main contribution from an algorithmic perspective is our training procedure: as described in the next section, we use the structured perceptron for learning the final layer of our model. We thus present a novel way to leverage a neural network representation in a structured prediction setting.

3 Semi-Supervised Structured Learning

In this work, we investigate a semi-supervised structured learning scheme that yields substantial improvements in accuracy over the baseline neural network model. There are two complementary contributions of our approach: (1) incorporating structured learning of the model and (2) utilizing unlabeled data. In both cases, we use the neural network to model the probability of each parsing action y as a soft-max function taking the final hidden layer as its input:

$$P(y) \propto \exp\{\beta_y^\top \mathbf{h}_i + b_y\}, \qquad (3)$$

where β_y is a M_i dimensional vector of weights for class y and i is the index of the final hidden layer of the network. At a high level our approach can be summarized as follows:

- First, we pre-train the network's hidden representations by learning probabilities of parsing actions. Fixing the hidden representations, we learn an additional final output layer using the structured perceptron that uses the output of the network's hidden layers. In practice this improves accuracy by ~0.6% absolute.

- Next, we show that we can supplement the gold data with a large corpus of high quality automatic parses. We show that incorporating unlabeled data in this way improves accuracy by as much as 1% absolute.

3.1 Backpropagation Pretraining

To learn the hidden representations, we use mini-batched averaged stochastic gradient descent (ASGD) (Bottou, 2010) with momentum (Hinton, 2012) to learn the parameters Θ of the network, where $\Theta = \{\mathbf{E}_g, \mathbf{W}_i, \mathbf{b}_i, \beta_y \mid \forall g, i, y\}$. We use backpropagation to minimize the multinomial logistic loss:

$$L(\Theta) = -\sum_j \log P(y_j \mid c_j, \Theta) + \lambda \sum_i \|\mathbf{W}_i\|_2^2, \quad (4)$$

where λ is a regularization hyper-parameter over the hidden layer parameters (we use $\lambda = 10^{-4}$ in all experiments) and j sums over all decisions and configurations $\{y_j, c_j\}$ extracted from gold parse trees in the dataset.

The specific update rule we apply at iteration t is as follows:

$$g_t = \mu g_{t-1} - \Delta L(\Theta_t), \quad (5)$$

$$\Theta_{t+1} = \Theta_t + \eta_t g_t, \quad (6)$$

where the descent direction g_t is computed by a weighted combination of the previous direction $g_{t-1}$and the current gradient $\Delta L(\Theta_t)$. The parameter $\mu \in [0, 1)$ is the momentum parameter while η_t is the traditional learning rate. In addition, since we did not tune the regularization parameter λ, we apply a simple exponential step-wise decay to η_t; for every γ rounds of updates, we multiply $\eta_t = 0.96\eta_{t-1}$.

The final component of the update is parameter averaging: we maintain averaged parameters $\bar{\Theta}_t = \alpha_t \bar{\Theta}_{t-1} + (1 - \alpha_t)\Theta_t$, where α_t is an averaging weight that increases from 0.1 to 0.9999 with $1/t$. Combined with averaging, careful tuning of the three hyperparameters μ, η_0, and γ using held-out data was crucial in our experiments.

3.2 Structured Perceptron Training

Given the hidden representations, we now describe how the perceptron can be trained to utilize these representations. The perceptron algorithm with early updates (Collins and Roark, 2004) requires a feature-vector definition ϕ that maps a sentence x together with a configuration c to a feature vector $\phi(x, c) \in \mathbb{R}^d$. There is a one-to-one mapping between configurations c and decision sequences $y_1 \dots y_{j-1}$ for any integer $j \geq 1$: we will use c and $y_1 \dots y_{j-1}$ interchangeably.

For a sentence x, define GEN(x) to be the set of parse trees for x. Each $y \in \text{GEN}(x)$ is a sequence of decisions $y_1 \dots y_m$ for some integer m. We use $\mathcal{Y}$ to denote the set of possible decisions in the parsing model. For each decision $y \in \mathcal{Y}$ we assume a parameter vector $\mathbf{v}(y) \in \mathbb{R}^d$. These parameters will be trained using the perceptron.

In decoding with the perceptron-trained model, we will use beam search to attempt to find:

$$\underset{y \in \text{GEN}(x)}{\text{argmax}} \sum_{j=1}^{m} \mathbf{v}(y_j) \cdot \phi(x, y_1 \dots y_{j-1}).$$

Thus each decision y_j receives a score:

$$\mathbf{v}(y_j) \cdot \phi(x, y_1 \dots y_{j-1}).$$

In the perceptron with early updates, the parameters $\mathbf{v}(y)$ are trained as follows. On each training example, we run beam search until the gold-standard parse tree falls out of the beam.[1] Define j to be the length of the beam at this point. A structured perceptron update is performed using the gold-standard decisions $y_1 \dots y_j$ as the target, and the highest scoring (incorrect) member of the beam as the negative example.

A key idea in this paper is to use the neural network to define the representation $\phi(x, c)$. Given the sentence x and the configuration c, assuming two hidden layers, the neural network defines values for $\mathbf{h}_1$, $\mathbf{h}_2$, and $P(y)$ for each decision y. We experimented with various definitions of ϕ (Section 5.2) and found that $\phi(x, c) = [\mathbf{h}_1\ \mathbf{h}_2\ P(y)]$ (the concatenation of the outputs from both hidden layers, as well as the probabilities for all decisions y possible in the current configuration) had the best accuracy on development data.

Note that it is possible to continue to use backpropagation to learn the representation $\phi(x, c)$ during perceptron training; however, we found using ASGD to pre-train the representation always led to faster, more accurate results in preliminary experiments, and we left further investigation for future work.

3.3 Incorporating Unlabeled Data

Given the high capacity, non-linear nature of the deep network we hypothesize that our model can

[1] If the gold parse tree stays within the beam until the end of the sentence, conventional perceptron updates are used.

be significantly improved by incorporating more data. One way to use unlabeled data is through unsupervised methods such as word clusters (Koo et al., 2008); we follow Chen and Manning (2014) and use pretrained word embeddings to initialize our model. The word embeddings capture similar distributional information as word clusters and give consistent improvements by providing a good initialization and information about words not seen in the treebank data.

However, obtaining more training data is even more important than a good initialization. One potential way to obtain additional training data is by parsing unlabeled data with previously trained models. McClosky et al. (2006) and Huang and Harper (2009) showed that iteratively re-training a single model ("self-training") can be used to improve parsers in certain settings; Petrov et al. (2010) built on this work and showed that a slow and accurate parser can be used to "up-train" a faster but less accurate parser.

In this work, we adopt the "tri-training" approach of Li et al. (2014): Two parsers are used to process the unlabeled corpus and only sentences for which both parsers produced the same parse tree are added to the training data. The intuition behind this idea is that the chance of the parse being correct is much higher when the two parsers agree: there is only one way to be correct, while there are many possible incorrect parses. Of course, this reasoning holds only as long as the parsers suffer from different biases.

We show that tri-training is far more effective than vanilla up-training for our neural network model. We use same setup as Li et al. (2014), intersecting the output of the BerkeleyParser (Petrov et al., 2006), and a reimplementation of ZPar (Zhang and Nivre, 2011) as our baseline parsers. The two parsers agree only 36% of the time on the tune set, but their accuracy on those sentences is 97.26% UAS, approaching the inter annotator agreement rate. These sentences are of course easier to parse, having an average length of 15 words, compared to 24 words for the tune set overall. However, because we only use these sentences to extract individual transition decisions, the shorter length does not seem to hurt their utility. We generate 10^7 tokens worth of new parses and use this data in the backpropagation stage of training.

4 Experiments

In this section we present our experimental setup and the main results of our work.

4.1 Experimental Setup

We conduct our experiments on two English language benchmarks: (1) the standard Wall Street Journal (WSJ) part of the Penn Treebank (Marcus et al., 1993) and (2) a more comprehensive union of publicly available treebanks spanning multiple domains. For the WSJ experiments, we follow standard practice and use sections 2-21 for training, section 22 for development and section 23 as the final test set. Since there are many hyperparameters in our models, we additionally use section 24 for tuning. We convert the constituency trees to Stanford style dependencies (De Marneffe et al., 2006) using version 3.3.0 of the converter. We use a CRF-based POS tagger to generate 5-fold jack-knifed POS tags on the training set and predicted tags on the dev, test and tune sets; our tagger gets comparable accuracy to the Stanford POS tagger (Toutanova et al., 2003) with 97.44% on the test set. We report unlabeled attachment score (UAS) and labeled attachment score (LAS) excluding punctuation on predicted POS tags, as is standard for English.

For the second set of experiments, we follow the same procedure as above, but with a more diverse dataset for training and evaluation. Following Vinyals et al. (2015), we use (in addition to the WSJ), the OntoNotes corpus version 5 (Hovy et al., 2006), the English Web Treebank (Petrov and McDonald, 2012), and the updated and corrected Question Treebank (Judge et al., 2006). We train on the union of each corpora's training set and test on each domain separately. We refer to this setup as the "Treebank Union" setup.

In our semi-supervised experiments, we use the corpus from Chelba et al. (2013) as our source of unlabeled data. We process it with the BerkeleyParser (Petrov et al., 2006), a latent variable constituency parser, and a reimplementation of ZPar (Zhang and Nivre, 2011), a transition-based parser with beam search. Both parsers are included as baselines in our evaluation. We select the first 10^7 tokens for which the two parsers agree as additional training data. For our tri-training experiments, we re-train the POS tagger using the POS tags assigned on the unlabeled data from the Berkeley constituency parser. This increases POS

Table 2: Final Treebank Union test set results. We report LAS only for brevity; see Appendix for full results. For these tri-training results, we sampled sentences to ensure the distribution of sentence lengths matched the distribution in the training set, which we found marginally improved the ZPar tri-training performance. For reference, the accuracy of the Berkeley constituency parser (after conversion) is 91.66% WSJ, 85.93% Web, and 93.45% QTB.

accuracy slightly to 97.57% on the WSJ.

4.2 Model Initialization & Hyperparameters

In all cases, we initialized $\mathbf{W}_i$ and β randomly using a Gaussian distribution with variance 10^{-4}. We used fixed initialization with $b_i = 0.2$, to ensure that most Relu units are activated during the initial rounds of training. We did not systematically compare this random scheme to others, but we found that it was sufficient for our purposes.

For the word embedding matrix $\mathbf{E}_{\text{word}}$, we initialized the parameters using pretrained word embeddings. We used the publicly available `word2vec`[2] tool (Mikolov et al., 2013) to learn CBOW embeddings following the sample configuration provided with the tool. For words not appearing in the unsupervised data and the special "NULL" etc. tokens, we used random initialization. In preliminary experiments we found no difference between training the word embeddings on 1 billion or 10 billion tokens. We therefore trained the word embeddings on the same corpus we used for tri-training (Chelba et al., 2013).

We set $D_{\text{word}} = 64$ and $D_{\text{tag}} = D_{\text{label}} = 32$ for embedding dimensions and $M_1 = M_2 = 2048$ hidden units in our final experiments. For the perceptron layer, we used $\phi(x, c) = [\mathbf{h}_1\ \mathbf{h}_2\ P(y)]$ (concatenation of all intermediate layers). All hyperparameters (including structure) were tuned using Section 24 of the WSJ only. When not tri-training, we used hyperparameters of $\gamma = 0.2$, $\eta_0 = 0.05$, $\mu = 0.9$, early stopping after roughly 16 hours of training time. With the tri-training data, we decreased $\eta_0 = 0.05$, increased $\gamma = 0.5$, and decreased the size of the network to $M_1 = 1024$, $M_2 = 256$ for run-time efficiency, and trained the network for approximately 4 days. For the Treebank Union setup, we set $M_1 = M_2 = 1024$ for the standard training set and for the tri-training setup.

4.3 Results

Table 1 shows our final results on the WSJ test set, and Table 2 shows the cross-domain results from the Treebank Union. We compare to the best dependency parsers in the literature. For (Chen and Manning, 2014) and (Dyer et al., 2015), we use reported results; the other baselines were run by Bernd Bohnet using version 3.3.0 of the Stanford dependencies and our predicted POS tags for all datasets to make comparisons as fair as possible. On the WSJ and Web tasks, our parser outperforms all dependency parsers in our comparison by a substantial margin. The Question (QTB) dataset is more sensitive to the smaller beam size we use in order to train the models in a reasonable time; if we increase to $B = 32$ at inference

[2] http://code.google.com/p/word2vec/

time only, our perceptron performance goes up to 92.29% LAS.

Since many of the baselines could not be directly compared to our semi-supervised approach, we re-implemented Zhang and Nivre (2011) and trained on the tri-training corpus. Although tri-training did help the baseline on the dev set (Figure 4), test set performance did not improve significantly. In contrast, it is quite exciting to see that after tri-training, even our greedy parser is more accurate than any of the baseline dependency parsers and competitive with the Berkeley-Parser used to generate the tri-training data. As expected, tri-training helps most dramatically to increase accuracy on the Treebank Union setup with diverse domains, yielding 0.4-1.0% absolute LAS improvement gains for our most accurate model.

Unfortunately we are not able to compare to several semi-supervised dependency parsers that achieve some of the highest reported accuracies on the WSJ, in particular Suzuki et al. (2009), Suzuki et al. (2011) and Chen et al. (2013). These parsers use the Yamada and Matsumoto (2003) dependency conversion and the accuracies are therefore not directly comparable. The highest of these is Suzuki et al. (2011), with a reported accuracy of 94.22% UAS. Even though the UAS is not directly comparable, it is typically similar, and this suggests that our model is competitive with some of the highest reported accuries for dependencies on WSJ.

5 Discussion

In this section, we investigate the contribution of the various components of our approach through ablation studies and other systematic experiments. We tune on Section 24, and use Section 22 for comparisons in order to not pollute the official test set (Section 23). We focus on UAS as we found the LAS scores to be strongly correlated. Unless otherwise specified, we use 200 hidden units in each layer to be able to run more ablative experiments in a reasonable amount of time.

5.1 Impact of Network Structure

In addition to initialization and hyperparameter tuning, there are several additional choices about model structure and size a practitioner faces when implementing a neural network model. We explore these questions and justify the particular choices we use in the following. Note that we do not use a beam for this analysis and therefore do not train the final perceptron layer. This is done in order to reduce training times and because the trends persist across settings.

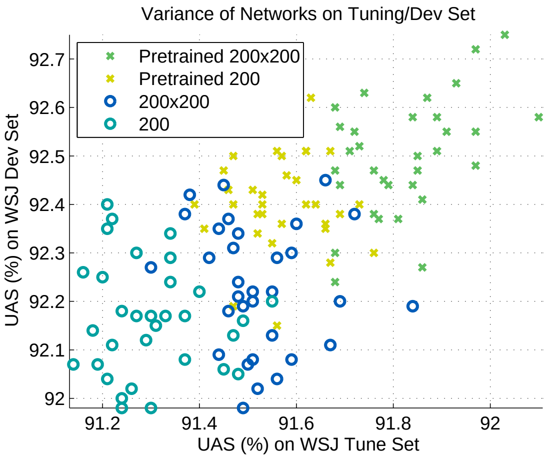

Figure 2: Effect of hidden layers and pre-training on variance of random restarts. Initialization was either completely random or initialized with `word2vec` embeddings ("Pretrained"), and either one or two hidden layers of size 200 were used ("200" vs "200x200"). Each point represents maximization over a small hyperparameter grid with early stopping based on WSJ tune set UAS score. $D_{\text{word}} = 64$, $D_{\text{tag}}, D_{\text{label}} = 16$.

Variance reduction with pre-trained embeddings. Since the learning problem is non-convex, different initializations of the parameters yield different solutions to the learning problem. Thus, for any given experiment, we ran multiple random restarts for every setting of our hyperparameters and picked the model that performed best using the held-out tune set. We found it important to allow the model to stop training early if tune set accuracy decreased.

We visualize the performance of 32 random restarts with one or two hidden layers and with and without pretrained word embeddings in Figure 2, and a summary of the figure in Table 3. While adding a second hidden layer results in a large gain on the tune set, there is no gain on the dev set if pre-trained embeddings are not used. In fact, while the overall UAS scores of the tune set and dev set are strongly correlated ($\rho = 0.64$, $p < 10^{-10}$), they are *not* significantly correlated if pre-trained embeddings are not used ($\rho = 0.12$, $p > 0.3$). This suggests that an additional benefit of pre-trained embeddings, aside from allowing learning to reach a more accurate solution, is to push learning towards a solution that generalizes to more data.

Pre	Hidden	WSJ §24 (Max)	WSJ §22
Y	200 × 200	92.10 ± 0.11	**92.58** ±0.12
Y	200	91.76 ± 0.09	92.30 ± 0.10
N	200 × 200	91.84 ± 0.11	92.19 ± 0.13
N	200	91.55 ± 0.10	92.20 ± 0.12

Table 3: Impact of network architecture on UAS for greedy inference. We select the best model from 32 random restarts based on the tune set and show the resulting dev set accuracy. We also show the standard deviation across the 32 restarts.

# Hidden	64	128	256	512	1024	2048
1 Layer	91.73	92.27	92.48	92.73	92.74	**92.83**
2 Layers	91.89	92.40	92.71	92.70	92.96	**93.13**

Table 4: Increasing hidden layer size increases WSJ Dev UAS. Shown is the average WSJ Dev UAS across hyperparameter tuning and early stopping with 3 random restarts with a greedy model.

Diminishing returns with increasing embedding dimensions. For these experiments, we fixed one embedding type to a high value and reduced the dimensionality of all others to very small values. The results are plotted in Figure 3, suggesting larger embeddings do not significantly improve results. We also ran tri-training on a very compact model with $D_{\text{word}} = 8$ and $D_{\text{tag}} = D_{\text{label}} = 2$ (8× fewer parameters than our full model) which resulted in 92.33% UAS accuracy on the dev set. This is comparable to the full model without tri-training, suggesting that more training data can compensate for fewer parameters.

Increasing hidden units yields large gains. For these experiments, we fixed the embedding sizes $D_{\text{word}} = 64$, $D_{\text{tag}} = D_{\text{label}} = 32$ and tried increasing and decreasing the dimensionality of the hidden layers on a logarthmic scale. Improvements in accuracy did not appear to saturate even with increasing the number of hidden units by an order of magnitude, though the network became too slow to train effectively past $M = 2048$. These results suggest that there are still gains to be made by increasing the efficiency of larger networks, even for greedy shift-reduce parsers.

5.2 Impact of Structured Perceptron

We now turn our attention to the importance of structured perceptron training as well as the impact of different latent representations.

Bias reduction through structured training. To evaluate the impact of structured training, we compare using the estimates $P(y)$ from the neural network directly for beam search to using the activations from all layers as features in the structured perceptron. Using the probability estimates directly is very similar to Ratnaparkhi (1997), where a maximum-entropy model was used to model the distribution over possible actions at each parser state, and beam search was used to search for the highest probability parse. A known problem with beam search in this setting is the label-bias problem. Table 5 shows the impact of using structured perceptron training over using the softmax function during beam search as a function of the beam size used. For reference, our reimplementation of Zhang and Nivre (2011) is trained equivalently for each setting. We also show the impact on beam size when tri-training is used. Although the beam does marginally improve accuracy for the softmax model, much greater gains are achieved when perceptron training is used.

Beam	1	2	4	8	16	32
WSJ Only						
ZN'11	90.55	91.36	92.54	92.62	92.88	**93.09**
Softmax	92.74	93.07	93.16	**93.25**	93.24	93.24
Perceptron	92.73	93.06	93.40	93.47	93.50	**93.58**
Tri-training						
ZN'11	91.65	92.37	**93.37**	93.24	93.21	93.18

Perceptron	93.69	94.00	94.23	**94.33**	94.31	94.32

Table 5: Beam search always yields significant gains but using perceptron training provides even larger benefits, especially for the tri-trained neural network model. The best result for each model is highlighted in bold.

$\phi(x, c)$	WSJ Only	Tri-training
$[\mathbf{h}_2]$	93.16	93.93
$[P(y)]$	93.26	93.80
$[\mathbf{h}_1\ \mathbf{h}_2]$	93.33	93.95
$[\mathbf{h}_1\ \mathbf{h}_2\ P(y)]$	**93.47**	**94.33**

Table 6: Utilizing all intermediate representations improves performance on the WSJ dev set. All results are with $B = 8$.

Using all hidden layers crucial for structured perceptron. We also investigated the impact of connecting the final perceptron layer to all prior hidden layers (Table 6). Our results suggest that all intermediate layers of the network are indeed discriminative. Nonetheless, aggregating all of their activations proved to be the most effective representation for the structured perceptron. This suggests that the representations learned by the network collectively contain the information re-

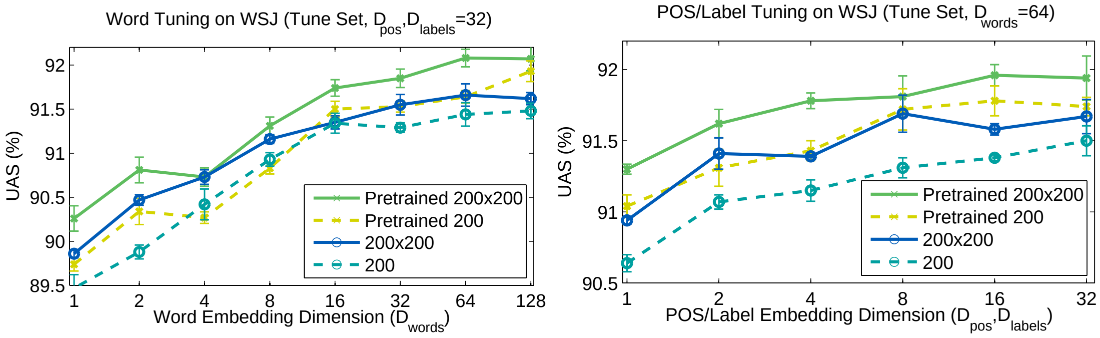

Figure 3: Effect of embedding dimensions on the WSJ tune set.

quired to reduce the bias of the model, but not when filtered through the softmax layer. Finally, we also experimented with connecting both hidden layers to the softmax layer during backpropagation training, but we found this did not significantly affect the performance of the greedy model.

5.3 Impact of Tri-Training

To evaluate the impact of the tri-training approach, we compared to up-training with the BerkelyParser (Petrov et al., 2006) alone. The results are summarized in Figure 4 for the greedy and perceptron neural net models as well as our reimplementated Zhang and Nivre (2011) baseline.

For our neural network model, training on the output of the BerkeleyParser yields only modest gains, while training on the data where the two parsers agree produces significantly better results. This was especially pronounced for the greedy models: after tri-training, the greedy neural network model surpasses the BerkeleyParser in accuracy. It is also interesting to note that up-training improved results far more than tri-training for the baseline. We speculate that this is due to the a lack of diversity in the tri-training data for this model, since the same baseline model was intersected with the BerkeleyParser to generate the tri-training data.

5.4 Error Analysis

Regardless of tri-training, using the structured perceptron improved error rates on some of the common and difficult labels: `ROOT`, `ccomp`, `cc`, `conj`, and `nsubj` all improved by >1%. We inspected the learned perceptron weights $\mathbf{v}$ for the softmax probabilities $P(y)$ (see Appendix) and found that the perceptron reweights the softmax probabilities based on common confusions; e.g. a strong negative weight for the action RIGHT(`ccomp`) given the softmax model outputs RIGHT(`conj`). Note that this trend did not hold when $\phi(x, c) = [P(y)]$; without the hidden layer, the perceptron was not able to reweight the softmax probabilities to account for the greedy model's biases.

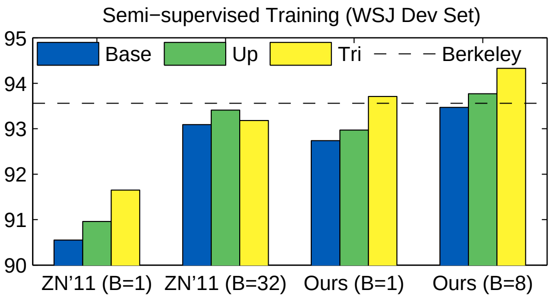

Figure 4: Semi-supervised training with 10^7 additional tokens, showing that tri-training gives significant improvements over up-training for our neural net model.

6 Conclusion

We presented a new state of the art in dependency parsing: a transition-based neural network parser trained with the structured perceptron and ASGD. We then combined this approach with unlabeled data and tri-training to further push state-of-the-art in semi-supervised dependency parsing. Nonetheless, our ablative analysis suggests that further gains are possible simply by scaling up our system to even larger representations. In future work, we will apply our method to other languages, explore end-to-end training of the system using structured learning, and scale up the method to larger datasets and network structures.

Acknowledgements

We would like to thank Bernd Bohnet for training his parsers and TurboParser on our setup. This paper benefitted tremendously from discussions with Ryan McDonald, Greg Coppola, Emily Pitler and Fernando Pereira. Finally, we are grateful to all members of the Google Parsing Team.

Abstract

We propose a technique for learning representations of parser states in transition-based dependency parsers. Our primary innovation is a new control structure for sequence-to-sequence neural networks—the stack LSTM. Like the conventional stack data structures used in transition-based parsing, elements can be pushed to or popped from the top of the stack in constant time, but, in addition, an LSTM maintains a continuous space embedding of the stack contents. This lets us formulate an efficient parsing model that captures three facets of a parser's state: (i) unbounded look-ahead into the buffer of incoming words, (ii) the complete history of actions taken by the parser, and (iii) the complete contents of the stack of partially built tree fragments, including their internal structures. Standard backpropagation techniques are used for training and yield state-of-the-art parsing performance.

1 Introduction

Transition-based dependency parsing formalizes the parsing problem as a series of decisions that read words sequentially from a buffer and combine them incrementally into syntactic structures (Yamada and Matsumoto, 2003; Nivre, 2003; Nivre, 2004). This formalization is attractive since the number of operations required to build any projective parse tree is linear in the length of the sentence, making transition-based parsing computationally efficient relative to graph- and grammar-based formalisms. The challenge in transition-based parsing is modeling which action should be taken in each of the unboundedly many states encountered as the parser progresses.

This challenge has been addressed by development of alternative transition sets that simplify the modeling problem by making better attachment decisions (Nivre, 2007; Nivre, 2008; Nivre, 2009; Choi and McCallum, 2013; Bohnet and Nivre, 2012), through feature engineering (Zhang and Nivre, 2011; Ballesteros and Nivre, 2014; Chen et al., 2014; Ballesteros and Bohnet, 2014) and more recently using neural networks (Chen and Manning, 2014; Stenetorp, 2013).

We extend this last line of work by learning representations of the parser state that are sensitive to the complete contents of the parser's state: that is, the complete input buffer, the complete history of parser actions, and the complete contents of the stack of partially constructed syntactic structures. This "global" sensitivity to the state contrasts with previous work in transition-based dependency parsing that uses only a narrow view of the parsing state when constructing representations (e.g., just the next few incoming words, the head words of the top few positions in the stack, etc.). Although our parser integrates large amounts of information, the representation used for prediction at each time step is constructed incrementally, and therefore parsing and training time remain linear in the length of the input sentence. The technical innovation that lets us do this is a variation of recurrent neural networks with long short-term memory units (LSTMs) which we call **stack LSTMs** (§2), and which support both reading (pushing) and "forgetting" (popping) inputs.

Our parsing model uses three stack LSTMs: one representing the input, one representing the stack of partial syntactic trees, and one representing the history of parse actions to encode parser states (§3). Since the stack of partial syntactic trees may contain both individual tokens and partial syntactic structures, representations of individual tree fragments are computed compositionally with recursive (i.e., similar to Socher et al., 2014) neural networks. The parameters are learned with backpropagation (§4), and we obtain state-of-the-art results on Chinese and English dependency parsing tasks (§5).

2 Stack LSTMs

In this section we provide a brief review of LSTMs (§2.1) and then define stack LSTMs (§2.2).

Notation. We follow the convention that vectors are written with lowercase, boldface letters (e.g., $\mathbf{v}$ or $\mathbf{v}_w$); matrices are written with uppercase, boldface letters (e.g., $\mathbf{M}$, $\mathbf{M}_a$, or $\mathbf{M}_{ab}$), and scalars are written as lowercase letters (e.g., s or q_z). Structured objects such as sequences of discrete symbols are written with lowercase, bold, italic letters (e.g., $\boldsymbol{w}$ refers to a sequence of input words). Discussion of dimensionality is deferred to the experiments section below (§5).

2.1 Long Short-Term Memories

LSTMs are a variant of recurrent neural networks (RNNs) designed to cope with the vanishing gradient problem inherent in RNNs (Hochreiter and Schmidhuber, 1997; Graves, 2013). RNNs read a vector $\mathbf{x}_t$ at each time step and compute a new (hidden) state $\mathbf{h}_t$ by applying a linear map to the concatenation of the previous time step's state $\mathbf{h}_{t-1}$ and the input, and passing this through a logistic sigmoid nonlinearity. Although RNNs can, in principle, model long-range dependencies, training them is difficult in practice since the repeated application of a squashing nonlinearity at each step results in an exponential decay in the error signal through time. LSTMs address this with an extra memory "cell" ($\mathbf{c}_t$) that is constructed as a linear combination of the previous state and signal from the input.

LSTM cells process inputs with three multiplicative gates which control what proportion of the current input to pass into the memory cell ($\mathbf{i}_t$) and what proportion of the previous memory cell to "forget" ($\mathbf{f}_t$). The updated value of the memory cell after an input $\mathbf{x}_t$ is computed as follows:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{ix}\mathbf{x}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + \mathbf{W}_{ic}\mathbf{c}_{t-1} + \mathbf{b}_i)\\
\mathbf{f}_t &= \sigma(\mathbf{W}_{fx}\mathbf{x}_t + \mathbf{W}_{fh}\mathbf{h}_{t-1} + \mathbf{W}_{fc}\mathbf{c}_{t-1} + \mathbf{b}_f)\\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \\
&\qquad \mathbf{i}_t \odot \tanh(\mathbf{W}_{cx}\mathbf{x}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + \mathbf{b}_c),
\end{aligned}$$

where σ is the component-wise logistic sigmoid function, and $\odot$ is the component-wise (Hadamard) product.

The value $\mathbf{h}_t$ of the LSTM at each time step is controlled by a third gate ($\mathbf{o}_t$) that is applied to the result of the application of a nonlinearity to the memory cell contents:

$$\begin{aligned}
\mathbf{o}_t &= \sigma(\mathbf{W}_{ox}\mathbf{x}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + \mathbf{W}_{oc}\mathbf{c}_t + \mathbf{b}_o)\\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t).
\end{aligned}$$

To improve the representational capacity of LSTMs (and RNNs generally), LSTMs can be stacked in "layers" (Pascanu et al., 2014). In these architectures, the input LSTM at higher layers at time t is the value of $\mathbf{h}_t$ computed by the lower layer (and $\mathbf{x}_t$ is the input at the lowest layer).

Finally, output is produced at each time step from the $\mathbf{h}_t$ value at the top layer:

$$\mathbf{y}_t = g(\mathbf{h}_t),$$

where g is an arbitrary differentiable function.

2.2 Stack Long Short-Term Memories

Conventional LSTMs model sequences in a left-to-right order.[1] Our innovation here is to augment the LSTM with a "stack pointer." Like a conventional LSTM, new inputs are always added in the right-most position, but in stack LSTMs, the current location of the stack pointer determines which cell in the LSTM provides $\mathbf{c}_{t-1}$ and $\mathbf{h}_{t-1}$ when computing the new memory cell contents.

In addition to adding elements to the end of the sequence, the stack LSTM provides a pop operation which moves the stack pointer to the previous element (i.e., the previous element that was extended, not necessarily the right-most element). Thus, the LSTM can be understood as a stack implemented so that contents are never overwritten, that is, push always adds a new entry at the end of the list that contains a back-pointer to the previous top, and pop only updates the stack pointer.[2] This control structure is schematized in Figure 1.

By querying the output vector to which the stack pointer points (i.e., the $\mathbf{h}_{\textsf{TOP}}$), a continuous-space "summary" of the contents of the current stack configuration is available. We refer to this value as the "stack summary."

What does the stack summary look like? Intuitively, elements near the top of the stack will

[1] Ours is not the first deviation from a strict left-to-right order: previous variations include bidirectional LSTMs (Graves and Schmidhuber, 2005) and multidimensional LSTMs (Graves et al., 2007).

[2] Goldberg et al. (2013) propose a similar stack construction to prevent stack operations from invalidating existing references to the stack in a beam-search parser that must (efficiently) maintain a priority queue of stacks.

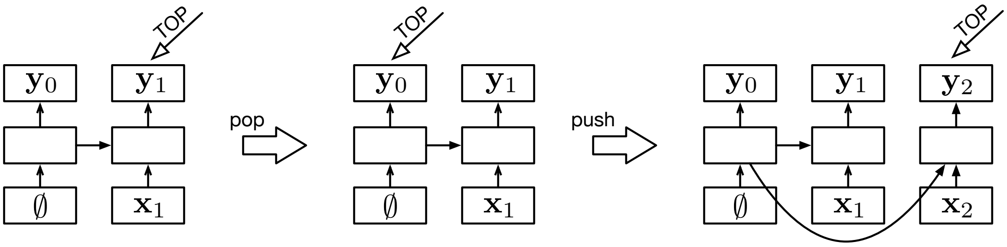

Figure 1: A stack LSTM extends a conventional left-to-right LSTM with the addition of a stack pointer (notated as TOP in the figure). This figure shows three configurations: a stack with a single element (left), the result of a pop operation to this (middle), and then the result of applying a push operation (right). The boxes in the lowest rows represent stack contents, which are the inputs to the LSTM, the upper rows are the outputs of the LSTM (in this paper, only the output pointed to by TOP is ever accessed), and the middle rows are the memory cells (the $\mathbf{c}_t$'s and $\mathbf{h}_t$'s) and gates. Arrows represent function applications (usually affine transformations followed by a nonlinearity), refer to §2.1 for specifics.

influence the representation of the stack. However, the LSTM has the flexibility to learn to extract information from arbitrary points in the stack (Hochreiter and Schmidhuber, 1997).

Although this architecture is to the best of our knowledge novel, it is reminiscent of the Recurrent Neural Network Pushdown Automaton (NNPDA) of Das et al. (1992), which added an external stack memory to an RNN. However, our architecture provides an embedding of the complete contents of the stack, whereas theirs made only the top of the stack visible to the RNN.

3 Dependency Parser

We now turn to the problem of learning representations of dependency parsers. We preserve the standard data structures of a transition-based dependency parser, namely a buffer of words (B) to be processed and a stack (S) of partially constructed syntactic elements. Each stack element is augmented with a continuous-space vector embedding representing a word and, in the case of S, any of its syntactic dependents. Additionally, we introduce a third stack (A) to represent the history of actions taken by the parser.[3] Each of these stacks is associated with a stack LSTM that provides an encoding of their current contents. The full architecture is illustrated in Figure 3, and we will review each of the components in turn.

3.1 Parser Operation

The dependency parser is initialized by pushing the words and their representations (we discuss word representations below in §3.3) of the input sentence in reverse order onto B such that the first word is at the top of B and the ROOT symbol is at the bottom, and S and A each contain an empty-stack token. At each time step, the parser computes a composite representation of the stack states (as determined by the current configurations of B, S, and A) and uses that to predict an action to take, which updates the stacks. Processing completes when B is empty (except for the empty-stack symbol), S contains two elements, one representing the full parse tree headed by the ROOT symbol and the other the empty-stack symbol, and A is the history of operations taken by the parser.

The parser state representation at time t, which we write $\mathbf{p}_t$, which is used to is determine the transition to take, is defined as follows:

$$\mathbf{p}_t = \max\{\mathbf{0}, \mathbf{W}[\mathbf{s}_t; \mathbf{b}_t; \mathbf{a}_t] + \mathbf{d}\},$$

where $\mathbf{W}$ is a learned parameter matrix, $\mathbf{b}_t$ is the stack LSTM encoding of the input buffer B, $\mathbf{s}_t$ is the stack LSTM encoding of S, $\mathbf{a}_t$ is the stack LSTM encoding of A, $\mathbf{d}$ is a bias term, then passed through a component-wise rectified linear unit (ReLU) nonlinearity (Glorot et al., 2011).[4]

Finally, the parser state $\mathbf{p}_t$ is used to compute

[3] The A stack is only ever pushed to; our use of a stack here is purely for implementational and expository convenience.

[4] In preliminary experiments, we tried several nonlinearities and found ReLU to work slightly better than the others.

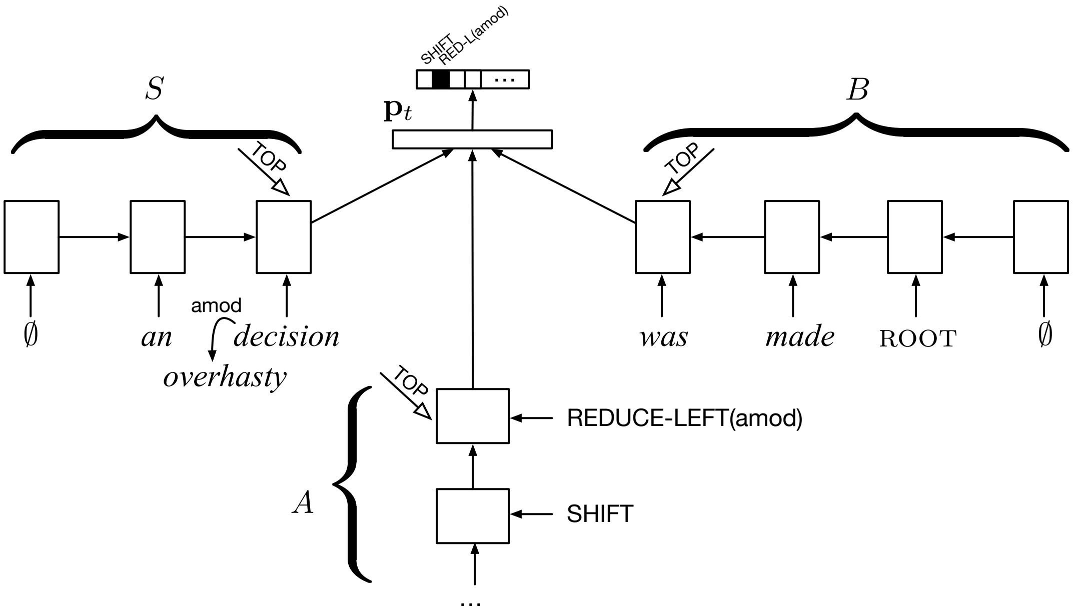

Figure 2: Parser state computation encountered while parsing the sentence "*an overhasty decision was made*." Here S designates the stack of partially constructed dependency subtrees and its LSTM encoding; B is the buffer of words remaining to be processed and its LSTM encoding; and A is the stack representing the history of actions taken by the parser. These are linearly transformed, passed through a ReLU nonlinearity to produce the parser state embedding $\mathbf{p}_t$. An affine transformation of this embedding is passed to a softmax layer to give a distribution over parsing decisions that can be taken.

the probability of the parser action at time t as:

$$p(z_t \mid \mathbf{p}_t) = \frac{\exp\left(\mathbf{g}_{z_t}^\top \mathbf{p}_t + q_{z_t}\right)}{\sum_{z' \in \mathcal{A}(S,B)} \exp\left(\mathbf{g}_{z'}^\top \mathbf{p}_t + q_{z'}\right)},$$

where $\mathbf{g}_z$ is a column vector representing the (output) embedding of the parser action z, and q_z is a bias term for action z. The set $\mathcal{A}(S,B)$ represents the valid actions that may be taken given the current contents of the stack and buffer.[5] Since $\mathbf{p}_t = f(\mathbf{s}_t, \mathbf{b}_t, \mathbf{a}_t)$ encodes information about all previous decisions made by the parser, the chain rule may be invoked to write the probability of any valid sequence of parse actions $\boldsymbol{z}$ conditional on the input as:

$$p(\boldsymbol{z} \mid \boldsymbol{w}) = \prod_{t=1}^{|\boldsymbol{z}|} p(z_t \mid \mathbf{p}_t). \tag{1}$$

3.2 Transition Operations

Our parser is based on the arc-standard transition inventory (Nivre, 2004), given in Figure 3.

Why arc-standard? Arc-standard transitions parse a sentence from left to right, using a stack to store partially built syntactic structures and a buffer that keeps the incoming tokens to be parsed. The parsing algorithm chooses an action at each configuration by means of a score. In arc-standard parsing, the dependency tree is constructed bottom-up, because right-dependents of a head are only attached after the subtree under the dependent is fully parsed. Since our parser recursively computes representations of tree fragments, this construction order guarantees that once a syntactic structure has been used to modify a head, the algorithm will not try to find another head for the dependent structure. This means we can evaluate composed representations of tree fragments incrementally; we discuss our strategy for this below (§3.4).

3.3 Token Embeddings and OOVs

To represent each input token, we concatenate three vectors: a learned vector representation for each word type ($\mathbf{w}$); a fixed vector representation from a neural language model ($\tilde{\mathbf{w}}_{\mathrm{LM}}$), and a learned representation ($\mathbf{t}$) of the POS tag of the token, provided as auxiliary input to the parser. A

[5] In general, $\mathcal{A}(S,B)$ is the complete set of parser actions discussed in §3.2, but in some cases not all actions are available. For example, when S is empty and words remain in B, a SHIFT operation is obligatory (Sartorio et al., 2013).

Stack$_t$	**Buffer**$_t$	**Action**	**Stack**$_{t+1}$	**Buffer**$_{t+1}$	**Dependency**
$(\mathbf{u}, u), (\mathbf{v}, v), S$	B	REDUCE-RIGHT(r)	$(g_r(\mathbf{u}, \mathbf{v}), u), S$	B	$u \xrightarrow{r} v$
$(\mathbf{u}, u), (\mathbf{v}, v), S$	B	REDUCE-LEFT(r)	$(g_r(\mathbf{v}, \mathbf{u}), v), S$	B	$u \xleftarrow{r} v$
S	$(\mathbf{u}, u), B$	SHIFT	$(\mathbf{u}, u), S$	B	—

Figure 3: Parser transitions indicating the action applied to the stack and buffer and the resulting stack and buffer states. Bold symbols indicate (learned) embeddings of words and relations, script symbols indicate the corresponding words and relations.

linear map ($\mathbf{V}$) is applied to the resulting vector and passed through a component-wise ReLU,

$$\mathbf{x} = \max\left\{\mathbf{0}, \mathbf{V}[\mathbf{w}; \tilde{\mathbf{w}}_{\text{LM}}; \mathbf{t}] + \mathbf{b}\right\}.$$

This mapping can be shown schematically as in Figure 4.

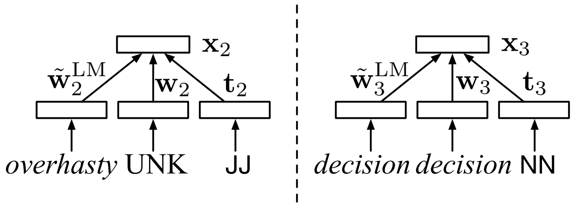

Figure 4: Token embedding of the words *decision*, which is present in both the parser's training data and the language model data, and *overhasty*, an adjective that is not present in the parser's training data but is present in the LM data.

This architecture lets us deal flexibly with out-of-vocabulary words—both those that are OOV in both the very limited parsing data but present in the pretraining LM, and words that are OOV in both. To ensure we have estimates of the OOVs in the parsing training data, we stochastically replace (with $p = 0.5$) each singleton word type in the parsing training data with the UNK token in each training iteration.

Pretrained word embeddings. A veritable cottage industry exists for creating word embeddings, meaning numerous pretraining options for $\tilde{\mathbf{w}}_{\text{LM}}$ are available. However, for syntax modeling problems, embedding approaches which discard order perform less well (Bansal et al., 2014); therefore we used a variant of the skip n-gram model introduced by Ling et al. (2015), named "structured skip n-gram," where a different set of parameters is used to predict each context word depending on its position relative to the target word. The hyperparameters of the model are the same as in the skip n-gram model defined in word2vec (Mikolov et al., 2013), and we set the window size to 5, used a negative sampling rate to 10, and ran 5 epochs through unannotated corpora described in §5.1.

3.4 Composition Functions

Recursive neural network models enable complex phrases to be represented compositionally in terms of their parts and the relations that link them (Socher et al., 2011; Socher et al., 2013c; Hermann and Blunsom, 2013; Socher et al., 2013b). We follow this previous line of work in embedding dependency tree fragments that are present in the stack S in the same vector space as the token embeddings discussed above.

A particular challenge here is that a syntactic head may, in general, have an arbitrary number of dependents. To simplify the parameterization of our composition function, we combine head-modifier pairs one at a time, building up more complicated structures in the order they are "reduced" in the parser, as illustrated in Figure 5. Each node in this expanded syntactic tree has a value computed as a function of its three arguments: the syntactic head ($\mathbf{h}$), the dependent ($\mathbf{d}$), and the syntactic relation being satisfied ($\mathbf{r}$). We define this by concatenating the vector embeddings of the head, dependent and relation, applying a linear operator and a component-wise non-linearity as follows:

$$\mathbf{c} = \tanh\left(\mathbf{U}[\mathbf{h}; \mathbf{d}; \mathbf{r}] + \mathbf{e}\right).$$

For the relation vector, we use an embedding of the parser action that was applied to construct the relation (i.e., the syntactic relation paired with the direction of attachment).

4 Training Procedure

We trained our parser to maximize the conditional log-likelihood (Eq. 1) of treebank parses given sentences. Our implementation constructs a computation graph for each sentence and runs forward- and backpropagation to obtain the gradients of this

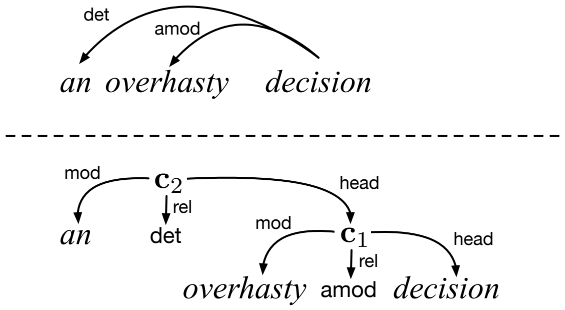

Figure 5: The representation of a dependency subtree (above) is computed by recursively applying composition functions to $\langle \text{head}, \text{modifier}, \text{relation} \rangle$ triples. In the case of multiple dependents of a single head, the recursive branching order is imposed by the order of the parser's reduce operations (below).

objective with respect to the model parameters. The computations for a single parsing model were run on a single thread on a CPU. Using the dimensions discussed in the next section, we required between 8 and 12 hours to reach convergence on a held-out dev set.[6]

Parameter optimization was performed using stochastic gradient descent with an initial learning rate of $\eta_0 = 0.1$, and the learning rate was updated on each pass through the training data as $\eta_t = \eta_0/(1 + \rho t)$, with $\rho = 0.1$ and where t is the number of epochs completed. No momentum was used. To mitigate the effects of "exploding" gradients, we clipped the ℓ_2 norm of the gradient to 5 before applying the weight update rule (Sutskever et al., 2014; Graves, 2013). An ℓ_2 penalty of 1×10^{-6} was applied to all weights.

Matrix and vector parameters were initialized with uniform samples in $\pm\sqrt{6/(r + c)}$, where r and c were the number of rows and columns in the structure (Glorot and Bengio, 2010).

Dimensionality. The full version of our parsing model sets dimensionalities as follows. LSTM hidden states are of size 100, and we use two layers of LSTMs for each stack. Embeddings of the parser actions used in the composition functions have 16 dimensions, and the output embedding size is 20 dimensions. Pretained word embeddings have 100 dimensions (English) and 80 dimensions (Chinese), and the learned word embeddings have 32 dimensions. Part of speech embeddings have 12 dimensions.

These dimensions were chosen based on intuitively reasonable values (words should have higher dimensionality than parsing actions, POS tags, and relations; LSTM states should be relatively large), and it was confirmed on development data that they performed well.[7] Future work might more carefully optimize these parameters; our reported architecture strikes a balance between minimizing computational expense and finding solutions that work.

5 Experiments

We applied our parsing model and several variations of it to two parsing tasks and report results below.

5.1 Data

We used the same data setup as Chen and Manning (2014), namely an English and a Chinese parsing task. This baseline configuration was chosen since they likewise used a neural parameterization to predict actions in an arc-standard transition-based parser.

- For English, we used the Stanford Dependencency (SD) treebank (de Marneffe et al., 2006) used in (Chen and Manning, 2014) which is the closest model published, with the same splits.[8] The part-of-speech tags are predicted by using the Stanford Tagger (Toutanova et al., 2003) with an accuracy of 97.3%. This treebank contains a negligible amount of non-projective arcs (Chen and Manning, 2014).

- For Chinese, we use the Penn Chinese Treebank 5.1 (CTB5) following Zhang and Clark (2008),[9] with gold part-of-speech tags which is also the same as in Chen and Manning (2014).

Language model word embeddings were generated, for English, from the AFP portion of the English Gigaword corpus (version 5), and from the complete Chinese Gigaword corpus (version 2),

[6] Software for replicating the experiments is available from `https://github.com/clab/lstm-parser`.

[7] We did perform preliminary experiments with LSTM states of 32, 50, and 80, but the other dimensions were our initial guesses.

[8] Training: 02-21. Development: 22. Test: 23.

[9] Training: 001–815, 1001–1136. Development: 886–931, 1148–1151. Test: 816–885, 1137–1147.

as segmented by the Stanford Chinese Segmenter (Tseng et al., 2005).

5.2 Experimental configurations

We report results on five experimental configurations per language, as well as the Chen and Manning (2014) baseline. These are: the full stack LSTM parsing model (S-LSTM), the stack LSTM parsing model without POS tags (−POS), the stack LSTM parsing model without pretrained language model embeddings (−pretraining), the stack LSTM parsing model that uses just head words on the stack instead of composed representations (−composition), and the full parsing model where rather than an LSTM, a classical recurrent neural network is used (S-RNN).

5.3 Results

Following Chen and Manning (2014) we exclude punctuation symbols for evaluation. Tables 1 and 2 show comparable results with Chen and Manning (2014), and we show that our model is better than their model in both the development set and the test set.

	Development		Test	
	UAS	LAS	UAS	LAS
S-LSTM	**93.2**	**90.9**	**93.1**	**90.9**
−POS	93.1	90.4	92.7	90.3
−pretraining	92.7	90.4	92.4	90.0
−composition	92.7	89.9	92.2	89.6
S-RNN	92.8	90.4	92.3	90.1
C&M (2014)	92.2	89.7	91.8	89.6

Table 1: English parsing results (SD)

	Dev. set		Test set	
	UAS	LAS	UAS	LAS
S-LSTM	**87.2**	**85.9**	**87.2**	**85.7**
−composition	85.8	84.0	85.3	83.6
−pretraining	86.3	84.7	85.7	84.1
−POS	82.8	79.8	82.2	79.1
S-RNN	86.3	84.7	86.1	84.6
C&M (2014)	84.0	82.4	83.9	82.4

Table 2: Chinese parsing results (CTB5)

5.4 Analysis

Overall, our parser substantially outperforms the baseline neural network parser of Chen and Manning (2014), both in the full configuration and in the various ablated conditions we report. The one exception to this is the −POS condition for the Chinese parsing task, which in which we underperform their baseline (which used gold POS tags), although we do still obtain reasonable parsing performance in this limited case. We note that predicted POS tags in English add very little value—suggesting that we can think of parsing sentences directly without first tagging them. We also find that using composed representations of dependency tree fragments outperforms using representations of head words alone, which has implications for theories of headedness. Finally, we find that while LSTMs outperform baselines that use only classical RNNs, these are still quite capable of learning good representations.

Effect of beam size. Beam search was determined to have minimal impact on scores (absolute improvements of $\leq 0.3\%$ were possible with small beams). Therefore, all results we report used greedy decoding—Chen and Manning (2014) likewise only report results with greedy decoding. This finding is in line with previous work that generates sequences from recurrent networks (Grefenstette et al., 2014), although Vinyals et al. (2015) did report much more substantial improvements with beam search on their "grammar as a foreign language" parser.[10]

6 Related Work

Our approach ties together several strands of previous work. First, several kinds of stack memories have been proposed to augment neural architectures. Das et al. (1992) proposed a neural network with an external stack memory based on recurrent neural networks. In contrast to our model, in which the entire contents of the stack are summarized in a single value, in their model, the network could only see the contents of the top of the stack. Mikkulainen (1996) proposed an architecture with a stack that had a summary feature, although the stack control was learned as a latent variable.

A variety of authors have used neural networks to predict parser actions in shift-reduce parsers. The earliest attempt we are aware of is due to Mayberry and Miikkulainen (1999). The resurgence of interest in neural networks has resulted

[10] Although superficially similar to ours, Vinyals et al. (2015) is a phrase-structure parser and adaptation to the dependency parsing scenario would have been nontrivial. We discuss their work in §6.

in in several applications to transition-based dependency parsers (Weiss et al., 2015; Chen and Manning, 2014; Stenetorp, 2013). In these works, the conditioning structure was manually crafted and sensitive to only certain properties of the state, while we are conditioning on the global state object. Like us, Stenetorp (2013) used recursively composed representations of the tree fragments (a head and its dependents). Neural networks have also been used to learn representations for use in chart parsing (Henderson, 2004; Titov and Henderson, 2007; Socher et al., 2013a; Le and Zuidema, 2014).

LSTMs have also recently been demonstrated as a mechanism for learning to represent parse structure.Vinyals et al. (2015) proposed a phrase-structure parser based on LSTMs which operated by first reading the entire input sentence in so as to obtain a vector representation of it, and then generating bracketing structures sequentially conditioned on this representation. Although superficially similar to our model, their approach has a number of disadvantages. First, they relied on a large amount of semi-supervised training data that was generated by parsing a large unannotated corpus with an off-the-shelf parser. Second, while they recognized that a stack-like shift-reduce parser control provided useful information, they only made the top word of the stack visible during training and decoding. Third, although it is impressive feat of learning that an entire parse tree be represented by a vector, it seems that this formulation makes the problem unnecessarily difficult.

Finally, our work can be understood as a progression toward using larger contexts in parsing. An exhaustive summary is beyond the scope of this paper, but some of the important milestones in this tradition are the use of cube pruning to efficiently include nonlocal features in discriminative chart reranking (Huang and Chiang, 2008), approximate decoding techniques based on LP relaxations in graph-based parsing to include higher-order features (Martins et al., 2010), and randomized hill-climbing methods that enable arbitrary nonlocal features in global discriminative parsing models (Zhang et al., 2014). Since our parser is sensitive to any part of the input, its history, or its stack contents, it is similar in spirit to the last approach, which permits truly arbitrary features.

