Van de Cruys (2014) recently presented a deep learning approach to SP acquisition. He trained a neural network to discriminate between felicitous and infelicitous arguments using the data constructed of positive (observed) and negative (randomly-generated) examples for training. The network weights were optimized by requiring the model to assign a higher score to an observed pair than to the unobserved one by a given margin.

2.2 Multi-modal methods in semantics

Previous work has used multimodal data to determine distributional similarity or to learn multimodal embeddings that project multiple modalities into the same vector space. Some studies rely on extensions of LDA to obtain correlations between words and visual features (Feng and Lapata, 2010; Roller and Schulte im Walde, 2013). Bruni et al. (2012) integrated visual features into distributional similarity models using simple vector concatenation. Instead of generic visual features, Silberer et al. (2013) relied on supervised learning to train 412 higher-level visual attribute classifiers.

Applications of multimodal embeddings include zero-shot object detection, i.e. recognizing objects in images without training data for the object class (Socher et al., 2013; Frome et al., 2013; Lazaridou et al., 2014), and automatic generation of image captions (Kulkarni et al., 2013), video descriptions (Rohrbach et al., 2013), or tags (Srivastava et al., 2014). Other applications of multimodal data include language modeling (Kiros et al., 2014) and knowledge mining from images (Chen et al., 2013; Divvala et al., 2014). Young et al. (2014) apply simplification rules to image captions, showing that the resulting hierarchy of mappings between natural language expressions and images can be used for entailment tasks.

3 Experimental data

Textual data. We extract linguistic features for our model from the BNC. In particular, we parse the corpus using the RASP parser (Briscoe et al., 2006) and extract subject–verb and verb–object relations from its dependency output. These relations are then used as features for clustering to obtain SP classes, as well as to quantify the strength of association between a particular verb and a particular argument class.

Visual data. For the visual features of our model, we mine the Yahoo! Webscope Flickr-100M dataset (Shamma, 2014). Flickr-100M contains 99.3 million images and 0.7 million videos with language tags annotated by users, enabling us to generalise SPs at a large scale. The tags reflect how humans describe objects and actions from a visual perspective. We first stem the tags and remove words that are absent in WordNet (typically named entities and misspellings), then identify their PoS based on their visual context and extract verb–noun co-occurrences.

4 Identifying visual verb-noun co-occurrence

In the Flickr-100M dataset, tags are assigned to images and videos in the form of sets of words, rather than grammatically coherent sentences. However, the roles that individual words play are still discernible from their visual context, as manifested by the other words in a given set. In order to identify verbs and nouns co-occurring in the same images, we propose a *list sense disambiguation* method that first maps each word to a set of possible WordNet senses (accompanied by PoS information) and then performs a joint optimization on the space of candidate word senses, such that their overall similarity is maximized. This amounts to assigning those senses and PoS tags to the words in the set that best fit together.

For a given word i and one of its candidate WordNet senses j, we consider an assignment variable x_{ij} and compute a sense frequency-based prior for it as $P_{ij} = \frac{1}{1+R}$, where R is the WordNet rank of the sense. We then compute a similarity score $S_{ij,i'j'}$ between all pairs of sense choices for two words i,i' and their respective candidate senses j,j'. For these, we rely on WordNet's taxonomic path-based similarities (Pedersen et al., 2004) in the case of noun-noun sense pairs, the Adapted Lesk similarity measure for adjective-adjective pairs, and finally, WordNet verb-groups and VerbNet class membership (Kipper-Schuler, 2005) for verb-verb pairs. Note that even parts of speech that are disregarded later on can still be helpful at this stage, as we aim at a joint optimization over all words. After the similarities have been obtained for all relevant sense pairs, we maximize the coherence of the senses of the words in the set as an Integer Linear Program, using the Gurobi Optimizer (Gurobi Optimization, 2014) and solving

$$\begin{aligned}&\textbf{maximize}\\ &\quad \sum_i P_{ij}x_{ij} + \sum_{ij}\sum_{i'j'} S_{ij,i'j'}B_{ij,i'j'}\\ &\textbf{subject to}\\ &\quad \textstyle\sum_j x_{ij} \le 1\,\forall i,\ \ x_{ij}\in\{0,1\}\,\forall i,j,\\ &\quad B_{ij,i'j'} \le x_{ij},\ \ B_{ij,i'j'} \le x_{i'j'},\\ &\quad B_{ij,i'j'} \in \{0,1\}\ \ \forall i,j,i'j'.\end{aligned}$$

The binary variables $B_{ij,i'j'}$ are 1 iff $x_{ij} = 1$ and $x_{i'j'} = 1$, indicating that both senses were simultaneously chosen. The optimizer disambiguates the input words by selecting sense tuples $x_{1j}, x_{2j}, \ldots$, from which we can directly obtain the corresponding PoS information. Verb-noun co-occurrence information is then extracted from the PoS-tagged sets.

5 Selectional preference model

5.1 Acquisition of argument classes

To address the issue of data sparsity, we generalise selectional preferences over argument classes, as opposed to individual arguments. We obtain SP classes by means of spectral clustering of nouns with lexico-syntactic features, which has been shown effective in previous lexical classification tasks (Brew and Schulte im Walde, 2002; Sun and Korhonen, 2009).

Spectral clustering partitions the data, relying on a similarity matrix that records similarities between all pairs of data points. We use *Jensen-Shannon divergence* to measure the similarity between feature vectors for two nouns, w_i and w_j, defined as follows:

$$d_{\mathrm{JS}}(w_i, w_j) = \frac{1}{2}d_{\mathrm{KL}}(w_i||m) + \frac{1}{2}d_{\mathrm{KL}}(w_j||m), \tag{1}$$

where d_{KL} is the Kullback-Leibler divergence, and m is the average of w_i and w_j. We construct the similarity matrix S computing similarities S_{ij} as $S_{ij} = \exp(-d_{\mathrm{JS}}(w_i, w_j))$. The matrix S then encodes a similarity graph G (over our nouns), where S_{ij} are the adjacency weights. The clustering problem can then be defined as identifying the optimal partition, or *cut*, of the graph into clusters, such that the intra-cluster weights are high and the inter-cluster weights are low. We use the multiway normalized cut (MNCut) algorithm of Meila and Shi (2001) for this purpose. The algorithm transforms S into a stochastic matrix P containing transition probabilities between the vertices in the graph as

$$P = D^{-1}S, \tag{2}$$

where the degree matrix D is a diagonal matrix with $D_{ii} = \sum_{j=1}^{N} S_{ij}$. It then computes the K leading eigenvectors of P, where K is the desired number of clusters. The graph is partitioned by finding approximately equal elements in the eigenvectors using a simpler clustering algorithm, such as *k-means*. Meila and Shi (2001) have shown that the partition I derived in this way minimizes the MNCut criterion:

$$\mathrm{MNCut}(I) = \sum_{k=1}^{K}(1 - P(I_k \rightarrow I_k|I_k)), \tag{3}$$

which is the sum of transition probabilities across different clusters. Since k-means starts from a random cluster assignment, we run the algorithm multiple times and select the partition that minimizes the cluster distortion, i.e. distances to cluster centroid.

We cluster nouns using linguistic and visual features in two independent experiments.

Clustering with linguistic features: We first cluster the 2,000 most frequent nouns in the BNC, using their grammatical relations as features. The features consist of verb lemmas appearing in the subject, direct object and indirect object relations with the given nouns in the RASP-parsed BNC, indexed by relation type. The feature vectors are first constructed from the corpus counts, and subsequently normalized by the sum of the feature values.

Clustering with visual features: We also cluster the 2,000 most frequent nouns in the Flickr data. Since our goal is to create argument classes for verb preferences, we extract co-occurrence features that map to verb-noun relations from PoS-disambiguated image tags. We use the verb lemmas co-occurring with the noun in the same images and videos as features for clustering. The feature values are again normalised by their sum.

SP classes: Example clusters produced using linguistic and visual features are shown in Figures 1 and 2. Our cluster analysis reveals that the image-derived clusters tend to capture scene-like relations (e.g. *beach* and *ocean*; *guitar* and *concert*), as opposed to types of entities, yielded by the linguistic features and better suited to generalise over

desire hostility anxiety passion doubt fear curiosity enthusiasm impulse instinct emotion feeling suspicion
official officer inspector journalist detective constable police policeman reporter
book statement account draft guide advertisement document report article letter

Figure 1: Clusters obtained using linguistic features

Figure 2: Clusters obtained using visual features

predicate-argument structure. In addition, the image features tend to be sparse for abstract concepts, reducing both the quality and the coverage of abstract clusters. We thus use the noun clusters derived with linguistic features as an approximation of SP classes.

5.2 Quantifying selectional preferences

Once the SP classes have been obtained, we need to quantify the strength of association of a given verb with each of the classes. We adopt an information theoretic measure proposed by Resnik (1993) for this purpose. Resnik first measures *selectional preference strength* (SPS) of a verb in terms of Kullback-Leibler divergence between the distribution of noun classes occurring as arguments of this verb, $p(c|v)$, and the prior distribution of the noun classes, $p(c)$.

$$\text{SPS}_R(v) = \sum_c p(c|v) \log \frac{p(c|v)}{p(c)}, \qquad (4)$$

where R is the grammatical relation for which SPs are computed. SPS measures how strongly the predicate constrains its arguments. Selectional association of the verb with a particular argument class is then defined as a relative contribution of that argument class to the overall SPS of the verb.

$$\text{Ass}_R(v,c) = \frac{1}{\text{SPS}_R(v)} p(c|v) \log \frac{p(c|v)}{p(c)} \qquad (5)$$

We use this measure to quantify verb SPs based on linguistic and visual co-occurrence information. We first extract verb-subject and verb-direct object relations from the RASP-parsed BNC, map the argument heads to SP classes and quantify selectional association of a given verb with each SP class, thus acquiring its *base* preferences. Since visual verb-noun co-occurrences do not contain information about grammatical relations, we rely on linguistic data to provide a set of base arguments of the verb for a given grammatical relation. We then interpolate the verb-argument probabilities from linguistic and visual models for the base arguments of the verb, thus preserving information about grammatical relations.

5.3 Linguistic and visual model interpolation

We investigate two model interpolation techniques: simple linear interpolation and predicate-driven linear interpolation.

Linear interpolation combines information from component models by computing a weighted average of their probabilities. The interpolated probability of an event e is derived as $p^{\text{LI}}(e) = \sum_i \lambda_i p_i(e)$, where $p_i(e)$ is the probability of e in the model i and λ_i is the interpolation weight defined such that $\sum_i \lambda_i = 1$; and $\lambda_i \in [0, 1]$. In our experiments, we interpolate the probabilities $p(c)$ and $p(c|v)$ in the linguistic (LM) and visual (VM) models, as follows:

$$p^{\text{LI}}(c) = \lambda_{\text{LM}} p_{\text{LM}}(c) + \lambda_{\text{VM}} p_{\text{VM}}(c) \qquad (6)$$

$$p^{\text{LI}}(c|v) = \lambda_{\text{LM}} p_{\text{LM}}(c|v) + \lambda_{\text{VM}} p_{\text{VM}}(c|v) \qquad (7)$$

We experiment with a number of parameter settings for λ_{LM} and λ_{VM}.

Predicate-driven linear interpolation derives predicate-specific interpolation weights directly from the data, as opposed to pre-setting them universally for all verbs. For each predicate v, we compute the interpolation weights based on its prominence in the respective corpus, as follows:

$$\lambda_i(v) = \frac{\text{rel}_i(v)}{\sum_k \text{rel}_k(v)}, \qquad (8)$$

where rel is the relevance function of model i for verb v, computed as its relative frequency in the respective corpus: $\text{rel}_i(v) = \frac{f_i(v)}{\sum_V f_i(v)}$. The interpolation weights for LM and VM are then computed as

$$\lambda_{\text{LM}}(v) = \frac{\text{rel}_{\text{LM}}(v)}{\text{rel}_{\text{LM}}(v) + \text{rel}_{\text{VM}}(v)} \qquad (9)$$

$$\lambda_{\text{VM}}(v) = \frac{\text{rel}_{\text{VM}}(v)}{\text{rel}_{\text{LM}}(v) + \text{rel}_{\text{VM}}(v)}. \qquad (10)$$

The motivation for this approach comes from the fact that not all verbs are represented equally well in linguistic and visual data. For instance, while concrete verbs, such as *run, push* or *throw*, are more likely to be prominent in visual data, abstract verbs, such as *understand* or *speculate*, are best represented in text. Relative linguistic and visual frequencies of a verb provide a way to estimate the relevance of linguistic and visual features to its SP learning.

6 Direct evaluation and data analysis

We evaluate the predicate-argument scores assigned by our models against a dataset of human plausibility judgements of verb-direct object pairs collected by Keller and Lapata (2003). Their dataset is balanced with respect to the frequency of verb-argument relations, as well as their plausibility and implausibility, thus creating a realistic SP evaluation task. Keller and Lapata selected 30 predicates and matched each of them to three arguments from different co-occurrence frequency bands according to their BNC counts, e.g. *divert attention* (high frequency), *divert water* (medium) and *divert fruit* (low). This constituted their dataset of *Seen* verb-noun pairs, 90 in total. Each of the predicates was then also paired with three randomly selected arguments with which it did not occur in the BNC, creating the *Unseen* dataset. The pairs in both datasets were then rated for their plausibility by 27 human subjects, and their judgements were aggregated into a gold standard. We compare the verb-argument scores generated by our linguistic (LSP), visual (VSP) and interpolated (ISP) SP models against these two datasets in terms of Pearson correlation coefficient, r, and Spearman rank correlation coefficient, ρ. The selectional association score of the cluster to which a given noun belongs is taken to represent the preference score of the verb for this noun. If a noun is not present in our argument clusters, we match it to its nearest cluster, as determined by its distributional similarity to the cluster centroid in terms of Jensen-Shannon divergence.

	Seen		Unseen	
	r	ρ	r	ρ
VSP	0.180	0.126	0.118	0.132

ISP: $\lambda_{\text{LM}} = 0.9$	**0.548**	0.699	0.342	0.429
ISP: Predicate-driven	0.476	0.597	0.391	0.551
LSP	0.512	0.688	**0.412**	**0.559**

Table 1: Model comparison on the plausibility data of Keller and Lapata (2003)

LSP: **(1)** 0.309 expenditure cost risk expense emission budget spending; **(2)** 0.201 dividend price rate premium rent rating salary wages; **(3)** 0.088 employment investment growth supplies sale import export production [..]

ISP predicate-driven $\lambda_{\text{LM}} = 0.65$
(1) 0.346 expenditure cost risk expense emission budget spending; **(2)** 0.211 dividend price rate premium rent rating salary wages; **(3)** 0.126 tail collar strand skirt trousers hair curtain sleeve

VSP: **(1)** 0.224 tail collar strand skirt trousers hair curtain sleeve; **(2)** 0.098 expenditure cost risk expense emission budget spending; **(3)** 0.090 management delivery maintenance transport service housing [..]

Figure 3: Top three direct object classes for *cut* and their association scores, assigned by different models

We first compare LSP, VSP and ISP with static and predicate-driven interpolation weights. The results, presented in Table 1, demonstrate that the interpolated model outperforms both LSP and VSP used on their own. The best performance is attained with the static interpolation weights of $\lambda_{\text{LM}} = 0.8$ ($r = 0.540$; $\rho = 0.728$) and $\lambda_{\text{LM}} = 0.9$ ($r = 0.548$; $\rho = 0.699$). This suggests that while linguistic input plays a crucial role in SP induction (by providing both semantic and syntactic information), visual features further enhance the quality of SPs, as we expected. Figure 3 shows LSP- and VSP-acquired direct object preferences of the verb *cut*, as well as the effects of merging the features in the interpolated model – the verbs' experiential arguments (e.g. *hair* or *fabric*) are emphasized by the visual features.

However, the model based on visual features alone performs poorly on the dataset of Keller and Lapata (2003). This is partly explained by the fact that a number of verbs in this dataset are abstract verbs, whose visual representations in the Flickr data are sparse. In addition, VSP (as other visual models used in isolation from text) is not syntax-aware and is unable to discriminate between different types of semantic relations. VSP thus acquires sets of verb-argument relations that are closer in nature to scene descriptions and semantic frames than to lexico-syntactic paradigms. Figure 4 shows the differences between linguistic and visual arguments of the verb *kill* ranked by LSP and VSP. While LSP produces mainly semantic objects of *kill*, VSP output contains other types of arguments, such as *weapon* (instrument) and *death* (consequence).

Taking the argument classes produced by the linguistic model as a basis and then re-ranking

LSP: **(1)** 0.523 girl other woman child person people; **(2)** 0.164 fleet soldier knight force rebel guard troops crew army pilot; **(3)** 0.133 sister daughter parent relative lover cousin friend wife mother husband brother father; **(4)** 0.048 being species sheep animal creature horse baby human fish male lamb bird rabbit [..]; **(5)** 0.045 victim bull teenager prisoner hero gang enemy rider offender youth killer thief [..]

VSP: **(1)** 0.180 defeat fall death tragedy loss collapse decline [..]; **(2)** 0.141 girl other woman child person people; **(3)** 0.128 abuse suicide killing offence murder breach crime; **(4)** 0.113 handle weapon horn knife blade stick sword [..]; **(5)** 0.095 victim bull teenager prisoner hero gang enemy rider offender youth killer thief [..]

them to incorporate visual statistics helps to avoid the above problem for the interpolated models, whose output corresponds to grammatical relations. However, static interpolation weights (emphasizing linguistic features over the visual ones for all verbs equally) outperformed the predicate-driven interpolation technique, attaining correlations of $r = 0.548$ and $r = 0.476$ respectively. This is mainly due to the fact that some verbs are over-represented in the visual data (e.g. the predicate-driven interpolation weight for the verb *drink* is $\lambda_{\text{LM}} = 0.08$). As a result, candidate argument classes (selected based on syntactically-parsed linguistic input) are ranked predominantly based on visual statistics. This makes it possible to emphasize incorrectly parsed arguments (such as subject relations in the direct object SP distribution and vice versa). The predicate-driven ISP output for direct object SPs of *drink*, for instance, contains a mixture of subject and direct object classes, as shown in Figure 5. Using a static model with a high λ_{LM} weight helps to avoid such errors and, therefore, leads to a better performance.

In order to investigate the composition of the visual and linguistic datasets, we assess the average level of concreteness of the verbs and nouns present in the datasets. We use the concreteness ratings from the MRC Psycholinguistic Database (Wilson, 1988) for this purpose. In this database, nouns and verbs are rated for concreteness on a scale from 100 (highly abstract) to 700 (highly concrete). We map the verbs and nouns in our textual and visual corpora to their MRC concreteness scores. We then calculate a dataset-wide concreteness score as an average of the concreteness scores of individual verbs and nouns weighted by their frequency in the respective corpus. The average concreteness scores in the visual dataset were 506.4 (nouns) and 498.1 (verbs). As expected, they are higher than the respective scores in the textual data: 433.1 (nouns) and 363.4 (verbs). In order to compare the types of actions that are common in each of the datasets, we map the verbs to their corresponding top level classes in WordNet. Figure 6 shows the comparison of prominent verb classes in visual and textual data. One can see from the Figure that the visual dataset is well suited for representing *motion, perception* and *contact*, while abstract verbs related to e.g. *communication, cognition, possession* or *change* are more common in textual data.

We also compare the performance of our models to existing SP induction methods: the EM-based clustering method of Rooth et al. (1999), the vector space similarity-based method of Padó et al. (2007) and the LDA topic modelling approach of Ó Séaghdha (2010)[1]. The best ISP configuration

[1] Since Rooth et al.'s (1999) and Padó et al.'s (2007) models were not originally evaluated on the same dataset, we use the

($\lambda_{\text{LM}} = 0.9$) outperforms all of these methods, as well as our own LSP, on the *Seen* dataset, confirming the positive contribution of visual features. However, it achieves less success on the *Unseen* data, where the methods of Ó Séaghdha (2010) and Rooth et al. (1999) are leading. This result speaks in favour of latent variable models for acquisition of SP estimates for rarely attested predicate-argument pairs. In turn, this suggests that integrating our ISP model (that currently outperforms others on more common pairs) with such techniques is likely to improve SP prediction across frequency bands.

7 Task-based evaluation

In order to investigate the applicability of perceptually grounded SPs in wider NLP, we evaluate them in the context of an external semantic task – that of metaphor interpretation. Since metaphor is based on transferring imagery and knowledge across domains – typically from more familiar domains of physical experiences to the sphere of vague and elusive abstract thought – metaphor interpretation provides an ideal framework for testing perceptually grounded SPs. Our experiments rely on the metaphor interpretation method of Shutova (2010), in which text-derived SPs are a central component of the system. We replace the SP component with our LSP and ISP ($\lambda_{\text{LM}} = 0.8$) models and compare their performance in the context of metaphor interpretation.

Shutova (2010) defined metaphor interpretation as a paraphrasing task, where literal paraphrases for metaphorical expressions are derived from corpus data using a set of statistical measures. For instance, their system interprets the metaphor "a carelessly *leaked* report" as "a carelessly disclosed report". Focusing on metaphorical verbs in subject and direct object constructions, Shutova first applies a maximum likelihood model to extract and rank candidate paraphrases for the verb given the context, as follows:

$$P(i, w_1, ..., w_N) = \frac{\prod_{n=1}^{N} f(w_n, i)}{(f(i))^{N-1} \cdot \sum_k f(i_k)}, \quad (11)$$

where $f(i)$ is the frequency of the paraphrase on its own and $f(w_n, i)$ the co-occurrence frequency of the paraphrase with the context word w_n. This model favours paraphrases that match the given context best. These candidates are then filtered based on the presence of shared features with the metaphorical verb, as defined by their location and distance in the WordNet hierarchy. All the candidates that have a common hypernym with the metaphorical verb within three levels of the WordNet hierarchy are selected. This results in a set of paraphrases retaining the meaning of the metaphorical verb. However, some of them are still figuratively used. Shutova further applies an SP model to discriminate between figurative and literal paraphrases, treating a strong selectional preference fit as a likely indicator of literalness. The candidates are re-ranked by the SP model, emphasizing the verbs whose preferences the noun in the context matches best. We use LSP and ISP scores to perform this re-ranking step.

We evaluate the performance of our models on this task using the metaphor paraphrasing gold standard of Shutova (2010). The dataset consists of 52 verb metaphors and their human-produced literal paraphrases. Following Shutova, we evaluate the performance in terms of mean average precision (MAP), which measures the ranking quality of GS paraphrases across the dataset. MAP is defined as follows:

$$\text{MAP} = \frac{1}{M} \sum_{j=1}^{M} \frac{1}{N_j} \sum_{i=1}^{N_j} P_{ji},$$

where M is the number of metaphorical expressions, N_j is the number of correct paraphrases for the metaphorical expression j, P_{ji} is the precision at each correct paraphrase (the number of correct paraphrases among the top i ranks). As compared to the gold standard, ISP attains a MAP score of 0.65, outperforming both the LSP (MAP = 0.62) and the original system of Shutova (2010) (MAP = 0.62), demonstrating the positive contribution of visual features.

8 Conclusion

We have presented the first SP induction method that simultaneously draws knowledge from text, images and videos. Our experiments show that it outperforms linguistic and visual models in isolation, as well as the previous approaches to SP learning. We believe that this model has a wide applicability in NLP, where many systems already rely on automatically induced SPs. It can also benefit image caption generation systems, which

results for their re-implementation reported by O'Seaghdha (2010), who conducted a comprehensive evaluation of SP models on the plausibility data of Keller and Lapata (2003).

typically focus on objects rather than actions, by providing information about predicate-argument structure.

In the future, it would be interesting to derive the information about predicate-argument relations from low-level visual features directly. However, to our knowledge, reliably mapping images to actions (i.e. verbs) at a large-scale is still a challenging task. Human-annotated image and video descriptions allow us to investigate what types of verb–noun relations are in principle present in the visual data and the ways in which they are different from the ones found in text. Our results show that visual data is better suited for capturing physical properties of concepts as well as containing relations not explicitly described in text.

The presented interpolation techniques are also applicable outside multi-modal semantics. For instance, they can be generalised to acquire SPs from unbalanced corpora of different sizes (e.g. for languages lacking balanced corpora) or to perform domain adaptation of SPs. In the future, we would like to apply SP interpolation to multilingual SP learning, i.e. integrating data from multiple languages for more accurate SP induction and projecting universal semantic relations to low-resource languages. It is also interesting to investigate SP learning at the level of semantic predicates (e.g. automatically inducing FrameNet-style frames), where combining the visual and linguistic knowledge is likely to outperform text-based models on their own.

Abstract

Existing methods for Japanese predicate argument structure (PAS) analysis identify case arguments of each predicate without considering interactions between the target PAS and others in a sentence. However, the argument structures of the predicates in a sentence are semantically related to each other. This paper proposes new methods for Japanese PAS analysis to jointly identify case arguments of all predicates in a sentence by (1) modeling multiple PAS interactions with a bipartite graph and (2) approximately searching optimal PAS combinations. Performing experiments on the NAIST Text Corpus, we demonstrate that our joint analysis methods substantially outperform a strong baseline and are comparable to previous work.

1 Introduction

Predicate argument structure (PAS) analysis is a shallow semantic parsing task that identifies basic semantic units of a sentence, such as *who does what to whom*, which is similar to semantic role labeling (SRL)[1].

In Japanese PAS analysis, one of the most problematic issues is that arguments are often omitted in the surface form, resulting in so-called *zero-pronouns*. Consider the sentence of Figure 1.

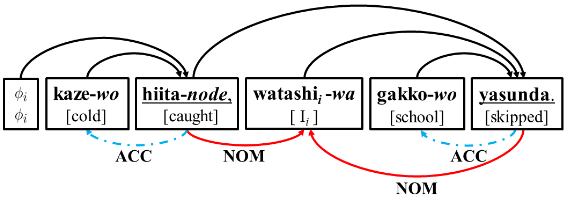

Figure 1: An example of Japanese PAS. The English translation is "Because ϕ_i caught a cold, I$_i$ skipped school.". The upper edges are dependency relations, and the under edges are case arguments. "NOM" and "ACC" represents the nominative and accusative arguments, respectively. "ϕ_i" is a *zero-pronoun*, referring to the *antecedent* "watashi$_i$".

The case role label "NOM" and "ACC" respectively represents the nominative and accusative roles, and ϕ_i represents a zero-pronoun. There are two predicates "hiita (caught)" and "yasunda (skipped)". For the predicate "yasunda (skipped)", "watashi$_i$-*wa* (I$_i$)" is the "skipper", and "gakko-*wo* (school)" is the "entity skipped". It is easy to identify these arguments, since syntactic dependency between an argument and its predicate is a strong clue. On the other hand, the nominative argument of the predicate "hiita (caught)" is "watashi$_i$-*wa* (I$_i$)", and this identification is more difficult because of the lack of the direct syntactic dependency with "hiita (caught)". The original nominative argument appears as a zero-pronoun, so that we have to explore the *antecedent*, an element referred to by a zero-pronoun, as the argument. As the example sentence shows, we cannot use effective syntactic information for identifying such arguments. This type of arguments is known as **implicit arguments**, a very problematic language

[1] We use "PAS analysis" in this paper following previous work on Japanese PAS analysis.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 961–970,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

phenomenon for PAS analysis (Gerber and Chai, 2010; Laparra and Rigau, 2013).

Previous work on Japanese PAS analysis attempted to solve this problem by identifying arguments per predicate without considering ***interactions*** between multiple predicates and arguments (Taira et al., 2008; Imamura et al., 2009). However, implicit arguments are likely to be shared by semantically-related predicates. In the above example (Figure 1), the implicit argument of the predicate "hiita (caught)" is shared by the other predicate "yasunda (skipped)" as its nominative argument "watashi$_i$ (I$_i$)".

Based on this intuition, we propose methods to jointly identify optimal case arguments of all predicates in a sentence taking their interactions into account. We represent the interactions as a bipartite graph that covers all predicates and candidate arguments in a sentence, and factorize the whole relation into the second-order relations. This interaction modeling results in a hard combinatorial problem because it is required to select the optimal PAS combination from all possible PAS combinations in a sentence. To solve this issue, we extend the randomized hill-climbing algorithm (Zhang et al., 2014) to search all possible PAS in the space of bipartite graphs.

We perform experiments on the NAIST Text Corpus (Iida et al., 2007), a standard benchmark for Japanese PAS analysis. Experimental results show that compared with a strong baseline, our methods achieve an improvement of 1.0-1.2 points in F-measure for total case argument identification, and especially improve performance for implicit argument identification by 2.0-2.5 points. In addition, although we exploit no external resources, we get comparable results to previous work exploiting large-scale external resources (Taira et al., 2008; Imamura et al., 2009; Sasano and Kurohashi, 2011). These results suggest that there is potential for more improvement by adding external resources.

The main contributions of this work are: (1) We present new methods to jointly identify case arguments of all predicates in a sentence. (2) We propose global feature templates that capture interactions over multiple PAS. (3) Performing experiments on the NAIST Text Corpus, we demonstrate our methods are superior to a strong baseline and comparable to the methods of representative previous work.

2 Japanese Predicate Argument Structure Analysis

2.1 Task Overview

In Japanese PAS analysis, we identify arguments taking part in the three major case roles, **nominative** (NOM), **accusative** (ACC) and **dative** (DAT) cases, for each predicate. Case arguments can be divided into three categories according to the positions relative to their predicates (Hayashibe et al., 2011):

Dep: The arguments that have direct syntactic dependency with the predicate.

Zero: The implicit arguments whose antecedents appear in the same sentence and have no direct syntactic dependency with the predicate.

Inter-Zero: The implicit arguments whose antecedents do not appear in the same sentence.

For example, in Figure 1, the accusative argument "gakko-*wo* (school)" of the predicate "yasunda (skipped)" is regarded as *Dep*, and the nominative argument "watashi$_i$-*wa* (I)" (the antecedent of zero-pronoun "ϕ_i") of the predicate "hiita (caught)" is *Zero*.

In this paper, we focus on the analysis for intra-sentential arguments (*Dep* and *Zero*). In order to identify inter-sentential arguments (*Inter-Zero*), it is required to search a much broader space, such as the whole document, resulting in a much harder analysis than intra-sentential arguments.[2] Therefore, we believe that quite different approaches are necessary to realize an inter-sentential PAS analysis with high accuracy, and leave it for future work.

2.2 Related Work

For Japanese PAS analysis research, the NAIST Text Corpus has been used as a standard benchmark (Iida et al., 2007). One of the representative researches using the NAIST Text Corpus is Imamura et al. (2009). They built three distinct models corresponding to the three case roles by extracting features defined on each pair of a predicate and a candidate argument. Using each model, they select the best candidate argument for each case per predicate. Their models are based on maximum entropy model and can easily incorporate various features, resulting in high accuracy.

[2] Around 10-20% in F measure has been achieved in previous work (Taira et al., 2008; Imamura et al., 2009; Sasano and Kurohashi, 2011).

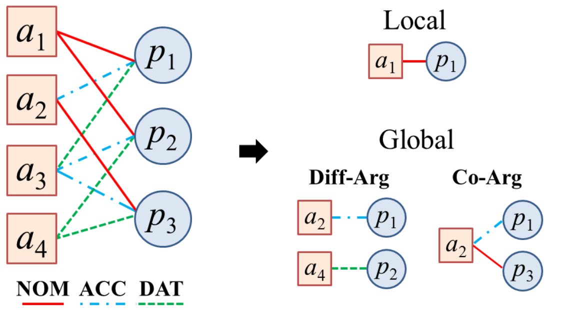

Figure 2: Intuitive image of a *predicate-argument graph*. This graph is factorized into the local and global features. The different line color/style indicate different cases.

While in Imamura et al. (2009) one case argument is identified at a time per predicate, the method proposed by Sasano and Kurohashi (2011) simultaneously determines all the three case arguments per predicate by exploiting large-scale case frames obtained from large raw texts. They focus on identification of implicit arguments (*Zero* and *Inter-Zero*), and achieves comparable results to Imamura et al. (2009).

In these approaches, case arguments were identified per predicate without considering interactions between multiple predicates and candidate arguments in a sentence. In the semantic role labeling (SRL) task, Yang and Zong (2014) pointed out that information of different predicates and their candidate arguments could help each other for identifying arguments taking part in semantic roles. They exploited a reranking method to capture the interactions between multiple predicates and candidate arguments, and jointly determine argument structures of all predicates in a sentence (Yang and Zong, 2014). In this paper, we propose new joint analysis methods for identifying case arguments of all predicates in a sentence capturing interactions between multiple predicates and candidate arguments.

3 Graph-Based Joint Models

3.1 A Predicate-Argument Graph

We define predicate argument relations by exploiting a bipartite graph, illustrated in Figure 2. The nodes of the graph consist of two disjoint sets: the left one is a set of *candidate arguments* and the right one is a set of *predicates*. In this paper, we call it a **predicate-argument (PA) graph**.

Each predicate node has three distinct edges corresponding to nominative (NOM), accusative (ACC), and dative (DAT) cases. Each edge with a case role label joins a candidate argument node with a predicate node, which represents a case argument of a predicate. For instance, in Figure 2 a_1 is the nominative argument of p_1, and a_3 is the accusative argument of p_2.

Formally, a PA graph is a bipartite graph $\langle A, P, E \rangle$, where A is the node set consisting of candidate arguments, P the node set consisting of predicates, and E the set of edges subject to that there is exactly one edge e with a case role label c outgoing from each of the predicate nodes p to a candidate argument node a. A PA graph is defined as follows:

$$
\begin{aligned}
& A = \{a_1, ..., a_n, a_{n+1} = \texttt{NULL}\} \\
& P = \{p_1, ..., p_m\} \\
& E = \{\langle a, p, c \rangle \mid deg(p, c) = 1, \\
& \qquad\qquad \forall a \in A,\ \forall p \in P,\ \forall c \in C\ \}
\end{aligned}
$$

where $deg(p, c)$ is the number of edges with a case role c outgoing from p, and C is the case role label set. We add a dummy node a_{n+1}, which is defined for the cases where the predicate requires no case argument or the required case argument does not appear in the sentence. An edge $e \in E$ is represented by a tuple $\langle a, p, c \rangle$, indicating the edge with a case role c joining a candidate argument node a and a predicate node p. An admissible PA graph satisfies the constraint $deg(p, c) = 1$, representing that each predicate node p has only one edge with a case role c.

To identify the whole PAS for a sentence x, we predict the PA graph with an edge set corresponding to the correct PAS from the admissible PA graph set $G(x)$ based on a **score** associated with a PA graph y as follows:

$$\tilde{y} = \underset{y \in G(x)}{\text{argmax}}\ Score(x, y)$$

A scoring function $Score(x, y)$ receives a sentence x and a candidate graph y as its input, and returns a scalar value.

In this paper, we propose two scoring functions as analysis models based on different assumptions: (1) **Per-Case Joint Model** assumes the interaction between multiple predicates (***predicate interaction***) and the independence between case roles, and (2) **All-Cases Joint Model** assumes the interaction between case roles (***case interaction***) as well as the *predicate interaction*.

3.2 Per-Case Joint Model

Per-Case Joint Model assumes that different case roles are independent from each other. However, for each case, interactions between multiple predicates are considered jointly.

We define the score of a PA graph y to be the sum of the scores for each case role c of the set of the case roles C:

$$Score_{per}(x, y) = \sum_{c \in C} Score_c(x, y) \qquad (1)$$

The scores for each case role are defined as the dot products between a weight vector $\boldsymbol{\theta_c}$ and a feature vector $\boldsymbol{\phi_c}(x, E(y, c))$:

$$Score_c(x, y) = \boldsymbol{\theta_c} \cdot \boldsymbol{\phi_c}(x, E(y, c)) \qquad (2)$$

where $E(y, c)$ is the edge set associated with a case role c in the candidate graph y, and the feature vector is defined on the edge set.

The edge set $E(y, c)$ in the equation (2) is utilized for the two types of features, the **local features** and **global features**, inspired by (Huang, 2008), defined as follows:

$$\boldsymbol{\theta_c} \cdot \boldsymbol{\phi_c}(x, E(y, c)) =$$

$$\sum_{e \in E(y,c)} \boldsymbol{\theta_c}\, \boldsymbol{\phi_l}(x, e) + \boldsymbol{\theta_c}\, \boldsymbol{\phi_g}(x, E(y, c)) \qquad (3)$$

where $\boldsymbol{\phi_l}(x, e)$ denotes the local feature vector, and $\boldsymbol{\phi_g}(x, E(y, c))$ the global feature vector. The local feature vector $\boldsymbol{\phi_l}(x, e)$ is defined on each edge e in the edge set $E(y, c)$ and a sentence x, which captures a predicate-argument pair. Consider the example of Figure 2. For Per-Case Joint Model, we use edges, $e_{a_1p_1}$, $e_{a_1p_2}$, and $e_{a_2p_3}$, as local features to compute the score of the edge set with the nominative case.

In addition, the global feature vector $\boldsymbol{\phi_g}(x, E(y, c))$ is defined on the edge set $E(y, c)$, and enables the model to utilize linguistically richer information over multiple predicate-argument pairs. In this paper, we exploit *second-order* relations, similar to the second-order edge factorization of dependency trees (McDonald and Pereira, 2006). We make a set of edge pairs E_{pair} by combining two edges e_i, e_j in the edge set $E(y, c)$, as follows:

$$E_{pair} = \{\ \{e_i, e_j\} \mid \forall e_i, e_j \in E(y, c),\ e_i \neq e_j\ \}$$

For instance, in the PA graph in Figure 2, to compute the score of the nominative arguments, we make three edge pairs:

$$\{\{e_{a_1p_1},\ e_{a_1p_2}\}, \{e_{a_1p_1},\ e_{a_2p_3}\}, \{e_{a_1p_2},\ e_{a_2p_3}\}\}$$

Then, features are extracted from these edge pairs and utilized for the score computation. For the accusative and dative cases, their scores are computed in the same manner. Then, we obtain the resulting score of the PA graph by summing up the scores of the local and global features. If we do not consider the global features, the model reduces to a per-case local model similar to previous work (Imamura et al., 2009).

3.3 All-Cases Joint Model

While Per-Case Joint Model assumes the *predicate interaction* with the independence between case roles, All-Cases Joint Model assumes the *case interaction* together with the *predicate interaction*. Our graph-based formulation is very flexible and easily enables the extension of Per-Case Joint Model to All-Cases Joint Model. Therefore, we extend Per-Case Joint Model to All-Cases Joint Model to capture the interactions between predicates and all case arguments in a sentence.

We define the score of a PA graph y based on the local and global features as follows:

$$Score_{all}(x, y) =$$

$$\sum_{e \in E(y)} \boldsymbol{\theta} \cdot \boldsymbol{\phi_l}(x, e) + \boldsymbol{\theta} \cdot \boldsymbol{\phi_g}(x, E(y)) \qquad (4)$$

where $E(y)$ is the edge set associated with all the case roles on the candidate graph y, $\boldsymbol{\phi_l}(x, e)$ is the local feature vector defined on each edge e in the edge set $E(y)$, and $\boldsymbol{\phi_g}(x, E(y))$ is the global feature vector defined on the edge set $E(y)$.

Consider the PA graph in Figure 2. The local features are extracted from each edge:

Nominative : $e_{a_1p_1}, e_{a_1p_2}, e_{a_2p_3}$
Accusative : $e_{a_2p_1}, e_{a_3p_2}, e_{a_3p_3}$
Dative : $e_{a_3p_1}, e_{a_4p_2}, e_{a_4p_3}$

For the global features, we make a set of edge pairs E_{pair} by combining two edges e_i, e_j in the edge set $E(y)$, like Per-Case Joint Model. However, in the All-Cases Joint Model, the global features may involve different cases (i.e. mixing edges with different case roles). For the PA graph in Figure 2, we make the edge pairs $\{e_{a_1p_1}, e_{a_2p_1}\}$, $\{e_{a_3p_1},\ e_{a_1p_2}\}$, $\{e_{a_3p_2},\ e_{a_4p_3}\}$, and so on. From these edge pairs, we extract information as global features to compute a graph score.

Structure	Name	Description
Diff-Arg	**PAIR**	$\langle$ p_i.rf $\circ$ p_j.rf $\circ$ p_i.vo $\circ$ p_j.vo $\rangle$, $\langle$ a_i.ax $\circ$ a_i.rp $\circ$ p_i.ax $\circ$ p_i.vo $\rangle$, $\langle$ a_j.ax $\circ$ a_j.rp $\circ$ p_j.ax $\circ$ p_j.vo $\rangle$

	QUAD	$\langle$ a_i.ax $\circ$ a_j.ax $\circ$ a_i.rp $\circ$ a_j.rp $\circ$ p_i.vo $\circ$ p_j.vo $\rangle$ $\langle$ a_i.ax $\circ$ a_j.ax $\circ$ p_i.ax $\circ$ p_j.ax $\circ$ a_i.rp $\circ$ a_j.rp $\circ$ p_i.vo $\circ$ p_j.vo $\rangle$ $\langle$ a_i.ax $\circ$ a_j.ax $\circ$ p_i.rf $\circ$ p_j.rf $\circ$ a_i.rp $\circ$ a_i.rp $\circ$ p_i.vo $\circ$ p_i.vo $\rangle$
Co-Arg	**BI-PREDS**	$\langle$ a_i.rp $\circ$ p_i.rf $\circ$ p_j.rf $\rangle$, $\langle$ a_i.ax $\circ$ a_i.rp $\circ$ p_i.rf $\circ$ p_j.rf $\rangle$
	DEP-REL	$\langle$ a_i.ax $\circ$ a_i.rp $\circ$ p_i.ax $\circ$ p_j.ax $\circ$ p_i.vo $\circ$ p_j.vo $\circ$ (x, y).dep $\rangle$ if x depends on y for x,y in (p_i,p_j), (a_i,p_i), (a_i,p_j), (p_i,a_i), (p_j,a_i)

Table 1: Global feature templates. p_i, p_j is a predicate, a_i is the argument connected with p_i, and a_j is the argument connected with p_j. Feature conjunction is indicated by $\circ$; ax=auxiliary, rp=relative position, vo=voice, rf=regular form, dep=dependency. All the features are conjoined with the relative position and the case role labels of the two predicates.