7 Conclusion

We presented stack LSTMs, recurrent neural networks for sequences, with push and pop operations, and used them to implement a state-of-the-art transition-based dependency parser. We conclude by remarking that stack memory offers intriguing possibilities for learning to solve general information processing problems (Mikkulainen, 1996). Here, we learned from observable stack manipulation operations (i.e., supervision from a treebank), and the computed embeddings of final parser states were not used for any further prediction. However, this could be reversed, giving a device that learns to construct context-free programs (e.g., expression trees) given only observed outputs; one application would be unsupervised parsing. Such an extension of the work would make it an alternative to architectures that have an explicit external memory such as neural Turing machines (Graves et al., 2014) and memory networks (Weston et al., 2015). However, as with those models, without supervision of the stack operations, formidable computational challenges must be solved (e.g., marginalizing over all latent stack operations), but sampling techniques and techniques from reinforcement learning have promise here (Zaremba and Sutskever, 2015), making this an intriguing avenue for future work.

Acknowledgments

The authors would like to thank Lingpeng Kong and Jacob Eisenstein for comments on an earlier version of this draft and Danqi Chen for assistance with the parsing datasets. This work was sponsored in part by the U. S. Army Research Laboratory and the U. S. Army Research Office under contract/grant number W911NF-10-1-0533, and in part by NSF CAREER grant IIS-1054319. Leveraging Linguistic Structure For Open Domain Information Extraction

Abstract

Relation triples produced by open domain information extraction (open IE) systems are useful for question answering, inference, and other IE tasks. Traditionally these are extracted using a large set of patterns; however, this approach is brittle on out-of-domain text and long-range dependencies, and gives no insight into the substructure of the arguments. We replace this large pattern set with a few patterns for canonically structured sentences, and shift the focus to a classifier which learns to extract self-contained clauses from longer sentences. We then run natural logic inference over these short clauses to determine the maximally specific arguments for each candidate triple. We show that our approach outperforms a state-of-the-art open IE system on the end-to-end TAC-KBP 2013 Slot Filling task.

1 Introduction

Open information extraction (open IE) has been shown to be useful in a number of NLP tasks, such as question answering (Fader et al., 2014), relation extraction (Soderland et al., 2010), and information retrieval (Etzioni, 2011). Conventionally, open IE systems search a collection of patterns over either the surface form or dependency tree of a sentence. Although a small set of patterns covers most simple sentences (e.g., subject verb object constructions), relevant relations are often spread across clauses (see Figure 1) or presented in a non-canonical form.

Systems like Ollie (Mausam et al., 2012) approach this problem by using a bootstrapping method to create a large corpus of broad-coverage partially lexicalized patterns. Although this is effective at capturing many of these patterns, it can lead to unintuitive behavior on out-of-domain text. For instance, while *Obama is president* is extracted correctly by Ollie as *(Obama; is; president)*, replacing *is* with *are* in *cats are felines* produces no extractions. Furthermore, existing systems struggle at producing canonical argument forms – for example, in Figure 1 the argument *Heinz Fischer of Austria* is likely less useful for downstream applications than *Heinz Fischer*.

Born in Honolulu, Hawaii, Obama is a US Citizen.

Our System	**Ollie**
(Obama; is; US citizen)	(Obama; is; a US citizen)
(Obama; born in;	(Obama; be born in; Honolulu)
Honolulu, Hawaii)	(Honolulu; be born in; Hawaii)
	(Obama; is citizen of; US)

Friends give true praise.
Enemies give fake praise.

Our System	**Ollie**
(friends; give; true praise)	(friends; give; true praise)
(friends; give; praise)	
(enemies; give; fake praise)	(enemies; give; fake praise)

Heinz Fischer of Austria visits the US

Our System	**Ollie**
(Heinz Fischer; visits; US)	(Heinz Fischer of Austria; visits; the US)

Figure 1: Open IE extractions produced by the system, alongside extractions from the state-of-the-art Ollie system. Generating coherent clauses before applying patterns helps reduce false matches such as *(Honolulu; be born in; Hawaii)*. Inference over the sub-structure of arguments, in turn, allows us to drop unnecessary information (e.g., *of Austria*), but only when it is warranted (e.g., keep *fake* in *fake praise*).

In this paper, we shift the burden of extracting informative and broad coverage triples away from this large pattern set. Rather, we first pre-process the sentence in linguistically motivated ways to produce coherent clauses which are (1) logically

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 344–354,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

entailed by the original sentence, and (2) easy to segment into open IE triples. Our approach consists of two stages: we first learn a classifier for splitting a sentence into shorter utterances (Section 3), and then appeal to natural logic (Sánchez Valencia, 1991) to maximally shorten these utterances while maintaining necessary context (Section 4.1). A small set of 14 hand-crafted patterns can then be used to segment an utterance into an open IE triple.

We treat the first stage as a greedy search problem: we traverse a dependency parse tree recursively, at each step predicting whether an edge should yield an independent clause. Importantly, in many cases naïvely yielding a clause on a dependency edge produces an incomplete utterance (e.g., *Born in Honolulu, Hawaii*, from Figure 1). These are often attributable to control relationships, where either the subject or object of the governing clause controls the subject of the subordinate clause. We therefore allow the produced clause to sometimes inherit the subject or object of its governor. This allows us to capture a large variety of long range dependencies with a concise classifier.

From these independent clauses, we then extract shorter sentences, which will produce shorter arguments more likely to be useful for downstream applications. A natural framework for solving this problem is natural logic – a proof system built on the syntax of human language (see Section 4.1). We can then observe that *Heinz Fischer of Austria visits China* entails that *Heinz Fischer visits China*. On the other hand, we respect situations where it is incorrect to shorten an argument. For example, *No house cats have rabies* should not entail that *cats have rabies*, or even that *house cats have rabies*.

When careful attention to logical validity is necessary – such as textual entailment – this approach captures even more subtle phenomena. For example, whereas *all rabbits eat fresh vegetables* yields *(rabbits; eat; vegetables)*, the apparently similar sentence *all young rabbits drink milk* does not yield *(rabbits; drink; milk)*.

We show that our new system performs well on a real world evaluation – the TAC KBP Slot Filling challenge (Surdeanu, 2013). We outperform both an official submission on open IE, and a baseline of replacing our extractor with Ollie, a state-of-the-art open IE systems.

2 Related Work

There is a large body of work on open information extraction. One line of work begins with TextRunner (Yates et al., 2007) and ReVerb (Fader et al., 2011), which make use of computationally efficient surface patterns over tokens. With the introduction of fast dependency parsers, Ollie (Mausam et al., 2012) continues in the same spirit but with learned dependency patterns, improving on the earlier WOE system (Wu and Weld, 2010). The Never Ending Language Learning project (Carlson et al., 2010) has a similar aim, iteratively learning more facts from the internet from a seed set of examples. Exemplar (Mesquita et al., 2013) adapts the open IE framework to n-ary relationships similar to semantic role labeling, but without the expensive machinery.

Open IE triples have been used in a number of applications – for example, learning entailment graphs for new triples (Berant et al., 2011), and matrix factorization for unifying open IE and structured relations (Yao et al., 2012; Riedel et al., 2013). In each of these cases, the concise extractions provided by open IE allow for efficient symbolic methods for entailment, such as Markov logic networks or matrix factorization.

Prior work on the KBP challenge can be categorized into a number of approaches. The most common of these are *distantly supervised* relation extractors (Craven and Kumlien, 1999; Wu and Weld, 2007; Mintz et al., 2009; Sun et al., 2011), and rule based systems (Soderland, 1997; Grishman and Min, 2010; Chen et al., 2010). However, both of these approaches require careful tuning to the task, and need to be trained explicitly on the KBP relation schema. Soderland et al. (2013) submitted a system to KBP making use of open IE relations and an easily constructed mapping to KBP relations; we use this as a baseline for our empirical evaluation.

Prior work has used natural logic for RTE-style textual entailment, as a formalism well-suited for formal semantics in neural networks, and as a framework for common-sense reasoning (MacCartney and Manning, 2009; Watanabe et al., 2012; Bowman et al., 2014; Angeli and Manning, 2013). We adopt the precise semantics of Icard and Moss (2014). Our approach of finding short entailments from a longer utterance is similar in spirit to work on textual entailment for information extraction (Romano et al., 2006).

Figure 2: An illustration of our approach. From left to right, a sentence yields a number of independent clauses (e.g., *she Born in a small town* – see Section 3). From top to bottom, each clause produces a set of entailed shorter utterances, and segments the ones which match an atomic pattern into a relation triple (see Section 4.1).

3 Inter-Clause Open IE

In the first stage of our method, we produce a set of self-contained clauses from a longer utterance. Our objective is to produce a set of clauses which can stand on their own syntactically and semantically, and are entailed by the original sentence (see Figure 2). Note that this task is not specific to extracting open IE triples. Conventional relation extractors, entailment systems, and other NLP applications may also benefit from such a system.

We frame this task as a search problem. At a given node in the parse tree, we classify each outgoing arc $e = p \xrightarrow{l} c$, from the governor p to a dependent c with [collapsed] Stanford Dependency label l, into an action to perform on that arc. Once we have chosen an action to take on that arc, we can recurse on the dependent node. We decompose the action into two parts: (1) the action to take on the outgoing edge e, and (2) the action to take on the governor p. For example, in our motivating example, we are considering the arc: $e = \textit{took} \xrightarrow{\textit{vmod}} \textit{born}$. In this case, the correct action is to (1) yield a new clause rooted at *born*, and (2) interpret the subject of *born* as the subject of *took*.

We proceed to describe this action space in more detail, followed by an explanation of our training data, and finally our classifier.

3.1 Action Space

The three actions we can perform on a dependency edge are:

Yield Yields a new clause on this dependency arc. A canonical case of this action is the arc $\textit{suggest} \xrightarrow{\textit{ccomp}} \textit{brush}$ in *Dentists suggest that you should brush your teeth*, yielding *you should brush your teeth*.

Recurse Recurse on this dependency arc, but do not yield it as a new clause. For example, in the sentence *faeries are dancing in the field where I lost my bike*, we must recurse through the intermediate constituent *the field where I lost my bike* – which itself is not relevant – to get to the clause of interest: *I lost my bike*.

Stop Do not recurse on this arc, as the subtree under this arc is not entailed by the parent sentence. This is the case, for example, for most leaf nodes (*furry cats are cute* should not entail the clause *furry*), and is an important action for the efficiency of the algorithm.

With these three actions, a search path through the tree becomes a sequence of **Recurse** and **Yield** actions, terminated by a **Stop** action (or leaf node). For example, a search sequence $A \xrightarrow{Recurse} B \xrightarrow{Yield} C \xrightarrow{Stop} D$ would yield a clause rooted at C. A sequence $A \xrightarrow{Yield} B \xrightarrow{Yield} C \xrightarrow{Stop} D$ would yield clauses rooted at both B and C. Finding all such sequences is in general exponential in the size of the tree. In practice, during training we run breadth first search to collect the first 10 000 sequences. During inference we run uniform cost search until our classifier predictions fall below a given threshold.

For the **Stop** action, we do not need to further specify an action to take on the parent node. However, for both of the other actions, it is often the case that we would like to capture a controller in the higher clause. We define three such common actions:

Subject Controller If the arc we are considering is not already a subject arc, we can copy the subject of the parent node and attach it as a subject of the child node. This is the action taken in the example *Born in a small town, she took the midnight train.*

Object Controller Analogous to the subject controller action above, but taking the object instead. This is the intended action for examples like *I persuaded Fred to leave the room.*[1]

Parent Subject If the arc we are taking is the only outgoing arc from a node, we take the parent node as the (passive) subject of the child. This is the action taken in the example *Obama, our 44th president* to yield a clause with the semantics of *Obama [is] our 44th president.*

Although additional actions are easy to imagine, we found empirically that these cover a wide range of applicable cases. We turn our attention to the training data for learning these actions.

3.2 Training

We collect a noisy dataset to train our clause generation model. We leverage the *distant supervision* assumption for relation extraction, which creates a noisy corpus of sentences annotated with relation mentions (subject and object spans in the sentence with a known relation). Then, we take this annotation as itself distant supervision for a correct sequence of actions to take: any sequence which recovers the known relation is correct.

We use a small subset of the KBP source documents for 2010 (Ji et al., 2010) and 2013 (Surdeanu, 2013) as our distantly supervised corpus. To try to maximize the density of known relations in the training sentences, we take all sentences which have at least one known relation for every 10 tokens in the sentence, resulting in 43 155 sentences. In addition, we incorporate the 23 725 manually annotated examples from Angeli et al. (2014).

Once we are given a collection of labeled sentences, we assume that a sequence of actions which leads to a correct extraction of a known relation is a *positive sequence*. A correct extraction is any extraction we produce from our model (see Section 4) which has the same arguments as the known relation. For instance, if we know that Obama was born in Hawaii from the sentence *Born in Hawaii, Obama* . . . , and an action sequence produces the triple *(*Obama, born in, Hawaii), then we take that action sequence as a positive sequence.

Any sequence of actions which results in a clause which produces no relations is in turn considered a *negative sequence*. The third case to consider is a sequence of actions which produces a relation, but it is not one of the annotated relations. This arises from the *incomplete negatives* problem in distantly supervised relation extraction (Min et al., 2013): since our knowledge base is not exhaustive, we cannot be sure if an extracted relation is incorrect or correct but previously unknown. Although many of these unmatched relations are indeed incorrect, the dataset is sufficiently biased towards the STOP action that the occasional false negative hurts end-to-end performance. Therefore, we simply discard such sequences.

Given a set of noisy positive and negative *sequences*, we construct training data for our action classifier. All but the last action in a positive sequence are added to the training set with the label **Recurse**; the last action is added with the label **Split**. Only the last action in a negative sequence is added with the label **Stop**. We partition the feature space of our dataset according to the action applied to the parent node.

3.3 Inference

We train a multinomial logistic regression classifier on our noisy training data, using the features in Table 1. The most salient features are the label of the edge being taken, the incoming edge to the parent of the edge being taken, neighboring edges for both the parent and child of the edge, and the part of speech tag of the endpoints of the edge. The dataset is weighted to give 3× weight to examples in the **Recurse** class, as precision errors in this class are relatively harmless for accuracy, while recall errors are directly harmful to recall.

Inference now reduces to a search problem. Be-

[1] The system currently misses most most such cases due to insufficient support in the training data.

Feature Class	Feature Templates
Edge taken	$\{l, \text{short\_name}(l)\}$
Last edge taken	$\{\text{incoming\_edge}(p)\}$
Neighbors of parent	$\{\text{nbr}(p), (p, \text{nbr}(p))\}$
Grandchild edges	$\{\text{out\_edge}(c),$ $(e, \text{out\_edge}(c))\}$
Grandchild count	$\{\text{count}\,(\text{nbr}(e_{\text{child}}))$ $(e, \text{count}\,(\text{nbr}(e_{\text{child}})))\}$
Has subject/object	$\forall_{e\in\{e,e_{\text{child}}\}}\forall_{l\in\{\textit{subj,obj}\}}$ $\mathbb{1}(l \in \text{nbr}(e))$
POS tag signature	$\{\text{pos}(p), \text{pos}(c),$ $(\text{pos}(p), \text{pos}(c))\}$
Features at root	$\{\mathbb{1}(p = \mathit{root}), \text{POS}(p)\}$

Table 1: Features for the clause splitter model, deciding to split on the arc $e = p \xrightarrow{l} c$. The feature class is a high level description of features; the feature templates are the particular templates used. For instance, the POS signature contains the tag of the parent, the tag of the child, and both tags joined in a single feature. Note that all features are joined with the action to be taken on the parent.

ginning at the root of the tree, we consider every outgoing edge. For every possible action to be performed on the parent (i.e., clone subject, clone root, no action), we apply our trained classifier to determine whether we (1) split the edge off as a clause, and recurse; (2) do not split the edge, and recurse; or (3) do not recurse. In the first two cases, we recurse on the child of the arc, and continue until either all arcs have been exhausted, or all remaining candidate arcs have been marked as not recursable.

We will use the scores from this classifier to inform the score assigned to our generated open IE extractions (Section 4). The score of a clause is the product of the scores of actions taken to reach the clause. The score of an extraction will be this score multiplied by the score of the extraction given the clause.

4 Intra-Clause Open IE

We now turn to the task of generating a maximally compact sentence which retains the core semantics of the original utterance, and parsing the sentence into a conventional open IE subject verb object triple. This is often a key component in downstream applications, where extractions need to be not only *correct*, but also *informative*. Whereas an argument like *Heinz Fischer of Austria* is often correct, a downstream application must apply further processing to recover information about either *Heinz Fischer*, or *Austria*. Moreover, it must do so without the ability to appeal to the larger context of the sentence.

4.1 Validating Deletions with Natural Logic

We adopt a subset of natural logic semantics dictating contexts in which lexical items can be removed. Natural logic as a formalism captures common logical inferences appealing directly to the form of language, rather than parsing to a specialized logical syntax. It provides a proof theory for lexical mutations to a sentence which either preserve or negate the truth of the premise.

For instance, if *all rabbits eat vegetables* then *all cute rabbits eat vegetables*, since we are allowed to mutate the lexical item *rabbit* to *cute rabbit*. This is done by observing that *rabbit* is in scope of the first argument to the operator *all*. Since *all* induces a *downward polarity* environment for its first argument, we are allowed to replace *rabbit* with an item which is more specific – in this case *cute rabbit*. To contrast, the operator *some* induces an *upward polarity* environment for its first argument, and therefore we may derive the inference from *cute rabbit* to *rabbit* in: *some cute rabbits are small* therefore *some rabbits are small*. For a more comprehensive introduction to natural logic, see van Benthem (2008).

We mark the scopes of all operators (*all*, *no*, *many*, etc.) in a sentence, and from this determine whether every lexical item can be replaced by something more general (has upward polarity), more specific (downward polarity), or neither. In the absence of operators, all items have upwards polarity.

Each dependency arc is then classified into whether deleting the dependent of that arc makes the governing constituent at that node more general, more specific (a rare case), or neither.[2] For example, removing the *amod* edge in *cute* $\xleftarrow{amod}$ *rabbit* yields the more general lexical item *rabbit*. However, removing the *nsubj* edge in *Fido* $\xleftarrow{nsubj}$ *runs* would yield the unentailed (and nonsensical) phrase *runs*. The last, rare, case is an edge that causes the resulting item to be more specific – e.g., *quantmod*: *about* $\xleftarrow{quantmod}$ *200* is more general than *200*.

[2] We use the Stanford Dependencies representation (de Marneffe and Manning, 2008).

For most dependencies, this semantics can be hard-coded with high accuracy. However, there are at least two cases where more attention is warranted. The first of these concerns non-subsective adjectives: for example a *fake gun* is not a gun. For this case, we make use of the list of non-subsective adjectives collected in Nayak et al. (2014), and prohibit their deletion as a hard constraint.

The second concern is with prepositional attachment, and direct object edges. For example, whereas *Alice went to the playground* $\xrightarrow{prep\_with}$ *Bob* entails that *Alice went to the playground*, it is not meaningful to infer that *Alice is friends* $\xrightarrow{prep\_with}$ *Bob* entails *Alice is friends*. Analogously, *Alice played* $\xrightarrow{dobj}$ *baseball on Sunday* entails that *Alice played on Sunday*; but, *Obama signed* $\xrightarrow{dobj}$ *the bill on Sunday* should not entail the awkward phrase **Obama signed on Sunday*.

We learn these attachment affinities empirically from the syntactic n-grams corpus of Goldberg and Orwant (2013). This gives us counts for how often object and preposition edges occur in the context of the governing verb and relevant neighboring edges. We hypothesize that edges which are frequently seen to co-occur are likely to be essential to the meaning of the sentence. To this end, we compute the probability of seeing an arc of a given type, conditioned on the most specific context we have statistics for. These contexts, and the order we back off to more general contexts, is given in Figure 3.

To compute a score s of *deleting* the edge from the affinity probability p collected from the syntactic n-grams, we simply cap the affinity and subtract it from 1:

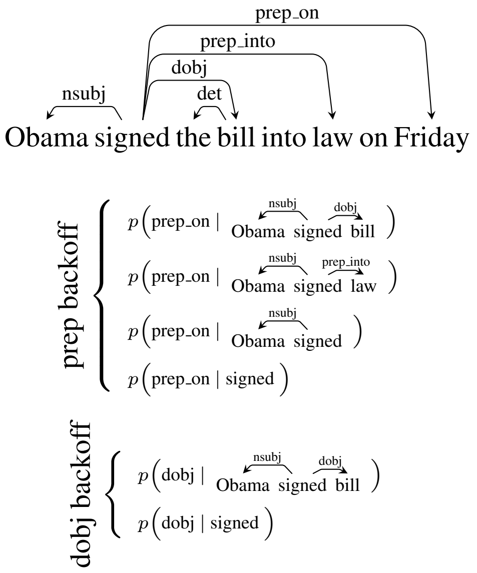
$$s = 1 - \min(1, \frac{p}{K})$$

where K is a hyperparameter denoting the minimum fraction of the time an edge should occur in a context to be considered entirely unremovable. In our experiments, we set $K = \frac{1}{3}$.

The score of an extraction, then, is the product of the scores of each deletion multiplied by the score from the clause splitting step in Section 3.

4.2 Atomic Patterns

Once a set of short entailed sentences is produced, it becomes straightforward to segment them into conventional open IE triples. We employ 6 simple dependency patterns, given in Table 2, which cover the majority of atomic relations we are interested in.



prep_on
prep_into

Table 2: The six dependency patterns used to segment an atomic sentence into an open IE triple.

When information is available to disambiguate the substructure of compound nouns (e.g., named entity segmentation), we extract additional relations with 5 dependency and 3 TokensRegex (Chang and Manning, 2014) surface form patterns. These are given in Table 3; we refer to these as *nominal relations*. Note that the constraint of named entity information is by no means required for the system. In other applications – for example, applications in vision – the otherwise trivial nominal relations could be quite useful.

Table 3: The eight patterns used to segment a noun phrase into an open IE triple. The first five are dependency patterns; the last three are surface patterns.

5 Mapping OpenIE to a Known Relation Schema

A common use case for open IE systems is to map them to a known relation schema. This can either be done manually with minimal annotation effort, or automatically from available training data. We use both methods in our TAC-KBP evaluation. A collection of relation mappings was constructed by a single annotator in approximately a day,[3] and a relation mapping was learned using the procedure described in this section.

We map open IE relations to the KBP schema by searching for co-occurring relations in a large distantly-labeled corpus, and marking open IE and KBP relation pairs which have a high PMI^2 value (Béatrice, 1994; Evert, 2005) conditioned on their type signatures matching. To compute PMI^2, we collect probabilities for the open IE and KBP relation co-occurring, the probability of the open IE relation occurring, and the probability of the KBP relation occurring. Each of these probabilities is conditioned on the type signature of the relation. For example, the joint probability of KBP relation r_k and open IE relation r_o, given a type signature of t_1, t_2, would be

$$p(r_k, r_o \mid t_1, t_2) = \frac{\text{count}(r_k, r_o, t_1, t_2)}{\sum_{r'_k, r'_o} \text{count}(r'_k, r'_o, t_1, t_2)}.$$

Omitting the conditioning on the type signature for notational convenience, and defining $p(r_k)$ and $p(r_o)$ analogously, we can then compute The PMI^2 value between the two relations:

$$\text{PMI}^2(r_k, r_o) = \log\left(\frac{p(r_k, r_o)^2}{p(r_k) \cdot p(r_o)}\right)$$

Note that in addition to being a measure related to PMI, this captures a notion similar to *alignment by agreement* (Liang et al., 2006); the formula can be equivalently written as $\log\left[p(r_k \mid r_o)p(r_o \mid r_k)\right]$. It is also functionally the same as the JC WordNet distance measure (Jiang and Conrath, 1997).

Some sample type checked relation mappings are given in Table 4. In addition to intuitive mappings (e.g., *found in* → Org:Founded), we can note some rare, but high precision pairs (e.g., *invest fund of* → Org:Founded_By). We can also see

[3] The official submission we compare against claimed two weeks for constructing their manual mapping, although a version of their system constructed in only 3 hours performs nearly as well.

the noise in distant supervision occasionally permeate the mapping, e.g., with *elect president of* → Per:LOC_Of_Death – a president is likely to die in his own country.

6 Evaluation

We evaluate our approach in the context of a real-world end-to-end relation extraction task – the TAC KBP Slot Filling challenge. In Slot Filling, we are given a large unlabeled corpus of text, a fixed schema of relations (see Section 5), and a set of query entities. The task is to find all relation triples in the corpus that have as a subject the query entity, and as a relation one of the defined relations. This can be viewed intuitively as populating Wikipedia Infoboxes from a large unstructured corpus of text.

We compare our approach to the University of Washington submission to TAC-KBP 2013 (Soderland et al., 2013). Their system used OpenIE v4.0 (a successor to Ollie) run over the KBP corpus and then they generated a mapping from the extracted relations to the fixed schema. Unlike our system, Open IE v4.0 employs a semantic role component extracting structured SRL frames, alongside a conventional open IE system. Furthermore, the UW submission allows for extracting relations and entities from substrings of an open IE triple argument. For example, from the triple *(Smith; was appointed; acting director of Acme Corporation)*, they extract that Smith is employed by Acme Corporation. We disallow such extractions, passing the burden of finding correct precise extractions to the open IE system itself (see Section 4).

For entity linking, the UW submission uses Tom Lin's entity linker (Lin et al., 2012); our submission uses the Illinois Wikifier (Ratinov et al., 2011) without the relational inference component, for efficiency. For coreference, UW uses the Stanford coreference system (Lee et al., 2011); we employ a variant of the simple coref system described in (Pink et al., 2014).

We report our results in Table 5.[4] UW Official refers to the official submission in the 2013 challenge; we show a 3.1 F_1 improvement (to 22.7 F_1) over this submission, evaluated using a comparable approach. A common technique in KBP systems but not employed by the official UW submission in 2013 is to add alternate names based on entity linking and coreference. Additionally, websites are often extracted using heuristic name-matching as they are hard to capture with traditional relation extraction techniques. If we make use of both of these, our end-to-end accuracy becomes 28.2 F_1.

System	**P**	**R**	$\mathbf{F_1}$
UW Official*	**69.8**	11.4	19.6
Ollie†	57.4	4.8	8.9
+ Nominal Rels*	57.7	11.8	19.6
Our System			
- Nominal Rels†	64.3	8.6	15.2
+ Nominal Rels*	61.9	13.9	22.7
+ Alt. Name	57.8	17.8	27.1
+ Alt. Name + Website	58.6	**18.6**	**28.3**

Table 5: A summary of our results on the end-to-end KBP Slot Filling task. UW official is the submission made to the 2013 challenge. The second row is the accuracy of Ollie embedded in our framework, and of Ollie evaluated with nominal relations from our system. Lastly, we report our system, our system with nominal relations removed, and our system combined with an alternate names detector and rule-based website detector. Comparable systems are marked with a dagger† or asterisk*.

We attempt to remove the variance in scores from the influence of other components in an end-to-end KBP system. We ran the Ollie open IE system (Mausam et al., 2012) in an identical framework to ours, and report accuracy in Table 5. Note that when an argument to an Ollie extraction contains a named entity, we take the argument to be that named entity. The low performance of this system can be partially attributed to its inability to extract nominal relations. To normalize for this, we report results when the Ollie extractions are supplemented with the nominal relations produced by our system (Ollie + Nominal Rels in Table 5). Conversely, we can remove the nominal relation extractions from our system; in both cases we outperform Ollie on the task.

[4] All results are reported with the `anydoc` flag set to true in the evaluation script, meaning that only the truth of the extracted knowledge base entry and not the associated provenance is scored. In absence of human evaluators, this is in order to not penalize our system unfairly for extracting a new correct provenance.

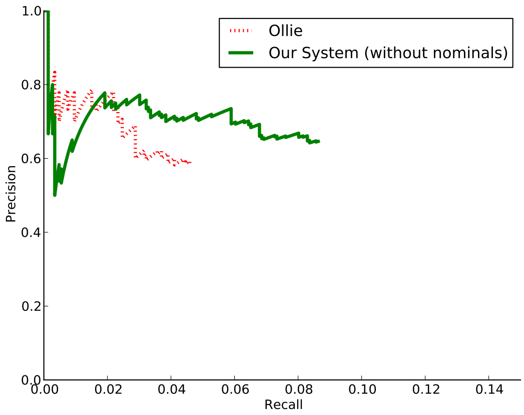

Figure 4: A precision/recall curve for Ollie and our system (without nominals). For clarity, recall is plotted on a range from 0 to 0.15.

6.1 Discussion

We plot a precision/recall curve of our extractions in Figure 4 in order to get an informal sense of the calibration of our confidence estimates. Since confidences only apply to standard extractions, we plot the curves without including any of the nominal relations. The confidence of a KBP extraction in our system is calculated as the sum of the confidences of the open IE extractions that support it. So, for instance, if we find (Obama; be bear in; Hawaii) n times with confidences $c_1 \ldots c_n$, the confidence of the KBP extraction would be $\sum_{i=0}^{n} c_i$. It is therefore important to note that the curve in Figure 4 necessarily conflates the confidences of individual extractions, and the frequency of an extraction.

With this in mind, the curves lend some interesting insights. Although our system is very high precision on the most confident extractions, it has a large dip in precision early in the curve. This suggests that the model is extracting multiple instances of a bad relation. Systematic errors in the clause splitter are the likely cause of these errors. While the approach of splitting sentences into clauses generalizes better to out-of-domain text, it is reasonable that the errors made in the clause splitter manifest across a range of sentences more often than the fine-grained patterns of Ollie would.

On the right half of the PR curve, however, our system achieves both higher precision and extends to a higher recall than Ollie. Furthermore, the curve is relatively smooth near the tail, suggesting that indeed we are learning a reasonable estimate of confidence for extractions that have only one supporting instance in the text – empirically, 46% of our extractions.

In total, we extract 42 662 862 open IE triples which link to a pair of entities in the corpus (i.e., are candidate KBP extractions), covering 1 180 770 relation types. 202 797 of these relation types appear in more than 10 extraction instances; 28 782 in more than 100 instances, and 4079 in more than 1000 instances. 308 293 relation types appear only once. Note that our system over-produces extractions when both a general and specific extraction are warranted; therefore these numbers are an overestimate of the number of semantically meaningful facts.

For comparison, Ollie extracted 12 274 319 triples, covering 2 873 239 relation types. 1 983 300 of these appeared only once; 69 010 appeared in more than 10 instances, 7951 in more than 100 instances, and 870 in more than 1000 instances.

7 Conclusion

We have presented a system for extracting open domain relation triples by breaking a long sentence into short, coherent clauses, and then finding the maximally simple relation triples which are warranted given each of these clauses. This allows the system to have a greater awareness of the context of each extraction, and to provide informative triples to downstream applications. We show that our approach performs well on one such downstream application: the KBP Slot Filling task.

Abstract

A standard pipeline for statistical relational learning involves two steps: one first constructs the knowledge base (KB) from text, and then performs the learning and reasoning tasks using probabilistic first-order logics. However, a key issue is that information extraction (IE) errors from text affect the quality of the KB, and propagate to the reasoning task. In this paper, we propose a statistical relational learning model for joint information extraction and reasoning. More specifically, we incorporate context-based entity extraction with structure learning (SL) in a scalable probabilistic logic framework. We then propose a latent context invention (LCI) approach to improve the performance. In experiments, we show that our approach outperforms state-of-the-art baselines over three real-world Wikipedia datasets from multiple domains; that joint learning and inference for IE and SL significantly improve both tasks; that latent context invention further improves the results.

1 Introduction

Information extraction (IE) is often an early stage in a pipeline that contains non-trivial downstream tasks, such as question answering (Mollá et al., 2006), machine translation (Babych and Hartley, 2003), or other applications (Wang and Hua, 2014; Li et al., 2014). Knowledge bases (KBs) populated by IE techniques have also been used as an input to systems that learn rules allowing further inferences to be drawn from the KB (Lao et al., 2011), a task sometimes called KB completion (Socher et al., 2013; Wang et al., 2014; West et al., 2014). Pipelines of this sort frequently suffer from error cascades, which reduces performance of the full system[1].

In this paper, we address this issue, and propose a joint model system for IE and KB completion in a statistical relational learning (SRL) setting (Sutton and McCallum, 2006; Getoor and Taskar, 2007). In particular, we outline a system which takes as input a partially-populated KB and a set of relation mentions in context, and jointly learns: 1) how to extract new KB facts from the relation mentions, and; 2) a set of logical rules that allow one to infer new KB facts. Evaluation of the KB facts inferred by the joint system shows that the joint model outperforms its individual components. We also introduce a novel extension of this model called Latent Context Invention (LCI), which associates latent states with context features for the IE component of the model. We show that LCI further improves performance, leading to a substantial improvement over prior state-of-the-art methods for joint relation-learning and IE.

To summarize our contributions:

- We present a joint model for IE and relational learning in a statistical relational learning setting which outperforms universal schemas (Riedel et al., 2013), a state-of-the-art joint method;
- We incorporate latent context into the joint SRL model, bringing additional improvements.

In next section, we discuss related work. We describe our approach in Section 3. The details of the datasets are introduced in Section 4. We show experimental results in Section 5, discuss in Section 6, and conclude in Section 7.

[1] For example, KBP slot filling is known for its complex pipeline, and the best overall F1 scores (Wiegand and Klakow, 2013; Angeli et al., 2014) for recent competitions are within the range of 30-40.

2 Related Work

In NLP, our work clearly aligns with recent work on joint models of individual text processing tasks. For example, Finkel and Manning (2009) work on the problem of joint IE and parsing, where they use tree representations to combine named entities and syntactic chunks. Recently, Devlin et al. (Devlin et al., 2014) use a joint neural network model for machine translation, and obtain an impressive 6.3 BLEU point improvement over a hierarchical phrase-based system.

In information extraction, weak supervision (Craven et al., 1999; Mintz et al., 2009) is a common technique for extracting knowledge from text, without large-scale annotations. In extracting Infobox information from Wikipedia text, Wu and Weld (2007; 2010) also use a similar idea. In an open IE project, Banko et al. (2007) use a seed KB, and utilize weak supervision techniques to extend it. Note that weakly supervised extraction approaches can be noisy, as a pair of entities in context may be associated with one, none, or several of the possible relation labels, a property which complicates the application of distant supervision methods (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012).

Lao et al. (2012) learned syntactic rules for finding relations defined by "lexico-semantic" paths spanning KB relations and text data. Wang et al. (2015) extends the methods used by Lao et al. to learn mutually recursive relations. Recently, Riedel et al. (2013) propose a matrix factorization technique for relation embedding, but their method requires a large amount of negative and unlabeled examples. Weston et al. (2013) connect text with KB embedding by adding a scoring term, though no shared parameters/embeddings are used. All these prior works make use of text and KBs. Unlike these prior works, our method is posed in an SRL setting, using a scalable probabilistic first-order logic, and allows learning of relational rules that are mutually recursive, thus allowing learning of multi-step inferences. Unlike some prior methods, our method also does not require negative examples, or large numbers of unlabeled examples.

3 Our Approach

In this section, we first briefly review the semantics, inference, and learning procedures of a newly proposed scalable probabilistic logic called ProPPR (Wang et al., 2013; Wang et al., 2014). Then, we describe the joint model for information extraction and relational learning. Finally, a latent context invention theory is proposed for enhancing the performance of the joint model.

```
about(X,Z) :- handLabeled(X,Z)         # base.
about(X,Z) :- sim(X,Y),about(Y,Z)      # prop.

   linkedBy(X,Y,W)                     # sim,word.
linkedBy(X,Y,W) :- true                # by(W).
```

Table 1: A simple program in ProPPR. See text for explanation.

3.1 ProPPR: Background

Below we will give an informal description of ProPPR, based on a small example. More formal descriptions can be found elsewhere (Wang et al., 2013).

ProPPR (for Programming with Personalized PageRank) is a stochastic extension of the logic programming language Prolog. A simple program in ProPPR is shown in Table 1. Roughly speaking, the upper-case tokens are variables, and the ":-" symbol means that the left-hand side (the *head* of a rule) is implied by the conjunction of conditions on the right-hand size (the *body*). In addition to the rules shown, a ProPPR program would include a *database* of *facts*: in this example, facts would take the form *handLabeled(page,label)*, *hasWord(page,word)*, or *linkedBy(page1,page2)*, representing labeled training data, a document-term matrix, and hyperlinks, respectively. The condition "true" in the last rule is "syntactic sugar" for an empty body.

In ProPPR, a user issues a query, such as "about(a,X)?", and the answer is a set of possible bindings for the free variables in the query (here there is just one such varable, "X"). To answer the query, ProPPR builds a *proof graph*. Each node in the graph is a list of conditions $R_1, \ldots, R_k$ that remain to prove, interpreted as a conjunction. To find the children of a node $R1, \ldots, Rk$, you look for either

1. database facts that match R_1, in which case the appropriate variables are bound, and R_1 is removed from the list, or;

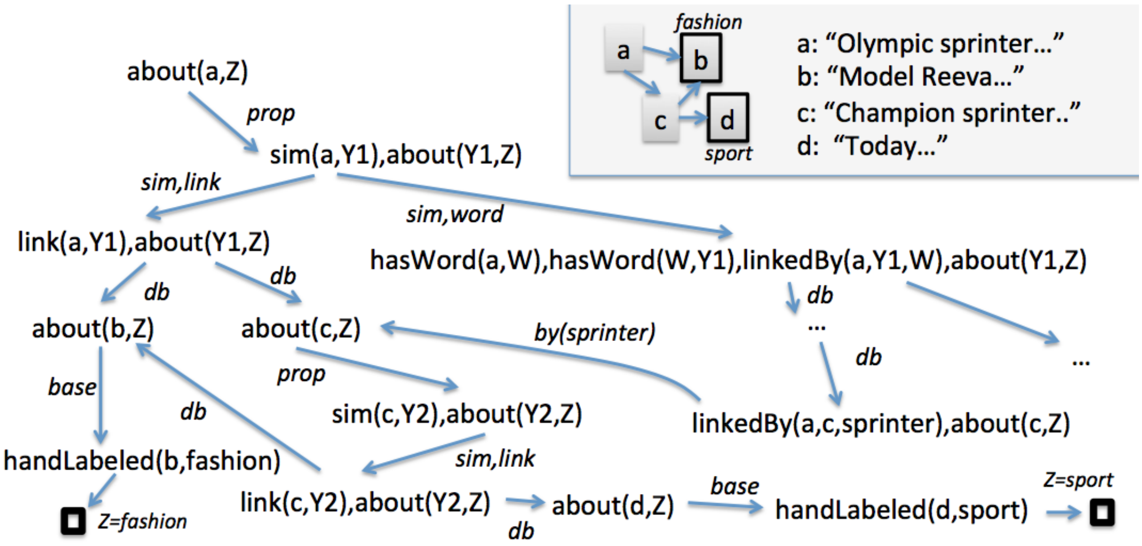

Figure 1: A partial proof graph for the query *about(a,Z)*. The upper right shows the link structure between documents a, b, c, and d, and some of the words in the documents. Restart links are not shown.

2. a rule $A \leftarrow B_1, \ldots, B_m$ with a head A that matches R_1, in which case again the appropriate variables are bound, and R_1 is replaced with the body of the rule, resulting in the new list $B_1, \ldots, B_m, R_2, \ldots, R_k$.

The procedures for "matching" and "appropriately binding variables" are illustrated in Figure 1.[2] An empty list of conditions (written □ in the figure) corresponds to a complete proof of the initial query, and by collecting the required variable bindings, this proof can be used to determine an answer to the initial query.

In Prolog, this proof graph is constructed on-the-fly in a depth-first, left-to-right way, returning the first solution found, and backtracking, if requested, to find additional solutions. In ProPPR, however, we will define a *stochastic process on the graph*, which will generate a score for each node, and hence a score for each answer to the query. The stochastic process used in ProPPR is *personalized PageRank* (Page et al., 1998; Csalogny et al., 2005), also known as random-walk-with-restart. Intuitively, this process upweights solution nodes that are reachable by *many short proofs* (i.e., short paths from the query node.) Formally, personalized PageRank is the fixed point of the iteration

$$\mathbf{p}^{t+1} = \alpha\chi_{v_0} + (1-\alpha)W\mathbf{p}^t \qquad (1)$$

where $\mathbf{p}[u]$ is the weight assigned to u, v_0 is the seed (i.e., query) node, χ_{v_0} is a vector with $\chi_{v_0}[v_0] = 1$ and $\chi_{v_0}[u] = 0$ for $u \neq v$, and W is a matrix of transition probabilities, i.e., $W[v,u]$ is the probability of transitioning from node u to a child node v. The parameter α is the reset probability, and the transition probabilities we use will be discussed below.

Like Prolog, ProPPR's proof graph is also constructed on-the-fly, but rather than using depth-first search, we use PageRank-Nibble, a fast approximate technique for incrementally exploring a large graph from a an initial "seed" node (Andersen et al., 2008). PageRank-Nibble takes a parameter ϵ and will return an approximation $\hat{\mathbf{p}}$ to the personalized PageRank vector $\mathbf{p}$, such that each node's estimated probability is within ϵ of correct.

We close this background section with some final brief comments about ProPPR.

Scalability. ProPPR is currently limited in that it uses memory to store the fact databases, and the proof graphs constructed from them. ProPPR uses a special-purpose scheme based on sparse matrix representations to store facts which are triples, which allows it to accomodate databases with hundreds of millions of facts in tens of gigabytes.

With respect to run-time, ProPPR's scalability is improved by the fast approximate inference scheme used, which is often an order of magnitude faster than power iteration for moderate-sized problems (Wang et al., 2013). Experimen-

[2] The edge annotations will be discussed later.

tation and learning are also sped up because with PageRank-Nibble, each query is answered using a "small"—size $O(\frac{1}{\alpha\epsilon})$—proof graph. Many operations required in learning and experimentation can thus be easily parallized on a multi-core machine, by simply distributing different proof graphs to different threads.

Parameter learning. Personalized PageRank scores are defined by a transition probability matrix W, which is parameterized as follows. ProPPR allows "feature generators" to be attached to its rules, as indicated by the code after the hashtags in the example program.[3] Since edges in the proof graph correspond to rule matches, the edges can also be labeled by features, and a weighted combination of these features can be used to define a total weight for each edge, which finally can be normalized used to define the transition matrix W. Learning can be used to tune these weights to data; ProPPR's learning uses a parallelized SGD method, in which inference on different examples is performed in different threads, and weight updates are synchronized.

Structure learning. Prior work (Wang et al., 2014) has studied the problem of learning a ProPPR theory, rather than simply tuning parameters in an existing theory, a process called *structure learning* (SL). In particular, Wang et al. (2014) propose a scheme called the *structural gradient* which scores rules in some (possibly large) user-defined space $\mathcal{R}$ of potential rules, which can be viewed as instantiations of rule templates, such as the ones shown in the left-hand side of Table 2.

For completeness, we will summarize briefly the approach used in (Wang et al., 2014). The space of potential rules $\mathcal{R}$ is defined by a "second-order abductive theory", which conceptually is an interpreter that constructs proofs using all rules in $\mathcal{R}$. Each rule template is mapped to two clauses in the interpreter: one simulates the template (for any binding), and one "abduces" the specific binding (facts) from the KB. Associated with the use of the abductive rule is a feature corresponding to a particular binding for the template. The gradient of these features indicates which instantiated rules can be usefully added to the theory. More details can be found in (Wang et al., 2014).

[3] For instance, when matching the rule "sim(X,Y) :- links(X,Y)" to a condition such as "sim(a,X)" the two features "sim" and "link" are generated; likewise when matching the rule "linkedBy(X,Y,W) :- true" to the condition "linkedBy(a,c,sprinter)" the feature "by(sprinter)" is generated.

	Rule template	ProPPR clause
Structure learning		
(a)	P(X,Y) :- R(X,Y)	interp(P,X,Y) :- interp0(R,X,Y),abduce_if(P,R).
		abduce_if(P,R) :- true # f_if(P,R).
(b)	P(X,Y) :- R(Y,X)	interp(P,X,Y) :- interp0(R,Y,X),abduce_ifInv(P,R).
		abduce_ifInv(P,R) :- true # f_ifInv(P,R).
(c)	P(X,Y) :- R1(X,Z),R2(Z,Y)	interp(P,X,Y) :- interp0(R1,X,Z),interp0(R2,Z,Y),
		abduce_chain(P,R1,R2).
		abduce_chain(P,R1,R2) :- true # f_chain(P,R1,R2).
	base case for SL interpreter	interp0(P,X,Y) :- rel(R,X,Y).
	insertion point for learned rules	interp0(P,X,Y) :- *any rules learned by SL.*
Information extraction		
(d)	R(X,Y) :- link(X,Y,W),	interp(R,X,Y) :- link(X,Y,W),abduce_indicates(W,R).
	indicates(W,R).	abduce_indicates(W,R) :- true #f_ind1(W,R).
(e)	R(X,Y) :- link(X,Y,W1),	interp(R,X,Y) :- link(X,Y,W1),link(X,Y,W2),
	link(X,Y,W2),	abduce_indicates(W1,W2,R).
	indicates(W1,W2,R).	abduce_indicates(W1,W2,R) :- true #f_ind2(W1,W2,R).
Latent context invention		
(f)	R(X,Y) :- latent(L),	interp(R,X,Y) :- latent(L),link(X,Y,W),abduce_latent(W,L,R).
	link(X,Y,W),	abduce_latent(W,L,R) :- true #f_latent1(W,L,R).
	indicates(W,L,R)	
(g)	R(X,Y) :- latent(L1),latent(L2)	interp(R,X,Y) :- latent(L1),latent(L2),link(X,Y,W),
	link(X,Y,W),	abduce_latent(W,L1,L2,R).
	indicates(W,L1,L2,R)	abduce_latent(W,L1,L2,R) :- true #f_latent2(W,L1,L2,R).

Table 2: The ProPPR template and clauses for joint structure learning and information extraction.

3.2 Joint Model for IE and SRL

Dataset Generation The KBs and text used in our experiments were derived from Wikipedia. Briefly, we choose a set of closely-related pages from a hand-selected Wikipedia list. These pages define a set of entities $\mathcal{E}$, and a set of commonly-used Infobox relations $\mathcal{R}$ between these entities define a KB. The relation mentions are hyperlinks between the pages, and the features of these relation mentions are words that appear nearby these links. This information is encoded in a single relation *link(X,Y,W)*, which indicates that there is hyperlink between Wikipedia pages X to Y which is near the context word W. The Infobox relation triples are stored in another relation, *rel(R,X,Y)*. [4]

Figure 2 shows an example. We first find the "*European royal families*" to find a list of entities $\mathcal{E}$. This list contains the page "*Louis VI of France*", the *source entity*, which contains an outlink to the *target entity page* "*Philip I of France*". On the source page, we can find the following text: "*Louis was born in Paris, the son of* ***Philip I*** *and his first wife, Bertha of Holland.*" From Infobox data, we also may know of a relationship between the source and target entities: in this case, the target entity is the *parent* of the source entity.

Theory for Joint IE and SL The structure learning templates we used are identical to those used in prior work (Wang et al., 2014), and are summarized by the clauses (a-c) in Table 2. In the templates in the left-hand side of the table, P, R, $R1$ and $R2$ are variables in the template, which will be bound to specific relations found to be useful in prediction. (The interpreter rules on the right-hand side are provided for completeness, and can be ignored by readers not deeply familiar with the work of (Wang et al., 2014).)

The second block of the table contains the templates used for IE. For example, to understand template (d), recall that the predicate *link* indicates a hyperlink from Wikipedia page X to

[4] In more detail, the extraction process was as follows. (1) We used a DBpedia dump of categories and hyperlink structure to find pages in a category; sometimes, this included crawling a supercategory page to find categories and then entities. (2) We used the DBpedia hyperlink graph to find the target entity pages, downloaded the most recent (2014) version of each of these pages, and collected relevant hyperlinks and anchor text, together with 80 characters of context to either side.

Y, which includes the context word W between two entities X and Y. The abductive predicate *abduce_indicates* activates a feature template, in which we learn the degree of association of a context word and a relation from the training data. These rules essentially act as a trainable classifier which classifies entity pairs based on the hyperlinks they that contain them, and classifies the hyperlinks according to the relation they reflect, based on context-word features.

Notice that the learner will attempt to tune word associations to match the gold *rel* facts used as training data, and that doing this does not require assigning labels to individual links, as would be done in a traditional distant supervision setting: instead these labels are essentially left latent in this model. Similar to "deep learning" approaches, the latent assignments are provided not by EM, but by hill-climbing search in parameter space.

A natural extension to this model is to add a bilexical version of this classifier in clause (e), where we learn a feature which conjoins word $W1$, word $W2$, and relation R.

Combining the clauses from (a) to (e), we derive a hybrid theory for joint SL and IE: the structure learning section involves a second-order probabilistic logic theory, where it searches the relational KB to form plausible first-order relational inference clauses. The information extraction section from (d) to (e) exploits the distributional similarity of contextual words for each relation, and extracts relation triples from the text, using distant supervision and latent labels for relation mentions (which in our case are hyperlinks). Training this theory as a whole trains it to perform joint reasoning to facts for multiple relations, based on relations that are known (from the partial KB) or inferred from the IE part of the theory. Both parameters for the IE portion of the theory and inference rules between KB relations are learned.[5]

Latent Context Invention Note that so far both the IE clauses (d-e) are fully observable: there are no latent predicates or variables. Recent work (Riedel et al., 2013) suggests that learning latent representations for words improves performance in predicting relations. Perhaps this is because such latent representations can better model the semantic information in surface forms, which are often ambiguous.

We call our method latent context invention (LCI), and it is inspired from literature in predicate invention (Kok and Domingos, 2007).[6] LCI applies the idea of predicate invention to the context space: instead of inventing new predicates, we now invent a *latent context property* that captures the regularities among the similar relational lexical items. To do this, we introduce some additional rules of the form *latent(1) :- true*, *latent(2) :- true*, etc, and allow the learner to find appropriate weights for pairing these arbitrarily-chosen values with specific words. This is implemented by template (f) in Table 2. Adding this to the joint theory means that we will learn to map surface-level lexical items (words) to the "invented" latent context values and also to relation.

Another view of LCI is that we are learning a latent embedding of words jointly with relations. In template (f) we model a single latent dimension, but to model higher-dimensional latent variables, we can add the clauses such as (g), which constructs a two-dimensional latent space. Below we will call this variant method hLCI.

4 Datasets

Using the data generation process that we described in subsection 3.2, we extract two datasets from the supercategories of "*European royal families*" and "*American people of English descent*, and third geographic dataset using three lists: "*List of countries by population*", "*List of largest cities and second largest cities by country*" and "*List of national capitals by population*".

For the *royal* dataset, we have 2,258 pages with 67,483 source-context-target mentions, and we use 40,000 for training, and 27,483 for testing. There are 15 relations[7]. In the *American* dataset, we have 679 pages with 11,726 mentions, and we use 7,000 for training, and 4,726 for testing. This dataset includes 30 relations[8]. As for the *Geo* dataset, there are 497

[5] In in addition to finding rules which instantiate the templates, weights on these rules are also learned.

[6] To give some background on this nomenclature, we note that the SL method is inspired by Cropper and Muggleton's Metagol system (Cropper and Muggleton, 2014), which includes predicate invention. In principle predicates could be invented by SL, by extending the interpreter to consider "invented" predicate symbols as binding to its template variables (e.g., P and R); however, in practice invented predicates leads to close dependencies between learned rules, and are highly sensitive to the level of noise in the data.

[7] birthPlace, child, commander, deathPlace, keyPerson, knownFor, monarch, parent, partner, predecessor, relation, restingPlace, spouse, successor, territory

[8] architect, associatedBand, associatedMusicalArtist, au-

pages with 43,475 mentions, and we use 30,000 for training, and 13,375 for testing. There are 10 relations[9]. The datasets are freely available for download at `http://www.cs.cmu.edu/~yww/data/jointIE+Reason.zip`.

5 Experiments

To evaluate these methods, we use the setting of Knowledge Base completion (Socher et al., 2013; Wang et al., 2014; West et al., 2014). We randomly remove a fixed percentage of facts in a training knowledge base, train the learner from the partial KB, and use the learned model to predict facts in the test KB. KB completion is a well-studied task in SRL, where multiple relations are often needed to fill in missing facts, and thus reconstruct the incomplete KB. Following prior work (Riedel et al., 2013; Wang et al., 2013), we use mean average precision (MAP) as the evaluation metric.

5.1 Baselines

To understand the performance of our joint model, we compare with three prior methods. **Structure Learning (SL)** includes the second-order relation learning templates (a-c) from Table 2. **Information Extraction (IE)** includes only templates (d) and (e). **Markov Logic Networks (MLN)** is the Alchemy's implementation[10] of Markov Logic Networks (Richardson and Domingos, 2006), using the first-order clauses learned from SL method[11]. We used conjugate gradient weight learning (Lowd and Domingos, 2007) with 10 iterations. Finally, **Universal Schema** is a state-of-the-art matrix factorization based universal method for jointly learning surface patterns and relations. We used the code and parameter settings for the best-performing model (NFE) from (Riedel et al., 2013).

As a final baseline method, we considered a simpler approach to clustering context words, which we called **Text Clustering**, which used the following template:

R(X,Y) :-
clusterID(C),link(X,Y,W),
cluster(C,W),related(R,W).

Here surface patterns are grouped to form latent clusters in a relation-*independent* fashion.

5.2 The Effectiveness of the Joint Model

Our experimental results are shown in 3. The leftmost part of the table concerns the Royal dataset. We see that the universal schema approach outperforms the MLN baseline in most cases, but ProPPR's SL method substantially improves over MLN's conjugated gradient learning method, and the universal schema approach. This is perhaps surprising, as the universal schema approach is also a joint method: we note that in our datasets, unlike the New York Times corpus used in (Riedel et al., 2013), large numbers of unlabeled examples are not available. The unigram and bilexical IE models in ProPPR also perform well—better than SL on this data. The joint model outperforms the baselines, as well as the separate models. The difference is most pronounced when the background KB gets noisier: the improvement with 10% missing setting is about 1.5 to 2.3% MAP, while with 50% missing data, the absolute MAP improvement is from 8% to 10%.

In the next few columns of Table 3, we show the KB completion results for the *Geo* dataset. This dataset has fewer relations, and the most common one is *country*. The overall MAP scores are much higher than the previous dataset. MLN's results are good, but still generally below the universal schema method. On this dataset, the universal schema method performs better than the IE only model for ProPPR in most settings. However, the ProPPRjoint model still shows large improvements over individual models and the baselines: the absolute MAP improvement is 22.4%.

Finally, in the rightmost columns of Table 3, we see that the overall MAP scores for the *American* dataset are relatively lower than other datasets, perhaps because it is the smallest of the three. The universal schema approach consistently outperforms the MLN model, but not ProPPR. On this dataset the SL-only model in ProPPR outperforms the IE-only models; however, the joint models still outperform individual ProPPR models from 1.5% to 6.4% in MAP.

Table 3: The MAP results for KB completion on three datasets. U: unigram. B: bigram. Best result in each column is highlighted in **bold**.

The averaged training runtimes on an ordinary PC for unigram joint model on the above *Royal, Geo, American* datasets are 38, 36, and 29 seconds respectively, while the average testing times are 11, 10, and 9 seconds. For bilexical joint models, the averaged training times are 25, 10, and 10 minutes respectively, whereas the testing times are 111, 28, and 26 seconds respectively.

5.3 The Effectiveness of LCI

Finally we consider the latent context invention (LCI) approach. The last three rows of Table 3 show the performances of LCI and hHCI. We compare it here with the best previous approach, the joint IE + SL model, and text clustering approach.

For the *Royal* dataset, first, the LCI and hLCI models clearly improve over joint IE and SL. In noisy conditions of missing 50% facts, the biggest improvement of LCI/hLCI is 2.4% absolute MAP.

From the *Geo* dataset, we see that the joint models and joint+latent models have similar performances in relatively clean conditions (10%-30%) facts missing. However, in noisy conditions, we the LCI and hLCI model has an advantage of between 1.5% to 1.8% in absolute MAP.

Finally, the results for the *American* dataset show a consistent trend: again, in noisy conditions (missing 40% to 50% facts), the latent context models outperform the joint IE + SL models by 2.9% and 3.7% absolute MAP scores.

Although the LCI approach is inspired by predicate invention in inductive logic programming, our result is also consistent with theories of generalized latent variable modeling in probabilistic graphical models and statistics (Skrondal and Rabe-Hesketh, 2004): modeling hidden variables helps take into account the measurement (observation) errors (Fornell and Larcker, 1981) and results in a more robust model.

6 Discussions

Compared to state-of-the-art joint models (Riedel et al., 2013) that learn the latent factor representations, our method gives strong improvements in performance on three datasets with various settings. Our model is also trained to retrieve a target entity from a relation name plus a source entity, and does not require large samples of unlabeled or negative examples in training.

Another advantage of the ProPPR model is that they are explainable. For example, below are the features with the highest weights after joint learning from the *Royal* dataset, written as predicates or rules:

indicates("mother",parent)
indicates("king",parent)
indicates("spouse",spouse)
indicates("married",spouse)
indicates("succeeded",successor)
indicates("son",successor)

parent(X,Y) :- successor(Y,X)
successor(X,Y) :- parent(Y,X)
spouse(X,Y) :- spouse(Y,X)
parent(X,Y) :- predecessor(X,Y)
successor(Y,X) :- spouse(X,Y)
predecessor(X,Y) :- parent(X,Y)

Here we see that our model is able to learn that the keywords "mother" and "king" that are indicators of the relation *parent*, that the keywords "spouse" and "married" indicate the relation *spouse*, and the keywords "succeeded" and "son" indicate the relation *successor*. Interestingly, our joint model is also able to learn the inverse relation *successor* for the relation *parent*, as well as the similar relational predicate *predecessor* for *parent*.

7 Conclusions

In this paper, we address the issue of joint information extraction and relational inference. To be more specific, we introduce a holistic probabilistic logic programming approach for fusing IE contexts with relational KBs, using locally groundable inference on a joint proof graph. We then propose a latent context invention technique that learns relation-specific latent clusterings for words. In experiments, we show that joint modeling for IE and SRL improves over prior state-of-the-art baselines by large margins, and that the LCI model outperforms various fully baselines on three real-world Wikipedia dataset from different domains. In the future, we are interested in extending these techniques to also exploit unlabeled data.

Abstract

Prepositional phrases (PPs) express crucial information that knowledge base construction methods need to extract. However, PPs are a major source of syntactic ambiguity and still pose problems in parsing. We present a method for resolving ambiguities arising from PPs, making extensive use of semantic knowledge from various resources. As training data, we use both labeled and unlabeled data, utilizing an expectation maximization algorithm for parameter estimation. Experiments show that our method yields improvements over existing methods including a state of the art dependency parser.

1 Introduction

Machine reading and information extraction (IE) projects have produced large resources with many millions of facts (Suchanek et al., 2007; Mitchell et al., 2015). This wealth of knowledge creates a positive feedback loop for automatic knowledge base construction efforts: the accumulated knowledge can be leveraged to improve machine reading; in turn, improved reading methods can be used to better extract knowledge expressed using complex and potentially ambiguous language. For example, prepositional phrases (PPs) express crucial information that IE methods need to extract. However, PPs are a major source of syntactic ambiguity. In this paper, we propose to use semantic knowledge to improve PP attachment disambiguation. PPs such as "in", "at", and "for" express details about the *where, when,* and *why* of relations and events. PPs also state attributes of nouns.

As an example, consider the following sentences: *S1.) Alice caught the butterfly with the spots. S2.) Alice caught the butterfly with the net.*

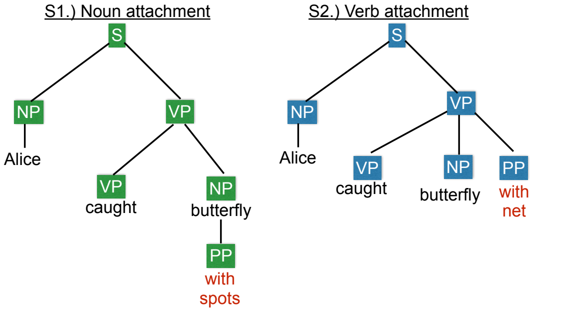

Figure 1: Parse trees where the prepositional phrase (PP) attaches to the noun, and to the verb.

Relations	Noun-Noun binary relations *(Paris, located in, France)* *(net, caught, butterfly)*
Nouns	Noun semantic categories *(butterfly, isA, animal)*
Verbs	Verb roles *caught(agent, patient, instrument)*
Prepositions	Preposition definitions *f(for)= used for, has purpose, ...* *f(with)= has, contains, ...*
Discourse	Context $n0 \in \{n0, v, n1, p, n2\}$

Table 1: Types of background knowledge used in this paper to determine PP attachment.

S1 and S2 are syntactically different, this is evident from their corresponding parse trees in Figure 1. Specifically, S1 and S2 differ in where their PPs attach. In S1, the butterfly has spots and therefore the PP, "with the spots", attaches to the *noun*. For relation extraction, we obtain a *binary* relation of the form: ⟨Alice⟩ caught ⟨butterfly with spots⟩. However, in S2, the net is the instrument used for catching and therefore the PP, "with the net", attaches to the *verb*. For relation extraction, we get a *ternary* extraction of the form: ⟨Alice⟩ caught ⟨butterfly⟩ with ⟨net⟩.

The PP attachment problem is often defined as follows: given a PP occurring within a sentence where there are multiple possible attachment sites

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics

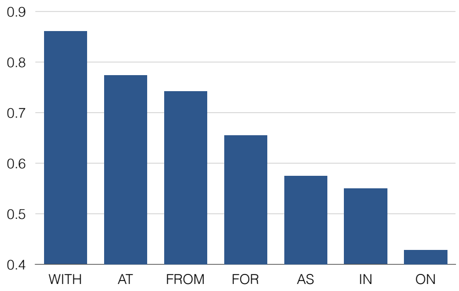

Figure 2: Dependency parser PP attachment accuracy for various frequent prepositions.

for the PP, choose the most plausible attachment site. In the literature, prior work going as far back as (Brill and Resnik, 1994; Ratnaparkhi et al., 1994; Collins and Brooks, 1995) has focused on the language pattern that causes most PP ambiguities, which is the 4-word sequence: $\{v, n1, p, n2\}$ (e.g., {*caught, butterfly, with, spots*}). The task is to determine if the prepositional phrase $(p, n2)$ attaches to the verb v or to the first noun $n1$. Following common practice, we focus on PPs occurring as $\{v, n1, p, n2\}$ quadruples — we shall refer to these as *PP quads*.

The approach we present here differs from prior work in two main ways. First, we make extensive use of semantic knowledge about nouns, verbs, prepositions, pairs of nouns, and the discourse context in which a PP quad occurs. Table 1 summarizes the types of knowledge we considered in our work. Second, in training our model, we rely on both labeled and unlabeled data, employing an expectation maximization (EM) algorithm (Dempster et al., 1977).

Contributions. In summary, our main contributions are:

1) Semantic Knowledge: Previous methods largely rely on corpus statistics. Our approach draws upon diverse sources of background knowledge, leading to performance improvements.

2) Unlabeled Data: In addition to training on labeled data, we also make use of a large amount of unlabeled data. This enhances our method's ability to generalize to diverse data sets.

3) Datasets: In addition to the standard Wall Street Journal corpus (WSJ) (Ratnaparkhi et al., 1994), we labeled two new datasets for testing purposes, one from Wikipedia (WKP), and another from the New York Times Corpus (NYTC). We make these datasets freely available for future research. In addition, we have applied our model to over 4 million 5-tuples of the form $\{n0, v, n1, p, n2\}$, and we also make this dataset available[1] for research into ternary relation extraction beyond spatial and temporal scoping.

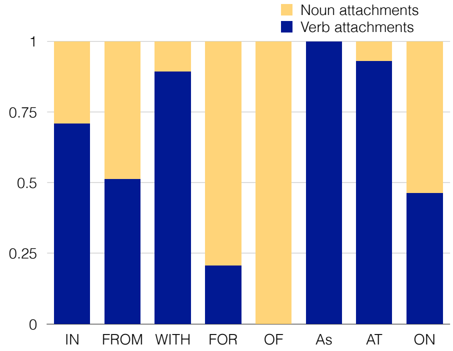

Figure 3: Noun vs. verb attachment proportions for frequent prepositions in the labeled NYTC dataset.

2 State of the Art

To quantitatively assess existing tools, we analyzed performance of the widely used Stanford parser[2] as of 2014, and the established baseline algorithm (Collins and Brooks, 1995), which has stood the test of time. We first manually labeled PP quads from the NYTC dataset, then prepended the noun phrase appearing before the quad, effectively creating sentences made up of 5 lexical items $(n0\ v\ n1\ p\ n2)$. We then applied the Stanford parser, obtaining the results summarized in Figure 2. The parser performs well on some prepositions, for example, "of", which tends to occur with noun attaching PPs as can be seen in Figure 3. However, for prepositions with an even distribution over verb and noun attachments, such as "on", precision is as low as 50%. The Collins baseline achieves 84% accuracy on the benchmark Wall Street Journal PP dataset. However, drawing a distinction in the precision of different prepositions provides useful insights on its performance. We re-implemented this baseline and found that when we remove the trivial preposition, "of", whose PPs are by default attached to the noun by this baseline, precision drops to 78%. This analysis suggests there is substantial room for improvement.

3 Related Work

Statistics-based Methods. Prominent prior methods learn to perform PP attachment based on corpus co-occurrence statistics, gathered either from manually annotated training data (Collins and Brooks, 1995; Brill and Resnik, 1994) or from automatically acquired training data that may be noisy (Ratnaparkhi, 1998; Pantel and Lin, 2000). These models collect statistics on how often a given quadruple, $\{v, n1, p, n2\}$, occurs in the training data as a verb attachment as opposed to a noun attachment. The issue with this approach is sparsity, that is, many quadruples occuring in the test data might not have been seen in the training data. Smoothing techniques are often employed to overcome sparsity. For example, (Collins and Brooks, 1995) proposed a back-off model that uses subsets of the words in the quadruple, by also keeping frequency counts of triples, pairs and single words. Another approach to overcoming sparsity has been to use WordNet (Fellbaum, 1998) classes, by replacing nouns with their WordNet classes (Stetina and Nagao, 1997; Toutanova et al., 2004) to obtain less sparse corpus statistics. Corpus-derived clusters of similar nouns and verbs have also been used (Pantel and Lin, 2000).

Hindle and Rooth proposed a lexical association approach based on how words are associated with each other (Hindle and Rooth, 1993). Lexical preference is used by computing co-occurrence frequencies (lexical associations) of verbs and nouns, with prepositions. In this manner, they would discover that, for example, the verb "send" is highly associated with the preposition *from*, indicating that in this case, the PP is likely to be a verb attachment.

Structure-based Methods. These methods are based on high-level observations that are then generalized into heuristics for PP attachment decisions. (Kimball, 1988) proposed a right association method, whose premise is that a word tends to attach to another word immediately to its right. (Frazier, 1978) introduced a minimal attachment method, which posits that words attach to an existing non-terminal word using the fewest additional syntactic nodes. While simple, in practice these methods have been found to perform poorly (Whittemore et al., 1990).

Rule-based Methods. (Brill and Resnik, 1994) proposed methods that learn a set of transformation rules from a corpus. The rules can be too specific to have broad applicability, resulting in low recall. To address low recall, knowledge about nouns, as found in WordNet, is used to replace certain words in rules with their WordNet classes.

Parser Correction Methods. The quadruples formulation of the PP problem can be seen as a simplified setting. This is because, with quadruples, there is no need to deal with complex sentences but only well-defined quadruples of the form $\{v, n1, p, n2\}$. Thus in the quadruples setting, there are only two possible attachment sites for the PP, the v and $n1$. An alternative setting is to work in the context of full sentences. In this setting the problem is cast as a dependency parser correction problem (Atterer and Schütze, 2007; Agirre et al., 2008; Anguiano and Candito, 2011). That is, given a dependency parse of a sentence, with potentially incorrect PP attachments, rectify it such that the prepositional phrases attach to the correct sites. Unlike our approach, these methods do not take semantic knowledge into account.

Sense Disambiguation. In addition to prior work on prepositional phrase attachment, a highly related problem is preposition sense disambiguation (Hovy et al., 2011; Srikumar and Roth, 2013). Even a syntactically correctly attached PP can still be semantically ambiguous with respect to questions of machine reading such as *where, when,* and *why*. Therefore, when extracting information from prepositions, the problem of preposition sense disambiguation (semantics) has to be addressed in addition to prepositional phrase attachment disambiguation (syntax). In this paper, our focus is on the latter.

4 Methodology

Our approach consists of first generating features from background knowledge and then training a model to learn with these features. The types of features considered in our experiments are summarized in Table 2. The choice of features was motivated by our empirically driven characterization of the problem as follows:

(Verb attach) $\longrightarrow$ *v* $\langle$*has-slot-filler*$\rangle$ *n2*

(Noun attach a.) $\longrightarrow$ *n1* $\langle$*described-by*$\rangle$ *n2*
(Noun attach b.) $\longrightarrow$ *n2* $\langle$*described-by*$\rangle$ *n1*

Feature Type	**#**	**Feature**	**Example**

	F5.	$hasRole(n2, r_i)$	For q1; $(net, instrument)$
Preposition Relational		**Source: $\mathcal{M}$**	
Definitions	F6.	$def(prep, v_i)\ \forall i :$	
		$\exists sv_io; v_i \in \mathcal{M} \wedge$	
		$svo(n1, v_i, n2)$	For q2; $def(with, has)$
Discourse Features		**Source: Sentence(s), $\mathcal{T}$**	
	F7.	$\forall t_i \in \mathcal{T}; isA(n0, t_i)$	$n0 \in \{n0, v, n1, p, n2\}$
Lexical Features		**Source: PP quads**	For q1;
	F8.	$(v, n1, p, n2)$	$(caught, butterfly, with, net)$
	F9.	$(v, n1, p)$	$(caught, butterfly, with)$
	F10.	$(v, p, n2)$	$(caught, with, net)$
	F11.	$(n1, p, n2)$	$(butterfly, with, net)$
	F12.	(v, p)	$(caught, with)$
	F13.	$(n1, p)$	$(butterfly, with)$
	F14.	$(p, n2)$	$(with, net)$
	F15.	(p)	$(with)$

Table 2: Types of features considered in our experiments. All features have values of 1 or 0. The PP quads used as running examples are: $q1 = \{caught, butterfly, with, net\} : V$, $q2 = \{caught, butterfly, with, spots\} : N$.

That is, we found that for verb-attaching PPs, $n2$ is usually a role filler for the verb, e.g., the net fills the role of an instrument for the verb *catch*. On the other hand, for noun-attaching PPs, one noun describes or elaborates on the other. In particular, we found two kinds of noun attachments. For the first kind of noun attachment, the second noun $n2$ describes the first noun $n1$, for example $n2$ might be an attribute or property of $n1$, as in the spots($n2$) are an attribute of the butterfly ($n1$). And for the second kind of noun attachment, the first noun $n1$ describes the second noun $n2$, as in the PP quad {*expect, decline, in, rates*}, where the PP "in rates", attaches to the *noun*. The decline:$n1$ that is expected:v is in the rates:$n2$. We sampled 50 PP quads from the WSJ dataset and found that every labeling could be explained using our characterization. We make this labeling available with the rest of the datasets.

We next describe in more detail how each type of feature is derived from the background knowledge in Table 1.

4.1 Feature Generation

We generate boolean-valued features for all the feature types we describe in this section.

4.1.1 Noun-Noun Binary Relations

The noun-noun binary relation features, F1-2 in Table 2, are boolean features $svo(n1, v_i, n2)$ (where v_i is any verb) and $svo(n2, v, n1)$ (where v is the verb in the PP quad, and the roles of $n2$ and $n1$ are reversed). These features describe diverse semantic relations between pairs of nouns (e.g., *butterfly-has-spots*, *clapton-played-guitar*). To obtain this type of knowledge, we dependency parsed all sentences in the 500 million English web pages of the ClueWeb09 corpus, then extracted subject-verb-object (SVO) triples from these parses, along with the frequency of each SVO triple in the corpus. The value of any given feature $svo(n1, v_i, n2)$ is defined to be 1 if that SVO triple was found at least 3 times in these SVO triples, and 0 otherwise. To see why these relations are relevant, let us suppose that we have the knowledge that *butterfly-has-spots*, $svo(n1, v_i, n2)$. From this, we can infer that the PP in $\{caught, butterfly, with, spots\}$ is likely to attach to the noun. Similarly, suppose we know that *net-caught-butterfly*, $svo(n2, v, n1)$. The fact that a net can be used to catch a butterfly can be used to predict that the PP in $\{caught, butterfly, with, net\}$ is likely to attach to the verb.

4.1.2 Noun Semantic Categories

Noun semantic type features, F3-4, are boolean features $isA(n1, t_i)$ and $isA(n2, t_i)$ where t_i is a noun category in a noun categorization scheme $\mathcal{T}$ such as WordNet classes. Knowledge about semantic types of nouns, for example that a butterfly is an animal, enables extrapolating predictions to other PP quads that contain nouns of the same type. We ran experiments with several noun categorizations including WordNet classes, knowledge base ontological types, and an unsupervised noun categorization produced by clustering nouns based on the verbs and adjectives with which they co-occur (distributional similarity).

4.1.3 Verb Role Fillers

The verb role feature, F5, is a boolean feature $hasRole(n2, r_i)$ where r_i is a role that $n2$ can fulfill for the verb v in the PP quad, according to background knowledge. Notice that if $n2$ fills a role for the verb, then the PP is a verb attachment. Consider the quad $\{caught, butterfly, with, net\}$, if we know that a net can play the role of an *instrument* for the verb *catch*, this suggests a likely verb attachment. We obtained background knowledge of verbs and their possible roles from the VerbNet lexical resource (Kipper et al., 2008). From VerbNet we obtained $2,573$ labeled sentences containing PP quads (verbs in the same VerbNet group are considered synonymous), and the labeled semantic roles filled by the second noun $n2$ in the PP quad. We use these example sentences to label similar PP quads, where similarity of PP quads is defined by verbs from the same VerbNet group.

4.1.4 Preposition Definitions

The preposition definition feature, $F6$, is a boolean feature $def(prep, v_i) = 1 \; if \; \exists v_i \in \mathcal{M} \wedge svo(n1, v_i, n2) = 1$, where $\mathcal{M}$ is a definition mapping of prepositions to verb phrases. This mapping defines prepositions, using verbs in our ClueWeb09 derived SVO corpus, in order to capture their senses using verbs; it contains definitions such as *def(with, *) = contains, accompanied by, ...* . If "with" is used in the sense of "contains" , then the PP is a likely noun attachment, as in $n1$ contains $n2$ in the quad $ate, cookies, with, cranberries$. However, if "with" is used in the sense of "accompanied by", then the PP is a likely verb attachment, as in the quad $visted, Paris, with, Sue$. To obtain the mapping, we took the labeled PP quads (WSJ, (Ratnaparkhi et al., 1994)) and computed a ranked list of verbs from SVOs, that appear frequently between pairs of nouns for a given preposition. Other sample mappings are: *def(for,*)= used for*, *def(in,*)= located in*. Notice that this feature $F6$ is a selective, more targeted version of $F2$.

4.1.5 Discourse and Lexical Features

The discourse feature, $F7$, is a boolean feature $isA(n0, t_i)$, for each noun category t_i found in a noun category ontology $\mathcal{T}$ such as WordNet semantic types. The context of the PP quad can contain relevant information for attachment decisions. We take into account the noun preceding a PP quad, in particular, its semantic type. This in effect makes the PP quad into a PP 5-tuple: $\{n0, v, n1, p, n2\}$, where the $n0$ provides additional context.

Finally, we use lexical features in the form of PP quads, features F8-15. To overcome sparsity of occurrences of PP quads, we also use counts of shorter sub-sequences, including triples, pairs and singles. We only use sub-sequences that contain the preposition, as the preposition has been found to be highly crucial in PP attachment decisions (Collins and Brooks, 1995).

4.2 Disambiguation Algorithm

We use the described features to train a model for making PP attachment decisions. Our goal is to compute $\mathbb{P}(y|x)$, the probability that the PP $(p, n2)$ in the tuple $\{v, n1, p, n2\}$ attaches to the *verb (v)* , $y = 1$ or to the $noun(n1)$, $y = 0$, given a feature vector x describing that tuple. As input to training the model, we are given a collection of PP quads, D where $d_i \in \mathcal{D} : d_i = \{v, n1, p, n2\}$. A small subset, $D^l \subset \mathcal{D}$ is labeled data, thus for each $d_i \in D^l$ we know the corresponding y_i. The rest of the quads, D^u, are unlabeled, hence their corresponding y_is are unknown. From each PP quad d_i, we extract a feature vector x_i according to the feature generation process discussed in Section 4.1.

4.2.1 Model

To model $\mathbb{P}(y|x)$, there a various possibilities. One could use a generative model (e.g., Naive Bayes) or a discriminative model (e.g., logistic regression). In our experiments we used both kinds of models, but found the discriminative model performed better. Therefore, we present details only for our discriminative model. We use the logistic function: $\mathbb{P}(y|x,\vec{\theta}) = \frac{e^{\vec{\theta}x}}{1+e^{\vec{\theta}x}}$, where $\vec{\theta}$ is a vector of model parameters. To estimate these parameters, we could use the labeled data as training data and use standard gradient descent to minimize the logistic regression cost function. However, we also leverage the unlabeled data.

4.2.2 Parameter Estimation

To estimate model parameters based on both labeled and unlabeled data, we use an Expectation Maximization (EM) algorithm. EM estimates model parameters that maximize the expected log likelihood of the full (observed and unobserved) data. Since we are using a discriminative model, our likelihood function is a conditional likelihood function:

$$\begin{aligned}\mathcal{L}(\theta) &= \sum_{i=1}^{N} \ln \mathbb{P}(y_i|x_i) \\ &= \sum_{i=1}^{N} y_i\theta^T x_i - \ln\left(1 + exp(\theta^T x_i)\right) \qquad (1)\end{aligned}$$

where i indexes over the N training examples.

The EM algorithm produces parameter estimates that correspond to a local maximum in the expected log likelihood of the data under the posterior distribution of the labels, given by: $\arg\max_\theta E_{p(y|x,\theta)}[\ln \mathbb{P}(y|x,\theta)]$. In the E-step, we use the current parameters θ^{t-1} to compute the posterior distribution over the y labels, give by $\mathbb{P}(y|x,\theta^{t-1})$. We then use this posterior distribution to find the expectation of the log of the complete-data conditional likelihood, this expectation is given by $\mathcal{Q}(\theta, \theta^{\mathbf{t-1}})$, defined as:

$$\mathcal{Q}(\theta, \theta^{t-1}) = \sum_{i=1}^{N} E_{\theta^{t-1}}[\ln \mathbb{P}(y|x,\theta)] \qquad (2)$$

In the M-step, a new estimate θ^t is then produced, by maximizing this Q function with respect to θ:

$$\theta^{\mathbf{t}} = \arg\max_\theta \mathcal{Q}(\theta, \theta^{\mathbf{t-1}}) \qquad (3)$$

EM iteratively computes parameters $\theta^0, \theta^1, ...\theta^t$, using the above update rule at each iteration t, halting when there is no further improvement in the value of the Q function. Our algorithm is summarized in Algorithm 1. The M-step solution for θ^t is obtained using gradient ascent to maximize the Q function.

Algorithm 1 The EM algorithm for PP attachment

```
Input: $\mathcal{X}, \mathcal{D} = D^l \cup D^u$
Output: $\theta^T$
for t = 1 . . . T do
  E-Step:
  Compute $p(y|x_i, \theta^{t-1})$
  $x_i : d_i \in D^u; p(y|x_i, \vec{\theta}) = \frac{e^{\vec{\theta}x}}{1+e^{\vec{\theta}x}}$
  $x_i : d_i \in D^l; p(y|x_i) = 1$ if $y = y_i$, else 0
  M-Step:
  Compute new parameters, $\theta^t$
  $\theta^{\mathbf{t}} = \arg\max_\theta \mathcal{Q}(\theta, \theta^{\mathbf{t-1}})$
    $\mathcal{Q}(\theta, \theta^{t-1}) = \sum_{i=1}^{N} \sum_{y \in \{0,1\}} p(y|x_i, \theta^{t-1}) \times$
        $(y\theta^T x_i - \ln(1 + exp(\theta^T x_i)))$
  if convergence($\mathcal{L}(\theta), \mathcal{L}(\theta^{t-1})$) then
    break
  end if
end for
return $\theta^T$
```

5 Experimental Evaluation

We evaluated our method on several datasets containing PP quads of the form $\{v, n1, p, n2\}$. The task is to predict if the PP $(p, n2)$ attaches to the verb v or to the first noun $n1$.

5.1 Experimental Setup

Datasets. Table 3 shows the datasets used in our experiments. As labeled training data, we used the

DataSet	# Training quads	# Test quads
Labeled data		
WSJ	20,801	3,097
NYTC	0	293
WKP	0	381
Unlabeled data		
WKP	100,000	4,473,072

Table 3: Training and test datasets used in our experiments.

	PPAD	PPAD-NB	Collins	Stanford
WKP	**0.793**	0.740	0.727	0.701
WKP \of	**0.759**	0.698	0.683	0.652
NYTC	**0.843**	0.792	0.809	0.679
NYTC \of	**0.815**	0.754	0.774	0.621
WSJ	**0.843**	0.816	0.841	N\A
WSJ \of	**0.779**	0.741	0.778	N\A

Table 4: PPAD vs. baselines.

Wall Street Journal (WSJ) dataset. For the unlabeled training data, we extracted PP quads from Wikipedia (WKP) and randomly selected $100,000$ which we found to be a sufficient amount of unlabeled data. The largest labeled test dataset is WSJ but it is also made up of a large fraction, of "of" PP quads, 30% , which trivially attach to the noun, as already seen in Figure 3. The New York Times (NYTC) and Wikipedia (WKP) datasets are smaller but contain fewer proportions of "of" PP quads, 15%, and 14%, respectively. Additionally, we applied our model to over 4 million unlabeled 5-tuples from Wikipedia. We make this data available for download, along with our manually labeled NYTC and WKP datasets. For the WKP & NYTC corpora, each quad has a preceding noun, $n0$, as context, resulting in PP 5-tuples of the form: $\{n0, v, n1, p, n2\}$. The WSJ dataset was only available to us in the form of PP quads with no other sentence information.

Methods Under Comparison. *1) PPAD* (Prepositional Phrase Attachment Disambiguator) is our proposed method. It uses diverse types of semantic knowledge, a mixture of labeled and unlabeled data for training data, a logistic regression classifier, and expectation maximization (EM) for parameter estimation *2) Collins* is the established baseline among PP attachment algorithms (Collins and Brooks, 1995). *3) Stanford Parser* is a state-of-the-art dependency parser, the 2014 online version. *4) PPAD Naive Bayes(NB)* is the same as PPAD but uses a generative model, as opposed to the discriminative model used in PPAD.

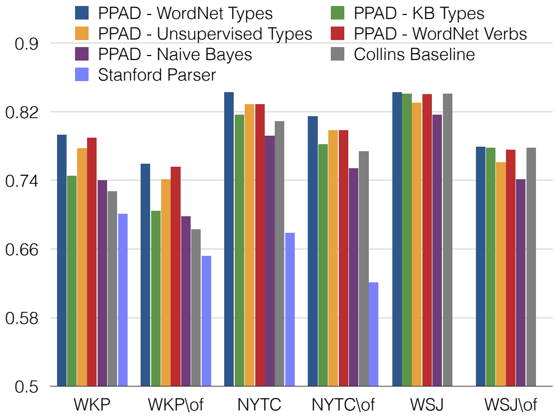

Figure 4: PPAD variations vs. baselines.

5.2 PPAD vs. Baselines

Comparison results of our method to the three baselines are shown in Table 4. For each dataset, we also show results when the "of" quads are removed, shown as "WKP\of", "NYTC\of", and "WSJ\of". Our method yields improvements over the baselines. Improvements are especially significant on the datasets for which no labeled data was available (NYTC and WKP). On WKP, our method is 7% and 9% ahead of the Collins baseline and the Stanford parser, respectively. On NYTC, our method is 4% and 6% ahead of the Collins baseline and the Stanford parser, respectively. On WSJ, which is the source of the labeled data, our method is not significantly better than the Collins baseline. We could not evaluate the Stanford parser on the WSJ dataset. The parser requires well-formed sentences which we could not generate from the WSJ dataset as it was only available to us in the form of PP quads with no other sentence information. For the same reason, we could not generate discourse features,$F7$, for the WSJ PP quads. For the NYTC and WKP datasets, we generated well-formed short sentences containing only the PP quad and the noun preceding it.

Feature Type	Precision	Recall	F1
Noun-Noun Binary Relations (F1-2)	*low*	*high*	*low*
Noun Semantic Categories (F3-4)	*high*	*high*	**high**
Verb Role Fillers (F5)	*high*	*low*	*low*
Preposition Definitions (F6)	*low*	*low*	*low*
Discourse Features (F7)	*high*	*low*	**high**
Lexical Features (F8-15)	*high*	*high*	**high**

Table 5: An approximate characterization of feature knowledge sources in terms of precision/recall/F1

5.3 Feature Analysis

We found that features $F2$ and $F6$ did not improve performance, therefore we excluded them from the final model, PPAD. This means that binary noun-noun relations were not useful when used permissively, feature $F2$, but when used selectively, feature $F1$, we found them to be useful. Our attempt at mapping prepositions to verb definitions produced some noisy mappings, resulting in feature $F6$ producing mixed results. To analyze the impact of the unlabeled data, we inspected the features and their weights as produced by the PPAD model. From the unlabeled data, new lexical features were discovered that were not in the original labeled data. Some sample new features with high weights for verb attachments are: *(perform,song,for,*), (lose,*,by,*), (buy,property,in,*).* And for noun attachments: *(*,conference,on,*), (obtain,degree,in,*), (abolish,taxes,on,*).*

We evaluated several variations of PPAD, the results are shown in Figure 4. For "PPAD-WordNet Verbs", we expanded the data by replacing verbs in PP quads with synonymous WordNet verbs, ignoring verb senses. This resulted in more instances of features F1, F8-10, & F12.

We also used different types of noun categorizations: WordNet classes, semantic types from the NELL knowledge base (Mitchell et al., 2015) and unsupervised types. The KB types and the unsupervised types did not perform well, possibly due to the noise found in these categorizations. WordNet classes showed the best results, hence they were used in the final PPAD model for features F3-4 & F7. In Section 5.1, PPAD corresponds to the best model.

5.4 Discussion: The F1 Score of Knowledge

Why did we not reach 100% accuracy? Should relational knowledge not be providing a much bigger performance boost than we have seen in the results? To answer these questions, we characterize our features in terms precision and recall, and F1 measure of their knowledge sources in Table 5. A low recall feature means that the feature does not fire on many examples, the feature's knowledge source suffers from low coverage. A low precision feature means that when it fires, the feature could be incorrect, the feature's knowledge source contains a lot of errors.

From Table 5, the noun-noun binary relation features $(F1 - 2)$ have low precision, but high recall. This is because the SVO data, extracted from the ClueWeb09 corpus, that we used as our relational knowledge source is very noisy but it is high coverage. The low precision of the SVO data causes these features to be detrimental to performance. Notice that when we used a filtered version of the data, in feature $F2$, the data was no longer detrimental to performance. However, the $F2$ feature is low recall, and therefore it's impact on performance is also limited. The noun semantic category features $(F3 - 4)$ have high recall and precision, hence it to be expected that their impact on performance is significant. The verb role filler features $(F5)$, obtained from VerbNet have high precision but low recall, hence their marginal impact on performance is also to be expected. The preposition definition features $(F6)$ poor precision made them unusable. The discourse features $(F7)$ are based noun semantic types and lexical features $(F8 - 15)$, both of which have high recall and precision, hence they useful impact on performance.

In summary, low precision in knowledge is detrimental to performance. In order for knowledge to make even more significant contributions to language understanding, high precision, high recall knowledge sources are required for all features types. Success in ongoing efforts in knowledge base construction projects, will make performance of our algorithm better.

Relation	Prep.	Attachment accuracy	Example(s)
acquired	from	**99.97**	BNY Mellon *acquired* Insight *from* Lloyds.
hasSpouse	in	**91.54**	David *married* Victoria *in* Ireland.
worksFor	as	**99.98**	Shubert *joined* CNN *as* reporter.
playsInstrument	with	**98.40**	Kushner *played* guitar *with* rock band Weezer.

Table 6: Binary relations extended to ternary relations by mapping to verb-preposition pairs in PP 5-tuples. PPAD predicted verb attachments with accuracy >90% in all relations.

5.5 Application to Ternary Relations

Through the application of ternary relation extraction, we further tested PPAD's PP disambiguation accuracy and illustrated its usefulness for knowledge base population. Recall that a PP 5-tuple of the form $\{n0, v, n1, p, n2\}$, whose enclosed PP attaches to the verb v, denotes a ternary relation with arguments *n0, n1, & n2*. Therefore, we can extract a ternary relation from every 5-tuple for which our method predicts a verb attachment. If we have a mapping between verbs and binary relations from a knowledge base (KB), we can extend KB relations to ternary relations by augmenting the KB relations with a third argument $n2$.

We considered four KB binary relations and their instances such as $worksFor(TimCook, Apple)$, from the NELL KB. We then took the collection of 4 million 5-tuples that we extracted from Wikipedia. We mapped verbs in 5-tuples to KB relations, based on significant overlaps in the instances of the KB relations, noun pairs such as $(TimCook, Apple)$ with the $n0, n1$ pairs in the Wikipedia PP 5-tuple collection. We found that, for example, instances of the noun-noun KB relation "worksFor" match $n0, n1$ pairs in tuples where $v = joined$ and $p = as$, with $n2$ referring to the job title. Other binary relations extended are: "hasSpouse" extended by "in" with wedding location, "acquired" extended by "from" with the seller of the company being acquired. Examples are shown in Table 6. In all these mappings, the proportion of verb attachments in the corresponding PP quads is significantly high ($> 90\%$). PPAD is overwhelming making the right attachment decisions in this setting.

Efforts in temporal and spatial relation extraction have shown that higher N-ary relation extraction is challenging. Since prepositions specify details that transform binary relations to higher N-ary relations, our method can be used to read information that can augment binary relations already in KBs. As future work, we would like to incorporate our method into a pipeline for reading beyond binary relations. One possible direction is to read details about the *where,why, who* of events and relations, effectively moving from extracting only binary relations to reading at a more general level.

6 Conclusion

We have presented a knowledge-intensive approach to prepositional phrase (PP) attachment disambiguation, which is a type of syntactic ambiguity. Our method incorporates knowledge about verbs, nouns, discourse, and noun-noun binary relations. We trained a model using labeled data and unlabeled data, making use of expectation maximization for parameter estimation. Our method can be seen as an example of tapping into a positive feedback loop for machine reading, which has only become possible in recent years due to the progress made by information extraction and knowledge base construction techniques. That is, using background knowledge from existing resources to read better in order to further populate knowledge bases with otherwise difficult to extract knowledge. As future work, we would like to use our method to extract more than just binary relations.

A Convolution Kernel Approach to Identifying Comparisons in Text

Abstract

Comparisons in text, such as in online reviews, serve as useful decision aids. In this paper, we focus on the task of identifying whether a comparison exists between a specific pair of entity mentions in a sentence. This formulation is transformative, as previous work only seeks to determine whether a sentence is comparative, which is presumptuous in the event the sentence mentions multiple entities and is comparing only some, not all, of them. Our approach leverages not only lexical features such as salient words, but also structural features expressing the relationships among words and entity mentions. To model these features seamlessly, we rely on a dependency tree representation, and investigate the applicability of a series of tree kernels. This leads to the development of a new context-sensitive tree kernel: Skip-node Kernel (SNK). We further describe both its exact and approximate computations. Through experiments on real-life datasets, we evaluate the effectiveness of our kernel-based approach for comparison identification, as well as the utility of SNK and its approximations.

1 Introduction

When weighing various alternatives, users increasingly turn to the social media, by scouring online reviews, discussion forums, etc. Our goal is to extract from such corpora those text snippets where users make direct comparisons of entities. While sentiment analysis (Pang and Lee, 2008) may be helpful in evaluating individual entities, comparison by the same author within a sentence provides an unambiguous and more equitable basis for the relative positions of two entities on some aspect. For example, the sentence s_1 in Table 1, taken from an Amazon review about a digital camera, makes two distinct comparisons: #1) between "A630" and "A-series cameras" and #2) between "A630" and "its competition", with a clear sense of which entity mention is the *greater* on some aspect ("larger"). Moreover, comparisons may be objective (e.g., larger) or subjective (e.g., better), while sentiments are primarily subjective.

Problem Given a sentence and a specific pair of entity mentions, we seek to determine if a comparison exists between those two mentions. In previous work, the problem was formulated as identifying *comparative sentences*, i.e., those containing at least one comparison (Jindal and Liu, 2006a). This is not ideal because a sentence may contain more than two entity mentions, and may be comparing only some of them. For instance, s_1 is comparative with respect to the pair (A630, A-series cameras) and the pair (A630, its competition), but not the pair (A-series cameras, its competition).

We therefore postulate that the more appropriate formulation is *comparisons within sentences*. If a sentence compares two entities (A, B) with respect to some aspect Z, it should be possible to reformulate it into another sentence such as: "A is better than B with respect to Z" (Kessler and Kuhn, 2014a). Based on this definition, there is no comparison between (A-series cameras, its competition) in s_1. Here, we adopt this apt definition with a slight restriction to make it more practical, and seek to identify such comparisons automatically. We consider only sentences with at least two entity mentions involved in gradable comparisons, i.e., a clear sense of scaling in the comparison (e.g., A is better than B.). Such comparisons are more useful in investigating the pros and cons of entities, as opposed to equative comparisons expressing parity between two mentions (e.g., A is as good as B.), or superlative comparisons expressing the primacy of an entity with respect to unknown reference entities (e.g., A is the best.).

Beijing, China, July 26-31, 2015.

ID	Sentence	Remarks
s_1	The A630 is slightly larger than previous generation A-series cameras, and also larger than much of its competition.	Contains two comparisons: (A630, A-series cameras) and (A630, its competition).
s_2	I got 30D for my wife because she wanted a better camera.	Includes comparative predicate "better", but contains no comparison.
s_3	I had D3100 and it was nice but the D5100 is truly amazing.	No comparative predicate, but has a comparison: (D3100, D5100).
s_4	D7000 and D7100 do better at high ISO than D300s.	Contains two comparisons: (D7000, D300s) and (D7100, D300s).

Table 1: Example Sentences with ≥ 2 Entity Mentions from Amazon.com Digital Cameras Reviews

Approach For English, there usually is a comparative predicate that anchors a comparison, such as "better" or "worse". However, many sentences with such predicate words are not comparisons. The sentence s_2 in Table 1 has the word "better", but does not contain any comparison between the entity mentions. Yet, other words (e.g., "amazing"), though not a comparative predicate, could signify a comparison, e.g., in s_3 in Table 1.

(Jindal and Liu, 2006a) considered the "context" around a predicate. A sentence is transformed into a sequence involving the predicate and the part of speech (POS) within a text window around the predicate (usually three words before and after). For instance, s_2 in Table 1 would be transformed into the sequence ⟨*PRP VBD DT better NN*⟩. Such sequences are labeled comparative or non-comparative, upon which (Jindal and Liu, 2006a) applies sequential pattern mining (Agrawal and Srikant, 1995; Ayres et al., 2002; Pei et al., 2001) to learn *class sequential rule* (CSR). These CSRs are then used as features in classifying comparative sentences.

While (Jindal and Liu, 2006a) makes some progress by considering context, its performance may be affected by several factors. First, CSRs are not sensitive to entity mentions. It may classify s_1 as comparative generally, missing the nuance that s_1 is not comparing the pair (A-series cameras, its competition). Second, as CSRs requires a list of comparative predicates, the quality and the completeness of the list are crucial. For instance, "amazing" is not in their list, and thus the comparison in s_3 may not be identifiable. Third, due to the windowing effect, CSRs has a limited ability to model long-range dependencies. For s_4, a window of three words around the predicate "better" excludes the word "than" that would have been very informative. Yet, enlarging the window might then bring in irrelevant associations.

What is important then is not so much whether a sentence is comparative as whether two entity mentions are related by a comparative relation. One insight we draw is how comparison identification is effectively a form of *relation extraction*. While there are diverse relation extraction formulations (Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Nguyen et al., 2009), our distinct relation type is comparison of two entity mentions.

Armed with this insight, we propose a kernel-based approach based on a dependency tree representation (Nivre, 2005), with significant innovations motivated by the comparative identification task. This proposed approach has several advantages over CSR. Most importantly, it models dependencies between any pair of words (including entity mentions), whereas CSR only relates a comparative predicate to nearby POS tags. For other advantages, unlike CSR, this approach is contingent on neither a pre-specified list of comparative predicates, nor a specific window length.

Contributions In this paper, we make the following contributions. *First*, we re-formulate the problem of automatic identification of comparative sentences into the more general task of identifying comparisons within sentences. *Second*, we propose to frame comparison identification as a relation extraction problem. This entails: #1) deriving an appropriate dependency tree representation of sentences to enable discrimination of comparison vs. non-comparison within the same sentence (see Section 2), and #2) a systematic exploration of the applicability of various tree kernel spaces to our task (see Section 3). *Third*, due to the limitation of the existing tree kernels, we propose a new tree kernel: Skip-node Kernel that is context-sensitive, and discuss both its exact and approximate computations (see Section 4). *Fourth*, we validate its effectiveness and efficiency through experiments on real-life datasets (see Section 5).

2 Overview

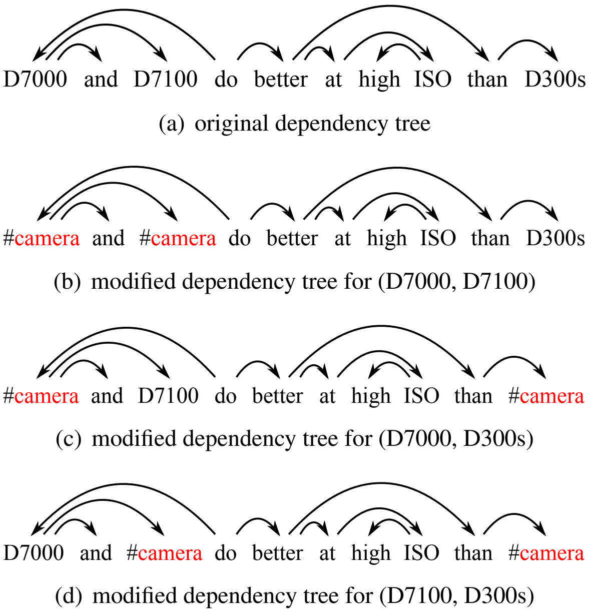
Task The input is a corpus of sentences $\mathcal{S}$ concerning a set of entities within a certain domain (e.g., digital cameras). Every sentence $s \in \mathcal{S}$ contains at least two entity mentions. The set of entity mentions in s is denoted M_s. For instance, the sentence s_4 in Table 1 contains three entity mentions: D7000, D7100, and D300s. The same entity may be mentioned more than once in a sentence, in which case every mention is a distinct instance.

As output, we seek to determine, for each pair of entity mentions $(m_i < m_j) \in M_s$ in a sentence $s \in \mathcal{S}$, a binary class label of whether s contains a comparison between m_i and m_j. For the pair (D7000, D7100) in s_4, the correct class is 0 (no comparison). For the other two pairs (D7000, D300s) and (D7100, D300s), the correct class is 1 (comparisons). We do not seek to identify the aspect of comparison, which is a different problem of independent research interest (see Section 6).

Dependency Tree In order to represent both the lexical units (words) as well their structural dependencies seamlessly, we represent each sentence s as a dependency tree T. For example, Figure 1(a) shows the dependency tree of s_4 in Table 1. The tree is rooted at the main verb ("do"), and each dependency relation associates a head word and a dependent word. To describe a tree or any of its substructures, we use the bracket notation. Figure 1(a) in this notation is `[do [D7000 [and] [D7100]] [better [at [ISO [high]]] [than [D300s]]]]`.

Here, we make two observations. First, there is one tree even for a sentence with multiple pairs of entity mentions. Second, the information signalling a comparison is borne by the structures around the mentions (e.g., `[better [than]]`, rather than the actual mentions (e.g., "D7000"). These lead us to introduce a *modified* dependency tree that is distinct for every pair of mentions, achieved by replacing each entity mention of interest by a placeholder token. Here, we use the token "#camera" for illustration. Figure 1(b) shows the modified tree for the pair (D7000, D7100). This enables learning in an entity-agnostic way, because the token ensures that sentences about different cameras are interpreted similarly.

Convolution Kernel Observe how the trees of the pair (D7000, D300s) in Figure 1(c) and the pair (D7100, D300s) in Figure 1(d), which are both comparisons, share certain substructures, such as `[do [better [than [#camera]]]]`. In contrast, the tree in Figure 1(b) for the pair (D7000, D7100), which is not a comparison, does not contain this substructure. What we need is a way to systematically examine tree substructures to determine the similarity between two trees.



D7000 and D7100 do better at high ISO than D300s
#camera and #camera do better at high ISO than D300s
#camera and D7100 do better at high ISO than #camera
D7000 and #camera do better at high ISO than #camera

(a) original dependency tree

(b) modified dependency tree for (D7000, D7100)

(c) modified dependency tree for (D7000, D300s)

(d) modified dependency tree for (D7100, D300s)

Figure 1: Modified dependency trees.

Kernel methods offer a way to measure the similarity by exploring an implicit feature space without enumerating all substructures explicitly. Suppose that $\mathbf{T}$ denotes the space of all possible instances. A kernel function K is a symmetric and positive semidefinite function that maps the instance space $\mathbf{T} \times \mathbf{T}$ to a real value in the range of $[0, \infty)$ (Haussler, 1999). A tree kernel function can be reformulated into a *convolution kernel* (Collins and Duffy, 2001), shown in Equation 1.

$$K(T_1, T_2) = \sum_{n_i \in T_1} \sum_{n_j \in T_2} D(n_i, n_j) \qquad (1)$$

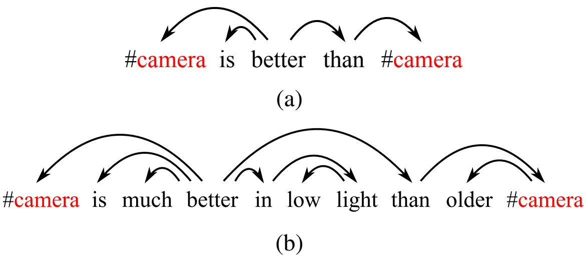
Here, n_i and n_j denote each node in their respective tree instances T_1 and T_2. $D(n_i, n_j)$ is the number of common substructure instances between the two sub-trees rooted in n_i and n_j respectively. The exact form of $D(n_i, n_j)$ depends on the specific definition of the tree kernel space. In Section 3, we systematically explore the applicability of various tree kernel spaces, leading to the introduction of the new *Skip-node Kernel*.

The appropriate kernel function can be embedded seamlessly in kernel methods for classification. In this work, we use the Support Vector Machines (SVM) (Steinwart and Christmann, 2008).

3 Tree Kernel Spaces

Tree kernels count substructures of a tree in some high-dimensional feature space. Different tree kernel spaces vary in the amount and the type of information they can capture, and thus may suit different purposes. To find a suitable tree kernel for the comparison identification task, we first systematically explore a progression of known tree kernel spaces, including Sub-tree, Subset Tree, and Partial Tree. Through the use of appropriate examples, we show how these existing tree kernel spaces may not be appropriate for certain instances. This section culminates in the introduction of a new feature space that we call Skip-node.

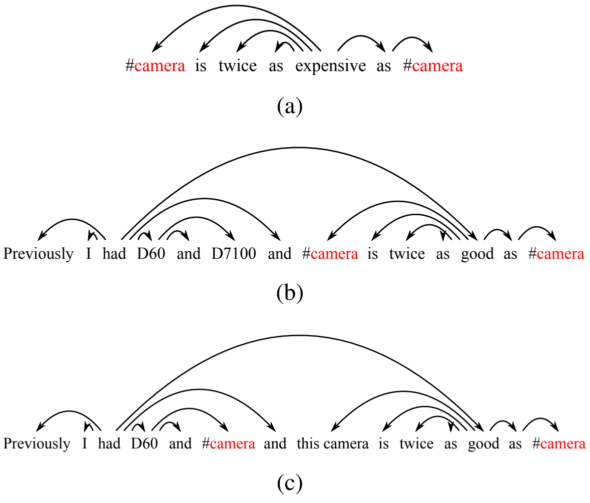
Sub-tree (ST) Space In this space, the basic substructure is a subgraph formed by a node along with all its descendants. Applying this kernel to two dependency trees of similar sentences may not be appropriate due to, for example, modifier words that change the dependency structure. To illustrate this, let us examine the two dependency parses in Figure 2. Both support comparisons, and ideally we can detect some level of similarity. However, if we consider only sub-trees, the two dependency trees share in common only two fragments: `[#camera]` and `[is]`. Neither of these fragments is indicative of a comparison.



#camera is better than #camera
(a)
#camera is much better in low light than older #camera
(b)

Figure 2: Dependency parses. Working example for the Sub-tree, Subset Tree, Partial Tree kernels.

Subset Tree (SST) Space We next consider the SST kernel, which computes similarity in a more general space of substructures than ST. Any subgraph of a tree that preserves production rules is counted. This definition suggests SST is intended more for a constituency parse (Moschitti, 2006a). In this feature space, the parses in Figure 2 now have in common the following fragments: `[#camera]`, `[is]`, `[than [#camera]]`. This representation is better than ST's, e.g., the fragment `[than [#camera]]` is informative. However, as a whole, the set of features are still insufficient to identify a comparison.



#camera is twice as expensive as #camera
(a)
Previously I had D60 and D7100 and #camera is twice as good as #camera
(b)
Previously I had D60 and #camera and this camera is twice as good as #camera
(c)

Figure 3: Dependency parses. Working example for the Partial Tree, Skip-node kernels.

Partial Tree (PT) Space In turn, the PT space allows breaking of production rules, making it a better choice than SST for dependency parses. PT kernel would find that the parse in Figure 2(a) with all its subgraphs can be matched as a whole within the parse in Figure 2(b), identifying a close match.

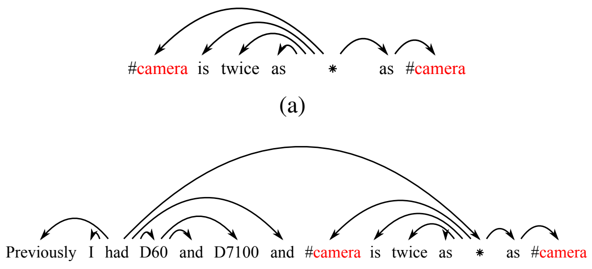
However, PT kernel is prone to two drawbacks. By generating an exponential feature space, it may overfit and degrade generalization (Cumby and Roth, 2003). More importantly, PT considers tree fragments independently from their contexts, resulting in features involving non-related parts of a sentence. This is particularly apparent when we consider multiple entities within a sentence.

Suppose that Figure 3(a) is in our training set, and we have the sentence below in the testing set:

> Previously, I had D60 and D7100, and this camera is twice as good as D60.

Figure 3(b) shows the parse for (this camera, D60), and Figure 3(c) for (D7100, D60). The former is a comparison, and should match Figure 3(a). The latter is not and should not match. PT kernel cannot resolve this ambiguity, computing the same similarity value to Figure 3(a) for both. The common features are: `[#camera]`, `[is]`, `[twice]`, `[as]`, and `[as [#camera]]`.

Skip-node (SN) Space Figures 3(a) and 3(b) share a similar substructure "twice as ... as", but because they use different words to express the comparisons ("expensive" vs. "good"), previous kernels treat their features disjointly, missing out on their similarity. To reduce this over-reliance on exact word similarity, we seek a feature space that



#camera is twice as ⁎ as #camera
Previously I had D60 and D7100 and #camera is twice as ⁎ as #camera

(a)

(b)

Figure 4: Dependency parses with skipped nodes.

would allow some degree of relaxation in determining the *structural* similarity between trees.

We therefore propose the Skip-node (SN) space, which represents a generalized space of tree fragments, where some nodes can be "skipped" or relabeled to a special symbol '$\star$' that would match nodes of any label. A restriction on this space is that each skip symbol must connect two non-skip (regular) nodes. The implication is that skips code for some notion of connecting distance between non-skip nodes. Moreover, the space would not include features such as [⋆ [⋆ [#camera]]] that serve only to indicate the presence of ancestors, and not any relationship of non-skip nodes.