4 Global Features

Features are extracted based on **feature templates**, which are functions that draw information from the given entity. For instance, one feature template $\phi_{100} = a.ax \circ p.vo$ is a conjunction of two atomic features $a.ax$ and $p.vo$, representing an auxiliary word attached to a candidate argument ($a.ax$) and the voice of a predicate ($p.vo$). We design several feature templates for characterizing each specific PA graph. Consider the PA graph constructed from the sentence in Figure 1, and a candidate argument "kaze-*wo* (a cold)" and a predicate "hiita (caught)" are connected with an edge. To characterize the graph, we draw some linguistic information associated with the edge. Since the auxiliary word attached to the candidate argument is "*wo*" and the voice of the predicate is "*active*", the above feature template ϕ_{100} will generate a feature instance as follows.

$$(a.ax = \textit{wo}) \circ (p.vo = \textit{active})$$

Such features are utilized for the local and global features in the joint models.

We propose the *global feature* templates that capture multiple PAS interactions based on the **Diff-Arg** and **Co-Arg** structures, depicted in the right part of Figure 1. The Diff-Arg structure represents that the two predicates have different candidate arguments, and the Co-Arg structure represents that the two predicates share the same candidate argument. Based on these structures, we define the global feature templates that receive a pair of edges in a PA graph as input and return a feature vector, shown in Table 1.

4.1 Diff-Arg Features

The feature templates based on the Diff-Arg structure are three types: **PAIR** (a pair of predicate-argument relation), **TRIANGLE** (a predicate and its two arguments relation), and **QUAD** (two predicate-argument relations).

PAIR These feature templates denote where the target argument is located relative to another argument and the two predicates in the Diff-Arg structure. We combine the relative position information (rp) with the auxiliary words (ax) and the voice of the two predicates (vo).

TRIANGLE This type of feature templates captures the interactions between three elements: two candidate arguments and a predicate. Like the PAIR feature templates, we encode the relative position information of two candidate arguments and a predicate with the auxiliary words and voice.

QUAD When we judge if a candidate argument takes part in a case role of a predicate, it would be beneficial to grasp information of another predicate-argument pair. The QUAD feature templates capture the mutual relation between four elements: two candidate arguments and predicates. We encode the relative position information, the auxiliary words, and the voice.

4.2 Co-Arg Features

To identify predicates that take implicit (*Zero*) arguments, we set two feature types, **BI-PREDS** and **DEP-REL**, based on the Co-Arg structure.

BI-PREDS For identifying an implicit argu-

```
Input: the set of cases to be analyzed $C$,
       parameter $\boldsymbol{\theta_c}$, sentence $x$
Output: a locally optimal PA graph $\tilde{y}$
 1: Sample a PA graph $y^{(0)}$ from $G(x)$
 2: $t \leftarrow 0$
 3: for each case $c \in C$ do
 4:     repeat
 5:         $Y_c \leftarrow NeighborG(y^{(t)}, c) \cup y^{(t)}$
 6:         $y^{(t+1)} \leftarrow \operatorname{argmax}_{y \in Y_c} \boldsymbol{\theta_c} \cdot \boldsymbol{\phi_c}(x, E(y, c))$
 7:         $t \leftarrow t + 1$
 8:     until $y^{(t)} = y^{(t+1)}$
 9: end for
10: return $\tilde{y} \leftarrow y^{(t)}$
```

Figure 3: Hill-Climbing for Per-Case Joint Model

```
Input: the set of cases to be analyzed $C$,
       parameter $\boldsymbol{\theta}$, sentence $x$
Output: a locally optimal PA graph $\tilde{y}$
1: Sample a PA graph $y^{(0)}$ from $G(x)$
2: $t \leftarrow 0$
3: repeat
4:     $Y \leftarrow NeighborG(y^{(t)}) \cup y^{(t)}$
5:     $y^{(t+1)} \leftarrow \operatorname{argmax}_{y \in Y} \boldsymbol{\theta} \cdot \boldsymbol{\phi}(x, E(y))$
6:     $t \leftarrow t + 1$
7: until $y^{(t)} = y^{(t+1)}$
8: return $\tilde{y} \leftarrow y^{(t)}$
```

Figure 4: Hill-Climbing for All-Cases Joint Model

ment of a predicate, information of another semantically-related predicate in the sentence could be effective. We utilize bi-grams of the regular forms (rf) of the two predicates in the Co-Arg structure to capture the predicates that are likely to share the same argument in the sentence.

DEP-REL We set five distinct feature templates to capture dependency relations (dep) between the shared argument and the two predicates. If two elements have a direct dependency relation, we encode its dependency relation with the auxiliary words and the voice.

5 Inference and Training

5.1 Inference for the Joint Models

Global features make the inference of finding the maximum scoring PA graph more difficult. For searching the graph with the highest score, we propose two greedy search algorithms by extending the *randomized hill-climbing* algorithm proposed in (Zhang et al., 2014), which has been shown to achieve the state-of-the-art performance in dependency parsing.

Figure 3 describes the pseudo code of our proposed algorithm for Per-Case Joint Model. Firstly, we set an initial PA graph $y^{(0)}$ sampled uniformly from the set of admissible PA graphs $G(x)$ (line 1 in Figure 3). Then, the union Y_c is constructed from the set of neighboring graphs with a case $NeighborG(y^{(t)}, c)$, which is a set of admissible graphs obtained by changing one edge with the case c in $y^{(t)}$, and the current graph $y^{(t)}$ (line 5). The current graph $y^{(t)}$ is updated to a higher scoring graph $y^{(t+1)}$ selected from the union Y_c (line 6). The algorithm continues until no more score improvement is possible by changing an edge with the case c in $y^{(t)}$ (line 8). This repetition is executed for other case roles in the same manner. As a result, we can get a locally optimal graph $\tilde{y}$.

Figure 4 describes the pseudo code of the algorithm for All-Cases Joint Model. The large part of the algorithm is the same as that for Per-Case Joint Model. The difference is that the union Y consists of the current graph $y^{(t)}$ and the neighboring graph set obtained by changing one edge in $y^{(t)}$ regardless of case roles (line 4 in Figure 4), and that the iteration process for each case role (line 3 in Figure 3) is removed. The algorithm also continues until no more score improvement is possible by changing an edge in $y^{(t)}$, resulting in a locally optimal graph $\tilde{y}$.

Following Zhang et al. (2014), for a given sentence x, we repeatedly run these algorithms with K consecutive restarts. Each run starts with initial graphs randomly sampled from the set of admissible PA graphs $G(x)$, so that we obtain K local optimal graphs by K restarts. Then the highest scoring one of K graphs is selected for the sentence x as the result. Each run of the algorithms is independent from each other, so that multiple runs are easily executable in parallel.

5.2 Training

Given a training data set $D = \{(\hat{x}, \hat{y})\}_i^N$, the weight vectors $\boldsymbol{\theta}$ ($\boldsymbol{\theta_c}$) in the scoring functions of the joint models are estimated by using machine learning techniques. We adopt averaged perceptron (Collins, 2002) with a max-margin technique:

$$\forall i \in \{1, ..., N\},\ y \in G(x_i),$$
$$Score(\hat{x}_i, \hat{y}_i) \geq Score(\hat{x}_i, y) + \|\hat{y}_i - y\|_1 - \xi_i$$

where $\xi_i \geq 0$ is the slack variable and $\|\hat{y}_i - y\|_1$ is the Hamming distance between the gold PA graph $\hat{y}_i$ and a candidate PA graph y of the admissible PA graphs $G(x_i)$. Following Zhang et al. (2014), we select the highest scoring graph $\tilde{y}$ as follows:

$$\text{TRAIN} : \tilde{y} = \underset{y \in G(\hat{x}_i)}{\text{argmax}} \{Score(\hat{x}_i, y) + \|\hat{y}_i - y\|_1\}$$
$$\text{TEST} : \tilde{y} = \underset{y \in G(x)}{\text{argmax}} \{Score(x, y)\}$$

Using the weight vector tuned by the training, we perform analysis on a sentence x in the test set.

6 Experiment

6.1 Experimental Settings

Data Set We evaluate our proposed methods on the NAIST Text Corpus 1.5, which consists of 40,000 sentences of Japanese newspaper text (Iida et al., 2007). While previous work has adopted the version 1.4 beta, we adopt the latest version. The major difference between version 1.4 beta and 1.5 is revision of dative case (corresponding to Japanese case particle "ni"). In 1.4 beta, most of adjunct usages of "ni" are mixed up with the argument usages of "ni", making the identification of dative cases seemingly easy. Therefore, our results are not directly comparable with previous work.

We adopt standard train/dev/test split (Taira et al., 2008) as follows:

Train	Articles: Jan 1-11,	Editorials: Jan-Aug
Dev	Articles: Jan 12-13,	Editorials: Sept
Test	Articles: Jan 14-17,	Editorials: Oct-Dec

We exclude inter-sentential arguments (*Inter-Zero*) in our experiments. Our features make use of the annotated POS tags, phrase boundaries, and dependency relations annotated in the NAIST Text Corpus. We do not use any external resources.

Baseline We adopt the pointwise method (using only local features) proposed by Imamura et al. (2009) as the baseline. They built three distinct models corresponding to the three case roles. By using each model, they estimate the likelihood that each candidate argument plays a case role of the target predicate as a score, and independently select the highest scoring one per predicate.

	feature	*Dep*	*Zero*	*Total*
PC Joint	*local*	84.59	42.55	77.89
	+ *global*	85.51	44.54	78.85
AC Joint	*local*	84.17	41.33	77.43
	+ *global*	85.92	44.45	79.17

Table 2: Global vs Local features on the development sets in F-measures. "PC Joint" denotes the Per-Case Joint Model, and "AC Joint" denotes the All-Cases Joint Model.

Features The baseline utilizes the *Baseline Features* used in Imamura et al. (2009) and *Grammatical* features used in Hayashibe et al. (2009), as the "Local Features". In addition, the joint models utilize the "Global Features" in Table 1.

Implementation Details For our joint models with hill-climbing, we report the average performance across ten independent runs with 10 restarts, which almost reaches convergence [3]. We train the baseline and our joint models for 20 iterations with averaged perceptron.

6.2 Results

Local Features vs Global Features

Table 2 shows the effectiveness of the global features on the development sets. We incrementally add the global features to the both models that utilize only the local features. The results show that the global features improve the performance by about 1.0 point in F-measures in total. For and are particularly beneficial to the implicit (*Zero*) argument identification (an improvement of 1.99 points in Per-Case Joint Model and 3.12 points in All-Cases Joint Model).

Pointwise Methods vs Joint Methods

Table 3 presents the F-measures of the baseline and our joint methods on the test set of the NAIST Text Corpus. We used the bootstrap resampling method as the significance test. In most of the metrics, our proposed joint methods outperform the baseline pointwise method. Note that since Per-Case Joint Model yields better results compared with the baseline, capturing the *predicate interaction* is beneficial to Japanese PAS analysis. In addition, the joint methods achieve a considerable improvement of 2.0-2.5 points in F-measure for

[3] Performance did not change when increasing the number of restarts

Case	Type	# of Args.	Baseline	PC Joint	AC Joint

TA08	75.53	88.20	89.51	30.15	11.41	3.66
IM09	87.0	93.9	80.8	50.0	30.8	0.0
S&K11	-	-	-	39.5	17.5	8.9
PC Joint	87.54	93.09	34.19	47.62	22.73	0.83
AC Joint	88.13	92.74	38.39	48.11	24.44	4.80

Table 4: Comparison with previous work using the NAIST Text Corpus in F-measure. TA08 is Taira et al. (2008), IM09 is Imamura et al. (2009), and S&K11 is Sasano & Kurohashi (2011). Their results are not directly comparable to ours since they use external resources and the NAIST Text Corpus 1.4 beta.

the implicit arguments (*Zero*), one of the problematic issues in Japanese PAS analysis.

Comparing the joint methods, each of our two joint methods is effective for a different case role. Per-Case Joint Model is better at the ACC case, and All-Cases Joint Model is better at the NOM and DAT cases. One of the possible explanations is that the distribution of ACC cases is different from NOM cases. While the ratio of *Dep* and *Zero* arguments for ACC cases is 90:10, the ratio for NOM cases is 75:25. This might have some negative effects on the ACC case identification with All-Cases Joint Model. However, in total, All-Cases Joint Model achieves significantly better results. This suggests that capturing *case interactions* improves performance of Japanese PAS analysis.

Existing Methods vs Joint Methods

To compare our proposed methods with previous work, we pick the three pieces of representative previous work exploiting the NAIST Text Corpus: Taira et al. (2008) (TA08), Imamura et al. (2009) (IM09), and Sasano and Kurohashi (2011) (S&K11). Sasano and Kurohashi (2011) focus on the analysis for the *Zero* and *Inter-Zero* arguments, and do not report the results on the *Dep* arguments. With respect to the *Dep* arguments, the All-Cases Joint Model achieves the best result for the NOM cases, Imamura et al. (2009) the best for the ACC cases, and Taira et al. (2008) the best for the DAT cases. In terms of the *Zero* arguments, Imamura et al. (2009) is the best for the NOM and ACC cases, and Sasano and Kurohashi (2011) the best for the DAT cases. Our joint methods achieve high performance comparable to Imamura et al. (2009).

However, because they used additional external resources and a different version of the NAIST Text Corpus, the results of previous work are not directly comparable to ours. Our research direction and contributions are orthogonal to theirs, and adding their external resources could potentially leads to much better results.

7 Conclusion

We have presented joint methods for Japanese PAS analysis, which model interactions between multiple predicates and arguments using a bipartite graph and greedily search the optimal PAS combination in a sentence. Experimental results shows that capturing the *predicate interaction* and *case interaction* is effective for Japanese PAS analysis. In particular, implicit (*Zero*) argument identification, one of the problematic issues in Japanese PAS analysis, is improved by taking such interactions into account. Since this framework is applicable to the *argument classification* in SRL, applying our methods to that task is an interesting line of the future research. In addition, the final results of our joint methods are comparable to representative existing methods despite using no external resources. For future work, we plan to incorporate external resources for our joint methods.

Jointly optimizing word representations for lexical and sentential tasks with the C-PHRASE model

Abstract

We introduce C-PHRASE, a distributional semantic model that learns word representations by optimizing context prediction for phrases at all levels in a syntactic tree, from single words to full sentences. C-PHRASE outperforms the state-of-the-art C-BOW model on a variety of lexical tasks. Moreover, since C-PHRASE word vectors are induced through a compositional learning objective (modeling the contexts of words combined into phrases), when they are summed, they produce sentence representations that rival those generated by *ad-hoc* compositional models.

1 Introduction

Distributional semantic models, that induce vector-based meaning representations from patterns of co-occurrence of words in corpora, have proven very successful at modeling many lexical relations, such as synonymy, co-hyponomy and analogy (Mikolov et al., 2013c; Turney and Pantel, 2010). The recent evaluation of Baroni et al. (2014b) suggests that the C-BOW model introduced by Mikolov et al. (2013a) is, consistently, the best across many tasks.[1]

Interestingly, C-BOW vectors are estimated with a simple compositional approach: The weights of adjacent words are jointly optimized so that their sum will predict the distribution of their contexts. This is reminiscent of how the parameters of some *compositional* distributional semantic models are estimated by optimizing the prediction of the contexts in which phrases occur in corpora (Baroni and Zamparelli, 2010; Guevara, 2010; Dinu et al., 2013). However, these compositional approaches assume that word vectors have already been constructed, and contextual evidence is only used to induce optimal combination rules to derive representations of phrases and sentences.

In this paper, we follow through on this observation to propose the new C-PHRASE model. Similarly to C-BOW, C-PHRASE learns word representations by optimizing their joint context prediction. However, unlike in flat, window-based C-BOW, C-PHRASE groups words according to their syntactic structure, and it simultaneously optimizes context-predictions at different levels of the syntactic hierarchy. For example, given training sentence *"A sad dog is howling in the park"*, C-PHRASE will optimize context prediction for *dog*, *sad dog*, *a sad dog*, *a sad dog is howling*, etc., but not, for example, for *howling in*, as these two words do not form a syntactic constituent by themselves.

C-PHRASE word representations outperform C-BOW on several word-level benchmarks. In addition, because they are estimated in a compositional way, C-PHRASE word vectors, when combined through simple addition, produce sentence representations that are better than those obtained when adding other kinds of vectors, and competitive against *ad-hoc* compositional methods on various sentence meaning benchmarks.

2 The C-PHRASE model

We start with a brief overview of the models proposed by Mikolov et al. (2013a), as C-PHRASE builds on them. The **Skip-gram** model derives the vector of a target word by setting its weights to predict the words surrounding it in the corpus.

[1] We refer here not only to the results reported in Baroni et al. (2014b), but also to the more extensive evaluation that Baroni and colleagues present in the companion website (http://clic.cimec.unitn.it/composes/semantic-vectors.html). The experiments there suggest that only the Glove vectors of Pennington et al. (2014) are competitive with C-BOW, and only when trained on a corpus several orders of magnitude larger than the one used for C-BOW.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 971–981,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

More specifically, the objective function is:

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t) \qquad (1)$$

where the word sequence $w_1, w_2, ..., w_T$ is the training corpus and c is the size of the window around the target word w_t, consisting of the context words w_{t+j} that must be predicted by the induced vector representation for the target.

While Skip-gram learns each word representation separately, the **C-BOW** model takes their combination into account. More precisely, it tries to predict a context word from the combination of the previous and following words, where the combination method is vector addition. The objective function is:

$$\frac{1}{T}\sum_{t=1}^{T}\log p(w_t|w_{t-c}..w_{t-1}, w_{t+1}..w_{t+c}) \qquad (2)$$

While other distributional models consider sequences of words jointly as *context* when estimating the parameters for a single word (Agirre et al., 2009; Melamud et al., 2014), C-BOW is unique in that it estimates the weights of a sequence of words jointly, based on their shared context. In this respect, C-BOW extends the distributional hypothesis (Harris, 1954) that words with similar context distributions should have similar meanings to longer sequences. However, the word combinations of C-BOW are not natural linguistic constituents, but arbitrary n-grams (e.g., sequences of 5 words with a gap in the middle). Moreover, the model does not attempt to capture the *hierarchical* nature of syntactic phrasing, such that *big brown dog* is a meaningful phrase, but so are its children *brown dog* and *dog*.

C-PHRASE aims at capturing the same intuition that word combinations with similar context distributions will have similar meaning, but it applies it to syntactically motivated, potentially nested phrases. More precisely, we estimate word vectors such that they and their summed combinations are able to predict the contexts of words, phrases and sentences. The model is formalized as follows. We start from a parsed text corpus $\mathbb{T}$, composed of constituents $\mathcal{C}[w_l, \cdots, w_r]$, where $w_l, \cdots, w_r$ are the words spanned by the constituent, located in positions l to r in the corpus. We minimize an objective function analogous to equations (1) and (2), but instead of just using individual words or bags of words to predict context, we use summed vector representations of well-formed constituents at all levels in the syntactic tree to predict the context of these constituents. There are similarities with both CBOW and Skip-gram. At the leaf nodes, C-PHRASE acts like Skip-gram, whereas at higher node in the parse tree, it behaves like CBOW model. Concretely, we try to predict the words located within a window $c_{\mathcal{C}}$ from every constituent in the parse tree.[2] In order to do so, we learn vector representations for words v_w by maximizing the sum of the log probabilities of the words in the context window of the well-formed constituents with stochastic gradient descent:

$$\sum_{\mathcal{C}[w_l,\cdots,w_r]\in\mathbb{T}}\sum_{1\leq j\leq c_{\mathcal{C}}}\Bigg(\log p(w_{l-j}|\mathcal{C}[w_l,\cdots,w_r]) + \log p(w_{r+j}|\mathcal{C}[w_l,\cdots,w_r])\Bigg) \qquad (3)$$

with p theoretically defined as:

$$p(w_O|\mathcal{C}[w_l,\cdots,w_r]) = \frac{\exp\left({v'}_{w_O}^{\top}\frac{\sum_{i=l}^{r}v_{w_i}}{r-l+1}\right)}{\sum_{w=1}^{W}\exp\left({v'}_{w}^{\top}\frac{\sum_{i=l}^{r}v_{w_i}}{r-l+1}\right)}$$

where W is the size of the vocabulary, v' and v denote output (context) and input vectors, respectively, and we take the input vectors to represent the words. In practice, since the normalization constant for the above probability is expensive to compute, we follow Mikolov et al. (2013b) and use negative sampling.

We let the context window size $c_{\mathcal{C}}$ vary as a function of the height of the constituent in the syntactic tree. The height $h(\mathcal{C})$ of a constituent is given by the maximum number of intermediate nodes separating it from any of the words it dominates (such that $h = 0$ for words, $h = 1$ for two-word phrases, etc.). Then, for a constituent of height $h(\mathcal{C})$, C-PHRASE considers $c_{\mathcal{C}} = c_1 + h(\mathcal{C})c_2$ context words to its left and right (the non-negative integers c_1 and c_2 are hyperparameters of the model; with $c_2 = 0$, context becomes constant

[2] Although here we only use single words as context, the latter can be extended to encompass any sensible linguistic item, e.g., frequent n-grams or, as discussed below, syntactically-mediated expressions

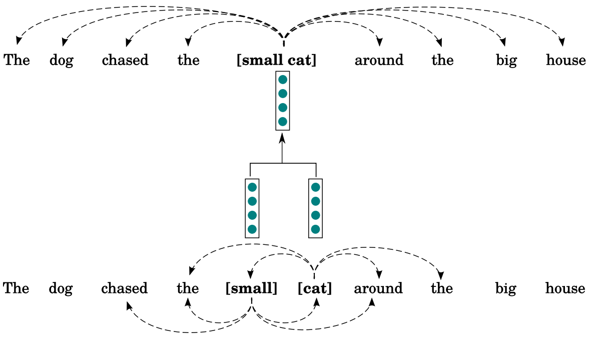

Figure 1: C-PHRASE context prediction objective for the phrase *small cat* and its children. The phrase vector is obtained by summing the word vectors. The predicted window is wider for the higher constituent (the phrase).

across heights). The intuition for enlarging the window proportionally to height is that, for shorter phrases, narrower contexts are likely to be most informative (e.g., a modifying adjective for a noun), whereas for longer phrases and sentences it might be better to focus on broader "topical" information spread across larger windows (paragraphs containing sentences about weather might also contain the words *rain* and *sun*, but without any tendency for these words to be perfectly adjacent to the target sentences).

Figure 1 illustrates the prediction objective for a two-word phrase and its children. Since all constituents (except the topmost) form parts of larger constituents, their representations will be learned both from the objective of predicting their own contexts, and from error propagation from the same objective applied higher in the tree. As a side effect, words, being lower in the syntactic tree, will have their vectors updated more often, and thus might have a greater impact on the learned parameters. This is another reason for varying window size with height, so that the latter effect will be counter-balanced by higher constituents having larger context windows to predict.

For lexical tasks, we directly use the vectors induced by C-PHRASE as word representations. For sentential tasks, we simply add the vectors of the words in a sentence to obtain its representation, exploiting the fact that C-PHRASE was trained to predict phrase contexts from the additive combination of their elements.

Joint optimization of word and phrase vectors The C-PHRASE hierarchical learning objective can capture, in parallel, generalizations about the contexts of words and phrases at different levels of complexity. This results, as we will see, in better word vectors, presumably because C-PHRASE is trained to predict how the contexts of a word change based on its phrasal collocates (*cup* will have very different contexts in *world cup* vs. *coffee cup*). At the same time, because the vectors are optimized based on their occurrence in phrases of different syntactic complexity, they produce good sentence representations when they are combined. To the best of our knowledge, C-PHRASE is the first model that is jointly optimized for lexical and compositional tasks. C-BOW uses shallow composition information to learn word vectors. Conversely, some compositional models –e.g., Kalchbrenner et al. (2014), Socher et al. (2013)– induce word representations, that are only optimized for a compositional task and are not tested at the lexical level. Somewhat relatedly to what we do, Hill et al. (2014) evaluated representations learned in a sentence translation task on word-level benchmarks. Some *a priori* justification for treating word and sentence learning as joint problems comes from human language acquisition, as it is obvious that children learn word and phrase meanings in parallel and interactively, not sequentially (Tomasello, 2003).

Knowledge-leanness and simplicity For training, C-PHRASE requires a large, syntactically-parsed corpus (more precisely, it only requires the constituent structure assigned by the parser, as it is blind to syntactic labels). Both large unannotated corpora and efficient pre-trained parsers are available for many languages, making the C-PHRASE knowledge demands feasible for practical purposes. There is no need to parse the sentences we want to build representations for at test time, since the component word vectors are simply added. The only parameters of the model are the word vectors; specifically, no extra parameters are needed for composition (composition models such as the one presented in Socher et al. (2012) require an extra parameter matrix for each word in the vocabulary, and even leaner models such as the one of Guevara (2010) must estimate a parameter matrix for each composition rule in the grammar). This makes C-PHRASE as simple as additive and multiplicative composition (Mitchell and

Lapata, 2010),[3] but C-PHRASE is both more effective in compositional tasks (see evaluation below), and it has the further advantage that it learns its own word vectors, thus reducing the number of arbitrary choices to be made in modeling.

Supervision Unlike many recent composition models (Kalchbrenner and Blunsom, 2013; Kalchbrenner et al., 2014; Socher et al., 2012; Socher et al., 2013, among others), the context-prediction objective of C-PHRASE does not require annotated data, and it is meant to provide general-purpose representations that can serve in different tasks. C-PHRASE vectors can also be used as initialization parameters for fully supervised, task-specific systems. Alternatively, the current unsupervised objective could be combined with task-specific supervised objectives to fine-tune C-PHRASE to specific purposes.

Sensitivity to syntactic structure During training, C-PHRASE is sensitive to syntactic structure. To cite an extreme example, *boy flowers* will be joined in a context-predicting phrase in *"these are considered [boy flowers]"*, but not in *"he gave [the boy] [flowers]"*. A more common case is that of determiners, that will only occur in phrases that also contain the following word, but not necessarily the preceding one. Sentence composition at test time, on the other hand, is additive, and thus syntax-insensitive. Still, the vectors being combined will reflect syntactic generalizations learned in training. Even if C-PHRASE produces the same representation for *red+car* and *car+red*, this representation combines a *red* vector that, during training, has often occurred in the modifier position of adjective-noun phrases, whereas *car* will have often occurred in the corresponding head position. So, presumably, the *red+car=car+red* vector will encode the adjective-noun asymmetry induced in learning. While the model won't be able to distinguish the rare cases in which *car red* is genuinely used as a phrase, in realistic scenarios this won't be a problem, because only *red car* will be encountered. In this respect, the successes and failures of C-PHRASE can tell us to what extent word order information is truly distinctive in practice, and to what extent it can instead be reconstructed from the typical role that words play in sentences.

Comparison with traditional syntax-sensitive word representations Syntax has often been exploited in distributional semantics for a richer characterization of *context*. By relying on a syntactic parse of the input corpus, a distributional model can take more informative contexts such as *subject-of-eat* vs. *object-of-eat* into account (Baroni and Lenci, 2010; Curran and Moens, 2002; Grefenstette, 1994; Erk and Padó, 2008; Levy and Goldberg, 2014a; Padó and Lapata, 2007; Rothenhäusler and Schütze, 2009). In this approach, syntactic information serves to select and/or enrich the *contexts* that are used to build representations of target units. On the other hand, we use syntax to determine the *target units* that we build representations for (in the sense that we jointly learn representations of their constituents). The focus is thus on unrelated aspects of model induction, and we could indeed use syntax-mediated contexts together with our phrasing strategy. Currently, given *eat (red apples)*, we treat *eat* as window-based context of *red apples*, but we could also take the context to be *object-of-eat*.

3 Evaluation

3.1 Data sets

Semantic relatedness of words In this classic lexical task, the models are required to quantify the degree of semantic similarity or relatedness of pairs of words in terms of cosines between the corresponding vectors. These scores are then compared to human gold standards. Performance is assessed by computing the correlation between system and human scores (Spearman correlation in all tasks except rg, where it is customary to report Pearson). We used, first of all, the MEN (**men**) data set of Bruni et al. (2014), that is split into 1K pairs for training/development, and 1K pairs for testing. We used the training set to tune the hyperparameters of our model, and report performance on the test set. The C-BOW model of Baroni et al. (2014b) achieved state-of-the art performance on MEN test. We also evaluate on the widely used WordSim353 set introduced by Finkelstein et al. (2002), which consists of 353 word pairs. The WordSim353 data were split by Agirre et al. (2009) into similarity (**wss**) and relatedness (**wsr**) subsets, focusing on strictly taxonomic (*television/radio*) vs. broader topical cases (*Maradona/football*), respectively. State-of-the-art performance on both sets is reported by Baroni

[3] We do not report results for component-wise multiplicative in our evaluation because it performed much worse than addition in all the tasks.

et al. (2014b), with the C-BOW model. We further consider the classic data set of Rubenstein and Goodenough (1965) (**rg**), consisting of 65 noun pairs. We report the state-of-the-art from Hassan and Mihalcea (2011), which exploited Wikipedia's linking structure.

Concept categorization Systems are asked to group a set of nominal concepts into broader categories (e.g. *arthritis* and *anthrax* into *illness*; *banana* and *grape* into *fruit*). As in previous work, we treat this as an unsupervised clustering task. We feed the similarity matrix produced by a model for all concepts in a test set to the CLUTO toolkit (Karypis, 2003), that clusters them into n groups, where n is the number of categories. We use standard CLUTO parameters from the literature, and quantify performance by cluster purity with respect to the gold categories. The Almuhareb-Poesio benchmark (Almuhareb, 2006) (**ap**) consists of 402 concepts belonging to 21 categories. A distributional model based on carefully chosen syntactic relations achieved top ap performance (Rothenhäusler and Schütze, 2009). The ESSLLI 2008 data set (Baroni et al., 2008) (**esslli**) consists of 6 categories and 42 concepts. State of the art was achieved by Katrenko and Adriaans (2008) by using full-Web queries and manually crafted patterns.

Semantic analogy The last lexical task we pick is analogy (**an**), introduced in Mikolov et al. (2013c). We focus on their *semantic* challenge, containing about 9K questions. In each question, the system is given a pair exemplifying a relation (*man*/*king*) and a test word (*woman*); it is then asked to find the word (*queen*) that instantiates the same relation with the test word as that of the example pair. Mikolov et al. (2013c) subtract the vector of the first word in a pair from the second, add the vector of the test word and look for the nearest neighbor of the resulting vector (e.g., find the word whose vector is closest to *king* - *man* + *woman*). We follow the method introduced by Levy and Goldberg (2014b), which returns the word x maximizing $\frac{\cos(king,x)\times\cos(woman,x)}{\cos(man,x)}$. This method yields better results for all models. Performance is measured by accuracy in retrieving the correct answer (in our search space of 180K words). The current state of the art on the semantic part and on the whole data set was reached by Pennington et al. (2014), who trained their word representations on a huge corpus consisting of 42B words.

Sentential semantic relatedness Similarly to word relatedness, composed sentence representations can be evaluated against benchmarks where humans provided relatedness/similarity scores for sentence pairs (sentences with high scores, such as *"A person in a black jacket is doing tricks on a motorbike"*/*"A man in a black jacket is doing tricks on a motorbike"* from the SICK data-set, tend to be near-paraphrases). Following previous work on these data sets, Pearson correlation is our figure of merit, and we report it between human scores and sentence vector cosine similarities computed by the models. SICK (Marelli et al., 2014) (**sick-r**) was created specifically for the purpose of evaluating compositional models, focusing on linguistic phenomena such as lexical variation and word order. Here we report performance of the systems on the test part of the data set, which contains 5K sentence pairs. The top performance (from the SICK SemEval shared task) was reached by Zhao et al. (2014) using a heterogeneous set of features that include WordNet and extra training corpora. Agirre et al. (2012) and Agirre et al. (2013) created two collections of sentential similarities consisting of subsets coming from different sources. From these, we pick the Microsoft Research video description dataset (**msrvid**), where near paraphrases are descriptions of the same short video, and the OnWN 2012 (**onwn1**) and OnWN 2013 (**onwn2**) data sets (each of these sets contains 750 pairs). The latter are quite different from other sentence relatedness benchmarks, since they compare definitions for the same or different words taken from WordNet and OntoNotes: these glosses often are syntactic fragments (*"cause something to pass or lead somewhere"*), rather than full sentences. We report top performance on these tasks from the respective shared challenges, as summarized by Agirre et al. (2012) and Agirre et al. (2013). Again, the top systems use feature-rich, supervised methods relying on distributional similarity as well as other sources, such as WordNet and named entity recognizers.

Sentential entailment Detecting the presence of entailment between sentences or longer passages is one of the most useful features that the computational analysis of text could provide (Dagan et al., 2009). We test our model on the SICK entailment task (**sick-e**) (Marelli et al., 2014). All SICK sentence pairs are labeled as ENTAILING (*"Two teams are competing in a football match"/"Two groups of people are playing football"*), CONTRADICTING (*"The brown horse is near a red barrel at the rodeo"/"The brown horse is far from a red barrel at the rodeo"*) or NEUTRAL (*"A man in a black jacket is doing tricks on a motorbike"/"A person is riding the bicycle on one wheel"*). For each model, we train a simple SVM classifier based on 2 features: cosine similarity between the two sentence vectors, as given by the models, and whether the sentence pair contains a negation word (the latter has been shown to be a very informative feature for SICK entailment). The current state-of-the-art is reached by Lai and Hockenmaier (2014), using a much richer set of features, that include WordNet, the denotation graph of Young et al. (2014) and extra training data from other resources.

Sentiment analysis Finally, as sentiment analysis has emerged as a popular area of application for compositional models, we test our methods on the Stanford Sentiment Treebank (Socher et al., 2013) (**sst**), consisting of 11,855 sentences from movie reviews, using the coarse annotation into 2 sentiment degrees (*negative/positive*). We follow the official split into train (8,544), development (1,101) and test (2,210) parts. We train an SVM classifier on the training set, using the sentence vectors composed by a model as features, and report accuracy on the test set. State of the art is obtained by Le and Mikolov (2014) with the Paragraph Vector approach we describe below.

3.2 Model implementation

The source corpus we use to build the lexical vectors is created by concatenating three sources: ukWaC,[4] a mid-2009 dump of the English Wikipedia[5] and the British National Corpus[6] (about 2.8B words in total). We build vectors for the 180K words occurring at least 100 times in the corpus. Since our training procedure requires parsed trees, we parse the corpus using the Stanford parser (Klein and Manning, 2003).

C-PHRASE has two hyperparameters (see Section 2 above), namely basic window size (c_1) and height-dependent window enlargement factor (c_2). Moreover, following Mikolov et al. (2013b), during training we sub-sample less informative, very frequent words: this option is controlled by a parameter t, resulting in aggressive subsampling of words with relative frequency above it. We tune on MEN-train, obtaining $c_1 = 5$, $c_2 = 2$ and $t = 10^{-5}$. As already mentioned, sentence vectors are built by summing the vectors of the words in them.

In lexical tasks, we compare our model to the best C-BOW model from Baroni et al. (2014b),[7] and to a Skip-gram model built using the same hyperparameters as C-PHRASE (that also led to the best MEN-train results for Skip-gram).

In sentential tasks, we compare our model against adding the best C-BOW vectors pretrained by Baroni and colleagues,[8] and adding our Skip-gram vectors. We compare the additive approaches to two sophisticated composition models. The first is the Practical Lexical Function (**PLF**) model of Paperno et al. (2014). This is a linguistically motivated model in the tradition of the "functional composition" approaches of Coecke et al. (2010) and Baroni et al. (2014a), and the only model in this line of research that has been shown to empirically scale up to real-life sentence challenges. In short, in the PLF model all words are represented by vectors. Words acting as argument-taking functions (such as verbs or adjectives) are also associated to one matrix for each argument they take (e.g., each transitive verb has a subject and an object matrix). Vector representations of arguments are recursively multiplied by function matrices, following the syntactic tree up to the top node. The final sentence representation is obtained by summing all the resulting vectors. The PLF approach requires syntactic parsing both in training and in testing and, more cumbersomely, to train a separate matrix for each argument slot of each function word (the training objective is again a context-predicting one). Here, we report PLF results on msrvid and onwn2 from Paperno et al. (2014), noting that they also used two simple but precious cues (word overlap and sentence length) we do not adopt here. We used their pre-trained vectors and matrices also for the SICK challenges, while the number of new ma-

[7] For fairness, we report their results when all tasks were evaluated with the same set of parameters, tuned on rg: this is row 8 of their Table 2.

[8] http://clic.cimec.unitn.it/composes/semantic-vectors.html

trices to estimate made it too time-consuming to implement this model in the onwn1 and sst tasks.

Finally, we test the Paragraph Vector (**PV**) approach recently proposed by Le and Mikolov (2014). Under PV, sentence representations are learned by predicting the words that occur in them. This unsupervised method has been shown by the authors to outperform much more sophisticated, supervised neural-network-based composition models on the sst task. We use our own implementation for this approach. Unlike in the original experiments, we found the PV-DBOW variant of PV to consistently outperform PV-DM, and so we report results obtained with the former.

Note that PV-DBOW aims mainly at providing representations for sentences, not words. When we do not need to induce vectors for sentences in the training corpus, i.e., only train to learn single words' representations and the softmax weights, PV-DBOW essentially reduces to Skip-gram. Therefore, we produce the PV-DBOW vectors for the sentences in the evaluation data sets using the softmax weights learned by Skip-gram. However, it is not clear that, if we were to train PV-DBOW jointly for words and sentences, we would get word vectors as good as those that Skip-gram induces.

4 Results

The results on the lexical tasks reported in Table 1 prove that C-PHRASE is providing excellent word representations, (nearly) as good or better than the C-BOW vectors of Baroni and colleagues in all cases, except for ap. Whenever C-PHRASE is not close to the state of the art results, the latter relied on richer knowledge sources and/or much larger corpora (ap, esslli, an).

Turning to the sentential tasks (Table 2), we first remark that using high-quality word vectors (such as C-BOW) and summing them leads to good results in all tasks, competitive with those obtained with more sophisticated composition models. This confirms the observation made by Blacoe and Lapata (2012) that simple-minded composition models are not necessarily worse than advanced approaches. Still, C-PHRASE is consistently better than C-BOW in all tasks, except sst, where the two models reach the same performance level.

C-PHRASE is outperforming PV on all tasks except sick-e, where the two models have the same performance, and onwn2, where PV is slightly better. C-PHRASE is outperforming PLF by a large margin on the SICK sets, whereas the two models are equal on msrvid, and PLF better on onwn2. Recall, however, that on the latter two benchmarks PLF used extra word overlap and sentence length features, so the comparison is not entirely fair.

The fact that state-of-the-art performance is well above our models is not surprising, since the SOA systems are invariably based on a wealth of knowledge sources, and highly optimized for a task. To put some of our results in a broader perspective, C-PHRASE's sick-r performance is 1% better than the median result of systems that participated in the SICK SemEval challenge, and comparable to that of Beltagy et al. (2014), who entered the competition with a system combining distributional semantics with a supervised probabilistic soft logic system. For sick-e (the entailment task), C-PHRASE's performance is less than one point below the median of the SemEval systems, and slightly above that of the Stanford submission, that used a recursive neural network with a tensor layer.

Finally, the performance of all our models, including PV, on sst is remarkably lower than the state-of-the-art performance of PV as reported by Le and Mikolov (2014). We believe that the crucial difference is that these authors estimated PV vectors *specifically on the sentiment treebank training data*, thus building *ad-hoc* vectors encoding the semantics of movie reviews. We leave it to further research to ascertain whether we could better fine-tune our models to sst by including the sentiment treebank training phrases in our source corpus.

Comparing vector lengths of C-BOW and C-PHRASE We gather some insight into how the C-PHRASE objective might adjust word representations for composition with respect to C-BOW by looking at how the length of word vectors changes across the two models.[9] While this is a very coarse measure, if a word vector is much longer/shorter (relative to the length of other word vectors of the same model) for C-PHRASE vs. C-BOW, it means that, when sentences are composed by addition, the effect of the word on the resulting sentence representation will be stronger/weaker.

[9] We performed the same analysis for C-PHRASE and Skip-gram, finding similar general trends to the ones we report for C-PHRASE and C-BOW.

Table 2: Sentential task performance. See Section 3.1 for figures of merit (all in percentage form) and state-of-the-art references. The PLF results on msrvid and onwn2 are taken from Paperno et al. 2014.

The relative-length-difference test returns the following words as the ones that are most severely de-emphasized by C-PHRASE compared to C-BOW: *be, that, an, not, they, he, who, when, well, have*. Clearly, C-PHRASE is weighting down grammatical terms that tend to be context-agnostic, and will be accompanied, in phrases, by more context-informative content words. Indeed, the list of terms that are instead emphasized by C-PHRASE include such content-rich, monosemous words as *gnawing, smackdown, demographics*. This is confirmed by a POS-level analysis that indicates that the categories that are, on average, most de-emphasized by C-PHRASE are: determiners, modals, pronouns, prepositions and (more surprisingly) proper nouns. The ones that are, in relative terms, more emphasized are: *-ing* verb forms, plural and singular nouns, adjectives and their superlatives. While this reliance on content words to the detriment of grammatical terms is not always good for sentential tasks (*"not always good"* means something very different from *"always good"*!), the convincing comparative performance of C-PHRASE in such tasks suggests that the semantic effect of grammatical terms is in any case beyond the scope of current corpus-based models, and often not crucial to attain competitive results on typical benchmarks (think, e.g., of how little modals, one of the categories that C-PHRASE downplays the most, will matter when detecting paraphrases that are based on picture descriptions).

We also applied the length difference test to words in specific categories, finding similar patterns. For example, looking at *-ly* adverbs only, those that are de-emphasized the most by C-PHRASE are *recently, eventually, originally, notably* and *currently* – all adverbs denoting temporal factors or speaker attitude. On the other hand, the ones that C-PHRASE lengthens the most, relative to C-BOW, are *clinically, divinely, ecologically, noisily* and *theatrically*: all adverbs with more specific, content-word-like meanings, that are better captured by distributional methods, and are likely to have a bigger impact on tasks such as paraphrasing or entailment.

Effects of joint optimization at word and phrase levels As we have argued before, C-PHRASE is able to obtain good word representations presumably because it learns to predict how the context of a word changes in the presence of different collocates. To gain further insight into this claim, we looked at the nearest neighbours of some example terms, like *neural*, *network* and *neural network* (the latter, composed by addition) both in C-PHRASE and C-BOW. The results for this particular example can be appreciated in Table 3.

Interestingly, while for C-BOW we observe some confusion between the meaning of the individual words and the phrase, C-PHRASE seems to provide more orthogonal representations for the lexical items. For example, *neural* in C-

C-BOW			C-PHRASE		
neural	*network*	*neural network*	*neural*	*network*	*neural network*
neuronal	networks	network	neuronal	networks	network
neurons	superjanet4	neural	cortical	internetwork	neural
hopfield	backhaul	networks	connectionist	wans	perceptron
cortical	fiber-optic	hopfield	neurophysiological	network.	networks
connectionist	point-to-multipoint	packet-switched	sensorimotor	multicasting	hebbian
feed-forward	nsfnet	small-world	sensorimotor	nsfnet	neurons
feedforward	multi-service	local-area	neocortex	networking	neocortex
neuron	circuit-switched	superjanet4	electrophysiological	tymnet	connectionist
backpropagation	wide-area	neuronal	neurobiological	x.25	neuronal

Table 3: Nearest neighbours of *neural*, *network* and *neural network* both for C-BOW and C-PHRASE

BOW contains neighbours that fit well with *neural network*, like *hopfield*, *connectionist* and *feedforward*. Conversely, *neural network* has neighbours that correspond to *network* like *local-area* and *packet-switched*. In contrast, C-PHRASE neighbours for *neural* are mostly related to the *brain* sense of the word, e.g., *cortical*, *neurophysiological*, etc. (with the only exception of *connectionist*). The first neighbour of *neural network*, excluding its own component words, quite sensibly, is *perceptron*.

5 Conclusion

We introduced C-PHRASE, a distributional semantic model that is trained on the task of predicting the contexts surrounding phrases at all levels of a hierarchical sentence parse, from single words to full sentences. Consequently, word vectors are induced by taking into account not only their contexts, but also how co-occurrence with other words within a syntactic constituent is affecting these contexts.

C-PHRASE vectors outperform state-of-the-art C-BOW vectors in a wide range of lexical tasks. Moreover, because of the way they are induced, when C-PHRASE vectors are summed, they produce sentence representations that are as good or better than those obtained with sophisticated composition methods.

C-PHRASE is a very parsimonious approach: The only major resource required, compared to a completely knowledge-free, unsupervised method, is an automated parse of the training corpus (but no syntactic labels are required, nor parsing at test time). C-PHRASE has only 3 hyperparameters and no composition-specific parameter to tune and store.

Having established a strong empirical baseline with this parsimonious approach, in future research we want to investigate the impact of possible extensions on both lexical and sentential tasks. When combining the vectors, either for induction or composition, we will try replacing plain addition with other operations, starting with something as simple as learning scalar weights for different words in a phrase (Mitchell and Lapata, 2010). We also intend to explore more systematic ways to incorporate supervised signals into learning, to fine-tune C-PHRASE vectors to specific tasks.

On the testing side, we are fascinated by the good performance of additive models, that (at test time, at least) do not take word order nor syntactic structure into account. We plan to perform a systematic analysis of both existing benchmarks and natural corpus data, both to assess the actual impact that such factors have on the aspects of meaning we are interested in (take two sentences in an entailment relation: how often does shuffling the words in them make it impossible to detect entailment?), and to construct new benchmarks that are more challenging for additive methods.

The C-PHRASE vectors described in this paper are made publicly available at: `http://clic.cimec.unitn.it/composes/`.

Abstract

The Abstract Meaning Representation (AMR) is a representation for open-domain rich semantics, with potential use in fields like event extraction and machine translation. Node generation, typically done using a simple dictionary lookup, is currently an important limiting factor in AMR parsing. We propose a small set of actions that derive AMR subgraphs by transformations on spans of text, which allows for more robust learning of this stage. Our set of construction actions generalize better than the previous approach, and can be learned with a simple classifier. We improve on the previous state-of-the-art result for AMR parsing, boosting end-to-end performance by 3 F_1 on both the LDC2013E117 and LDC2014T12 datasets.

1 Introduction

The Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a rich, graph-based language for expressing semantics over a broad domain. The formalism is backed by a large data-labeling effort, and it holds promise for enabling a new breed of natural language applications ranging from semantically aware MT to rich broad-domain QA over text-based knowledge bases. Figure 1 shows an example AMR for "he gleefully ran to his dog Rover," and we give a brief introduction to AMR in Section 2. This paper focuses on AMR parsing, the task of mapping a natural language sentence into an AMR graph.

We follow previous work (Flanigan et al., 2014) in dividing AMR parsing into two steps. The first step is *concept identification*, which generates AMR nodes from text, and which we'll refer to as *NER++* (Section 3.1). The second step is *relation identification*, which adds arcs to link these nodes into a fully connected AMR graph, which we'll call *SRL++* (Section 3.2).

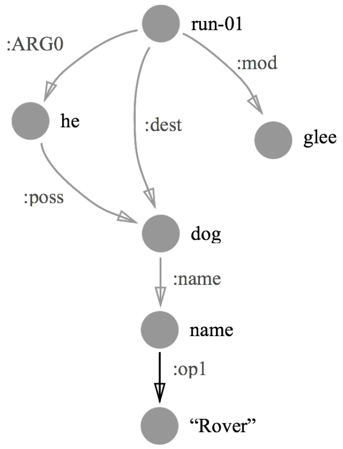

Figure 1: The AMR graph for *He gleefully ran to his dog Rover*. We show that improving the generation of low level subgraphs (e.g., *Rover* generating *name* $\xrightarrow{:op1}$ *"Rover"*) significantly improves end-to-end performance.

We observe that SRL++ is not the hard part of AMR parsing; rather, much of the difficulty in AMR is generating high accuracy concept subgraphs from the NER++ component. For example, when the existing AMR parser JAMR (Flanigan et al., 2014) is given a gold NER++ output, and must only perform SRL++ over given subgraphs it scores 80 F_1 – nearly the inter-annotator agreement of 83 F_1, and far higher than its end to end accuracy of 59 F_1.

SRL++ within AMR is *relatively* easy given a perfect NER++ output, because so much pressure is put on the output of NER++ to carry meaningful information. For example, there's a strong type-check feature for the existence and type of any arc just by looking at its end-points, and syntactic dependency features are very informative for removing any remaining ambiguity. If a system is con-

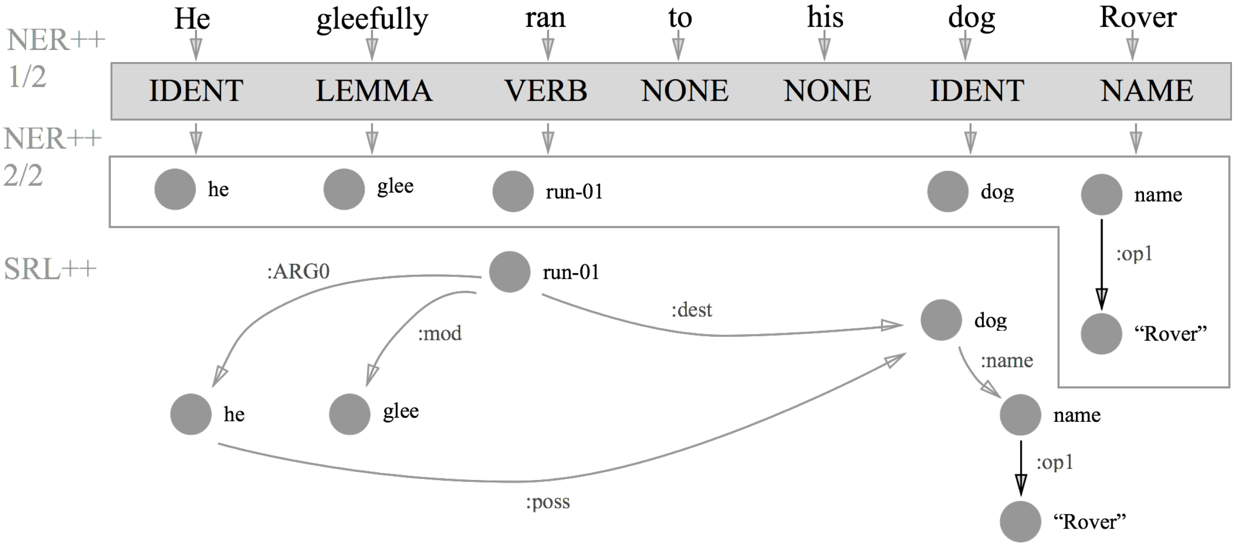

Figure 2: A graphical explanation of our method. We represent the derivation process for *He gleefully ran to his dog Rover*. First the tokens in the sentence are labeled with derivation actions, then these actions are used to generate AMR subgraphs, which are then stitched together to form a coherent whole.

sidering how to link the node *run-01* in Figure 1, the verb-sense frame for "run-01" leaves very little uncertainty for what we could assign as an *ARG0* arc. It must be a noun, which leaves either *he* or *dog*, and this is easily decided in favor of *he* by looking for an nsubj arc in the dependency parse.

The primary contribution of this paper is a novel approach to the NER++ task, illustrated in Figure 2. We notice that the subgraphs aligned to lexical items can often be generated from a small set of *generative actions* which generalize across tokens. For example, most verbs generate an AMR node corresponding to the verb sense of the appropriate PropBank frame – e.g., *run* generates *run-01* in Figure 1. This allows us to frame the NER++ task as the task of classifying one of a small number of *actions* for each token, rather than choosing a specific AMR subgraph for every token in the sentence.

Our approach to the end-to-end AMR parsing task is therefore as follows: we define an action space for generating AMR concepts, and create a classifier for classifying lexical items into one of these actions (Section 4). This classifier is trained from automatically generated alignments between the gold AMR trees and their associated sentences (Section 5), using an objective which favors alignment mistakes which are least harmful to the NER++ component. Finally, the concept subgraphs are combined into a coherent AMR parse using the maximum spanning connected subgraph algorithm of Flanigan et al. (2014).

We show that our approach provides a large boost to recall over previous approaches, and that end to end performance is improved from 59 to 62 *smatch* (an F_1 measure of correct AMR arcs; see Cai and Knight (2013)) when incorporated into the SRL++ parser of Flanigan et al. (2014). When evaluating the performance of our action classifier in isolation, we obtain an action classification accuracy of 84.1%.

2 The AMR Formalism

AMR is a language for expressing semantics as a rooted, directed, and potentially cyclic graph, where nodes represent concepts and arcs are relationships between concepts. AMR is based on neo-Davidsonian semantics, (Davidson, 1967; Parsons, 1990). The nodes (concepts) in an AMR graph do not have to be explicitly grounded in the source sentence, and while such an alignment is often generated to train AMR parsers, it is not provided in the training corpora. The semantics of nodes can represent lexical items (e.g., *dog*), sense tagged lexical items (e.g., *run-01*), type markers (e.g., *date-entity*), and a host of other phenomena.

The edges (relationships) in AMR describe one of a number of semantic relationships between concepts. The most salient of these is semantic role labels, such as the *ARG0* and *destination* arcs in Figure 2. However, often these arcs define

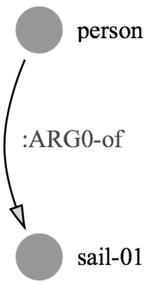

Figure 3: AMR representation of the word *sailor*, which is notable for breaking the word up into a self-contained multi-node unit unpacking the derivational morphology of the word.

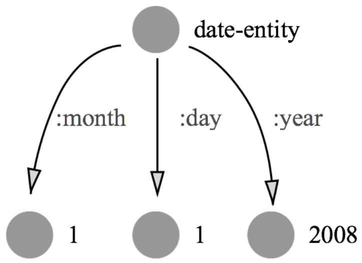

Figure 4: AMR representation of the span *January 1, 2008*, an example of how AMR can represent structured data by creating additional nodes such as *date-entity* to signify the presence of special structure.

a semantics more akin to syntactic dependencies (e.g., *mod* standing in for adjective and adverbial modification), or take on domain-specific meaning (e.g., the month, day, and year arcs of a *date-entity*).

To introduce AMR and its notation in more detail, we'll unpack the translation of the sentence "he gleefully ran to his dog Rover." We show in Figure 1 the interpretation of this sentence as an AMR graph.

The root node of the graph is labeled *run-01*, corresponding to the PropBank (Palmer et al., 2005) definition of the verb *ran*. *run-01* has an outgoing *ARG0* arc to a node *he*, with the usual PropBank semantics. The outgoing *mod* edge from *run-01* to *glee* takes a general purpose semantics corresponding to adjective, adverbial, or other modification of the governor by the dependent. We note that *run-01* has a *destination* arc to *dog*. The label for *destination* is taken from a finite set of special arc sense tags similar to the preposition senses found in (Srikumar, 2013). The last portion of the figure parses *dog* to a node which serves as a type marker similar to named entity types, and *Rover* into the larger subgraph indicating a concept with name "Rover."

2.1 AMR Subgraphs

The mapping from tokens of a sentence to AMR nodes is not one-to-one. A single token or span of tokens can generate a *subgraph* of AMR consisting of multiple nodes. These subgraphs can logically be considered the expression of a single concept, and are useful to treat as such (e.g., see Section 3.1).

Many of these multi-node subgraphs capture structured data such as time expressions, as in Figure 4. In this example, a *date-entity* node is created to signify that this cluster of nodes is part of a structured sub-component representing a date, where the nodes and arcs within the component have specific semantics. This illustrates a broader recurring pattern in AMR: an artificial node may, based on its title, have expected children with special semantics. A particularly salient example of this pattern is the *name* node (see *"Rover"* in Figure 1) which signifies that all outgoing arcs with label *op* comprise the tokens of a name object.

The ability to decouple the meaning representation of a lexical item from its surface form allows for rich semantic interpretations of certain concepts in a sentence. For example, the token *sailor* is represented in Figure 3 by a concept graph representing a person who performs the action *sail-01*. Whereas often the AMR node aligned to a span of text is a straightforward function of the text, these cases remain difficult to capture in a principled way beyond memorizing mappings between tokens and subgraphs.

3 Task Decomposition

To the best of our knowledge, the JAMR parser is the only published end-to-end AMR parser at the time of publication. An important insight in JAMR is that AMR parsing can be broken into two distinct tasks: (1) **NER++** (*concept identification*): the task of interpreting what entities are being referred to in the text, realized by generating the best AMR subgraphs for a given set of tokens, and (2) **SRL++** (*relation identification*): the task of discovering what relationships exist between entities, realized by taking the disjoint subgraphs generated by NER++ and creating a fully-connected graph. We describe both tasks in more detail below.

3.1 NER++

Much of the difficulty of parsing to AMR lies in generating local subgraphs representing the meaning of token spans. For instance, the formalism implicitly demands rich notions of NER, lemmatization, word sense disambiguation, number normalization, and temporal parsing; among others. To illustrate, a correct parse of the sentence in Figure 2 requires lemmatization (*gleefully* → *glee*), word sense tagging (*run* → *run-01*), and open domain NER (i.e., *Rover*), Furthermore, many of the generated subgraphs (e.g., *sailor* in Figure 3) have rich semantics beyond those produced by standard NLP systems.

Formally, NER++ is the task of generating a disjoint set of subgraphs representing the meanings of localized spans of words in the sentence. For NER++, JAMR uses a simple Viterbi sequence model to directly generate AMR-subgraphs from memorized mappings of text spans to subgraphs. This paper's main contribution, presented in Section 4, is to make use of generative *actions* to generate these subgraphs, rather than appealing to a memorized mapping.

3.2 SRL++

The second stage of the AMR decomposition consists of generating a coherent graph from the set of disjoint subgraphs produced by NER++. Whereas NER++ produces subgraphs whose arcs encode domain-specific semantics (e.g., *month*), the arcs in SRL++ tend to have generally applicable semantics. For example, the many arcs encode conventional semantic roles (e.g., *ARG0* and *destination* in Figure 2), or a notion akin to syntactic dependencies (e.g., *mod* and *poss* in Figure 2). For SRL++, JAMR uses a variation of the maximum spanning connected graph algorithm augmented by dual decomposition to impose linguistically motivated constraints on a maximum likelihood objective.

4 A Novel NER++ Method

The training sets currently available for AMR are not large. To illustrate, 38% of the words in the LDC2014E113 dev set are unseen during training time. With training sets this small, memorization-based approaches are extremely brittle. We remove much of the necessity to memorize mappings in NER++ by partitioning the AMR subgraph search space in terms of the actions needed to derive a node from its aligned token. At test time we do a sequence labeling of input tokens with these actions, and then deterministically derive the AMR subgraphs from spans of tokens by applying the transformation decreed by their actions. We explain in Section 4.1 how exactly we manage this partition, and in Section 4.3 how we create training data from existing resources to setup and train an action-type classifier.

4.1 Derivation actions

We partition the AMR subgraph space into a set of 9 actions, each corresponding to an action that will be taken by the NER++ system if a token receives this classification.

IDENTITY This action handles the common case that the title of the node corresponding to a token is identical to the source token. To execute the action, we take the lowercased version of the token to be the title of the corresponding node.

NONE This action corresponds to ignoring this token, in the case that the node should not align to any corresponding AMR fragment.

VERB This action captures the verb-sense disambiguation feature of AMR. To execute on a token, we find the most similar verb in PropBank based on Jaro-Winkler distance, and adopt its most frequent sense. This serves as a reasonable baseline for word sense disambiguation, although of course accuracy would be expected to improve if a sophisticated system were incorporated.

VALUE This action interprets a token by its integer value. The AMR representation is sensitive to the difference between a node with a title of *5* (the integer value) and "5" or "five" – the string value. This is a rare action, but is nonetheless distinct from any of the other classes. We execute this action by extracting an integer value with a regex based number normalizer, and using the result as the title of the generated node.

LEMMA AMR often performs stemming and part-of-speech transformations on the source token in generating a node. For example, we get *glee* from *gleefully*. We capture this by a **LEMMA** action, which is executed by using the lemma of the source token as the generated node title. Note that this does not capture all lemmatizations, as there are often discrepancies between the lemma generated by the lemmatizer and the correct AMR lemma.

NAME AMR often references names with a special structured data type: the *name* construction. For example, *Rover* in Figure 1. We can capture this phenomenon on unseen names by attaching a created *name* node to the top of a span.

PERSON A variant of the NAME action, this action produces a subgraph identical to the NAME action, but adds a node *person* as a parent. This is, in effect, a *name* node with an implicit entity type of person. Due to discrepancies between the output of our named entity tagger and the richer AMR named entity ontology, we only apply this tag to the person named entity tag.

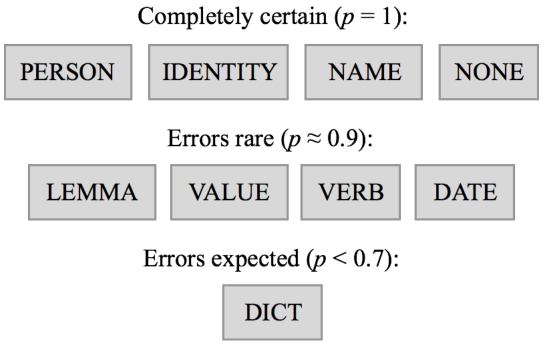
DATE The most frequent of the structured data type in the data, after *name*, is the *date-entity* construction (for an example see Figure 4). We deterministically take the output of SUTime (Chang and Manning, 2012) and convert it into the *date-entity* AMR representation.

DICT This class serves as a back-off for the other classes, implementing an approach similar to Flanigan et al. (2014). In particular, we memorize a simple mapping from spans of text (such as *sailor*) to their corresponding most frequently aligned AMR subgraphs in the training data (i.e., the graph in Figure 3). See Section 5 for details on the alignment process. At test time we can do a lookup in this dictionary for any element that gets labeled with a **DICT** action. If an entry is not found in the mapping, we back off to the second most probable class proposed by the classifier.

It is worth observing at this point that our actions derive much of their power from the similarity between English words and their AMR counterparts; creating an analogue of these actions for other languages remains an open problem.

4.2 Action Reliability

In many cases, multiple actions could yield the same subgraph when applied to a node. In this section we introduce a method for resolving this ambiguity based on comparing the reliability with which actions generate the correct subgraph, and discuss implications.



Completely certain ($p = 1$):
PERSON
IDENTITY
NAME
NONE
Errors rare ($p \approx 0.9$):
LEMMA
VALUE
VERB
DATE
Errors expected ($p < 0.7$):
DICT

Figure 5: Reliability of each action. The top row are actions which are deterministic; the second row occasionally produce errors. DICT is the least preferred action, with a relatively high error rate.

Even given a perfect action classification for a token, certain action executions can introduce errors. Some of our actions are entirely deterministic in their conversion from the word to the AMR subgraph (e.g., IDENTITY), but others are prone to making mistakes in this conversion (e.g., VERB, DICT). We define the notion of *action reliability* as the probability of deriving the correct node from a span of tokens, conditioned on having chosen the correct action.

To provide a concrete example, our dictionary lookup classifier predicts the correct AMR subgraph 67% of the time on the dev set. We therefore define the reliability of the **DICT** action as 0.67. In contrast to **DICT**, correctly labeling a node as **IDENTITY**, **NAME**, **PERSON**, and **NONE** have action reliability of 1.0, since there is no ambiguity in the node generation once one of those actions have been selected, and we are guaranteed to generate the correct node given the correct action.

We can therefore construct a hierarchy of reliability (Figure 5) – all else being equal, we prefer to generate actions from higher in the hierarchy, as they are more likely to produce the correct subgraph. This hierarchy is useful in resolving ambiguity throughout our system. During the creation of training data for our classifier (Section 4.3) from our aligner, when two actions could both generate the aligned AMR node we prefer the more reliable one. In turn, in our aligner we bias alignments towards those which generating more reliable action sequences as training data (see Section 5).

The primary benefit of this action-based NER++ approach is that we can reduce the usage of low reliability actions, like **DICT**. The approach taken in Flanigan et al. (2014) can be

Action	# Tokens	% Total
NONE	41538	36.2
DICT	30027	26.1
IDENTITY	19034	16.6
VERB	11739	10.2
LEMMA	5029	4.5
NAME	4537	3.9
DATE	1418	1.1
PERSON	1336	1.1
VALUE	122	0.1

Table 1: Distribution of action types in the proxy section of the newswire section of the LDC2014T12 dataset, generated from automatically aligned data.

Input token; word embedding

thought of as equivalent to classifying every token as the **DICT** action.

We analyze the empirical distribution of actions in our automatically aligned corpus in Table 1. The cumulative frequency of the non-**DICT** actions is striking: we can generate 74% of the tokens with high reliability ($p \geq 0.9$) actions. In this light, it is unsurprising that our results demonstrate a large gain in recall on the test set.

4.3 Training the Action Classifier

Given a set of AMR training data, in the form of *(graph, sentence)* pairs, we first induce alignments from the graph nodes to the sentence (see Section 5). Formally, for every node n_i in the AMR graph, alignment gives us some token s_j (at the jth index in the sentence) that we believe generated the node n_i.

Then, for each action type, we can ask whether or not that action type is able to take token s_j and correctly generate n_i. For concreteness, imagine the token s_j is *running*, and the node n_i has the title *run-01*. The two action types we find that are able to correctly generate this node are DICT and VERB. We choose the most reliable action type of those available (see Figure 5) to generate the observed node – in this case, VERB.

In cases where an AMR subgraph is generated from multiple tokens, we assign the action label to each token which generates the subgraph. Each of these tokens are added to the training set; at test time, we collapse sequences of adjacent identical action labels, and apply the action once to the resulting token span.

Inducing the most reliable action (according to the alignments) for every token in the training corpus provides a supervised training set for our action classifier, with some noise introduced by the automatically generated alignments. We then train a simple maxent classifier[1] to make action decisions at each node. At test time, the classifier takes as input a pair $\langle i, S \rangle$, where i is the index of the token in the input sentence, and S is a sequence tokens representing the source sentence. It then uses the features in Table 2 to predict the actions to take at that node.

5 Automatic Alignment of Training Data

AMR training data is in the form of bi-text, where we are given a set of (sentence, graph) pairs, with no explicit alignments between them. We would like to induce a mapping from each node in the AMR graph to the token it represents. It is perfectly possible for multiple nodes to align to the same token – this is the case with *sailors*, for instance.

It is not possible, within our framework, to represent a single node being sourced from multiple tokens. Note that a subgraph can consist of many individual nodes; in cases where a subgraph should align to multiple tokens, we generate an alignment from the subgraph's nodes to the associated tokens in the sentence. It is empirically very rare for a subgraph to have more nodes than the token span it should align to.

There have been two previous attempts at producing automatic AMR alignments. The first was

[1] A sequence model was tried and showed no improvement over a simple maxent classifier.

published as a component of JAMR, and used a rule-based approach to perform alignments. This was shown to work well on the sample of 100 hand-labeled sentences used to develop the system. Pourdamghani et al. (2014) approached the alignment problem in the framework of the IBM alignment models. They rendered AMR graphs as text, and then used traditional machine translation alignment techniques to generate an alignment.

We propose a novel alignment method, since our decomposition of the AMR node generation process into a set of actions provides an additional objective for the aligner to optimize, in addition to the accuracy of the alignment itself. We would like to produce the most *reliable* sequence of actions for the NER++ model to train from, where reliable is taken in the sense defined in Section 4.2. To give an example, a sequence of all **DICT** actions could generate any AMR graph, but is very low reliability. A sequence of all **IDENTITY** actions could only generate one set of nodes, but does it with absolute certainty.

We formulate this objective as a Boolean LP problem. Let $\mathbf{Q}$ be a matrix in $\{0,1\}^{|\mathbf{N}|\times|\mathbf{S}|}$ of Boolean constrained variables, where $\mathbf{N}$ are the nodes in an AMR graph, and $\mathbf{S}$ are the tokens in the sentence. The meaning of $\mathbf{Q}_{i,j} = \mathbb{1}$ can be interpreted as node n_i having being aligned to token s_j. Furthermore, let $\mathbf{V}$ be a matrix $\mathcal{T}^{|\mathbf{N}|\times|\mathbf{S}|}$, where $\mathcal{T}$ is the set of NER++ actions from Section 4. Each matrix element $\mathbf{V}_{i,j}$ is assigned the most reliable action which would generate node n_i from token s_j. We would like to maximize the probability of the actions collectively generating a perfect set of nodes. This can be formulated linearly by maximizing the log-likelihood of the actions. Let the function $\text{REL}(l)$ be the reliability of action l (probability of generating intended node). Our objective can then be formulated as follows:

$$\max_{\mathbf{Q}} \quad \sum_{i,j} \mathbf{Q}_{i,j} \left[\log(\text{REL}(\mathbf{V}_{i,j})) + \alpha \mathcal{E}_{i,j}\right] \qquad (1)$$

$$\text{s.t.} \quad \sum_{j} \mathbf{Q}_{i,j} = 1 \quad \forall i \qquad (2)$$

$$\mathbf{Q}_{k,j} + \mathbf{Q}_{l,j} \leq 1 \quad \forall k,l,j;\ n_k \nleftrightarrow n_l \qquad (3)$$

where $\mathcal{E}$ is the Jaro-Winkler similarity between the title of the node i and the token j, α is a hyperparameter (set to 0.8 in our experiments), and the operator $\nleftrightarrow$ denotes that two nodes in the AMR graph are both not adjacent and do not have the same title.

The constraint (2), combined with the binary constraint on $\mathbf{Q}$, ensures that every node in the graph is aligned to exactly one token in the source sentence. The constraint (3) ensures that only adjacent nodes or nodes that share a title can refer to the same token.

The objective value penalizes alignments which map to the unreliable DICT tag, while rewarding alignments with high overlap between the title of the node and the token. Note that most incorrect alignments fall into the DICT class by default, as no other action could generate the correct AMR subgraph. Therefore, if there exists an alignment that would consume the token using another action, the optimization prefers that alignment. The Jaro-Winkler similarity term, in turn, serves as a tie-breaker between equally (un)reliable alignments.

There are many packages which can solve this Boolean LP efficiently. We used Gurobi (Gurobi Optimization, 2015). Given a matrix $\mathbf{Q}$ that maximizes our objective, we can decode our solved alignment as follows: for each i, align n_i to the j s.t. $\mathbf{Q}_{i,j} = 1$. By our constraints, exactly one such j must exist.

6 Related Work

Prior work in AMR and related formalisms include Jones et al. (2012), and Flanigan et al. (2014). Jones et al. (2012), motivated by applications in Machine Translation, proposed a graphical semantic meaning representation that predates AMR, but is intimately related. They propose a hyper-edge replacement grammar (HRG) approach to parsing into and out of this graphical semantic form. Flanigan et al. (2014) forms the basis of the approach of this paper. Their system introduces the two-stage approach we use: they implement a rule-based alignment to learn a mapping from tokens to subgraphs, and train a variant of a maximum spanning tree parser adapted to graphs and with additional constraints for their relation identifications (SRL++) component. Wang et al. (2015) uses a transition based algorithm to transform dependency trees into AMR parses. They achieve 64/62/63 P/R/F$_1$ with contributions roughly orthogonal to our own. Their transformation action set could be easily augmented by the robust subgraph generation we propose here, although we leave this to future work.

Beyond the connection of our work with Flanigan et al. (2014), we note that the NER++ component of AMR encapsulates a number of lexical NLP tasks. These include named entity recognition (Nadeau and Sekine, 2007; Finkel et al., 2005), word sense disambiguation (Yarowsky, 1995; Banerjee and Pedersen, 2002), lemmatization, and a number of more domain specific tasks. For example, a full understanding of AMR requires normalizing temporal expressions (Verhagen et al., 2010; Strötgen and Gertz, 2010; Chang and Manning, 2012).

In turn, the SRL++ facet of AMR takes many insights from semantic role labeling (Gildea and Jurafsky, 2002; Punyakanok et al., 2004; Srikumar, 2013; Das et al., 2014) to capture the relations between verbs and their arguments. In addition, many of the arcs in AMR have nearly syntactic interpretations (e.g., *mod* for adjective/adverb modification, *op* for compound noun expressions). These are similar to representations used in syntactic dependency parsing (de Marneffe and Manning, 2008; McDonald et al., 2005; Buchholz and Marsi, 2006).

More generally, parsing to a semantic representation is has been explored in depth for when the representation is a logical form (Kate et al., 2005; Zettlemoyer and Collins, 2005; Liang et al., 2011). Recent work has applied semantic parsing techniques to representations beyond lambda calculus expressions. For example, work by Berant et al. (2014) parses text into a formal representation of a biological process. Hosseini et al. (2014) solves algebraic word problems by parsing them into a structured meaning representation. In contrast to these approaches, AMR attempts to capture open domain semantics over arbitrary text.

Interlingua (Mitamura et al., 1991; Carbonell et al., 1999; Levin et al., 1998) are an important inspiration for decoupling the semantics of the AMR language from the surface form of the text being parsed; although, AMR has a self-admitted English bias.

7 Results

We present improvements in end-to-end AMR parsing on two datasets using our NER++ component. Action type classifier accuracy on an automatically aligned corpus and alignment accuracy on a small hand-labeled corpus are also reported.

Dataset	**System**	**P**	**R**	**F$_1$**
2014T12	JAMR	**67.1**	53.2	59.3
	Our System	66.6	**58.3**	**62.2**
2013E117	JAMR	**66.9**	52.9	59.1
	Our System	65.9	**59.0**	**62.3**

Table 3: Results on two AMR datasets for JAMR and our NER++ embedded in the JAMR SRL++ component. Note that recall is consistently higher across both datasets, with only a small loss in precision.

7.1 End-to-end AMR Parsing

We evaluate our NER++ component in the context of end-to-end AMR parsing on two corpora: the newswire section of LDC2014T12 and the split given in Flanigan et al. (2014) of LDC2013E117, both consisting primarily of newswire. We compare two systems: the JAMR parser (Flanigan et al., 2014),[2] and the JAMR SRL++ component with our NER++ approach.

AMR parsing accuracy is measured with a metric called *smatch* (Cai and Knight, 2013), which stands for "s(emantic) match." The metric is the F$_1$ of a best-match between triples implied by the target graph, and triples in the parsed graph – that is, the set of (parent, edge, child) triples in the graph.

Our results are given in Table 3. We report much higher recall numbers on both datasets, with only small ($\leq$ 1 point) loss in precision. This is natural considering our approach. A better NER++ system allows for more correct AMR subgraphs to be generated – improving recall – but does not in itself necessarily improve the accuracy of the SRL++ system it is integrated in.

7.2 Component Accuracy

We evaluate our aligner on a small set of 100 hand-labeled alignments, and evaluate our NER++ classifier on automatically generated alignments over the whole corpus,

On a hand-annotated dataset of 100 AMR parses from the LDC2014T12 corpus,[3] our aligner achieves an accuracy of **83.2**. This is a measurement of the percentage of AMR nodes that are aligned to the correct token in their source sentence. Note that this is a different metric than the

[2] Available at `https://github.com/jflanigan/jamr`.

[3] Our dataset is publicly available at `http://nlp.stanford.edu/projects/amr`

precision/recall of prior work on alignments, and is based on both a different alignment dataset and subtly different alignment annotation scheme. In particular, we require that every AMR node aligns to some token in the sentence, which forces the system to always align nodes, even when unsure. A standard semantics and annotation guideline for AMR alignment is left for future work; our accuracy should be considered only an informal metric.

We find our informativeness-based alignment objective slightly improves end-to-end performance when compared to the rule-based approach of (Flanigan et al., 2014), improving F_1 by roughly 1 point (64/59/61 P/R/F_1 to 65/59/62 P/R/F_1).

On the automatic alignments over the LDC2014T12 corpus, our action classifier achieved a test accuracy of **0.841**. The classifier's most common class of mistakes are incorrect **DICT** classifications. It is reassuring that some of these errors can be recovered from by the naïve dictionary lookup finding the correct mapping.

The **DICT** action lookup table achieved an accuracy of **0.67**. This is particularly impressive given that our model moves many of the difficult semantic tasks onto the **DICT** tag, and that this lookup does not make use of any learning beyond a simple count of observed span to subgraph mappings.

8 Conclusion

We address a key challenge in AMR parsing: the task of generating subgraphs from lexical items in the sentence. We show that a simple classifier over *actions* which generate these subgraphs improves end-to-end recall for AMR parsing with only a small drop in precision, leading to an overall gain in F_1. A clear direction of future work is improving the coverage of the defined actions. For example, a richer lemmatizer could shift the burden of lemmatizing unknown words into the AMR lemma semantics and away from the dictionary lookup component. We hope our decomposition provides a useful framework to guide future work in NER++ and AMR in general.

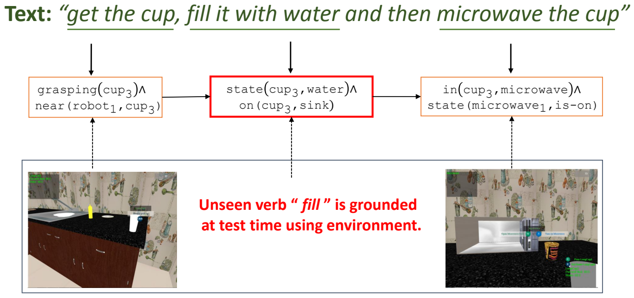
Abstract

We focus on the task of interpreting complex natural language instructions to a robot, in which we must ground high-level commands such as *microwave the cup* to low-level actions such as grasping. Previous approaches that learn a lexicon during training have inadequate coverage at test time, and pure search strategies cannot handle the exponential search space. We propose a new hybrid approach that leverages the environment to induce new lexical entries at test time, even for new verbs. Our semantic parsing model jointly reasons about the text, logical forms, and environment over multi-stage instruction sequences. We introduce a new dataset and show that our approach is able to successfully ground new verbs such as *distribute, mix, arrange* to complex logical forms, each containing up to four predicates.

1 Introduction

The task of mapping natural language instructions to actions for a robot has been gaining momentum in recent years (Artzi and Zettlemoyer, 2013; Tellex et al., 2011; Misra et al., 2014; Bollini et al., 2011; Guadarrama et al., 2013; Matuszek et al., 2012b; Fasola and Mataric, 2013). We are particularly interested in instructions containing verbs such as "*microwave*" denoting high-level concepts, which correspond to more than 10 low-level symbolic actions such as `grasp`. In this setting, it is common to find new verbs requiring new concepts at test time. For example, in Figure 1, suppose that we have never seen the verb "*fill*". Can we impute the correct interpretation, and moreover seize the opportunity to learn what "*fill*" means in a way that generalizes to future instructions?



Text: "get the cup, fill it with water and then microwave the cup"
grasping(cup3)∧ near(robot1,cup3)
state(cup3,water)∧ on(cup3,sink)
in(cup3,microwave)∧ state(microwave1,is-on)
Unseen verb " fill " is grounded at test time using environment.

Figure 1: A lexicon learned on the training data cannot possibly cover all the verb-concept mappings needed at test time. Our algorithm learns the meaning of new verbs (e.g., "*fill*") using the environment context.

Previous work in semantic parsing handles lexical coverage in one of two ways. Kwiatkowski et al. (2010) induces a highly constrained CCG lexicon capable of mapping words to complex logical forms, but it would have to skip new words (which in Figure 1 would lead to microwaving an empty cup). Others (Berant and Liang, 2014) take a freer approach by performing a search over logical forms, which can handle new words, but the logical forms there are much simpler than the ones we consider.

In this paper, we present an hybrid approach that uses a lexicon to represent complex concepts but also strongly leverages the environment to guide the search space. The environment can provide helpful cues in several ways:

- Only a few environments are likely for a given scenario—e.g., the text is unlikely to ask the robot to microwave an empty cup or put books on the floor.
- The logical form of one segment of text constrains that of the next segment—e.g., the text is unlikely to ask the robot to pick a cup and then put it back immediately in the same spot.

We show that this environment context provides

Figure 2: Graphical model overview: we first deterministically shallow parse the text x into a control flow graph consisting of shallow structures $\{c_i\}$. Given an initial environment e_1, our semantic parsing model maps these frame nodes to logical forms $\{z_i\}$ representing the postconditions. From this, a planner and simulator generate the action sequences $\{a_i\}$ and resulting environments $\{e_i\}$.

a signal for inducing new lexical entries that map previously unseen verbs to novel concepts. In the example in Figure 1, the algorithm learns that microwaving an empty cup is unlikely and this suggests that the verb "*fill*" must map to actions that end up making the cup not empty.

Another contribution of this paper is using postconditions as logical forms rather than actions, as in previous work (Artzi and Zettlemoyer, 2013; Misra et al., 2014). Postconditions not only reduce the search space of logical forms, but are also a more natural representation of verbs. We define a conditional random field (CRF) model over postconditions, and use a planner to convert postconditions into action sequences and a simulator to generate new environments.

At test time, we use the lexicon induced from the training data, but also perform an environment-guided search over logical forms to induce new lexical entries on-the-fly. If the predicted action sequence uses a new lexical entry generated by the search, it is added to the lexicon, where it can be reused in subsequent test examples.

We evaluate our algorithm on a new corpus containing text commands for a household robot. The two key findings of our experiments are: First, the environment and task context contain enough information to allow us to learn lexical entries for new verbs such as "*distribute*" and "*mix*" with complex semantics. Second, using both lexical entries generated by a test-time search and those from the lexicon induced by the training data outperforms the two individual approaches. This suggests that environment context can help alleviate the problem of having a limited lexicon for grounded language acquisition.

2 Problem Statement

At training time, we are given a set of examples $D = \{(x^{(m)}, e^{(m)}, a^{(m)}, \pi^{(m)})\}_{m=1}^{M}$, where $x^{(m)}$ is a text containing natural language instructions, $e^{(m)}$ is an initial environment, $a^{(m)}$ is a human-annotated sequence of actions, and $\pi^{(m)}$ specifies a monotonic alignment between segments of $x^{(m)}$ and segments of $a^{(m)}$. For example, given words $x^{(m)} = x_1 x_2$ and $a^{(m)} = a_1 a_2 a_3$, $\pi^{(m)}$ might specify that x_1 aligns to $a_1 a_2$ and x_2 aligns to a_3.

At test time, given a sequence of text-environment pairs as input $\{(x^{(n)}, e^{(n)})\}_{n=1}^{N}$, we wish to generate a sequence of actions $a^{(n)}$ for each input pair. Note that our system is allowed to use information about one test example to improve performance on subsequent ones. We evaluate a system on its ability to recover a human-annotated sequence of actions.

3 Approach Overview

Figure 2 shows our approach for mapping text x to actions $a_{1:k}$ given the initial environment e_1.

3.1 Representation

We use the following representation for the different variables in Figure 2.

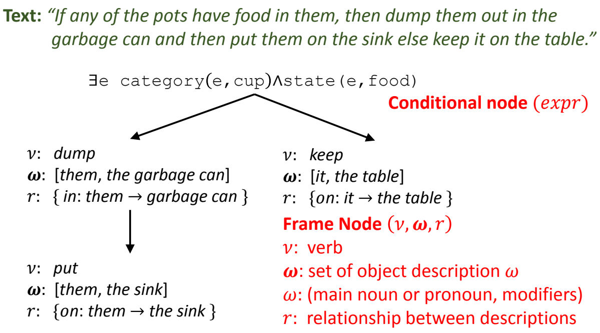
Environment. An environment e_i is represented by a graph whose nodes are objects and edges represent spatial relations between these objects. We consider five basic spatial relations: `near`, `grasping`, `on`, `in` and `below`. Each object has an instance ID (e.g., $\texttt{book}_9$), a category name (e.g., *chair, xbox*), a set of properties such as *graspable, pourable* used for planning and a set of boolean states such as $\texttt{has-water}$, $\texttt{at-channel3}$, whose values can be changed by robot actions. The robot is also an object in the environment. For example, the objects $\texttt{xbox}_1, \texttt{snacktable}_2$, are two objects in e_1 in Figure 2 with relation on between them.