Figure 4 resolves the ambiguity in Figure 3 by skipping the words "expensive" and "good", introducing a new set of features: [⋆ [#camera] [is] [twice] [as] [as [#camera]]]. Note how in this case the skip symbol effectively serves as a "context" that pulls together the previously disjoint features identified by the PT kernel. These new context-sensitive features would allow a match between the earlier Figures 3(a) and 3(b), but not Figure 3(c).

Thus, SN space effectively generalizes over the PT space, and enriches it with context-sensitive features. To avoid overfitting, in addition to decay parameter λ used in PT kernel, we associate SN kernel with two other parameters. The SN space consists of rooted ordered trees where some nodes are labeled with a special skip symbol '$\star$', such that the number of regular nodes (not marked with '$\star$') is at most S, and each skip node is within a distance of L from a non-skip node. This engenders a graceful gradation of similarity as the number of skip nodes in a substructure grows, yet imposes a limit to the extent of relaxation.

4 Skip-node Kernel Computation

We now discuss the computation of Skip-node Kernel, first exactly, and thereafter approximately.

4.1 Exact Computation

We define the alignment of common fragments between two trees in the Skip-node space. When $S = 1$, only singleton nodes with the same labels contribute to the kernel, and alignment is straightforward. When aligning fragments with two regular nodes ($S > 1$), we consider their connection structure and the order of the child nodes to prevent over-counting substructures with the same labels (e.g., [⋆[as][as]] in Figure 4). To preserve the natural order of words in a sentence, we enumerate the tree nodes according to preorder, left-to-right depth-first search (DFS) traversal.

In turn, the connection structure is defined by the skip-node path connecting two regular nodes. This can be expressed as a sequence of upward (towards the root) and downward (towards the leaves) steps we need to perform to get from the leftmost to the rightmost regular node. Due to the natural ordering of regular nodes, upward steps are followed by downward steps. The sequence can be expressed as a pair of numbers: $\langle \rho(n_l, u), \rho(n_r, u) \rangle$, where n_l is the leftmost regular node of a fragment, n_r is the rightmost one, $u = \sigma(n_l, n_r)$ is the lowest common ancestor of nodes n_l, n_r, and ρ returns the number of edges in the shortest path connecting two nodes.

Suppose a rooted tree $T = (N, E)$ has preorder DFS enumeration $N = (n_1, n_2, ..., n_{|N|})$. For $i < j$, we define a function $\pi(n_i, n_j)$, which canonically represents the way two nodes are connected in a tree, as follows:

$$\pi(n_i, n_j) = \langle \rho(n_i, \sigma(n_i, n_j)), \rho(n_j, \sigma(n_i, n_j)) \rangle.$$

DEFINITION 1 (STRUCTURAL ISOMORPHISM): Given two trees $T_1 = (N_1, E_1)$, $T_2 = (N_2, E_2)$, we say that pairs of nodes $(v_i, u_{i'}), (v_j, u_{j'}) \in N_1 \times N_2$ are *structurally isomorphic* and write $(v_i, u_{i'}) \leftrightsquigarrow (v_j, u_{j'})$ when $\pi(v_i, v_j) = \pi(u_{i'}, u_{j'})$ on the valid domain.

It can be shown that structural isomorphism is a transitive relation. This property allows us to grow aligned fragments by adding one node at a time:

$$(v_i, u_{i'}) \leftrightsquigarrow (v_j, u_{j'}) \wedge (v_j, v_{j'}) \leftrightsquigarrow (v_k, u_{k'}) \Rightarrow (v_i, u_{i'}) \leftrightsquigarrow (v_k, u_{k'}).$$

To compute the kernel, we use a graph-based approach to enumerate all the common substructures in the Skip-node space. Given two trees T_1 and T_2, we begin by aligning their nodes. The sets of nodes in T_1 and T_2 are N_1 and N_2 respectively. Let N_G be a set of pairs $(n_i, n_j) \in N_1 \times N_2$, where n_i and n_j have the same label. On top of N_G, we build a graph $G = (N_G, E_G)$. We draw an edge between two vertices $(v_i, v_k), (u_j, u_l) \in N_G$, if $(v_i, u_j) \leftrightsquigarrow (v_k, u_l)$ and $\rho(v_i, v_k) \leq L$.

Any connected subgraph of G represents a feature in the Skip-node space common to both T_1 and T_2. The kernel then needs to count the number of connected subgraphs of sizes not more than S. To see that this procedure is correct, we simply need to trace back the construction of graph G, and build an bijection from a subgraph of G to the corresponding fragments of T_1 and T_2.

Enumerating all the connected subgraphs of a given graph requires exponential time. The algorithm described above requires $\mathcal{O}(|N_1||N_2| + \sum_{i=1}^{S} \binom{|N_G|}{i})$ time, assuming that the distance between two nodes in a tree can be computed in $\mathcal{O}(1)$ with appropriate linear preprocessing. See (Bender and Farach-Colton, 2000) for insight. The exact computation is still tractable on the condition that S and L are not very large. This condition would probably hold in most realistic scenarios. Yet, to improve the practicality of the kernel, we propose a couple of approximations as follows.

4.2 Approximate Computation

One reason for the complexity of the Skip-node kernel is that although the graph G is formed by aligning two trees, by allowing connections through skips, G itself may not necessarily be in the form of a tree. In deriving an approximation, our strategy is to form G through alignment of linear substructures of the original two trees. A Skip-node space over linear structures can be computed in polynomial time using dynamic programming.

Linear Skip-node One approximation is to consider linear substructures in the form of root-paths. A root-path is a path from the root of a tree to a leaf. Given two trees T_1 and T_2, with DFS enumerated nodes $N_1 = (v_1, v_2, ..., v_{m_1})$ and $N_2 = (u_1, u_2, ..., u_{m_2})$ respectively. Here, v_1 and u_1 are roots, and v_{m_1} and u_{m_2} are the leaves. Starting with common fragments at the leaves, we grow them into larger common fragments towards the root. We call this approximation *Linear Skip-node*. Figure 5(a) shows examples of features considered by Linear Skip-node for the illustrated tree T in skip-node space $(S = 3, L = 2)$.

The kernel function can be decomposed into:

$$K(T_1, T_2) = \sum_{v_i \in N_1} \sum_{u_j \in N_2} \sum_{s=1}^{S} \lambda^s D(v_i, u_j, s),$$

where $D(v_i, u_j, s)$ is the number of common substructures of size s with the leftmost regular nodes v_i and u_j. λ is a decay factor for substructure size.

The recursive definition of the kernel is:

$$D(v_i, u_j, s) =$$

$$\sum_{i<k\leq m_1} \sum_{j<l\leq m_2} I(v_i, v_k, u_j, u_l) D(v_k, u_l, s-1),$$

$$D(v_i, u_j, 1) = \begin{cases} 1 & \text{if } \mathit{label}(v_i) = \mathit{label}(u_j), \\ 0 & \text{otherwise;} \end{cases}$$

$$I(v_i, v_k, u_j, u_l) = \mathbb{1}_{(v_i,u_j) \leftrightsquigarrow (v_k,u_l)}$$

$$\mathbb{1}_{\rho(v_i,v_k)\leq L} \cdot \mathbb{1}_{(v_i \text{ is an ancestor of } v_k)},$$

where $\mathbb{1}_c$ equals 1 when constraint c is satisfied and 0 otherwise. Note that the first two factors of indicator function I just represent the general Skip-node space constraints, the last factor ensures that features are computed along the root-paths.

Lookahead Skip-node The second approximation, *Lookahead Skip-node*, is related to the observation that when growing a substructure, we do not have to confine the growth only towards ancestors, as DFS traversal already ensures iterative manner of computation. In other words, the constraint v_i is an ancestor of v_k can be dropped:

$$I(v_i, v_k, u_j, u_l) = \mathbb{1}_{(v_i,u_j) \leftrightsquigarrow (v_k,u_l)} \cdot \mathbb{1}_{\rho(v_i,v_k)\leq L}.$$

In addition to those features generated by Linear Skip-node in Figure 5(a), Lookahead Skip-node can generate additional tree substructures, shown in Figure 5(b). The approximation can be computed using different DFS enumerations, which may result in different feature sets. In our experiments, we used pre-order left-to-right enumeration. Given the enumeration of tree T as in Figure 5, we start to grow feature fragments from node n_4. According to the Skip-node space constraints, the growth can only proceed to nodes n_1 or n_2. Once any of these nodes is attached to n_4, we lose tree fragments containing n_3, as the procedure allows us to grow substructures only towards nodes with smaller (earlier) DFS enumer-

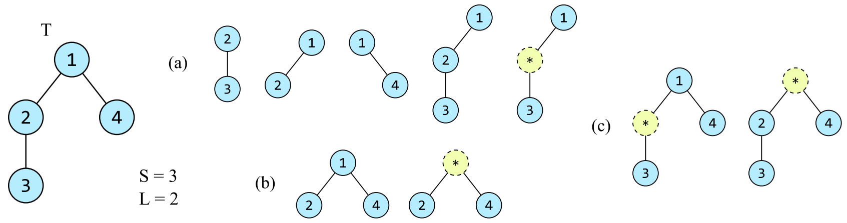


Figure 5: Features of T in skip-node space ($S = 3, L = 2$). Numbers indicates pre-order left-to-right DFS enumeration of T. Dashed circles represent skip nodes. Subfigures: (a) - modeled by all; (b) - modeled by Lookahead Skip-node, not by Linear Skip-node; (c) - modeled only by Exact Skip-node.

ation numbers. Figure 5(c) shows the fragments that Lookahead Skip-node cannot capture[1].

The computation procedure is similar for both approximations and requires $\mathcal{O}(S|N_1|^2|N_2|^2)$.

5 Experiments

Data For experiments, we compiled two annotated datasets in two domains: Digital Camera and Cell Phone from online review sentences. The reviews were collected from *Amazon* and *Epinions*[2].

We identified the entity mentions through dictionary matching, followed by manual annotation to weed out false positives. Each dictionary entry is a product name (e.g., *Canon PowerShot D20*, *D7100*) or a common product reference (e.g., *this camera*, *that phone*). The dataset includes only sentences that contain at least two entity mentions. Every pair of entities within a sentence was annotated with a comparative label according to the definition given in Section 2. A sentence is comparative if at least one pair of entities within it is in a comparative relation. Table 2 shows the dataset properties, in terms of the number sentences and the percentage that are comparative sentences, as well as the number of pairs of entity mentions and the percentage that are comparative relations. There are more pairs than sentences, i.e., many sentences mention more than two entities.

This dataset subsumes the annotated gradable comparisons of (Kessler and Kuhn, 2014a) derived from *Epinions* reviews on Digital Cameras. (Jindal and Liu, 2006a)'s dataset is inapplicable, due to its lack of entity-centric comparison.

Evaluation The experiments were carried out with SVM-light-TK framework[3] (Joachims, 1999; Moschitti, 2006b), into which we built Skip-node Kernel. We further release a separate standalone library that we built, called Tree-SVM[4], which does SVM optimization using the tree kernels described in this paper. The sentences were parsed and lemmatized with the use of the Stanford NLP software (Chen and Manning, 2014).

The experiments were done on 10 random data splits in 80:20 proportion of training vs. testing. Performance is measured by using F_1, which is the harmonic mean of precision P and recall R: $F_1 = \frac{2PR}{P+R}$. The statistical significance[5] is measured by randomization test (Yeh, 2000). The hyper-parameters, including the baselines', were optimized for F_1 through grid-search.

5.1 Comparison Identification

Our first and primary objective is to investigate the effectiveness of the proposed approach on the task of identifying comparisons between a pair of en-

[1] In this particular case, all features could have been computed by Lookahead Skip-node using preorder right-to-left DFS enumeration, although it may not be true in general.

[2] We used already available snapshots for *Epinions* dataset: http://groups.csail.mit.edu/rbg/code/precis/.

[3] http://disi.unitn.it/moschitti/Tree-Kernel.htm

[4] http://github.com/sitfoxfly/tree-svm

[5] When presenting the results, an asterisk indicates that the outperformance over the second-best result is significant at 0.05 level. Two asterisks indicate the same at 0.1 level.

	P	R	F1	P	R	F1
CSR	74.6	51.7	60.9	50.9	**61.2***	55.3
BoW	77.5	**76.3**	76.8	63.4	57.7	60.2
BoW†	77.6	72.4	74.9	70.9	57.3	63.2
SNK	**81.0***	75.2	**78.0****	**77.9***	54.8	**64.2**

Table 4: Comparative sentence identification task

tity mentions. Previous work focused on identifying comparative sentences. We compare to three baselines. One is CSR, implemented following the description in (Jindal and Liu, 2006a). Another is BoW, classification using bag-of-words as features. For the baselines, if a comparative sentence contains more than one pair of entities, we assume that every pair is in comparative relation. The third baseline, BoW†, considers only the words in between of the two target entities.

Table 3 shows the performance on the comparison identification task (best results are in bold). In terms of F_1, it is evident that SNK outperforms the baselines. This is achieved through significant gains in precision. It is expected that the baselines tend to have a high recall. CSR benefits from the human-constructed predefined list of comparative keywords and key phrases that a kernel-based method is unable to learn from a training split. BoW† tends to have a higher precision than the other baselines, as it is able to distinguish between different pairs of entities within one sentence.

While SNK may have an inherent advantage over CSR or BoW due to its entity orientation, to investigate the effectiveness of the method itself, we now compare them on the previous task of comparative sentence identification. Table 4 shows that even in this task, SNK still performs better than the baselines. Comparing Table 3 and Table 4, the results also concur with the intuition: once we fold up multiple entity pairs in a sentence into a comparative sentence, we observe a drop in recall and an increase in precision.

5.2 Tree Kernel Spaces

Our second objective is to explore the progression of feature spaces discussed in Section 3. Table 5 reports the results on comparison identification task. The F_1 columns show that the performance gradually increases from STK to SNK along with the increase in the complexity of feature space. PTK and SNK can be considered high-variance estimators due to the power of their feature spaces. The data is such that these kernels may not have fully modeled the feature space completely enough to show even sharper differences.

	Camera			Cell		
	P	R	F1	P	R	F1
STK	67.5	64.0	64.9	43.7	41.9	42.6
SSTK	72.1	72.6	71.8	**79.6**	42.4	54.9
PTK	79.2	74.9	76.9	72.3	**56.0****	62.7
SNK	**80.5***	**75.2**	**77.7****	77.2	55.1	**64.1***

Table 5: Tree kernels

	Camera			Cell		
	P	R	F1	P	R	F1
STK$_{\text{BoW}}$	79.9	65.1	71.7	**77.5**	45.3	56.8
SSTK$_{\text{BoW}}$	78.0	73.5	75.6	71.8	54.5	61.6
PTK$_{\text{BoW}}$	78.6	74.1	76.2	71.0	53.8	60.8
SNK	**80.5**	**75.2****	**77.7***	77.2	**55.1**	**64.1****

Table 6: Tree kernels combined with bag-of-words

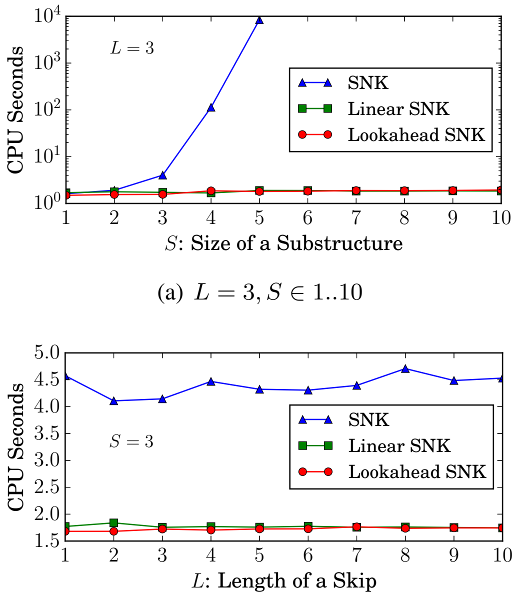
SNK's parameters were optimized to non-trivial cases ($S > 1$ and $L > 1$) by the grid-search, i.e., $S = 3$ and $L = 2$ for Digital Camera and $S = 2$ and $L = 3$ for Cell Phone. The trivial case $S = 1$ represents a standard bag-of-words feature space, i.e., this space is embedded into Skip-node space whenever $S > 1$. To show that SNK does not merely take advantage of this simple space to compete with structural kernels, we carried out another experiment where we combined STK, SSTK, and PTK with bag-of-word representation of a sentence. Table 6 shows that surprisingly this combination harms the quality of PTK. STK and SSTK gain more from bag-of-words features. Nevertheless, the overall outperformance by SNK remains.

5.3 Skip-node Kernel Approximations

Our third objective is to study the utility of the approximations of SNK described in Section 4. Table 7 reports the performance of the approximations. For Camera, the performance of Lookahead

	Camera			Cell		
	P	R	F1	P	R	F1
Linear SNK	78.9	**77.1***	**77.9**	71.8	**55.3**	62.2
Lookahead SNK	**80.5**	75.2	77.7	71.8	**55.3**	62.2
SNK	**80.5**	75.2	77.7	**77.2***	55.1	**64.1**

Table 7: Effectiveness: SNK vs. approximations



(a) $L = 3, S \in 1..10$

(b) $S = 3, L \in 1..10$

Figure 6: Efficiency: SNK vs. approximations

SNK and SNK are the same. In turn, Linear SNK represents more restricted features, yielding a drop in precision and a gain in recall, resulting in the best F_1. For Cell Phone, the approximations are close, but the original SNK has the best F_1.

To study the running time, we randomly select 500 sentences. Figure 6 shows the time for applying a kernel function to 250k pairs of sentences when we vary two parameters: S and L. When S varies, SNK running time has exponential behaviour, whereas the approximations show fairly linear curves. L seems to influence the computation time linearly for SNK and and its approximations. The experiments were carried out on a PC with Intel Core i5 CPU 3.2 GHz and 4Gb RAM.

This experiment shows that the original SNK is still tractable for small S and L, which turn out to be the case for optimal effectiveness. If efficiency is of paramount importance, the two approximations are significantly faster, without much degradation (none in some cases) of effectiveness.

6 Related Work

Exploiting comparisons in text begins with identifying comparisons within sentences. The previous state of the art for English is the baseline CSR approach (Jindal and Liu, 2006a). For scientific text, (Park and Blake, 2012) explored handcrafted syntactic rules that might not cross domains well. Comparisons are also studied in other languages, such as Chinese, Japanese, and Korean (Huang et al., 2008; Yang and Ko, 2009; Kurashima et al., 2008; Yang and Ko, 2009; Zhang and Jin, 2012).

A different task seeks to identify the "components" within comparative sentences, i.e., entities, aspect, comparative predicate (Jindal and Liu, 2006b; Hou and Li, 2008; Kessler and Kuhn, 2014b; Kessler and Kuhn, 2013; Feldman et al., 2007). Others are interested in yet another task to identify the direction of the comparisons (Ganapathibhotla and Liu, 2008; Tkachenko and Lauw, 2014), or the aggregated ranking (Kurashima et al., 2008; Zhang et al., 2013; Li et al., 2011). Our task precedes these tasks in the pipeline.

Other than comparison identification, dependency grammar has also found applications in natural language-related tasks, such as sentiment classification (Nakagawa et al., 2010), question answering (Punyakanok et al., 2004; Lin and Pantel, 2001), as well as relation extraction (Culotta and Sorensen, 2004; Bunescu and Mooney, 2005).

(Collins and Duffy, 2001) applied convolution kernels (Haussler, 1999; Watkins, 1999) to natural language objects, which evolved into tree kernels, e.g., sub-tree (Vishwanathan and Smola, 2004), subset tree (Collins and Duffy, 2002), descending-path kernel (Lin et al., 2014), partial tree (Moschitti, 2006a). Skip-node kernel joins the list of tree kernels applicable to dependency trees. These kernels may also apply to other types of trees, e.g., constituency trees (Zhou et al., 2007).

(Croce et al., 2011; Srivastava et al., 2013) proposed to capture semantic information along with tree structure, by allowing soft label matching via lexical similarity over distributional word representation. Skip-node gives another perspective on sparsity, using structural alignment of the tree fragments with non-matching labels. As lexical similarity can be incorporated into Skip-node kernel, we consider it orthogonal and complementary.

7 Conclusion

We study the effectiveness of a convolution kernel approach for the novel formulation of extracting comparisons within sentences. Our approach outperforms the baselines in identifying comparisons and comparative sentences. Skip-node kernel and its approximations are particularly effective for comparison identification, and potentially applicable to other relation extraction or natural-language tasks (the direction of our future work).

Abstract

The last few years have seen a surge in the number of accurate, fast, publicly available dependency parsers. At the same time, the use of dependency parsing in NLP applications has increased. It can be difficult for a non-expert to select a good "off-the-shelf" parser. We present a comparative analysis of ten leading statistical dependency parsers on a multi-genre corpus of English. For our analysis, we developed a new web-based tool that gives a convenient way of comparing dependency parser outputs. Our analysis will help practitioners choose a parser to optimize their desired speed/accuracy tradeoff, and our tool will help practitioners examine and compare parser output.

1 Introduction

Dependency parsing is a valuable form of syntactic processing for NLP applications due to its transparent lexicalized representation and robustness with respect to flexible word order languages. Thanks to over a decade of research on statistical dependency parsing, many dependency parsers are now publicly available. In this paper, we report on a comparative analysis of leading statistical dependency parsers using a multi-genre corpus. Our purpose is not to introduce a new parsing algorithm but to assess the performance of existing systems across different genres of language use and to provide tools and recommendations that practitioners can use to choose a dependency parser. The contributions of this work include:

- A comparison of the accuracy and speed of ten state-of-the-art dependency parsers, covering a range of approaches, on a large multi-genre corpus of English.
- A new web-based tool, DependAble, for side-by-side comparison and visualization of the output from multiple dependency parsers.
- A detailed error analysis for these parsers using DependAble, with recommendations for parser choice for different factors.
- The release of the set of dependencies used in our experiments, the test outputs from all parsers, and the parser-specific models.

2 Related Work

There have been several shared tasks on dependency parsing conducted by CoNLL (Buchholz and Marsi, 2006; Nivre and others, 2007; Surdeanu and others, 2008; Hajič and others, 2009), SANCL (Petrov and McDonald, 2012), SPMRL (Seddah and others, 2013), and SemEval (Oepen and others, 2014). These shared tasks have led to the public release of numerous statistical parsers. The primary metrics reported in these shared tasks are: labeled attachment score (**LAS**) – the percentage of predicted dependencies where the arc and the label are assigned correctly; unlabeled attachment score (**UAS**) – where the arc is assigned correctly; label accuracy score (**LS**) – where the label is assigned correctly; and exact match (**EM**) – the percentage of sentences whose predicted trees are entirely correct.

Although shared tasks have been tremendously useful for advancing the state of the art in dependency parsing, most English evaluation has employed a single-genre corpus, the WSJ portion of the Penn Treebank (Marcus et al., 1993), so it is not immediately clear how these results gen-

eralize.[1] Furthermore, a detailed comparative error analysis is typically lacking. The most detailed comparison of dependency parsers to date was performed by McDonald and Nivre (2007; 2011); they analyzed accuracy as a function of sentence length, dependency distance, valency, non-projectivity, part-of-speech tags and dependency labels.[2] Since then, additional analyses of dependency parsers have been performed, but either with respect to specific linguistic phenomena (e.g. (Nivre et al., 2010; Bender et al., 2011)) or to downstream tasks (e.g. (Miwa and others, 2010; Petrov et al., 2010; Yuret et al., 2013)).

3 Data

3.1 OntoNotes 5

We used the English portion of the OntoNotes 5 corpus, a large multi-lingual, multi-genre corpus annotated with syntactic structure, predicate-argument structure, word senses, named entities, and coreference (Weischedel and others, 2011; Pradhan and others, 2013). We chose this corpus rather than the Penn Treebank used in most previous work because it is larger (2.9M vs. 1M tokens) and more diverse (7 vs. 1 genres). We used the standard data split used in CoNLL'12 [3], but removed sentences containing only one token so as not to artificially inflate accuracy.

Table 1 shows the distribution across genres of training, development, and test data. For the most strict and realistic comparison, we trained all ten parsers using automatically assigned POS tags from the tagger in ClearNLP (Choi and Palmer, 2012a), which achieved accuracies of 97.34 and 97.52 on the development and test data, respectively. We also excluded any "morphological" feature from the input, as these are often not available in non-annotated data.

3.2 Dependency Conversion

OntoNotes provides annotation of constituency trees only. Several programs are available for converting constituency trees into dependency trees. Table 2 shows a comparison between three of the most widely used: the LTH (Johansson and Nugues, 2007),[4], Stanford (de Marneffe and Manning, 2008),[5] and ClearNLP (Choi and Palmer, 2012b)[6] dependency converters. Compared to the Stanford converter, the ClearNLP converter produces a similar set of dependency labels but generates fewer unclassified dependencies (0.23% vs. 3.62%), which makes the training data less noisy.

Both the LTH and ClearNLP converters produce long-distance dependencies and use function tags for the generation of dependency relations, which allows one to generate rich dependency structures including non-projective dependencies. However, only the ClearNLP converter adapted the new Treebank guidelines used in OntoNotes. It can also produce secondary dependencies (e.g. right-node raising, referent), which can be used for further analysis. We used the ClearNLP converter to produce dependencies for our experiments.

	LTH	Stanford	ClearNLP
Long-distance	✓		✓
Secondary	1	2	4
Function tags	✓		✓
New TB format			✓

Table 2: Dependency converters. The "secondary" row shows how many types of secondary dependencies that can be produced by each converter.

[1] The SANCL shared task used OntoNotes and the Web Treebanks instead for better generalization.

[2] A detailed error analysis of constituency parsing was performed by (Kummerfeld and others, 2012).

Table 3: Dependency parsers used in our experiments.

4 Parsers

We compared ten state of the art parsers representing a wide range of contemporary approaches to statistical dependency parsing (Table 3). We trained each parser using the training data from OntoNotes. For all parsers we trained using the automatic POS tags generated during data preprocessing, as described above.

Training settings For most parsers, we used the default settings for training. For the SNN parser, following the recommendation of the developers, we used the word embeddings from (Collobert and others, 2011).

Development data ClearNLP, LTDP, SNN and Yara make use of the development data (for parameter tuning). Mate and Turbo self-tune parameter settings using the training data. The others were trained using their default/“standard” parameter settings.

Beam search ClearNLP, LTDP, Redshift and Yara have the option of different beam settings. The higher the beam size, the more accurate the parser usually becomes, but typically at the expense of speed. For LTDP and Redshift, we experimented with beams of 1, 8, 16 and 64 and found that the highest accuracy was achieved at beam 8.[17] For ClearNLP and Yara, a beam size of 64 produced the best accuracy, while a beam size of 1 for LTDT, ClearNLP, and Yara produced the best speed performance. Given this trend, we also include how those three parsers perform at beam 1 in our analyses.

Feature Sets RBG, Turbo and Yara have the options of different feature sets. A more complex or larger feature set has the advantage of accuracy, but often at the expense of speed. For RBG and Turbo, we use the ”Standard” setting and for Yara, we use the default (”not basic”) feature setting.

Output All the parsers other than LTDP output labeled dependencies. The ClearNLP, Mate, RBG, and Turbo parsers can generate non-projective dependencies.

5 DEPENDABLE: Web-based Evaluation and Visualization Tool

There are several very useful tools for evaluating the output of dependency parsers, including the venerable `eval.pl`[18] script used in the CoNLL shared tasks, and newer Java-based tools that support visualization of and search over parse trees such as TedEval (Tsarfaty et al., 2011),[19] MaltEval (Nilsson and Nivre, 2008)[20] and “What’s wrong with my NLP?”.[21] Recently, there is momentum towards web-based tools for annotation and visualization of NLP pipelines (Stenetorp and others, 2012). For this work, we used a new web-based tool, DEPENDABLE, developed by the first author of this paper. It requires no installation and so provides a convenient way to evaluate and compare dependency parsers. The following are key features of DEPENDABLE:

Figure 2: Screenshot of our visualization tool.

- It reads any type of Tab Separated Value (TSV) format, including the CoNLL formats.
- It computes LAS, UAS and LS for parse outputs from multiple parsers against gold (manual) parses.
- It computes exact match scores for multiple parsers, and "oracle ensemble" output, the upper bound performance obtainable by combining all parser outputs.
- It allows the user to exclude symbol tokens, projective trees, or non-projective trees.
- It produces detailed analyses by POS tags, dependency labels, sentence lengths, and dependency distances.
- It reports statistical significance values for all parse outputs (using McNemar's test).

DEPENDABLE can be also used for visualizing and comparing multiple dependency trees together (Figure 2). A key feature is that the user may select parse trees by specifying a range of accuracy scores; this enabled us to perform the error analyses in Section 6.5. DEPENDABLE allows one to filter trees by sentence length and highlights arc and label errors. The evaluation and comparison tools are publicly available at http://nlp.mathcs.emory.edu/clearnlp/dependable.

6 Results and Error Analysis

In this section, we report overall parser accuracy and speed. We analyze parser accuracy by sentence length, dependency distance, non-projectivity, POS tags and dependency labels, and genre. We report detailed manual error analyses focusing on sentences that multiple parsers parsed incorrectly.[22] All analyses, other than parsing speed, were conducted using the DEPENDABLE tool.[23] The full set of outputs from all parsers, as well as the trained models for each parser, available at http://amandastent.com/dependable/.

We also include the greedy parsing results of ClearNLP, LTDP, and Yara in two of our analyses to better illustrate the differences between the greedy and non-greedy settings. The greedy parsing results are denoted by the subscript '$_g$'. These two analyses are the overall accuracy results, presented in Section 6.1 (Table 4), and the overall speed results, presented in Section 6.2 ((Table 5 and Figure). All other analyses exclude the ClearNLP$_g$, LTDP$_g$ and Yara$_g$.

[22] For one sentence in the NW data, the LTDP parser failed to produce a complete parse containing all tokens, so we removed this sentence for all parsers, leaving 11,696 trees (216,313 tokens) in the test data.

[23] We compared the results produced by DEPENDABLE with those produced by eval07.pl, and verified that LAS, UAS, LA, and EM were the same when punctuation was included. Our tool uses a slightly different symbol set than eval07.pl: !"#$%&'()*+,-./:;<=>?@[\]^_`{|}~

Table 4: Overall parsing accuracy. The top 6 rows and the bottom 7 rows show accuracies for greedy and non-greedy parsers, respectively.

6.1 Overall Accuracy

In Table 4, we report overall accuracy for each parser. For clarity, we report results separately for greedy and non-greedy versions of the parsers. Over all the different metrics, MATE is a clear winner, though ClearNLP, RBG, Redshift, Turbo and Yara are very close in performance. Looking at only the greedy parsers, ClearNLP$_g$ shows a significant advantage over the others.

We conducted a statistical significance test for the the parsers (greedy versions excluded). All LAS differences are statistically significant at $p < .01$ (using McNemar's test), except for: RBG vs. Redshift, Turbo vs. Yara, Turbo vs. ClearNLP and Yara vs. ClearNLP. All UAS differences are statistically significant at $p < .01$ (using McNemar's test), except for: SNN vs. LTDP, Turbo vs. Redshift, Yara vs. RBG and ClearNLP vs. Yara.

6.2 Overall Speed

We ran timing experiments on a 64 core machine with 16 Intel Xeon E5620 2.40 GHz processors and 24G RAM, and used the unix `time` command to time each run. Some parsers are multi-threaded; for these, we ran in single-thread mode (since any parser can be externally parallelized). Most parsers do not report model load time, so we first ran each parser five times with a test set of 10 sentences, and then averaged the middle three times to get the average model load time.[24] Next, we ran each parser five times with the entire test set and derived the overall parse time by averaging the middle three parse times. We then subtracted the average model time from the average parse time and averaged over the number of sentences and tokens.

	Sent/Sec	Tokens/Sec	Language
ClearNLP$_g$	555	10,271	Java
GN13	95	1,757	Python
LTDP$_g$	232	4,287	Python
SNN	465	8,602	Java
spaCy	**755**	**13,963**	Cython
Yara$_g$	532	9,838	Java

Turbo	19	349	C++
Yara	18	340	Java

Table 5: Overall parsing speed.

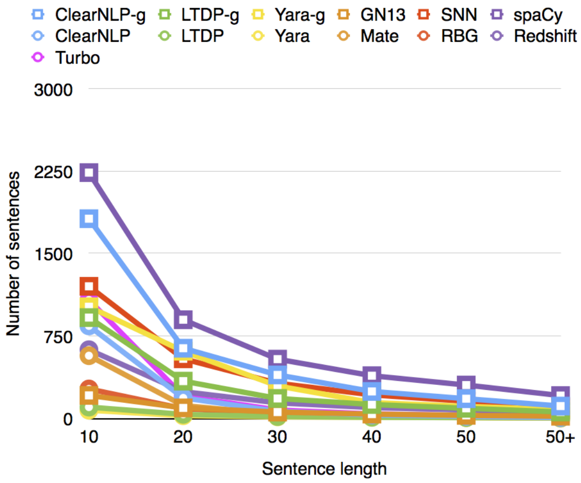

Figure 3: Number of sentences parsed per second by each parser with respect to sentence length.

Table 5 shows overall parsing speed for each parser. spaCy is the fastest greedy parser and Redshift is the fastest non-greedy parser. Figure 3

[24] Recall we exclude single-token sentences from our tests.

shows an analysis of parsing speed by sentence length in bins of length 10. As expected, as sentence length increases, parsing speed decreases remarkably.

6.3 Detailed Accuracy Analyses

For the following more detailed analyses, we used all tokens (including punctuation). As mentioned earlier, we exclude ClearNLP$_g$, LTDP$_g$ and Yara$_g$ from these analyses and instead use their respective non-greedy modes yielding higher accuracy.

Sentence Length We analyzed parser accuracy by sentence length in bins of length 10 (Figure 4). As expected, all parsers perform better on shorter sentences. For sentences under length 10, UAS ranges from 93.49 to 95.5; however, UAS declines to a range of 81.66 and 86.61 for sentence lengths greater than 50. The most accurate parsers (ClearNLP, Mate, RBG, Redshift, Turbo, and Yara) separate from the remaining when sentence length is more than 20 tokens.

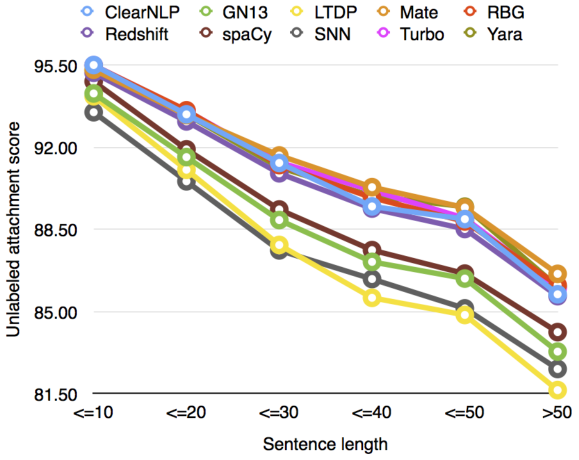

Figure 4: UAS by sentence length.

Dependency Distance We analyzed parser accuracy by dependency distance (depth from each dependent to its head; Figure 5). Accuracy falls off more slowly as dependency distance increases for the top 6 parsers vs. the rest.

Projectivity Some of our parsers only produce projective parses. Table 6 shows parsing accuracy for trees containing only projective arcs (11,231 trees, 202,521 tokens) and for trees containing non-projective arcs (465 trees, 13,792 tokens). As before, all differences are statistically significant at $p < .01$ except for: Redshift vs. RBG for overall LAS; LTDP vs. SNN for overall UAS; and Turbo vs. SpaCy for overall UAS. For strictly projective trees, the LTDP parser is 5th from the top in UAS. Apart from this, the grouping between "very good" and "good" parsers does not change.

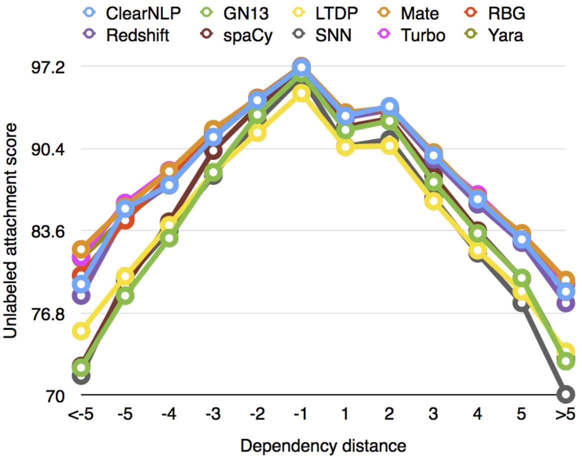

Figure 5: UAS by dependency distance.

	Projective only		Non-proj. only	
	LAS	UAS	LAS	UAS
ClearNLP	90.20	91.62	85.10	86.72
GN13	88.00	89.57	81.56	83.37
LTDP	n/a	90.24	n/a	57.83
Mate	**90.34**	**91.91**	**85.51**	**87.40**
RBG	89.86	91.72	84.83	86.94
Redshift	89.90	91.41	83.30	85.12
SNN	86.83	88.55	80.37	82.32
spaCy	88.31	89.99	82.15	84.08
Turbo	88.36	89.90	83.50	85.30
Yara	90.20	91.74	83.92	85.74

Table 6: Accuracy for proj. and non-proj. trees.

Dependency Relations We were interested in which dependency relations were computed with high/low overall accuracy, and for which accuracy varied between parsers. The dependency relations with the highest average LAS scores ($>$ 97%) were `possessive`, `hyph`, `expl`, `hmod`, `aux`, `det` and `poss`. These relations have strong lexical clues (e.g. `possessive`) or occur very often (e.g. `det`). Those with the lowest LAS scores ($<$ 50%) were `csubjpass`, `meta`, `dep`, `nmod` and `parataxis`. These either occur rarely or are very general (`dep`).

The most "confusing" dependency relations (those with the biggest range of accuracies across parsers) were `csubj`, `preconj`, `csubjpass`, `parataxis`, `meta` and `oprd` (all with a spread of $>$ 20%). The Mate and Yara parsers each had the highest accuracy for 3 out of the top 10 "confusing" dependency relations. The RBG parser had the highest accuracy for 4 out of the top 10 “most accurate” dependency relations. SNN had the lowest accuracy for 5 out of the top 10 “least accurate” dependency relations, while the RBG had the lowest accuracy for another 4.

POS Tags We also examined error types by part of speech tag of the dependent. The POS tags with the highest average LAS scores ($>$ 97%) were the highly unambiguous tags POS, WP$, MD, TO, HYPH, EX, PRP and PRP$. With the exception of WP$, these tags occur frequently. Those with the lowest average LAS scores ($<$ 75%) were punctuation markers ((,) and :, and the rare tags AFX, FW, NFP and LS.

Genres Table 7 shows parsing accuracy for each parser for each of the seven genres comprising the English portion of OntoNotes 5. Mate and ClearNLP are responsible for the highest accuracy for some genres, although accuracy differences among the top four parsers are generally small. Accuracy is highest for PT (pivot text, the Bible) and lowest for TC (telephone conversation) and WB (web data). The web data is itself multi-genre and includes translations from Arabic and Chinese, while telephone conversation data includes disfluencies and informal language.

6.4 Oracle Ensemble Performance

One popular method for achieving higher accuracy on a classification task is to use system combination (Björkelund and others, 2014; Le Roux and others, 2012; Le Roux et al., 2013; Sagae and Lavie, 2006; Sagae and Tsujii, 2010; Haffari et al., 2011). DependAble reports ensemble upper bound performance assuming that the best *tree* can be identified by an oracle (**macro**), or that the best *arc* can be identified by an oracle (**micro**). Table 8 provides an upper bound on ensemble performance for future work.

	LAS	**UAS**	**LS**
Macro	94.66	96.00	97.82
Micro	96.52	97.61	98.40

Table 8: Oracle ensemble performance.

The highest match was achieved between the RBG and Mate parser (62.22 UAS). ClearNLP, GN13 and LTDP all matched with Redshift the best, and RBG, Redshift and Turbo matched with Mate the best. SNN, spaCy and Turbo did not match well with other parsers; their respective ”best match” score was never higher than 55.

6.5 Error Analysis

From the test data, we pulled out parses where only one parser achieved very high accuracy, and parses where only one parser had low accuracy (Table 9). As with the detailed performance analyses, we used the most accurate version of each parser for this analysis. Mate has the highest number of “generally good” parses, while the SNN parser has the highest number of “uniquely bad” parses. The SNN parser tended to choose the wrong root, but this did not appear to be tied to the number of verbs in the sentence - rather, the SNN parser just makes the earliest “reasonable” choice of root.

Parser UAS	**≥ 90**	**= 100**	**< 90**	**< 90**
All others UAS	**< 90**	**< 90**	**≥ 90**	**= 100**
ClearNLP	42	11	45	15
LTDP	29	12	182	36
GN13	26	8	148	65
Mate	**75**	19	44	10
RBG	49	21	49	15
Redshift	38	17	28	8
SNN	70	**23**	**417**	**142**
spaCy	48	17	218	73
Turbo	54	15	28	14
Yara	33	15	27	7

Table 9: Differential parsing accuracies.

To further analyze these results, we first looked at the parse trees for “errorful” sentences where the parsers agreed. From the test data, we extracted parses for sentences where at least two parsers got UAS of $<$ 50%. This gave us 253 sentences. The distribution of these errors across genres varied: PT - 2.8%, MZ - 3.5%, BN - 9.8%, NW - 10.3%, WB - 17.4%, BC - 25.3%, TC - 30.8%.

By manual comparison using the DependAble tool, we identified frequently occurring potential sources of error. We then manually annotated all sentences for these error types. Figure 6 shows the number of “errorful” sentences of each type. Punctuation attachment “errors” are prevalent. For genres with “noisy” text (e.g. broadcast conversation, telephone conversation) a significant proportion of errors come from fragmented sentences or those containing backchannels or disfluencies. There are also a number of sentences with what appeared to be manual dependency labeling errors in the gold annotation.

6.6 Recommendations

Each of the transition-based parsers that was included in this evaluation can use varying beam widths to trade off speed vs. accuracy, and each parser has numerous other parameters that can be tuned. Notwithstanding all these variables, we can make some recommendations. Figure 7 illustrates the speed vs. accuracy tradeoff across the parsers. For highest accuracy (e.g. in dialog systems), Mate, RBG, Turbo, ClearNLP and Yara are good choices. For highest speed (e.g. in web-scale NLP), spaCy and ClearNLP$_g$ are good choices; SNN and Yara$_g$ are also good choices when accuracy is relatively not as important.

7 Conclusions and Future Work

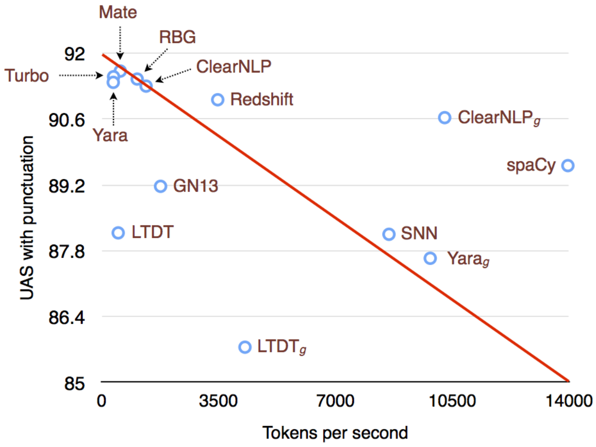

Figure 7: Speed with respect to accuracy.

In this paper we have: (a) provided a detailed comparative analysis of several state-of-the-art statistical dependency parsers, focusing on accuracy and speed; and (b) presented DEPENDABLE, a new web-based evaluation and visualization tool for analyzing dependency parsers. DEPENDABLE supports a wide range of useful functionalities. In the future, we plan to add regular expression search over parses, and sorting within results tables. Our hope is that the results from the evaluation as well as the tool will give non-experts in parsing better insight into which parsing tool works well under differing conditions. We also hope that the tool can be used to facilitate evaluation and be used as a teaching aid in NLP courses.

Supplements to this paper include the tool, the parse outputs, the statistical models for each parser, and the new set of dependency trees for OntoNotes 5 created using the ClearNLP dependency converter. We do recommend examining one's data and task before choosing and/or training a parser. Are non-projective parses likely or desirable? Does the data contain disfluencies, sentence fragments, and other "noisy text" phenomena? What is the average and standard deviation for sentence length and dependency length? The analyses in this paper can be used to select a parser if one has the answers to these questions.

In this work we did not implement an ensemble of parsers, partly because an ensemble necessarily entails complexity and/or speed delays that render it unusable by all but experts. However, our analyses indicate that it may be possible to achieve small but significant increases in accuracy of dependency parsing through ensemble methods. A good place to start would be with ClearNLP, Mate, or Redshift in combination with LTDP and Turbo, SNN or spaCy. In addition, it may be possible to achieve good performance in particular genres by doing "mini-ensembles" trained on general purpose data (e.g. WB) and genre-specific data. We leave this for future work. We also leave for future work the comparison of these parsers across languages.

It remains to be seen what downstream impact differences in parsing accuracy of 2-5% have on the goal task. If the impact is small, then speed and ease of use are the criteria to optimize, and here spaCy, ClearNLP$_g$, Yara$_g$ and SNN are good choices.

Acknowledgments

We would like to thank the researchers who have made available data (especially OntoNotes), parsers (especially those compared in this work), and evaluation and visualization tools. Special thanks go to Boris Abramzon, Matthew Honnibal, Tao Lei, Danqi Li and Mohammad Sadegh Rasooli for assistance in installation, trouble-shooting and general discussion. Additional thanks goes to the kind folks from the SANCL-SPMRL community for an informative discussion of evaluation and visualization tools. Finally, we would like to thank the three reviewers, as well as Martin Chodorow, Dean Foster, Joseph Le Roux and Robert Stine, for feedback on this paper.

Abstract

Semantic role labeling (SRL) is crucial to natural language understanding as it identifies the predicate-argument structure in text with semantic labels. Unfortunately, resources required to construct SRL models are expensive to obtain and simply do not exist for most languages. In this paper, we present a two-stage method to enable the construction of SRL models for resource-poor languages by exploiting monolingual SRL and multilingual parallel data. Experimental results show that our method outperforms existing methods. We use our method to generate Proposition Banks with high to reasonable quality for 7 languages in three language families and release these resources to the research community.

1 Introduction

Semantic role labeling (SRL) is the task of automatically labeling predicates and arguments in a sentence with shallow semantic labels. This level of analysis provides a more stable semantic representation across syntactically different sentences, thereby enabling a range of NLP tasks such as information extraction and question answering (Shen and Lapata, 2007; Maqsud et al., 2014). Projects such as the Proposition Bank (PropBank) (Palmer et al., 2005) spent considerable effort to annotate corpora with semantic labels, in turn enabling supervised learning of statistical SRL parsers for English. Unfortunately, due to the high costs of manual annotation, comparable SRL resources do not exist for most other languages, with few exceptions (Hajič et al., 2009; Erk et al., 2003; Zaghouani et al., 2010; Vaidya et al., 2011).

As a cost-effective alternative to manual annotation, previous work has investigated the *direct projection* of semantic labels from a resource rich language (English) to a resource poor target language (TL) in parallel corpora (Pado, 2007; Van der Plas et al., 2011). The underlying assumption is that original and translated sentences in parallel corpora are semantically broadly equivalent. Hence, if English sentences of a parallel corpus are automatically labeled using an SRL system, these labels can be projected onto aligned words in the TL corpus, thereby automatically labeling the TL corpus with semantic labels. This way, PropBank-like resources can automatically be created that enable the training of statistical SRL systems for new TLs.

However, as noted in previous work (Pado, 2007; Van der Plas et al., 2011), aligned sentences in parallel corpora often exibit issues such as *translation*

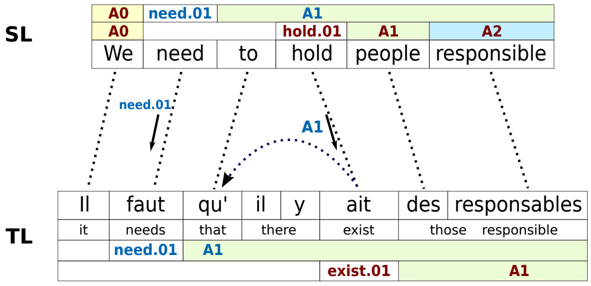

Figure 1: Pair of parallel sentences from French$_{gold}$with word alignments (dotted lines), SRL labels for the English sentence, and gold SRL labels for the French sentence. Only two of the seven English SRL labels should be projected here.

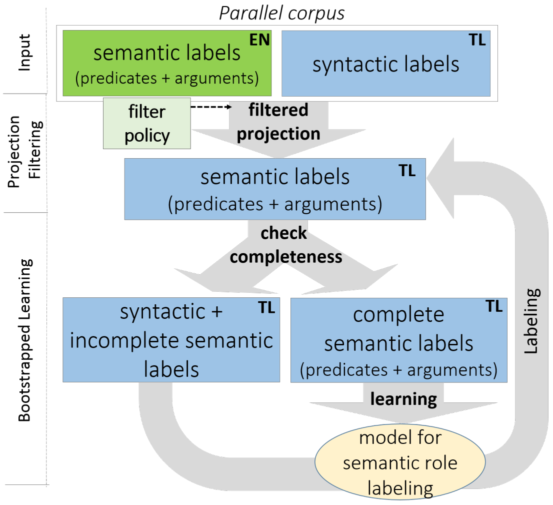

Figure 2: Overview of the proposed two-stage approach for projecting English (EN) semantic role labels onto a TL corpus.

shifts that go against this assumption. For example, in Fig. 1, the English sentence "*We need to **hold** people responsible*" is translated into a French sentence that literally reads as "*There need to **exist** those responsible*". Hence, the predicate label of the English word "*hold*" should not be projected onto the French verb, which has a different meaning. As the example in Fig. 1 shows, this means that only a subset of all SL labels can be directly projected.

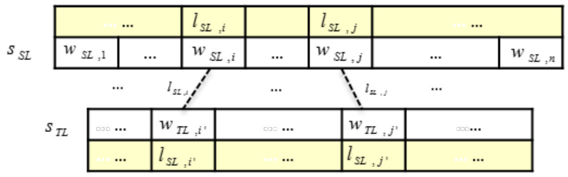
In this paper, we aim to create PropBank-like resources for a range of languages from different language groups. To this end, we propose a two-stage approach to cross-lingual semantic labeling that addresses such errors, shown in Fig. 2: Given a parallel corpus in which the source language (SL) side is automatically labeled with PropBank labels and the TL side is syntactically parsed, we use a *filtered projection* approach that allows the projection only of high-confidence SL labels. This results in a TL corpus with low recall but high precision. In the second stage, we repeatedly sample a subset of complete TL sentences and train a classifier to iteratively add new labels, significantly increasing the recall in the TL corpus while retaining the improvement in precision.

Our contributions are: (1) We propose *filtered projection* focused specifically on raising the precision of projected labels, based on a detailed analysis of direct projection errors. (2) We propose a *bootstrap learning approach* to retrain the SRL to iteratively improve recall without a significant reduction of precision, especially for arguments; (3) We demonstrate the effectiveness and generalizability of our approach via an extensive set of experiments over 7 different language pairs. (4) We generate PropBanks for each of these languages and release them to the research community.[1]

2 Stage 1: Filtered Annotation Projection

Stage 1 of our approach (Fig. 2) is designed to create a TL corpus with high precision semantic labels.

Direct Projection The idea of direct annotation projection (Van der Plas et al., 2011) is to transfer semantic labels from SL sentences to TL sentences according to word alignments. Formally, for each pair of sentences s_{SL} and s_{TL} in the parallel corpus, the word alignment produces alignment pairs ($w_{\text{SL},i}$, $w_{\text{TL},i'}$), where $w_{\text{SL},i}$ and $w_{\text{TL},i'}$ are words from s_{SL} and s_{TL} respectively. Under direct projection, if $l_{\text{SL},i}$ is a predicate label for $w_{\text{SL},i}$ and ($w_{\text{SL},i}$, $w_{\text{TL},i'}$) is an alignment pair, then $l_{\text{SL},i}$ is transferred to $w_{\text{TL},i'}$; If $l_{\text{SL},j}$ is a predicate-argument label for ($w_{\text{SL},i}$, $w_{\text{SL},j}$), and ($w_{\text{SL},i}$, $w_{\text{TL},i'}$) and ($w_{\text{SL},j}$, $w_{\text{TL},j'}$) are alignment pairs, then $l_{\text{SL},j}$ is transferred to ($w_{\text{TL},i'}$, $w_{\text{TL},j'}$), as illustrated below.



Filtered Projection As discussed earlier, direct projection is vulnerable to errors stemming from issues such as translation shifts. We propose *filtered projection* focused specifically on improving the precision of projected labels. Specifically, for a pair of sentences s_{SL} and s_{TL} in the parallel corpus, we retain the semantic label $l_{\text{SL},i}$ projected from $w_{\text{SL},i}$ onto $w_{\text{TL},i'}$ if and only if it satisfies the filtering policies. This results in a target corpus containing fewer labels but of higher precision compared to that obtained via direct projection.

In the rest of the section, we analyze typical errors in direct projection (Sec. 2.2), present a set of filters to handle such errors (Sec. 2.3), and experimentally evaluate their effectiveness (Sec. 2.4).

2.1 Experimental Setup

Data For experiments in this section and Sec. 3, we used the gold data set compiled by (Van der Plas et al., 2011), referred to as `French`$_{\text{gold}}$. It consists of 1,000 sentence-pairs from the English-French `Europarl` corpus (Koehn, 2005) with French sentences manually labeled with predicate and argument labels from the English Propbank.

Evaluation In line with previous work (Van der Plas et al., 2010), we count synonymous predicate labels sharing the same VerbNet (Schuler, 2005) class as true positives.[2] In addition, we exclude modal verbs from the evaluation due to inconsistent annotation.

Source Language SRL Throughout the rest of the paper, we use ClearNLP (Choi and McCallum, 2013), a state-of-the-art SRL system, to produce semantic labels for English text.

2.2 Error Analysis

We observe that direct projection labels have both low precision and low recall (see Tab. 3 (*Direct*)).

Analysis of False Negatives The low recall of direct projection is not surprising; most semantic labels in the French sentences do not appear in the corresponding English sentences at all. Specifically, among 1,741 predicate labels in the French sentences, only 778 exist in the corresponding English sentences, imposing a 45% upper bound on the recall for projected predicates. Similarly, of the 5,061 argument labels in the French sentences, only 1,757 exist in the corresponding English sentences, resulting in a 35% upper bound on recall for arguments.[3]

Analysis of False Positives While the recall produced by direct projection is close to the theoretical upper bound, the precision is far from the theoretical upper bound of 100%. To understand causes of false positives, we examine a random sample of 200 false positives, of which 100 are incorrect predicate labels, and 100 are incorrect argument labels belonging to correctly projected predicates. Tab. 1 and 2 show the detailed breakdown of errors for predicates and arguments, respectively. We first analyze the most common types of errors and discuss the residual errors later in Sec. 2.5.

- **Translation Shift: Predicate Mismatch** The most common predicate errors (37%) are translation shifts in which an English predicate is aligned to a French verb with a different meaning. Fig. 1 illustrates such a translation shift: label *hold.01* of English verb *hold* is wrongly projected onto the French verb *ait*, which is labeled as *exist.01* in `French`$_{\text{gold}}$.

- **Translation Shift: Verb→Non-Verb** is another common predicate error (36%). English verbs may be aligned with TL words other than verbs, which is often indicative of translation shifts. For instance, in the following sentence pair

s_{SL}	`We`	`know`	`what`	`happened`
s_{FR}	`On`	`connait`	`la`	`suite`
	We	know	the	result

the English verb *happen* is aligned to the French noun *suite (result)*, causing it to be wrongly projected with the English predicate label *happen.01*.

- **Non-Argument Head** The most common argument error (33%) is caused by the projection of argument labels onto words other than the syntactic head of a target verb's argument. For example, in Fig. 1 the label *A1* on the English *hold* is wrongly transferred to the French *ait*, which is not the syntactic head of the complement.

[2] For instance, the French verb *sembler* may be correctly labeled as either of the synonyms: *seem.01* or *appear.02*.

[3] This upper bound is different from the one reported in (Van der Plas et al., 2011) which corresponds to the interannotator agreement over manual annotation of 100 sentences.

2.3 Filters

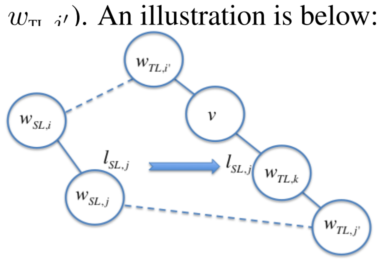
We consider the following filters to remove the most common types of false positives.

Verb Filter (VF) targets Verb→Non-Verb translation shift errors (Van der Plas et al., 2011). Formally, if direct projection transfers predicate label $l_{\text{SL},i}$ from $w_{\text{SL},i}$ onto $w_{\text{TL},i'}$, retain $l_{\text{SL},i}$ only if both $w_{\text{SL},i}$ and $w_{\text{TL},i'}$ are verbs.

Translation Filter (TF) handles both Predicate Mismatch and Verb→Non-Verb translation shift errors. It makes use of a translation dictionary and allows projection only if the TL verb is a valid translation of the SL verb. In addition, in order to ensure consistent predicate labels throughout the TL corpus, if a SL verb has several possible synonymous translations, it allows projection only for the most commonly observed translation.

Formally, for an aligned pair $(w_{\text{SL},i}, w_{\text{TL},i'})$ where $w_{\text{SL},i}$ has predicate label $l_{\text{SL},i}$, if $(w_{\text{SL},i}, w_{\text{TL},i'})$ is not a verb to verb translation from SL to TL, assign no label to $w_{\text{TL},i'}$. Otherwise, split the set of SL translations of $w_{\text{TL},i'}$ into synonym sets $S_1, S_2, \ldots$; For each k, let W^k be the subset of S_k most commonly aligned with $w_{\text{TL},i'}$; If $w_{\text{SL},i}$ is in one of these W^k, assign label $l_{\text{SL},i}$ to $w_{\text{TL},i'}$; Otherwise assign no label to $w_{\text{TL},i'}$.

Reattachment Heuristic (RH) targets non-argument head errors that occur if a TL argument is not the direct child of a verb in the dependency parse tree of its sentence.[4] Assume direct projection transfers the predicate-argument label $l_{\text{SL},j}$ from ($w_{\text{SL},i}$, $w_{\text{SL},j}$) onto ($w_{\text{TL},i'}$, $w_{\text{TL},j'}$). Find the immediate ancestor verb of $w_{\text{TL},j'}$ in the dependency parse tree. Denote as $w_{\text{TL},k}$ its child that is an ancestor of $w_{\text{TL},j'}$. Assign the label $l_{\text{SL},j}$ to ($w_{\text{TL},i'}$, $w_{\text{TL},k}$) instead of ($w_{\text{TL},i'}$, $w_{\text{TL},j'}$). An illustration is below:



RH ensures that labels are always attached to the syntactic heads of their respective arguments, as determined by the dependency tree. An example of such reattachment is illustrated in Fig. 1 (curved arrow on TL sentence).

	PREDICATE			ARGUMENT		
PROJECTION	P	R	F1	P	R	F1
Direct	0.45	0.4	0.43	0.43	0.31	0.36
VF	0.59	0.4	0.48	0.53	0.31	0.39
TF	**0.88**	0.36	0.51	0.58	0.17	0.27
VF+RH	0.59	0.4	0.48	0.68	0.35	0.46
TF+RH	**0.88**	0.36	0.51	**0.75**	0.2	0.31
Upper Bound	1	0.45	0.62	1	0.35	0.51

Table 3: Quality of predicate and argument labels for different projection methods on $\texttt{French}_{\text{gold}}$, including upper bound.

2.4 Filter Effectiveness

We now present an initial validation on the effectiveness of the aforementioned filters by evaluating their contribution to annotation projection quality for $\texttt{French}_{\text{gold}}$, as summarized in Tab. 3.

VF reduces the number of wrongly projected predicate labels, resulting in an increase of predicate precision to 59% (↑14 pp), without impact to recall. As a side effect, argument precision also increases to 53% (↑10 pp), since, if a predicate label cannot be projected, none of its arguments can be projected.

TF[5] reduces the number of wrongly projected predicate labels even more significantly, increasing predicate precision to 88% (↑43 pp), at a small cost to recall. Again, argument precision increases as a side effect. However, as expected, argument recall decreases significantly (↓14 pp, to 17%), as many arguments can no longer be projected.

RH targets argument labels directly (unlike VF and TF), significantly increasing argument precision and slightly increasing argument recall.

In summary, initial experiments confirm that our proposed filters are effective in improving precision of projected labels at a small cost in recall. In fact, TF+RH results in nearly 100% improvement in predicate and argument labels precision with a much smaller drop in recall.

2.5 Residual Errors

Filtered projection removes the most common errors discussed in Sec. 2.2. Most of the remaining errors

[4] In (Padó and Lapata, 2009), a similar filtering method is defined over constituent-based trees to reduce the set of viable nodes for argument labels to all nodes that are not a child of some ancestor of the predicate.

[5] In all experiments in this paper, we derived the translation dictionaries from the WIKTIONARY project and used VERBNET and WORDNET to find SL synonym groups.

come from the following sources.

SRL Errors The most common residual errors in the remaining projected labels, especially for argument labels, are caused by mistakes made by the English SRL system. Any wrong label it assigns to an English sentence may be projected onto the TL sentence, resulting in false positives.

No English Equivalent A small number of errors occur due to French particularities that do not exist in English. Such errors include certain French verbs for which no appropriate English PropBank labels exists, and French-specific syntactic particularities.[6]

Gold Data Errors Our evaluation so far relies on French$_{\text{gold}}$ as ground truth. Unfortunately, French$_{\text{gold}}$ does contain a small number of errors (e.g. missing argument labels). As a result, some correctly projected labels are being mistaken as false positives, causing a drop in both precision and recall. We therefore expect the true precision and recall of the approach to be somewhat higher than the estimate based on French$_{\text{gold}}$.

3 Stage 2: Bootstrapped Training of SRL

As discussed earlier, the TL corpus generated via filtered projection suffers from low recall. We address this issue with the second stage of our method.

Relabeling The idea of relabeling (Van der Plas et al., 2011) is to first train an SRL system over a TL corpus labeled using direct projection (with VF filter) and then use this SRL to relabel the corpus, effectively overwriting the projected labels with potentially less noisy predicted labels.

We first present an analysis on relabeling in concert with our proposed filters (Sec. 3.1), which motivates our bootstrap algorithm (Sec. 3.2).

3.1 Analysis of Relabeling Approach

We use the same experimental setup as in Sec. 2, and produce a labeled French corpus for each filtered annotation method. We then train an off-the-shelf SRL system (Björkelund et al., 2009) on each generated corpus and use it to relabel the corpus.

We measure precision and recall of each resulting TL corpus against French$_{\text{gold}}$ (see Tab. 4). Across all experiments, relabeling consistently improves recall over projection. The results also show how different factors affect the performance of relabeling.

PROJECTION	PREDICATE			ARGUMENT		
SRL training	P	R	F1	P	R	F1
DIRECT						
–	0.45	0.40	0.43	0.43	0.31	0.36
relabel (SP)	0.49	0.57	0.53	0.52	0.43	0.47

Table 4: Experiments on French$_{\text{gold}}$, with different projection and SRL training methods. SP=Supplement; OW=Overwrite.

Supplement vs. Overwrite Projected Labels The labels produced by the trained SRL can be used to either *overwrite* projected labels as in (Van der Plas et al., 2011), or to *supplement* them (supplying labels only for words w/o projected labels). Whether to overwrite or supplement depends on whether labels produced by the trained SRL are of higher quality than the projected labels. We find that while predicted labels are of higher precision than directly projected labels, they are of lower precision than labels post filtered projection. Therefore, for filtered projection, it makes more sense to allow predicted labels to only *supplement* projected labels.

Impact of Sampling Method We are further interested in learning the impact of sampling the data on the quality of relabeling. For the best filter found earlier (TF+RH), we compare SRL trained on the entire data set ($_{\text{full data}}$) with SRL trained only on the subset of completely annotated sentences ($_{\text{comp. sent.}}$), where completeness is defined as:

Definition 1. *A direct component of a labeled sentence s_{TL} is either a verb in s_{TL} or a syntactic dependent of a verb. Then s_{TL} is **k-complete** if s_{TL} contains equal to or fewer than k unlabeled direct compo-*

[6] French negations, for instance, are split into a particle and a connegative. In the annotation scheme used in French$_{\text{gold}}$, particles and connegatives are labeled differently.

  end for
```

nents. 0-complete is abbreviated as ***complete****.*

We observe that for TF+RH, when new labels supplement projected labels, relabeling over complete sentences results in better recall at slightly reduced precision, while including incomplete sentences into the training data reduces recall, but improves precision. While this finding may seem counterintuitive, it can be explained by how statistical SRL works. A densely labeled training data (such as comp. sent.) usually results in an SRL that generates densely labeled sentences, resulting in better recall but poorer precision. On the other hand, training data that is sparsely labeled results in an SRL that weighs the option of not assigning a label with higher probability, resulting in better precision and poorer recall. In short, one can control the tradeoff between precision and recall of SRL output by manipulating the completeness of the training data.

3.2 Bootstrap Learning

Building on the observation that we can sample data in such a way as to either favor precision or recall, we propose a bootstrapping algorithm to train an SRL iteratively over k*-complete* subsets of the data which are supplemented by high precision labels produced from previous iteration. The detailed algorithm is depicted in Algorithm 1.

Resampling Threshold Our goal is to use bootstrap learning to improve recall without sacrificing too much precision.

Proposition 1. *Under any resampling threshold, the set of labels L_{TL} increases monotonically in each iteration of Algorithm 1.*

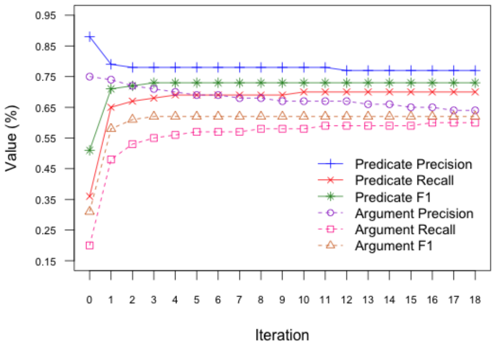

Figure 3: Values at each bootstrap iteration.

Since Prop. 1 guarantees the increase of the set of labels, we need to select a resampling function to favor precision while improving recall. Specifically, we use the formula $k(i) = \max(k_0 - i, 0)$, where k_0 is sufficiently large. Since the precision of labels generated by the SRL is lower than the precision of labels obtained from filtered projection, the precision of the training data is expected to decrease with the increase in recall. Therefore, starting with a high k seeks to ensure high precision labels are added to the training data in the first iterations. Decreasing k in each iteration seeks to ensure that resampling is done in an increasingly restrictive way to ensure that only high-quality annotated sentences are added to the training data, thus maintaining a high confidence in the learned SRL model.

3.3 Effectiveness of Bootstrapping

We experimentally evaluate the effectiveness of our model with $k_0 = 9$.[7] As shown in Tab 4, bootstrapping outperforms relabeling, producing labels with best overall quality in terms of F_1 measure and recall for both predicates and arguments, with a relatively small cost in precision.

While Algorithm 1 guarantees the increase of recall (Prop. 1), it provides no such guarantee on precision. Therefore, it is important to experimentally decide an early termination cutoff before the SRL gets overtrained. To do so, we evaluated the performance of the bootstrapping algorithm at each iteration (Fig. 3). We observe that for the first 3 iterations, F_1-measure for both predicates and arguments rises due to large increase in recall which offsets the smaller drop in precision. Then F_1-measure remains stable, with recall rising and pre-

[7] We found that setting k_0 to larger values had little impact on the final results .

cision falling slightly at each iteration until convergence. To optimize precision and avoid overtraining, we set an iteration cutoff of 3. This combination of TF+RH filters, bootstrapping with $k_0 = 9$ and an iteration cutoff of 3 is used in the rest of our evaluation (Sec. 4), denoted as $\texttt{FB}_{best}$.

4 Multilingual Experiments

We use our method to generate Proposition Banks for 7 languages and evaluate the generated resources. We seek to answer the following questions: (1) What is the estimated quality for the generated PropBanks? How well does the approach work without language-specific adaptation? (2) Are there notable differences in quality from language to language; if so, why? We also present initial investigations on how different factors affect the performance of our method.

4.1 Experimental Setup

Data Tab. 5 lists the 7 different TLs and resources used in our experiments.[8] We chose these TLs because (1) they are among top 10 most influential languages in the world (Weber, 1997); and (2) we could find language experts to evaluate the results. English is used as SL in all our experiments.

Approach Tested For each TL, we used $\texttt{FB}_{best}$ (Sec. 3.3) to generate a corpus with semantic labels. From each TL corpus, we extracted all complete sentences to form the generated PropBanks.

		PREDICATE			ARGUMENT

Table 6: Estimated precision and recall over seven languages.

Manual Evaluation While a gold annotated corpus for French ($\texttt{French}_{\text{gold}}$) was available for our experiments in the previous Sections, no such resources existed for the other TLs we wished to evaluate. We therefore chose to conduct a manual evaluation for each TL, each executed identically: For each TL we randomly selected 100 complete sentences with their generated semantic labels and assigned them to two language experts who were instructed to evaluate the semantic labels (based on their English descriptions) for the predicates and their core arguments. For each label, they were asked to determine (1) whether the label is correct; (2) if yes, then whether the boundary of the labeled constituent is correct: If also yes, mark the label as *fully correct*, otherwise as *partially correct*.

Metrics We used the standard measures of precision, recall, and F1 to measure the performance of the SRLs, with the following two schemes: (1) *Exact*: Only fully correct labels are considered as true positives; (2) *Partial*: Both fully and partially correct matches are considered as true positives.[9]

4.2 Experimental Results

Tab. 6 summarizes the estimated quality of semantic labels generated by our method for all seven TL. As can be seen, our method performed well for all

[8] From each parallel corpus, we only keep sentences that are considered well-formed based on a set of standard heuristics. For example, we require a well-formed sentence to end in punctuation and not to contain certain special characters. For Arabic, as the dependency parser we use has relatively poor parsing accuracy, we additionally require sentences to be shorter than 100 characters.

[9] Note that since the manually evaluated semantic labels are only a small fraction of the labels generated, the performance numbers obtained from manual evaluation is only an estimate of the actual quality for the generated resources.Thus the numbers obtained based on manual evaluation cannot be directly compared against the numbers computed over $\texttt{French}_{\text{gold}}$.

PropBank	#Complete	%Complete	#Verbs

seven languages and generated high quality semantics labels across the board. For predicate labels, the precision is over 95% and the recall is over 85% for all languages except for Hindi. For argument labels, when considering partially correct matches, the precision is at least 85% (above 90% for most languages) and the recall is between 66% to 83% for all the languages. These encouraging results obtained from a diverse set of languages implies the generalizability of our method. In addition, the inter-annotator agreement is very high for all the languages, indicating that the results obtained based on manual evaluation are very reliable.

In addition, we make a number of interesting observations:

Dependency Parsing Accuracy The precision for exact argument labels is significantly below partial matches, particularly for Hindi (↓35 pp) and Arabic (↓19 pp). Since argument boundaries are determined syntactically, such errors are caused by dependency parsing. The fact that Hindi and Arbic suffer the most from this issue is consistent with the poorer performance of their dependency parsers compared to other languages (Nivre et al., 2006; Green and Manning, 2010).

Hindi as the Main Outlier The results for Hindi are much worse than the results for other languages. Besides the poorer dependency parser performance, the size of the parallel corpus used could be a factor: Hindencorp is one to two orders of magnitude smaller than the other corpora. The quality of the parallel corpus could be a reason as well: Hindencorp was collected from various sources, while both UN and Europarl were extracted from governmental proceedings.

Language-specific Errors Certain errors occur more frequently in some languages than others. An example are deverbal nouns in Chinese (Xue, 2006) in formal passive constructions with support verb 受. Since we currently only consider verbs for predicate labels, predicate labels are projected onto the support verbs instead of the deverbal nouns. Such errors appear for light verb constructions in all languages, but particularly affect Chinese due to the high frequency of this passive construction in the UN corpus.

Low Fraction of Complete Sentences As Tab. 7 shows, the fraction of complete sentences in the generated PropBanks is rather low, indicating the impact of moderate recall on the size of generated PropBanks. Especially for languages for which only small parallel corpora are available, such as Hindi, this points to the need to address recall issues in future work.

4.3 Additional Experiments

The observations made in Sec. 4.2 suggests a few factors that may potentially affect the performance of our method. To better understand their impact, we conducted the following initial investigation. SRL models produced in this set of experiments were evaluated using French$_{gold}$, sampled and evaluated in the same way as other experiments in this section for comparability.

Data Size We varied the data size for French by downsampling the UN corpus. As one can see from Tab. 8, downsampling the dataset by one order of magnitude (to 250k sentences) only slightly affects precision, while downsampling to 25k sentences has a more pronounced but still small impact on recall. It appears that data size does not have significant impact on the performance of our method.

Language-specific Customizations While our method is language-agnostic, intuitively language-specific customization can be helpful in addressing language-specific errors. As an initial experiment, we added a simple heuristic to filter out French verbs that are commonly used for "existential there" constructions, as one type of common errors for French involves the syntactic expletive *il* (Danlos, 2005) in "existential there" constructions such as *il faut* (see Fig. 1 (TL sentence) for an example) wrongly labeled with with role information. As shown in Tab. 9, this simple customization results in a small increase in precision, suggesting that language-specific customization can be helpful.

Quality of English SRL As noted in Sec. 2.5, errors made by English SRL are often prorogated to the TL via projection. To assess the impact of English SRL quality, we used two different English SRL systems: CLEARNLP and MATE-SRL. As can be seen from Tab. 9, the impact of English SRL quality is substantial on argument labeling.

4.4 Multilingual PropBanks

To facilitate future research on multilingual SRL, we release the created PropBanks for all 7 languages to the research community to encourage further research. Tab. 7 gives an overview over the resources.

5 Related Work

Annotation Projection in Parallel Corpora to train monolingual tools for new languages was introduced in the context of learning a PoS tagger (Yarowsky et al., 2001). Similar in spirit to our approach of using filters to increase the precision of projected labels, recent work (Täckström et al., 2013) uses token and type constraints to guide learning in cross-lingual PoS tagging.

Projection of Semantic Labels was considered for FrameNet (Baker et al., 1998) in (Padó and Lapata, 2009; Basili et al., 2009). Recently, however, most work in the area focuses on PropBank, which has been identified as a more suitable annotation scheme for joint syntactic-semantics settings due to broader coverage (Merlo and van der Plas, 2009), and was shown to be usable for languages other than English (Monachesi et al., 2007).

Direct projection of PropBank annotations was considered in (Van der Plas et al., 2011). Our approach significantly outperforms theirs in terms of recall and F_1 for both predicates and arguments (Section 3). A approach was proposed in (Van der Plas et al., 2014) in which information is aggregated at the corpus level, resulting in a significantly better SRL corpus for French. However, this approach has several practical limitations: (1) it does not consider the problem of argument identification of SRL systems, treating arguments as already given; (2) it generates rules for the argument classification step preferably from manually annotated data; (3) it has been demonstrated for a single language (French), and was not applied to any other language. In contrast, our approach trains an SRL system for both predicate and argument labels, in a completely automatic fashion. Furthermore, we have applied our approach to generate PropBanks for 7 languages and conducted experiments that indicate a high F_1 measure for all languages (Section 4).

Other Related Work A number of approaches such as model transfer (Kozhevnikov and Titov, 2013) and role induction (Titov and Klementiev, 2012) exist for the argument classification step in the SRL pipeline. In contrast, our work addresses the full SRL pipeline and seeks to generate SRL resources for TLs with English PropBank labels.

6 Conclusion

We proposed a two-staged method to construct multilingual SRL resources using monolingual SRL and parallel data and showed that our method outperforms previous approaches in both precision and recall. More importantly, through comprehensive experiments over seven languages from three language families, we show that our proposed method works well across different languages without any language specific customization. Preliminary results from additional experiments indicate that better English SRL and language-specific customization can further improve the results, which we aim to investigate in future work. A qualitative comparison against existing or under-construction PropBanks for Chinese (Xue, 2008), Hindi (Vaidya et al., 2011) or Arabic (Zaghouani et al., 2010) may be interesting, both for comparison of resources and for defining language-specific customizations. In addition, we plan to expand our experiments both to more languages as well as NomBank (Meyers et al., 2004)-style noun labels.

Abstract

We propose a cross-lingual framework for fine-grained opinion mining using bitext projection. The only requirements are a running system in a source language and word-aligned parallel data. Our method projects opinion frames from the source to the target language, and then trains a system on the target language using the automatic annotations. Key to our approach is a novel dependency-based model for opinion mining, which we show, as a byproduct, to be on par with the current state of the art for English, while avoiding the need for integer programming or reranking. In cross-lingual mode (English to Portuguese), our approach compares favorably to a supervised system (with scarce labeled data), and to a delexicalized model trained using universal tags and bilingual word embeddings.

1 Introduction

The goal of **opinion mining** is to extract opinions and sentiments from text (Pang and Lee, 2008; Wilson, 2008; Liu, 2012). With the advent of social media and the increasing amount of data available on the Web, this has become a very active area of research, with applications in summarization of customer reviews (Hu and Liu, 2004; Wu et al., 2011), tracking of newswire and blogs (Ku et al., 2006), question answering (Yu and Hatzivassiloglou, 2003), and text-to-speech synthesis (Alm et al., 2005).

While early work has focused on determining sentiment at document and sentence level (Pang et al., 2002; Turney, 2002; Balog et al., 2006), research has gradually progressed towards **fine-grained opinion mining**, where rather than determining global sentiment, the goal is to parse text into **opinion frames**, identifying opinion expressions, agents, targets, and polarities (Ding et al., 2008), or addressing compositionality (Socher et al., 2013b). Since the release of the MPQA corpus[1] (Wiebe et al., 2005; Wilson, 2008), a standard corpus for fine-grained opinion mining of news documents, a long string of work has been produced (reviewed in §2). Despite the large volume of prior work, opinion mining has by and large been limited to monolingual approaches in English.[2] This is explained by the heavy effort of annotation necessary for current learning-based approaches to succeed, which delays the deployment of opinion miners for new languages.

We bridge the existing gap by proposing a cross-lingual approach to fine-grained opinion mining via **bitext projection**. This technique has been quite effective in several NLP tasks, such as part-of-speech (POS) tagging (Täckström et al., 2013), named entity recognition (Wang and Manning, 2014), syntactic parsing (Yarowsky and Ngai, 2001; Hwa et al., 2005), semantic role labeling (Padó and Lapata, 2009), and coreference resolution (Martins, 2015). Given a corpus of parallel sentences (bitext), the idea is to run a pre-trained system on the source side and then to use word alignments to transfer the produced annotations to the target side, creating an automatic training corpus for the impoverished language.

To alleviate the complexity of the task, we start by introducing a lightweight representation—called **dependency-based opinion mining**—and convert the MPQA corpus to this formalism (§3). We propose a simple arc-factored model that permits easy decoding (§4) and we show that, despite

[1] `http://mpqa.cs.pitt.edu/corpora/mpqa_corpus`.

[2] Besides English, monolingual systems have also been developed for Chinese and Japanese (Seki et al., 2007), German (Clematide et al., 2012) and Bengali (Das and Bandyopadhyay, 2010).

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 408–418,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

its simplicity, this model is on par with state-of-the-art opinion mining systems for English (§5). Then, through bitext projection, we transfer these dependency-based opinion frames to Portuguese (our target language), and train a system on the resulting corpus (§6).

As part of this work, a validation corpus in Portuguese with subjectivity annotations was created, along with a translation of the MPQA Subjectivity lexicon of Wilson et al. (2005).[3] Experimental evaluation (§7) shows that our cross-lingual approach surpasses a supervised system trained on a small corpus in the target language, as well as a delexicalized baseline trained using universal POS tags, bilingual word embeddings and a projected lexicon.

2 Related Work

A considerable amount of work on fine-grained opinion mining is based on the MPQA corpus. Kim and Hovy (2006) proposed a method for finding opinion holders and topics, with the aid of a semantic role labeler. Choi et al. (2005) and Breck et al. (2007) used CRFs for finding opinion holders and recognizing opinion expressions, respectively. The two things are predicted jointly by Choi et al. (2006), with integer programming, and Johansson and Moschitti (2010), via reranking. The same method was applied later for joint prediction of opinion expressions and their polarities (Johansson and Moschitti, 2011). The advantage of a joint model was also shown by Choi and Cardie (2010) and Yang and Cardie (2014). Yang and Cardie (2012) classified expressions with a semi-Markov decoder, outperforming a B-I-O tagger; in later work, the same authors proposed an ILP decoder to jointly retrieve opinion expressions, holders, and targets (Yang and Cardie, 2013). A more recent work (İrsoy and Cardie, 2014) proposes a recurrent neural network to identify opinion spans.

All the approaches above rely on a span-based representation of the opinion elements. This makes joint decoding procedures more complicated, since they must forbid overlap of opinion elements or add further constraints, leading to integer programming or reranking strategies. Besides, there is little consensus about what should be the correct span boundaries, the inter-annotator agreement being quite low (Wiebe et al., 2005). In constrast, we use dependencies to model opinion elements and relations, leading to a compact representation that does not depend on spans and which is tractable to decode. A dependency scheme was also used by Wu et al. (2011) for fine-grained opinion mining. Our work differs in which we mine opinions in news articles instead of product reviews, a considerably different task. In addition, the approach of Wu et al. (2011) relies on "span nodes" (instead of head words), requiring solving an ILP followed by an approximate heuristic.

Query-based multilingual opinion mining was addressed in several NTCIR shared tasks (Seki et al., 2007; Seki et al., 2010).[4] However, to our best knowledge, a cross-lingual approach has never been attempted. Some steps were taken by Mihalcea et al. (2007) and Banea et al. (2008), who translated an English lexicon and the MPQA corpus to Romanian and Spanish, but for the much simpler task of sentence-level subjectivity analysis. Cross-lingual sentiment classification was addressed by Wan (2009), Prettenhofer and Stein (2010) and Wei and Pal (2010) at document level, and by Lu et al. (2011) at sentence level. Recently, Gui et al. (2013) applied projection learning for opinion mining in Chinese. However, this work only addresses agent detection and requires translating the MPQA corpus. While all these works are relevant, none addresses fine-grained opinion mining in its full generality, where the goal is to predict full opinion frames.

3 Dependency-Based Opinion Mining

This work addresses various elements of subjectivity annotated in the MPQA corpus, namely:

- direct-subjective expressions (henceforth, **opinions**) that are direct mentions of a private state, *e.g.* opinions, beliefs, emotions, sentiments, speculations, goals, *etc.*;
- the opinion **agent**, *i.e.*, the holder of the opinion;
- the opinion **target**, *i.e.*, what is being argued about;
- the opinion **polarity**, *i.e.*, the sentiment (positive, negative or neutral) towards the target.

As an example, consider the sentence in Figure 1, which has two opinions, expressed by the

[3] The Portuguese corpus and the lexicon are available at `http://labs.priberam.com/Resources`.

[4] NTCIR-8 had a cross-lingual track but in a very different sense: there, queries and documents are in different languages; in contrast, we transfer a model accross languages.

spans "is believed" (O_1) and "are against" (O_2). The first opinion has an implicit agent and a neutral polarity toward the target "the rich elites" (T_1). This target is also the agent (A_2) of the second opinion, which has a negative polarity toward "Hugo Chávez" (T_2).

3.1 Motivation

As noted in prior work (Choi et al., 2005; Kim and Hovy, 2006; Johansson and Moschitti, 2010), one source of difficulty when learning opinion miners on MPQA is with the boundaries of the entity spans. The fact that no criterion for choosing these boundaries is explicitly defined in the annotation guidelines (Wiebe et al., 2005) leads to a low inter-annotator agreement. To circumvent this problem and make the learning task easier, we depart from the classical span-based approaches toward **dependency-based opinion mining**. This decision is inspired by the success of dependency models for syntax and semantics (Buchholz and Marsi, 2006; Surdeanu et al., 2008). These dependency relations can be further converted to opinion spans (as described in §3.3), or directly used as features in downstream applications. As we will see, a compact representation based on dependencies can achieve state-of-the-art results and has the advantage of being easily transferred to other languages through a parallel corpus.

3.2 Dependency Graph

Figure 1 depicts a sentence-level dependency representation for fine-grained opinion mining. The overall structure is a graph whose nodes are head words (plus two special nodes, `root` and `null`), connected by labeled arcs, as outlined below.

Determining head nodes. The three opinion elements that we want to detect (opinions, agents and targets) are each represented by a **head node**, which corresponds to a single word (underlined in Figure 1). When converting the MPQA corpus to dependencies, we determine this "representative" word automatically, by using the following simple heuristic: we first parse the sentence using the Stanford dependency parser (Socher et al., 2013a); then, we pick the last word in the span whose syntactic parent is outside the span (if the span is a syntactic phrase, there is only one word whose parent is outside the span, which is the lexical head). The same heuristic has been used for identifying the heads of mention spans in coreference resolution (Durrett and Klein, 2013).

Defining labeled arcs. The opinion relations are represented as **labeled arcs** that link these head nodes. Two artificial nodes are added: a `root` node, which links to all nodes that represent opinion words, with the label OPINION; and a `null` node, which is used for representing implicit relations. To represent opinion-agent relations, we draw an arc labeled AGENT toward the agent word. For opinion-target relations, the arc is toward the target word and has one of the labels TARGET:0, TARGET:+, or TARGET:-; this encodes the polarity in addition to the type of relation. We also include implicit arcs for opinion elements whose agent or target is not mentioned inside the sentence—these are modeled as arcs pointing to the `null` node.

Dependency opinion graph. We have the following requirements for a well-formed dependency opinion graph:

1. No self-arcs or arcs linking `root` to `null`.
2. An arc is labeled as OPINION if and only if it comes from the `root` node.
3. Arcs labeled as AGENT or TARGET must come from an opinion node (*i.e.*, a node with an incoming OPINION arc).
4. Every opinion node has exactly one AGENT and one TARGET outgoing arcs (possibly implicit).[5]

Similarly to prior work (Choi and Cardie, 2010; Johansson and Moschitti, 2011; Johansson and Moschitti, 2013), we map the MPQA's polarity-into three levels: positive, negative and neutral, where the latter includes spans without polarity annotation or annotated as "both". As in Johansson and Moschitti (2013), we also ignore the "uncertain" aspect of the annotated polarities.

3.3 Dependency-to-Span Conversion

To evaluate the opinion miner against manual annotations and compare with other systems, we need a procedure to convert back from predicted dependencies to spans. In this work, we used a very simple procedure that we next describe,

[5] Even though this assumption is not always met in practice, it is typical in MPQA (only 10% of the opinions have multiple agents, typically coreferent; and only 13% have multiple targets). When multiple agents or targets exist, we keep the ones that are closest to the opinion expression.

Figure 1: Example of an opinion mining graph in our dependency formalism. Heads are underlined.

which assumes the sentence was previously parsed using a syntactic dependency parser.

To generate agent and target spans, we compute the largest span, containing the head word, whose words are all descendants in the dependency parse tree and that are, simultaneously, not punctuations. To generate opinion spans, we start with the head word and expand the span by adding all neighbouring verbal words. In the case of English, we also allow adverbs, adjectives, modal verbs and the word *to*, when expanding to the left.

The application of this simple approach to the gold dependency graphs in the training partition of the MPQA leads to oracle F_1 scores of 86.0%, 95.8% and 93.0% in the reconstruction of opinion, agent and target spans, respectively, according to the proportional scores described in §5.2.

4 Arc-Factored Model

One of the advantages of the dependency representation is that we can easily decode opinion-agent-target relations without the need of complicated constrained sequence models or integer programming, as done in prior work (Choi et al., 2006; Yang and Cardie, 2012; Yang and Cardie, 2013).

4.1 Decoding

We model dependency-based opinion mining as a structured classification problem. Let x be a sentence and $y \in \mathcal{Y}(x)$ a set of well-formed dependency graphs, according to the constraints stated in §3. We define a score function that decomposes as a sum of labeled arc scores,

$$f(x,y) = \sum_{a \in y} f_a(x, y_a) \qquad (1)$$

where y_a is a labeled arc and the sum is over the arcs of the graph y. We use a linear model with weight vector $\boldsymbol{w}$ and local features $\boldsymbol{\phi}_a(x, y_a)$:

$$f_a(x, y_a) = \boldsymbol{w} \cdot \boldsymbol{\phi}_a(x, y_a). \qquad (2)$$

For making predictions, we need to compute

$$\widehat{y} = \arg\max_{y \in \mathcal{Y}(x)} f(x,y). \qquad (3)$$

Under the assumptions stated in §3, this problem decouples into independent maximization problems (one for each possible opinion word in the sentence). The detailed procedure is as follows, where arcs a can take the form $o \rightarrow h$ (opinion to agent) and $o \rightarrow t$ (opinion to target). For every candidate opinion word o:

1. Obtain the most compatible agent word, $\widehat{h} := \arg\max_h f_{o\rightarrow h}(x, \text{AGENT})$;
2. Obtain the best target word and its polarity, $(\widehat{t}, \widehat{p}) := \arg\max_{t,p} f_{o\rightarrow t}(x, \text{TARGET:}p)$;
3. Compute the total score of this candidate opinion as $s_o := f_{\texttt{root}\rightarrow o}(x, \text{OPINION}) + f_{o\rightarrow \widehat{h}}(x, \text{AGENT}) + f_{o\rightarrow \widehat{t}}(x, \text{TARGET:}\widehat{p})$. Then, if $s_o \geq 0$, add the arcs $\texttt{root} \rightarrow o$, $o \rightarrow \widehat{h}$, and $o \rightarrow \widehat{t}$ to the dependency graph, respectively with labels OPINION, AGENT, and TARGET:$\widehat{p}$.

For a sentence with L words, this decoding procedure takes $O(L^2)$ time. In practice, we speed up this process by pruning from the candidate list arcs whose connected POS were not observed in the training set and whose length were larger than the ones observed in the training set.

4.2 Features

We now describe our features $\boldsymbol{\phi}_a$, which are computed after processing the sentence to predict POS tags, syntactic dependency trees, lemmas and voice (active or passive) information. For English, we used the Stanford dependency parser (Socher et al., 2013a) for the syntactic annotations, the Porter stemmer to compute word stems, and a set of rules for computing the voice of each word. Our Portuguese corpus include all these preprocessing elements (§6.3), with the exception of the voice information (features depending on voice were only used for English).

We also used the Subjectivity Lexicon[6] of Wilson et al. (2005) that we translated to Portuguese

[6] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon/

(§6.3), and a set of negation words (*e.g. not*, *never*, *nor*) and quantity words (*e.g. very*, *much*, *less*) collected for both languages.

Our arc-factored features are described below; they are inspired by prior work on dependency parsing (Martins et al., 2013) and fine-grained opinion mining (Breck et al., 2007; Johansson and Moschitti, 2013).

Opinion features. We define a set of features that only look at the opinion word; special symbols are used if the opinion is connected to a `root` or `null` node. The features below are also conjoined with the arc label.

- OPINION WORD. The word itself, the lemma, the POS, and the voice. Conjunction of the word with the POS, and of the lemma with the POS.
- BIGRAMS. Bigrams of words and POS corresponding to the opinion word conjoined with its previous (and next) word.
- LEXICON (BASIC). Conjunction of the strength and polarity of the opinion word in the Subjectivity Lexicon[6] (e.g., "weaksubj+neg").
- LEXICON (COUNT). Number of subjective words (total, positive and negative) in a sentence, with and without being conjoined with the polarity of the opinion word in the lexicon.
- LEXICON (CONTEXT). For each word that is in the lexicon and within the 4-word context of the opinion, the form and the polarity of that word in the lexicon, with and without being conjoined with the form and the polarity in the lexicon of the opinion word. Besides the 4-word context, we also used the next/previous word in the sentence which is in the lexicon.
- NEGATION AND QUANTITY WORDS. Within the 4-word context, features indicating if a word is a negation or quantity word, conjoined with the word itself and the opinion word.
- SYNTACTIC PATH. The number of words up to the top of the syntactic dependency tree, and the sequence of POS tags in that path.

Opinion-Argument features. In case of arcs that neither connect to `null` nor `root`, the features above are also conjoined with the binned distance between the two words.For these arcs, we did not use the LEXICON (COUNT)/(CONTEXT) features, but we added features regarding the pair of opinion-argument words (below).

- OPINION-ARGUMENT WORD PAIR. Several conjunctions of word form, POS, voice and syntactic dependency relations corresponding to the pair opinion-argument.
- OPINION-ARGUMENT SYNTACTIC PATH. The syntactic path from the opinion word to the argument, conjoined with the POS and the dependency relations in the path (in Figure 1, for the agent "elites" headed by "are" with relation `nsuj`, we have: "VBP↓NNS" and "`nsuj`↓").

For arcs that neither connect to `null` or `root`, we conjoin voice features with the label, distance, and the direction of the arc. For these arcs, we also include back-off features where the polarity information is removed from the (target) labels.

5 English Monolingual Experiments

In a first set of experiments, we evaluated the performance of our dependency-based model for opinion mining (§3) in the MPQA English corpus.

5.1 Learning

We trained arc-factored models by running 25 epochs of max-loss MIRA (Crammer et al., 2006). Our cost function takes into account mismatches between predicted and gold dependencies, with a cost C_P on labeled arcs incorrectly predicted (false positives) and a cost $C_R = 1 - C_P$ on missed gold labeled arcs (false negatives). The cost C_P, the regularization constant, and the number of epochs were tuned in the development set.

5.2 Evaluation Metrics

Opinion spans (Op.) are evaluated with F_1 scores, according to two matching criteria commonly used in the literature: **overlap matching** (OM), where a predicted span is counted as correct if it overlaps a gold one, and **proportional matching** (PM), proposed by Johansson and Moschitti (2010). For the latter, we use the following formula for the recall, where we consider the sets of gold ($\mathcal{G}$) and predicted ($\mathcal{P}$) opinion spans:[7]

$$R(\mathcal{G}, \mathcal{P}) = \sum_{p \in \mathcal{P}} \max_{g \in \mathcal{G}} \frac{|g \bigcap p| / |p|}{|\mathcal{P}|}; \qquad (4)$$

[7] This metric is slightly different from the PM metric of Johansson and Moschitti (2010), in which recall was computed as $R(\mathcal{G}, \mathcal{P}) = \sum_{p \in \mathcal{P}} \sum_{g \in \mathcal{G}} \frac{|g \cap p| / |p|}{|\mathcal{P}|}$. The reason why we replace the "sum" by a "max" is that each predicted span p in (4) could contribute to the recall with a value greater than 1. Since most of the predicted spans only overlap a single gold span, this fix has a very small effect in the final scores.

the precision is $P(\mathcal{G}, \mathcal{P}) = R(\mathcal{P}, \mathcal{G})$. We also report metrics based on a **head matching** (HM) criterion, where a predicted span is considered correct if its syntactic head matches the head of the gold span. We consider that a pair opinion-agent (Op-Ag.) or opinion-target (Op-Tg.) is correctly extracted according to the OM or the HM criteria, if both the elements satisfy these criteria and the relation holds in the gold data. We also compute the metric described in Johansson and Moschitti (2010) which measures how well agents of opinions are predicted based on a proportional matching (PM) criterion. This metric is applied to evaluate the extraction of both agents and targets. Finally, to evaluate the opinions' polarities (Op-Pol. metric) we consider as correct opinions where the span and polarity both match the gold ones.

5.3 Results: Dependency-Based Model

We assess the quality of our monolingual dependency-based model by comparing it to the recent state-of-the-art approach of Johansson and Moschitti (2013), whose code is available online.[8] That paper reports the performance of a basic span-based pipeline system (which extracts opinions with a CRF, followed by two separate classifiers to detect polarities and agents), and of a more sophisticated system that applies a reranking procedure to account for more complex features that consider interactions accross opinion elements.

We ran experiments using the same data and MPQA partitions as Johansson and Moschitti (2013). However, since our system is designed for predicting opinion, agents and targets together, we removed the documents that were not annotated with targets. The final train/development/test sets have a total of 6,774/1,404/2,559 sentences and 3,834/881/1,426 opinions, respectively.

Table 1 reports the results; since the systems of Johansson and Moschitti (2013) do not predict targets, Table 1 omits target scores.[9] We observe that our dependency-based system achieves results competitive with the best results of Johansson and Moschitti (2013) and clearly above the ones reached by their basic system that does not use re-ranking features. Though the two systems are not fully comparable,[10] the results in Table 1 show that our dependency-based approach (§3.2) followed by a simple dependency-to-span conversion (§3.3) is, despite its simplicity, on par with a top-performing opinion mining system. We conjecture that this is due to the ability to extract opinions, agents, and targets jointly using exact decoding. Note that our proposed dependency scheme would also be able to include additional global features relating pairs of opinions (by adding scores to pairs of opinion arcs) or two opinions having the same agent (by adding scores to pairs of agent arcs sharing its argument), similar to the reranking features used by Johansson and Moschitti (2013). Similar second-order scores have been used in syntactic and semantic dependency parsing (Martins et al., 2013; Martins and Almeida, 2014), but with an increase in the complexity of the model and of the decoder.

6 Cross-Lingual Opinion Mining

We now turn to the problem of learning a opinion mining system for a resource-poor language (Portuguese), in a cross-lingual manner. We use a bitext projection approach (§6.1), whose only requirements are a model for a resource-rich language (English) and parallel data (§6.2).

6.1 Bitext Projection

Our methodology is outlined as Algorithm 1. For simplicity, we call the source and target languages English (e) and "foreign" (f), respectively. The procedure is inspired by the idea of bitext projection (Yarowsky and Ngai, 2001). We start by training an English system on the labeled data $\mathcal{L}^e$ (line 1), which in our case is the MPQA v.2.0 corpus. This system is then used to label the English side of the parallel data, automatically identifying opinion frames (line 2). The next step is to run a word aligner on the parallel data (line 3). The automatic alignments are then used to project the opinion frames to the target language (along with some filtering), yielding an automatic corpus $\widehat{D}^{(f)}$ (line 4), which finally serves to train a system for the target language (line 5).

6.2 Parallel Data

We use an English-Portuguese parallel corpus based on the scientific news Brazilian magazine *Revista Pesquisa FAPESP*, collected by Aziz and

[8] `http://demo.spraakdata.gu.se/richard/unitn_opinion/details.html`

[9] We will report target scores later in §7.

[10] Our system makes use of target annotations to predict the opinion frames, while Johansson and Moschitti (2013) has access not only to *direct subjective* spans but also to *subjective expressions* annotations with their agents and polarity information.

$\mathcal{S}^f \leftarrow$ LearnOpinionMiner($\widehat{\mathcal{D}}^f$)
```

Specia (2011). Though this corpus is in Brazilian Portuguese (while our validation corpus is in European Portuguese), we preferred FAPESP over other commonly used parallel corpora (such as the Europarl and UN datasets), since it is closer to our newswire target domain, with a smaller prominence of direct speech. We computed word alignments using the Berkeley aligner (Liang et al., 2006), intersected them and filtered out all the alignments whose confidence is below 0.95.

After annotating the English side of FAPESP with the pre-trained system ($\widehat{\mathcal{D}}^e$ in Algorithm 1, with a total of 166,719 sentences and 81,492 opinions), the high confidence alignments ($D^{e\leftrightarrow f}$) are used to project the annotations to the Portuguese side of the corpus. The automatic annotations produced by our dependency-based system are easily transferred at a word level (for words with high confidence alignments), as illustrated in Figure 2. To improve the quality of the resulting corpus, we excluded sentences whose alignments cover less than 70% of the words in the target side of the corpus, or sentences whose opinion elements were not fully projected through high confidence alignments. At this point, we obtain an automatically annotated corpus in Portuguese ($\widehat{\mathcal{D}}^f$), with 106,064 sentences and 32,817 opinions.

6.3 Portuguese Opinion Mining Corpus

For validation purposes, we also created a Portuguese corpus with manually annotated fine-grained opinions. The corpus consists of a subset of the documents of the Priberam Compressive Summarization Corpus[11] (Almeida et al., 2014), which contains 80 news topics with 10 documents each, collected from several Portuguese newspapers, TV and radio websites in the biennia 2010–2011 and 2012–2013. In the scope of the current work, we selected and annotated one document of each of the 80 topics. The first biennium was selected as the test set and the second biennium was split into development and training sets (see Ta-

Op-Pol.	49.4	49.1	50.7

Table 3: Inter-annotator agreement in the test partition (shown are F_1 scores).

The corpus was annotated in a similar vein as the MPQA (Wiebe et al., 2005), with the addition of the head node for each element of the opinion frame. It includes spans for direct-subjective expressions with intensity and polarity information; agent spans; and target spans. The annotation was carried out by three linguists, after reading the MPQA annotation guidelines (Wiebe et al., 2005; Wilson, 2008) and having a small practice period using the provided examples and some MPQA annotated sentences. Each document was annotated by two of the three linguists and then revised by the third linguist, who (in case of any doubts) discussed with the initial annotators to reach for the final consensus. Scores for inter-annotator agreement are shown in Table 3.

The corpus was annotated with automatic POS tags and dependency parse trees using TurboParser (Martins et al., 2013).[12] We used an in-house lemmatizer to obtain lemmas for each inflected word in the corpus. A Portuguese lexicon of subjectivity was created by translating the words in the Subjectivity Lexicon of Wilson et al. (2005). The annotated corpus and the translated subjectivity lexicon are available at `http://labs.priberam.com/Resources/Fine-Grained-Opinion-Corpus`, and `http://labs.priberam.com/Resources/Subjectivity-Lexicon-PT`, respectively.

7 Cross-Lingual Experiments

In a final set of experiments, we compare three systems of fine-grained opinion mining for Portuguese. All were trained as described in §5.1.

7.1 System Description

Baseline #1: Supervised System. A Supervised system was trained on the small Portuguese training set described in §6.3. Though being a small training corpus, this is, to the best of our knowledge, the only existing corpus with fine-grained opinions in Portuguese. We used the same arc-factored model and features described in §4.

Baseline #2: Delexicalized System with Bilingual Embeddings. This baseline consists of a direct model transfer: a Delexicalized system is trained in the source language, without language specific features, so that it can be directly applied to the target language. Despite its simplicity, this strategy managed to provide a fairly strong baseline in several NLP tasks (Zeman and Resnik, 2008; McDonald et al., 2011; Søgaard, 2011).

To achieve a unified feature representation, we mapped all language-specific POS tags to universal tags (Petrov et al., 2012), and removed all features depending on the dependency relations, but maintained those depending on the syntactic path (but not on the dependency relations themselves). In addition, we replaced the lexical features by 128-dimensional cross-lingual word embeddings.[13] To obtain these bilingual neural embeddings, we ran the method of Hermann and Blunsom (2014) on the parallel data (§6.1). We scaled the embeddings by a factor of 2.0 (selected on the dev-set), following the procedure described in Turian et al. (2010).

We trained the English delexicalized system on the MPQA corpus, using the same test documents

[12] `http://www.ark.cs.cmu.edu/TurboParser`

[13] A delexicalized system trained without the word embeddings had a worse performance.

Op-Pol.	24.1	23.8	24.7	16.6	16.4	17.6	**35.7***	**34.1***	**35.7***

Table 5: Comparison of cross-lingual approaches. F_1 scores obtained in our Portuguese validation corpus using: a SUPERVISED system trained on the small available data, a DELEXICALIZED system trained with universal POS tags and multilingual embeddings and our BITEXT PROJECTION OF DEPENDENCIES. The symbol * indicates that the best system beats the other systems with statistical significance, with $p < 0.05$ and according to a bootstrap resampling test (Koehn, 2004).

as Riloff and Wiebe (2003) and whose list is available with the corpus, but selecting only documents annotated with targets. We randomly split the remaining documents into train and development sets, respectively with a total of 6,471 and 782 sentences.[14] Table 4 shows the performance of the delexicalized baseline in English, compared with a lexicalized system. We will see how this model behaves in a cross-lingual setting in §7.2.

Our System: Bitext Projection of Opinion Dependencies. Finally, we implemented our cross-lingual BITEXT approach (§6). We trained the (lexicalized) English model on the MPQA corpus (the performance of this model is shown in Table 4). Then, we ran this model on the English side of the parallel corpus, generating automatic annotations, and projected these annotations to the Portuguese side, as described in §6.2. Finally, a Portuguese model was trained on these projected annotations using the arc-factored model and features described in §4.

7.2 Comparison

Table 5 shows the F_1 scores obtained by the three systems on the Portuguese test partition. We observe that the BITEXT approach outperformed the SUPERVISED and the DELEXICALIZED ones in all metrics with a considerable margin, which shows the effectiveness of our proposed method. The SUPERVISED system suffers from the fact that the training set is too small to allow good generalization; the bitext projection method, in contrast, can create arbitrarily large training corpora without any annotation effort. The performance of the DELEXICALIZED system is rather disappointing. This result is justified by a decrease of performance in English due to the delexicalization (cf. Table 4), followed by an extra loss of quality due to language differences.

Though our BITEXT approach scores the best, the scores are behind the range of values obtained for English (Table 4), and far from the inter-annotator agreement numbers (Table 3), suggesting room for improvement. The polarity scores in Table 5 appear to be relatively low. This fact is probably be justified with the annotator agreement scores (Table 3) which are considerably lower for these metrics.

8 Conclusions

We presented a cross-lingual framework for fine-grained opinion mining. We used a bitext projection technique to transfer dependency-based opinion frames from English to Portuguese. Experimentally, our dependency model achieved state-of-the-art results for English, and the Portuguese system trained with bitext projection outperformed two baselines: a supervised system trained on a small dataset, and a delexicalized model with bilingual word embeddings.

9 Acknowledgements

We would like to thank the anonymous reviewers for their insightful comments, and Richard Johansson for sharing his code and for answering several questions. This work was partially supported by the EU/FEDER programme, QREN/POR Lisboa (Portugal), under the Intelligo project (contract 2012/24803) and by a FCT grants UID/EEA/50008/2013 and PTDC/EEI-SII/2312/2012.

[14] Note that this split is different from the one we used in §5. There we used the same split as Johansson and Moschitti (2013), for a fair comparison with their system; here, we follow the standard MPQA test partition.

Abstract

Cross-lingual sentiment analysis is a task of identifying sentiment polarities of texts in a low-resource language by using sentiment knowledge in a resource-abundant language. While most existing approaches are driven by transfer learning, their performance does not reach to a promising level due to the transferred errors. In this paper, we propose to integrate into knowledge transfer a knowledge validation model, which aims to prevent the negative influence from the wrong knowledge by distinguishing highly credible knowledge. Experiment results demonstrate the necessity and effectiveness of the model.

1 Introduction

With the wide range of business value, sentiment analysis has drawn increasing attention in the past years. The extensive research and development efforts produce a variety of reliable sentiment resources for English, one of the most popular language in the world. These available rich resources become the treasure of knowledge to help conduct or enhance sentiment analysis in the other languages, which is a task known as cross-lingual sentiment analysis (CLSA). In the literature of CSLA, the language with abundant reliable resources is called the source language (e.g., English), while the low-resource language is referred to as the target language (e.g., Chinese). However, in this paper, the situation is a low resource language scenario, where the source language is English, and the target language is Chinese.

The main idea of existing CLSA researches is to first build up the connection between the source and target languages to overcome the language barrier, and then develop an appropriate knowledge transfer approach to leverage the annotated data from the source language to train a sentiment classification model in the target language, either supervised or semi-supervised. In particular, these approaches exploit and convert the knowledge learned from the source language to automatically generate and expand the pseudo-training data for the target language.

The machine translation (MT) service is one of the most common ways used to build the language connection (Wan, 2008; Banea et al., 2008; Wan, 2009; Wei and Pal, 2010; Gui et al., 2014). Although it is claimed in Duh et al. (2011) that the MT service is ripe for CLSA, the imperfect MT quality hinders existing MT-based CLSA approaches from the further advance. In our preliminary study, we find that even the Google translator[1] (i.e., one of the most widely used online MT service (Shankland 2013)) may unavoidably changes the sentiment polarity of the translated text, as illustrated below, with a percentage of around 10%.

*[**Original English Text**]: I am at home on bed rest and desperate for something good to read.*
*[Sentiment Label: **Negative**]*
*[**Translated Chinese Text**]:* 我在家卧床休息和绝望的东西很好看。 {*Meaning: I am in bed to rest at home and feel that desperate things are also good to read.*}*[Sentiment Label: **Positive**]*

The noisy data generated by MT errors for sure will weaken the contribution of the transferred knowledge and even worse may create conflicting knowledge. While it is a critical step in CLSA to localize the sentiment knowledge learned from the source language in the target language, to the best of our knowledge, hardly any previous research has focused on knowledge validation to filter out the noisy knowledge having sentiment changes caused by wrong translations during knowledge transfer.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 419–429,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

To reduce the noisy sentiment knowledge introduced into the target language, we are motivated to validate the knowledge transferred from the source language by checking its linguistic distributions and sentiment polarity consistency with the known knowledge in the target language. Different from previous co-training based approaches where two language views recommend knowledge to each other in the same manner, we consider the source language as the "supervisor" and the target language as the "learner". The "supervisor" boosts itself with its own accumulated labeled data (called knowledge) and meanwhile recommends its confident knowledge to the "learner". The "learner" tries to select trustworthy knowledge based on the recommendation to update and expand its training data. Adding a process to efficiently filter out noisy knowledge and retain the self-adaptive and interested new knowledge makes the subsequent boosting process more credible. This is why our approach can outperform state-of-the-art CLSA approaches.