Postconditions. A postcondition is a conjunction of atoms or their negations. Each atom consists of either a spatial relation between two objects (e.g., $\texttt{on}(\texttt{book}_9, \texttt{shelf}_3)$) or a state and a value (e.g., $\texttt{state}(\texttt{cup}_4, \texttt{has-water})$). Given an environment e, the postcondition evaluates to true or false.

Actions. Each action in an action sequence a_i consists of an action name with a list of arguments (e.g., $\texttt{grasp}(\texttt{xbox}_1)$). The action name is one of 15 values ($\texttt{grasp}, \texttt{moveto}, \texttt{wait}$, etc.), and each argument is either an object in the environment (e.g., $\texttt{xbox}_1$), a spatial relation (e.g., $\texttt{in}$ for $\texttt{keep}(\texttt{ramen}_2, \texttt{in}, \texttt{kettle}_1)$), or a postcondition (e.g., for $\texttt{wait}(\texttt{state}(\texttt{kettle}_1, \texttt{boiling}))$).

Logical Forms. The logical form z_i is a pair (ℓ, ξ) containing a lexical entry ℓ and a mapping ξ. The lexical entry ℓ contains a parameterized postcondition such as $\lambda\vec{\texttt{v}}.\texttt{grasping}(\texttt{v}_1, \texttt{v}_2)$ $\wedge\neg\texttt{near}(\texttt{v}_3, \texttt{v}_2)$, and ξ maps the variables $\vec{\texttt{v}}$ to objects in the environment. Applying the parameterized postcondition on ξ yields a postcondition; note that a postcondition can be represented by different logical forms. A lexical entry contains other information which are used for defining features, which is detailed in Section 4.

Control Flow Graphs. Following previous work (Tellex et al., 2011; Misra et al., 2014), we convert the text x to a shallow representation. The particular representation we choose is a *control flow graph*, which encodes the sequential relation between atomic segments in the text. Figure 3 shows the control flow graph for an example text. In a *control flow graph*, each node is either a frame node or a conditional node. A frame node represents a single clause (e.g., "*change the channel to a movie*") and has at most one successor node. Specifically, a frame node consists of a verb ν (e.g., *arrange*, *collect*), a set of object descriptions $\{\omega_i\}$ which are the arguments of the verb (e.g., *the guinness book*, *movie channel*), and spatial relations r between the arguments (e.g., *between*, *near*). The object description ω is either an anaphoric reference (such as "*it*") or a tuple containing the main noun, associated modifiers, and relative clauses.



Text: "If any of the pots have food in them, then dump them out in the garbage can and then put them on the sink else keep it on the table."
∃e category(e,cup)∧state(e,food)
Conditional node (expr)
ν: dump
ω: [them, the garbage can]
r: { in: them → garbage can }
ν: put
ω: [them, the sink]
r: {on: them → the sink }
ν: keep
ω: [it, the table]
r: {on: it → the table }
Frame Node (ν, ω, r)
ν: verb
ω: set of object description ω
ω: (main noun or pronoun, modifiers)
r: relationship between descriptions

Figure 3: We deterministically parse text into a shallow structure called a control flow graph.

A conditional node contains a logical postcondition with at most one existentially quantified variable (in contrast to a frame node, which contains natural language). For example, in Figure 3 the conditional node contains the expression corresponding to the text *"if any of the pots has food"* There are two types of conditional nodes: branching and temporal. A branching conditional node represents an "*if*" statement and has two successor nodes corresponding to whether the condition evaluates to true or false in the current environment. A temporal conditional node represents an "*until*" statement and waits until the condition is false in the environment.

3.2 Formal Overview

Shallow Parsing. We deterministically convert the text x into its *control flow graph* G using a set of manual rules applied on its constituency parse tree from the Stanford parser (Klein and Manning, 2003). Conditionals in our dataset are simple and can be converted into postconditions directly using a few rules, unlike the action verbs (e.g., "*fill*"), which is the focus of this paper. The details of our shallow parsing procedure is described in the appendix.

Given an environment e_1, G is reduced to a single sequence of frame nodes $c_1, \ldots, c_k$, by evaluating all the branch conditionals on e_1.

Semantic Parsing Model. For each frame node c_i and given the current environment e_i, the semantic parsing model (Section 5) places a distribution over logical forms z_i. This logical form z_i represents a postcondition on the environment after executing the instructions in c_i.

Planner and Simulator. Since our semantic representations involve postconditions but our model is based on the environment, we need to connect the two. We use planner and a simulator that together specify a deterministic mapping from the current environment e_i and a logical form z_i to a new environment e_{i+1}. Specifically, the planner takes the current environment e_i and a logical form z_i and computes the action sequence $a_i = \textit{planner}(e_i, z_i)$ for achieving the post condition represented by z_i.[1] The simulator takes the current environment e_i and an action sequence a_i and returns a new environment $e_{i+1} = \textit{simulator}(e_i, a_i)$.

4 Anchored Verb Lexicons

Like many semantic parsers, we use a lexicon to map words to logical forms. Since the environment plays an central role in our approach, we propose an *anchored verb lexicon*, in which we store additional information about the environment in which lexical entries were previously used. We focus only on verbs since they have the most complex semantics; object references such as "*cup*" can be mapped easily, as described in Section 5.

More formally, an anchored verb lexicon Λ contains lexical entries ℓ of the following form: $[\nu \Rightarrow (\lambda\vec{v}.S, \xi)]$ where, ν is a verb, S is a postcondition with free variables $\vec{v}$, and ξ is a mapping of these variables to objects. An example lexical entry is: $[\textit{pour} \Rightarrow (\lambda v_1 v_2 v_3.S, \xi)]$, where:

$S = \texttt{grasping}(\texttt{v}_1, \texttt{v}_2) \wedge \texttt{near}(\texttt{v}_1, \texttt{v}_3) \wedge \neg\texttt{state}(\texttt{v}_2, \texttt{milk})$
$\quad \wedge\, \texttt{state}(\texttt{v}_3, \texttt{milk})$

$\xi = \{\texttt{v}_1 \rightarrow \texttt{robot}_1, \texttt{v}_2 \rightarrow \texttt{cup}_1, \texttt{v}_3 \rightarrow \texttt{bowl}_3\}$ (anchoring)

As Table 1 shows, a single verb will in general have multiple entries due to a combination of polysemy and the fact that language is higher-level than postconditions.

Advantages of Postconditions. In contrast to previous work (Artzi and Zettlemoyer, 2013; Misra et al., 2014), we use postconditions instead of action sequence for two main reasons. First, postconditions generalize better. To illustrate this, consider the action sequence for the simple task of filling a cup with water. At the time of learning the lexicon, the action sequence might correspond to using a tap for filling the cup while at test time, the environment may not have a tap but instead have a pot with water. Thus, if the lexicon maps to action sequence, then it will not be applicable at test time whereas the postcondition $\texttt{state}(\texttt{z}_1, \texttt{water})$ is valid in both cases. We thus shift the load of inferring environment-specific actions onto planners and use postconditions for representation, which better captures the semantics of verbs.

Table 1: Some lexical entries for the verb "*turn*"

Sentence Context	Lexical entry $[turn \Rightarrow (\lambda\vec{v}.S, \xi)]$
"turn on the TV"	$\texttt{state}(\texttt{v}_1, \texttt{is-on}) \wedge \texttt{near}(\texttt{v}_2, \texttt{v}_1)$ $\xi : \texttt{v}_1 \rightarrow \texttt{tv}_1, \texttt{v}_2 \rightarrow \texttt{robot}_1$
"turn on the right back burner"	$\texttt{state}(\texttt{v}_1, \texttt{fire3}) \wedge \texttt{near}(\texttt{v}_2, \texttt{v}_1)$ $\xi : \texttt{v}_1 \rightarrow \texttt{stove}_1, \texttt{v}_2 \rightarrow \texttt{robot}_1$
"turn off the water"	$\neg\texttt{state}(\texttt{v}_1, \texttt{tap-on})$ $\xi : \texttt{v}_1 \rightarrow \texttt{sink}_1$
"turn the television input to xbox"	$\texttt{state}(\texttt{v}_1, \texttt{channel6}) \wedge \texttt{near}(\texttt{v}_1, \texttt{v}_2)$ $\xi : \texttt{v}_1 \rightarrow \texttt{tv}_1, \texttt{v}_2 \rightarrow \texttt{xbox}_1$

Second, because postconditions are higher-level, the number of atoms needed to represent a verb is much less than the corresponding number of actions. For example, the text *"microwave a cup"*, maps to action sequence with 10–15 actions, the postcondition only has two atoms: $\texttt{in}(\texttt{cup}_2, \texttt{microwave}_1) \wedge \texttt{state}(\texttt{microwave}, \texttt{is-on})$. This makes searching for new logical forms more tractable.

Advantages of Anchoring. Similar to the VEIL templates of Misra et al. (2014), the free variables $\vec{v}$ are associated with a mapping ξ to concrete objects. This is useful for resolving ellipsis. Suppose the following lexical entry was created at training time based on the text "*throw the drinks in the trash bag*":

$[\ell$: *throw* $\Rightarrow \lambda xyz.S(x, y, z)]$, where

$S = \texttt{in}(\texttt{x}, \texttt{y}) \wedge \neg\texttt{grasping}(\texttt{z}, \texttt{x}) \wedge \neg\texttt{state}(\texttt{z}, \texttt{closed})$

$\xi = \{\texttt{x} \rightarrow \texttt{coke}_1, \texttt{y} \rightarrow \texttt{garbageBin}_1, \texttt{z} \rightarrow \texttt{robot}_1\}$

Now consider a new text at test time "*throw away the chips*", which does not explicitly mention where to throw the chips. Our semantic parsing algorithm (Section 5) will use the previous mapping $y \rightarrow \texttt{garbabeBin}_1$ to choose an object most similar to a garbage bin.

5 Semantic Parsing Model

Given a sequence of frame nodes $c_{1:k}$ and an initial environment e_1, our semantic parsing model defines a joint distribution over logical forms $z_{1:k}$. Specifically, we define a conditional random field (CRF) over $z_{1:k}$, as shown in Figure 2:

$$p_\theta(z_{1:k} \mid c_{1:k}, e_1) \propto \exp\left(\sum_{i=1}^{k} \phi(c_i, z_{i-1}, z_i, e_i) \cdot \theta\right), \quad (1)$$

where $\phi(c_i, z_{i-1}, z_i, e_i)$ is the feature vector and θ is the weight vector. Note that the environments $e_{1:k}$ are a deterministic function of the logical forms $z_{1:k}$ through the recurrence $e_{i+1} = \textit{simulator}(e_i, \textit{planner}(e_i, z_i))$, which couples the different time steps.

[1] We use the symbolic planner of Rintanen (2012) which can perform complex planning. For example, to pick up a bottle that is blocked by a stack of books, the planner will first remove the books before grasping the bottle. In contrast, Artzi and Zettlemoyer (2013) use a simple search over implicit actions.

Features. The feature vector $\phi(c_i, z_{i-1}, z_i, e_i)$ contains 16 features which capture the dependencies between text, logical forms, and environment. Recall that $z_i = ([\nu \Rightarrow (\lambda\vec{v}.S, \xi)], \xi_i)$, where ξ is the environment in which the lexical entry was created and ξ_i is the current environment. Let $f_i = (\lambda\vec{v}.S)(\xi_i)$ be the current postcondition. Here we briefly describe the important features (see the supplemental material for the full list):

- *Language and logical form*: The logical form z_i should generally reference objects mentioned in the text. Assume we have computed a correlation $\rho(\omega, o)$ between each object description ω and object o, whose construction is described later. We then define two features: precision correlation, which encourages z_i to only use objects referred to in c_i; and recall correlation, which encourages z_i to use all the objects referred to in c_i.
- *Logical form*: The postcondition f_i should be based on previously seen environments. For example, microwaving an empty cup and grasping a couch are unlikely postconditions. We define features corresponding to the average probability (based on the training data) of all conjunctions of at most two atoms in the postcondition (e.g., $\mathtt{grasping(robot, cup)}\}$). We do the same with their abstract versions ($\{\mathtt{grasping(v_1, v_2)}\}$). In addition, we build the same set of four probability tables conditioned on verbs in the training data. For example, the abstract postcondition $\mathtt{state(v_1, water)}$ has a higher probability conditioned on the verb "*fill*". This gives us a total of 8 features of this type.
- *Logical form and environment*: Recall that anchoring helps us in dealing with ellipsis and noise. We add a feature based on the average correlation between the objects of the new mapping ξ_i with the corresponding objects in the anchored mapping ξ.

The other features are based on the relationship between object descriptions, similarity between ξ and ξ_i and transition probabilities between logical forms z_{i-1} and z_i. These probabilities are also learned from training data.

Mapping Object Descriptions. Our features rely on a mapping from object descriptions ω (e.g., "*the red shiny cup*") to objects o (e.g., $\mathtt{cup_8}$), which has been addressed in many recent works (Matuszek et al., 2012a; Guadarrama et al., 2014; Fasola and Matari'c, 2014).

One key idea is: instead of computing rigid lexical entries such as *cup* → $\mathtt{cup_1}$, we use a continuous correlation score $\rho(\omega, o) \in [0, 1]$ that measures how well ω describes o. This flexibility allows the algorithm to use objects not explicitly mentioned in text. Given "*get me a tank of water*", we might choose an approximate vessel (e.g., $\mathtt{cup_2}$).

Given an object description ω, an object o, and a set of previously seen objects (used for anaphoric resolution), we define the correlation $\rho(\omega, o)$ using the following approach:

- If ω *is a pronoun*, $\rho(\omega, o)$ is the ratio of the position of the last reference of o to the length of the action sequence computed so far, thus preferring recent objects.
- Otherwise, we compute the correlation using various sources: the object's category; the object's state for handling metonymy (e.g., the description "*coffee*" correlates well with the object $\mathtt{mug_1}$ if $\mathtt{mug_1}$ contains coffee—$\mathtt{state(mug_1, has\text{-}coffee)}$ is true), WordNet (Fellbaum, 1998) for dealing synonymy and hyponymy; and word alignments between the objects and text from Giza++ (Och and Ney, 2003) to learn domain-specific references (e.g., "*Guinness book*" refers to $\mathtt{book_1}$, not $\mathtt{book_2}$). More details can be found in the supplemental material.

6 Lexicon Induction from Training Data

In order to map text to logical forms, we first induce an initial anchored lexicon Λ from the training data $\{(x^{(m)}, e^{(m)}, a^{(m)}, \pi^{(m)})\}_{m=1}^{M}$. At test time, we add new lexical entries (Section 7) to Λ.

Recall that shallow parsing $x^{(m)}$ yields a list of frame nodes $c_{1:k}$. For each frame node c_i and its aligned action sequence a_i, we take the conjunction of all the atoms (and their negations) which are false in the current one e_i but true in the next environment e_{i+1}. We parametrize this conjunction by replacing each object with a variable, yielding a postcondition S parametrized by free variables $\vec{v}$ and the mapping ξ from $\vec{v}$ to objects in e_i. We then add the lexical entry $[verb(c_i) \Rightarrow (\lambda\vec{v}.S, \xi)]$ to Λ.

Instantiating Lexical Entries. At test time, for a given clause c_i and environment e_i, we generate set of logical forms $z_i = (\ell_i, \xi_i)$. To do this, we consider the lexical entries in Λ with the same verb as c_i. For each such lexical entry ℓ_i, we can map its free variables $\vec{v}$ to objects in e_i in an exponential number of ways. Therefore, for each ℓ_i we only consider the logical form (ℓ_i, ξ_i) where the mapping ξ_i obtains the highest score under the current model: $\xi_i = \arg\max_{\xi'} \phi(c_i, z_{i-1}, (\ell_i, \xi'), e_i) \cdot \theta$. For the feature vector ϕ that we consider, this approximately translates to solving an integer quadratic program with variables $[y_{ij}] \in \{0,1\}$, where $y_{ij} = 1$ only if v_i maps to object j.

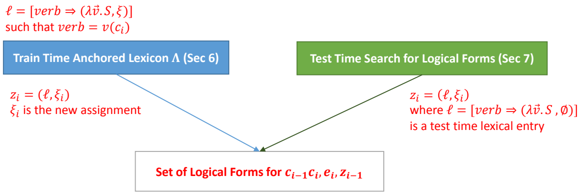
7 Environment-Driven Lexicon Induction at Test Time

Unfortunately, we cannot expect the initial lexicon Λ induced from the training set to have full coverage of the required postconditions. Even after using 90% of the data for training, we encountered 17% new postconditions on the remaining 10%. We therefore propose generating new lexical entries at test time and adding them to Λ.

Formally, for a given environment e_i and frame node c_i, we want to generate likely logical forms. Although the space of all possible logical forms is very large, the environment constrains the possible interpretations. We first compute the set of atoms that are false in e_i and that only contain objects o that are "referred" to by either c_i or c_{i-1}, where "refers" means that there exists some argument ω in c_i for which $o \in \arg\max_{o'} \rho(\omega, o')$. For example, if c_i corresponds to the text "*distribute pillows among the couches*", we consider the atom $\texttt{on}(\texttt{pillow}_1, \texttt{armchair}_1)$ but not $\texttt{on}(\texttt{pillow}_1, \texttt{snacktable}_2)$ since the object $\texttt{armchair}_1$ has the highest correlation to the description "*couches*".

Next, for each atom, we convert it into a logical form $z = (\ell, \xi)$ by replacing each object with a variable. While this generalization gives us a mapping ξ, we create a lexical entry $\ell_i = [\nu \Rightarrow (\lambda\vec{v}.S, \emptyset)]$ without it, where S is the parameterized atom. Note that the anchored mapping is empty, representing the fact that this lexical entry was unseen during training time. For example, the atom $\texttt{state}(\texttt{tv}_1, \texttt{mute})$ would be converted to the logical form (ℓ, ξ), where $\ell = [verb(c_i) \Rightarrow (\lambda v.\texttt{state}(v, \texttt{mute}), \emptyset]$ and $\xi = \{v \rightarrow \texttt{tv}_1\}$. We do not generalize state names (e.g., $\texttt{mute}$) because they generally are part of the meaning of the verb.

The score $\phi(c_i, z_{i-1}, z_i, e_i) \cdot \theta$ is computed for the logical form z_i produced by each postcondition. We then take the conjunction of every pair of postconditions corresponding to the 200 highest-scoring logical forms. This gives us new set of postconditions on which we repeat the generalization-scoring-conjunction cycle. We keep doing this while the scores of the new logical forms is increasing or while there are logical forms remaining.



$\ell = [verb \Rightarrow (\lambda\vec{v}.S, \xi)]$
such that $verb = v(c_i)$
Train Time Anchored Lexicon Λ (Sec 6)
Test Time Search for Logical Forms (Sec 7)
$z_i = (\ell, \xi_i)$
ξ_i is the new assignment
$z_i = (\ell, \xi_i)$
where $\ell = [verb \Rightarrow (\lambda\vec{v}.S, \emptyset)]$
is a test time lexical entry
Set of Logical Forms for $c_{i-1} c_i, e_i, z_{i-1}$

Figure 4: Logical forms for a given clause c_i, environment e_i, and previous logical form z_{i-1} are generated from both a lexicon induced from training data and a test-time search procedure based on the environment.

If a logical form $z = ([\nu \Rightarrow (\lambda\vec{v}.S, \emptyset)], \xi)$ is used by the predicted action sequence, we add the lexical entry $[\nu \Rightarrow (\lambda\vec{v}.S, \xi)]$ to the lexicon Λ. This is different to other lexicon induction procedures such as GENLEX (Zettlemoyer and Collins, 2007) which are done at training time only and require more supervision. Moreover, GENLEX does not use the environment context in creating new lexical entries and thus is not appropriate at test time, since it would vastly overgenerate lexical entries compared to our approach. For us, the environment thus provides implicit supervision for lexicon induction.

8 Inference and Parameter Estimation

Inference. Given a text x (which is converted to $c_{1:k}$ via Section 3.2) and an initial environment e_1, we wish to predict an action sequence a based on $p_\theta(a_{1:k} \mid c_{1:k}, e_1)$, which marginalizes over all logical forms $z_{1:k}$ (see Figure 2).

To enumerate possible logical forms, semantic parsers typically lean heavily on a lexicon (Artzi and Zettlemoyer, 2013), leading to high precision but lower recall, or search more aggressively (Berant et al., 2013), leading to higher recall but lower precision. We adopt the following hybrid approach: Given e_i, c_{i-1}, c_i and z_{i-1}, we use both the lexical entries in Λ as explained in Section 6 and the search procedure in Section 7 to generate the set of possible logical forms for z_i (see Figure 4). We use beam search, keeping only the highest-scoring logical form with satisfiable postconditions for each $i \in \{1, \dots, k\}$ and resulting action sequence $a_{1:i}$.

Parameter Estimation. We split 10% of our training data into a separate tuning set (the 90% was used to infer the lexicon). On each example in this set, we extracted the full sequence of logical forms $z_{1:k}$ from the action sequence $a_{1:k}$ based on Section 6. For efficiency, we used an objective similar to pseudolikelihood to estimate the parameters θ. Specifically, we maximize the average log-likelihood over each adjacent pair of logical forms under $\tilde{p}_\theta$:

$$\tilde{p}_\theta(z_i \mid z_{i-1}, c_i, e_i) \propto \exp(\phi(c_i, z_{i-1}, z_i, e_i)^\top \theta). \qquad (2)$$

The weights were initialized to 0. We performed 300 iterations over the validation set with a learning rate of $\frac{0.005}{N}$.

9 Dataset and Experiments

9.1 Dataset

We collected a dataset of 500 examples from 62 people using a crowdsourcing system similar to Misra et al. (2014). We consider two different 3D scenarios: a kitchen and a living room, each containing an average of 40 objects. Both of these scenarios have 10 environments consisting of different sets of objects in different configurations. We define 10 high-level objectives, 5 per scenario, such as *clean the room*, *make coffee*, *prepare room for movie night*, etc.

One group of users wrote natural language commands to achieve the high-level objectives. Another group controlled a virtual robot to accomplish the commands given by the first group. The dataset contains considerable variety, consisting of 148 different verbs, an average of 48.7 words per text, and an average of 21.5 actions per action sequence. Users make spelling and grammar errors in addition to occasionally taking random actions not relevant to the text. The supplementary material contains more details.

We filtered out 31 examples containing fewer than two action sequences. Of the remaining examples, 378 were used for training and 91 were used for test. Our algorithm is tested on four new environments (two from each scenario).

9.2 Experiments and Results

Evaluation Metrics. We consider two metrics, *IED* and *END*, which measure accuracy based on the action sequence and environment, respectively. Specifically, the *IED* metric (Misra et al., 2014) is the edit distance between predicted and true action sequence. The *END* metric is the Jaccard index of sets A and B, where A is the set of atoms (e.g., $\texttt{on(cup}_1\texttt{,table}_1\texttt{)}$) whose truth value changed due to simulating the predicted action sequence, and B is that of the true action sequence.

Baselines. We compare our algorithm with the following baselines:

Table 3: Results on the metrics and baselines described in section 9.2. The numbers are normalized to 100 with larger values being better.

Algorithm	IED	END
Chance	0.3	0.5
Manually Defined Templates	2.5	1.8
UBL- Best Parse (Kwiatkowski et al., 2010)	5.3	6.9
VEIL (Misra et al., 2014)	14.8	20.7
Model with only train-time lexicon induction	20.8	26.8
Model with only test-time lexicon induction	21.9	25.9
Full Model	**22.3**	**28.8**

1. *Chance:* Randomly selects a logical form for every frame node from the set of logical forms generated by generalizing all possible postconditions that do not hold in the current environment. These postconditions could contain up to 93 atoms.
2. *Manually Defined Templates:* Defines a set of postcondition templates for verbs similar to Guadarrama (2013).
3. *UBL-Best Parse (Kwiatkowski et al., 2010)*: UBL algorithm trained on text aligned with postconditions and a noun-phrase seed lexicon. The planner uses the highest scoring postcondition given by UBL to infer the action sequence.
4. *VEIL (Misra et al., 2014)*: Uses action sequences as logical forms and does not generate lexical entries at test time.

We also consider two variations of our model: (i) using only lexical entries induced using the training data, and (ii) using only the logical forms induced at test-time by the search procedure.

The results are presented in Table 3. We observe that our full model outperforms the baseline and the two pure search- and lexicon-based variations of our model. We further observe that adding the search procedure (Section 7) improved the accuracy by 1.5% on IED and 2% on END. The logical forms generated by the search were able to successfully map 48% of the new verbs.

Table 2 shows new verbs and concepts that the algorithm was able to induce at test time. The algorithm was able to correctly learn the lexical entries for the verbs "*distribute*" and "*mix*", while the ones for verbs "*change*" and "*boil*" were only partly correct. The postconditions in Table 2 are not structurally isomorphic to previously-seen logical forms; hence they could not have been handled by using synonyms or factored lexicons (Kwiatkowski et al., 2011). The poor performance of UBL was because the best logical form often produced an unsatisfiable postcondition. This can be remedied by joint modeling with the environ-

Table 2: New verbs and concepts induced at test time (Section 7).

Text	Postcondition represented by the learned logical form	# Log. forms explored
"mix it with ice cream and syrup"	$\mathtt{state}(\mathtt{cup}_2, \mathtt{ice\text{-}cream}_1) \wedge \mathtt{state}(\mathtt{cup}_2, \mathtt{vanilla})$	15
"distribute among the couches"	$\wedge_{\mathtt{j} \in \{1,3\}} \mathtt{on}(\mathtt{pillow}_{\mathtt{j}}, \mathtt{loveseat}_1) \wedge \mathtt{on}(\mathtt{pillow}_{\mathtt{i}+1}, \mathtt{armchair}_{\mathtt{i}+1})$	386
"boil it on the stove"	$\mathtt{state}(\mathtt{stove}, \mathtt{stovefire1}) \wedge \mathtt{state}(\mathtt{kettle}, \mathtt{water})$	109
"change the channel to a movie"	$\mathtt{state}(\mathtt{tv}_1, \mathtt{channel4}) \wedge \mathtt{on}(\mathtt{book}_1, \mathtt{loveseat}_1)$	98

ment. The VEIL baseline used actions for representation and does not generalize as well as the postconditions in our logical forms.

It is also instructive to examine the alternate postconditions that the search procedure considers. For the first example in Table 2, the following postcondition was considered by not selected:

$\mathtt{grasping}(\mathtt{robot}, \mathtt{icecream}_2) \wedge \mathtt{grasping}(\mathtt{robot}, \mathtt{syrup}_1)$

While this postcondition uses all the objects described in the text, the environment-based features suggest it makes little sense for the task to end with the robot eternally grasping objects. For the second example, alternate postconditions considered included:

1. $\mathtt{on}(\mathtt{pillow}_1, \mathtt{pillow}_2) \wedge \mathtt{on}(\mathtt{pillow}_3, \mathtt{pillow}_4)$
2. $\wedge_{\mathtt{j}=1}^{4} \mathtt{on}(\mathtt{pillow}_{\mathtt{j}}, \mathtt{loveseat}_1)$
3. $\wedge_{\mathtt{j}=1}^{3} \mathtt{near}(\mathtt{robot}_1, \mathtt{armchair}_{\mathtt{j}})$

The algorithm did not choose options 1 or 3 since the environment-based features recognizes these as unlikely configurations. Option 2 was ruled out since the recall correlation feature realizes that not all the couches are mentioned in the postcondition.

To test how much features on the environment help, we removed all such features from our full model. We found that the accuracy fell to 16.0% on the IED metric and 16.6% on the END metric, showing that the environment is crucial.

In this work, we relied on a simple deterministic shallow parsing step. We found that shallow parsing was able to correctly process the text in only 46% of the test examples, suggesting that improving this initial component or at least modeling the uncertainty there would be beneficial.

10 Related Work

Our work uses semantic parsing to map natural language instructions to actions via novel concepts, which brings together several themes: actions, semantic parsing, novel concepts, and robotics.

Mapping Text to Actions. Several works (Branavan et al., 2009; Branavan et al., 2010; Vogel and Jurafsky, 2010) use reinforcement learning to directly map to text to actions, and do not even require an explicit model of the environment. However, they can only handle simple actions, whereas our planner and simulator allows us to work with postconditions, and thus tackle high-level instructions. Branavan et al. (2012) extract precondition relations from text, learn to map text to subgoals (postconditions) for a planner. However, their postconditions are atomic, whereas ours are complex conjunctions.

Other works (Chen and Mooney, 2011; Kim and Mooney, 2012; Kollar et al., 2010; Fasola and Mataric, 2013) have focused only on navigational verbs and spatial relations, but do not handle high-level verbs. Artzi and Zettlemoyer (2013) also fall into the above category and offer a more compositional treatment. They focus on how words compose; we focus on unraveling single words.

The broader problem of grounded language acquisition, involving connecting words to aspects of a situated context has been heavily studied (Duvallet et al., 2014; Yu and Siskind, 2013; Chu et al., 2013; Chen and Mooney, 2008; Mooney, 2008; Fleischman and Roy, 2005; Liang et al., 2009).

Semantic Parsing. In semantic parsing, much work has leveraged CCG (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010). One challenge behind lexically-heavy approaches is ensuring adequate lexical coverage. Kwiatkowski et al. (2011) enhanced generalization by factoring a lexical entry into a template plus a lexeme, but the rigidity of the template remains. This is satisfactory when words map to one (or two) predicates, which is the case in most existing semantic parsing tasks. For example, in Artzi and Zettlemoyer (2013), verbs are associated with single predicates ("*move*" to move, "*walk*" to walk, etc.) In our setting, verbs contain multi-predicate postconditions, for which these techniques would not be suitable.

As annotated logical forms for training semantic parsers are expensive to obtain, several works (Clarke et al., 2010; Liang et al., 2011; Berant et al., 2013; Kwiatkowski et al., 2013) have developed methods to learn from weaker supervision, and as in our work, use the execution of the logical forms to guide the search. Our supervision is even weaker in that we are able to learn at test time from partial environment constraints.

Grounding to Novel Concepts. Guadarrama et al. (2014) map open vocabulary text to objects in an image using a large database. Matuszek et al. (2012a) create new predicates for every new adjective at test time. Others (Kirk et al., 2014) ask users for clarification. In contrast, we neither have access to large databases for this problem, nor do we do create new predicates or use explicit supervision at test time.

Robotic Applications. Our motivation behind this work is to build robotic systems capable of taking commands from users. Other works in this area have considered mapping text to a variety of manipulation actions (Sung et al., 2015). Levine et al. (2015) and Lenz et al. (2015) focus on specific manipulation actions. In order to build a representation of the environment, Ren et al. (2012) and Wu et al. (2014) present vision algorithms but only output symbolic labels, which could act as inputs to our system. In future work, we also plan to integrate our work with RoboBrain (Saxena et al., 2014) to leverage these existing systems for building a robotic system capable of working with physical world data.

11 Conclusion

We have presented an algorithm for mapping text to actions that induces lexical entries at test time using the environment. Our algorithm couples the lexicon extracted from training data with a test-time search that uses the environment to reduce the space of logical forms. Our results suggest that using the environment to provide lexical coverage of high-level concepts is a promising avenue for further research.

Reproducibility. Code, data, and experiments for this paper are available on the CodaLab platform at `https://www.codalab.org/worksheets/0x7f9151ec074f4f589e4d4786db7bb6de/`. Demos can be found at `http://tellmedave.com`.

Appendix: Parsing Text into Control Flow Graph.

We first decompose the text x into its control flow graph G using a simple set of rules:

- The parse tree of x is generated using the Stanford parser (Klein and Manning, 2003) and a frame node is created for each non-auxiliary verb node in the tree.
- Conditional nodes are discovered by looking for the keywords *until, if, after, when.* The associated subtree is then parsed deterministically using a set of a rules. For example, a rule parses *"for x minutes"* to `for(digit:x,unit:minutes)`. We found that all conditionals can be interpreted against the initial environment e_1, since our world is fully-observable, deterministic, and the user giving the command has full view of the world.
- To find objects, we look for anaphoric terminal nodes or nominals whose parent is not a nominal or which have a PP sibling. These are processed into object descriptions ω.
- Object descriptions ω are attached to the frame node, whose verb is nearest in the parse tree to the main noun of ω.
- Nodes corresponding to {*IN,TO,CC,","*} are added as the relation between the corresponding argument objects.
- If there is a conjunction between two objects in a frame node and if these objects have the same relation to other objects, then we split the frame node into two sequential frame nodes around these objects. For example, a frame node corresponding to the text segment "*take the cup and bowl from table*" is split into two frame nodes corresponding to "*take the cup from table*" and "*take bowl from table*".
- A temporal edge is added between successive frame nodes in the same branch of a condition. A temporal edge is added between a conditional node and head of the true and false branches of the condition. The end of all branches in a sentence are joined to the starting node of the successive sentence.

Structural Representations for Learning Relations between Pairs of Texts

Simone Filice and **Giovanni Da San Martino** and **Alessandro Moschitti**
ALT, Qatar Computing Research Institute, Hamad Bin Khalifa University
{sfilice,gmartino,amoschitti}@qf.org.qa

Abstract

This paper studies the use of structural representations for learning relations between pairs of short texts (e.g., sentences or paragraphs) of the kind: the second text answers to, or conveys exactly the same information of, or is implied by, the first text. Engineering effective features that can capture syntactic and semantic relations between the constituents composing the target text pairs is rather complex. Thus, we define syntactic and semantic structures representing the text pairs and then apply graph and tree kernels to them for automatically engineering features in Support Vector Machines. We carry out an extensive comparative analysis of state-of-the-art models for this type of relational learning. Our findings allow for achieving the highest accuracy in two different and important related tasks, i.e., Paraphrasing Identification and Textual Entailment Recognition.

1 Introduction

Advanced NLP systems, e.g., IBM Watson system (Ferrucci et al., 2010), are the result of effective use of syntactic/semantic information along with relational learning (RL) methods. This research area is rather vast including, extraction of syntactic relations, e.g., (Nastase et al., 2013), predicate relations, e.g., Semantic Role Labeling (Carreras and Màrquez, 2005) or FrameNet parsing (Gildea and Jurafsky, 2002) and relation extraction between named entities, e.g., (Mintz et al., 2009).

Although extremely interesting, the above methods target relations only between text constituents whereas the final goal of an intelligent system would be to interpret the semantics of larger pieces of text, e.g., sentences or paragraphs. This line of research relates to three broad fields, namely, Question Answering (QA) (Voorhees and Tice, 1999), Paraphrasing Identification (PI) (Dolan et al., 2004) and Recognition of Textual Entailments (RTE) (Giampiccolo et al., 2007). More generally, RL from text can be denied as follows: given two text fragments, the main goal is to derive relations between them, e.g., either if the second fragment answers the question, or conveys exactly the same information or is implied by the first text fragment. For example, the following two sentences:

- *License revenue slid 21 percent, however, to $107.6 million.*
- *License sales, a key measure of demand, fell 21 percent to $107.6 million.*

express exactly the same meaning, whereas the next one:

- *She was transferred again to Navy when the American Civil War began, 1861.*

implies:

- *The American Civil War started in 1861.*

Automatic learning a model for deriving the relations above is rather complex as any of the text constituents, e.g., *License revenue*, *a key measure of demand*, in the two sentences plays an important role. Therefore, a suitable approach should exploit representations that can structure the two sentences and put their constituents in relation. Since the dependencies between constituents can be an exponential number and representing structures in learning algorithms is rather challenging, automatic feature engineering through kernel methods (Shawe-Taylor and Cristianini, 2004; Moschitti, 2006) can be a promising direction.

In particular, in (Zanzotto and Moschitti, 2006), we represented the two evaluating sentences for the RTE task with syntactic structures and then applied tree kernels to them. The resulting system was very accurate but, unfortunately, it could not scale to large datasets as it is based on a compu-

tationally exponential algorithm. This prevents its application to PI tasks, which typically require a large dataset to train the related systems.

In this paper, we carry out an extensive experimentation using different kernels based on trees and graphs and their combinations with the aim of assessing the best model for relation learning between two entire sentences (or even paragraphs). More in detail, (i) we design many models for RL combining state-of-the-art tree kernels and graph kernels and apply them to innovative computational structures. These innovative combinations use for the fist time semantic/syntactic tree kernels and graph kernels for the tackled tasks. (ii) Our kernels provide effective and efficient solutions, which solve the previous scalability problem and, at the same time, exceed the state of the art on both RTE and PI. Finally, our study suggests research directions for designing effective graph kernels for RL.

2 Related Work

In this paper, we apply kernel methods, which enable an efficient comparison of structures in huge, possibly infinite, feature spaces. While for trees, a comparison using all possible subtrees is possible, designing kernel functions for graphs with such property is an NP-Hard problem (i.e., it shows the same complexity of the graph isomorphism problem) (Gartner et al., 2003). Thus most kernels for graphs only associate specific types of substructures with features, such as paths (Borgwardt and Kriegel, 2005; Heinonen et al., 2012), walks (Kashima et al., 2003; Vishwanathan et al., 2006) and tree structures (Cilia and Moschitti, 2007; Mahé and Vert, 2008; Shervashidze et al., 2011; Da San Martino et al., 2012).

We exploit structural kernels for PI, whose task is to evaluate whether a given pair of sentences is in the paraphrase class or not, (see for example (Dolan et al., 2004)). Paraphrases can be seen as a restatement of a text in another form that preserves the original meaning. This task has a primary importance in many other NLP and IR tasks such as Machine Translation, Plagiarism Detection and QA. Several approaches have been proposed, e.g., (Socher et al., 2011) apply a recursive auto encoder with dynamic pooling, and (Madnani et al., 2012) use eight machine translation metrics to achieve the state of the art. To our knowledge no previous model based on kernel methods has been applied before: with such methods, we outperform the state of the art in PI.

A description of RTE can be found in (Giampiccolo et al., 2007): it is defined as a directional relation extraction between two text fragments, called *text* and *hypothesis*. The implication is supposed to be detectable only based on the text content. Its applications are in QA, Information Extraction, Summarization and Machine translation. One of the most performing approaches of RTE 3 was (Iftene and Balahur-Dobrescu, 2007), which largely relies on external resources (i.e., WordNet, Wikipedia, acronyms dictionaries) and a base of knowledge developed ad hoc for the dataset. In (Zanzotto and Moschitti, 2006), we designed an interesting but computationally expensive model using simple syntactic tree kernels. In this paper, we develop models that do not use external resources but, at the same time, are efficient and approach the state of the art in RTE.

3 Structural kernels

Kernel Machines carry out learning and classification by only relying on the inner product between instances. This can be efficiently and implicitly computed by kernel functions by exploiting the following dual formulation of the model (hyperplane): $\sum_{i=1..l} y_i \alpha_i \phi(o_i) \cdot \phi(o) + b = 0$, where y_i are the example labels, α_i the support vector coefficients, o_i and o are two objects, ϕ is a mapping from the objects to feature vectors $\vec{x_i}$ and $\phi(o_i) \cdot \phi(o) = K(o_i, o)$ is the kernel function implicitly defining such mapping. In case of structural kernels, K maps objects in substructures, thus determining their size and shape. Given two structures S_1 and S_2, our general definition of structural kernels is the following:

$$K(S_1, S_2) = \sum_{s_1 \subseteq S_1, s_2 \subseteq S_2, s_i \in \mathcal{S}} k_{iso}(s_1, s_2), \quad (1)$$

where s_i are substructures of S_i, $\mathcal{S}$ is the set of admissible substructures, and k_{iso} determines if the two substructures are isomorphic, i.e., it outputs 1 if s_1 and s_2 are isomorphic and 0 otherwise.

In the following, we also provide a more computational-oriented definition of structural kernels to more easily describe those we use in our work:

Let the set $\mathcal{S} = \{s_1, s_2, \ldots, s_{|\mathcal{S}|}\}$ be the substructure space and $\chi_i(n)$ be an indicator function, equal to 1 if the target s_i is rooted at node n and equal to 0 otherwise. A structural-kernel function over S_1 and S_2 is

$$K(S_1, S_2) = \sum_{n_1 \in N_{S_1}} \sum_{n_2 \in N_{S_2}} \Delta(n_1, n_2), \qquad (2)$$

where N_{S_1} and N_{S_2} are the sets of the S_1's and S_2's nodes, respectively and

$$\Delta(n_1, n_2) = \sum_{i=1}^{|S|} \chi_i(n_1)\chi_i(n_2). \qquad (3)$$

The latter is equal to the number of common substructures rooted in the n_1 and n_2 nodes. In order to have a similarity score between 0 and 1, a normalization in the kernel space, i.e., $\frac{K(S_1,S_2)}{\sqrt{K(S_1,S_1)\times K(S_2,S_2)}}$ is usually applied. From a practical computation viewpoint, it is convenient to divide structural kernels in two classes of algorithms working either on trees or graphs.