The rest of this paper is organized as follows. Section 2 summarizes the related work. Section 3 explains the proposed model. Section 4 presents experimental results. Finally, Section 5 concludes the paper and suggests future work.

2 Related Work

2.1 Sentiment Analysis

Sentiment has been analyzed in different language granularity, e.g., entity, aspect, sentence and document. This paper focuses on sentiment analysis of online product reviews in the document level.

Existing approaches are generally categorized into lexicon-based and machine learning based approaches (Liu, 2012). Lexicon-based approaches highly depend on sentiment lexicons. Turney (2002) derives the overall phrase and document sentiment scores by averaging the sentiment scores provided in a lexicon over the words included. Similar idea is adopted in (Hiroshi et al., 2004; Kennedy and Inkpen, 2006). Machine learning based approaches, on the other hand, apply classification models. The task-specific features are designed to train sentiment polarity classifiers. Pang et al. (2002) compare the performance of NB, SVM and ME on movie reviews. SVM is found more effective. Gamon (2004) shows that SVM with deep linguistic features can further improve the performance. A variety of other machine learning approaches are also proposed to sentiment classification (Mullen and Collier, 2004; Read, 2005; Hassan and Radev, 2010; Socher et al., 2013).

Cross-domain sentiment classification (CDSC) shares certain common characteristics with cross-lingual sentiment classification (CLSC) (Tan et al., 2007; Li et al., 2009; Pan and Yang, 2010; He et al., 2011a; Glorot et al., 2011). Notice that the gap between source domain and target domain is the main difference between CDSC and CLSC. CLSC copes with two different datasets in two different languages. This difference makes CLSC a new challenge, drawing specific attention to researcher recently.

2.2 Cross-lingual Sentiment Analysis

There are two alternative solutions to cross-lingual sentiment analysis. One is ensemble learning that combines multiple classifiers. The other is transfer learning that develops strategies to adapt the knowledge from one language to the other. Wan (2008) is among the pioneers to develop the ensemble learning solutions, where multiple classifiers learned from different training datasets including those in original languages and translated languages are combined by voting. Most researches, on the other hand, explore transfer learning and focus on knowledge adaptation. For example, Wan (2009) applies a supervised co-training framework to iteratively adapt knowledge learned from the two languages by transferring translated texts to each other. Other similar work includes (Wei and Pal, 2010) and (He, 2011b). All these approaches rely on MT to build language connection.

Meanwhile, the unlabeled parallel data is also employed to fill the gap between two languages. To solve the feature coverage problem with the EM algorithm, Meng et al. (2012) leverage the unlabeled parallel data to learn unseen sentiment words. Similarly, Popat et al. (2013) use the unlabeled parallel data to cluster features in order to reduce the data sparsity problem. Meng et al. (2012) and Popat et al. (2013) also use the unlabeled parallel data to reduce the negative influence of the noisy and incorrect sentiment labels introduced by machine translation and knowledge transfer. However, the parallel data is also a scarce resource.

Some existing transfer learning based CLSA methods have attempted to address the noisy knowledge problem caused by wrong labels by checking label consistency. For example, to filter out the unconfident labels in Chinese, the supervised learning method proposed by (Xu et al., 2011) runs boosting in Chinese by checking consistency between the labels manually annotated in English and predicted by Chinese classifiers on translated Chinese. The work in (Gui et al., 2014) follows the same line although it considers knowledge transferring between two languages. On the contrary, the main focus of our work is to filter out the noisy knowledge having sentiment changes by wrong translations. Actually, both label consistency checking and linguistic distribution checking are important. Any one alone cannot work well. In fact, both of them are considered as the knowledge validation in our work, though the later is our focus.

3 Credible Boosting Model

In this paper, we propose a knowledge validation approach to improve the effectiveness of knowledge transfer without directly using extra parallel data. Our target is to filter out the noisy sentiment labels introduced by MT and the incorrect sentiment labels generated by imperfect classifier in the source language. Here, the knowledge is referred to as a collection of distributed document presentations with sentiment labels that have been verified to be robust in sentiment classification (Le and Mikolov, 2014). A novel credible boosting model, namely CredBoost is proposed to apply transfer-supervised learning with an added self-validation mechanism to guarantee the knowledge transferred highly credible and self-adaptive.

3.1 Problem Description

In a standard cross-lingual sentiment analysis setting, the training data includes labeled English reviews $L_{EN} = \{(x_i^{l_{en}}, y_i)\}_{i=1}^{M}$ and unlabeled Chinese reviews $U_{CN} = \{x_j^{u_{cn}}\}_{j=1}^{N}$, where x_i^k $(k = l_{en} \, or \, u_{cn})$ represents review i and $y_i \in \{-1, 1\}$ is the sentiment label of review x_i^l. The test data is Chinese reviews $T_{CN} = \{x_s^{t_{cn}}\}_{s=1}^{S}$.

We now introduce the unlabeled data into credBoost's setting. L_{EN} is divided into two disjoint parts L_{EN}^T and L_{EN}^B, where L_{EN}^T for basic training and L_{EN}^B for self-boosting. We translate L_{EN} into Chinese to obtain extra labeled Chinese pseudo-reviews $L_{TrCN} = \{(x_i^{l_{cnTr}}, y_i)\}_{i=1}^{M}$ and U_{CN} into English to obtain extra unlabeled English pseudo-reviews $U_{TrEN} = \{x_j^{l_{enTr}}\}_{j=1}^{N}$. Thereby, we obtain a pair of pseudo-parallel data (U_{CN}, U_{TrEN}).

The task is to use L_{EN} and U_{CN} to train a Chinese classifier to predict sentiment polarity for the test data T_{CN}. It is a standard transfer learning problem. We consider two language views, i.e., source language view D_S and target language view $D_\mathcal{T}$. D_S boosts itself with the labeled English data and recommend translated knowledge to $D_\mathcal{T}$, while D_t selects self-adaptive ones to boost itself.

3.2 Framework of CredBoost

The CredBoost model involves two synchronously boosting views for two languages respectively. During training, one view acts as a "supervisor" that recommends and passes the knowledge to the other view. The same knowledge is also added into its own view for boosting by automatically updating the weights of the labeled data. The other view acts as a "learner" that receives the recommended knowledge and selects the best-suited new knowledge to learn.

As mentioned before, the knowledge transferred through MT is not reliable. The source language view may also make wrong predictions and thus transfer the wrong knowledge to the target language even the translations are correct. Whether or not the "learner" can benefit from its "supervisor" and how much it benefits highly depends on the credibility and adaptiveness of the recommended knowledge accepted by the "learner". Knowledge validation is necessary to ensure the quality of learning. The objective of knowledge validation is to identify the new and acquired knowledge from recommendations. Both language views are iteratively trained until learning converges or reaches the iteration upper bound.

In the **source language view**, at iteration (t), the CredBoost model first uses $L_{EN}^{T(t)}$ to train a basic classifier $\mathcal{C}_{EN}^{(t)}$ and then uses $\mathcal{C}_{EN}^{(t)}$ to predict $L_{EN}^{B(t)}$ and $U_{TrEN}^{(t)}$. Top m and top n instances are sampled from $L_{EN}^{B(t)}$ and $U_{TrEN}^{(t)}$ respectively, by Formula (1) :

$$\begin{aligned} O_{EN}^{(t)} &= \{(x_{i'}^{LB}, \hat{y}_{i'}^{LB})\}_{i'=1}^{m_{en}} \\ TR_{EN}^{(t)} &= \{(x_i^{UTr}, \hat{y}_i^{UTr})\}_{i=1}^{n_{en}} \end{aligned} \tag{1}$$

where $O_{EN}^{(t)}$ denotes the candidates to be added into the training data, and $TR_{EN}^{(t)}$ the knowledge to be recommended to the target language view. We use the source knowledge validation function $V_{\mathcal{S}}(O_{EN}^{(t)})$ to identify the acquired knowledge $K_{'Ac}^{(t)}$ learned in the previous learning process and the new knowledge $K_{'Nw}^{(t)}$ fresh to the current knowledge system from $O_{EN}^{(t)}$. The importance of each training instance is updated according to the performance of prediction by Formula (2) :

$$\omega_{i'}^{'Ac} = \begin{cases} e^{\epsilon(t)} \cdot \sqrt{\nu_{i'}^{(t)} \cdot c_{i'}^{(t)}} & \text{if } \hat{y}_{i'}^{'Ac} \neq y_{i'}^{'Ac} \\ \sqrt{\nu_{i'}^{(t)} \cdot c_{i'}^{(t)}} & \text{otherwise;} \end{cases}$$
$$\omega_{j'}^{'Nw} = \begin{cases} e^{\epsilon(t)} \cdot \log\left(1 + \sqrt{e} \cdot c_{j'}^{(t)}\right) & \text{if } \hat{y}_{j'}^{'Ac} \neq y_{j'}^{'Ac} \\ \log\left(1 + \sqrt{e} \cdot c_{j'}^{(t)}\right) & \text{otherwise.} \end{cases} \quad (2)$$

where $c_{j'}^{(t)}$ is the confidence of an instance given by $\mathcal{C}_{EN}^{(t)}$, thus $\log\left(1 + \sqrt{e} \cdot c_{j'}^{(t)}\right) > 1$ is to enhance the weight of new knowledge because of the higher significance contributing to the later learning. $\nu_{i'}^{(t)} (< 1)$ is the adaptiveness score given by the source knowledge validation function $V_{\mathcal{S}}(O_{EN}^{(t)})$. $\epsilon_{(t)} (> 1)$ is the error rate of $\mathcal{C}_{EN}^{(t)}$, thus $e^{\epsilon(t)} > 1$ is to reward the wrongly predicted data in the next iteration. $\hat{y}_{i'}^{'Ac}$ is the label given by $\mathcal{C}_{EN}^{(t)}$ and $y_{i'}^{'Ac}$ is the manually annotated label. For the incorrectly predicted instance, the weight is boosted inversely to the performance of the current classifier. The instance identified as the new knowledge which contributes more to performance improvement is given a reward parameter to enhance its significant in the next training iteration. Data sets update by Formula (3). The training starts with iteration (1), the training data is initially set as $L_{EN}^{T(1)} = L_{EN}^{T}$.

$$\begin{aligned} L_{EN}^{T(t+1)} &= L_{EN}^{T(t)} \cup K_{'Ac}^{(t)} \cup K_{'Nw}^{(t)} \\ L_{EN}^{B(t+1)} &= L_{EN}^{B(t)} - (K_{'Ac}^{(t)} \cup K_{'Nw}^{(t)}) \end{aligned} \quad (3)$$

In the **target language view**, at iteration (t), the CredBoost model receives the recommended knowledge $TR_{EN}^{(t)}$ and projects it to $O_{CN}^{(t)}$ from the unlabeled Chinese data $U_{CN}^{(t)}$ with the pseudo-parallel data $(U_{CN}^{(t)}, U_{TrEN}^{(t)})$. $O_{(t)}^{CN}$ is validated by the target knowledge validation function $V_{\mathcal{T}}(O_{CN}^{(t)})$ to identify the acquired knowledge $K_{Ac}^{(t)}$ and the new knowledge $K_{Nw}^{(t)}$. $K_{Ac}^{(t)}$ and $K_{Nw}^{(t)}$ are projected to $K_{*Ac}^{(t)}$ and $K_{*Nw}^{(t)}$ from the unlabeled English pseudo-data $U_{TrEN}^{(t)}$. The weight of an instance is updated by Formula (4), and the parameter setting is similar to that in the source language view. The confidence $c_i^{(t)}$ is directly transferred from D_s. We reward the validated knowledge to raise their significance in the training data considering they are originally Chinese.

$$\begin{aligned} \omega_i^{Ac} &= \sqrt{c_i^{(t)} \cdot \log(1 + \sqrt{e} \cdot v_i^{(t)})} \\ \omega_j^{Nw} &= e^{\log\left(1+\sqrt{e} \cdot c_j^{(t)}\right)} = 1 + \sqrt{e} \cdot c_j^{(t)} \end{aligned} \quad (4)$$

We update the data setting by Formula (5). The training data is initially set as $U_{CN}^{T(1)} = U_{CN}^{T}$. The CredBoost model is illustrated in Algorithm 1.

$$\begin{aligned} L_{TrCN}^{(t+1)} &= L_{TrCN}^{(t)} \cup K_{Ac}^{(t)} \cup K_{Nw}^{(t)} \\ U_{CN}^{(t+1)} &= U_{CN}^{(t)} - (K_{Ac}^{(t)} \cup K_{Nw}^{(t)}) \\ U_{TrEN}^{(t+1)} &= U_{TrEN}^{(t)} - (K_{*Ac}^{(t)} \cup K_{*Nw}^{(t)}) \end{aligned} \quad (5)$$

Algorithm 1 CredBoost Model

```
Input: English labeled data $L_{EN}^{T}$ and $L_{EN}^{B}$, translated English unlabeled data $U_{TrEN}$, translated Chinese data $L_{TrCN}$ and unlabeled Chinese data $U_{CN}$;
Initialize: Weights $W_{EN}^{(1)} = \{1\}^M$ for $L_{EN}^{T}$ and $W_{TrCN}^{(1)} = \{1\}^M$ for $L_{TrCN}$;
For $t = 1, \cdots, T$:
    1. Use $L_{EN}^{T(t)}$ to learn English classifier $C_{EN(t)}$;
    2. Use $\mathcal{C}_{EN}^{(t)}$ to predict $L_{EN}^{B(t)}$ and $U_{TrEN}^{(t)}$ sample top $m$ and top $n$ instances from $L_{EN}^{B(t)}$ and $U_{TrEN}^{(t)}$, $O_{EN}^{(t)}$ and $TR_{EN}^{(t)}$;
    3. Validate $O_{EN}^{(t)}$ by knowledge validation function $V_{\mathcal{S}}(O_{EN}^{(t)})$ to identify acquired knowledge $K_{'Ac}^{(t)}$ and new knowledge $K_{'Nw}^{(t)}$, generate the weights for them by Formula (2), then recommend $TR_{EN}^{(t)}$ to $D_{\mathcal{T}}$;
    4. Project $TR_{EN}^{(t)}$ to $O_{CN}^{(t)}$ with pseudo-parallel data $(U_{CN}^{(t)}, U_{TrEN}^{(t)})$, and use knowledge validation function $V_{\mathcal{T}}(O_{CN}^{(t)})$ to identify acquired knowledge $K_{Ac}^{(t)}$ and new knowledge $K_{Nw}^{(t)}$, then generate weights for them by Formula (4);
    5. Update $D_{\mathcal{S}}$ by Formula (2) and $D_{\mathcal{T}}$ by Formula (5);
End For.
Output: Chinese classifier $\mathcal{C}_{CN}^{(T)}$.
```

3.3 Knowledge Validation

Knowledge is familiarity, awareness or understanding of someone or something, such as facts, information or skills, which is acquired through experience or education by perceiving, discovering or learning[2]. It can be implicit or explicit.

In machine learning, natural language knowledge is a continuously improving hypothesis that consists of both semantic and significant domain

[2] Definition from Oxford Dictionary of English, available at: `http://oxforddictionaries.com/view/entry/m_en_us126`.

characters. While language is the expression of semantic, semantic is the carrier of sentiment. Using another word, two texts with more smaller semantic distance have higher probability to share the same sentiment polarity. Choi and Cardie (2008) assert that the sentiment polarity of natural language can be better inferred by compositional semantics. They also suggest that incorporating compositional semantics into learning can improve the performance of sentiment classifiers. Saif et al. (2012) also demonstrate that the addition of extra semantic features can further improve performance.

In order to filter out noisy and incorrect sentiment labels, we propose a knowledge validation approach to reduce these noisy data that hinder the improvement of learning performance. Knowledge validation is a way to identify the acquired knowledge implied in current knowledge system and also the new knowledge fresh to current knowledge system. The knowledge can be represented in the semantic space. (Le and Mikolov, 2014) project documents into a low-dimension semantic space with a deep learning approach, known as document-to-vector (Doc2Vec[3]). Considering that Dov2Vec has been verified to be efficient in many NLP tasks including sentiment analysis, we follow previous research to represent knowledge embedded in product reviews with the vectors generated by Doc2Vec.

Suppose distributed representations (i.e., low-dimensional vectors) of the all reviews including $\{L^T_{EN}, L^B_{EN}, U_{TrEN}\}$ and $\{L_{TrCN}, U_{CN}\}$ are $\{\mathcal{V}(L^T_{EN}), \mathcal{V}(L^B_{EN}), \mathcal{V}(U_{TrEN})\}$ and $\{\mathcal{V}(L_{TrCN}), \mathcal{V}(U_{CN})\}$ respectively. At iteration (t), $\mathcal{V}(L^{T(t)}_{EN})$ is the current knowledge system of the English view and $\mathcal{V}(L^{(t)}_{TrCN})$ is that of the Chinese. The knowledge validation runs separately in the source and target views.

In the **target language view**, at iteration (t), suppose the prediction confidence of the candidate $(x^U_i, \hat{y}^U_i) \in O^{(t)}_{CN}$ is $c^{(t)}_i$. We define the adaptiveness score as the average distance of top ζ_+ semantic distances between the instance x^{LB}_i and the positive cluster of $L^{(t)}_{TrCN}$, denoted as $L^{(t)+}_{TrCN}$, and top $\zeta^{(t)}_- = \zeta_+ \cdot \frac{\mathcal{L}^{(t)}_+}{\mathcal{L}^{(t)}_-}$ semantic distances between x^U_i and the negative cluster, denoted as $L^{(t)-}_{TrCN}$, where $\mathcal{L}^{(t)}_+$ and $\mathcal{L}^{(t)}_-$ are the numbers of the elements in $L^{(t)+}_{TrCN}$ and $L^{(t)-}_{TrCN}$ respectively. The validation parameters are defined by Formula (6), ω_r is the weight of training instance $\mathcal{V}(r)$, $\nu^{(t)}_i$ is the adaptiveness score, and $\mathcal{V}^{label}_* \in \{1, -1\}$ is the validated label which denotes the knowledge belonging to the positive cluster $L^{(t)+}_{TrCN}$ or the negative cluster $L^{(t)-}_{TrCN}$. The validation process is illustrated in Algorithm 2, where the acquired knowledge is $k^{(t)}_{Ac}$, and the new knowledge is $k^{(t)}_{Nw}$.

$$
\begin{aligned}
&\mathcal{D}(\mathcal{V}(x^{LB}_i), \mathcal{V}(r)) = \frac{\mathcal{V}(x^{LB}_i)^T \cdot \mathcal{V}(r)}{\parallel \mathcal{V}(x^{LB}_i) \parallel \cdot \parallel \mathcal{V}(r) \parallel} \\
&\Rightarrow \begin{cases} \nu^{(t)+}_i = \frac{1}{\zeta+} \sum\limits_{r \in L^{(t)+}_{EN}} \omega_r \ \mathcal{D}(\mathcal{V}(x^{LB}_i), \mathcal{V}(r)) \\ \nu^{(t)-}_i = \frac{1}{\zeta^{(t)}_-} \sum\limits_{r' \in L^{(t)-}_{EN}} \omega_{r'} \ \mathcal{D}(\mathcal{V}(x^{LB}_i), \mathcal{V}(r')) \end{cases} \\
&\Rightarrow \quad \Delta(\nu^{(t)}_i) = \nu^{(t)+}_i - \nu^{(t)-}_i \\
&\Rightarrow \quad \delta^{(t)}_i = \frac{1}{e^{1+\Delta(\nu^{(t)}_i)}} \\
&\Rightarrow \quad \mathcal{V}^{label}_* = \begin{cases} 1 & \text{if } \delta^{(t)}_i > 0.5, \\ -1 & \text{if } \delta^{(t)}_i \leq 0.5. \end{cases} \\
&\Rightarrow \quad \nu^{(t)}_i = \begin{cases} \nu^{(t)+}_i & \text{if } \mathcal{V}^{label}_* = 1, \\ \nu^{(t)-}_i & \text{if } \mathcal{V}^{label}_* = -1. \end{cases}
\end{aligned}
\tag{6}
$$

where $\mathcal{D}(\mathcal{V}(x^{LB}_i), \mathcal{V}(r))$ is the Cosine distance between the distributed representations of the two reviews. $\nu^{(t)+}_i$ and $\nu^{(t)-}_i$ are the weighted averages of the semantic distances. $\delta^{(t)}_i$ is the Sigmoid function which computes the probability that the data is distributed in the positive cluster $L^{(t)+}_{TrCN}$.

In the **source language view**, at iteration (t), let's suppose the prediction confidence of candidate $(x^{LB}_{i'}, \hat{y}^{LB}_{i'}) \in O^{(t)}_{EN}$ to be $c^{(t)}_{i'}$. The definitions of validation parameters are similar to those in the target language view. The validation process is illustrated in Algorithm 3. The validation is looser, because the training data and candidates are both in English. This differs from it in the target view.

4 Experiments

4.1 Experimental Setup

We evaluate the proposed CredBoost model on an open cross-lingual sentiment analysis task in NLP&CC 2013[4]. The data set provided is a

[3] Doc2Vec is one of the models implemented in the free python library ***Gensim*** which can be freely downloaded at: `https://pypi.python.org/pypi/gensim`.

[4] NLP&CC is an annual conference of Chinese information technology professional committee organized by Chinese computer Federation (CCF). It mainly focuses on the study and application novelty of natural language processing and Chinese computation. CLSA task is the task 3 of NLP&CC 2013. For more details and open

Algorithm 2 Knowledge Validation $V_{\tau}(D_{\tau})$

```
Input: Labeled Chinese training data $L^{(t)}_{TrCN}$, weights of labeled data $W^{(t)}_{CN}$ and semantics vectors of all English data for iteration $(t)$: $\{\mathcal{V}(L^{(t)}_{TrCN}), \mathcal{V}(U^{(t)}_{CN})\}$;
Initialize: $K^{(1)}_{'Ac} = \phi$, $K^{(1)}_{'Nw} = \phi$;
For  $x^U_i$ in $O^{(t)}_{CN}$:
    1. Use $L^{(t)}_{TrCN}$ to train a classifier $\mathcal{C}^{(t)}_{CN}$,
       then use $\mathcal{C}^{(t)}_{CN}$ predict $x^U_i$, giving label $y^{CN}_i$;
    2. Get validated label $\mathcal{V}^{label}_*$, positive and
       negative average distances $\nu^{(t)+}_i$, $\nu^{(t)-}_i$
       of $x^U_i$ by fomula (6);
    3. If $\nu^{(t)+}_i < \psi$ and $\nu^{(t)-}_i < \psi$:
           If $\hat{y}^{LB}_i = \mathcal{V}^{label}_*$:
           Then $K^{(t)}_{Nw} \leftarrow K^{(t)}_{Nw} + x^U_i$;
       Else:
           If $\hat{y}^{LB}_i = \mathcal{V}^{label}_* = y^{CN}_i$:
           Then $K^{(t)}_{Ac} \leftarrow K^{(t)}_{Ac} + x^U_i$;
End For.
Output: $K^{(t)}_{Nw}$, $K^{(t)}_{Ac}$.
```

Algorithm 3 Knowledge Validation $V_{\mathcal{S}}(D_{\mathcal{S}})$

```
Input: Weights of labeled data $W^{(1)}_{EN}$ and semantics vectors of all English data for iteration $(t)$:
$\{\mathcal{V}(L^{T(t)}_{EN}), \mathcal{V}(L^{B(t)}_{EN}), \mathcal{V}(U^{(t)}_{TrEN})\}$;
Initialize: $K^{(1)}_{'Ac} = \phi$, $K^{(1)}_{'Nw} = \phi$;
For  $x^{LB}_{i'}$ in $O^{(t)}_{EN}$:
    1. Get validated label $\mathcal{V}^{label}_{'}$, positive and
       negative average distances $\nu^{(t)+}_{i'}$, $\nu^{(t)-}_{i'}$
       of $x^{LB}_{i'}$ by fomula (6);
    2. If $\nu^{(t)+}_{i'} < \psi$ and $\nu^{(t)-}_{i'} < \psi$:
           If $\hat{y}^{LB}_{i'} = \mathcal{V}^{label}_{'}$:
           Then $K^{(t)}_{'Nw} \leftarrow K^{(t)}_{'Nw} + x^{LB}_{i'}$;
       Else:
           If $\hat{y}^{LB}_{i'} = \mathcal{V}^{label}_{'}$:
           Then $K^{(t)}_{'Ac} \leftarrow K^{(t)}_{'Ac} + x^{LB}_{i'}$;
End For.
Output: $K^{(t)}_{'Nw}$, $K^{(t)}_{'Ac}$.
```

collection of bilingual Amazon product reviews in Books, DVD and Music domains. It contains 4,000 labeled English reviews, 4,000 Chinese test reviews, and 17,814, 47,071, 29,677 unlabeled Chinese reviews in three different domains. We randomly select 2,000 unlabeled Chinese reviews in each domain to train classifiers. Besides, the pseudo-data sets described in CredBoost model are translated with Google translator. The data set is summarized in Table 1.

To better illustrate the significance of knowledge validation during knowledge transfer, we compare the proposed method with the following baseline methods:

Lexicon-based (LB): The standard English MPQA sentiment lexicons are translated into Chinese and then utilized together with a small number of Chinese turning words, negations and intensifiers to predict the sentiment polarities of the Chinese test reviews.

Domain		English		Chinese	
		L	U	L	U
Books	Train	4,000	-	-	2,000
	Test	-	-	4,000	-
DVD	Train	4,000	-	-	2,000
	Test	-	-	4,000	-
Music	Train	4,000	-	-	2,000
	Test	-	-	4,000	-

Table 1: Experimental data sets. All data sets are balanced, L represents labeled data and U represents unlabeled data.

Basic SVM (BSVM-CN): The labeled English reviews are translated into Chinese, which are then used as the pseudo-training data to train a Chinese SVM classifier.

Primarily boost transfer learning (BTL-1): The labeled English reviews are used to train the English classifier, which is applied to label the English translations of the unlabeled Chinese reviews. These labeled Chinese reviews obtained via MT together with the Chinese translations of the labeled English reviews are then used as the pseudo-training data to train a Chinese sentiment classifier.

Best result in NLP&CC 2013 (BR2013): This is the best result reported in NLP&CC 2013. Unfortunately, the specification of the method is not available.

Self-boost (SB-CN) in Chinese: The labeled English reviews are translated into Chinese, which are used as the pseudo-training data to train a basic Chinese classifier. This classifier is iteratively refined by choosing the most confidently predicted English reviews to add into the Chinese training data until a predefined iteration number reaches. It can be also considered as a self-adaptive boosting approach.

Iteratively boost transfer learning (BTL-2): This is an enhanced transfer learning method sharing the same learning framework with CredBoost but it ignores knowledge validation. It iteratively transfers the knowledge from English to Chinese. The learning in both languages iteratively boosts themselves separately. The transfer size is 16, comparable to that in CredBoost.

Basic co-training (CoTr): The co-training method proposed in (Wan, 2009) is implemented. It is bidirectional transfer learning. In each

resource, you can available at: `http://tcci.ccf.org.cn/conference/2013/index.html`.

iteration, 10 positive and 10 negative reviews are transferred from one language to the other.

Doc2vec feature CredBoost (dCredB): This method is similar to CredBoost except that document-to-vector is used to generate features when training basic classifiers. The vectors are obtained from both original and translated reviews. The dimension of doc2vec is 300, while the other parameters are set as default.

The baseline methods described above are categorized into three classes: the first four which are preliminary methods, the middle three which are several state-of-the-art models being comparable to our proposed model, and the last one which is a comparison to suggest that the knowledge representation is not the answer to the performance improvement. For all the methods excluding LB and BR2013, we use support vector machines (SVMs) as basic classifiers. We use the Liblinear package (Fan et al., 2008) with the linear kernel[5]. All methods use Unigram+Bigram features to train the basic classifiers, except for dCredB.

4.2 Experimental Result

In this work, there are two main parameters that may significantly influence the performance of our proposed model. They are the new knowledge validation boundary ψ and the validation scale ζ_+ in the training data. We set the values of parameters with the grid search strategy. We first fix initial $\zeta_+ = 14$ to search the best new knowledge validation boundary ψ from an empirical value set $\{0.30, 0.35, 0.40, 0.45, 0.50\}$. We then fix the best $\psi = 0.40$ to check the suitable validation scale ζ_+ from the initial value set $\{6, 8, 9, 10, 11, 12, 14, 16\}$ in which values are comparable with the knowledge transfer scale of CoTr in the training data. Besides, the recommendation size m for English is set to 20 and the recommendation size n for Chinese is set to 40. The final settings are listed in Table 2. The performance is evaluated in terms of accuracy (Ac) defined by Formula (7).

$$Ac(f) = \frac{p^f}{P^f}, \qquad Avg\_Ac = \frac{1}{3} \cdot \sum_{f' \in \mathcal{F}} Ac(f') \quad (7)$$

where p^f is the number of correct predictions and P^f is the total number of the test data; $\mathcal{F} \in \{Books, DVD, Music\}$ is the domain set.

Domain	ψ	ζ_+	m	n
Books	0.45	12	20	40
DVD	0.40	12	20	40
Music	0.40	9	20	40

Table 2: Parameter settings of three domains in this paper.

Approaches	Domain			Avg_Ac
	Books	DVD	Music	
LB	0.7770	0.7832	0.7595	0.7709
BSVM-CN	0.7940	0.7995	0.7778	0.7904

Table 3: Macro performance of all approaches in three domains. All values are accuracies and Avg-Ac represents the average accuracy in three domains.

The performances are reported in Tables 3 and 4. As shown, CredBoost outperforms all the other comparison methods. The first four baselines have poor performances compared to others. This suggests that the CLSA problem cannot be well solved by directly learning from the labeled translated data without any knowledge adaption or knowledge validation. SB-CN, BTL-2 and CoTr employ iterative boosting to adapt knowledge from the source English to the target Chinese without validating the transferred knowledge. They inevitably mis-recommend the massive noisy data into Chinese. CredBoost, in contrast, introduces knowledge validation into transfer learning with iterative boosting. It better adapts knowledge from English to Chinese and thus ensures the credibility of the accepted knowledge. Its best result justifies our assumption.

Specifically, SB-CN leverages both the Chinese training data translated from the labeled English data and the unlabeled Chinese data used for boosting. The boosting in Chinese iteratively selects the trustworthy data with the labels assigned by the Chinese classifier. Our proposed method, however, exploits two different languages simultaneously with an additional boosting step, i.e., it transfers knowledge from English to Chinese during boosting. We then use knowledge validation model to validate the unlabeled Chinese data whose labels are assigned by the English

[5] The parameter setting used in this paper is '-*s 7*'.

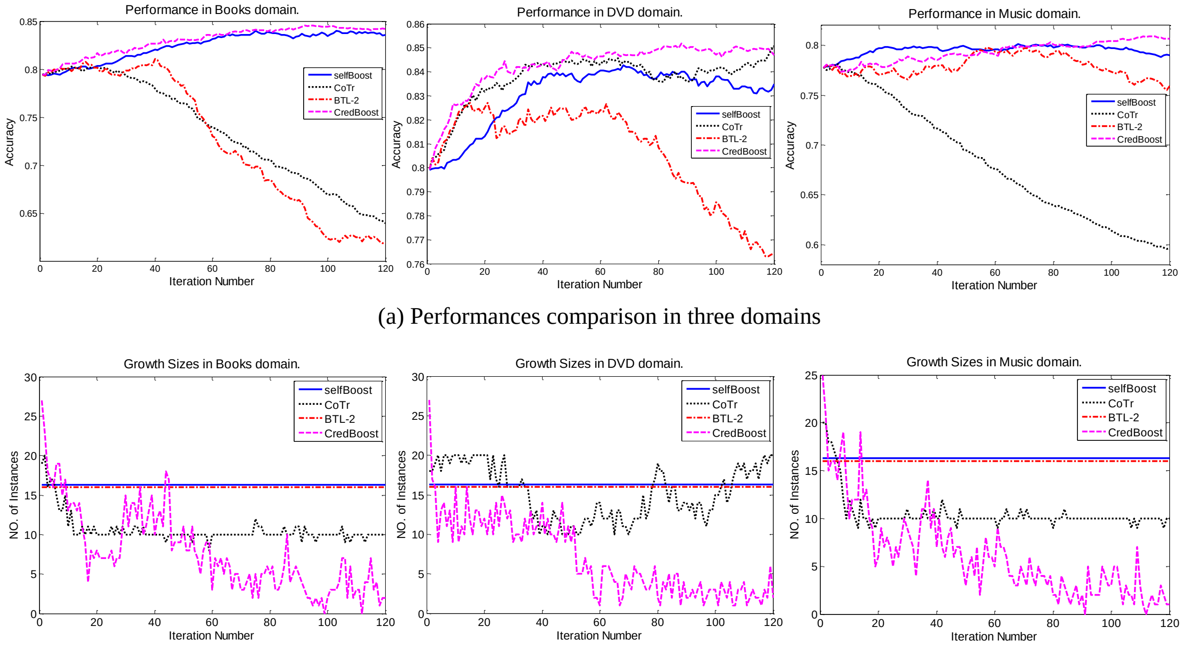
classifier. It is reasonable that a Chinese classifier performs better on Chinese text than an English classifier performs on the translated English text due to the different language distributions and MT errors. However, as shown in Tables 3 and 4, the better performance of our proposed method compared with that of the self-boosting method further suggests the effectiveness of our proposed knowledge validation model.

Figure 1 illustrates the continuous changes of performances vs. the corresponding growth sizes of the training data sets for SB-CN, BTL-2, CoTr, and CredBoost. According to our common sense, noisy data have negative influence on performance improvement. Compared to the other three methods, CredBoost accepts less number of training instances during learning while it achieves more improvement. This verifies the ability of CredBoost that can filter out the noisy data recommended by the English sentiment classifier.

In Figure 1(a), the curves of BTL-2 and CoTr suggest that directly transferring the knowledge recommended from English imports many noisy data into Chinese. It is also obvious that the performance curve of CredBoost implies a stable improvement trend while the other three decrease after certain iterations because of the accumulated negative influence from the noisy data. Figure 1(b) shows CredBoost accepts decreased training instances after certain iterations because the number of “high-quality” instances decrease when learning proceeds. This finding suggests that knowledge validation would rather abandon “less-credible” knowledge with higher probability than easily accept it. Knowledge validation in the proposed model guarantees highly-credible learning when transferring knowledge from English to Chinese. The results also show that CredBoost has great potential to achieve better performance approaching to supervised approaches if more unlabeled Chinese data are available.

Another interesting finding is also observed.



(a) Performances comparison in three domains

(b) Growth sizes comparison in three domains

Figure 1: Performances vs. Growth Sizes for SB-CN, CoTr, BTL-2, and CredBoost in three domains. The similar performance curves of CoTr is also reported in (Gui et al., 2014).

Although document-to-vector represents content semantic well, it cannot determine the sentiment polarity of text well, even when the document-to-vectors that are used to train basic classifiers are learned on the mixture of the translated and original reviews. The superior performance of CredBoost to dCredB suggests that the semantic representation is effective to identify highly-credible acquired knowledge and new knowledge but it alone may not be sufficient enough to model the sentiment information.

We also conduct some other experiments to study the sensitivity of the new knowledge validation boundary ψ and the validation scale ζ_+ in the training data. The experimental results show that the performances with different parameter settings fluctuate around the best result reported in Tables 3 and 4 in a small range. Our model is basically quite stable.

5 Conclusion

In this paper, we propose a semi-supervised learning model, called CredBoost, to address cross-lingual (English vs Chinese) sentiment analysis without direct labeled Chinese data nor direct parallel data. We propose to introduce knowledge validation during transfer learning to reduce the noisy data caused by machine translation errors or inevitable mistakes made by the source language sentiment classifier. The experimental result demonstrates the effectiveness of the proposed model. In the future, we will explore more suitable knowledge representations and knowledge validation in the CredBoost framework.

Abstract

The sentiment classification performance relies on high-quality sentiment resources. However, these resources are imbalanced in different languages. Cross-language sentiment classification (CLSC) can leverage the rich resources in one language (source language) for sentiment classification in a resource-scarce language (target language). Bilingual embeddings could eliminate the semantic gap between two languages for CLSC, but ignore the sentiment information of text. This paper proposes an approach to learning bilingual sentiment word embeddings (BSWE) for English-Chinese CLSC. The proposed B-SWE incorporate sentiment information of text into bilingual embeddings. Furthermore, we can learn high-quality BSWE by simply employing labeled corpora and their translations, without relying on large-scale parallel corpora. Experiments on NLP&CC 2013 CLSC dataset show that our approach outperforms the state-of-the-art systems.

1 Introduction

Sentiment classification is a task of predicting sentiment polarity of text, which has attracted considerable interest in the NLP field. To date, a number of corpus-based approaches (Pang et al., 2002; Pang and Lee, 2004; Kennedy and Inkpen, 2006) have been developed for sentiment classification. The approaches heavily rely on quality and quantity of the labeled corpora, which are considered as the most valuable resources in sentiment classification task. However, such sentiment resources are imbalanced in different languages. To leverage resources in the source language to improve the sentiment classification performance in the target language, cross-language sentiment classification (CLSC) approaches have been investigated.

The traditional CLSC approaches employ machine translation (MT) systems to translate corpora in the source language into the target language, and train the sentiment classifiers in the target language (Banea et al., 2008). Directly employing the translated resources for sentiment classification in the target language is simple and could get acceptable results. However, the gap between the source language and target language inevitably impacts the performance of sentiment classification. To improve the classification accuracy, multi-view approaches have been proposed. In these approaches, the resources in the source language and their translations in the target language are both used to train sentiment classifiers in two independent views (Wan, 2009; Gui et al., 2013; Zhou et al., 2014a). The final results are determined by ensemble classifiers in these two views to overcome the weakness of monolingual classifiers. However, learning language-specific classifiers in each view fails to capture the common sentiment information of two languages during training process.

With the revival of interest in deep learning (Hinton and Salakhutdinov, 2006), shared deep representations (or embeddings) (Bengio et al., 2013) are employed for CLSC (Chandar A P et al., 2013). Usually, paired sentences from parallel corpora are used to learn word embeddings across languages (Chandar A P et al., 2013; Chandar A P et al., 2014), eliminating the need of MT systems. The learned bilingual embeddings could easily project the training data and test data into a common space, where training and testing are performed. However, high-quality bilingual embeddings rely on the large-scale task-related parallel corpora, which are not always readily available. Meanwhile, though semantic similarities across languages are captured during bilingual embedding learning process, sentiment information of

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 430–440,
Beijing, China, July 26-31, 2015.

text is ignored. That is, bilingual embeddings learned from unlabeled parallel corpora are not effective enough for CLSC because of a lack of explicit sentiment information. Tang and Wan (2014) first proposed a bilingual sentiment embedding model using the original training data and the corresponding translations through a linear mapping rather than deep learning technique.

This paper proposes a denoising autoencoder based approach to learning bilingual sentiment word embeddings (**BSWE**) for CLSC, which incorporates sentiment polarities of text into the bilingual embeddings. The proposed approach learns BSWE with the original labeled documents and their translations instead of parallel corpora. The BSWE learning process consists of two phases: the unsupervised phase of semantic learning and the supervised phase of sentiment learning. In the unsupervised phase, sentiment words and their negation features are extracted from the source training data and their translations to represent paired documents. These features are used as inputs for a denoising autoencoder to learn the bilingual embeddings. In the supervised phase, sentiment polarity labels of documents are used to guide BSWE learning for incorporating sentiment information into the bilingual embeddings.

The learned BSWE are applied to project English training data and Chinese test data into a common space. In this space, a linear support vector machine (SVM) is used to perform training and testing. The experiments are carried on NLP&CC 2013 CLSC dataset, including book, DVD and music categories. Experimental results show that our approach achieves 80.68% average accuracy, which outperforms the state-of-the-art systems on this dataset. Although the BSWE are only evaluated on English-Chinese CLSC here, it can be popularized to many other languages.

The major contributions of this work can be summarized as follows:

- We propose bilingual sentiment word embeddings (BSWE) for CLSC based on deep learning technique. Experimental results show that the proposed BSWE significantly outperform the bilingual embeddings by incorporating sentiment information.

- Instead of large-scale parallel corpora, only the labeled English corpora and English-to-Chinese translations are required for BSWE learning. It is proved that in spite of the small-scale of training set, our approach outperforms the state-of-the-art systems in NLP&CC 2013 CLSC share task.

- We employ sentiment words and their negation features rather than all words in documents to learn sentiment-specific embeddings, which significantly reduces the dimension of input vectors as well as improves sentiment classification performance.

2 Related Work

In this section, we review the literature related to this paper from two perspectives: cross-language sentiment classification and embedding learning for sentiment classification.

2.1 Cross-language Sentiment Classification (CLSC)

The critical problem of CLSC is how to bridge the gap between the source language and target language. Machine translations or parallel corpora are usually employed to solve this problem. We present a brief review of CLSC from two aspects: machine translation based approaches and parallel corpora based approaches.

Machine translation based approaches use MT systems to project training data into the target language or test data into the source language. Wan (2009) proposed a co-training approach for CLSC. The approach first translated Chinese test data into English, and English training data into Chinese. Then, they performed training and testing in two independent views: English view and Chinese view. Gui et al. (2013) combined self-training approach with co-training approach by estimating the confidence of each monolingual system. Li et al. (2013) selected the samples in the source language that were similar to those in the target language to decrease the gap between two languages. Zhou et al. (2014a) proposed a combination CLSC model, which adopted denoising autoencoders (Vincent et al., 2008) to enhance the robustness to translation errors of the input.

Most recently, a number of studies adopt deep learning technique to learn bilingual representations with parallel corpora. Bilingual representations have been successfully applied in many NLP tasks, such as machine translation (Zou et al., 2013), sentiment classification (Chandar A P et al., 2013; Zhou et al., 2014b), text classification (Chandar A P et al., 2014), etc.

Chandar A P et al. (2013) learned bilingual representations with aligned sentences throughout two phases: the language-specific representation learning phase and the shared representation learning phase. In the language-specific representation learning phase, they applied autoencoders to obtain a language-specific representation for each entity in two languages respectively. In shared representation learning phase, pairs of parallel language-specific representations were passed to an autoencoder to learn bilingual representations. To joint language-specific representations and bilingual representations, Chandar A P et al. (2014) integrated the two learning phases into a unified process to learn bilingual embeddings. Zhou et al. (2014b) employed bilingual representations for English-Chinese CLSC. The work mentioned above employed aligned sentences in bilingual embedding learning process. However, in the sentiment classification process, only representations in the source language are used for training, and representations in the target language are used for testing, which ignores the interactions of semantic information between the source language and target language.

2.2 Embedding Learning for Sentiment Classification

Bilingual embedding learning algorithms focus on capturing syntactic and semantic similarities across languages, but ignore sentiment information. To date, many embedding learning algorithms have been developed for sentiment classification problem by incorporating sentiment information into word embeddings. Maas et al. (2011) presented a probabilistic model that combined unsupervised and supervised techniques to learn word vectors, capturing semantic information as well as sentiment information. Wang et al. (2014) introduced sentiment labels into Neural Network Language Models (Bengio et al., 2003) to enhance sentiment expression ability of word vectors. Tang et al. (2014) theoretically and empirically analyzed the effects of the syntactic context and sentiment information in word vectors, and showed that the syntactic context and sentiment information were equally important to sentiment classification.

Recent years have seen a surge of interest in word embeddings with deep learning technique (Bespalov et al., 2011; Glorot et al., 2011; Socher et al., 2011; Socher et al., 2012), which have been empirically shown to preserve linguistic regularities (Mikolov et al., 2013). Our work focuses on learning bilingual sentiment word embeddings (B-SWE) with deep learning technique. Unlike the work of Chandar A P et al. (2014) that adopted parallel corpora to learn bilingual embeddings, we only use training data and their translations to learn BSWE. More importantly, sentiment information is integrated into bilingual embeddings to improve their performance in CLSC.

3 Bilingual Sentiment Word Embeddings (BSWE) for Cross-language Sentiment Classification

3.1 Denoising Autoencoder

It has been demonstrated that the denoising autoencoder could decrease the effects of translation errors on the performance of CLSC (Zhou et al., 2014a). This paper proposes a deep learning based approach, which employs the denoising autoencoder to learn the bilingual embeddings for CLSC.

A denoising autoencoder is the modification of an autoencoder. The autoencoder (Bengio et al., 2007) includes an encoder f_θ and a decoder $g_{\theta'}$. The encoder maps a d-dimensional input vector $\mathbf{x} \in [0,1]^d$ to a hidden representation $\mathbf{y} \in [0,1]^{d'}$ through a deterministic mapping $\mathbf{y} = f_\theta(\mathbf{x}) = \sigma(\mathbf{W}\mathbf{x} + \mathbf{b})$, parameterized by $\theta = \{\mathbf{W}, \mathbf{b}\}$. $\mathbf{W}$ is a weight matrix, $\mathbf{b}$ is a bias term, and $\sigma(x)$ is the activation function. The decoder maps $\mathbf{y}$ back to a reconstructed vector $\hat{\mathbf{x}} = g_{\theta'}(\mathbf{y}) = \sigma(\mathbf{W}^T\mathbf{y} + \mathbf{c})$, parameterized by $\theta' = \{\mathbf{W}^T, \mathbf{c}\}$, where $\mathbf{c}$ is the bias term for reconstruction.

Through the process of encoding and decoding, the parameters θ and θ' of the autoencoder will be trained by gradient descent to minimize the loss function. The sum of reconstruction cross-entropies across the training set is usually used as the loss function:

$$l(x) = -\sum_{i=1}^{d}[\mathbf{x}_i \log \hat{\mathbf{x}}_i + (1-\mathbf{x}_i)\log(1-\hat{\mathbf{x}}_i)] \quad (1)$$

A denoising autoencoder enhances robustness to noises by corrupting the input $\mathbf{x}$ to a partially destroyed version $\tilde{\mathbf{x}}$. The desired noise level of the input $\mathbf{x}$ can be changed by adjusting the destruction fraction ν. For each input $\mathbf{x}$, a fixed number νd (d is the dimension of $\mathbf{x}$) of components are selected randomly, and their values are set to 0, while the others are left untouched. Like an autoencoder, the destroyed input $\tilde{\mathbf{x}}$ is mapped to a latent representation $\mathbf{y} = f_\theta(\tilde{\mathbf{x}}) = \sigma(\mathbf{W}\tilde{\mathbf{x}} + \mathbf{b})$. Then $\mathbf{y}$ is mapped back to a reconstructed vector $\hat{\mathbf{x}}$ through $\hat{\mathbf{x}} = g_{\theta'}(\mathbf{y}) = \sigma(\mathbf{W}^T\mathbf{y} + \mathbf{c})$. The loss function of a denoising autoencoder is the same as that of an autoencoder. Minimizing the loss makes $\hat{\mathbf{x}}$ close to the input $\mathbf{x}$ rather than $\tilde{\mathbf{x}}$.

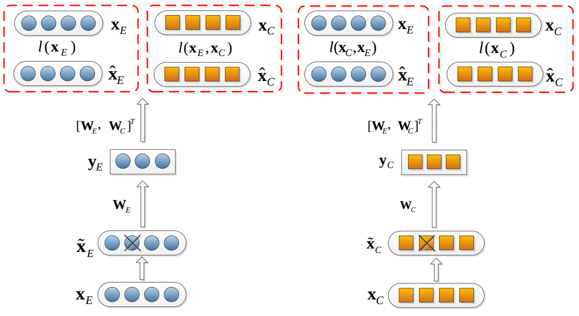
Our BSWE learning process can be divided into two phases: the unsupervised phase of semantic learning and the supervised phase of sentiment learning. In the unsupervised phase, a denoising autoencoder is employed to learn the bilingual embeddings. In the supervised phase, the sentiment information is incorporated into the bilingual embeddings based on sentiment labels of documents to obtain BSWE.

3.2 Unsupervised Phase of the Bilingual Embedding Learning

In the unsupervised phase, the English training documents and their Chinese translations are employed to learn the bilingual embeddings (Sentiment polarity labels of documents are not employed in this phase). Based on the English documents, 2,000 English sentiment words in MPQA subjectivity lexicon[1] are extracted by the Chi-square method (Galavotti et al., 2000). Their corresponding Chinese translations are used as Chinese sentiment words. Besides, some sentiment words are often modified by negation words, which lead to inversion of their polarities. Therefore, negation features are introduced to each sentiment word to represent its negative form.

We take into account 14 frequently-used negation words in English such as *not* and *none*; 5 negation words in Chinese such as 不 (*no/not*) and 没有 (*without*). A sentiment word modified by these negation words in the window [-2, 2] is considered as its negative form in this paper, while sentiment word features remain the initial meaning. Negation features use binary expressions. If a sentiment word is not modified by negation words, the value of its negation features is set to 0. Thus, the sentiment words and their corresponding negation features in English and Chinese are adopted to represent the document pairs $(\mathbf{x}_E, \mathbf{x}_C)$.

We expect that pairs of documents could be forced to capture the common semantic information of two languages. To achieve this, a denoising autoencoder is used to perform the reconstructions of paired documents in both English and Chinese. Figure 1 shows the framework of bilingual embedding learning.



(a) reconstruction from $\mathbf{x}_E$ (b) reconstruction from $\mathbf{x}_C$

Figure 1: The framework of bilingual embedding learning.

For the corrupted versions $\tilde{\mathbf{x}}_E$ ($\tilde{\mathbf{x}}_C$) of the initial input vector $\mathbf{x}_E$ ($\mathbf{x}_C$), we use the sigmoid function as the activation function to extract latent representations:

$$\mathbf{y}_E = f_\theta(\tilde{\mathbf{x}}_E) = \sigma(\mathbf{W}_E\tilde{\mathbf{x}}_E + \mathbf{b}) \tag{2}$$

$$\mathbf{y}_C = f_\theta(\tilde{\mathbf{x}}_C) = \sigma(\mathbf{W}_C\tilde{\mathbf{x}}_C + \mathbf{b}) \tag{3}$$

where $\mathbf{W}_E$ and $\mathbf{W}_C$ are the language-specific word representation matrices, corresponding to English and Chinese respectively. Notice that the bias $\mathbf{b}$ is shared to ensure that the produced representations in two languages are on the same scale.

For the latent representations in either language, we would like two decoders to perform reconstructions in English and Chinese respectively. As shown in Figure 1(a), for the latent representation $\mathbf{y}_E$ in English, one decoder is used to map $\mathbf{y}_E$ back to a reconstruction $\hat{\mathbf{x}}_E$ in English, and the other is used to map $\mathbf{y}_E$ back to a reconstruction $\hat{\mathbf{x}}_C$ in Chinese such that:

$$\hat{\mathbf{x}}_E = g_{\theta'}(\mathbf{y}_E) = \sigma(\mathbf{W}_E^T\mathbf{y}_E + \mathbf{c}_E) \tag{4}$$

$$\hat{\mathbf{x}}_C = g_{\theta'}(\mathbf{y}_E) = \sigma(\mathbf{W}_C^T\mathbf{y}_E + \mathbf{c}_C) \tag{5}$$

where $\mathbf{c}_E$ and $\mathbf{c}_C$ are the biases of the decoders in English and Chinese, respectively. Similarly, the same steps repeat for the latent representation $\mathbf{y}_C$ in Chinese, which are shown in Figure 1(b).

The encoder and decoder structures allow us to learn a mapping within and across languages. Specifically, for a given document pair $(\mathbf{x}_E, \mathbf{x}_C)$, we can learn bilingual embeddings to reconstruct $\mathbf{x}_E$ from itself (loss $l(\mathbf{x}_E)$), reconstruct $\mathbf{x}_C$ from itself (loss $l(\mathbf{x}_C)$), construct $\mathbf{x}_C$ from

[1] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon

$\mathbf{x}_E$ (loss $l(\mathbf{x}_E, \mathbf{x}_C)$), construct $\mathbf{x}_E$ from $\mathbf{x}_C$ (loss $l(\mathbf{x}_C, \mathbf{x}_E)$) and reconstruct the concatenation of $\mathbf{x}_E$ and $\mathbf{x}_C$ ($[\mathbf{x}_E, \mathbf{x}_C]$) from itself (loss $l([\mathbf{x}_E, \mathbf{x}_C], [\hat{\mathbf{x}}_E, \hat{\mathbf{x}}_C])$). The sum of 5 losses is used as the loss function of bilingual embeddings:

$$\begin{aligned} L =& l(\mathbf{x}_E) + l(\mathbf{x}_C) + l(\mathbf{x}_E, \mathbf{x}_C) + l(\mathbf{x}_C, \mathbf{x}_E) \\ & + l([\mathbf{x}_E, \mathbf{x}_C], [\hat{\mathbf{x}}_E, \hat{\mathbf{x}}_C]) \end{aligned} \tag{6}$$

3.3 Supervised Phase of Sentiment Learning

In the unsupervised phase, we have learned the bilingual embeddings, which could capture the semantic information within and across languages. However, the sentiment polarities of text are ignored in the unsupervised phase. Bilingual embeddings without sentiment information are not effective enough for sentiment classification task. This paper proposes an approach to learning B-SWE for CLSC, which introduces a supervised learning phase to incorporate sentiment information into the bilingual embeddings. The process of supervised phase is shown in Figure 2.

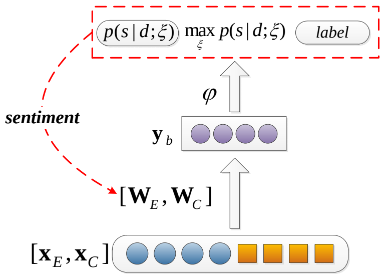


Figure 2: The supervised learning process.

For paired documents $[\mathbf{x}_E, \mathbf{x}_C]$, the sigmoid function is adopted as the activation function to extract latent bilingual representations $\mathbf{y}_b = \sigma([\mathbf{W}_E, \mathbf{W}_C][\mathbf{x}_E, \mathbf{x}_C] + \mathbf{b})$, where $[\mathbf{W}_E, \mathbf{W}_C]$ is the concatenation of $\mathbf{W}_E$ and $\mathbf{W}_C$.