3.1 The Partial Tree Kernel (PTK)

PTK (Moschitti, 2006) generalizes a large class of tree kernels as it computes one of the most general tree substructure spaces. Given two trees S_1 and S_2, PTK considers any connected subset of nodes as possible feature of the substructure space, and counts how many of them are shared by S_1 and S_2. Its computation is carried out by Eq. 2 using the following Δ_{PTK} function:

if the labels of n_1 and n_2 are different $\Delta_{PTK}(n_1, n_2) = 0$; **else** $\Delta_{PTK}(n_1, n_2) =$

$$\mu\Big(\lambda^2 + \sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1) = l(\vec{I}_2)} \lambda^{d(\vec{I}_1)+d(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta_{PTK}(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))\Big)$$

where $\mu, \lambda \in [0, 1]$ are two decay factors, $\vec{I}_1$ and $\vec{I}_2$ are two sequences of indices, which index subsequences of children u, $\vec{I} = (i_1, ..., i_{|u|})$, in sequences of children s, $1 \leq i_1 < ... < i_{|u|} \leq |s|$, i.e., such that $u = s_{i_1}..s_{i_{|u|}}$, and $d(\vec{I}) = i_{|u|} - i_1 + 1$ is the distance between the first and last child. The PTK computational complexity is $O(p\rho^2|N_{S_1}||N_{S_2}|)$ (Moschitti, 2006), where p is the largest subsequence of children that we want to consider and ρ is the maximal outdegree observed in the two trees. However the average running time tends to be linear for natural language syntactic trees (Moschitti, 2006).

3.2 Smoothed Partial Tree Kernel ($SPTK$)

Constraining the application of lexical similarity to words embedded in similar structures provides clear advantages over all-vs-all words similarity, which tends to semantically diverge. Indeed, syntax provides the necessary restrictions to compute an effective semantic similarity. $SPTK$ (Croce et al., 2011) generalizes PTK by enabling node similarity during substructure matching. More formally, $SPTK$ is computed by Eq. 2 using the following $\Delta_{SPTK}(n_1, n_2) = \sum_{i,j=1}^{|S|} \chi_i(n_1)\chi_j(n_2)\Sigma(s_i, s_j)$, where Σ is a similarity between structures[1]. The recursive definition of Δ_{SPTK} is the following:

1. **if** n_1 and n_2 are leaves $\Delta_{SPTK}(n_1, n_2) = \mu\lambda\sigma(n_1, n_2)$;
2. **else** $\Delta_{SPTK}(n_1, n_2) = \mu\sigma(n_1, n_2) \times \Big(\lambda^2 +$

$$\sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1) = l(\vec{I}_2)} \lambda^{d(\vec{I}_1)+d(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta_\sigma(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))\Big),$$

where σ is any similarity between nodes, e.g., between their lexical labels, and the other variables are the same of PTK. The worst case complexity of $SPTK$ is identical to PTK and in practice is not higher than $O(|N_{S_1}||N_{S_2}|)$.

3.3 Neighborhood Subgraph Pairwise Distance Kernel ($NSPDK$)

When general subgraphs are used as features in a kernel computation, eq. 1 and 2 become computationally intractable (Gartner et al., 2003). To solve this problem, we need to restrict the set of considered substructures $\mathcal{S}$. (Costa and De Grave, 2010) defined $NSPDK$ such that the feature space is only constituted by pairs of subgraphs (substructures) that are (i) centered in two nodes n_1 and n_2 such that their distance is not more than D; and (ii) constituted by all nodes (and their edges) at an exact distance h from n_1 or n_2, where the distance between two nodes is defined as the number of edges in the shortest path connecting them. More formally, let G, N_G and E_G be a graph and its set of nodes and edges, respectively, the substructure space $\mathcal{S} = S_G(H, D)$ used by $NSPDK$ in eqs 2 and 3 is:

$$\{(\gamma_h(n), \gamma_h(n')) : 1 \leq h \leq H, n, n' \in N_G, \\ d(n, n') \leq D\},$$

where $\gamma_h(n)$ returns the subgraph obtained by executing h steps of a breadth-first visit of G starting from node n and $d(n, n')$ is the distance between two nodes in the graph. Note that (i) any feature

[1] Note that this generalizes Eq. 3.

of the space is basically a pair of substructures; and (ii) there is currently no efficient (implicit) formulation for computing such kernel. In contrast, when H and D are limited, it is simple to compute the space $S_G(H, D)$ explicitly. In such case, the complexity of the kernel is given by the substructure extraction step, which is $O(|N_G| \times h\rho \log \rho)$.

3.4 Kernel Combinations

Previous sections have shown three different kernels. Among them, $NSPDK$ is actually an explicit kernel, where the features are automatically extracted with a procedure. In NLP, features are often manually defined by domain experts, who know the linguistic phenomena involved in the task. When available, such features are important as they encode some of the background knowledge on the task. Therefore, combining different feature spaces is typically very useful. Fortunately, kernel methods enable an easy integration of different kernels or feature spaces, i.e., the kernel sum produces the joint feature space and it is still a valid kernel. In the next section, we show representations of text, i.e., structures and features, specific to PI and RTE.

4 Representations for RL from text

The kernels described in the previous section can be applied to generic trees and graphs. Automatic feature engineering using structural kernels requires the design of structures for representing data examples that are specific to the learning task we want to tackle. In our case, we focus on RL, which consists in deriving the semantic relation between two entire pieces of text. We focus on two well-understood relations, namely, paraphrasing and textual implications. The tasks are simply defined as: given two texts a_1 and a_2, automatically classify if (i) a_1 is a paraphrase of a_2 and/or (ii) a_1 implies a_2. Although the two tasks are linguistically and conceptually rather different, they can be modeled in a similar way from a shallow representation viewpoint. This is exactly the perspective we would like to keep for showing the advantage of using kernel methods. Therefore, in the following, we define sentence representations that can be suitably used for both tasks and then we rely on structural kernels and the adopted learning algorithm for exploring the substructures relevant to the different tasks.

4.1 Tree Representations

An intuitive understanding of our target tasks suggests that syntactic information is essential to achieve high accuracy. Therefore, we consider the syntactic parse trees of the pair of sentences involved in the evaluation. For example, Fig. 1 shows the syntactic constituency trees of the sentences reported in the introduction (these do not include the green label REL and the dashed edges). Given two pairs of sentences, $p_a = \langle a_1, a_2 \rangle$ and $p_b = \langle b_1, b_2 \rangle$, an initial kernel for learning the tasks, can be the simple tree kernel sum, e.g., $PTK(a_1, b_1) + PTK(a_2, b_2)$ as was defined in (Moschitti, 2008). This kernel works in the space of the union of the sets of all subtrees from the upper and lower trees, e.g.:

a_1: $\{$`[PP [TO [to::t]][NP [QP [$ [$::$]][QP [CD [107.6::c]]]]]], [PP [TO][NP [QP [$][QP [CD [107]]]]]], [PP [TO][NP [QP [QP [CD]]]]], [PP [NP [QP [QP]]]], ...`$\}$

$$\cup$$

a_2: $\{$`[NP [NP [DT [a::d]] [JJ [key::j] NN]][PP]], [NP [NP [DT] [JJ NN]][PP]], [NP [NP [JJ NN]][PP]], [NP [NP [NN]][PP]], [NP [NP [JJ]][PP]], ...`$\}$

However, such features cannot capture the relations between the constituents (or semantic lexical units) from the two trees. In contrast, these are essential to learn the relation between the two entire sentences[2].

To overcome this problem, in (Zanzotto and Moschitti, 2006), we proposed the use of *placeholders* for RTE: the main idea was to annotate the matches between the constituents of the two sentences, e.g., *107.6 millions*, on both trees. This way the tree fragments in the generated kernel space contained an index capturing the correspondences between a_1 and a_2. The critical drawback of this approach is that other pairs, e.g., p_b, will have in general different indices, making the representation very sparse. Alternatively, we experimented with models that select the best match between all possible placeholder assignments across the two pairs. Although we obtained a good improvement, such solution required an exponential computational time and the selection of the max

[2] Of course assuming that text meaning is compositional.

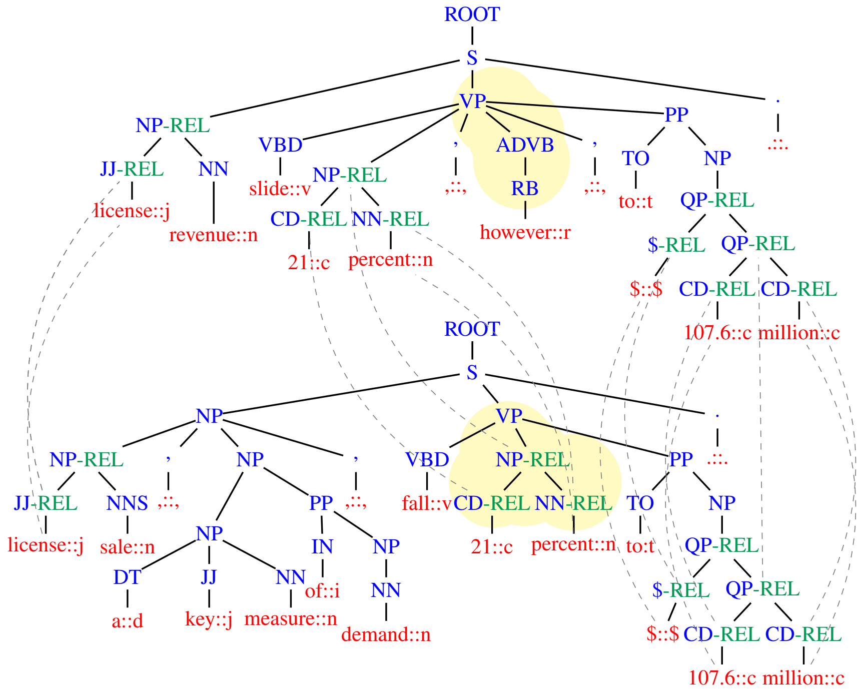

Figure 1: Text representations for PI and RTE: (i) pair of trees, a_1 (upper) and a_2 (lower), (ii) combined in a graph with dashed edges, and (iii) labelled with the tag REL (in green). The nodes highlighted in yellow constitute a feature for the $NSPDK$ kernel ($h = 1$, $D = 3$) centered at the nodes ADVB and NP-REL.

assignment made our similarity function a non-valid kernel.

Thus, for this paper, we prefer to rely on a more recent solution we proposed for passage reranking in the QA domain (Severyn and Moschitti, 2012; Severyn et al., 2013a; Severyn et al., 2013b), and for Answer Selection (Severyn and Moschitti, 2013). It consists in simply labeling matching nodes with a special tag, e.g., REL, which indicates the correspondences between words. REL is attached to the father and grandfather nodes of the matching words. Fig. 1 shows several green REL tags attached to the usual POS-tag and constituent node labels of the parse trees. For example, the lemma *license* is matched by the two sentences, thus both its father, JJ, and its grandfather, NP, nodes are marked with REL. Thanks to such relational labeling the simple kernel, $PTK(a_1, b_1) + PTK(a_2, b_2)$, can generate relational features from a_1, e.g., [NP [NP-REL [JJ-REL] NN]][PP]], [NP [NP-REL [NN]][PP]], [NP [NP-REL [JJ-REL]][PP]],... If such features are matched in b_1, they provide the fuzzy information: *there should be a match similar to* [NP [NP-REL [JJ-REL]] *also between* a_2 *and* b_2. This kind of matches establishes a sort of relational pair features.

It should be noted that we proposed more complex REL tagging policies for Passage Reranking, exploiting additional resources such as Linked Open Data or WordNet (Tymoshenko et al., 2014). Another interesting application of this RL framework is the Machine Translation Evaluation (Guzmán et al., 2014). Finally, we used a similar model for translating questions to SQL queries in (Giordani and Moschitti, 2012).

4.2 Graph Representations

The relational tree representation can capture relational features but the use of the same REL tag for any match between the two trees prevents to deterministically establish the correspondences between nodes. For exactly representing such matches (without incurring in non-valid kernels or sparsity problems), a graph representation is needed. If we connect matching nodes (or also nodes labelled as REL) in Fig. 1 (see dashed lines), we obtain a relational graph. Substructures of such graph clearly indicate how constituents, e.g., NPs, VPs, PPs, from one sentence map into the other sentence. If such mappings observed in a pair of paraphrase sentences are matched in another sentence pair, there may be evidence that also the second pair contains paraphrase sentences.

Unfortunately, the kernel computing the space of all substructures of a graph (even if only considering connected nodes) is an intractable problem as mentioned in Sec. 3.3. Thus, we opt for the use of $NSPDK$, which generates specific pairs of structures. Intuitively, the latter can capture relational features between constituents of the two trees. Figure 1 shows an example of features generated by the $NSPDK$ with parameters $H = 1$, $D = 3$ (the substructures are highlighted in yellow), i.e., `[ADVB [VP] [RB]]`, `[NP-REL [VP] [CD-REL] [NN-REL]]`.

4.3 Basic Features

In addition to structural representations, we also use typical features for capturing the degrees of similarity between two sentences. In contrast, with the previous kernels these similarities are computed intra-pair, e.g., between a_1 and a_2. Note that any similarity measure generates only one feature. Their description follows:

– *Syntactic similarities*, which apply the cosine function to vectors of n-grams (with $n = 1, 2, 3, 4$) of word lemmas and part-of-speech tags.

– *Kernel similarities*, which use PTK or $SPTK$ applied to the sentences within the pair.

We also used similarity features from the DKPro of the UKP Lab (Bär et al., 2012), tested in the Semantic Textual Similarity (STS) task:

– *Longest common substring measure* and *Longest common subsequence measure*, which determine the length of the longest substring shared by two text segments.

– *Running-Karp-Rabin Greedy String Tiling* provides a similarity between two sentences by counting the number of shuffles in their subparts.

– *Resnik similarity* based on the WordNet hierarchy.

– *Explicit Semantic Analysis* (ESA) similarity (Gabrilovich and Markovitch, 2007) represents documents as weighted vectors of concepts learned from Wikipedia, WordNet and Wiktionary.

– *Lexical Substitution* (Szarvas et al., 2013): a supervised word sense disambiguation system is used to substitute a wide selection of high-frequency English nouns with generalizations, then Resnik and ESA features are computed on the transformed text.

4.4 Combined representations

As mentioned in Sec. 3.4, we can combine kernels for engineering new features. Let K be PTK or $SPTK$, given two pairs of sentences $p_a = \langle a_1, a_2\rangle$ and $p_b = \langle b_1, b_2\rangle$, we build the following kernel combinations for the RTE task:

(i) $K^+(p_a, p_b) = K(a_1, b_1) + K(a_2, b_2)$, which simply sums the similarities between the first two sentences and the second two sentences whose implication has to be derived.

(ii) An alternative kernel combines the two similarity scores above with the product: $K^\times(p_a, p_b) = K(a_1, b_1) \cdot K(a_2, b_2)$.

(iii) The symmetry of the PI task requires different kernels. The most intuitive applies K between all member combinations and sum all contributions: $all_K^+(p_a, p_b)$=$K(a_1, b_1) + K(a_2, b_2) + K(a_1, b_2) + K(a_2, b_1)$.

(iv) It is also possible to combine pairs of corresponding kernels with the product: $all_K^\times(p_a, p_b) = K(a_1, b_1)K(a_2, b_2) + K(a_1, b_2)K(a_2, b_1)$.

(v) An alternative kernel selects only the best between the two products above: $M_K(p_a, p_b)$ = max$(K(a_1, b_1)K(a_2, b_2), K(a_1, b_2)K(a_2, b_1))$. This is motivated by the observation that before measuring the similarity between two pairs, we need to establish which a_i is more similar to b_j. However, the max operator causes M_K not to be a valid kernel function, thus we substitute it with a *softmax* function, which is a valid kernel, i.e., $SM_K(p_a, p_b)$ = *softmax*$(K(a_1, b_1)K(a_2, b_2), K(a_1, b_2)K(a_2, b_1))$, where *softmax*$(x_1, x_2) = \frac{1}{c}log(e^{cx_1} + e^{cx_2})$ (c=100 was accurate enough).

The linear kernel (LK) over the basic features (described previously) and/or $NSPDK$ can be of course added to all the above kernels.

5 Experiments

5.1 Setup

MSR Paraphrasing: we used the Microsoft Research Paraphrase Corpus (Dolan et al., 2004) consisting of 4,076 sentence pairs in the training set and 1,725 sentence pairs in test set, with a distribution of about 66% between positive and negative

Table 1: Results on Paraphrasing Identification

examples. These pairs were extracted from topically similar Web news articles, applying some heuristics that select potential paraphrases to be annotated by human experts.

RTE-3. We adopted the RTE-3 dataset (Giampiccolo et al., 2007), which is composed by 800 text-hypothesis pairs in both the training and test sets, collected by human annotators. The distribution of the examples among the positive and negative classes is balanced.

5.1.1 Models and Parameterization

We train our classifiers with the C-SVM learning algorithm (Chang and Lin, 2011) within KeLP[3], a Kernel-based Machine Learning platform that implements tree kernels. In both tasks, we applied the kernels described in Sec. 4, where the trees are generated with the Stanford parser[4].

$SPTK$ uses a node similarity function $\sigma(n_1, n_2)$ implemented as follows: if n_1 and n_2 are two identical syntactic nodes $\sigma = 1$. If n_1 and n_2 are two lexical nodes with the same POS tag, their similarity is evaluated computing the cosine similarity of their corresponding vectors in a wordspace. In all the other cases $\sigma = 0$. We generated two different wordspaces. The first is a co-occurrence LSA embedding as described in (Croce and Previtali, 2010). The second space is derived by applying a skip-gram model (Mikolov et al., 2013) with the word2vec tool[5]. $SPTK$ using the LSA will be referred to as $SPTK_{LSA}$, while when adopting word2vec it will be indicated with $SPTK_{W2V}$. We used default parameters both for PTK and $SPTK$ whereas we selected h and D parameters of $NSPDK$ that obtained the best average accuracy using a 5-fold cross validation on the training set.

5.1.2 Performance measures

The two considered tasks are binary classification problems thus we used Accuracy, Precision, Recall and F1. The adopted corpora have a predefined split between training and test sets thus we tested our models according to such settings for exactly comparing with previous work. Additionally, to better assess our results, we performed a 5-fold cross validation on the complete datasets. In case of PI, the same sentence can appear in multiple pairs thus we distributed the pairs such that the same sentence can only appear in one fold at a time.

Table 2: Results on Textual Entailment Recognition

5.2 Results on PI

The results are reported in Table 1. The first column shows the use of the relational tag REL in the structures (discussed in Sec. 4.1). The second column indicates the kernel models described in sections 3 and 4 as well as the combination of the best models. Columns 3-6 report Accuracy, Precision, Recall and F1 derived on the fixed test set, whereas the remaining columns regard the results obtained with cross validation. We note that:

First, when REL information is not used in the structures, the linear kernel (LK) on basic features outperforms all the structural kernels, which all perform similarly. The best structural kernel is the graph kernel, $NSPDK$ (GK in short). This is not surprising as without REL, GK is the only kernel that can express relational features.

Second, $SPTK$ is only slightly better than PTK. The reason is mainly due to the approach used for building the dataset: potential paraphrases are retrieved applying some heuristics mostly based on the lexical overlap between sentences. Thus, in most cases, the lexical similarity used in $SPTK$ is not needed as hard matches occur between the words of the sentences.

Third, when REL is used on the structures, all kernels reach or outperform the F1 (official measure of the challenge) of LK. The relational structures seem to drastically reduce the inconsistent matching between positive and negative examples, reflecting in remarkable increasing in Precision. In particular, $SM_{SPTK_{LSA}}$ achieves the state of the art[6], i.e., 84.1 (Madnani et al., 2012).

Next, combining our best models produces a significant improvement of the state of the art, e.g., $LK + GK + SM_{SPTK_{W2V}}$ outperforms the result in (Madnani et al., 2012) by 1.7% in accuracy and 1.1 points in F1.

Finally, the cross-validation experiments confirm the system behavior observed on the fixed test set. The Std. Dev. (specified after the ± sign) shows that in most cases the system differences are significant.

5.3 Results on RTE

We used the same experimental settings performed for PI to carry out the experiments on RTE. The results are shown in Table 2 structured in the same way as the previous table. We note that:

(i) Findings similar to PI are obtained.

(ii) Again the relational structures (using REL) provide a remarkable improvement in Accuracy (RTE challenge measure), allowing tree kernels to compete with the state of the art. This is an impressive result considering that our models do not use any external resource, e.g., as in (Iftene and Balahur-Dobrescu, 2007).

(iii) This time, $SPTK^\times_{W2V}$ improves on PTK by 1 absolute percent point.

[6] The performance of the several best systems improved by our models are nicely summarized at `http://aclweb.org/aclwiki/index.php?title=Paraphrase_Identification_(State_of_the_art)`

(iv) The kernel combinations are not more effective than $SPTK$ alone.

Finally, the cross-fold validation experiments confirm the fixed-test set results.

6 Discussion and Conclusions

In this paper, we have engineered and studied several models for relation learning. We utilized state-of-the-art kernels for structures and created new ones by combining kernels together. Additionally, we provide a novel definition of effective and computationally feasible structural kernels. Most importantly, we have designed novel computational structures for trees and graphs, which are for the first time tested in NLP tasks. Our kernels are computationally efficient thus solving one of the most important problems of previous work.

We empirically tested our kernels on two of the most representative tasks of RL from text, namely, PI and RTE. The extensive experimentation using many kernel models also combined with traditional feature vector approaches sheds some light on how engineering effective graph and tree kernels for learning from pairs of entire text fragments. In particular, our best models significantly outperform the state of the art in PI and the best kernel model for RTE 3, with Accuracy close to the one of the best system of RTE 3.

It should be stressed that the design of previous state-of-the-art models involved the use of several resources, annotation and heavy manually engineering of specific rules and features: this makes the portability of such systems on other domains and tasks extremely difficult. Moreover the unavailability of the used resources and the opacity of the used rules have also made such systems very difficult to replicate.

On the contrary, the models we propose enable researchers to:

(i) build their system without the use of specific resources. We use a standard syntactic parser, and for some models we use well-known and available corpora for automatically learning similarities with word embedding algorithms; and

(ii) reuse our work for different (similar) tasks (see paraphrasing) and data.

The simplicity and portability of our system is a significant contribution to a very complex research area such as RL from two entire pieces of text.

Our study has indeed shown that our kernel models, which are very simple to be implemented, reach the state of the art and can be used with large datasets.

Furthermore, it should be noted that our models outperform the best tree kernel approach of the RTE challenges (Zanzotto and Moschitti, 2006) and also its extension that we proposed in (Zanzotto et al., 2009). These systems are also adaptable and easy to replicate, but they are subject to an exponential computational complexity and can thus only be used on very small datasets (e.g., they cannot be applied to the MSR Paraphrase corpus). In contrast, the model we proposed in this paper can be used on large datasets, because its kernel complexity is about linear (on average).

We believe that disseminating these findings to the research community is very important, as it will foster research on RL, e.g., on RTE, using structural kernel methods. Such research has had a sudden stop as the RTE data in the latest challenges increased from 800 instances to several thousands and no tree kernel model has been enough accurate to replace our computational expensive models (Zanzotto et al., 2009).

In the future, it would be interesting defining graph kernels that can combine more than two substructures. Another possible extension regards the use of node similarity in graph kernels. Additionally, we would like to test our models on other RTE challenges and on several QA datasets, which for space constraints we could not do in this work.

Acknowledgments

This research is part of the Interactive sYstems for Answer Search (IYAS) project, conducted by the Arabic Language Technologies (ALT) group at Qatar Computing Research Institute (QCRI) within the Hamad Bin Khalifa University and Qatar Foundation.

Learning Semantic Representations of Users and Products for Document Level Sentiment Classification

Duyu Tang, Bing Qin*, Ting Liu
Harbin Institute of Technology, Harbin, China
{dytang, qinb, tliu}@ir.hit.edu.cn

Abstract

Neural network methods have achieved promising results for sentiment classification of text. However, these models only use semantics of texts, while ignoring users who express the sentiment and products which are evaluated, both of which have great influences on interpreting the sentiment of text. In this paper, we address this issue by incorporating user- and product- level information into a neural network approach for document level sentiment classification. Users and products are modeled using vector space models, the representations of which capture important global clues such as individual preferences of users or overall qualities of products. Such global evidence in turn facilitates embedding learning procedure at document level, yielding better text representations. By combining evidence at user-, product- and document-level in a unified neural framework, the proposed model achieves state-of-the-art performances on IMDB and Yelp datasets[1].

1 Introduction

Document-level sentiment classification is a fundamental problem in the field of sentiment analysis and opinion mining (Pang and Lee, 2008; Liu, 2012). The task is to infer the sentiment polarity or intensity (e.g. 1-5 or 1-10 stars on review sites) of a document. Dominating studies follow Pang et al. (2002; 2005) and regard this problem as a multi-class classification task. They usually use machine learning algorithms, and build sentiment classifier from documents with accompanying sentiment labels. Since the performance of a machine learner is heavily dependent on the choice of data representations (Domingos, 2012), many works focus on designing effective features (Pang et al., 2002; Qu et al., 2010; Kiritchenko et al., 2014) or learning discriminative features from data with neural networks (Socher et al., 2013; Kalchbrenner et al., 2014; Le and Mikolov, 2014).

Despite the apparent success of neural network methods, they typically only use text information while ignoring the important influences of users and products. Let us take reviews with respect to 1-5 rating scales as an example. A critical user might write a review "*it works great*" and mark 4 stars, while a lenient user might give 5 stars even if he posts an (almost) identical review. In this case, user preference affects the sentiment rating of a review. Product quality also has an impact on review sentiment rating. Reviews towards high-quality products (e.g. *Macbook*) tend to receive higher ratings than those towards low-quality products. Therefore, it is feasible to leverage individual preferences of users and overall qualities of products to build a smarter sentiment classifier and achieve better performance[2].

In this paper, we propose a new model dubbed User Product Neural Network (**UPNN**) to capture user- and product-level information for sentiment classification of documents (e.g. reviews). UPNN takes as input a variable-sized document as well as the user who writes the review and the product which is evaluated. It outputs sentiment polarity label of a document. Users and products are encoded in continuous vector spaces, the representations of which capture important global clues such

[1] The codes and datasets are available at http://ir.hit.edu.cn/~dytang/

[2] One can manually design a small number of user and product features (Gao et al., 2013). However, we argue that they are not effective enough to capture sophisticated semantics of users and products.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1014–1023,
Beijing, China, July 26-31, 2015.

as user preferences and product qualities. These representations are further integrated with continuous text representation in a unified neural framework for sentiment classification.

We apply UPNN to three datasets derived from IMDB and Yelp Dataset Challenge. We compare to several neural network models including recursive neural networks (Socher et al., 2013), paragraph vector (Le and Mikolov, 2014), sentiment-specific word embedding (Tang et al., 2014b), and a state-of-the-art recommendation algorithm JMARS (Diao et al., 2014). Experimental results show that: (1) UPNN outperforms baseline methods for sentiment classification of documents; (2) incorporating representations of users and products significantly improves classification accuracy. The main contributions of this work are as follows:

- We present a new neural network method (UPNN) by leveraging users and products for document-level sentiment classification.
- We validate the influences of users and products in terms of sentiment and text on massive IMDB and Yelp reviews.
- We report empirical results on three datasets, and show that UPNN outperforms state-of-the-art methods for sentiment classification.

2 Consistency Assumption Verification

We detail the effects of users and products in terms of sentiment (e.g. 1-5 rating stars) and text, and verify them on review datasets.

We argue that the influences of users and products include the following four aspects.

- **user-sentiment consistency**. A user has specific preference on providing sentiment ratings. Some users favor giving higher ratings like 5 stars and some users tend to give lower ratings. In other words, sentiment ratings from the same user are more consistent than those from different users.
- **product-sentiment consistency**. Similar with user-sentiment consistency, a product also has its "preference" to receive different average ratings on account of its overall quality. Sentiment ratings towards the same product are more consistent than those towards different products.
- **user-text consistency**. A user likes to use personalized sentiment words when expressing opinion polarity or intensity. For example, a strict user might use "*good*" to express an excellent attitude, but a lenient user may use "*good*" to evaluate an ordinary product.

Algorithm 1 Consistency Assumption Testing

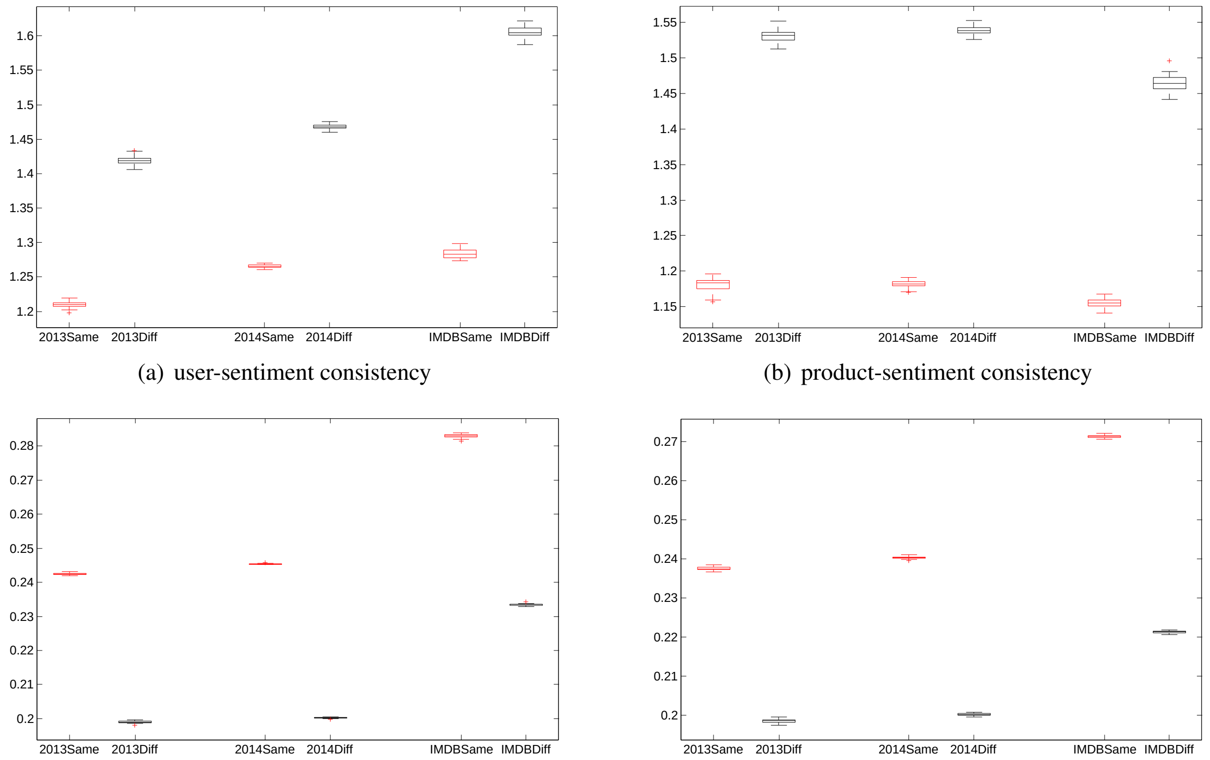
```
**Input:** data $X$, number of users/products $m$,
number of iterations $n$
**Output:** $meaSame_k, meaDiff_k, 1 \leq k \leq n$
**for** $k = 1$ **to** $n$ **do**
  $meaSame_k = 0, meaSame_k = 0$
  **for** $i = 1$ **to** $m$ **do**
    Sample $x_i, x_i^+, x_i^-$ from $X$
    $meaSame_k$ += $measure(x_i, x_i^+)$
    $meaDiff_k$ += $measure(x_i, x_i^-)$
  **end for**
  $meaSame_k$ /= $m$, $meaDiff_k$ /= $m$
**end for**
```

- **product-text consistency**. Similar with user-text consistency, a product also has a collection of product-specific words suited to evaluate it. For example, people prefer using "*sleek*" and "*stable*" to evaluate a smartphone, while like to use "*wireless*" and "*mechanical*" to evaluate a keyboard.

We test four consistency assumptions mentioned above with the same testing criterion, which is formalized in Algorithm 1. For each consistency assumption, we test it for n = 50 iterations on each of IMDB, Yelp Dataset Challenge 2013 and 2014 datasets. Taking user-sentiment consistency as an example, in each iteration, we randomly select two reviews x_i, x_i^+ written by the same user u_i, and a review x_i^- written by another randomly selected user. Afterwards, we calculate the measurements of $(x_i,\ x_i^+)$ and $(x_i,\ x_i^-)$, and aggregate these statistics for m users. In user-sentiment assumption test, we use absolute rating difference $||rating_a - rating_b||$ as the measurement between two reviews a and b. We illustrate the results in Figure 1 (a)[3], where $2013same/2014same/amzsame$ (red plots) means that two reviews are written by a same user, and $2013diff/2014diff/amzdiff$ (black plots) means that two reviews are written by different users. We can find that: the absolute rating differences between two reviews written by a same user are lower than those written by different users (t-test with p-value $<$ 0.01). In other words, sentiment ratings from the same user are more consistent than those from different users. This validates the user-sentiment consistency.

For testing product-sentiment consistency, we

[3] Since the rating scale of IMDB (1-10) is different from Yelp (1-5), we divide the rating difference of IMDB reviews by two for better visualizing and analyzing the results.



(a) user-sentiment consistency

(b) product-sentiment consistency

(c) user-text consistency

(d) product-text consistency

Figure 1: Assumption testing of user-sentiment, product-sentiment, user-text and product-text consistencies. We test them on the datasets from IMDB and Yelp Dataset Challenge in 2013 and 2014.

use absolute rating difference as the measurement. The reviews x_i, x_i^+ are towards a same product p_i, and x_i^- is towards another randomly selected product. From Figure 1 (b), we can see that sentiment ratings towards the same product are more consistent than those towards different products. In order to verify the assumptions of user-text and product-text consistencies, we use cosine similarity between bag-of-words of two reviews as the measurement. Results are given in Figure 1 (c) and (d). We can see that the textual similarity between two reviews written by a same user (or towards a same product) are higher than those written by different users (or towards different products).

3 User Product Neural Network (UPNN) for Sentiment Classification

We present the details of User Product Neural Network (UPNN) for sentiment classification. An illustration of UPNN is given in Figure 2. It takes as input a *review*, the *user* who posts the review, and the *product* which is evaluated. UPNN captures four kinds of consistencies which are verified in Section 2. It outputs the sentiment category (e.g. 1-5 stars) of a review by considering not only the semantics of review text, but also the information of user and product. In following subsections, we first describe the use of neural network for modeling semantics of variable-sized documents. We then present the methods for incorporating user and product information, followed by the use of UPNN in a supervised learning framework for sentiment classification.

3.1 Modeling Semantics of Document

We model the semantics of documents based on the principle of compositionality (Frege, 1892), which states that the meaning of a longer expression (e.g. a sentence or a document) comes from the meanings of its words and the rules used to combine them. Since a document consists of a list of sentences and each sentence is made up of a list of words, we model the semantic representation of a document in two stages. We first produce continuous vector of each sentence from word representations. Afterwards, we feed sentence vectors as inputs to compose document representation.

For modeling the semantics of words, we represent each word as a low dimensional, continu-

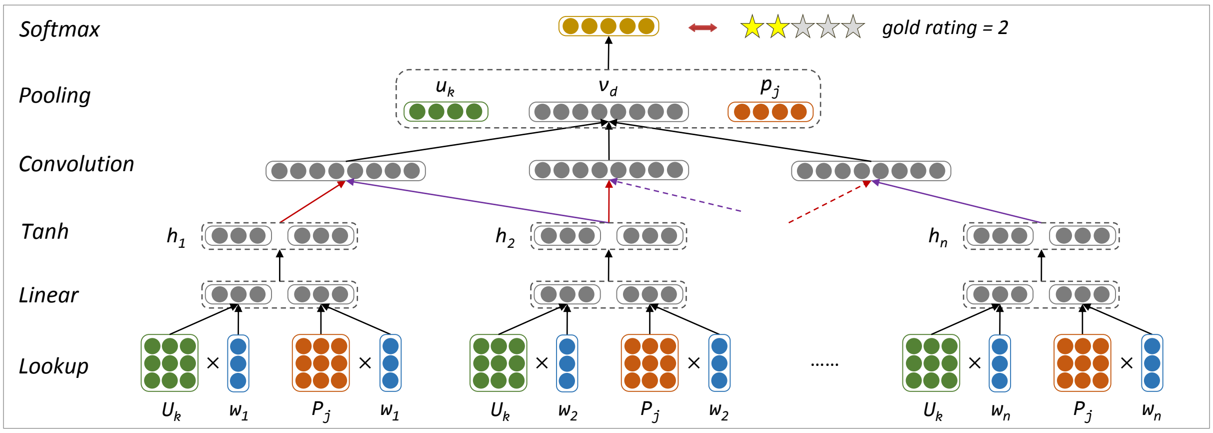


Figure 2: An illustration of the neural network approach for sentiment classification. w_i means the i-th word of a review text. u_k and p_j are continuous vector representations of user k and product j for capturing user-sentiment and product-sentiment consistencies. U_k and P_j are continuous matrix representations of user k and product j for capturing user-text and product-text consistencies.

ous and real-valued vector, also known as word embedding (Bengio et al., 2003). All the word vectors are stacked in a word embedding matrix $L_w \in \mathbb{R}^{d \times |V|}$, where d is the dimension of word vector and $|V|$ is the size of word vocabulary. These word vectors can be randomly initialized from a uniform distribution, regarded as a parameter and jointly trained with other parameters of neural networks. Alternatively, they can be pretrained from text corpus with embedding learning algorithms (Mikolov et al., 2013; Pennington et al., 2014; Tang et al., 2014b), and applied as initial values of word embedding matrix. We adopt the latter strategy which better exploits the semantic and grammatical associations of words.

To model semantic representations of sentences, convolutional neural network (CNN) and recursive neural network (Socher et al., 2013) are two state-of-the-art methods. We use CNN (Kim, 2014; Kalchbrenner et al., 2014) in this work as it does not rely on external parse tree. Specifically, we use multiple convolutional filters with different widths to produce sentence representation. The reason is that they are capable of capturing local semantics of n-grams of various granularities, which are proven powerful for sentiment classification. The convolutional filter with a width of 3 essentially captures the semantics of trigrams in a sentence. Accordingly, multiple convolutional filters with widths of 1, 2 and 3 encode the semantics of unigrams, bigrams and trigrams in a sentence.

An illustration of CNN with three convolutional filters is given in Figure 3. Let us denote a sentence consisting of n words as $\{w_1, w_2, ...w_i, ...w_n\}$. Each word w_i is mapped to its embedding representation $e_i \in \mathbb{R}^d$. A convolutional filter is a list of linear layers with shared parameters. Let l_{cf} be the width of a convolutional filter, and let W_{cf}, b_{cf} be the shared parameters of linear layers in the filter. The input of a linear layer is the concatenation of word embeddings in a fixed-length window size l_{cf}, which is denoted as $I_{cf} = [e_i; e_{i+1}; ...; e_{i+l_{cf}-1}] \in \mathbb{R}^{d \cdot l_{cf}}$. The output of a linear layer is calculated as

$$O_{cf} = W_{cf} \cdot I_{cf} + b_{cf} \qquad (1)$$

where $W_{cf} \in \mathbb{R}^{len \times d \cdot l_{cf}}$, $b_{cf} \in \mathbb{R}^{len}$, len is the output length of linear layer. In order to capture the global semantics of a sentence, we feed the output of a convolutional filter to an *average* pooling layer, resulting in an output vector with fixed-length. We further add hyperbolic tangent functions ($tanh$) to incorporate element-wise nonlinearity, and *fold* (*average*) their outputs to generate sentence representation.

We feed sentence vectors as the input of an *average* pooling layer to obtain the document representation. Alternative document modeling approaches include CNN or recurrent neural network. However, we prefer *average* pooling for its computational efficiency and good performance in our experiment.

3.2 Modeling Semantics of Users and Products

We integrate semantic representations of users and products in UPNN to capture user-sentiment,

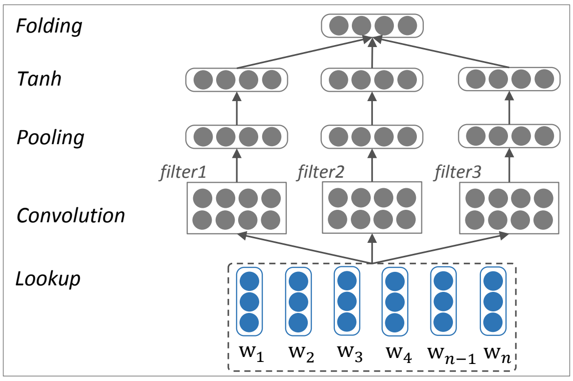

Figure 3: Convolutional neural network with multiple convolutional filters for sentence modeling.

product-sentiment, user-text and product-text consistencies.

For modeling **user-sentiment** and **product-sentiment** consistencies, we embed each user as a continuous vector $u_k \in \mathbb{R}^{d_u}$ and embed each product as a continuous vector $p_j \in \mathbb{R}^{d_p}$, where d_u and d_p are dimensions of user vector and product vector, respectively. The basic idea behind this is to map users with similar rating preferences (e.g. prefer assigning 4 stars) into close vectors in user embedding space. Similarly, the products which receive similar averaged ratings are mapped into neighboring vectors in product embedding space.

In order to model **user-text** consistency, we represent each user as a continuous matrix $U_k \in \mathbb{R}^{d_U \times d}$, which acts as an operator to modify the semantic meaning of a word. This is on the basis of vector based semantic composition (Mitchell and Lapata, 2010). They regard compositional modifier as a matrix X_1 to modify another component x_2, and use matrix-vector multiplication $y = X_1 \times x_2$ as the composition function. Multiplicative semantic composition is suitable for our need of user modifying word meaning, and it has been successfully utilized to model adjective-noun composition (Clark et al., 2008; Baroni and Zamparelli, 2010) and adverb-adjective composition (Socher et al., 2012). Similarly, we model **product-text** consistency by encoding each product as a matrix $P_j \in \mathbb{R}^{d_P \times d}$, where d is the dimension of word vector, d_P is the output length of product-word multiplicative composition. After conducting user-word multiplication and product-word multiplication operations, we concatenate their outputs and feed them to CNN (detailed in Section 3.1) for producing user and product enhanced document representation.

3.3 Sentiment Classification

We apply UPNN to document level sentiment classification under a supervised learning framework (Pang and Lee, 2005). Instead of using hand-crafted features, we use continuous representation of documents, users and products as discriminative features. The sentiment classifier is built from documents with gold standard sentiment labels.

As is shown in Figure 2, the feature representation for building rating predictor is the concatenation of three parts: continuous user representation u_k, continuous product representation p_j and continuous document representation v_d, where v_d encodes user-text consistency, product-text consistency and document level semantic composition. We use $softmax$ to build the classifier because its outputs can be interpreted as conditional probabilities. $Softmax$ is calculated as given in Equation 2, where C is the category number (e.g. 5 or 10).

$$softmax_i = \frac{exp(x_i)}{\sum_{i'=1}^{C} exp(x_{i'})} \tag{2}$$

We regard cross-entropy error between gold sentiment distribution and predicted sentiment distribution as the loss function of $softmax$. We take the derivative of loss function through back-propagation with respect to the whole set of parameters $\theta = [W_{cf}^{1,2,3}; b_{cf}^{1,2,3}; u_k; p_j; U_k; P_j; W_{softmax}, b_{softmax}]$, and update parameters with stochastic gradient descent. We set the widths of three convolutional filters as 1, 2 and 3. We learn 200-dimensional sentiment-specific word embeddings (Tang et al., 2014b) on each dataset separately, randomly initialize other parameters from a uniform distribution $U(-0.01, 0.01)$, and set learning rate as 0.03.

4 Experiment

We conduct experiments to evaluate UPNN by applying it to sentiment classification of documents.

4.1 Experimental Setting

Existing benchmark datasets for sentiment classification such as Stanford Sentiment Treebank (Socher et al., 2013) typically only have text information, but do not contain users who express the sentiment or products which are evaluated. Therefore, we build the datasets by ourselves. In order to obtain large scale corpora without manual annotation, we derive three datasets from IMDB (Diao

Dataset	#users	#products	#reviews	#docs/user	#docs/product	#sents/doc	#words/doc
IMDB	1,310	1,635	84,919	64.82	51.94	16.08	394.6
Yelp 2014	4,818	4,194	231,163	47.97	55.11	11.41	196.9
Yelp 2013	1,631	1,633	78,966	48.42	48.36	10.89	189.3

Table 1: Statistical information of IMDB, Yelp 2014 and Yelp 2013 datasets used for sentiment classification. The rating scale of IMDB dataset is 1-10. The rating scale of Yelp 2014 and Yelp 2013 datasets is 1-5. $|V|$ is the vocabulary size of words in each dataset. #users is the number of users, #docs/user means the average number of documents per user posts in the corpus.

et al., 2014) and Yelp Dataset Challenge[4] in 2013 and 2014. Statistical information of the generated datasets are given in Table 1.

We split each corpus into training, development and testing sets with a 80/10/10 split, and conduct tokenization and sentence splitting with Stanford CoreNLP (Manning et al., 2014). We use standard *accuracy* (Manning and Schütze, 1999; Jurafsky and Martin, 2000) to measure the overall sentiment classification performance, and use MAE and $RMSE$ to measure the divergences between predicted sentiment ratings (pr) and ground truth ratings (gd).

$$MAE = \frac{\sum_i |gd_i - pr_i|}{N} \tag{3}$$

$$RMSE = \sqrt{\frac{\sum_i (gd_i - pr_i)^2}{N}} \tag{4}$$

4.2 Baseline Methods

We compare UPNN with the following baseline methods for document-level sentiment classification.

(1) *Majority* is a heuristic baseline method, which assigns the majority sentiment category in training set to each review in the test dataset.

(2) In *Trigram*, we use unigrams, bigrams and trigrams as features and train classifier with supported vector machine (SVM) (Fan et al., 2008).

(3) In *TextFeature*, we implement hand-crafted text features including word/character ngrams, sentiment lexicon features, negation features, etc al. (Kiritchenko et al., 2014).

(4) We extract user-leniency features (Gao et al., 2013) and corresponding product features (denoted as *UPF*) from training data, and concatenate them with the features in baseline (2) and (3).

(5) We learn word embeddings from training and development sets with *word2vec* (Mikolov et al., 2013), average word embeddings to get document representation, and train a SVM classifier.

(6) We learn sentiment-specific word embeddings (SSWE) from training and development sets, and use max/min/average pooling (Tang et al., 2014b) to generate document representation.

(7) We represent sentence with RNTN (Socher et al., 2013) and compose document representation with recurrent neural network. We average hidden vectors of recurrent neural network as the features for sentiment classification.

(8) We re-implement PVDM in Paragraph Vector (Le and Mikolov, 2014) because its codes are not officially provided. The window size is tuned on development set.

(9) We compare with a state-of-the-art recommendation algorithm JMARS (Diao et al., 2014), which leverages user and aspects of a review with collaborative filtering and topic modeling.

4.3 Model Comparisons

Experimental results are given in Table 2. The results are separated into two groups: the methods above only use texts of review, and the methods below also use user and product information.

From the first group, we can see that majority performs very poor because it does not capture any text or user information. SVM classifiers with trigrams and hand-crafted text features are powerful for document level sentiment classification and hard to beat. We compare the word embedding learnt from each corpus with off-the-shell general word embeddings[5]. Results show that tailored word embedding from each corpus performs slightly better than general word embeddings (about 0.01 improvement in terms of accuracy). SSWE performs better than context-based word embedding by incorporating sentiment information of texts. Setting a large window size (e.g. 15) is crucial for effectively training SSWE from documents with accompanying senti-

Table 2: Sentiment classification on IMDB, Yelp 2014 and Yelp 2013 datasets. Evaluation metrics are accuracy (Acc, higher is better), MAE (lower is better) and RMSE (lower is better). Our full model is UPNN (full). Our model without using user and product information is abbreviated as UPNN (no UP). The best method in each group is in **bold**.

ment labels. *RNTN+Reccurent* is a strong performer by effectively modeling document representation with semantic composition. Our text based model (UPNN no UP) performs slightly better than *RNTN+Reccurent*, trigram and text features.

From the second group, we can see that concatenating user product feature (*UPF*) with existing feature sets does not show significant improvements. This is because the dimension of existing feature sets is typically huge (e.g. 1M trigram features in Yelp 2014), so that concatenating a small number of *UPF* features does not have a great influence on the whole model. We do not evaluate JMARS in terms of *accuracy* because JMARS outputs real-valued ratings. Our full model UPNN yields the best performance on all three datasets. Incorporating semantic representations of user and product significantly (t-test with p-value $<$ 0.01) boosts our text based model (UPNN no UP). This shows the effectiveness of UPNN over standard trigrams and hand-crafted features when incorporating user and product information.

4.4 Model Analysis: Effect of User and Product Representations

We investigate the effects of vector based user and product representations (u_k, p_j) as well as matrix based user and product representations (U_k, P_j) for sentiment classification. We remove vector based representations (u_k, p_j) and matrix based representations (U_k, P_j) from UPNN separately, and conduct experiments on three datasets. From Table 3, we can find that vector based representations (u_k, p_j) are more effective than matrix based representations (U_k, P_j). This is because u_k and p_j encode user-sentiment and product-sentiment consistencies, which are more directly associated with sentiment labels than user-text (U_k) and product-text (P_j) consistencies. Another reason might be that the parameters of vector representations are less than the matrix representations, so that the vector representations are better estimated. We also see the contribution from each of user and product by removing (U_k, u_k) and (P_j, p_j) separately. Results are given in Table 3. It is interesting to find that user representations are obviously more effective than product representations for review rating prediction.

4.5 Discussion: Out-Of-Vocabulary Users and Products

Out-of-vocabulary (OOV) situation occurs if a user or a product in testing/decoding process is never seen in training data. We give two natural solutions (avg UP and unk UP) to deal with OOV users and products. One solution (avg UP) is to regard the averaged representations of users/products in training data as the representation of OOV user/product. Another way (unk UP) is to learn a shared "unknown" user/product representation for low-frequency users in training data, and apply it to OOV user/product.

	IMDB			Yelp 2014			Yelp 2013		
	Acc	MAE	RMSE	Acc	MAE	RMSE	Acc	MAE	RMSE
UPNN (full)	0.435	0.979	1.602	0.608	0.447	0.764	0.596	0.464	0.784
UPNN $- u_k - p_j$	0.409	1.021	1.622	0.585	0.483	0.808	0.572	0.491	0.823
UPNN $- U_k - P_j$	0.426	0.993	1.607	0.597	0.465	0.789	0.585	0.482	0.802
UPNN $- U_k - u_k$	0.324	1.209	1.743	0.577	0.475	0.778	0.566	0.505	0.828
UPNN $- P_j - p_j$	0.397	1.075	1.712	0.595	0.462	0.776	0.590	0.476	0.802

Table 3: Influence of user and product representations. For user k and product j, u_k and p_j are their continuous vector representations, U_k and P_j are their continuous matrix representations (see Figure 2).

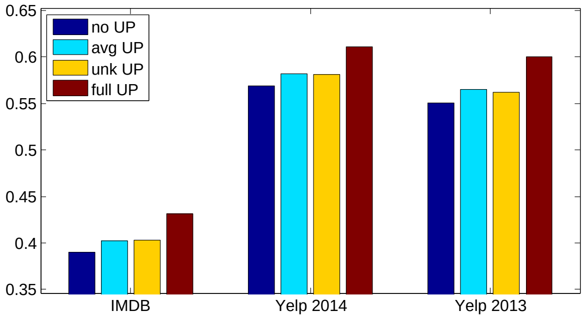

Figure 4: Accuracy of OOV user and product on OOV test set.

In order to evaluate the two strategies for OOV problem, we randomly select 10 percent users and products from each development set, and mask their user and product information. We run avg UP, unk UP together with UPNN (no UP) which only uses text information, and UPNN (full) which learns tailored representation for each user and product. We evaluate classification accuracy on the extracted OOV test set. Experimental results are given in Figure 5. We can find that these two strategies perform slightly better than UPNN (no UP), but still worse than the full model.

5 Related Work

5.1 Sentiment Classification

Sentiment classification is a fundamental problem in sentiment analysis, which targets at inferring the sentiment label of a document. Pang and Lee (2002; 2005) cast this problem a classification task, and use machine learning method in a supervised learning framework. Goldberg and Zhu (2006) use unlabelled reviews in a graph-based semi-supervised learning method. Many studies design effective features, such as text topic (Ganu et al., 2009), bag-of-opinion (Qu et al., 2010) and sentiment lexicon features (Kiritchenko et al., 2014). User information is also used for sentiment classification. Gao et al. (2013) design user-specific features to capture user leniency. Li et al. (2014) incorporate textual topic and user-word factors with supervised topic modeling. Tan et al. (2011) and Hu et al. (2013) utilize user-text and user-user relations for Twitter sentiment analysis. Unlike most previous studies that use hand-crafted features, we learn discriminative features from data. We differ from Li et al. (2014) in that we encode four kinds of consistencies and use neural network approach. User representation is also leveraged for recommendation (Weston et al., 2013), web search (Song et al., 2014) and social media analytics (Perozzi et al., 2014).

5.2 Neural Network for Sentiment Classification

Neural networks have achieved promising results for sentiment classification. Existing neural network methods can be divided into two groups: word embedding and semantic composition. For learning word embeddings, (Mikolov et al., 2013; Pennington et al., 2014) use local and global contexts, (Maas et al., 2011; Labutov and Lipson, 2013; Tang et al., 2014b; Tang et al., 2014a; Zhou et al., 2015) further incorporate sentiment of texts. For learning semantic composition, Glorot et al. (2011) use stacked denoising autoencoder, Socher et al. (2013) introduce a family of recursive deep neural networks (RNN). RNN is extended with adaptive composition functions (Dong et al., 2014), global feedbackward (Paulus et al., 2014), feature weight tuning (Li, 2014), and also used for opinion relation detection (Xu et al., 2014). Li et al. (2015) compare the effectiveness of recursive neural network and recurrent neural network on five NLP tasks including sentiment classification. (Kalchbrenner et al., 2014; Kim, 2014; Johnson and Zhang, 2014) use convolutional neural networks. Le and Mikolov (2014) introduce

Paragraph Vector. Unlike existing neural network approaches that only use the semantics of texts, we take consideration of user and product representations and leverage their connections with text semantics for sentiment classification. This work is an extension of our previous work (Tang et al., 2015), which only takes consideration of user-word association.

6 Conclusion

In this paper, we introduce User Product Neural Network (UPNN) for document level sentiment classification under a supervised learning framework. We validate user-sentiment, product-sentiment, user-text and product-text consistencies on massive reviews, and effectively integrate them in UPNN. We apply the model to three datasets derived from IMDB and Yelp Dataset Challenge. Empirical results show that: (1) UPNN outperforms state-of-the-art methods for document level sentiment classification; (2) incorporating continuous user and product representations significantly boosts sentiment classification accuracy.

Abstract

Central to many sentiment analysis tasks are sentiment lexicons (SLs). SLs exhibit polarity inconsistencies. Previous work studied the problem of checking the consistency of an SL for the case when the entries have categorical labels (positive, negative or neutral) and showed that it is NP-hard. In this paper, we address the more general problem, in which polarity tags take the form of a continuous distribution in the interval [0, 1]. We show that this problem is polynomial. We develop a general framework for addressing the consistency problem using linear programming (LP) theory. LP tools allow us to uncover inconsistencies efficiently, paving the way to building SL debugging tools. We show that previous work corresponds to 0-1 integer programming, a particular case of LP. Our experimental studies show a strong correlation between polarity consistency in SLs and the accuracy of sentiment tagging in practice.

1 Introduction

Many sentiment analysis algorithms rely on *sentiment lexicons* (SLs), where word forms or word senses[1] are tagged as conveying positive, negative or neutral sentiments. SLs are constructed by one of three methods (Liu, 2012; Feldman, 2013): (1) **Manual** tagging by human annotators is generally reliable, but because it is labor-intensive, slow, and costly, this method has produced small-sized SLs comprising a few thousand words, e.g., Opinion Finder (OF) (Wilson et al., 2005), Appraisal Lexicon (AL) (Taboada and Grieve, 2004), General Inquirer (GI) (Stone et al., 1966), and Micro-WNOp (Cerini et al., 2007). (2) **Dictionary-based** acquisition relies on a set of seed words to expand its coverage to similar words. There are over thirty dictionary-based techniques (Andreevskaia and Bergler, 2006; Blum et al., 2004; Chen and Skiena, 2014; Choi and Wiebe, 2014; Esuli and Sebastiani, 2006; Feng et al., 2013; Hassan and Radev, 2010; Kamps et al., 2004; Mohammad et al., 2009; Takamura et al., 2005; Turney, 2002; Williams and Anand, 2009), most of them based on WordNet (Fellbaum, 1998), such as SentiWordNet (SWN)(Baccianella et al., 2010) and Q-WordNet (QWN) (Agerri and García-Serrano, 2010). (3) **Corpus-based** acquisition expands a set of seed words with the use of a large document corpus (Breck et al., 2007; Bross and Ehrig, 2013; Choi and Cardie, 2009; Ding et al., 2008; Du et al., 2010; Hatzivassiloglou and McKeown, 1997; Jijkoun et al., 2010; Kaji and Kitsuregawa, 2007; Klebanov et al., 2013; Lu et al., 2011; Peng and Park, 2011; Tang et al., 2014; Wu and Wen, 2010). Method (1) generally produces the most reliable annotations, however the considerable effort required to yield substantial lexicons makes it less useful in practice. The appeals of (2) and (3) lie in the formalism of their models and their capability of producing large-sized SLs. SLs are either word or sense/synset oriented. We refer to the former as Sentiment Word Lexicons (SWLs), e.g., GI, OF, and AL, and to the latter as Sentiment Sense Lexions (SSLs), e.g., SWN, QWN, and Micro-WNOp. Besides the method of compilation, SLs may also vary with regard to sentiment annotation.

Polarity disagreements are noted across SLs that do (SWN, Q-WordNet) and do not (AL, GI) reference WordNet. For instance, the adjectives `panicky` and `terrified`, have negative and positive polarities in OF, respectively. They each have only one synset which they share in WordNet: *"thrown into a state of intense fear or desperation"*. Assuming that there is an intrinsic re-

[1] We refer to a string of letters or sounds as a word form & to a pairing of a word form with a meaning as a word sense.

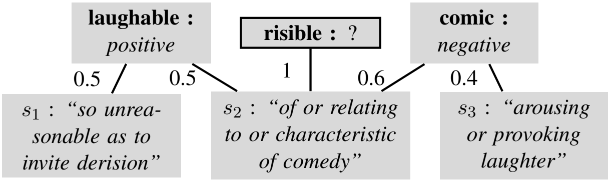
Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1024–1034,
Beijing, China, July 26-31, 2015.

lationship between the sentiments of a word and its meanings, a single synset polarity assignment to this synset cannot agree with both *positive* and *negative* at the word level. If the information given in WordNet is accurate (the Oxford and Cambridge dictionaries give only this meaning for both words) then there must be an annotation inconsistency in OF, called a *polarity inconsistency*. While some inconsistencies are easy to detect, manual consistency checking of an entire SL is an impractical endeavor, primarily because of the sheer size (SWN has over 206,000 word-sense pairs). Additionally, WordNet's complex network structure renders manual checking virtually impossible; an instance of a polarity inconsistency may entail an entire sub-network of words and senses. In this paper we develop a rigorous formal method based on linear programming (LP)(Schrijver, 1986) for *polarity consistency checking* of SLs with accompanying methods to unearth mislabeled words and synsets when consistency is not satisfied.

We translate the *polarity consistency problem* (PCP) into a form of the LP problem, suitable as the input to a standard LP solver, and utilize the functionality available in modern LP software (e.g., identifying an irreducible infeasible subset) to pinpoint the sources of inconsistencies when they occur. In our experimentation we are able to quickly uncover numerous intra- and inter-lexicon inconsistencies in all of the input SLs tested and to suggest lexicon entries for a linguist to focus on in "debugging" the lexicon.

Background and Previous Work

Sentiment resources have taken two basic approaches to polarity annotation: discrete and fractional. In the discrete approach, polarity is defined to be one of the discrete values *positive*, *negative*, or *neutral*. A word or a synset takes exactly one of the three values. QWN, AL, GI, and OF follow the *discrete polarity annotation*. In the fractional approach, polarity is defined as a 3-tuple of non-negative real numbers that sum to 1, corresponding to the positive, negative, and neutral values respectively. SWN, Micro-WNOp, and Hassan and Radev (2010) employ a *fractional polarity annotation*. For example, the single synset of the adjective `admissible` in WordNet has the sentiment tags *positive* in QWN and $\langle .25, .625, .125\rangle$ in SWN, so here SWN gives a primarily negative polarity with some positive and less neutral polarity. We denote by PCP-D and PCP-F the polarity consistency problem for the discrete and fractional polarity annotations, respectively.



laughable : *positive*
risible : ?
comic : *negative*

0.4
s_1 : *"so unreasonable as to invite derision"*
s_2 : *"of or relating to or characteristic of comedy"*
s_3 : *"arousing or provoking laughter"*

Figure 1: Discrete vs. fractional polarity consistency. Example taken from Dragut et al. (2012).

Dragut et al. (2012) introduces the PCP for domain independent SLs and gives a solution to a particular form of the PCP-D, but that method cannot solve PCP-F. For example, they show that the adjectives `laughable`, `comic`, and `risible` (Figure 1) constitute an inconsistency in the discrete case. AL gives positive polarity for `laughable` and OF gives negative for `comic`. If s_2 is not *positive* then `laughable` is not positive and if s_2 is not *negative* then `comic` is not negative, so there is no assignment of s_2 that satisfies the whole system. Hence there is an inconsistency. However, the following *fractional* polarity tags do satisfy the system: $s_1 : \langle 1, 0, 0\rangle$, $s_2 : \langle .66, .34, 0\rangle$, $s_3 : \langle 0, 1, 0\rangle$, where the meaning of the second tag, for instance, is that s_2 is .66 positive, .34 negative, and 0 neutral. We thus see that the discrete polarity annotation is rigid and leads to more inconsistencies, whereas the fractional annotation captures more naturally the polarity spectrum of a word or synset. In this paper we give a solution to the PCP-F. The differences between our solution and that of Dragut et al. (2012) give some insight into the general differences between the fractional and discrete problems. First, the discrete case is intractable, i.e., computationally NP-complete (Dragut et al., 2012); we show in this paper (Section 3.2) that the fractional case is tractable (solvable in polynomial time). Second, the PCP-D is solved in Dragut et al. (2012) by translation to the Boolean satisfiability problem (SAT) (Schaefer, 1978); here we recast the PCP-F in terms of LP theory. Third, we show that the LP framework is a natural setting for the PCP as a whole, and that the PCP-D corresponds to the 0-1 integer LP problem (Section 3.2), a classic NP-complete problem (Karp, 2010).

Our experiments (Section 5.4) show that correcting even a small number of inconsistencies can greatly improve the accuracy of sentiment annotation tasks. We implement our algorithm as a versatile tool for debugging SLs, which helps locate the sources of error in SLs. We apply our algorithm to both SWLs and SSLs and demonstrate the usefulness of our approach to improving SLs.

The main contributions of this paper are:

- solve the PCP-F;
- show that the PCP-F is tractable;
- show that the PCP is an instance of LP;
- develop a technique for identifying inconsistencies in SLs of various types;
- implement our algorithm as a prototype SL debugger;
- show that there is a strong correlation between polarity inconsistency in SLs and the performance of sentiment tagging tools developed on them.

2 Problem Definition

In this section we give a formal characterization of the polarity assignment of words and synsets in SLs using WordNet. We use $-$, $+$, 0 to denote negative, positive, and neutral polarities, respectively, throughout the paper.

2.1 Polarity Representation

We define the polarity of a synset or word r in WordNet to be a discrete probability distribution, called a **polarity distribution**: $P_+(r), P_-(r), P_0(r) \geq 0$ with $P_+(r) + P_-(r) + P_0(r) = 1$. $P_+(r)$, $P_-(r)$ and $P_0(r)$ represent the "likelihoods" that r is positive, negative or neutral, respectively. For instance, the WordNet synset *"worthy of reliance or trust"* of the adjective `reliable` is given the polarity distribution $P_+ = .375, P_- = .0$ and $P_0 = .625$ in SentiWordNet. We may drop r from the notation if the meaning is clear from context. The use of a polarity distribution to describe the polarity of a word or synset is shared with many previous works (Andreevskaia and Bergler, 2006; Baccianella et al., 2010; Kim and Hovy, 2006).

2.2 WordNet

A **word-synset network** $\mathcal{N}$ is a 4-tuple $(\mathcal{W}, \mathcal{S}, \mathcal{E}, f)$ where $\mathcal{W}$ is a finite set of words, $\mathcal{S}$ is a finite set of synsets, $\mathcal{E} \subseteq \mathcal{W} \times \mathcal{S}$ and f is a function assigning a positive integer to each element in $\mathcal{E}$. For any word w and synset s, s is a synset of w if $(w, s) \in \mathcal{E}$. For a pair $(w, s) \in \mathcal{E}$, $f(w, s)$ is called the **frequency of use** of w in the sense given by s. For a word w, we let $freq(w)$ denote the sum of all $f(w, s)$ such that $(w, s) \in \mathcal{E}$. We define the **relative frequency** of w with s by $rf(w, s) = \frac{f(w,s)}{freq(w)}$. If $f(w, s) = 0$, the frequency of each synset of w is increased by a small constant ϵ. We use $\epsilon = .1$ in our prototype.

2.3 Word Polarities

We contend that there exists a relation between the sentiment orientation of a word and the polarities of its related senses (synsets), and we make the assumption that this relation takes the form of a linear function. Thus, for $w \in \mathcal{W}$ and $p \in \{+, -, 0\}$, the polarity distribution of w is defined as:

$$P_p(w) = \sum_{s \in S_w} g(w, s) \cdot P_p(s), \qquad (1)$$

where $P_p(s)$ is the polarity value of synset s with polarity p and $g(w, s)$ is a rational number. For example, g can be the relative frequency of s with respect to w in WordNet: $g(w, s) = rf(w, s); \forall w \in \mathcal{W}, s \in \mathcal{S}$. Alternatively, for each word w we can draw $g(w, \cdot)$ from a Zipfian distribution, following the observation that the distribution of word senses roughly follows a Zipfian power-law (Kilgarriff, 2004; Sanderson, 1999). In this paper, we will assume $g(w, s) = rf(w, s)$.

For example, the three synsets of the adjective `reliable` with relative frequencies $\frac{9}{11}$, $\frac{1}{11}$, and $\frac{1}{11}$, respectively, are given the distributions $\langle .375, 0, .625 \rangle$, $\langle .5, 0, .5 \rangle$, and $\langle .625, 0, .375 \rangle$ in SentiWordNet. So for `reliable` we have $P_+ = \frac{9}{11}0.375 + \frac{1}{11}0.5 + \frac{1}{11}0.625 \approx 0.41$, $P_- = 0$, and $P_0 = \frac{9}{11}0.625 + \frac{1}{11}0.5 + \frac{1}{11}0.375 \approx 0.59$.

2.4 Modeling Sentiment Orientation in SLs

Words and synsets have *unique* polarities in some SLs, e.g., AL and OF. For instance, `reliable` has positive polarity in AL, GI, and OF. The question is: what does a discrete annotation of `reliable` tell us about its polarity distribution? One might take it to mean that the polarity distribution is simply $\langle 1, 0, 0 \rangle$. This contradicts the information in SWN, which gives some neutral polarity for all of the synsets of `reliable`. So a better polarity distribution would allow $P_0 > 0$. Furthermore, given that $\langle .41, 0, .59 \rangle$, $\langle .40, 0, .60 \rangle$, and $\langle .45, 0, .55 \rangle$ give virtually identical information to a sentiment analyst, it seems unreasonable to expect exactly one to be the correct polarity tag for `reliable` and the other two incorrect. Therefore, instead of claiming to pinpoint an exact polarity distribution for a word, we propose to set a boundary on its variation. This establishes a range of values, instead of a single point, in which SLs can be said to agree.

Thus, for a word w, we can define

$$\text{polarity}(w) = \begin{cases} + & \text{if } P_+ > P_- \\ - & \text{if } P_- > P_+ \end{cases} \quad (2)$$

which we refer to as MAX_POL. This model is adopted either explicitly or implicitly by numerous works (Hassan and Radev, 2010; Kim and Hovy, 2004; Kim and Hovy, 2006; Qiu et al., 2009). Another model is the *majority sense model*, called MAJORITY, (Dragut et al., 2012), where

$$\text{polarity}(w) = \begin{cases} + & \text{if } P_+ > P_- + P_0 \\ - & \text{if } P_- > P_+ + P_0 \end{cases} \quad (3)$$

Another polarity model, MAX, is defined as

$$\text{polarity}(w) = \begin{cases} + & \text{if } P_+ > P_- \,\&\, P_+ > P_0 \\ - & \text{if } P_- > P_+ \,\&\, P_- > P_0 \end{cases} \quad (4)$$

For instance, `reliable` conveys positive polarity according to MAX_POL, since $P_+ > P_-$, but neutral according to MAJORITY. When the condition of being neither positive nor negative can be phrased as a conjunction of linear inequalities, as is the case with MAJORITY and MAX_POL, then we define neutral as not positive and not negative. These model definitions can be applied to synsets as well.

2.5 Polarity Consistency Definition

Instead of defining consistency for SLs dependent on a choice of model, we develop a generic definition applicable to a wide variety of models, including all of those discussed above. We require that the polarity of a word or synset in the network $\mathcal{N}$ be characterized by a *set of linear inequalities (constraints)* with rational coefficients. Formally, for each word $w \in \mathcal{W}$, the knowledge that w has a discrete polarity $p \in \{+, -, 0\}$ is characterized by a set of linear inequalities:

$$\psi(w, p) = \{a_{i,0}P_+ + a_{i,1}P_- + a_{i,2}P_0 \preceq b_i\}, \quad (5)$$

where $\preceq \in \{\le, <\}$ and $a_{i,0}, a_{i,1}, a_{i,2}, b_i \in \mathbb{Q}$, $i = 0, 1, \ldots, m$. For instance, if the MAX model is used, for $w =$ `worship` whose polarity is positive in OF, we get the following set of inequalities: $\psi(w, +) = \{P_+ - P_- > 0, P_+ - P_0 > 0\} = \{(-1)P_+ + 1P_- + 0P_0 < 0, (-1)P_+ + 0P_- + 1P_0 < 0\}$.

Let $\mathcal{L}$ be an SL. We denote the system of inequalities introduced by all words and synsets in $\mathcal{L}$ with known polarities in the network $\mathcal{N}$ by $\Psi'(\mathcal{N}, \mathcal{L})$. The variables in $\Psi'(\mathcal{N}, \mathcal{L})$ are $P_+(r), P_-(r)$ and $P_0(r)$, $r \in \mathcal{W} \cup \mathcal{S}$. Denote by $\Upsilon'(\mathcal{N}, \mathcal{L})$ the set of constraints implied by the polarity distributions for all $r \in \mathcal{L}$: $P_+(r) + P_-(r) + P_0(r) = 1$ and $P_{p \in \{+,-,0\}}(r) \ge 0, \forall r \in \mathcal{W} \cup \mathcal{S}$. Let $\Phi'(\mathcal{N}, \mathcal{L}) = \Psi'(\mathcal{N}, \mathcal{L}) \cup \Upsilon'(\mathcal{N}, \mathcal{L})$.

Figure 2: A network of 4 words and 3 synsets

Example 1. *Let w_1, w_2, w_3, and w_4 be the nouns* `perseverance`, `persistence`, `pertinacity`, *and* `tenacity`, *respectively, which are in OF with polarities $+$, 0, $-$, and $+$, respectively (Figure 2). Assuming the MAJORITY model, $\psi(w_1, +) = \{P_+(w_1) > P_-(w_1) + P_0(w_1)\} = \{P_+(w_1) > 1 - P_+(w_1)\} = \{-P_+(w_1) < -\frac{1}{2}\}$, and $\psi(w_2, 0) = \{P_+(w_2) \le P_-(w_2) + P_0(w_2), P_-(w_2) \le P_+(w_2) + P_0(w_2)\} = \{P_+(w_2) \le \frac{1}{2}, P_-(w_2) \le \frac{1}{2}\}$. Similarly, $\psi(w_3, -) = \{-P_-(w_3) < -\frac{1}{2}\}$ and $\psi(w_4, -) = \{-P_+(w_4) < -\frac{1}{2}\}$.*

Definition 1. *A sentiment lexicon $\mathcal{L}$ is* ***consistent*** *if the system $\Phi'(\mathcal{N}, \mathcal{L})$ is feasible, i.e., has a solution.*

The PCP is then the problem of deciding if a given SL $\mathcal{L}$ is consistent. In general, PCP can be stated as follows: *Given an assignment of polarities to the words, does there exist an assignment of polarities to the synsets that agrees with that of the words*? If the polarity annotation is discrete, we have the PCP-D; if the polarity is fractional, we have PCP-F. Our focus is PCP-F in this paper.

The benefits of a generic problem model are at least two-fold. First, different linguists may have different views about the kinds of inequalities one should use to express the probability distribution of a word with a unique polarity in some SL. The new model can accommodate divergent views as long as they are expressed as linear constraints. Second, the results proven for the generic model will hold for any particular instance of the model.

3 Polarity Consistency: an LP Approach

A careful analysis of the proposed formulation of the problem of SL consistency checking reveals that this can be naturally translated into an LP problem. The goal of LP is the optimization of a linear objective function, subject to linear (in)equality constraints. LP problems are expressed in *standard* form as follows:

$$\text{minimize } \mathbf{c}^{\mathrm{T}}\mathbf{x}$$
$$\text{subject to } \mathbf{A}\mathbf{x} \leq \mathbf{b} \quad (6)$$
$$\text{and } \mathbf{x} \geq \mathbf{0}$$

$\mathbf{x}$ represents the vector of variables (to be determined), $\mathbf{c}$ and $\mathbf{b}$ are vectors of (known) coefficients, $\mathbf{A}$ is a (known) matrix of coefficients, and $(\cdot)^{\mathrm{T}}$ is the matrix transpose. An LP algorithm finds a point in the *feasible region* where $\mathbf{c}^{\mathrm{T}}\mathbf{x}$ has the smallest value, if such a point exists. The feasible region is the set of $\mathbf{x}$ that satisfy the constraints $\mathbf{A}\mathbf{x} \leq \mathbf{b}$ and $\mathbf{x} \geq \mathbf{0}$.

There are several non-trivial challenges that need to be addressed in transforming our problem (i.e., the system $\Phi'(\mathcal{N}, \mathcal{L})$) into an LP problem. For instance, we have both strict and weak inequalities in our model, whereas standard LP does not include strict inequalities. We describe the steps of this transformation next.

3.1 Translation to LP

In our problem, $\mathbf{x}$ is the concatenation of all the triplets $\langle P_+(r), P_-(r), P_0(r)\rangle$ for all $r \in \mathcal{W} \cup \mathcal{S}$.

Eliminate Word Related Variables. For each word $w \in \mathcal{L}$ we replace $P_+(w), P_-(w)$ and $P_0(w)$ with their corresponding expressions according to Equation 1; then the linear system $\Phi'(\mathcal{N}, \mathcal{L})$ has only the synset variables $P_+(s), P_-(s)$ and $P_0(s)$ for $s \in \mathcal{S}$.

Example (continued). *Using the relative frequencies of Figure 2 in Equation 1 we get:*
$\psi(w_1,+) = \{-.5P_+(s_1) - .5P_+(s_2) < -\frac{1}{2}\}$,
$\psi(w_2,0) = \{.29P_+(s_1) + .01P_+(s_2) + .7P_+(s_3) \leq \frac{1}{2}$,
$.29P_-(s_1) + .01P_-(s_2) + .7P_-(s_3) \leq \frac{1}{2}\}$,
$\psi(w_3,-) = \{-P_-(s_1) < -\frac{1}{2}\}$, *and*
$\psi(w_4,+) = \{-P_+(s_1) < -\frac{1}{2}\}$.

Equality. The system $\Phi'(\mathcal{N}, \mathcal{L})$ contains constraints of the form $P_+(s) + P_-(s) + P_0(s) = 1$ for each $s \in \mathcal{S}$, but observe that there are no equality constraints in the standard LP form (Equation 6). The usual conversion procedure is to replace a given equality constraint: $\mathbf{a}^{\mathrm{T}}\mathbf{x} = b$, with: $\mathbf{a}^{\mathrm{T}}\mathbf{x} \leq b$ and $-\mathbf{a}^{\mathrm{T}}\mathbf{x} \leq -b$. However, this procedure increases the number of constraints in $\Phi'(\mathcal{N}, \mathcal{L})$ linearly. This can have a significant computation impact since $\Phi'(\mathcal{N}, \mathcal{L})$ may have thousands of constraints (see discussion in Section 5.3). Instead, we can show that the system F obtained by performing the following two-step transformation is equivalent to $\Phi'(\mathcal{N}, \mathcal{L})$, in the sense that F is feasible iff $\Phi'(\mathcal{N}, \mathcal{L})$ is feasible. For every $s \in \mathcal{S}$, (Step 1) we convert each $P_+(s) + P_-(s) + P_0(s) = 1$ to $P_+(s) + P_-(s) \leq 1$, and (Step 2) we replace every $P_0(s)$ in $\Phi'(\mathcal{N}, \mathcal{L})$ with $1 - P_+(s) - P_-(s)$.

Strict Inequalities. Strict inequalities are not allowed in LP and their presence in inequality systems in general poses difficulties to inequality system solvers (Goberna et al., 2003; Goberna and Rodriguez, 2006; Ghaoui et al., 1994). Fortunately results developed by the LP community allow us to overcome this obstacle and maintain the flexibility of our proposed model. We introduce a new variable $y \geq 0$, and for every strict constraint of the form $\mathbf{a}^{\mathrm{T}}\mathbf{x} < b$, we rewrite the inequality as $\mathbf{a}^{\mathrm{T}}\mathbf{x} + y \leq b$. Let $\Phi''(\mathcal{N}, \mathcal{L})$ be this new system of constraints. We modify the objective function (previously null) to maximize y (i.e., minimize $-y$). Denote by F' the LP that maximizes y subject to $\Phi''(\mathcal{N}, \mathcal{L})$. We can show that $\Phi'(\mathcal{N}, \mathcal{L})$ is feasible iff F' is feasible and $y \neq 0$. A sketch of the proof is as follows: if $y > 0$ then $\mathbf{a}^{\mathrm{T}}\mathbf{x} + y \leq b$ implies $\mathbf{a}^{\mathrm{T}}\mathbf{x} < b$. Conversely, if $\mathbf{a}^{\mathrm{T}}\mathbf{x} < b$ then $\exists y > 0$ such that $\mathbf{a}^{\mathrm{T}}\mathbf{x} + y \leq b$, and maximizing for y will yield a $y > 0$ iff one is feasible. This step is omitted if we have no strict constraints in $\Phi'(\mathcal{N}, \mathcal{L})$.

Example (continued). *The formulations of* $\psi(w_1, +)$, $\psi(w_3, -)$, *and* $\psi(w_4, +)$ *involve strict inequalities, so they are rewritten in* $\Phi''(\mathcal{N}, \mathcal{L})$, *e.g.,* $\psi''(w_4, +) = \{-P_+(s_1) + y \leq -\frac{1}{2}\}$.

We denote by $\Phi(\mathcal{N}, \mathcal{L})$ the standard form of $\Phi'(\mathcal{N}, \mathcal{L})$ obtained by applying the above steps. This is the input to an LP solver.

Theorem 1. *Sentiment lexicon $\mathcal{L}$ is polarity consistent iff $\Phi(\mathcal{N}, \mathcal{L})$ is feasible.*

3.2 Time Complexity

For the network $\mathcal{N}$ and an SL $\mathcal{L}$, the above translation algorithm converts the PCP into an LP problem on the order of $O(|\mathcal{E}|)$, a polynomial time conversion. The general class of linear programming problems includes subclasses that are NP-hard, such as the *integer linear programming* (ILP) problems, as well as polynomial solvable subclasses. We observe that our problem is represented by a system of *rational* linear inequalities. This class of LP problems is solvable in polynomial time (Khachiyan, 1980; Gács and Lovász, 1981). This (informally) proves that the PCP-F is solvable in polynomial time. PCP is NP-complete in the discrete case (Dragut et al., 2012). This is not surprising since in our LP formulation of the

PCP, the discrete case corresponds to the 0-1 integer programming (BIP) subclass. (Recall that in the discrete case each synset has a unique polarity.) BIP is the special case of integer programming where variables are required to be 0 or 1. BIP is a classic NP-hard problem (Garey and Johnson, 1990). We summarize these statements in the following theorem.

Theorem 2. *The PCP-F problem is P and the PCP-D is NP-complete.*

We proved a more general and more comprehensive result than Dragut et al. (2012). The PCP solved by Dragut et al. (2012) is a particular case of PCP-D: it can be obtained by instantiating our framework with the MAJORITY model (Equation 3) and requiring each synset to take a unique polarity. We believe that the ability to encompass both fractional and discrete cases within one framework, that of LP, is an important contribution, because it helps to give structure to the general problem of polarity consistency and to contextualize the difference between the approaches.

4 Towards Debugging SLs

Simply stating that an SL is *inconsistent* is of little practical use unless accompanying assistance in diagnosing and repairing inconsistencies is provided. Automated assistance is necessary in the face of the scale and complexity of modern SLs: e.g., AL has close to 7,000 entries, SWN annotates the entirety of WordNet, over 206,000 word-sense pairs. There are unique and interesting problems associated with inconsistent SLs, among them: (1) isolate a (small) subset of words/synsets that is polarity inconsistent, but becomes consistent if one of them is removed; we call this an Irreducible Polarity Inconsistent Subset (IPIS); (2) return an IPIS with smallest cardinality (intuitively, such a set is easiest to repair); (3) find all IPISs, and (4) find the largest polarity consistent subset of an inconsistent SL. In the framework of linear systems of constraints, the problems (1) - (4) correspond to (i) the identification of an Irreducible Infeasible Subset (IIS) of constraints within $\Phi(\mathcal{N}, \mathcal{L})$, (ii) finding IIS of minimum cardinality, (iii) finding all IISs and (iv) finding the largest set of constraints in $\Phi(\mathcal{N}, \mathcal{L})$ that is feasible, respectively. An IIS is an infeasible subset of constraints that becomes feasible if any single constraint is removed. Problems (ii) - (iv) are NP-hard and some may even be difficult to approximate (Amaldi and Kann, 1998; Chinneck, 2008; Chakravarti, 1994; Tamiz et al., 1996). We focus on problem (1) in this paper, which we solve via IIS discovery. We keep a bijective mapping from words and synsets to constraints such that for any given constraint, we can uniquely identify the word or synset in $\Phi(\mathcal{N}, \mathcal{L})$ from which it was introduced. Hence, once an IIS is isolated, we know the corresponding words or synsets. Modern LP solvers typically can give an IIS when a system is found to be infeasible, but none give all IISs or the IIS of minimum size.

Example (continued). *The polarity assignments of w_1, w_2, w_3, and w_4, are consistent iff there exist polarity distributions $\langle P_+(s_i),\ P_-(s_i),\ P_0(s_i)\rangle$ for $i = 1, 2, 3$, such that:* $y > 0$

$\psi(w_1, +): -.5P_+(s_1) + .5P_+(s_2) + y \leq -\frac{1}{2}$,

$\psi(w_2,0): .29P_+(s_1) + .01P_+(s_2) + .7P_+(s_3) \leq \frac{1}{2}$

AND $.29P_-(s_1) + .01P_-(s_2) + .7P_-(s_3) \leq \frac{1}{2}$,

$\psi(w_3, -) : -P_-(s_1) + y \leq -\frac{1}{2}$,

$\psi(w_4, +) : -P_+(s_1) + y \leq -\frac{1}{2}$,

$\upsilon(s_1): P_+(s_1) + P_-(s_1) \leq 1$ *AND* $P_+(s_1), P_-(s_1) \geq 0$,

$\upsilon(s_2): P_+(s_2) + P_-(s_2) \leq 1$ *AND* $P_+(s_2), P_-(s_2) \geq 0$,

$\upsilon(s_3): P_+(s_3) + P_-(s_3) \leq 1$ *AND* $P_+(s_3), P_-(s_3) \geq 0$.