The latent bilingual representation $\mathbf{y}_b$ is used to obtain the positive polarity probability $p(s = 1|d; \xi)$ of a document through a sigmoid function:

$$p(s = 1|d; \xi) = \sigma(\varphi^T \mathbf{y}_b + b_l) \tag{7}$$

where φ is the logistic regression weight vector and b_l is the bias of logistic regression. The sentiment label s is a Boolean value representing sentiment polarity of a document: $s = 0$ represents negative polarity and $s = 1$ represents positive polarity. Parameter $\xi^* = \{[\mathbf{W}_E, \mathbf{W}_C]^*, \mathbf{b}^*, \varphi^*, b_l^*\}$ is learned by maximizing the objective function according to the sentiment polarity label s_i of document d_i:

$$\xi^* = \arg\max_{\xi} \sum_{i=1} \log p(s_i|d_i; \xi) \tag{8}$$

Through the supervised learning phase, $[\mathbf{W}_E, \mathbf{W}_C]$ is optimized by maximizing sentiment polarity probability. Thus, rich sentiment information is encoded into the bilingual embeddings.

The following experiments will prove that the proposed BSWE outperform the traditional bilingual embeddings significantly in CLSC.

3.4 Bilingual Document Representation Method (BDR)

Once we have learned BSWE $[\mathbf{W}_E, \mathbf{W}_C]$, whose columns are representations for sentiment words, we can use them to represent documents in two languages.

Given an English training document d_E containing 2,000 sentiment word features $s_1, s_2, \cdots, s_{2,000}$ and 2,000 corresponding negation features, we represent it as the TF-IDF weighted sum of BSWE:

$$\phi_{d_E} = \sum_{i=1}^{4,000} TF-IDF(s_i)\mathbf{W}_{E.,s_i} \tag{9}$$

Similarly, for its Chinese translation d_C containing 2,000 sentiment word features $t_1, t_2, \cdots, t_{2,000}$ and 2,000 corresponding negation features, we represent it as:

$$\phi_{d_C} = \sum_{j=1}^{4,000} TF-IDF(t_j)\mathbf{W}_{C.,t_j} \tag{10}$$

We propose a bilingual document representation method (**BDR**) in this paper, which represents each document d_i with the concatenation of its English and Chinese representations $[\phi_{d_E}, \phi_{d_C}]$. B-DR is expected to enhance the ability of sentiment expression for further improving the classification performance. Such bilingual document representations are fed to a linear SVM to perform sentiment classification.

4 Experiment

4.1 Experimental Settings

Data Set. The proposed approach is evaluated on NLP&CC 2013 CLSC dataset[2] [3]. The dataset con-

[2] http://tcci.ccf.org.cn/conference/2013/dldoc/evsam03.zip

[3] http://tcci.ccf.org.cn/conference/2013/dldoc/evdata03.zip

sists of product reviews on three categories: book, DVD, and music. Each category contains 4,000 English labeled data as training data (the ratio of the number of positive and negative samples is 1:1) and 4,000 Chinese unlabeled data as test data.

Tools. In our experiments, Google Translate[4] is adopted for both English-to-Chinese and Chinese-to-English translation. ICTCLAS (Zhang et al., 2003) is used as Chinese word segmentation tool. A denoising autoencoder is developed based on Theano system (Bergstra et al., 2010). BSWE are trained for 50 and 30 epochs in unsupervised phase and supervised phases respectively. SVM^{light} (Joachims, 1999) is used to train linear SVM sentiment classifiers

Evaluation Metric. The performance is evaluated by the classification accuracy for each category, and the average accuracy of three categories, respectively. The category accuracy is defined as:

$$Accuracy_c = \frac{\#system\_correct_c}{\#system\_total_c} \quad (11)$$

where c is one of the three categories, and $\#system\_correct_c$ and $\#system\_total_c$ stand for the number of being correctly classified reviews and the number of total reviews in the category c, respectively.

The average accuracy is shown as:

$$Average = \frac{1}{3}\sum_c Accuracy_c \quad (12)$$

4.2 Evaluations on BSWE

In this section, we evaluate the quality of BSWE for CLSC. The dimension of bilingual embeddings d is set to 50, and destruction fraction ν is set to 0.2.

Effects of Bilingual Embedding Learning Methods

We first compare our unsupervised bilingual embedding learning method with the parallel corpora based method. The parallel corpora based method uses the paired documents in the parallel corpus[5] to learn bilingual embeddings, while our method only uses the English training documents and their Chinese translations (Sentiment polarity labels of documents are not employed here). The Boolean feature weight calculation method is adopted to represent documents for bilingual embedding learning and BDR is employed to represent training data and test data for sentiment classification. To represent the paired documents in the parallel corpus, 27,597 English words and 31,786 Chinese words are extracted for bilingual embedding learning. Our method only needs 2,000 English sentiment words, 2,000 Chinese sentiment words, and their negation features, which significantly reduces the dimension of input vectors.

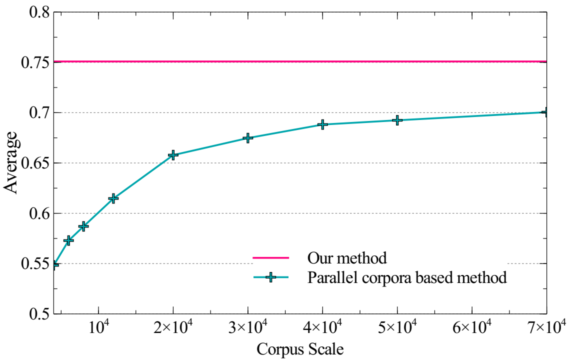

Figure 3: Our unsupervised bilingual embedding learning method vs. Parallel corpora based method.

The average accuracies on NLP&CC 2013 test data of the two bilingual embedding learning methods are shown in Figure 3. As can be seen from Figure 3, when the corpus scales of the two methods are the same (4,000 paired documents), our method (75.09% average accuracy) surpasses the parallel corpora method (54.82% average accuracy) by about 20%. With the scale of the parallel corpora increasing, the performance of parallel corpora based method is steadily improved. However, the performance is not as good as our bilingual embedding learning method. Though the document number of the parallel corpus is up to 70,000 , the average accuracy is only 70.05%. It is proved that our method is more suitable for learning bilingual embeddings for cross-language sentiment classification than the parallel corpora based method.

Effects of Feature Weight in Bilingual Embeddings

In this part, we compare the Boolean and TF-IDF feature weight calculation methods in bilingual embedding learning process.

Table 1 shows the classification accuracy with

[4] http://translate.google.cn/

[5] http://www.datatang.com/data/45485

Category	book	DVD	music	Average
Boolean	76.22%	74.30%	74.75%	75.09%
TF-IDF	76.65%	77.60%	74.50%	76.25%

Table 1: The classification accuracy with the Boolean and TF-IDF methods.

the Boolean and TF-IDF methods. Generally, the TF-IDF method performs better than the Boolean method. The average accuracy of the TF-IDF method is 1.16% higher than the Boolean method, which illustrates that the TF-IDF method could reflect the latent contribution of sentiment words to each document effectively. The TF-IDF weight calculation method is exploited in the following experiments. Notice that sentiment information is not yet introduced in the bilingual embeddings here.

Effects of Sentiment Information in BSWE

Incorporating sentiment information in the bilingual embeddings, the performance of bilingual embeddings (without sentiment information) and BSWE (with sentiment information) is compared in Figure 4.

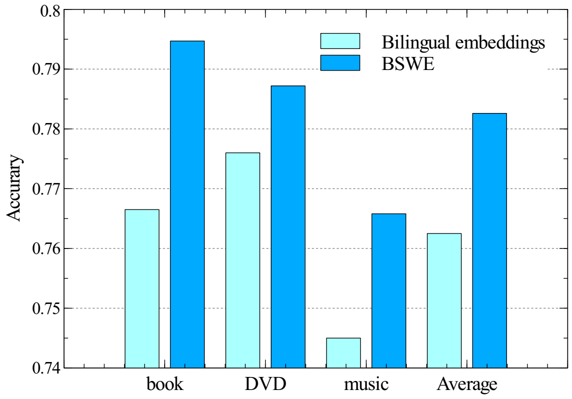

Figure 4: Performance comparison of the bilingual embeddings and BSWE.

As can be seen from Figure 4, by encoding sentiment information in the bilingual embeddings, the performance in book, DVD and music categories significantly improves to 79.47%, 78.72% and 76.58% respectively (2.82% increase in book, 1.12% in DVD, and 2.08% in music). The average accuracy reaches 78.26%, which is 2.01% higher than that of the bilingual embeddings. The experimental results indicate the effectiveness of sentiment information in the bilingual embedding learning. The BSWE learning approach is employed for CLSC in the following experiments.

Effects of Bilingual Document Representation Method

In this experiment, our bilingual document representation method (BDR) is compared with the following monolingual document representation methods.

En-En: This method represents training and test documents in English only with $\mathbf{W}_E$. English training documents and Chinese-to-English translations of test documents are both represented with $\mathbf{W}_E$.

Cn-Cn: This method represents training and test documents in Chinese only with $\mathbf{W}_C$. English-to-Chinese translations of training documents and Chinese test documents are both represented with $\mathbf{W}_C$.

En-Cn: This method represents English training documents with $\mathbf{W}_E$, while represents Chinese test documents with $\mathbf{W}_C$. Chandar A P et al. (2014) employed this method in their work.

BDR: This method adopts our bilingual document representation method, which represents training and test documents with both $\mathbf{W}_E$ and $\mathbf{W}_C$.

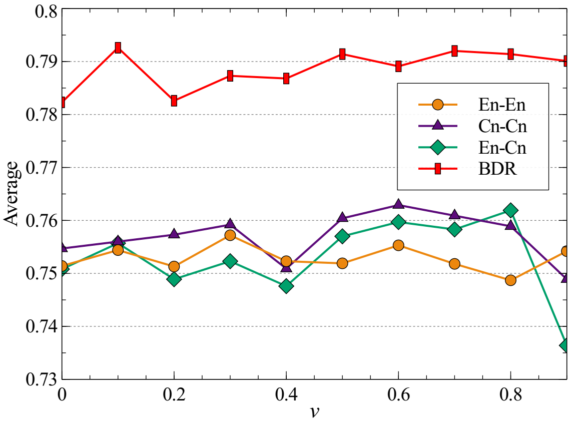

Figure 5: Effects of bilingual document representation method (BDR).

Figure 5 shows the average accuracy curves of different document representation methods with different destruction fraction ν. We vary ν from 0 to 0.9 with an interval of 0.1.

From Figure 5 we can see that En-En, Cn-Cn, and En-Cn get similar results. BDR performs constantly better than the other representation methods throughout the interval [0, 0.9]. The absolute superiority of BDR benefits from the enhanced ability of sentiment expression.

Meanwhile, when the input $\mathbf{x}$ is partially destroyed (ν varies from 0.1 to 0.9), the performance of En-En, Cn-Cn and En-Cn remains stable, which illustrates the robustness of the denoising autoencoder to corrupting noises. In addition, the average accuracies of BDR in the interval $\nu \in [0.1, 0.9]$ are all higher than the average accuracy under the condition $\nu = 0$ (78.23%). Therefore, adding noises properly to the training data could improve the performance of BSWE for CLSC.

4.3 Influences of Dimension d and Destruction Fraction ν

Figure 6 shows the relationship between accuracies and dimension d of BSWE as well as that between accuracies and destruction fraction ν in autoencoders in different categories. Dimension of embeddings d varies from 50 to 500, and destruction fraction ν varies from 0.1 to 0.9.

As shown in Figure 6, the average accuracies generally move upward as dimension of BSWE increasing. Generally, the average accuracies keep higher than 80% with ν varying from 0.1 to 0.5 as well as dimension varying from 300 to 500. When $\nu = 0.1$ and $d = 400$, the average accuracy reaches the peak value 80.68% (category accuracy of 81.05% in book, 81.60% in DVD, and 79.40% in music). The experimental results show that in BSWE learning process, increasing the dimension of embeddings or properly adding noises to the training data helps improve the performance of CLSC. In this paper, we only evaluate BSWE when dimension d varies from 50 to 500. However, there is still space for further improvement if d continues to increase.

4.4 Comparison with Related Work

Table 2 shows comparisons of the performance between our approach and some state-of-the-art systems on NLP&CC 2013 CLSC dataset. Our approach achieves the best performance with an 80.68% average accuracy. Compared with the recent related work, our approach is more effective and suitable for eliminating the language gap.

Chen et al. (2014) translated Chinese test data into English and then gave different weights to sentiment words according to the subject-predicate component of sentiment words. They got 77.09% accuracy and took the 2nd place in NLP&CC 2013 CLSC share task. The machine translation based approach was limited by the translation errors.

System	book	DVD	music	Average
Chen et al. (2014)	77.00%	78.33%	75.95%	77.09%
Gui et al. (2013)	78.70%	79.65%	78.30%	78.89%
Gui et al. (2014)	80.10%	81.60%	78.60%	80.10%
Zhou et al. (2014a)	80.63%	80.95%	78.48%	80.02%
Our approach	**81.05%**	**81.60%**	**79.40%**	**80.68%**

Table 2: Performance comparisons on the NLP&CC 2013 CLSC dataset.

Gui et al. (2013; 2014) and Zhou et al. (2014a) adopted the multi-view approach to bridge the language gap. Gui et al. (2013) proposed a mixed CLSC model by combining co-training and transfer learning strategies. They achieved the highest accuracy of 78.89% in NLP&CC CLSC share task. Gui et al. (2014) further improved the accuracy to 80.10% by removing noise from the transferred samples to avoid negative transfers. Zhou et al. (2014a) built denoising autoencoders in two independent views to enhance the robustness to translation errors in the inputs and achieved 80.02% accuracy. The multi-view approach learns language-specific classifiers in each view during training process, which is difficult to capture the common sentiment information of the two languages. Our approach integrates the bilingual embedding learning into a unified process, and outperforms Chen et al. (2014), Gui et al. (2013), Gui et al. (2014) and Zhou et al. (2014a) by 3.59%, 1.79%, 0.58%, and 0.66% respectively. The superiority of our approach benefits from the unified bilingual embedding learning process and the integration of semantic and sentiment information.

5 Conclusion and Future Work

This paper proposes an approach to learning BSWE by incorporating sentiment information into the bilingual embeddings for CLSC. The proposed approach learns BSWE with the labeled documents and their translations rather than parallel corpora. In addition, BDR is proposed to enhance the sentiment expression ability which combines English and Chinese representations. Experiments on the NLP&CC 2013 CLSC dataset show that our approach outperforms the previous state-of-the-art systems as well as traditional bilingual embedding systems. The proposed BSWE are only evaluated on English-Chinese CLSC in this paper, but it can be popularized to other languages.

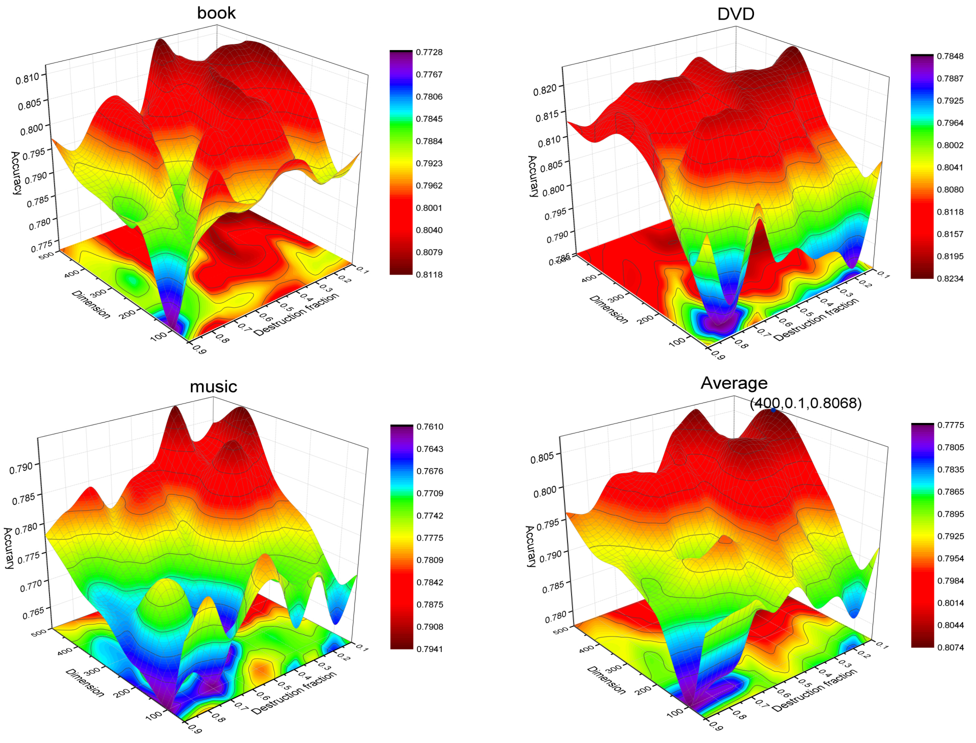

Figure 6: The relationship between accuracies and dimension d as well as that between accuracies and destruction fraction ν.

Both semantic and sentiment information play an important role in sentiment classification. In the following work, we will further investigate the relationship between semantic and sentiment information for CLSC, and balance their functions to optimize their combination for CLSC.

Abstract

We present a new factoid-annotated dataset for evaluating content models for scientific survey article generation containing 3,425 sentences from 7 topics in *natural language processing*. We also introduce a novel HITS-based content model for automated survey article generation called HITSUM that exploits the lexical network structure between sentences from citing and cited papers. Using the factoid-annotated data, we conduct a pyramid evaluation and compare HITSUM with two previous state-of-the-art content models: C-Lexrank, a network based content model, and TOPICSUM, a Bayesian content model. Our experiments show that our new content model captures useful survey-worthy information and outperforms C-Lexrank by 4% and TOPICSUM by 7% in pyramid evaluation.

1 Introduction

Survey article generation is the task of automatically building informative surveys for scientific topics. Given the rapid growth of publications in scientific fields, the development of such systems is crucial as human-written surveys exist for a limited number of topics and get outdated quickly. In this paper, we investigate content models for extracting survey-worthy information from scientific papers. Such models are an essential component of any system for automatic survey article generation. Earlier work in the area of survey article generation has investigated content models based on lexical networks (Mohammad et al., 2009; Qazvinian and Radev, 2008). These models take as input citing sentences that describe important papers on the topic and assign them a salience score based on centrality in a lexical network formed by the input citing sentences. In this paper, we propose a new content model based on network structure previously unexplored for this task that exploits the lexical relationship between citing sentences and the sentences from the original papers that they cite. Our new formulation of the lexical network structure fits nicely with the hubs and authorities model for identifying important nodes in a network (Kleinberg, 1999), leading to a new content model called HITSUM. In addition to this new content model, we also describe how Bayesian content models previously explored in the news domain can be adapted for the content modeling task for survey generation.

Table 1: Sample factoids from the topics of *question answering* and *dependency parsing* along with their factoid weights.

For the task of evaluating various content models discussed in this paper, we have annotated a total of 3,425 sentences across 7 topics in the field of *natural language processing* with factoids from each of the topics. The factoids we use were extracted from existing survey articles and tutorials on each topic (Jha et al., 2013), and thus represent information that must be captured by a survey article on the corresponding topic. Each of the factoids is assigned a weight based on its frequency in the surveys/tutorials, which allows us to do pyra-

mid evaluation of our content models. Some sample factoids are shown in Table 1. Evaluation using factoids extracted from existing survey articles can help us understand the limits of automated survey article generation and how well these systems can be expected to perform. For example, if certain kinds of factoids are missing consistently from our input sentences, improvements in content models are unlikely to get us closer to the goal of generating survey articles that match those generated by humans, and effort must be directed to extracting text from other sources that will contain the missing information. On the other hand, if most of the factoids exist in the input sentences but important factoids are not found by the content models, we can think of strategies for improving these models by doing error analysis.

The main contributions of this paper are:

- HITSUM, a new HITS-based content model for automatic survey generation for scientific topics.

- A new dataset of 3,425 factoid-annotated sentences for scientific articles in 7 topics.

- Experimental results for pyramid evaluation comparing three existing content models (Lexrank, C-Lexrank, TOPICSUM) with HITSUM.

The rest of this paper is organized as follows. Section 2 describes the dataset used in our experiment and the factoid annotation process. Section 3 describes each of the content models used in our experiments including HITSUM. Section 4 describes our experiments and Section 5 summarizes the results. We summarize the related work in Section 6 and conclude in Section 7.

2 Data

Prior research in automatic survey generation has explored using text from different parts of scientific papers. Some of the recent work has treated survey generation as a direct extension of single paper summarization (Qazvinian and Radev, 2008) and used citing sentences to a set of relevant papers as the input for the summarizer (Mohammad et al., 2009; Qazvinian et al., 2013). However, in our prior work, we have observed that it's difficult to generate coherent and readable summaries using just citing sentences and have proposed the use of sentences from introductory texts of papers that cite a number of important papers on a topic (Jha et al., 2015). The use of full text allows for the use of discourse structure of these documents in framing coherent and readable surveys. Since the content models we explore are meant to be part of a larger system that should be able to generate coherent and readable survey articles, we use the introduction sentences for our experiments as well.

The corpus we used for extracting our experimental data was the ACL Anthology Network, a comprehensive bibliographic dataset that contains full text and citations for papers in most of the important venues in *natural language processing* (Radev et al., 2013). An oracle method is used for selecting the initial set of papers for each topic. For each topic, the bibliographies of at least three human-written surveys were extracted, and any papers that appeared in more than one survey were added to the target document set for the topic.

The text for summarization is extracted from introductory sections of papers that cite papers in the target document set. The intuition behind this is that the introductory sections of papers that cite these target document summarize the research in papers from the target document set as well as the relationships between these papers. Thus, these introductions can be thought of as mini-surveys for specific aspects of the topic; combining text from these introductory sections should allow us to generate good comprehensive survey articles for the topic[1]. For our experiments, we sort the citing papers based on the number of papers they cite

[1] Other sections of papers might have such information, e.g. related work. Initial data analysis showed, however, that not all papers in our corpus had related work sections. Thus for consistency, we decided to use introduction sections. The perfect system for this task would be able to extract "related work style" text segments from an entire paper.

Input sentence	Factoids
According to [1] , the corpus based supervised machine learning methods are the most successful approaches to WSD where contextual features have been used mainly to distinguish ambiguous words in these methods.	supervised wsd, corpus based wsd
Compared with supervised methods, unsupervised methods do not require tagged corpus, but the precision is usually lower than that of the supervised methods.	supervised wsd, unsupervised wsd
Word sense disambiguation (WSD) has been a hot topic in natural language processing, which is to determine the sense of an ambiguous word in a specific context.	definition of word sense disambiguation
Improvement in the accuracy of identifying the correct word sense will result in better machine translation systems, information retrieval systems, etc.	wsd for machine translation, wsd for information retrieval
The SENSEVAL evaluation framework (Kilgarriff 1998) was a DARPA-style competition designed to bring some conformity to the field of WSD, although it has yet to achieve that aim completely.	senseval

Table 3: Sample input sentences from the topic of *word sense disambiguation* annotated with factoids.

in the target document set, pick the top 20 papers, and extract sentences from their introductions to form the input text for the summarizer. The seven topics used in our experiments and input size for each topic are shown in Table 2.

Once the input text for each topic has been extracted, we annotate the sentences in the input text with factoids for that topic. Some annotated sentences in the topic of *word sense disambiguation* are shown in Table 3. Given this new annotated data, we can compare how the factoids are distributed across different citing sentences (as annotated by Jha et al. (2013)) and introduction sentences that we have annotated. For this, we divide the factoids into five categories: definitions, venue, resources, methodology, and applications. The fractional distribution of factoids in these categories is shown in Table 4. We can see that the distribution of factoids relating to venues, methodology and applications is similar for the two datasets. However, factoids related to definitional sentences are almost completely missing in the citing sentences data. This lack of background information in citing sentences is one of the motivations for using introduction sentences for survey article generation as opposed to previous work.

The complete set of factoids as well as annotated sentences for all the topics is available for download at `http://clair.si.umich.edu/corpora/Surveyor_CM_Data.tar.gz`.

3 Content Models

We now describe each of the content models used in our experiments.

Factoid category	% Citing	% Intro
definitions	0	4
venue	6	6
resources	18	2
methodology	70	83
applications	6	5

Table 4: Fractional distribution of factoids across various categories in citing sentences vs introduction sentences.

3.1 Lexrank

Lexrank is a network-based content selection algorithm that serves as a baseline for our experiments. Given an input set of sentences, it first creates a network using these sentences where each node represents a sentence and each edge represents the tf-idf cosine similarity between the sentences. Two methods for creating the network are possible. First, we can remove all edges that are lower than a certain threshold of similarity (generally set to 0.1). The Lexrank value for a node $p(u)$ in this case is calculated as:

$$\frac{1-d}{N} + d \sum_{v \in adj[u]} \frac{p(v)}{deg(v)}$$

Where N is the total number of sentences, d is the damping factor that controls the probability of a random jump (usually set to 0.85), $deg(v)$ is the degree of the node v, and $adj[u]$ is the set of nodes connected to the node u. A different way of creating the network is to treat the sentence similarities as edge weights and use the adjacency matrix as a transition matrix after normalizing the rows; the formula then becomes:

A dictionary such as the LDOCE has broad coverage of word senses, useful for WSD .

This paper describes a program that disambiguates English word senses in unrestricted text using statistical models of the major Roget's Thesaurus categories.

Our technique offers benefits both for online semantic processing and for the challenging task of mapping word senses across multiple MRDs in creating a merged lexical database.

The words in the sentences may be any of the 28,000 headwords in Longman's Dictionary of Contemporary English (LDOCE) and are disambiguated relative to the senses given in LDOCE.

This paper describes a heuristic approach to automatically identifying which senses of a machine-readable dictionary (MRD) headword are semantically related versus those which correspond to fundamentally different senses of the word.

Figure 1: A sentence from P_{citing} with a high hub score (bolded) and some of sentences from P_{cited} that it links to (italicised). The sentence from P_{citing} obtain a high hub score by being connected to the sentences with high authority scores.

$$\frac{1-d}{N} + d \sum_{v \in adj[u]} \frac{cos(u,v)}{TotalCos_v} p(v)$$

Where $cos(u, v)$ gives the tf-idf cosine similarity between sentence u and v and $TotalCos_v = \sum_{z \in adj[v]} cos(z, v)$. In our experiments, we employ this second formulation. The above equation can be solved efficiently using the power method (Newman, 2010) to obtain $p(u)$ for each node, which is then used as the score for ordering the sentences. The final Lexrank values $p(u)$ for a node represent the stationary distribution of the Markov chain represented by the transition matrix. Lexrank has been shown to perform well in summarization experiments (Erkan and Radev, 2004).

3.2 C-Lexrank

C-Lexrank is a clustering-based summarization system that was proposed by Qazvinian and Radev (2008) to summarize different perspectives in citing sentences that reference a paper or a topic. To create summaries, C-LexRank constructs a fully connected network in which vertices are sentences, and edges are cosine similarities calculated using the tf-idf vectors of citation sentences. It then employs a hierarchical agglomeration clustering algorithm proposed by Clauset et al. (2004) to find communities of sentences that discuss the same scientific contributions. Once the graph is clustered and communities are formed, the method extracts sentences from different clusters to build a summary. It iterates through the clusters from largest to smallest, choosing the most salient sentence of each cluster, until the summary length limit is reached. The salience of a sentence in its cluster is defined as its Lexrank value in the lexical network formed by sentences in the cluster.

3.3 HITSUM

The input set of sentences in our data come from introductory sections of papers that cite important papers on a topic. We'll refer to the set of citing papers that provide the input text for the summarizer as P_{citing} and the set of important papers that represent the research we are trying to summarize as P_{cited}. Both Lexrank and C-Lexrank work by finding central sentences in a network formed by the input sentences and thus, only use the lexical information present in P_{citing}, while ignoring additional lexical information from the papers in P_{cited}. We now present a formulation that uses the network structure that exists between the sentences in the two sets of papers to incorporate additional lexical information into the summarization system. This system is based on the hubs and authorities or the HITS model (Kleinberg, 1999) and hence is called HITSUM.

HITSUM, in addition to the sentences from the introductory sections of papers in P_{citing}, also uses sentences from the abstracts of P_{cited}. It starts by computing the tf-idf cosine similarity between the sentences of each paper $p_i \in P_{citing}$ with the sentences in the abstracts of each paper $p_j \in P_{cited}$ that is directly cited by p_i. A directed edge is created between every sentence s_i in p_i and s_j in p_j if $sim(s_i, s_j) > s_{min}$, where s_{min} is a similarity threshold (set to 0.1 for our experiments). Once this process has been completed for all papers in P_{citing}, we end up with a bipartite graph between sentences from P_{citing} and P_{cited}.

In this bipartite graph, sentences in P_{cited} that

Figure 2: Top words from different word distributions learned by TopicSum on our input document set of 15 topics. ϕ_B is the background word distribution that captures stop words. $\phi_{C/QA}$ and $\phi_{C/NER}$ are the word distributions for the topics of *question answering* and *named entity recognition* respectively. $\phi_{D/J07-1005}$ is the document-specific word distribution for a single paper in *question answering* that focuses on clinical question answering. $\phi_{D/I08-1071}$ is the document-specific word distribution for a single paper in *named entity recognition* that focuses on named entity recognition in Wikipedia articles.

have a lot of incoming edges represent sentences that presented important contributions in the field. Similarly, sentences in P_{citing} that have a lot of outgoing edges represent sentences that summarize a number of important contributions in the field. This suggests using the HITS algorithm, which, given a network, assigns hubs and authorities scores to each node in the network in a mutually reinforcing way. Thus, nodes with high authority scores are those that are pointed to by a number of good hubs, and nodes with high hub scores are those that point to a number of good authorities. This can be formalized with the following equation for the hub score of a node:

$$h(v) \quad = \sum_{u \in successors(v)} a(u)$$

Where $h(v)$ is the hub score for node v, $successors(v)$ is the set of all nodes that v has an edge to, and $a(u)$ is the authority score for node u. Similarly, the authority score for each node is computed as:

$$a(v) \quad = \sum_{u \in predecessors(v)} h(u)$$

Where $predecessors(v)$ is the set of all nodes that have an edge to v. The hub and authority score for each node can be computed using the power method that starts with an initial value and iteratively updates the scores for each node based on the above equations until the hub and authority scores for each node converge to within a tolerance value (set to 1E-08 for our experiments).

In our bipartite lexical network, we expect sentences in P_{cited} receiving high authority scores to be the ones reporting important contributions and sentences in P_{citing} that receive high hub scores to be sentences summarizing important contributions. Figure 1 shows an example of a sentence with a high hub score from the topic of *word sense disambiguation*, along with some of the sentences that it points to. HitSum computes the hub and authority score for each sentence in the lexical network and then uses the hub scores for sentences in P_{citing} as their relevance score. Sentences from P_{cited} are part of the lexical network, but are not used in the output summary.

3.4 TopicSum

TopicSum is a probabilistic content model presented in Haghighi and Vanderwende (2009) and is very similar to an earlier model called BayesSum proposed by Daumé and Marcu (2006). It is a hierarchical, LDA (Latent Dirichlet Allocation) style model that is based on the following generative story:[2] words in any sentence in the corpus can come from one of three word distributions: a background word distribution ϕ_B that flexibly models stop words, a content word distribution ϕ_C for each document set that models content relevant to the entire document set, and a document-specific word distribution ϕ_D. The word distributions are learned using Gibbs sampling. Given n document sets each with k doc-

[2] To avoid confusion in use of the term "topic," in this paper we refer to topics in the LDA sense as "word distributions." "Topics" in this paper refer to the natural language processing topics such as *question answering*, *word sense disambiguation*, etc.

Topic	Lexrank	C-Lexrank	TopicSum	HitSum

Average	**0.66**	**0.72**	**0.69**	**0.76***

Table 5: Pyramid scores obtained by different content models for each topic along with average scores for each model across all topics. For each topic as well as the average, the best performing method has been highlighted with a *.

uments, we get n content word distributions and $n * k$ document-specific distributions leading to a total of $1 + n + n * k$ word distributions.

To illustrate the kind of distributions TopicSum learns in our dataset, Figure 2 shows the top words along with their probabilities from the background word distribution, two content distributions and two document-specific word distributions. We see that the model effectively captures general content words for each topic. $\phi_{C/QA}$ is the word distribution for the topic of *question answering*, while $\phi_{D/J07-1005}$ is the document-specific word distribution for a specific paper in the document set for *question answering*[3] that focuses on clinical question answering. The word distribution $\phi_{D/J07-1005}$ contains words that are relevant to the specific subtopic in the paper, while $\phi_{C/QA}$ contains content words relevant to the general topic of *question answering*. Similar results can be seen in the word distributions for *named entity recognition* $\phi_{C/NER}$ and the document-specific word distribution for a specific paper in the topic $\phi_{D/I08-1071}$[4] that focuses on comparable entity mining.

These topics, learned using Gibbs sampling, can be used to select sentences for a summary in the following way. To summarize a document set, we greedily select sentences that minimize the KL-divergence of our summary to the document-set-specific topic. Thus, the score for each sentence s is $KL(\phi_C||P_s)$ where P_s is the sentence word distribution with add-one smoothing applied to both distributions. Using this objective, sentences that contain words from the content word distribution with high probability are more likely to be selected in the generated summary.

We implemented TopicSum in Python using Numpy and then optimized it using Scipy Weave. This code is available for use at `https://github.com/rahuljha/content-models`. The repository also contains Python code for HitSum.

4 Experiments

For evaluating our content models, we generated 2,000-character-long summaries using each of the systems (Lexrank, C-Lexrank, HitSum, and TopicSum) for each of the topics. The summaries are generated by ranking the input sentences using each content model and picking the top sentences till the budget of 2,000 characters is reached. Each of these summaries is then given a pyramid score (Nenkova and Passonneau, 2004) computed using the factoids assigned to each sentence.

For the pyramid evaluation, the factoids are organized in a pyramid of order n. The top tier in this pyramid contains the highest weighted factoids, the next tier contains the second highest weighted factoids, and so on. The score assigned to a summary is the ratio of the sum of the weights of the factoids it contains to the sum of weights of an optimal summary with the same number of factoids. Pyramid evaluation allows us to capture how each content model performs in terms of selecting sentences with the most highly weighted factoids. Since the factoids have been extracted from human-written surveys and tutorials on each of the topics, the pyramid score gives us an idea of the survey-worthiness of the sentences selected by

[3] Dina Demner-Fushman and Jimmy Lin. 2007. *Answering Clinical Questions with Knowledge-Based and Statistical Techniques.* Computational Linguistics.

[4] Wisam Dakka and Silviu Cucerzan. 2008. *Augmenting wikipedia with named entity tags.* In Proceedings of IJCNLP.

Question classification is a crucial component of modern question answering system.

A what-type question is defined as the one whose question word is 'what', 'which', 'name' or 'list'.

This metaclassifier beats all published numbers on standard question classification benchmarks [4.4].

Due to its challenge, this paper focuses on what-type question classification.

In this paper, we focus on fine-category classification.

The promise of a machine learning approach is that the QA system builder can now focus on designing features and providing labeled data, rather than coding and maintaining complex heuristic rule bases.

Figure 3: Part of the summary generated by HitSum for the topic of *question answering*.

each content model.

5 Results and Discussion

The results of pyramid evaluation are summarized in Table 5. It shows the pyramid score obtained by each system on each of the topics as well as the average score. The highest performing system on average is HitSum with an average performance of 76%. HitSum does especially well for the topics of *dependency parsing*, *question answering*, and *word sense disambiguation*. The second best performing system is C-Lexrank, which is not surprising because it was developed specifically for the task of scientific paper summarization. However, HitSum outperforms C-Lexrank on several topics and by 4% on average.

Figure 3 shows part of the summary generated by HitSum for the topic of question answering. The summary contains mostly informative sentences about different aspects of question answering. One obvious drawback of this summary is that it's not very coherent and readable. However, previous work has shown how network based content models can be combined with discourse models to generate informative yet readable summaries (Jha et al., 2015). We looked at some of the network statistics of the lexical networks used by HitSum. One of the things we noticed is that the lexical networks for topics where HitSum performs well seem to have higher degree assortativity compared to the topics for which it doesn't perform well. High degree assortativity in lexical networks means sentences with high degree tend to be linked to other sentences with high degree. This suggests that HITS performs well for topics where a set of important factoids are mentioned in many citing and source sentences. A larger evaluation dataset is needed for a more thorough analysis of how the network properties of these lexical networks correlate with the performance of various content models.

TopicSum does well on the topics of *named entity recognition* and *sentiment analysis*, but does not do well on average. This can be attributed to the fact that it was developed as a content model for the domain of news summarization and does not translate well to our domain. All systems outperform Lexrank, which achieves the lowest average score. This result is also intuitive, because every other system in our evaluation uses additional information not used by Lexrank: C-Lexrank exploits the community structure in the input set of sentences, HitSum exploits the lexical information from cited sentences, and TopicSum exploits information about global word distribution across all topics.

The different systems we tried in our evaluation depend on using different lexical information and seem to perform well for different topics. This suggests that further gains can be made by combining these systems. For example, C-Lexrank and HitSum can be combined by utilizing both the network formed by citing sentences and the network between the citing sentences and the cited sentences into a larger lexical network. TopicSum scores can be combined with these network-based system by using the TopicSum scores as a prior for each node, and then running either Pagerank or HITS on top of it. We leave exploration of such hybrid systems to future work.

6 Related Work

The goal of content models in the context of summarization is to extract a representation from input text that can help in identifying important sentences that should be in the output summary. Our work is related to two main classes of content models: network-based methods and probabilistic methods. We summarize related work for each of these classes of content models, followed by a short summary of the related work in the domain of scientific summarization.

Network-based content models: Network-based content models (Erkan and Radev, 2004; Mihalcea and Tarau, 2004) work by converting the input sentences into a network. Each sentence is represented by a node in the network, and the edges between sentences are given weight based on the similarities of sentences. They then run Pagerank on this network, and sentences are selected based on their Pagerank score in the network. For computing Pagerank, the network can either be pruned by removing edges that have weights less than a certain threshold, or a weighted version of Pagerank can be run on the network. The method can also be modified for query-focused summarization (Otterbacher et al., 2009). C-Lexrank (Qazvinian and Radev, 2008) modifies Lexrank by first running a clustering algorithm on the network to partition the network into different communities and then selecting sentences from each community by running Lexrank on the sub-network within each community. C-Lexrank was also used in the task of automated survey generation with encouraging results (Mohammad et al., 2009).

Probabilistic content models: One of the first probabilistic content models seems to be BAYESSUM (Daumé and Marcu, 2006), designed for query-focused summarization. BAYESSUM models a set of document collections using a hierarchical LDA style model. Each word in a sentence can be generated using one of three language models: 1) a general English language model that captures English filler or background knowledge, 2) a document-specific language model, and 3) a query language model. These language models are inferred using expectation propagation, and then sentences are ranked based on their likelihood of being generated from the query language model. A similar model for general multidocument summarization called TOPICSUM was proposed by Haghighi and Vanderwende (2009), where the query language model is replaced by a document-collection-specific language model; thus sentences are selected based on how likely they are to contain information that summarizes the entire document collection instead of information pertaining to individual documents or background knowledge.

Barzilay and Lee (2004) present a Hidden Markov Model (HMM) based content model where the hidden states of the HMM represent the topics in the text. The transition probabilities are learned through Viterbi decoding. They show that the HMM model can be used for both reordering of sentences for coherence and discriminative scoring of sentences for extractive summarization. Fung and Ngai (2006) present a similar HMM-based model for multi-document summarization. Jiang and Zhai (2005) proposed an HMM-based model for the problem of extracting coherent passages relevant to a query from a relevant document. They learn an HMM with two background states (B_1 and B_2) and a query-relevant state (R), each associated with a language model. The HMM starts in background state B_1, switches to relevant state R and then switches to the next background state B_2. The sentences that the HMM emits while in R constitute the query-relevant passage from the document.

Scientific summarization: Early work in scientific summarization used abstracts of scientific articles to produce summaries of specific scientific papers (Kupiec et al., 1995). However, later work (Elkiss et al., 2008) showed that citation sentences are as important in understanding the main contributions of a paper.

Nanba and Okumura (1999) explored using reference information to build a system for supporting writing survey articles. Their system extracts citing sentences that describe a referred paper and identify the type of reference relationships. The type of references can be one of the three: 1) type B that base on other researcher's theory, 2) type C that compare with related works, or 3) type O representing relationships other than B or C. They posit that type C sentences are the most important for survey generation and can help show the similarities and differences among cited papers.

Teufel and Moens (2002) propose a method for summarizing scientific articles based on rhetorical status of sentences in scientific articles. They annotate sentences in a corpus of 80 scientific articles with rhetorical status, where the rhetorical status can be one of aim (specific research goal), textual (section structure), own (neutral description of own work), background (generally accepted background), contrast (comparison with other work), basis (agreement with or continuation of other work), and other (neutral description of other's work). They describe classifiers for tagging the rhetorical status of sentences automatically and present a method for using this to assign relevance score to sentences.

In other work, Kan et al. (2002) use a corpus of 2000 annotated bibliographies for scientific papers as a first step towards a supervised summarization system. They found that summaries in their corpus were mostly single-document abstractive summaries that were both indicative and informative and were organized around a "theme," making them ideal for query-based summarization. Mei and Zhai (2008) presented an impact-based summarization method for single-paper summarization that assigns relevance scores to sentences in a paper based on their similarity to the set of citing sentences that reference the paper.

More recently, Hoang and Kan (2010) present a method for automated related work generation. Their system takes as input a set of keywords arranged in a hierarchical fashion that describes a target paper's topic. They hypothesize that sentences in a related work provide either background information or specific contributions. They use two different models to extract these two kinds of sentences using the input tree and combines them to create the final output summary. Zhang et al. (2013) explore methods for biomedical summarization by identifying cliques in a network of semantic predications extracted from citations. These cliques are then clustered and labeled to identify different points of view represented in the summary.

7 Conclusion and Future Work

We have presented a new factoid-annotated dataset for evaluating content models for scientific survey article generation by annotating sentences from seven topics in *natural language processing*. We also introduce a new HITS-based content model called HITSUM for survey article generation that exploits the lexical information from cited papers along with citing papers to rank input sentences for survey-worthiness. We conduct pyramid evaluation using our factoid dataset to compare HITSUM with existing network-based methods (Lexrank, C-Lexrank) as well as methods based on Bayesian content modeling (TOPICSUM). On average, HITSUM outperforms C-Lexrank by 4% and TOPICSUM by 7%. Since the different content models use different kinds of lexical information, further gains might be obtained by combining some of these models into a joint model. We plan to explore this in future work.

Abstract

We present a novel syntax-based natural language generation system that is trainable from unaligned pairs of input meaning representations and output sentences. It is divided into sentence planning, which incrementally builds deep-syntactic dependency trees, and surface realization. Sentence planner is based on A* search with a perceptron ranker that uses novel differing subtree updates and a simple future promise estimation; surface realization uses a rule-based pipeline from the Treex NLP toolkit.

Our first results show that training from unaligned data is feasible, the outputs of our generator are mostly fluent and relevant.

1 Introduction

We present a novel approach to natural language generation (NLG) that does not require fine-grained alignment in training data and uses deep dependency syntax for sentence plans. We include our first results on the BAGEL restaurant recommendation data set of Mairesse et al. (2010).

In our setting, the task of a natural language generator is that of converting an abstract meaning representation (MR) into a natural language utterance. This corresponds to the sentence planning and surface realization NLG stages as described by Reiter and Dale (2000). It also reflects the intended usage in a spoken dialogue system (SDS), where the NLG component is supposed to translate a system output action into a sentence. While the content planning NLG stage has been used in SDS (e.g., Rieser and Lemon (2010)), we believe that deciding upon the contents of the system's utterance is generally a task for the dialogue manager. We focus mainly on the sentence planning part in this work, and reuse an existing rule-based surface realizer to test the capabilities of the generator in an end-to-end setting.

Current NLG systems usually require a separate training data alignment step (Mairesse et al., 2010; Konstas and Lapata, 2013). Many of them use a CFG or operate in a phrase-based fashion (Angeli et al., 2010; Mairesse et al., 2010), which limits their ability to capture long-range syntactic dependencies. Our generator includes alignment learning into sentence planner training and uses deep-syntactic trees with a rule-based surface realization step, which ensures grammatical correctness of the outputs. Unlike previous approaches to trainable sentence planning (e.g., Walker et al. (2001); Stent et al. (2004)), our generator does not require a handcrafted base sentence planner.

This paper is structured as follows: in Section 2, we describe the architecture of our generator. Sections 3 and 4 then provide further details on its main components. In Section 5, we describe our experiments on the BAGEL data set, followed by an analysis of the results in Section 6. Section 7 compares our generator to previous related works and Section 8 concludes the paper.

2 Generator Architecture

Our generator (see Figure 1) operates in two stages that roughly correspond to the traditional NLG stages of sentence planning and surface realization. In the first stage, a statistical sentence planner generates deep-syntactic dependency trees from the input meaning representation. These are converted into plain text sentences in the second stage by the (mostly rule-based) surface realizer.

We use deep-syntax dependency trees to represent the *sentence plan*, i.e. the intermediate data structure between the two aforementioned stages. These are ordered dependency trees that only contain nodes for content words (nouns, full verbs, adjectives, adverbs) and coordinating conjunctions.

Figure 1: Overall structure of our generator

Each node has a *lemma* and a *formeme* – a concise description of its surface morphosyntactic form, which may include prepositions and/or subordinate conjunctions (Dušek et al., 2012). This structure is based on the deep-syntax trees of the Functional Generative Description (Sgall et al., 1986), but it has been simplified to fit our purposes (see Figure 1 in the middle).

There are several reasons for taking the traditional two-step approach to generation (as opposed to joint approaches, see Section 7) and using deep syntax trees as the sentence plan format: First, generating into deep syntax simplifies the task for the statistical sentence planner – the planner does not need to handle surface morphology and auxiliary words. Second, a rule-based syntactic realizer allows us to ensure grammatical correctness of the output sentences, which would be more difficult in a sequence-based and/or statistical approach.[1] And third, a rule-based surface realizer from our sentence plan format is relatively easy to implement and can be reused for any domain within the same language. As in our case, it is also possible to reuse and/or adapt an existing surface realizer (see Section 4).

Deep-syntax annotation of sentences in the training set is needed to train the sentence planner, but we assume automatic annotation and reuse an existing deep-syntactic analyzer from the Treex NLP framework (Popel and Žabokrtský, 2010).[2]

We use dialogue acts (DA) as defined in the BAGEL restaurant data set of Mairesse et al. (2010) as a MR in our experiments throughout this paper. Here, a DA consists of a dialogue act type, which is always “inform” in the set, and a list of slot-value pairs (SVPs) that contain information about a restaurant, such as food type or location (see the top of Figure 1). Our generator can be easily adapted to a different MR, though.

3 Sentence Planner

The sentence planner is based on a variant of the A* algorithm (Hart et al., 1968; Och et al., 2001; Koehn et al., 2003). It starts from an empty sentence plan tree and tries to find a path to the optimal sentence plan by iteratively adding nodes. It keeps two sets of hypotheses, i.e., candidate sentence plan trees, sorted by their score – hypotheses to expand (*open set*) and already expanded (*closed set*). It uses the following two subcomponents to guide the search:

- a *candidate generator* that is able to incrementally generate candidate sentence plan trees (see Section 3.1),
- a *scorer/ranker* that scores the appropriateness of these trees for the input MR (see Section 3.2).

[1] This issue would become more pressing in languages with richer morphology than English.

[2] See `http://ufal.mff.cuni.cz/treex`. Domain-independent deep syntax analysis for several languages is included in this framework; the English pipeline used here involves a statistical part-of-speech tagger (Spoustová et al., 2007) and a dependency parser (McDonald et al., 2005), followed by a rule-based conversion to deep syntax trees.

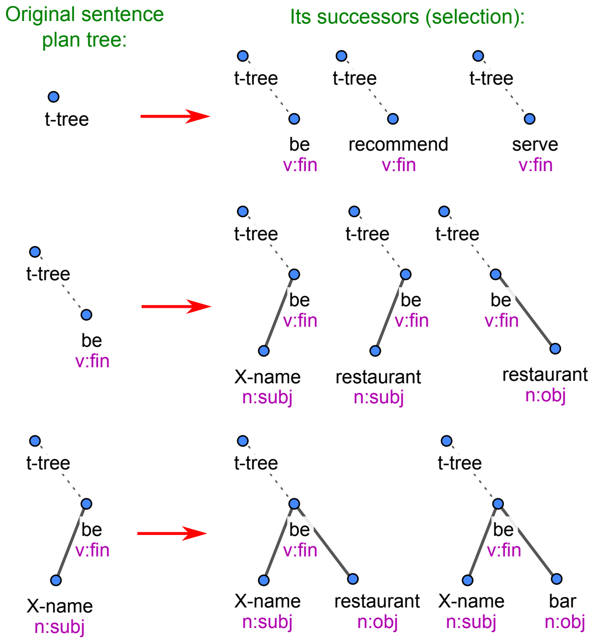

Figure 2: Candidate generator example inputs and outputs

The basic workflow of the sentence planner algorithm then looks as follows:

Init: Start from an *open set* with a single empty sentence plan tree and an empty *closed set*.

Loop:

1. Select the best-scoring candidate C from the *open set*. Add C to *closed set*.
2. The candidate generator generates $\mathbf{C}$, a set of possible successors to C. These are trees that have more nodes than C and are deemed viable. Note that $\mathbf{C}$ may be empty.
3. The scorer scores all successors in $\mathbf{C}$ and if they are not already in the *closed set*, it adds them to the *open set*.
4. Check if the best successor in the *open set* scores better than the best candidate in the *closed set*.

Stop: The algorithm finishes if the top score in the *open set* is lower than the top score in the *closed set* for d consecutive iterations, or if there are no more candidates in the *open set*. It returns the best-scoring candidate from both sets.

3.1 Generating Sentence Plan Candidates

Given a sentence plan tree, which is typically incomplete and may be even empty, the candidate generator generates its successors by adding one new node in all possible positions and with all possible lemmas and formemes (see Figure 2). While a naive implementation – trying out any combination of lemmas and formemes found in the training data – works in principle, it leads to an unmanageable number of candidate trees even for a very small domain. Therefore, we include several rules that limit the number of trees generated:

1. Lemma-formeme compatibility – only nodes with a combination of lemma and formeme seen in the training data are generated.
2. Syntactic viability – the new node must be compatible with its parent node (i.e., this combination, including the dependency left/right direction, must be seen in the training data).
3. Number of children – no node can have more children than the maximum for this lemma-formeme combination seen in the training data.
4. Tree size – the generated tree cannot have more nodes than trees seen in the training data. The same limitation applies to the individual depth levels – the training data limit the number of nodes on the n-th depth level as well as the maximum depth of any tree.

   This is further conditioned on the input SVPs – the maximums are only taken from training examples that contain the same SVPs that appear on the current input.
5. Weak semantic compatibility – we only include nodes that appear in the training data alongside the elements of the input DA, i.e., nodes that appear in training examples containing SVPs from the current input,
6. Strong semantic compatibility – for each node (lemma and formeme), we make a "compatibility list" of SVPs and slots that are present in all training data examples containing this node. We then only allow generating this node if all of them are present in the current input DA. To allow for more generalization, this rule can be applied just to lemmas

(disregarding formemes), and a certain number of SVPs/slots from the compatibility list may be required at maximum.

Only Rules 4 (partly), 5, and 6 depend on the format of the input meaning representation. Using a different MR would require changing these rules to work with atomic substructures of the new MR instead of SVPs.

While especially Rules 5 and 6 exclude a vast number of potential candidate trees, this limitation is still much weaker than using hard alignment links between the elements of the MR and the output words or phrases. It leaves enough room to generate many combinations unseen in the training data (cf. Section 6) while keeping the search space manageable. To limit the space of potential tree candidates even further, one could also use automatic alignment scores between the elements of the input MR and the tree nodes (obtained using a tool such as GIZA++ (Och and Ney, 2003)).

3.2 Scoring Sentence Plan Trees

The scorer for the individual sentence plan tree candidates is a function that maps global features from the whole sentence plan tree t and the input MR m to a real-valued score that describes the fitness of t in the context of m.

We first describe the basic version of the scorer and then our two improvements – differing subtree updates and future promise estimation.

Basic perceptron scorer

The basic scorer is based on the linear perceptron ranker of Collins and Duffy (2002), where the score is computed as a simple dot product of the features and the corresponding weight vector:

$$\text{score}(t, m) = \mathbf{w}^\top \cdot \text{feat}(t, m)$$

In the training phase, the weights $\mathbf{w}$ are initialized to one. For each input MR, the system tries to generate the best sentence plan tree given current weights, t_{top}. The score of this tree is then compared to the score of the correct gold-standard tree t_{gold}.[3] If $t_{top} \neq t_{gold}$ and the gold-standard tree ranks worse than the generated one ($\text{score}(t_{top}, m) > \text{score}(t_{gold}, m)$), the weight vector is updated by the feature value difference of the generated and the gold-standard tree:

$$\mathbf{w} = \mathbf{w} + \alpha \cdot (\text{feat}(t_{gold}, m) - \text{feat}(t_{top}, m))$$

where α is a predefined learning rate.

Differing subtree updates

In the basic version described above, the scorer is trained to score full sentence plan trees. However, it is also used to score incomplete sentence plans during the decoding. This leads to a bias towards bigger trees regardless of their fitness for the input MR. Therefore, we introduced a novel modification of the perceptron updates to improve scoring of incomplete sentence plans: In addition to updating the weights using the top-scoring candidate t_{top} and the gold-standard tree t_{gold} (see above), we also use their *differing subtrees* t^i_{top}, t^i_{gold} for additional updates.

Starting from the common subtree t_c of t_{top} and t_{gold}, pairs of differing subtrees t^i_{top}, t^i_{gold} are created by gradually adding nodes from t_{top} into t^i_{top} and from t_{gold} into t^i_{gold} (see Figure 3). To maintain the symmetry of the updates in case that the sizes of t_{top} and t_{gold} differ, more nodes may be added in one step.[4] The additional updates then look as follows:

```
$t^0_{top} = t^0_{gold} = t_c$
for $i$ in $1, \ldots \min\{|t_{top}| - |t_c|, |t_{gold}| - |t_c|\} - 1$ :
    $t^i_{top} = t^{i-1}_{top}$ + node(s) from $t_{top}$
    $t^i_{gold} = t^{i-1}_{gold}$ + node(s) from $t_{gold}$
    $\mathbf{w} = \mathbf{w} + \alpha \cdot (\text{feat}(t^i_{gold}, m) - \text{feat}(t^i_{top}, m))$
```

Future promise estimation

To further improve scoring of incomplete sentence plan trees, we incorporate a simple *future promise* estimation for the A* search intended to boost scores of sentence plans that are expected to further grow.[5] It is based on the expected number of children $E_c(n)$ of different node types (lemma-formeme pairs).[6] Given all nodes $n_1 \ldots n_{|t|}$ in a

[3] Note that the "gold-standard" sentence plan trees are actually produced by automatic annotation. For the purposes of scoring, they are, however, treated as gold standard.