Upon examination, if $y > 0$, then $\psi(w_3, -)$ implies $P_-(s_1) > \frac{1}{2}$ and $\psi(w_4, +)$ implies $P_+(s_1) > \frac{1}{2}$. Then $P_+(s_1) + P_-(s_1) > 1$, contradicting $\upsilon(s_1)$. Hence, this LP system is infeasible. Moreover $\{\psi(w_3, -), \psi(w_4, +), \upsilon(s_1)\}$ is an IIS. Tracing back we get that the set of words $\{w_3, w_4\}$ is inconsistent. Therefore it is an IPIS.

Isolating IPISs helps focus SL diagnosis and repair efforts. Fixing SLs via IIS isolation proceeds iteratively: (1) isolate an IIS, (2) determine a repair for this IIS, (3) if the model is still infeasible, go to step (1). This approach is well summarized by Greenberg's aphorism: "diagnosis = isolation + explanation" (Greenberg, 1993). The proposed use requires human interaction to effect the changes to the lexicon. One might ask if this involvement is strictly necessary; in response we draw a parallel between our SL debugger and a software debugger. A software debugger can identify a known programming error, say the use of an undefined variable. It informs the programmer, but it does not assign a value to the variable itself. It requires the user to make the desired assignment. Similarly, our debugger can deterministically identify an inconsistent component, but it cannot deterministically decide which elements to adjust. In most cases, this is simply not an objective decision. To illustrate this point, from our example, we know that minimally one

of `pertinacity`$(-)$ and `tenacity`$(+)$ must be adjusted, but the determination as to which requires the subjective analysis of a domain expert.

In this paper, we do not repair any of the discovered inconsistencies. We focus on isolating as many IPISs as possible.

5 Experiments

The purpose of our experimental work is manifold, we show that: (1) inconsistencies exist in and between SLs, (2) our algorithm is effective at uncovering them in the various types of SLs proposed in the literature, (3) fractional polarity representation is more flexible than discrete, giving orders of magnitude fewer inconsistencies, and (4) sentiment analysis is significantly improved when the inconsistencies of a basis SL are corrected.

Experiment Setup: We use four SWLs: GI, AL, OF and their union, denoted UN, and three SSLs: QWN, SWN and MicroWN-Op. The distribution of their entries is given in Table 1. The MAJORITY model (Equation 3) is used in all trials. This allows for direct comparison with Dragut et al. (2012). We implemented our algorithm in Java interfacing with the GUROBI LP solver[2], and ran the tests on a 4 × 1.70GHz core computer with 6GB of main memory.

5.1 Inconsistencies in SWLs

In this set of experiments, we apply our algorithm to GI, AL, OF and UN. We find *no* inconsistencies in AL, only 2 in GI, and 35 in both UN and OF (Table 2). (Recall that an inconsistency is a *set* of words whose polarities cannot be concomitantly satisfied.) These numbers *do not* represent all possible inconsistencies (See discussion in Section 4). In general, the number of IISs for an infeasible system can be exponential in the size of the system $\Phi(\mathcal{N}, \mathcal{L})$ (Chakravarti, 1994), however our results suggest that in practice this does not occur.

Compared with Dragut et al. (2012), we see a marked decrease in the number of inconsistencies.

OF	0.66	0.87	0.82	0.77	0.76

Table 3: SentiWordNet paired with SWLs

They found 249, 2, 14, and 240 inconsistencies in UN, AL, GI, and OF, respectively. These inconsistencies are obtained in the first iteration of their SAT-Solver. *This shows that about 86% of inconsistent words in a discrete framework can be made consistent in a fractional system.*

5.2 Inconsistencies in SSLs

In this set of experiments we check the polarity inconsistencies between SWLs and SSLs. We pair each SSL with each of the SWLs.

SentiWordNet. SWN is an automatically generated SL with a fractional polarity annotation of every synset in WordNet. Since SWN annotates *every* synset in WordNet, there are no free variables in this trial. Each variable $P_{p \in \{+,-,0\}}(s)$ for $s \in \mathcal{S}$ is fully determined by SWN, so this amounts to a constant on the left hand side of each inequality. Our task is to simply check whether the inequality holds between the constant on the left and that on the right. Table 3 gives the proportion of words from each SWL that is inconsistent with SWN. We see there is substantial disagreement between SWN and all of the SWLs, in most cases more than 70% disagreement. For example, 5,260 of the 6,921 words in OF do not agree with the polarities assigned to their senses in SWN. This outcome is deeply surprising given that all these SLs are *domain independent* – no step in their construction processes hints to a specific domain knowledge. This opens up the door to future analysis of SL acquisition. For instance, examining the impact that model choice (e.g., MAJORITY vs. MAX) has on inter-lexicon agreement.

Q-WordNet. QWN gives a discrete polarity for 15,510 WordNet synsets. When a synset is annotated in QWN, its variables, $P_{p \in \{+,-,0\}}(s)$, are assigned the QWN values in Φ; a feasible assignment is sought for the remaining free variables. An inconsistency may occur among a set of words, or

[2] www.gurobi.com

	UN	AL	GI	OF
total	345	34	139	325

Table 4: Q-WordNet paired with SWLs.

a set of words and synsets. Table 4 depicts the outcome of this study. We obtain 345 inconsistencies between QWN and UN. The reduced number of inconsistencies with AL (34) is explained by their limited "overlay" (QWN has only 40 adverb synsets). Dragut et al. (2012) reports 455 inconsistencies between QWN and UN, 110 more than we found here. Again, this difference is due to the rigidity of the discrete case, which leads to more inconsistencies in general.

Micro-WNOp. This is a fractional SSL of 1,105 synsets from WordNet manually annotated by five annotators. The synsets are divided into three groups: 110 annotated by the consensus of the annotators, 496 annotated individually by three annotators, and 499 annotated individually by two annotators. We take the average polarities of groups 2 and 3 and include this data as two additional sets of values. Table 5 gives the inconsistencies per user in each group. For Groups 2 and 3, we give the average number of inconsistencies among the users (Avg. Incons. in Table 5) as well as the inconsistencies of the averaged annotations (Avg. User in Table 5).

Micro-WNOp gives us an opportunity to analyze the robustness of our method by comparing the number of inconsistencies of the individual users to that of the averaged annotation. Intuitively, we expect that the average number of inconsistencies in a group of users to be close to the number of inconsistencies for the user averaged annotations. This is clearly apparent from Table 5, when comparing Lines 4 and 5 in Group 2 and Lines 3 and 4 in Group 3. For example, Group 2 has an average of 68 inconsistencies for OF, which is very close to the number of inconsistencies, 63, obtained for the group averaged annotations. This study suggests a potential application of our algorithm: to estimate the confidence weight (trust) of a user's polarity annotation. A user with good polarity consistency receives a higher weight than one with poor polarity consistency. This can be applied in a multi-annotator SL scenario.

5.3 Computation

We provide information about the runtime execution of our method in this section. Over all of our experiments, the resulting systems of constraints can be as small as 2 constraints with 2 variables and as large as 3,330 constraints with 4,946 variables. We achieve very good overall execution times, 68 sec. on average. At its peak, our algorithm requires 770MB of memory. Compared to the SAT approach by Dragut et al. (2012), which takes about 10 min. and requires about 10GB of memory, our method is several orders of magnitude more efficient and more practical, paving the way to building practical SL debugging tools.

		UN	AL	GI	OF

Table 5: Micro-WNOp – SWD Inconsistencies

5.4 Inconsistency & Sentiment Annotation

This experiment has two objectives: (1) show that two inconsistent SLs give very different results when applied to sentiment analysis tasks and (2) given an inconsistent SL D, and D' an improved version of D with fewer inconsistencies, show that D' gives better results than D in sentiment analysis tasks. We use a third-party sentiment annotation tool that utilizes SLs, Opinion Parser (Liu, 2012). We give the instantiations of D below.

In (1), we use the dataset **aclImdb** (Maas et al., 2011), which consists of 50,000 reviews, and the SLs UN and SWN. Let UN$'$ and SWN$'$ be the subsets of UN and SWN, respectively, with the property that they have the same set of $(word, pos)$ pair entries and $word$ appears in **aclImdb**. UN$'$ and SWN$'$ have 6,003 entries. We select from **aclImdb** the reviews with the property that they contain at least 50 words in SWN$'$ and UN$'$. This gives 516 negative and 567 positive reviews, a total of 1,083 reviews containing a total of 31,701 sentences. Opinion Parser is run on these sentences using SWN$'$ and UN$'$. We obtain that 16,741 (52.8%) sentences acquire different polarities between the two SLs.

In (2), we use 110 randomly selected sentences from **aclImdb**, which we manually tagged with their overall polarities. We use OF and OF$'$, where OF$'$ is the version of OF after just six inconsistencies are manually fixed. We run Opinion Parser on these sentences using OF and OF$'$. We obtain an accuracy of 42% with OF and 47% with OF$'$, an improvement of 8.5% for just a small fraction of corrected inconsistencies.

These two experiments show a strong correlation between polarity inconsistency in SLs and its effect on sentiment tagging in practice.

6 Conclusion

Resolving polarity inconsistencies helps to improve the accuracy of sentiment analysis tasks. We show that LP theory provides a natural framework for the polarity consistency problem. We give a polynomial time algorithm for deciding whether an SL is polarity consistent. If an SL is found to be inconsistent, we provide an efficient method to uncover sets of words or word senses that are inconsistent and require linguists' attention. Effective SL debugging tools such as this will help in the development of improved SLs for use in sentiment analysis tasks.

7 Acknowledgments

We would like to thank Bing Liu for running the experiments of Section 5.4 on his commercial tool Opinion Parser, Christiane Fellbaum for the discussions on polarity inconsistency, and Prasad Sistla for the discussions on linear programming. We would also like to thank the reviewers for their time, effort, and insightful feedback.

Sparse, Contextually Informed Models for Irony Detection: Exploiting User Communities, Entities and Sentiment

Byron C. Wallace

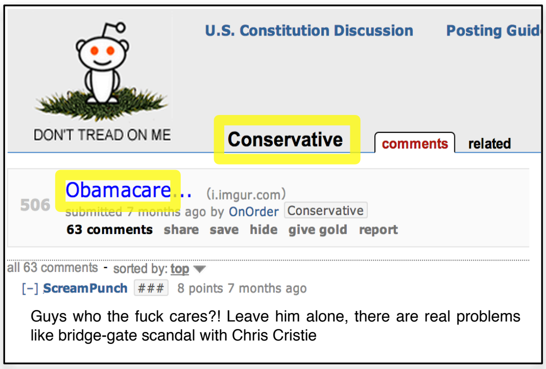
Abstract

Automatically detecting verbal irony (roughly, sarcasm) in online content is important for many practical applications (e.g., sentiment detection), but it is difficult. Previous approaches have relied predominantly on signal gleaned from word counts and grammatical cues. But such approaches fail to exploit the *context* in which comments are embedded. We thus propose a novel strategy for verbal irony classification that exploits contextual features, specifically by combining noun phrases and sentiment extracted from comments with the forum type (e.g., conservative or liberal) to which they were posted. We show that this approach improves verbal irony classification performance. Furthermore, because this method generates a very large feature space (and we expect predictive contextual features to be strong but few), we propose a mixed regularization strategy that places a sparsity-inducing ℓ_1 penalty on the contextual feature weights on top of the ℓ_2 penalty applied to all model coefficients. This increases model sparsity and reduces the variance of model performance.



Guys who the fuck cares?! Leave him alone, there are real problems like bridge-gate scandal with Chris Cristie

Figure 1: A reddit comment illustrating contextualizing features that we propose leveraging to improve classification. Here the highlighted entities (external the comment text itself) provide contextual signals indicating that the shown comment was intended ironically. As we shall see, *Obamacare* is in general a strong indicator of irony when present in posts to the *conservative* subreddit, but less so in posts to the *progressive* subreddit.

1 Introduction and Motivation

Automated verbal irony detection is a challenging problem.[1] But recognizing when an author has intended a statement ironically is practically important for many text classification tasks (e.g., sentiment detection).

Previous models for irony detection (Tsur et al., 2010; Lukin and Walker, 2013; Riloff et al., 2013) have relied predominantly on features *intrinsic* to the texts to be classified. By contrast, here we propose exploiting *contextualizing* information, which is often available for web-based classification tasks. More specifically, we exploit signal gleaned from the conversational *threads* to which comments belong. Our approach capitalizes on the intuition that members of different user communities are likely to be sarcastic about different things. As a proxy for user community, we leverage knowledge of the specific forums to which comments were posted. For example, one may surmise that the statement 'I really am proud of Obama' is likely to have been intended ironically if it was posted to a forum frequented by political conservatives. But if this same utterance were posted to a liberal-leaning forum, it is more likely to have been intended in earnest. This sort of information is often directly or indirectly available on social media, but previous models have not capitalized on it. This is problematic; recent work has shown that humans require such contextualizing information to infer ironic intent (Wallace et

[1] In this paper we will be a bit cavalier in using the terms 'verbal irony' and 'sarcasm' interchangeably. We recognize that the latter is a special type of the former, the definition of which is difficult to pin down precisely.

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 1035–1044,
Beijing, China, July 26-31, 2015.

al., 2014).

As a concrete example, we consider the task of identifying verbal irony in comments posted to reddit (`http://www.reddit.com`), a social-news website. Users post content (e.g., links to news stories) to reddit, which are then voted on by the community. Users may also discuss this content on the website; these are the comments that we will work with here. Reddit comprises many *subreddits*, which are user communities centered around specific topics of interest. In this work we consider comments posted to two pairs of polarized user communities, or subreddits: (1) *progressive* and *conservative* subreddits (comprising individuals on the left and right of the US political spectrum, respectively), and (2) *atheism* and *Christianity* subreddits.

Our aim is to develop a model that can recognize verbal irony in comments posted to such forums, e.g., automatically discern that the user who posted the comment shown in Figure 1 intended his or her comment ironically. To this end, we propose a strategy that capitalizes on available contextualizing information, such as interactions between the user community (subreddit) that comments were posted to, extracted entities (here we use noun phrases, or NNPs) and inferred sentiment.

The contributions of this work are summarized as follows.

- We demonstrate that contextual information, such as inferred user-community (in this case, the subreddit) can be crossed with extracted entities and sentiment to improve detection of verbal irony. This improves performance over baseline models (including those that exploit inferred sentiment, but not context).

- We introduce a novel composite regularization strategy that applies a sparsifying ℓ_1 penalty to the contextual/sentiment/entity feature weights in addition to the standard squared ℓ_2 penalty to all feature weights. This induces more compact, interpretable models that exhibit lower variance.

While discerning ironic comments on reddit is our immediate task, the proposed approach is generally applicable to a wide-range of subjective, web-based text classification tasks. Indeed, this approach would be useful for any scenario in which we expect different groups of individuals producing content to tend to discuss different entities in a way that correlates with the target categorization. The key is in identifying an available proxy for user groupings (here we rely on the subreddits to which a comment was posted). Such information is often available (or can be derived) for comments posted to different mediums on the web: for example on Twitter we know who a user follows; and on YouTube we know the channels to which videos belong.

2 Exploiting context

2.1 Communities and sentiment

As discussed above, a shortcoming with existing models for detecting sarcasm/verbal irony on the web is their failure to capitalize on contextualizing information. But such information is critical to discerning irony. A large body of work on the use and interpretation of verbal irony supports this supposition (Grice, 1975; Clark and Gerrig, 1984; Wallace, 2013; Wallace et al., 2014). Individuals will be more likely, in general, to use sarcasm when discussing specific entities. Which entities will depend in part on the community to which the individual belongs. As a proxy for user community, here we leverage the subreddits to which comments were posted.

Sentiment may also play an important role. In general, verbal irony is almost always used to convey negative views via ostensibly positive utterances (Sperber and Wilson, 1981). And recent work (Riloff et al., 2013) has exploited features based on sentiment to improve irony detection.

To summarize: when assuming an ironic voice we expect that individuals will convey ostensibly positive sentiment about entities, and that these entities will depend on the type of individual in question. We propose capitalizing on such information by introducing features that encode subreddits, sentiment and noun phrases (NNPs), as we describe next.

2.2 Features

We leverage the feature sets enumerated in Table 1. Subreddits are observed variables. Noun phrase (NNP) extraction and sentiment inference are performed automatically via state of the art NLP tools. In particular, we use the Stanford Sentiment Analysis tool (Socher et al., 2013) to infer sentiment. To extract NNPs we use the Stanford

Feature	Description
Sentiment	The inferred sentiment (*negative/neutral* or *positive*) for a given comment.
Subreddit	the subreddit (e.g., *progressive* or *conservative*; *atheism* or *Christianity*) to which a comment was posted.
NNP	Noun phrases (e.g., proper nouns) extracted from comment texts.
NNP+	Noun phrases extracted from comment texts *and* the thread to which they belong (for example, 'Obamacare' from the title in Figure 1).

Table 1: Feature types that we exploit. We view the (observed) subreddit as a proxy for *user type*. We combine this with sentiment and extracted noun phrases (NNPs) to improve classifier performance.

Part of Speech tagger (Toutanova et al., 2003). We then introduce 'bag-of-NNP' features and features that indicate whether the sentiment inferred for a given sentence was positive or not.

Additionally, we introduce 'interaction' features that capture combinations of these. For example, a feature that indicates whether a given sentence mentions Obamacare (which will be one of many NNPs automatically extracted) *and* was posted in the *conservative* subreddit. This is an example of a two-way interaction. We also experiment with three-way interactions, crossing sentiment with NNPs and subreddits. An example is a feature that indicates if a sentence was: inferred to be positive *and* mentions Obamacare (NNP) *and* was part of a comment made in the conservative subreddit. Finally, we experiment with adding NNPs extracted from the comment thread in addition to the comment text.

These are rich features that capture signal not directly available from the sentences themselves. Features that encode subreddits crossed with extracted NNP's, in particular, offer a chance to explicitly account for differences in how the ironic device is used by individuals in different communities. However, this has the downside of introducing a large number of irrelevant terms into the model: we expect, *a priori*, that many entities will not correlate with the use of verbal irony. We would therefore expect this strategy to exhibit high variance in terms of predictive performance, and we later confirm this empirically. Ideally, a model would perform feature selection during parameter estimation, thus dropping irrelevant interaction terms. We next introduce a composite ℓ_1/ℓ_2 regularization strategy toward this end.

3 Enforcing sparsity

3.1 Preliminaries

In this work we consider linear models with binary outputs ($y \in \{-1, +1\}$). We will assume we have access to a training dataset comprising n instances, $\mathbf{x} = \{\mathbf{x}_1, ..., \mathbf{x}_n\}$ and associated labels $\mathbf{y} = \{y_1, ..., y_n\}$. We then aim to find a weight-vector $\mathbf{w}$ that optimizes the following objective.

$$\underset{\mathbf{w}}{\operatorname{argmin}} \sum_{i=1}^{n} \mathcal{L}(\text{sign}\{\mathbf{w} \cdot \mathbf{x}_i\}, y_i) + \alpha \mathcal{R}(\mathbf{w}) \quad (1)$$

Where $\mathcal{L}$ is a loss function, $\mathcal{R}(\mathbf{w})$ is a regularization term and α is a parameter expressing the relative emphasis placed on achieving minimum empirical loss versus producing a simple model (i.e., a weight vector with small weights). Typically one searches for a good α using the available training data. For $\mathcal{L}$, we will use the log-loss in this work, though other loss functions may be used in its place.

3.2 Sparsity via Regularization

Concerning $\mathcal{R}$, one popular regularization function is the squared ℓ_2 norm:

$$\sum_j \mathbf{w}_j^2 \quad (2)$$

This is the norm used in the standard Support Vector Machine (SVM) formulation, for example, and has been shown empirically to work well for text classification (Joachims, 1998). An alternative is to use the ℓ_1 norm:

$$\sum_j |\mathbf{w}_j| \quad (3)$$

Which has the advantage of inducing sparse models: i.e., using the ℓ_1 norm as a penalty tends to drive feature weights to 0.

Returning to the present task of detecting verbal irony in comments, it seems reasonable to assume that there will be a relatively small set of entities that correlate with sarcasm. But because we are introducing 'interaction' features that enumerate the cross-product of subreddits and entities (and, in some cases, sentiment), we have a large feature-space. This space includes features that correspond to NNPs extracted from, and sentiment inferred for, the sentence itself: we will denote the indices for these by $\mathcal{I}$. Other interaction features correspond to entities extracted from the *threads* associated with comments: we denote the corresponding set of indices by $\mathcal{T}$. We expect only a fraction of the features comprising both $\mathcal{I}$ and $\mathcal{T}$ to have non-zero weights (i.e., to signal ironic intent).

This scenario is prone to the undesirable property of high-variance, and hence calls for stronger regularization. But in general replacing the squared ℓ_2 norm with an ℓ_1 penalty (over all weights) hampers classification performance (indeed, as we later report, this strategy performs very poorly here). Therefore, in our scenario we would like to place a sparsifying ℓ_1 regularizer over the contextual (interaction) features while still leveraging the squared ℓ_2-norm penalty for the standard bag-of-words (BoW) features.[2] We thus propose the following composite penalty:

$$\sum_j \mathbf{w}_j^2 + \sum_{k \in \mathcal{I}} |\mathbf{w}_k| + \sum_{l \in \mathcal{T}} |\mathbf{w}_l| \qquad (4)$$

The idea is that this will drive many of the weights associated with the contextual features to zero, which is desirable in light of the intuition that a relatively small number of entities will likely indicate sarcasm. At the same time, this composite penalty applies only the squared ℓ_2 norm to the standard BoW features, given the comparatively strong predictive performance realized with this strategy.

Putting this together, we modify the original objective (Equation 1) as follows:

$$\begin{aligned}\underset{\mathbf{w}}{\operatorname{argmin}} \sum_{i=1}^{n} \mathcal{L}(\operatorname{sign}\{\mathbf{w} \cdot \mathbf{x}_i\}, y_i) + \\ \alpha_0 \sum_j \mathbf{w}_j^2 + \alpha_1 \sum_{k \in \mathcal{I}} |\mathbf{w}_k| + \alpha_2 \sum_{l \in \mathcal{T}} |\mathbf{w}_l| \quad (5)\end{aligned}$$

Where we have placed separate α scalars on the respective penalty terms. Note that this is similar to the *elastic net* (Zou and Hastie, 2005) joint regularization and variable selection strategy. The distinction here is that we only apply the ℓ_1 penalty to (i.e., perform feature selection for) the subset of 'interaction' feature weights, which is in contrast to the elastic net, which imposes the composite penalty to *all* feature weights. One can view this as using the regularizer to encourage a sparsity pattern specific to the task at hand.

3.3 Inference

We fit this model via Stochastic Gradient Descent (SGD).[3] During each update, we impose both the squared ℓ_2 and ℓ_1 penalties; the latter is applied only to the contextual/interaction features in $\mathcal{I}$ and $\mathcal{T}$. For the ℓ_1 penalty, we adopt the cumulative truncated gradient method proposed by Tsuruoka et al. (2009).

4 Experimental Setup

4.1 Datasets

For our development dataset, we used a subset of the reddit irony corpus (Wallace et al., 2014) comprising annotated comments from the *progressive* and *conservative* subreddits. We also report results from experiments performed using a separate, held-out portion of this data, which we did not use during model refinement. Furthermore, we later present results on comments from the *atheism* and *Christianity* subreddits (we did not use this data during model development, either).

The development dataset includes 1,825 annotated comments (876 and 949 from the *progressive* and *conservative* subreddits, respectively). These comprise 5,625 sentences in total, each of which was independently labeled by three annotators as having been intended *ironically* or not. For additional details on the annotation process, see (Wallace et al., 2014). For simplicity, we consider a sentence to be 'ironic' ($y = 1$) when at least two of the three annotators designated it as such, and 'unironic' ($y = -1$) otherwise. Using this criteria, 286 (5%) of the labeled sentences are labeled 'ironic'.

The test portion of the political dataset comprises 996 annotated comments (409 *progressive* and 587 *conservative* comments), totalling 2,884 sentences. Using the same criteria as above – at least 2/3 annotators labeling a given sentence as 'ironic' – we have 154 'ironic' sentences (again about 5%).

The 'religion' dataset (comments from *atheism* and *Christianity*) contains 1,682 labeled comments comprising 5615 sentences (2,966 and 2,649 from the atheism and Christian subreddits, respectively); 313 (∼6%) were deemed 'ironic'.

[2] Note that we apply both ℓ_1 and ℓ_2 penalties to the features in $\mathcal{I}$ and $\mathcal{T}$.

[3] We have implemented this within the *sklearn* package (Pedregosa et al., 2011).

4.2 Experimental Details

We recorded results from 500 independently performed experiments on random train (80%)/test (20%) splits of the data. These splits were performed at the *comment* (rather than sentence) level, so as not to test on sentences belonging to comments encountered in the training set. We measured performance, however, at the sentence level (often only a single sentence in a given comment will have been labeled as ‘ironic’).

Our baseline approach is a standard squared-ℓ_2 regularized log-loss linear model (fit via SGD) that leverages uni- and bi-grams and features indicating grammatical cues, such as exclamation points and emoticons. We also experiment with a model that includes inferred sentiment indicators, but not context. We performed standard English stopwording, and we used Term Frequency Inverse-Document Frequency (TF-IDF) feature weighting. For the gradient descent procedure, we used a decaying learning rate (specifically, $\frac{1}{t}$, where t is the update count). We performed a coarse grid search to find values for α that maximize $F1$ on the training datasets. We took five full passes over the training data before terminating descent.

We report paired *recalls* and *precisions*, as observed on each random train/test split of the data. The former is defined as $\frac{TP}{TP+FN}$ and the latter as $\frac{TP}{TP+FP}$, where TP denotes the true positive count, FN the number of false negatives and FP the false positive count. We report these separately - rather than collapsing into $F1$ - because it is not clear that one would value recall and precision equally for irony detection, and because this allows us to tease out *how* the models differ in performance. Notably, for example, sentiment and context features both improve recall, but the latter does so without harming precision.

5 Results

5.1 Results on the Development Corpus

Figure 2 and Table 2 summarize the performance of the different approaches over 500 independently performed train/test splits of the political development corpus. For reference, a random chance strategy (which predicts ‘ironic’ with probability equal to the observed prevalence) achieves a median recall of 0.048 and a median precision of 0.047.

Figure 2 shows histograms of the observed absolute differences between the baseline linear classifier and the proposed augmentations. Adding the proposed features (which capitalize on sentiment and NNP-mentions on specific subreddits) increases absolute median recall by 3.4 percentage points (a relative gain of ∼12%). And this is achieved without sacrificing precision (in contrast to exploiting only sentiment). Furthermore, as we can see in Figures 2 and 3, the proposed regularization strategy shrinks the variance of the classifier. This variance reduction is achieved through greater model sparsity, as can be seen in Figure 4, which improves interpretability. We note that leveraging *only* an ℓ_1 regularization penalty (with the full feature-set) results in very poor performance (median recall and precision of 0.05 and 0.09, respectively). Similarly, the elastic-net strategy (Zou and Hastie, 2005) (in which we do not specify which features to apply the ℓ_1 penalty to), here achieves a median recall of 0.11 and a median precision of 0.07.

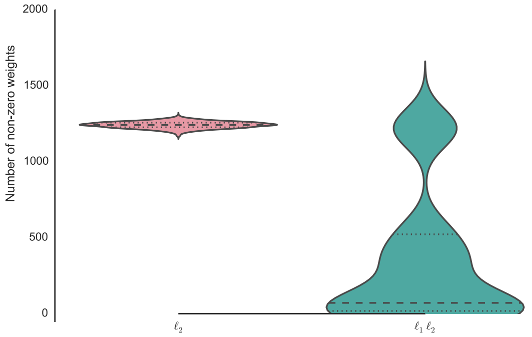


Figure 4: Empirical distributions (violin plots) of non-zero feature counts in the NNP × subreddit model (rows 3 and 4 in Figure 3) using standard ℓ_2-norm (left) and the proposed $\ell_1\ell_2$-norm (right) regularization approaches on the *atheism/Christianity* data over 500 independent train/test splits. The composite norm achieves much greater sparsity, resulting in lower variance. This sparsity also (arguably) provides greater interpretability; one can inspect contextual features with non-zero weights.

5.2 Results on the Held-out (Test) Corpus

Table 4 reports results on the held-out political test dataset, achieved after training the models on the entirety of the development corpus. To account for the variance inherent to inference via SGD, we performed 100 runs of the SGD procedure and report median results from these runs. These results mostly agree with those reported for the development corpus: the proposed strategy improves median recall on the held-out corpus by nearly 4.0 percentage points, at a median cost of about 1 point in precision. By contrast, sentiment alone provides a 2% absolute improvement in recall at

	mean; median (25th, 75th)	mean; median (25th, 75th)

NNP+ × sent. × subreddit + sent. (ℓ_1 ℓ_2)	+0.035; +0.034 (+0.000, +0.062)	+0.001; +0.000 (-0.011, +0.011)

Table 2: Summary results over 500 random train/test splits of the development dataset. The top row reports mean and median baseline (BoW) recall and precision and lower and upper (25th and 75th) percentiles. We report pairwise differences w.r.t. this baseline in terms of recall and precision for each strategy. Exploiting NNP features and subreddits improves recall with little to not cost in precision. Capitalizing on sentiment alone improves recall but at a greater cost in precision. The proposed $\ell_1\ell_2$ regularization strategy achieves comparable performance with fewer features, and shrinks the variance over different train/test splits (as can bee seen in Figure 2).

NNP	+0.018; +0.018 (+0.000, +0.039)	-0.009; -0.010 (-0.021, +0.001)
NNP × subreddit	+0.024; +0.025 (+0.000, +0.046)	+0.002; +0.001 (-0.011, +0.013)
NNP × subreddit (ℓ_1 ℓ_2)	+0.013; +0.015 (+0.000, +0.033)	+0.002; +0.002 (-0.009, +0.011)
NNP+ × sent. × subreddit + sent.	+0.023; +0.024 (+0.000, +0.046)	+0.001; +0.001 (-0.012, +0.013)
NNP+ × sent. × subreddit + sent. (ℓ_1 ℓ_2)	+0.014; +0.015 (+0.000, +0.036)	-0.008; -0.008 (-0.021, +0.004)

Table 3: Results on the *atheism* and *Christianity* subreddits. In general sentiment does not help on this dataset (see row 1). But the NNP and subreddit features again consistently improve recall without hurting precision. And, as above, $\ell_1\ell_2$ regularization shrinks variance (see Figures 2 and 3).

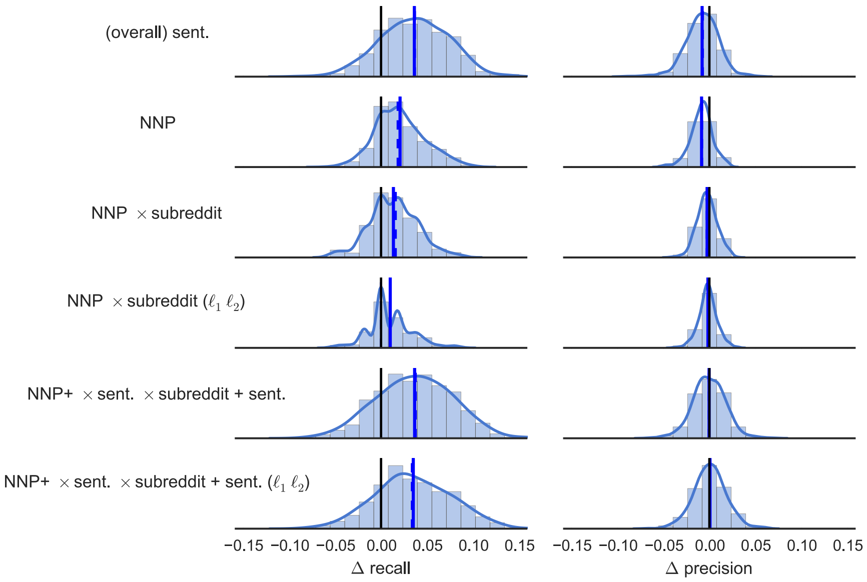

Figure 2: Results from 500 independent train/test splits of the development subset of our political data. Shown are histograms with smoothed kernel density estimates of differences in recall and precision between the baseline bag-of-words based approach and each feature space/method (one per row). The solid black line at 0 indicates no difference; solid and dotted blue lines demarcate means and medians, respectively. Features are as in Table 1. The × symbol denotes interactions; + indicates addition. The proposed contextual features substantially improve recall, with little to no loss in precision. Moreover, in general, the $\ell_1\ell_2$ regularization approach reduces variance. (We note that in constructing histograms we have excluded a handful of points – never more than 1% – where the difference exceeded 0.15).

	median recall (std. dev.)	median precision (std. dev.)
baseline	0.331 (0.146)	0.148 (0.022)
(overall) sent.	0.351 (0.054)	0.125 (0.003)
NNP	0.364 (0.119)	0.135 (0.021)
NNP × subreddit	0.357 (0.108)	0.143 (0.020)
NNP+ × sent. × subreddit	0.344 (0.116)	0.142 (0.019)
NNP+ × sent. × subreddit (ℓ_1 ℓ_2)	0.325 (0.052)	0.141 (0.008)
NNP+ × sent. × subreddit + sent.	0.377 (0.104)	0.141 (0.014)
NNP+ × sent. × subreddit + sent. (ℓ_1 ℓ_2)	0.370 (0.056)	0.140 (0.008)

Table 4: Results on the held-out political dataset, using the entire development corpus as a training set. Abbreviations are as described in the caption for Figure 2. Due to the variance inherent to the stochastic gradient descent procedure, we repeat the experiment 100 times and report the median performance and standard deviations (of different SGD runs). Results are consistent with those reported for the development corpus.

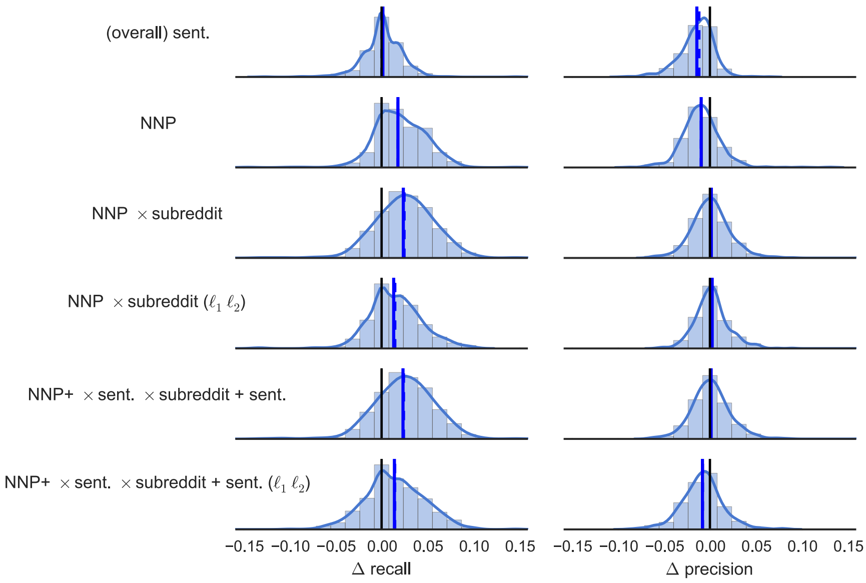

Figure 3: Results from 500 independent train/test splits of the development subset of the religion corpus). The description is the same as for Figure 2.

the expense of more than 2 points in precision.

5.3 Results on the religion dataset

To assess the general applicability of the proposed approach, we also evaluate the method on comments from a separate pair of polarized communities: *atheism* and *Christianity*, as described in Section 4.1. This dataset was not used during model development. We follow the experimental setup described in Section 4.2.

In this case, capitalizing on the NNP × subreddit features produces a mean 2.3% absolute gain in recall (median: 2.4%) over the baseline approach, with a (very) slight gain in precision. The ℓ_1 ℓ_2 approach achieves a lower expected gain in recall (median: 1.5%), but again shrinks the variance w.r.t. model performance (see Figure 3). Moreover, as we show in Figure 4, this is achieved with a much more compact (sparser) model. We note that for the religion data, inferred sentiment features do not seem to improve performance, in contrast to the results on the political subreddits. At present, we are not sure why this is the case.

These results demonstrate that introducing features that encode entities and user communities (NNPs × subreddit) improve recall for irony detection in comments addressing relatively diverse topics (politics and religion).

5.4 Predictive features

We report the interaction features that are the best predictors of verbal irony in the respective subreddits (for both polar community pairs). Specifically, we estimated the weights for every interaction feature using the entire training dataset, and repeated this process 100 times to account for variation due to the SGD procedure.

progressive		*conservative*	
feature	weight	feature	weight
freedom	0.102 (0.048)	racist	0.148 (0.043)
god	0.085 (0.045)	news	0.100 (0.044)
christmas	0.081 (0.046)	way	0.078 (0.044)
jesus	0.060 (0.038)	obamacare	0.068 (0.041)
kenya	0.052 (0.035)	white	0.059 (0.037)
brave	0.043 (0.035)	let	0.058 (0.038)
bravo	0.041 (0.035)	course	0.046 (0.033)
know	0.038 (0.030)	huh	0.044 (0.036)
dennis	0.038 (0.029)	education	0.043 (0.032)
ronald	0.036 (0.030)	president	0.039 (0.031)

Table 5: Average weights (and standard deviations calculated across samples) for top 10 NNP × subreddit features from the *progressive* and *conservative* subreddits.

Table 5 displays the top 10 NNP × subreddit features for the political subreddits, with respect to the mean magnitude of the weights associated with them. We report these means and the standard deviations calculated across the 100 runs. This table implies, for example, that mentions of ‘freedom’ and ‘kenya’ indicate irony in the *progressive* subreddit; while mentions of ‘obamacare’ and ‘president’ (for example) in the *conservative* subreddit tend to imply irony.

Table 6 reports analagous results for the religion subreddits. Here we can see, e.g., that ‘god’ is a good predictor of irony in the *atheism* subreddit, and ‘professor’ is in the *Christianity* subreddit.

We also report the top ranking ‘three-way’ interaction features that cross NNP’s extracted from

atheism		*Christianity*	
feature	weight	feature	weight

Table 7: Average weights for top 10 NNP × subreddit × sentiment features. The parenthetical '+' indicates that the inferred sentiment was positive. In general, (ostensibly) positive sentiment indicates irony.

sentences with subreddits and the inferred sentiment for the political corpus (Table 7). This would imply, e.g., that if a sentence in the *progressive* subreddit conveys an ostensibly positive sentiment about the political commentator 'Ollie',[4] then this sentence is likely to have been intended ironically.

Some of these may seem counter-intuitive, such as ostensibly positive sentiment regarding 'Cruz' (as in the conservative senator Ted Cruz) in the conservative subreddit. On inspection of the comments, it would seem Ted Cruz does not find general support even in this community. Example comments include: "Stay classy Ted Cruz" and "Great idea on the talkathon Cruz". The 'mr' and 'king' terms are almost exclusively references to Obama in the *conservative* subreddit. In any case, because these are three-way interaction terms, they are all relatively rare: therefore we would caution against over interpretation here.

6 Related Work

The task of automated irony detection has recently received a great deal of attention from the NLP and ML communities (Tepperman et al., 2006; Davidov et al., 2010; Carvalho et al., 2009; Burfoot and Baldwin, 2009; Tsur et al., 2010; González-Ibáñez et al., 2011; Filatova, 2012; Reyes et al., 2012; Lukin and Walker, 2013; Riloff et al., 2013). This work has mostly focussed on exploiting token-based indicators of verbal irony. For example, it is clear that gratuitous punctuation (e.g. "oh really??!!!") signals irony (Carvalho et al., 2009).

Davidov et al. (2010) proposed a semi-supervised approach in which they look for sentence *templates* indicative of irony. Elsewhere, Riloff et al. (2013) proposed a method that exploits apparently contrasting sentiment in the same utterance to detect irony. While innovative, these approaches still rely on features intrinsic to comments; i.e., they do not attempt to capitalize on contextualizing features external to the comment text. This means that there will necessarily be certain (subtle) ironies that escape detection by such approaches. For example, without any additional information about the speaker, it would be impossible to deduce whether the comment "Obamacare is a great program" is intended sarcastically.

Other related recent work has shown the promise of sparse models, both for prediction and interpretation (Eisenstein et al., 2011a; Eisenstein et al., 2011b; Yogatama and Smith, 2014a). Yogatama (2014a; 2014b), e.g., has leveraged the *group lasso* approach to impose 'structured' sparsity on feature weights. Our work here may similarly be viewed as assuming a specific sparsity pattern (specifically that feature weights for 'interaction features' will be sparse) and expressing this via regularization.

7 Conclusions and Future Directions

We have shown that we can leverage contextualizing information to improve identification of verbal irony in online comments. This is in contrast to previous models, which have relied predominantly on features that are *intrinsic* to the texts to be classified. We exploited features that indicate user communities crossed with sentiment and extracted noun phrases. This led to consistently improved recall with little to no cost in precision. We also proposed a novel composite regularization strategy that imposes a sparsifying ℓ_1 penalty on the interaction features, as we expect most of these to be irrelevant. This reduced performance variance.

Future work will include expanding the corpus and experimenting with datasets outside of the political domain. We also plan to evaluate this strategy on data from different online sources, e.g., Twitter or YouTube.

[4] 'Ollie' is a conservative political commentator.

Abstract

Predicting emotion categories, such as *anger*, *joy*, and *anxiety*, expressed by a sentence is challenging due to its inherent multi-label classification difficulty and data sparseness. In this paper, we address above two challenges by incorporating the label dependence among the emotion labels and the context dependence among the contextual instances into a factor graph model. Specifically, we recast sentence-level emotion classification as a factor graph inferring problem in which the label and context dependence are modeled as various factor functions. Empirical evaluation demonstrates the great potential and effectiveness of our proposed approach to sentence-level emotion classification.