[4] For example, if t_{gold} has 6 more nodes than t_c and t_{top} has 4 more, there will be 3 pairs of differing subtrees, with t^i_{gold} having 2, 4, and 5 more nodes than t_c and t^i_{top} having 1, 2, and 3 more nodes than t_c.

We have also evaluated a variant where both sets of subtrees t^i_{gold}, t^i_{top} were not equal in size, but this resulted in degraded performance.

[5] Note that this is not the same as future path cost in the original A* path search, but it plays an analogous role: weighing hypotheses of different size.

[6] $E_c(n)$ is measured as the average number of children over all occurrences of the given node type in the training data. It is expected to be domain-specific.

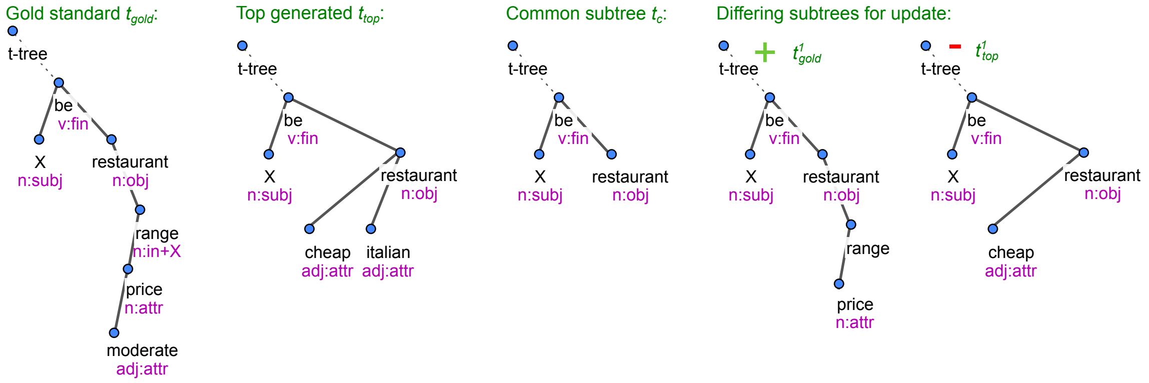

Figure 3: An example of differing subtrees

The gold standard tree t_{gold} has three more nodes than the common subtree t_c, while the top generated tree t_{top} has two more. Only one pair of differing subtrees t^1_{gold}, t^1_{top} is built, where two nodes are added into t^1_{gold} and one node into t^1_{top}.

sentence plan tree t, the future promise is computed in the following way:

$$\text{fp} = \lambda \cdot \sum \mathbf{w} \cdot \sum_{i=1}^{|t|} \max\{0, E_c(n_i) - c(n_i)\}$$

where $c(n_i)$ is the current number of children of node n_i, λ is a preset weight parameter, and $\sum \mathbf{w}$ is the sum of the current perceptron weights. Multiplying by the weights sum makes future promise values comparable to trees scores.

Future promise is added to tree scores throughout the tree generation process, but it is disregarded for the termination criterion in the *Stop* step of the generation algorithm and in perceptron weight updates.

Averaging weights and parallel training

To speed up training using parallel processing, we use the iterative parameter mixing approach of McDonald et al. (2010), where training data are split into several parts and weight updates are averaged after each pass through the training data. Following Collins (2002), we record the weights after each training pass, take an average at the end, and use this as the final weights for prediction.

4 Surface Realizer

We use the English surface realizer from the Treex NLP toolkit (cf. Section 2 and (Ptáček, 2008)). It is a simple pipeline of mostly rule-based blocks that gradually change the deep-syntactic trees into surface dependency trees, which are then linearized to sentences. It includes the following steps:

- *Agreement* – morphological attributes of some nodes are deduced based on agreement with other nodes (such as in subject-predicate agreement).
- *Word ordering* – the input trees are already ordered, so only a few rules for grammatical words are applied.
- *Compound verb forms* – additional verbal nodes are added for verbal particles (infinitive or phrasal verbs) and for compound expressions of tense, mood, and modality.
- *Grammatical words* – prepositions, subordinating conjunctions, negation particles, articles, and other grammatical words are added into the sentence.
- *Punctuation* – nodes for commas, final punctuation, quotes, and brackets are introduced.
- *Word Inflection* – words are inflected according to the information from formemes and agreement.
- *Phonetic changes* – English “a” becomes “an” based on the following word.

The realizer is designed as domain-independent and handles most English grammatical phenomena. A simple “round-trip” test – using automatic analysis with subsequent generation – reached a BLEU score (Papineni et al., 2002) of 89.79% against the original sentences on the whole BAGEL data set, showing only minor differences between the input sentence and generation output (mostly in punctuation).

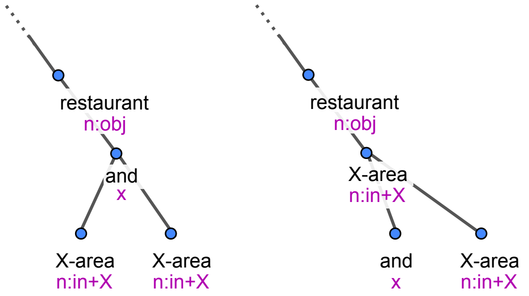

Figure 4: Coordination structures conversion: original (left) and our format (right).

5 Experimental Setup

Here we describe the data set used in our experiments, the needed preprocessing steps, and the settings of our generator specific to the data set.

5.1 Data set

We performed our experiments on the BAGEL data set of Mairesse et al. (2010), which fits our usage scenario in a spoken dialogue system and is freely available.[7] It contains a total of 404 sentences from a restaurant information domain (describing the restaurant location, food type, etc.), which correspond to 202 dialogue acts, i.e., each dialogue act has two paraphrases. Restaurant names, phone numbers, and other "non-enumerable" properties are abstracted – replaced by an "X" symbol – throughout the generation process. Note that while the data set contains alignment of source SVPs to target phrases, we do not use it in our experiments.

For sentence planner training, we automatically annotate all the sentences using the Treex deep syntactic analyzer (see Section 2). The annotation obtained from the Treex analyzer is further simplified for the sentence planner in two ways:

- Only lemmas and formemes are used in the sentence planner. Other node attributes are added in the surface realization step (see Section 5.2).
- We convert the representation of coordination structures into a format inspired by Universal Dependencies.[8] In the original Treex annotation style, the conjunction heads both conjuncts, whereas in our modification, the first conjunct is at the top, heading the coordination and the second conjunct (see Figure 4).

The coordinations can be easily converted back for the surface realizer, and the change makes the task easier for the sentence planner: it may first generate one node and then decide whether it will add a conjunction and a second conjunct.

5.2 Generator settings

In our candidate generator, we use all the limitation heuristics described in Section 3.1. For strong semantic compatibility (Rule 6), we use just lemmas and require at most 5 SVPs/slots from the lemma's compatibility list in the input DA.

We use the following feature types for our sentence planner scorer:

- current tree properties – tree depth, total number of nodes, number of repeated nodes
- tree and input DA – number of nodes per SVP and number of repeated nodes per repeated SVP,
- node features – lemma, formeme, and number of children of all nodes in the current tree, and combinations thereof,
- input features – whole SVPs (slot + value), just slots, and pairs of slots in the DA,
- combinations of node and input features,
- repeat features – occurrence of repeated lemmas and/or formemes in the current tree combined with repeated slots in the input DA,
- dependency features – parent-child pairs for lemmas and/or formemes, including and excluding their left-right order,
- sibling features – sibling pairs for lemmas and/or formemes, also combined with SVPs,
- bigram features – pairs of lemmas and/or formemes adjacent in the tree's left-right order, also combined with SVPs.

All feature values are normalized to have a mean of 0 and a standard deviation of 1, with normalization coefficients estimated from training data.

The feature set can be adapted for a different MR format – it only must capture all important parts of the MR, e.g., for a tree-like MR, the nodes and edges, and possibly combinations thereof.

Table 1: Evaluation on the BAGEL data set (averaged over all ten cross-validation folds)
"Training portion" denotes the percentage of the training data used in the experiment. "Basic perc." = basic perceptron updates, "+ Diff-tree upd." = with differing subtree perceptron updates, "+ Future promise" = with future promise estimation. BLEU scores are shown as percentages.

Based on our preliminary experiments, we use 100 passes over the training data and limit the number of iterations d that do not improve score to 3 for training and 4 for testing. We use a hard maximum of 200 sentence planner iterations per input DA. The learning rate α is set to 0.1. We use training data parts of 36 or 37 training examples (1/10th of the full training set) in parallel training. If future promise is used, its weight λ is set to 0.3.

The Treex English realizer expects not only lemmas and formemes, but also additional grammatical attributes for all nodes. In our experiments, we simply use the most common values found in the training data for the particular nodes as this is sufficient for our domain. In larger domains, some of these attributes may have to be also included in sentence plans.

6 Results

Same as Mairesse et al. (2010), we use 10-fold cross-validation where DAs seen at training time are never used for testing, i.e., both paraphrases or none of them are present in the full training set. We evaluate using BLEU and NIST scores (Papineni et al., 2002; Doddington, 2002) against both reference paraphrases for a given test DA.

The results of our generator are shown in Table 1, both for standard perceptron updates and our improvements – differing subtree updates and future promise estimation (see Section 3.2).

Our generator did not achieve the same performance as that of Mairesse et al. (2010) (ca. 67%).[9] However, our task is substantially harder since the generator also needs to learn the alignment of phrases to SVPs and determine whether all required information is present on the output (see also Section 7). Our differing tree updates clearly bring a substantial improvement over standard perceptron updates, and scores keep increasing with bigger amounts of training data used, whereas with plain perceptron updates, the scores stay flat. The increase with 100% is smaller since all training DAs are in fact used twice, each time with a different paraphrase.[10] A larger training set with different DAs should bring a bigger improvement. Using future promise estimation boosts the scores even further, by a smaller amount for BLEU but noticeably for NIST. Both improvements on the full training set are considered statistically significant at 95% confidence level by the paired bootstrap resampling test (Koehn, 2004). A manual inspection of a small sample of the results confirmed that the automatic scores reflect the quality of the generated sentences well.

If we look closer at the generated sentences (see Table 2), it becomes clear that the generator learns to produce meaningful utterances which mostly correspond well to the input DA. It is able to produce original paraphrases and generalizes to previously unseen DAs.

On the other hand, not all required information is always present, and some facts are sometimes repeated or irrelevant information appears. This mostly happens with input slot-value pairs that occur only rarely in the training data; we believe that a larger training set will solve this problem. Alternatively, one could introduce additional scorer features to discourage conflicting information. Another problem is posed by repeated slots in the input DA, which are sometimes not reflected properly in the generated sentence. This suggests that a further refinement of the scorer feature set may be needed.

[9] Mairesse et al. (2010) do not give a precise BLEU score number in their paper, they only show the values in a graph.

[10] We used the two paraphrases that come with each DA as independent training instances. While having two different gold-standard outputs for a single input is admittedly not ideal for a discriminative learner, it still brings an improvement in our case.

Input DA	inform(name=X-name, type=placetoeat, eattype=restaurant, near=X-near, food=Continental, food=French)
Reference	X is a French and continental restaurant near X.
Generated	X is a French and continental restaurant near X.
Input DA	inform(name=X-name, type=placetoeat, area=riverside, near=X-near, eattype=restaurant)
Reference	X restaurant is near X on the riverside.
Generated	X is a restaurant in the riverside area near X.
Input DA	inform(name=X-name, type=placetoeat, area=X-area, pricerange=moderate, eattype=restaurant)
Reference	X is a moderately priced restaurant in X.
Generated	X is a restaurant in the X area.
Input DA	inform(name=X-name, type=placetoeat, eattype=restaurant, area=riverside, food=French)
Reference	X is a French restaurant on the riverside.
Generated	X is a French restaurant in the riverside area which serves French food.
Input DA	inform(name=X-name, type=placetoeat, eattype=restaurant, pricerange=moderate, area=X-area, food=Contemporary, food=English)
Reference	X is a moderately priced English contemporary restaurant in X.
Generated	X is an English restaurant in the X area which serves expensive food in the moderate price range located in X.
Input DA	inform(name=X-name, type=placetoeat, eattype=restaurant, area=citycentre, near=X-near, food="Chinese takeaway", food=Japanese)
Reference	X is a Chinese takeaway and Japanese restaurant in the city centre near X.
Generated	X is a Japanese restaurant in the centre of town near X and X.
Input DA	inform(name=X-name, type=placetoeat, pricerange=moderate, eattype=restaurant)
Reference	X is a restaurant that offers moderate price range.
Generated	X is a restaurant in the moderate price range.

Sentences generated when training on the full set and using differing subtree updates and future promise estimation.

7 Related Work

Previous trainable methods in sentence planning use in principle two techniques: First, in the overgeneration and ranking approach (Walker et al., 2001; Stent et al., 2004), many sentence plans are generated using a rule-based planner and then the best one is selected by a statistical ranker. Second, parameter optimization trains adjustable parameters of a handcrafted generator to produce outputs with desired properties (Paiva and Evans, 2005; Mairesse and Walker, 2008). As opposed to our approach, both methods require an existing handcrafted sentence planner.

Other previous works combine sentence planning and surface realization into a single step and do not require a handcrafted base module. Wong and Mooney (2007) experiment with a phrase-based machine translation system, comparing and combining it with an inverted semantic parser based on synchronous context-free grammars. Lu et al. (2009) use tree conditional random fields over hybrid trees that combine natural language phrases with formal semantic expressions. Angeli et al. (2010) generate text from database records through a sequence of classifiers, gradually selecting database records, fields, and corresponding textual realizations to describe them. Konstas and Lapata (2013) recast the whole NLG problem as parsing over a probabilistic context-free grammar estimated from database records and their descriptions. Mairesse et al. (2010) convert input DAs into "semantic stacks", which correspond to natural language phrases and contain slots and their values on top of each other. Their generation model uses two dynamic Bayesian networks: the first one performs an ordering of the input semantic stacks, inserting intermediary stacks which correspond to grammatical phrases, the second one then produces a concrete surface realization. Dethlefs et al. (2013) approach generation as a sequence labeling task and use a conditional random field classifier, assigning a word or a phrase to each input MR element.

Unlike our work, the joint approaches typically include the alignment of input MR elements to output words in a separate preprocessing step (Wong and Mooney, 2007; Angeli et al., 2010), or require pre-aligned training data (Mairesse et al., 2010; Dethlefs et al., 2013). In addition, their basic algorithm often requires a specific input MR format, e.g., a tree (Wong and Mooney, 2007; Lu et al., 2009) or a flat database (Angeli et al., 2010; Konstas and Lapata, 2013; Mairesse et al., 2010).

While dependency-based deep syntax has been used previously in statistical NLG, the approaches known to us (Bohnet et al., 2010; Belz et al., 2012; Ballesteros et al., 2014) focus only on the surface realization step and do not include a sentence planner, whereas our work is mainly focused on statistical sentence planning and uses a rule-based realizer.

Our approach to sentence planning is most similar to Zettlemoyer and Collins (2007), which use a candidate generator and a perceptron ranker for CCG parsing. Apart from proceeding in the inverse direction and using dependency trees, we use only very generic rules in our candidate generator instead of language-specific ones, and we incorporate differing subtree updates and future promise estimation into our ranker.

8 Conclusions and Further Work

We have presented a novel natural language generator, capable of learning from unaligned pairs of input meaning representation and output utterances. It consists of a novel, A*-search-based sentence planner and a largely rule-based surface realizer from the Treex NLP toolkit. The sentence planner is, to our knowledge, first to use dependency syntax and learn alignment of semantic elements to words or phrases jointly with sentence planning.

We tested our generator on the BAGEL restaurant information data set of Mairesse et al. (2010). We have achieved very promising results, the utterances produced by our generator are mostly fluent and relevant. They did not surpass the BLEU score of the original authors; however, our task is substantially harder as our generator does not require fine-grained alignments on the input. Our novel feature of the sentence planner ranker – using differing subtrees for perceptron weight updates – has brought a significant performance improvement.

The generator source code, along with configuration files for experiments on the BAGEL data set, is available for download on Github.[11]

In future work, we plan to evaluate our generator on further domains, such as geographic information (Kate et al., 2005), weather reports (Liang et al., 2009), or flight information (Dahl et al., 1994). In order to improve the performance of our generator and remove the dependency on domain-specific features, we plan to replace the perceptron ranker with a neural network. We also want to experiment with removing the dependency on the Treex surface realizer by generating directly into dependency trees or structures into which dependency trees can be converted in a language-independent way.

Abstract

We propose an event-driven model for headline generation. Given an input document, the system identifies a key event chain by extracting a set of structural events that describe them. Then a novel multi-sentence compression algorithm is used to fuse the extracted events, generating a headline for the document. Our model can be viewed as a novel combination of extractive and abstractive headline generation, combining the advantages of both methods using event structures. Standard evaluation shows that our model achieves the best performance compared with previous state-of-the-art systems.

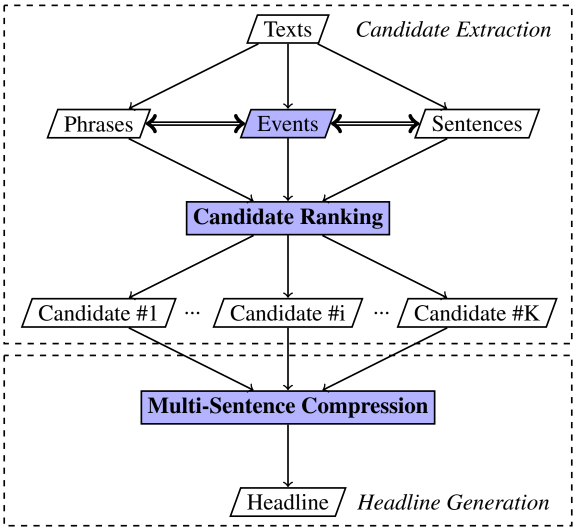

Figure 1: System framework.

1 Introduction

Headline generation (HG) is a text summarization task, which aims to describe an article (or a set of related paragraphs) using a single short sentence. The task is useful in a number of practical scenarios, such as compressing text for mobile device users (Corston-Oliver, 2001), generating table of contents (Erbs et al., 2013), and email summarization (Wan and McKeown, 2004). This task is challenging in not only informativeness and readability, which are challenges to common summarization tasks, but also the length reduction, which is unique for headline generation.

Previous headline generation models fall into two main categories, namely extractive HG and abstractive HG (Woodsend et al., 2010; Alfonseca et al., 2013). Both consist of two steps: candidate extraction and headline generation. Extractive models choose a set of salient sentences in candidate extraction, and then exploit sentence compression techniques to achieve headline generation (Dorr et al., 2003; Zajic et al., 2005). Abstractive models choose a set of informative phrases for candidate extraction, and then exploit sentence synthesis techniques for headline generation (Soricut and Marcu, 2007; Woodsend et al., 2010; Xu et al., 2010).

Extractive HG and abstractive HG have their respective advantages and disadvantages. Extractive models can generate more readable headlines, because the final title is derived by tailoring human-written sentences. However, extractive models give less informative titles (Alfonseca et al., 2013), because sentences are very sparse, making high-recall candidate extraction difficult. In contrast, abstractive models use phrases as the basic processing units, which are much less sparse. However, it is more difficult for abstractive HG to ensure the grammaticality of the generated titles, given that sentence synthesis is still very inaccurate based on a set of phrases with little grammatical information (Zhang, 2013).

In this paper, we propose an event-driven model for headline generation, which alleviates the

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 462–472,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

disadvantages of both extractive and abstractive HG. The framework of the proposed model is shown in Figure 1. In particular, we use *events* as the basic processing units for candidate extraction. We use structured tuples to represent the subject, predicate and object of an event. This form of event representation is widely used in open information extraction (Fader et al., 2011; Qiu and Zhang, 2014). Intuitively, events can be regarded as a trade-off between sentences and phrases. Events are meaningful structures, containing necessary grammatical information, and yet are much less sparse than sentences. We use salience measures of both sentences and phrases for event extraction, and thus our model can be regarded as a combination of extractive and abstractive HG.

During the headline generation step, A graph-based multi-sentence compression (MSC) model is proposed to generate a final title, given multiple events. First a directed acyclic word graph is constructed based on the extracted events, and then a beam-search algorithm is used to find the best title based on path scoring.

We conduct experiments on standard datasets for headline generation. The results show that headline generation can benefit not only from exploiting events as the basic processing units, but also from the proposed graph-based MSC model. Both our candidate extraction and headline generation methods outperform competitive baseline methods, and our model achieves the best results compared with previous state-of-the-art systems.

2 Background

Previous extractive and abstractive models take two main steps, namely candidate extraction and headline generation. Here, we introduce these two types of models according to the two steps.

2.1 Extractive Headline Generation

Candidate Extraction. Extractive models exploit sentences as the basic processing units in this step. Sentences are ranked by their salience according to specific strategies (Dorr et al., 2003; Erkan and Radev, 2004; Zajic et al., 2005). One of the state-of-the-art approaches is the work of Erkan and Radev (2004), which exploits centroid, position and length features to compute sentence salience. We re-implemented this method as our baseline sentence ranking method. In this paper, we use `SentRank` to denote this method.

Headline Generation. Given a set of sentences, extractive models exploit sentence compression techniques to generate a final title. Most previous work exploits single-sentence compression (SSC) techniques. Dorr et al. (2003) proposed the Hedge Trimmer algorithm to compress a sentence by making use of handcrafted linguistically-based rules. Alfonseca et al. (2013) introduce a multi-sentence compression (MSC) model into headline generation, using it as a baseline in their work. They indicated that the most important information is distributed across several sentences in the text.

2.2 Abstractive Headline Generation

Candidate Extraction. Different from extractive models, abstractive models exploit phrases as the basic processing units. A set of salient phrases are selected according to specific principles during candidate extraction (Schwartz, 01; Soricut and Marcu, 2007; Xu et al., 2010; Woodsend et al., 2010). Xu et al. (2010) propose to rank phrases using background knowledge extracted from Wikipedia. Woodsend et al. (2010) use supervised models to learn the salience score of each phrase. Here, we use the work of Soricut and Marcu (2007) , namely `PhraseRank`, as our baseline phrase ranking method, which is an unsupervised model without external resources. The method exploits unsupervised topic discovery to find a set of salient phrases.

Headline Generation. In the headline generation step, abstractive models exploit sentence synthesis technologies to accomplish headline generation. Zajic et al. (2005) exploit unsupervised topic discovery to find key phrases, and use the Hedge Trimmer algorithm to compress candidate sentences. One or more key phrases are added into the compressed fragment according to the length of the headline. Soricut and Marcu (2007) employ WIDL-expressions to generate headlines. Xu et al. (2010) employ keyword clustering based on several bag-of-words models to construct a headline. Woodsend et al. (2010) use quasi-synchronous grammar (QG) to optimize phrase selection and surface realization preferences jointly.

3 Our Model

Similar to extractive and abstractive models, the proposed event-driven model consists of two steps, namely candidate extraction and headline generation.

3.1 Candidate Extraction

We exploit events as the basic units for candidate extraction. Here an event is a tuple (S, P, O), where S is the subject, P is the predicate and O is the object. For example, for the sentence *"Ukraine Delays Announcement of New Government"*, the event is *(Ukraine, Delays, Announcement)*. This type of event structures has been used in open information extraction (Fader et al., 2011), and has a range of NLP applications (Ding et al., 2014; Ng et al., 2014).

A sentence is a well-formed structure with complete syntactic information, but can contain redundant information for text summarization, which makes sentences very sparse. Phrases can be used to avoid the sparsity problem, but with little syntactic information between phrases, fluent headline generation is difficult. Events can be regarded as a trade-off between sentences and phrases. They are meaningful structures without redundant components, less sparse than sentences and containing more syntactic information than phrases.

In our system, candidate event extraction is performed on a bipartite graph, where the two types of nodes are lexical chains (Section 3.1.2) and events (Section 3.1.1), respectively. Mutual Reinforcement Principle (Zha, 2002) is applied to jointly learn chain and event salience on the bipartite graph for a given input. We obtain the top-*k* candidate events by their salience measures.

3.1.1 Extracting Events

We apply an open-domain event extraction approach. Different from traditional event extraction, for which types and arguments are predefined, open event extraction does not have a closed set of entities and relations (Fader et al., 2011). We follow Hu's work (Hu et al., 2013) to extract events.

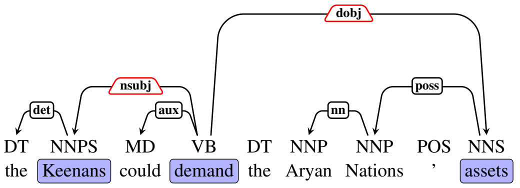

Figure 2: Dependency tree for the sentence *"the Keenans could demand the Aryan Nations' assets"*.

Given a text, we first use the Stanford dependency parser[1] to obtain the Stanford typed dependency structures of the sentences (Marneffe and Manning, 2008). Then we focus on two relations, *nsubj* and *dobj*, for extracting event arguments. Event arguments that have the same predicate are merged into one event, represented by tuple (*Subject, Predicate, Object*). For example, given the sentence, *"the Keenans could demand the Aryan Nations' assets"*, Figure 2 present its partial parsing tree. Based on the parsing results, two event arguments are obtained: *nsubj(demand, Keenans)* and *dobj(demand, assets)*. The two event arguments are merged into one event: *(Keenans, demand, assets)*.

3.1.2 Extracting Lexical Chains

Lexical chains are used to link semantically-related words and phrases (Morris and Hirst, 1991; Barzilay and Elhadad, 1997). A lexical chain is analogous to a semantic synset. Compared with words, lexical chains are less sparse for event ranking.

Given a text, we follow Boudin and Morin (2013) to construct lexical chains based on the following principles:

1. All words that are identical after stemming are treated as one word;

2. All NPs with the same head word fall into one lexical chain;[2]

3. A pronoun is added to the corresponding lexical chain if it refers to a word in the chain (The coreference resolution is performed using the Stanford Coreference Resolution system);[3]

4. Lexical chains are merged if their main words are in the same synset of WordNet.[4]

[1] http://nlp.stanford.edu/software/lex-parser.shtml

[2] NPs are extracted according to the dependency relations *nn* and *amod*. As shown in Figure 2, we can extract the noun phrase *Aryan Nations* according to the dependency relation *nn(Nations, Aryan)*.

[3] http://nlp.stanford.edu/software/dcoref.shtml

[4] http://wordnet.princeton.edu/

At initialization, each word in the document is a lexical chain. We repeatedly merge existing chains by the four principles above until convergence. In particular, we focus on content words only, including verbs, nouns and adjective words. After the merging, each lexical chain represents a word cluster, and the first occuring word in it can be used as the main word of chain.

3.1.3 Learning Salient Events

Intuitively, one word should be more important if it occurs in more important events. Similarly, one event should be more important if it includes more important words. Inspired by this, we construct a bipartite graph between lexical chains and events, shown in Figure 3, and then exploit MRP to jointly learn the salience of lexical chains and events. MRP has been demonstrated effective for jointly learning the vertex weights of a bipartite graph (Zhang et al., 2008; Ventura et al., 2013).

Given a text, we construct bipartite graph between the lexical chains and events, with an edge being constructed between a lexical chain and an event if the event contains a word in the lexical chain. Suppose that there are n events $\{e_1, \cdots, e_n\}$ and m lexical chains: $\{l_1, \cdots, l_m\}$ in the bipartite graph G_{bi}. Their scores are represented by $sal(e) = \{sal(e_1), \cdots, sal(e_n)\}$ and $sal(l) = \{sal(l_1), \cdots, sal(l_m)\}$, respectively. We compute the final $sal(e)$ and $sal(l)$ iteratively by MRP. At each step, $sal(e_i)$ and $sal(l_j)$ are computed as follows:

$$\begin{aligned} sal(e_i) &\propto \sum_{j=1}^{m} r_{ij} \times sal(l_j) \\ sal(l_j) &\propto \sum_{i=1}^{n} r_{ij} \times sal(e_i) \\ r_{ij} &= \frac{\sum_{(l_j, e_i) \in G_{bi}} w(l_j) \cdot w(e_i)}{A} \end{aligned} \tag{1}$$

where $r_{ij} \in R$ denotes the cohesion between lexicon chain l_i and event e_j, A is a normalization factor, $sal(\cdot)$ denotes the salience, and the initial values of $sal(e)$ and $sal(t)$ can be assigned randomly.

The remaining problem is how to define the salience score of a given lexicon chain l_i and a given event e_j. In this work, we use the guidance of abstractive and extractive models to compute $sal(l_j)$ and $sal(e_i)$, respectively, as shown below:

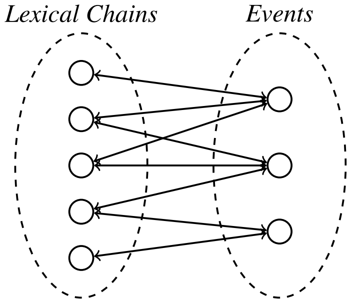

Figure 3: Bipartite graph where two vertex sets denote lexical chains and events, respectively.

$$\begin{aligned} w(l_j) &= \sum_{w \in l_j} sal_{abs}(w) \\ w(e_i) &= \sum_{s \in Sen(e_i)} sal_{ext}(s) \end{aligned} \tag{2}$$

where $sal_{abs}(\cdot)$ denotes the word salience score of an abstractive model, $sal_{ext}(\cdot)$ denotes the sentence salience score of an extractive model, and $Sen(e_i)$ denotes the sentence set where e_i is extracted from. We exploit our baseline sentence ranking method, `SentRank`, to obtain the sentence salience score, and use our baseline phrase ranking method, `PhraseRank`, to obtain the phrase salience score.

3.2 Headline Generation

We use a graph-based multi-sentence compression (MSC) model to generate the final title for the proposed event-driven model. The model is inspired by Filippova (2010). First, a weighted directed acyclic word graph is built, with a start node and an end node in the graph. A headline can be obtained by any path from the start node to the end node. We measure each candidate path by a scoring function. Based on the measurement, we exploit a beam-search algorithm to find the optimum path.

3.2.1 Word-Graph Construction

Given a set of candidate events CE, we extract all the sentences that contain the events. In particular, we add two artificial words, $\langle S \rangle$ and $\langle E \rangle$, to the start position and end position of all sentences, respectively. Following Filippova (2010), we extract all words in the sentences as graph vertexes, and then construct edges based on these words. Filippova (2010) adds edges

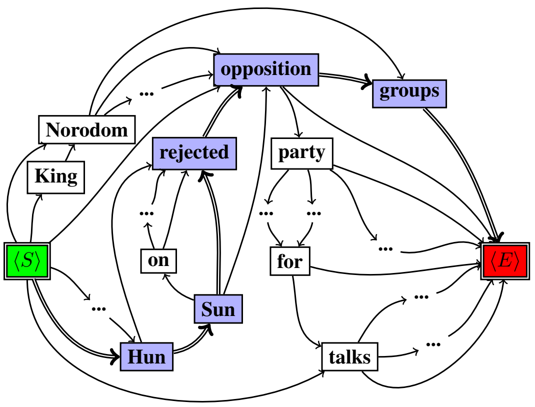

Figure 4: Word graph generated from candidates and a possible compression path.

for all the word pairs that are adjacent in one sentence. The title generated using this strategy can mistakenly contain common word bigrams(i.e. adjacent words) in different sentences. To address this, we change the strategy slightly, by adding edges for **a**ll word pairs of one sentence in the original order. In another words, if word w_j occurs after w_i in one sentence, then we add an edge $w_i \rightarrow w_j$ for the graph. Figure 4 gives an example of the word graph. The search space of the graph is larger compared with that of Filippova (2010) because of more added edges.

Different from Filippova (2010), salience information is introduced into the calculation of the weights of vertexes. One word that occurs in more salient candidate should have higher weight. Given a graph $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{V_1, \cdots, V_n\}$ denotes the word nodes and $\mathcal{E} = \{E_{ij} \in \{0,1\}, i,j \in [1,n]\}$ denotes the edges. The vertex weight is computed as follows:

$$w(V_i) = \sum_{e \in CE} sal(e) \exp\{-dist(V_i.w, e)\} \quad (3)$$

where $sal(e)$ is the salience score of an event from the candidate extraction step, $V_i.w$ denotes the word of vertex V_i, and $dist(w, e)$ denotes the distance from the word w to the event e, which are defined by the minimum distance from w to all the related words of e in a sentence by the dependency path[5] between them. Intuitively, equation 3 demonstrates that a vertex is salient when its corresponding word is close to salient events. It is worth noting that the formula can adapt to extractive and abstractive models as well, by replacing events with sentences and phrases. We use them for the `SentRank` and `PhraseRank` baseline systems in Section 4.3, respectively.

The equation to compute the edge weight is adopted from Filippova (2010):

$$\begin{aligned} w'(E_{ij}) &= \sum_{s} rdist(V_i.w, V_j.w) \\ w(E_{ij}) &= \frac{w(V_i)w(V_j) \cdot w'(E_{ij})}{w(V_i) + w(V_j)} \end{aligned} \quad (4)$$

where $w'(E_{ij})$ refers to the sum of $rdist(V_i.w, V_j.w)$ over all sentences, and $rdist(\cdot)$ denotes the reciprocal distance of two words in a sentence by the dependency path. By the formula, an edge is salient when the corresponding vertex weights are large or the corresponding words are close.

3.2.2 Scoring Method

The key to our MSC model is the path scoring function. We measure a candidate path based on two aspects. Besides the sum edge score of the path, we exploit a trigram language model to compute a fluency score of the path. Language models have been commonly used to generate more readable titles.

The overall score of a path is compute by:

$$\begin{aligned} score(p) &= edge(p) + \lambda \times flu(p) \\ edge(p) &= \frac{\sum_{E_{ij} \in p} \ln\{w(E_{ij})\}}{n} \\ flu(p) &= \frac{\sum_i \ln\{p(w_i | w_{i-2} w_{i-1})\}}{n} \end{aligned} \quad (5)$$

where p is a candidate path and the corresponding word sequence of p is $w_1 \cdots w_n$. A trigram language model is trained using SRILM[6] on English Gigaword (LDC2011T07).

3.2.3 Beam Search

Beam search has been widely used aiming to find the sub optimum result (Collins and Roark, 2004; Zhang and Clark, 2011), when exact inference is extremely difficult. Assuming our word graph has a vertex size of n, the worst computation complexity is $O(n^4)$ when using a trigram language model, which is time consuming.

[5] The distance is $+\infty$ when e and w are not in one sentence.

[6] http://www.speech.sri.com/projects/srilm/

```
Input: $G \leftarrow (\mathcal{V}, \mathcal{E})$, LM, B
Output: best
candidates ← { {⟨S⟩} }
 loop do
   beam ← { }
   for each candidate in candidates
     if candidate endwith ⟨E⟩
       AddToBeam(beam, candidate)
       continue
     for each $V_i$ in $\mathcal{V}$
       candidate ← AddVertex(candidate, $V_i$)
       ComputeScore(candidate, LM)
       AddToBeam(beam, candidate)
     end for
   end for
   candidates ← Top-K(beam, B)
   if candidates all endwith ⟨E⟩ : break
 end loop
 best ← Best(candidates)
```

Figure 5: The beam-search algorithm.

Using beam search, assuming the beam size is B, the time complexity decreases to $O(Bn^2)$.

Pseudo-code of our beam search algorithm is shown in Figure 5. During search, we use *candidates* to save a fixed size (B) of partial results. For each iteration, we generate a set of new candidates by adding one vertex from the graph, computing their scores, and maintaining the top B candidates for the next iteration. If one candidate reaches the end of the graph, we do not expand it, directly adding it into the new candidate set according to its current score. If all the candidates reach the end, the searching algorithm terminates and the result path is the candidate from *candidates* with the highest score.

4 Experiment

4.1 Settings

We use the standard HG test dataset to evaluate our model, which consists of 500 articles from DUC–04 task 1[7], where each article is provided with four reference headlines. In particular, we use the first 100 articles from DUC–07 as our development set. There are averaged 40 events per article in the two datasets. All the pre-processing steps, including POS tagging, lemma analysis, dependency parsing and anaphora resolution, are conducted using the Stanford NLP tools (Marneffe and Manning, 2008). The MRP iteration number is set to 10.

We use ROUGE (Lin, 2004) to automatically measure the model performance, which has been widely used in summarization tasks (Wang et al., 2013; Ng et al., 2014). We focus on Rouge1 and Rouge2 scores, following Xu et al. (2010). In addition, we conduct human evaluations, using the same method as Woodsend et al. (2010). Four participants are asked to rate the generated headlines by three criteria: informativeness (how much important information in the article does the headline describe?), fluency (is it fluent to read?) and coherence (does it capture the topic of article?). Each headline is given a subjective score from 0 to 5, with 0 being the worst and 5 being the best. The first 50 documents from the test set and their corresponding headlines are selected for human rating. We conduct significant tests using t-test.

4.2 Development Results

There are three important parameters in the proposed event-driven model, including the beam size B, the fluency weight λ and the number of candidate events N. We find the optimum parameters on development dataset in this section. For efficiency, the three parameters are optimized separately. The best performance is achieved with $B = 8$, $\lambda = 0.4$ and $N = 10$. We report the model results on the development dataset to study the influences of the three parameters, respectively, with the other two parameters being set with their best value.

4.2.1 Influence of Beam Size

We perform experiments with different beam widths. Figure 6 shows the results of the proposed model with beam sizes of 1, 2, 4, 8, 16, 32, 64. As can be seen, our model can achieve the best performances when the beam size is set to 8. Larger beam sizes do not bring better results.

4.2.2 Influence of Fluency Weight

The fluency score is used for generating readable titles, while the edge score is used for generating informative titles. The balance between them is important. By default, we set one to the weight of edge score, and find the best weight λ for the fluency score. We set λ ranging from 0 to 1 with and interval of 0.1, to investigate the influence of

[7] http://duc.nist.gov/duc2004/tasks.html

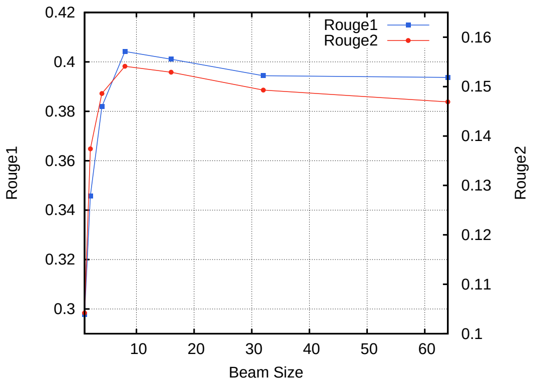

Figure 6: Results with different beam sizes.

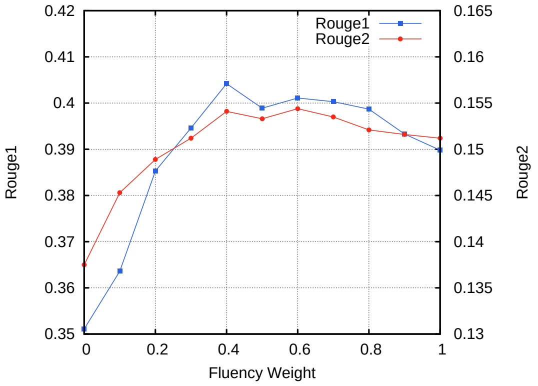

Figure 7: Results using different fluency weights.

this parameter[8]. Figure 7 shows the results. The best result is obtained when $\lambda = 0.4$.

4.2.3 Influence of Candidate Event Count

Ideally, all the sentences of an original text should be considered in multi-sentence compression. But an excess of sentences would bring more noise. We suppose that the number of candidate events N is important as well. To study its influence, we report the model results with different N, from 1 to 15 with an interval of 1. As shown in Figure 8, the performance increases significantly from 1 to 10, and no more gains when $N > 10$. The performance decreases drastically when M ranges from 12 to 15.

4.3 Final Results

Table 1 shows the final results on the test dataset. The performances of the proposed event-driven model are shown by `EventRank`. In addition, we use our graph-based MSC model to generate titles for `SentRank` and `PhraseRank`, respectively, as mentioned in Section 3.2.1. By comparison with the two models, we can examine the effectiveness of the event-driven model. As shown in Table 1, the event-driven model achieves the best scores on both Rouge1 and Rouge2, demonstrating events are more effective than sentences and phrases.

Further, we compare our proposed MSC method with the MSC proposed by Filippova (2010), to study the effectiveness of our novel MSC. We use `MSC`[10] and `SalMSC`[11] to

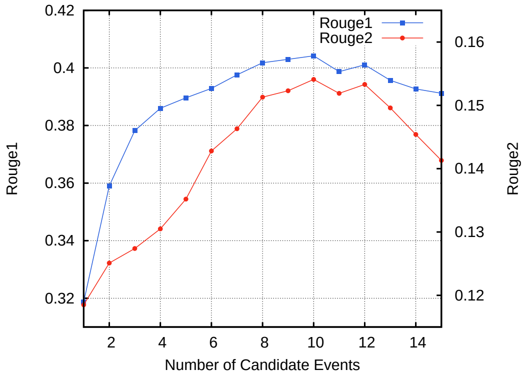

Figure 8: Results using different numbers of candidate events.

Method	Model Type	Rouge1	Rouge2
Our SalMSC			
SentRank	Extractive	0.3511	0.1375
PhraseRank	Abstractive	0.3706	0.1415
EventRank	Event-driven	**0.4247**‡	**0.1484**‡
Using MSC			
SentRank	Extractive	0.2773	0.0980
PhraseRank	Abstractive	0.3652	0.1299
EventRank	Event-driven	**0.3822**‡	**0.1380**‡
Other work			
SentRank+SSC	Extractive	0.2752	0.0855
Topiary	Abstractive	0.2835	0.0872
Woodsend	Abstractive	0.26*	0.06*[9]

Table 1: Performance comparison for automatic evaluation. The mark ‡ denotes that the result is significantly better with a p-value below 0.01.

[8] Preliminary results show that λ is better below one.

[9] The mark $*$ denotes the results are inaccurate, which are guessed from the figures in the published paper.

[10] The MSC source code, published by Boudin and Morin (2013), is available at https://github.com/boudinfl/takahe.

[11] Our source code is available at https://github.com/dram218/WordGraphCompression.

Method	Info.	Infu.	Cohe.
SentRank	4.13	2.85	2.54
PhraseRank	4.21	3.25	2.62
EventRank	**4.35**‡	**3.41**‡	**3.22**‡

Table 2: Results from the manual evaluation. The mark ‡ denotes the result is significantly better with a p-value below 0.01.

SentRank, PhraseRank and EventRank to denote their MSC method and our proposed MSC, respectively, applying them, respectively. As shown in Table 1, better performance is achieved by our MSC, demonstrating the effectiveness of our proposed MSC. Similarly, the event-driven model can achieve the best results.

We report results of previous state-of-the-art systems as well. SentRank+SSC denotes the result of Erkan and Radev (2004), which uses our SentRank and SSC to obtain the final title. Topiary denotes the result of Zajic et al. (2005), which is an early abstractive model. Woodsend denotes the result of Woodsend et al. (2010), which is an abstractive model using a quasi-synchronous grammar to generate a title. As shown in Table 1, MSC is significantly better than SSC, and our event-driven model achieves the best performance, compared with state-of-the-art systems.

Following Alfonseca et al. (2013), we conduct human evaluation also. The results are shown in Table 2, by three aspects: informativeness, fluency and coherence. The overall tendency is similar to the results, and the event-driven model achieves the best results.

4.4 Example Outputs

We show several representative examples of the proposed event-driven model, in comparison with the extractive and abstractive models. The examples are shown in Table 3.

In the first example, the results of both SentRank and PhraseRank contain the redundant phrase “catastrophe Tuesday”. The output of PhraseRank is less fluent compared with that of SentRank. The preposition “for” is not recovered by the headline generation system PhraseRank. In contrast, the output of EventRank is better, capturing the major event in the reference title.

Method	Generated Headlines
Reference	Honduras, other Caribbean countries brace for the wrath of Hurricane Mitch
SentRank	Honduras braced for potential catastrophe Tuesday as Hurricane Mitch roared through northwest Caribbean
PhraseRank	Honduras braced catastrophe Tuesday Hurricane Mitch roared northwest Caribbean
EventRank	Honduras braced for Hurricane Mitch roared through northwest Caribbean
Reference	At Ibero-American summit Castro protests arrest of Pinochet in London
SentRank	Castro disagreed with the arrest Augusto Pinochet calling international meddling
PhraseRank	Cuban President Fidel Castro disagreed arrest London Chilean dictator Augusto Pinochet
EventRank	Fidel Castro disagreed with arrest in London of Chilean dictator Augusto Pinochet
Reference	Cambodian leader Hun Sen rejects opposition demands for talks in Beijing
SentRank	Hun Sen accusing opposition parties of internationalize the political crisis
PhraseRank	opposition parties demands talks internationalize political crisis
EventRank	Cambodian leader Hun Sen rejected opposition parties demands for talks

Table 3: Comparison of headlines generated by the different methods.

In the second example, the outputs of three systems all lose the phrase “Ibero-American summit”. SentRank gives different additional information compared with PhraseRank and EventRank. Overall, the three outputs can be regarded as comparable. PhraseRank also has a fluency problem by ignoring some function words.

In the third example, SentRank does not capture the information on “demands for talks”. PhraseRank discards the preposition word “for”. The output of EventRank is better, being both more fluent and more informative.

From the three examples, we can see that SentRank tends to generate more readable titles, but may lose some important information. PhraseRank tends to generate a title with more important words, but the fluency is relatively weak even with MSC. EventRank combines the advantages of both SentRank and PhraseRank, generating titles that contain more important events with complete structures. The observation verifies our hypothesis in the introduction — that extractive models have the problem of low information coverage, and abstractive models have the problem of poor grammaticality. The event-driven mothod can alleviate both issues since event offer a trade-off between sentence and phrase.

5 Related Work

Our event-driven model is different from traditional extractive (Dorr et al., 2003; Erkan and Radev, 2004; Alfonseca et al., 2013) and abstractive models (Zajic et al., 2005; Soricut and Marcu, 2007; Woodsend et al., 2010; Xu et al., 2010) in that events are used as the basic processing units instead of sentences and phrases. As mentioned above, events are a trade-off between sentences and phrases, avoiding sparsity and structureless problems. In particular, our event-driven model can interact with sentences and phrases, thus is a light combination for two traditional models.

The event-driven model is mainly inspired by Alfonseca et al. (2013), who exploit events for multi-document headline generation. They leverage titles of sub-documents for supervised training. In contrast, we generate a title for a single document using an unsupervised model. We use novel approaches for event ranking and title generation.

In recent years, sentence compression (Galanis and Androutsopoulos, 2010; Yoshikawa and Iida, 2012; Wang et al., 2013; Li et al., 2014; Thadani, 2014) has received much attention. Some methods can be directly applied for multi-document summarization (Wang et al., 2013; Li et al., 2014). To our knowledge, few studies have been explored on applying them in headline generation.

Multi-sentence compression based on word graph was first proposed by Filippova (2010). Some subsequent work was presented recently. Boudin and Morin (2013) propose that the key phrase is helpful to sentence generation. The key phrases are extracted according to syntactic pattern and introduced to identify shortest path in their work. Mehdad et al. (2013; Mehdad et al. (2014) introduce the MSC based on word graph into meeting summarization. Tzouridis et al. (2014) cast multi-sentence compression as a structured predication problem. They use a large-margin approach to adapt parameterised edge weights to the data in order to acquire the shortest path. In their work, the sentences introduced to a word graph are treated equally, and the edges in the graph are constructed according to the adjacent order in original sentence.

Our MSC model is also inspired by Filippova (2010). Our approach is more aggressive than their approach, generating compressions with arbitrary length by using a different edge construction strategy. In addition, our search algorithm is also different from theirs. Our graph-based MSC model is also similar in spirit to sentence fusion, which has been used for multi-document summarization (Barzilay and McKeown, 2005; Elsner and Santhanam, 2011).

6 Conclusion and Future Work

We proposed an event-driven model headline generation, introducing a graph-based MSC model to generate the final title, based on a set of events. Our event-driven model can incorporate sentence and phrase salience, which has been used in extractive and abstractive HG models. The proposed graph-based MSC model is not limited to our event-driven model. It can be applied on extractive and abstractive models as well. Experimental results on DUC–04 demonstrate that event-driven model can achieve better results than extractive and abstractive models, and the proposed graph-based MSC model can bring improved performances compared with previous MSC techniques. Our final event-driven model obtains the best result on this dataset.

For future work, we plan to explore two directions. Firstly, we plan to introduce event relations to learning event salience. In addition, we plan to investigate other methods about multi-sentence compression and sentence fusion, such as supervised methods.

New Transfer Learning Techniques for Disparate Label Sets

Abstract

In natural language understanding (NLU), a user utterance can be labeled differently depending on the domain or application (e.g., weather vs. calendar). Standard domain adaptation techniques are not directly applicable to take advantage of the existing annotations because they assume that the label set is invariant. We propose a solution based on label embeddings induced from canonical correlation analysis (CCA) that reduces the problem to a standard domain adaptation task and allows use of a number of transfer learning techniques. We also introduce a new transfer learning technique based on pretraining of hidden-unit CRFs (HUCRFs). We perform extensive experiments on slot tagging on eight personal digital assistant domains and demonstrate that the proposed methods are superior to strong baselines.

1 Introduction

The main goal of NLU is to automatically extract the meaning of spoken or typed queries. In recent years, this task has become increasingly important as more and more speech-based applications have emerged. Recent releases of personal digital assistants such as Siri, Google Now, Dragon Go and Cortana in smart phones provide natural language based interface for a variety of domains (e.g. places, weather, communications, reminders). The NLU in these domains are based on statistical machine learned models which require annotated training data. Typically each domain has its own schema to annotate the words and queries. However the meaning of words and utterances could be different in each domain. For example, "sunny" is considered a weather condition in the weather domain but it may be a song title in a music domain. Thus every time a new application is developed or a new domain is built, a significant amount of resources is invested in creating annotations specific to that application or domain.

One might attempt to apply existing techniques (Blitzer et al., 2006; Daumé III, 2007) in domain adaption to this problem, but a straightforward application is not possible because these techniques assume that the label set is invariant.

In this work, we provide a simple and effective solution to this problem by abstracting the label types using the canonical correlation analysis (CCA) by Hotelling (Hotelling, 1936) a powerful and flexible statistical technique for dimensionality reduction. We derive a low dimensional representation for each label type that is maximally correlated to the average context of that label via CCA. These shared label representations, or label embeddings, allow us to map label types across different domains and reduce the setting to a standard domain adaptation problem. After the mapping, we can apply the standard transfer learning techniques to solve the problem.

Additionally, we introduce a novel pretraining technique for hidden-unit CRFs (HUCRFs) to effectively transfer knowledge from one domain to another. In our experiments, we find that our pretraining method is almost always superior to strong baselines such as the popular domain adaptation method of Daumé III (2007).

2 Problem description and related work

Let $\mathcal{D}$ be the number of distinct domains. Let X_i be the space of observed samples for the i-th domain. Let Y_i be the space of possible labels for the i-th domain. In most previous works in domain adaptation (Blitzer et al., 2006; Daumé III, 2007), observed data samples may vary but label space is

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 473–482,
Beijing, China, July 26-31, 2015.

invariant[1]. That is,

$$Y_i = Y_j \qquad \forall i,j \in \{1 \ldots \mathcal{D}\}$$

but $X_i \neq X_j$ for some domains i and j. For example, in part-of-speech (POS) tagging on newswire and biomedical domains, the observed data sample may be radically different but the POS tag set remains the same.

In practice, there are cases, where the same query is labeled differently depending on the domain or application and the context. For example, *Fred Myer* can be tagged differently; "send a text message to *Fred Myer*" and "get me driving direction to *Fred Myer* ". In the first case, *Fred Myer* is person in user's contact list but it is a grocery store in the second one.

So, we relax the constraint that label spaces must be the same. Instead, we assume that surface forms (i.e words) are similar. This is a natural setting in developing multiple applications on speech utterances; input spaces (service request utterances) do not change drastically but output spaces (slot tags) might.

Multi-task learning differs from our task. In general multi-task learning aims to improve performance across all domains while our domain adaptation objective is to optimize the performance of semantic slot tagger on the target domain.

Below, we review related work in domain adaption and natural language understanding (NLU).

2.1 Related Work

Domain adaptation has been widely used in many natural language processing (NLP) applications including part-of-speech tagging (Schnabel and Schütze, 2014), parsing (McClosky et al., 2010), and machine translation (Foster et al., 2010). Most of the work can be classified either supervised domain adaptation (Chelba and Acero, 2006; Blitzer et al., 2006; Daume III and Marcu, 2006; Daumé III, 2007; Finkel and Manning, 2009; Chen et al., 2011) or semi-supervised adaptation (Ando and Zhang, 2005; Jiang and Zhai, 2007; Kumar et al., 2010; Huang and Yates, 2010). Our problem setting falls into the former.

Multi-task learning has become popular in NLP. Sutton and McCallum (2005) showed that joint learning and/or decoding of sub-tasks helps to improve performance. Collobert and Weston (2008) proved the similar claim in a deep learning architecture. While our problem resembles their settings, there are two clear distinctions. First, we aim to optimize performance on the target domain by minimizing the gap between source and target domain while multi-task learning jointly learns the shared tasks. Second, in our problem the domains are different, but they are closely related. On the other hand, prior work focuses on multiple subtasks of the same data.

Despite the increasing interest in NLU (De Mori et al., 2008; Xu and Sarikaya, 2013; Sarikaya et al., 2014; Xu and Sarikaya, 2014; Anastasakos et al., 2014; El-Kahky et al., 2014; Liu and Sarikaya, 2014; Marin et al., 2014; Celikyilmaz et al., 2015; Ma et al., 2015; Kim et al., 2015), transfer learning in the context of NLU has not been much explored. The most relevant previous work is Tur (2006) and Li et al. (2011), which described both the effectiveness of multi-task learning in the context of NLU. For multi-task learning, they used shared slots by associating each slot type with aggregate active feature weight vector based on an existing domain specific slot tagger. Our empirical results shows that these vector representation might be helpful to find shared slots across domain, but cannot find bijective mapping between domains.