1 Introduction

Predicting emotion categories, such as *anger*, *joy*, and *anxiety*, expressed by a piece of text encompasses a variety of applications, such as online chatting (Galik et al., 2012), news classification (Liu et al., 2013) and stock marketing (Bollen et al., 2011). Over the past decade, there has been a substantial body of research on emotion classification, where a considerable amount of work has focused on document-level emotion classification.

Recently, the research community has become increasingly aware of the need on sentence-level emotion classification due to its wide potential applications, e.g. the massively growing importance of analyzing short text in social media (Kiritchenko et al., 2014; Wen and Wan, 2014). In general, sentence-level emotion classification exhibits two challenges.

……

<S1>*她们都睡了，我蹑手蹑脚摸黑上了床，凑上去想亲嫣一下，她突然一个转身，小手‘啪’地搭在了我的脸颊上。*</S1> <S2>*现在我终于如愿以偿。*</S2> <S3>*感受着小手的温度，享受着这份她对我的依恋，生怕动一下，会让她的小手离我而去。*</S3>**……**

(English: **……**

<**S1**> *The girls fall to sleep, so I make my way noiselessly onto the bed, wishing I could get a chance to give a kiss to Yan, suddenly she turn over to me and her little soft hand fall onto my face.*</**S1**> <**S2**>*Praise the Lord, that is all I want.*</**S2**> <**S3**>*Feeling the warm of her hand and the attachment she hold to me, I couldn't afford to move even a little, fearing I may lost her hand.*</**S3**>)……)

Sentence-level Emotion Classification

➢**Input**: **S1**, **S2**, **S3**

➢**Output**: **S1** : *joy*, *love*
S2: *joy*
S3: *joy*, *love*, *anxiety*

Figure 1: An example of a paragraph and the sentences therein with their emotion categories from the corpus collected by Quan and Ren (2009)

On one hand, like document-level emotion classification, sentence-level emotion classification is naturally a multi-label classification problem. That is, each sentence might involve more than one emotion category. For example, as shown in Figure 1, in one paragraph, two sentences, i.e., **S1** and **S3**, have two and three emotion categories respectively. Automatically classifying instances with multiple possible categories is

[*] Corresponding author

Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

sometimes much more difficult than classifying instances with a single label.

On the other hand, unlike document-level emotion classification, sentence-level emotion classification is prone to the data sparseness problem because a sentence normally contains much less content. Given the short text of a sentence, it is often difficult to predict its emotion due to the limited information therein. For example, in **S2**, only one phrase "*如愿以偿(that is all I want)*" expresses the *joy* emotion. Once this phrase fails to appear in the training data, it will be hard for the classifier to give a correct prediction according to the limited content in this sentence.

In this paper, we address above two challenges in sentence-level emotion classification by modeling both the label and context dependence. Here, the label dependence indicates that multiple emotion labels of an instance are highly correlated to each other. For instance, the two positive emotions, *joy* and *love,* are more likely to appear at the same time than the two counterpart emotions, *joy* and *hate*. The context dependence indicates that two neighboring sentences or two sentences in the same paragraph (or document) might share the same emotion categories. For instance, in Figure 1, **S1**, **S2**, and **S3**, from the same paragraph, all share the emotion category *joy*.

Specifically, we propose a factor graph, namely Dependence Factor Graph (DFG), to model the label and context dependence in sentence-level emotion classification. In our DFG approach, both the label and context dependence are modeled as various factor functions and the learning task aims to maximize the joint probability of all these factor functions. Empirical evaluation demonstrates the effectiveness of our DFG approach to capturing the inherent label and context dependence. To the best of our knowledge, this work is the first attempt to incorporate both the label and context dependence of sentence-level emotion classification into a unified framework.

The remainder of this paper is organized as follows. Section 2 overviews related work on emotion analysis. Section 3 presents our observations on label and context dependence in the corpus. Section 4 proposes our DFG approach to sentence-level emotion classification. Section 5 evaluates the proposed approach. Finally, Section 6 gives the conclusion and future work.

2 Related Work

Over the last decade, there has been an explosion of work exploring various aspects of emotion analysis, such as emotion resource creation (Wiebe et al., 2005; Quan and Ren, 2009; Xu et al., 2010), writer's emotion vs. reader's emotion analysis (Lin et al., 2008; Liu et al., 2013), emotion cause event analysis (Chen et al., 2010), document-level emotion classification (Alm et al., 2005; Li et al., 2014) and sentence-level or short text-level emotion classification (Tokushisa et al., 2008; Bhowmick et al., 2009; Xu et al., 2012). This work focuses on sentence-level emotion classification.

Among the studies on sentence-level emotion classification, Tokushisa et al. (2008) propose a data-oriented method for inferring the emotion of an utterance sentence in a dialog system. They leverage a huge collection of emotion-provoking event instances from the Web to deal with the data sparseness problem in sentence-level emotion classification. Bhowmick et al. (2009) and Bhowmick et al. (2010) apply KNN-based classification algorithms to classify news sentences into multiple reader emotion categories. Although the multi-label classification difficulty has been noticed in their study, the label dependence is not exploited. More recently, Xu et al. (2012) proposes a coarse-to-fine strategy for sentence-level emotion classification. They deal with the data sparseness problem by incorporating the transfer probabilities from the neighboring sentences to refine the emotion categories. To some extent, this can be seen a specific kind of context information. However, they ignore the label dependence by directly applying Binary Relevance to overcome the multi-label classification difficulty.

Unlike all above studies, this paper emphasizes the importance of the label dependence and exploits it in sentence-level emotion classification via a factor graph model. Moreover, besides the label dependence, our factor graph-based approach incorporates the context dependence in a unified framework to further improve the performance of sentence-level emotion classification.

3 Observations

To better illustrate our motivation of modeling the label and context dependence, we systematically investigate both dependence phenomena in our evaluation corpus.

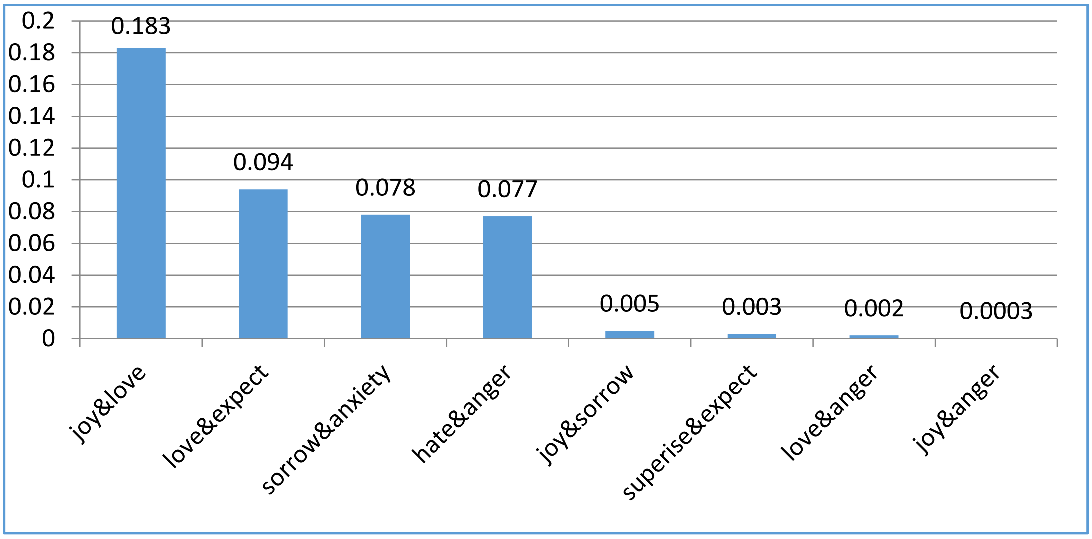

Figure 2: Probability distribution of most and least frequently-occurred pairs of emotion categories, with left four most frequently-occurred and right four least frequently-occurred, among all 28 pairs

The corpus contains 100 documents, randomly selected from Quan and Ren (2009). There are totally 2751 sentences and each of them is manually annotated with one or more emotion labels.

Table 1: The numbers of the sentences in each emotion category

Emotion	#Sentence	Emotion	#Sentence
joy	691	*anxiety*	567
hate	532	*surprise*	180
love	1025	*anger*	287
sorrow	611	*expect*	603

Table 2: The numbers of the sentences grouped by the emotion labels they contain

	#Sentence
No Label	180
One Label	1096
Two Labels	1081
Three Labels	346
Four or more labels	48
ALL	**2751**

Table 1 shows the sentence distribution of the eight emotion categories. Obviously, the distribution is a bit imbalanced. While about to one quarter of sentences express the emotion category *love,* only ~6% and ~10% express surprise and anger respectively, with the remaining 5 emotion categories distributed rather evenly from ~20% to ~25%. Table 2 shows the numbers of the sentences grouped by the emotion labels they contain. From this table, we can see that more than half sentences have two or more emotion labels. This indicates the popularity of the multi-label issue in sentence-level emotion classification.

To investigate the phenomenon of label dependence, we first assume that $X \subset R^d$ denotes an input domain of instances and $Y = \{l_1, l_2, ..., l_m\}$ be a finite domain of possible emotion labels. Each instance is associated with a subset of Y and this subset is described as an m-dimensional vector $y = \{y^1, y^2, ..., y^m\}$ where $y^i = 1$ only if instance x has label l_i. and $y^i = 0$ otherwise. Then, we can calculate the probability that an instance takes both emotion labels l_i and l_j, denoted as $p(l_i, l_j)$. Figure 2 shows the probability distribution of most and least frequently-occurred pairs of emotion categories, with left four most frequently-occurred and right four least frequently-occurred, among all 28 pairs. From this figure, we can see that some pairs, e.g., *joy* and *love*, are much more likely to be taken by one sentence than some other pairs, e.g. *joy* and *anger*.

Finally, we investigate the phenomenon of the context dependence by calculating the probabilities that two instances x_k and x_l have at least one identical emotion label, i.e., $p(y_k \cap$ in different settings.

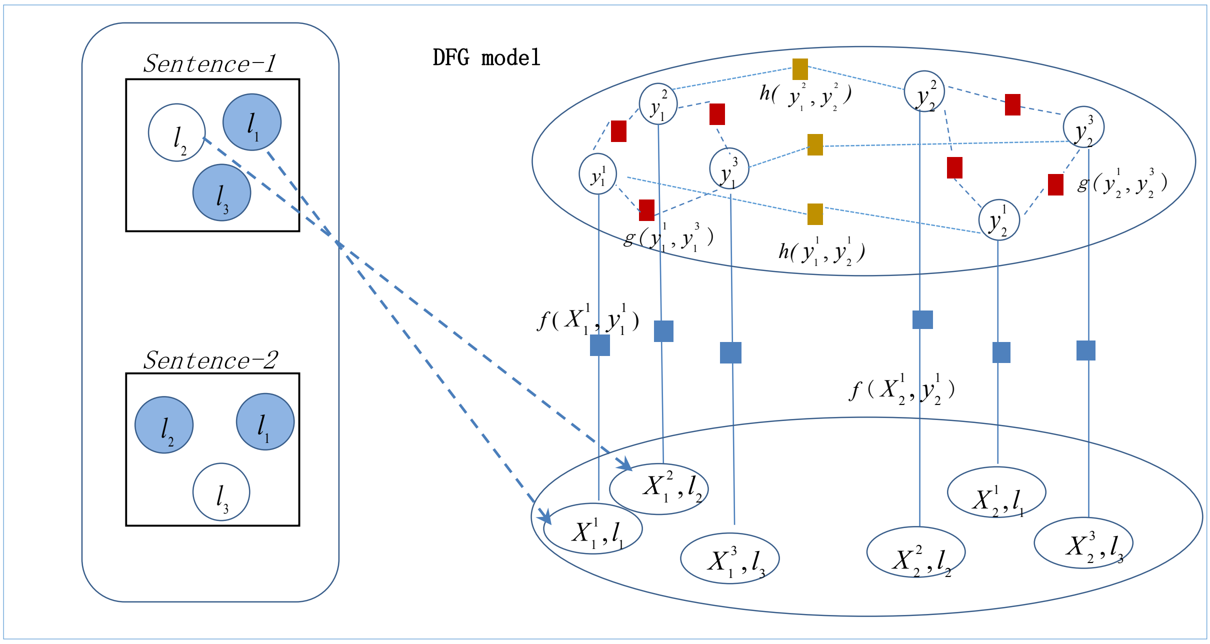

Figure 4: An example of DFG when two instances are involved: *sentence-1* with the label vector [1, 0, 1] and *sentence-2* with the label vector [1, 1, 0]

Note: each multi-label instance is transformed into three pseudo samples, represented as X_i^k $(k=1,2,3)$. $f(\cdot)$ represents a factor function for modeling textual features. $g(\cdot)$ represents a factor function for modeling the label dependence between two pseudo samples. $h(\cdot)$ represents a factor function for modeling the context dependence between two instances in the same context.

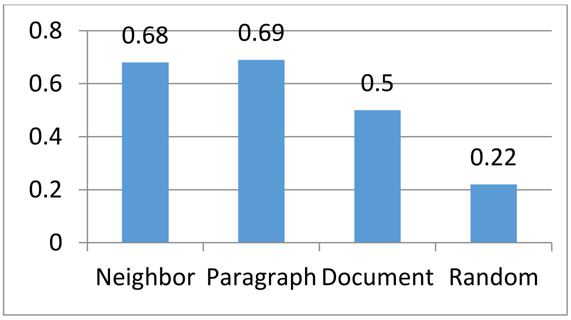

Figure 3: Probabilities that two instances have an identical emotion label in different settings

Figure 3 shows the probabilities that two instances have at least one identical emotion label in different settings, where *neighbor, paragraph, document and random* mean two neighboring instances, two instances from the same paragraph, two instances from the same document, and two instances from a random selection, respectively. From this figure, we can see that two instances from the same context are much more likely to take an identical emotion label than two random instances.

From above statistics, we come to two basic observations:

1) **Label dependency**: One sentence is more likely to take some pair of emotion labels, e.g., *hate* and *angry* than some other pair of emotion labels, e.g., *hate* and *happy*.
2) **Context dependency**: Two instances from the same context are more likely to share the same emotion label than those from a random selection.

4 Dependence Factor Graph Model

In this section, we propose a dependence factor graph (DFG) model for learning emotion labels of sentences with both label and context dependence.

4.1 Preliminary

Factor Graph

A factor graph consists of two layers of nodes, i.e., variable nodes and factor nodes, with links between them. The joint distribution over the whole set of variables can be factorized as a product of all factors. Figure 4 gives an example of our dependence factor graph (DFG) when two instances, i.e., *sentence-1* and *sentence-2* are involved.

Binary Relevance

A popular solution to multi-label classification is called binary relevance which constructs a binary classifier for each label, resulting a set of independent binary classification problems (Tsoumakas and Katakis, 2007; Tsoumakas et al., 2009). In our approach, binary relevance is utilized as a preliminary step so that each original instance is transformed into K pseudo samples, where K is the number of categories. For example, in Figure 4, X_1^1, X_1^2, and X_1^3 represent the three pseudo samples, generated from the same original instance *sentence-1*.

4.2 Model Definition

Formally, let $G=(V,E,X)$ represent an instance network, where V denotes a set of sentence instances. $E \subset V \times V$ is a set of relationships between sentences. Two kinds of relationship exist in our instance network: One represents the label dependence between each two pseudo instances generated from the same original instance, while the other represents the context dependence when the two instances are from the same context, e.g., the same paragraph. X is the textual feature vector associated with a sentence.

We model the above network with a factor graph and our objective is to infer the emotion categories of instances by learning the following joint distribution:

$$P(Y|G) = \prod_k \prod_i f\left(X_i^k, y_i^k\right) g\left(y_i^k, G\left(y_i^k\right)\right) h\left(y_i^k, H\left(y_i^k\right)\right) \quad (1)$$

where three kinds of factor functions are used.

1) **Textual feature factor function:** $f\left(X_i^k, y_i^k\right)$ denotes the traditional textual feature factor functions associated with each text X_i^k. The textual feature factor function is instantiated as follows:

$$f\left(X_i^k, y_i^k\right) = \frac{1}{Z_1} \exp\left(\sum_j \alpha_{kj} \Phi\left(x_{ij}^k, y_i^k\right)\right) \quad (2)$$

Where $\Phi\left(x_{ij}^k, y_i^k\right)$ is a feature function and x_{ij}^k represents a textual feature, i.e., a word feature in this study.

2) **Label dependence factor function:** $g\left(y_i^k, G\left(y_i^k\right)\right)$ denotes the additional label dependence relationship among the pseudo instances, where $G\left(y_i^k\right)$ is the label set of the instances connected to y_i^k. $G\left(y_i^k\right)$ and y_i^k are labels of the pseudo instances generated from the same original instance. The label dependence factor function is instantiated as follows:

$$g\left(y_i^k, G(y_i^k)\right) = \frac{1}{Z_2} \exp\left\{ \sum_{y_i^l \in G(y_i^k)} \beta_{ikl} \left(y_i^k - y_i^l\right)^2 \right\} \quad (3)$$

Where β_{ikl} is the weight of the function, representing the influence degree of the two instances y_i^k and y_i^l.

3) **Context dependence factor function:** $h\left(y_i^k, H\left(y_i^k\right)\right)$ denotes the additional context dependence relationship among the instances, where $H\left(y_i^k\right)$ is the set of the instances connected to y_i^k. $H\left(y_i^k\right)$ and y_i^k are the labels of the pseudo instances from the same context but generated from different original instances. The context dependence factor function is instantiated as follows:

$$h\left(y_i^k, H(y_i^k)\right) = \frac{1}{Z_3} \exp\left\{ \sum_{y_j^k \in H(y_i^k)} \delta_{ijk} \left(y_i^k - y_j^k\right)^2 \right\} \quad (4)$$

Where δ_{ijk} is the weight of the function, representing the influence degree of the two instances y_i^k and y_j^k.

4.3 Model Learning

Learning the DFG model is to estimate the best parameter configuration $\theta = (\{\alpha\},\{\beta\},\{\delta\})$ to maximize the log-likelihood objective function $L(\theta) = \log P_\theta\left(Y|G\right)$, i.e.,

$$\theta^* = \arg\max L(\theta) \quad (5)$$

In this study, we employ the gradient decent method to optimize the objective function. For example, we can write the gradient of each α_{kj} with regard to the objective function:

$$\frac{\partial L(\theta)}{\partial \alpha_{kj}} = E\left[\Phi\left(x_{ij}, y_i^k\right)\right] - E_{P_{\alpha_{kj}}(Y|G)}\left[\Phi\left(x_{ij}, y_i^k\right)\right] \quad (6)$$

Where $E\left[\Phi\left(x_{ij}, y_i^k\right)\right]$ is the expectation of feature function $\Phi\left(x_{ij}, y_i^k\right)$ given the data distribution. $E_{P_{\alpha_{kj}}(Y|G)}\left[\Phi\left(x_{ij}, y_i^k\right)\right]$ is the expectation of feature function $\Phi\left(x_{ij}, y_i^k\right)$ under the distribution $P_{\alpha_{kj}}\left(Y|G\right)$ given by the estimated model. Figure 5 illustrates the detailed algorithm for learning the parameter α. Note that LBP denotes the Loopy

Belief Propagation (LBP) algorithm which is applied to approximately infer the marginal distribution in a factor graph (Frey and MacKay, 1998). A similar gradient can be derived for the other parameters.

```
Input: Learning rate $\eta$
Output: Estimated parameters $\alpha$
Initialize $\alpha \leftarrow 0$
Repeat
  1) Calculate $E\left[\Phi\left(x_{ij}, y_i^k\right)\right]$ using LBP
  2) Calculate $E_{P_{\alpha_{kj}}(Y|G)}\left[\Phi\left(x_{ij}, y_i^k\right)\right]$ using LBP
  3) Calculate the gradient of $\alpha$ according to Eq. (6)
  4) Update parameter $\alpha$ with the learning rate $\eta$
         $\alpha_{\text{new}} = \alpha_{\text{old}} + \eta \frac{L(\alpha)}{\alpha}$
Until Convergence
```

Figure 5: The learning algorithm for DGP model

4.4 Model Prediction

With the learned parameter configuration θ, the prediction task is to find a Y^{U*} which optimizes the objective function, i.e.,

$$Y^{U*} = \arg\max P\left(Y^U \middle| Y^L, G, \theta\right) \tag{7}$$

Where Y^{U*} are the labels of the instances in the testing data.

Again, we utilize LBP to calculate the marginal probability of each instance $P\left(y_i^k \middle| Y^L, G, \theta\right)$ and predict the label with the largest marginal probability. As all instances in the test data are concerned, above prediction is performed in an iteration process until the results converge.

5 Experimentation

We have systematically evaluated our DFG approach to sentence-level emotion classification.

5.1 Experimental Setting

Corpus

The corpus contains 100 documents (2751 sentences) from the Ren-CECps corpus (Quan and Ren, 2009). In our experiments, we use 80 documents as the training data and the remaining 20 documents as the test data.

Features

Each instance is treated as a bag-of-words and transformed into a binary vector encoding the presence or absence of word unigrams.

Evaluation Metrics

In our study, we employ three evaluation metrics to measure the performances of different approaches to sentence-level emotion classification. These metrics have been popularly used in some multi-label classification problems (Godbole and Sarawagi, 2004; Schapire and Singer, 2000).

1) *Hamming loss*: It evaluates how many times an instance-label pair is misclassified considering the predicted set of labels and the ground truth set of labels, i.e.,

$$hloss = 1 - \frac{1}{mq}\sum_{i=1}^{q}\sum_{j=1}^{m} 1_{y_i^{j'} = y_i^j} \tag{8}$$

where q is the number of all test instances and m is the number of all emotion labels. $y_i^{j'}$ is the estimated label while y_i^j is the true label.

2) *Accuracy*: It gives an average degree of the similarity between the predicted and the ground truth label sets of all test examples, i.e.,

$$Accuracy = \frac{1}{q}\sum_{i=1}^{q}\left|\frac{y_i \cap y_i^{'}}{y_i \cup y_i^{'}}\right| \tag{9}$$

3) *F1-measure*: It is the harmonic mean between precision and recall. It can be calculated from true positives, true negatives, false positive and false negatives based on the predictions and the corresponding actual values, i.e.,

$$F1 = \frac{1}{q}\sum_{i=1}^{q}\frac{\left|y_i \cap y_i^{'}\right|}{\left|y_i\right| + \left|y_i^{'}\right|} \tag{10}$$

Note that smaller *Hamming loss* corresponds to better classification quality, while larger *accuracy* and *F-measure* corresponds to better classification quality.

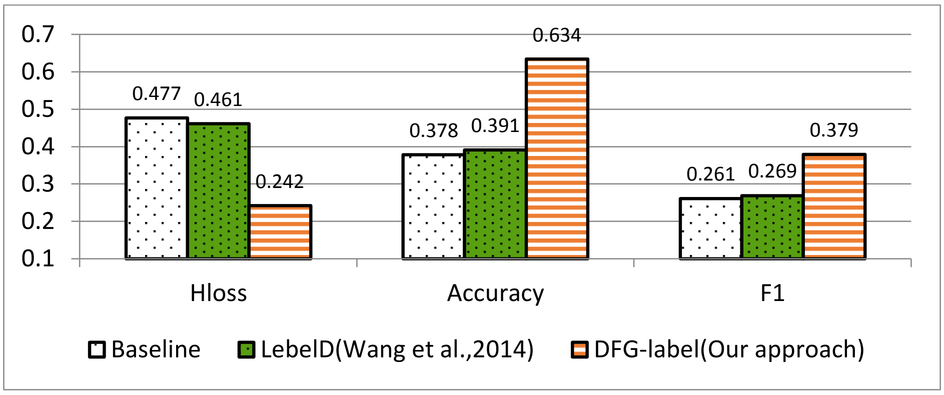

Figure 6: Performance comparison of different approaches to sentence-level emotion classification with the label dependence only

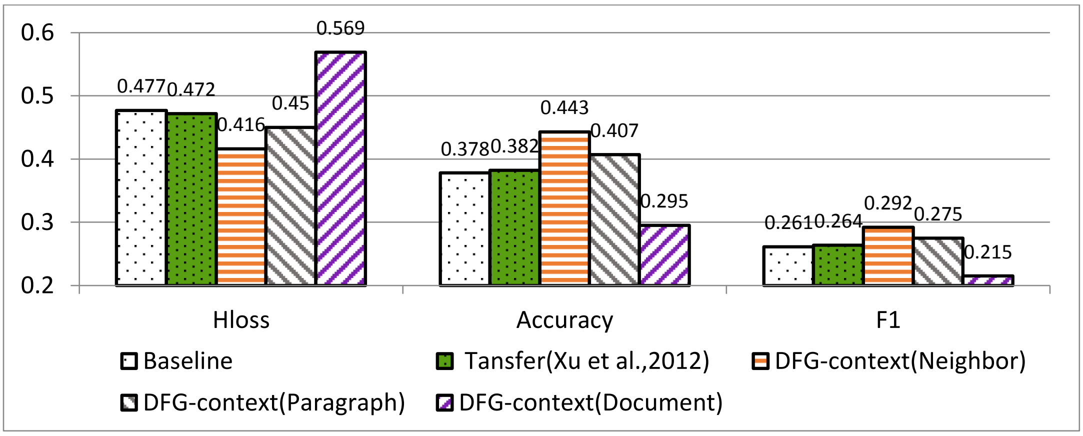

Figure 7: Performance comparison of different approaches to sentence-level emotion classification with the context dependence only

5.2 Experimental Results with Label Dependence

In this section, we compare following approaches which only consider the label dependence among pseudo instances:

- **Baseline**: As a baseline, this approach applies a maximum entropy (ME) classifier with only textual features, ignoring both the label and context dependence.
- **LabelD**: As the state-of-the-art approach to handling multi-label classification, this approach incorporates label dependence, as described in (Wang et al., 2014). Specifically, this approach first utilizes a Bayesian network to infer the relationship among the labels and then employ them in the classifier.
- **DFG-label**: Our DFG approach with the label dependence.

Figure 6 compares the performance of different approaches to sentence-level emotion classification with the label dependence. From this figure, we can see that our DFG approach improves the baseline approach with an impressive improvement in all three kinds of evaluation metrics, i.e., 23.5% reduction in *Hloss*, 25.6% increase in *Accuracy*, and 11.8% increase in *F1*. This result verifies the effectiveness of incorporating the label dependence in sentence-level emotion classification. Compared to the state-of-the-art LabelD approach, our DFG approach is much superior. Significant test show that our DFG approach significantly outperforms both the baseline approach and LabelD (p-value<0.01). One reason that LabelD performs worse than our approach is possibly due to their separating learning on textual features and label relationships. Also, different from ours, their approach could not capture the information between two conflict emotion labels, such as "*happy*" and "*sad*" (they are not possibly appearing together).

5.3 Experimental Results with Context Dependence

In this section, we compare following approaches which only consider the context dependence among pseudo instances:

- **Baseline**: same as the one in Section 5.2, which applies a maximum entropy (ME) classifier with only textual features, ignoring both the label and context dependence.
- **Transfer**: As the state-of-the-art approach to incorporating contextual information in sentence-level emotion classification (Xu et al., 2012), this approach utilizes the label transformation probability to refine the classification results.
- **DFG-label (Neighbor)**: Our DFG approach with the context dependence only. Specifically, the neighboring instances are considered as context.
- **DFG-label (Paragraph)**: Our DFG approach with the context dependence only. Specifically, the instances in the same paragraph are considered as context.
- **DFG-label (Document)**: Our DFG approach with the context dependence only. Specifically, the instances in the same document are considered as context.

Figure 7 compares the performance of different approaches to sentence-level emotion classification with the context dependence only. From this figure, we can see that our DFG approach consistently improves the state-of-the-art in all three kinds of evaluation metrics, i.e., 6.1% reduction in *Hloss*, 6.5% increase in *Accuracy*, and 3.1% increase in *F1* when the neighboring instances are considered as context. Among the three kinds of context, the neighboring setting performs best. We also find that using the whole document as the context is not helpful and it performs even worse than the baseline approach. Compared to the state-of-the-art Transfer approach, our DFG approach with the neighboring context dependence is much superior. Significant test show that our DFG approach with the neighboring context dependence significantly outperforms the baseline approach and the state-of-the-art LabelD approach (*p*-value<0.01).

5.4 Experimental Results with Both Label and Context Dependence

Table 3 shows the performance of our DFG approach with both label and context dependence, denoted as DGF-both. From this table, we can see that using both label and context dependence further improves the performance.

Figure 8 shows the performance of our DGF-both approach when different sizes of training data are used to train the model. From this figure, we can see that incorporating both the label and context dependence consistently improves the performance with a large margin, irrespective of the amount of training data available.

Table 3: Performance of our DFG approach with both label and context dependence

	Hloss	*Accuracy*	*F1*
Baseline	0.447	0.378	0.261
DFG-label	0.254	0.621	0.372
DFG-context	0.416	0.443	0.292
DFG-both	**0.242**	**0.634**	**0.379**

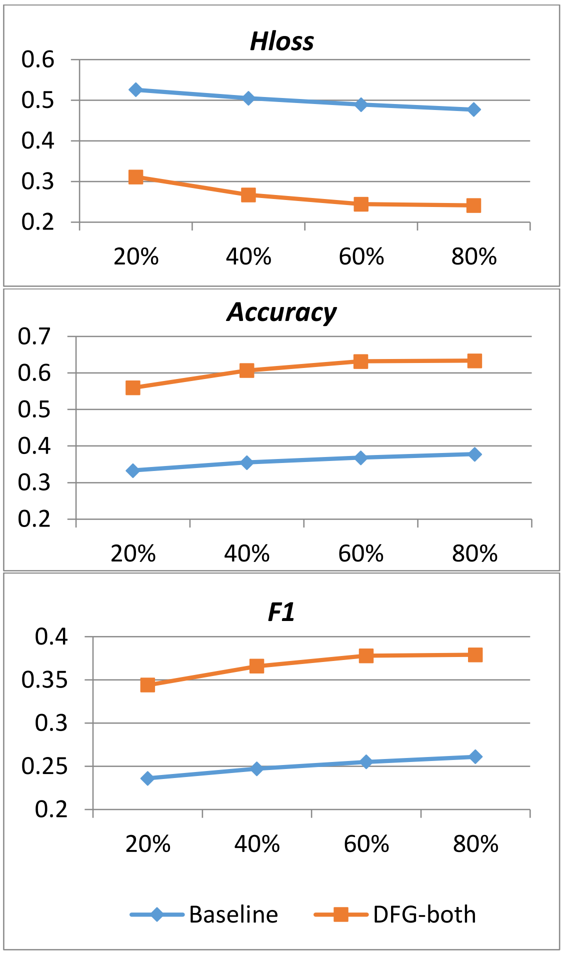

Figure 8: Performance of our DGF-both approach when different sizes of training data are used

6 Conclusion

In this paper, we propose a novel approach to sentence-level emotion classification by incorporating both the label dependence among the emotion labels and the context dependence among the contextual instances into a factor graph, where the label and context dependence is modeled as various factor functions. Empirical evaluation shows that our DFG approach performs significantly better than the state-of-the-art.

In the future work, we would like to explore better ways of modeling the label and context dependence and apply our DFG approach in more applications, e.g. micro-blogging emotion classification.

Abstract

A review text is normally represented as a bag-of-words (BOW) in sentiment classification. Such a simplified BOW model has fundamental deficiencies in modeling some complex linguistic phenomena such as negation. In this work, we propose a dual-view co-training algorithm based on dual-view BOW representation for semi-supervised sentiment classification. In dual-view BOW, we automatically construct antonymous reviews and model a review text by a pair of bags-of-words with opposite views. We make use of the original and antonymous views in pairs, in the training, bootstrapping and testing process, all based on a joint observation of two views. The experimental results demonstrate the advantages of our approach, in meeting the two co-training requirements, addressing the negation problem, and enhancing the semi-supervised sentiment classification efficiency.

1 Introduction

In the past decade, there has been an explosion of user-generated subjective texts on the Internet in forms of online reviews, blogs and microblogs. With the need of automatically identifying sentiments and opinions from those online texts, sentiment classification has attracted much attention in the field of natural language processing.

Lots of previous research focused on the task of supervised sentiment classification. However, in some domains, it is hard to obtain a sufficient amount of labeled training data. Manual annotation is also very expensive and time-consuming. To address this problem, semi-supervised learning approaches were employed in sentiment classification, to reduce the need for labeled reviews by taking advantage of unlabeled reviews.

The dominating text representation method in both supervised and semi-supervised sentiment classification is known as the bag-of-words (BOW) model, which is difficult to meet the requirements for understanding the review text and dealing with complex linguistic structures such as negation. For example, the BOW representations of two opposite reviews “It works well” and “It doesn’t work well” are considered to be very similar by most statistical learning algorithms.

In supervised sentiment classification, many approaches have been proposed in addressing the negation problem (Pang et al., 2002; Na et al., 2004; Polanyi and Zaenen , 2004; Kennedy and Inkpen, 2006; Ikeda et al., 2008; Li et al., 2010b; Orimaye et al., 2012; Xia et al., 2013). Nevertheless, in semi-supervised sentiment classification, most of the current approaches directly apply standard semi-supervised learning algorithms, without paying attention to appropriate representation for review texts. For example, Aue and Gamon (2005) applied the naïve Bayes EM algorithm (Nigam et al., 2000). Goldberg and Zhu (2006) applied a graph-based semi-supervised learning algorithm by (Zhu et al., 2003). Wan (2009) employed a co-training approach for cross-language sentiment classification. Li et al. (2010a) employed co-training with personal and impersonal views. Ren et al. (2011) explored the use of label propagation (Zhu and Ghahramani, 2002).

As pointed by (Goldberg and Zhu, 2006): it is necessary to investigate better review text representations and similarity measures based on linguistic knowledge, as well as reviews’ sentiment patterns. However, to the best knowledge, such investigations are very scarce in the research of semi-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1054–1063,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

supervised sentiment classification.

In (Xia et al., 2013), we have developed a dual sentiment analysis approach, which creates antonymous reviews and makes use of original and antonymous reviews together for supervised sentiment classification. In this work, we propose a dual-view co-training approach based on dual-view BOW representation for semi-supervised sentiment classification. Specifically, we model both the original and antonymous reviews by a pair of bags-of-words with opposite views. Based on such a dual-view representation, we design a dual-view co-training approach. The training, bootstrapping and testing processes are all performed by observing two opposite sides of one review. That is, we consider not only how positive/negative the original review is, but also how negative/positive the antonymous review is.

In comparison with traditional methods, our dual-view co-training approach has the following advantages:

- Effectively address the negation problem;
- Automatically learn the associations among antonyms;
- Better meet the two co-training requirements in (Blum and Mitchell, 1998).

2 Related Work

The mainstream of the research in sentiment classification focused on supervised and unsupervised learning tasks. In comparison, semi-supervised sentiment classification has much less related studies. In this section, we focus on reviewing the work of semi-supervised sentiment classification.

Aue and Gamon (2005) combined a small amount of labeled data with a large amount of unlabeled data in target domain for cross-domain sentiment classification based on the EM algorithm. Goldberg and Zhu (2006) presented a graph-based semi-supervised learning algorithm (Zhu et al., 2003) for the sentiment analysis task of rating inference. Dasgupta and Ng (2009) proposed a semi-supervised approach to mine the unambiguous reviews at first and then exploiting them to classify the ambiguous reviews, via a combination of active learning, transductive learning and ensemble learning. Ren et al. (2011) explored the use of label propagation (LP) (Zhu and Ghahramani, 2002) in building a semi-supervised sentiment classifier, and compared their results with Transductive SVMs(T-SVM). LP and T-SVM are transductive learning methods where the test data should participate in the training process.

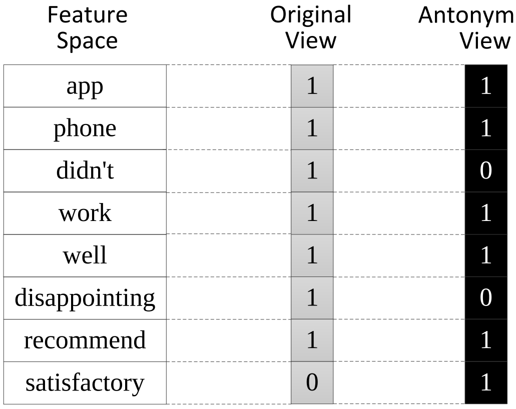
Zhou et al. (2010) proposed a deep learning approach called active deep networks to address semi-supervised sentiment classification with active learning. Socher et al. (2012) introduced a deep learning framework called semi-supervised recursive autoencoders for predicting sentence-level sentiment distributions. The limitation of deep learning approaches might be their dependence on a considerable amount of unlabeled data to learn the representations and the inability to explicitly model the negation problem.

One line of semi-supervised learning research is to bootstrap class labels using techniques like self-training, co-training and their variations. Wan (2009) proposed a co-training approach to address the cross-lingual sentiment classification problem. They made use of the machine translation service to produce two views (a English view and a Chinese view) for co-training a Chinese review sentiment classifier, based on English corpus and unlabeled Chinese corpus. Li et al. (2010a) proposed an unsupervised method at first to automatically separate the review text into a personal view and an impersonal view, based on which the standard co-training algorithm is then applied to build a semi-supervised sentiment classifier. Li et al. (2011) further studied semi-supervised learning for imbalanced sentiment classification by using a dynamic co-training approach. Su et al. (2012) proposed a multi-view learning approach to semi-supervised sentiment classification with both feature partition and language translation strategies (Wan , 2009). Following (Li et al., 2010a), Li (2013) proposed a co-training approach which exploits subjective and objective views for semi-supervised sentiment classification. Our approach can also be viewed as a variation of co-training. The innovation of our approach is the dual-view construction technique by incorporating antonymous reviews and the bootstrapping mechanism by observing two opposite sides of one review.

3 The Proposed Approach

3.1 Dual-view BOW Representation for Review Texts

Every coin has two sizes. In this work, we are motivated to automatically construct the antonymous reviews, consider the original and antonymous reviews as two opposite sides of one review, and rep-



Feature Space	Original View	Antonymous View
app	1	1
phone	1	1
didn't	1	0
work	1	1
well	1	1
disappointing	1	0
recommend	1	1
satisfactory	0	1

Figure 1: An illustration of the dual-view BOW representation. The feature vector with black font color and grey background denotes the original view; while the one with white font color and black background denotes the reversed antonymous view.

resent them in pairs by a dual-view BOW model.

Look at the following example:

> **Original Review**: "The app doesn't work well on my phone. Disappointing. Don't recommend it."
>
> **Antonymous Review**: "The app works well on my phone. Satisfactory. Recommend it."

Given an original review, its antonymous review is automatically created as follows[1]: 1) We first detect the negations in each subsentence of the review text; 2) If there is a negation, we remove negators in that subsentence; 3) Otherwise, we reverse all the sentiment words in the subsentence into their antonyms, according to a pre-defined antonym dictionary[2].

We subsequently use a dual-view BOW model to represent such a pair of reviews, as shown in Figure 1. The original and antonymous reviews will be used in pairs in our dual-view semi-supervised learning approach. As we determine the sentiment of one review, we could observe not only the original view, but also the antonymous view.

Figure 2: The process of dual-view co-training. Again, the white font color and black background are used to denote the antonymous view.

It is important to notice that the antonymous view removes all negations and incorporates antonymous features. On this basis, we design a dual-view co-training approach. We will introduce our approach in detail in Section 3.2, and analyze its potential advantages in Section 3.3.

3.2 The Dual-view Co-training Approach

Since the original and antonymous views form two different views of one review text, it is natural to employ the co-training algorithm, which requires two views for semi-supervised classification.

Co-training is a typical bootstrapping algorithm that first learns a separate classifier for each view using the labeled data. The most confident predictions of each classifier on the unlabeled data are then used to construct additional labeled training data iteratively. Co-training has been extensively used in NLP, including statistical parsing (Sarkar , 2001), reference resolution (Ng and Cardie, 2003), part-of-speech tagging (Clark et al., 2003), word sense disambiguation (Mihalcea, 2004), and sentiment classification (Wan , 2009; Li et al., 2010a).

But it should be noted that the dual views in our approach are different from traditional views. One important property of our approach is that two views are opposite and therefore associated with opposite class labels. Figure 2 illustrates the process of dual-view co-training.

[1] It is worth noting that our emphasis here is not to generate natural-language-like review texts. Since either the original or the created antonymous review will be represented as a vector of independent words in the BOW model, the grammatical requirement is not as strict as that in human languages.

[2] In our experiments, we extract the antonym dictionary from the WordNet lexicon `http://wordnet.princeton.edu/`.

(1) Dual-view training

For each instance in the initial labeled set, we construct the dual-view representations. Let x_o^l and x_a^l denote the bags of words in the original view and the antonymous view, respectively. Note that the class labels in two views are kept opposite: $y_a^l = 1 - y_o^l$ $(y \in \{0, 1\})$. That is, we reverse the class label in the original view (i.e., positive to negative, or vice versa), as the class label of the created antonymous view.

Suppose $\mathcal{L}$ is the labeled set, with $\mathcal{L}_o$ and $\mathcal{L}_a$ denoting the original-view and antonymous-view labeled sets, respectively. We train two distinct classifiers: the original-view classifier h_o and the antonymous-view classifier h_a , based on $\mathcal{L}_o$ and $\mathcal{L}_a$, respectively. We further train a joint classifier by using $\mathcal{L}_o$ and $\mathcal{L}_a$ together as the training data, and refer to it as h_d.

(2) Dual-view bootstrapping

In standard co-training, we allow each classifier to examine the unlabeled set $\mathcal{U}$ and select the most confidently predicted examples in each category. The selected examples are then added into $\mathcal{L}$, along with the predicted class labels.

In this work, we design a dual-view co-training algorithm to bootstrap the class labels by a joint observation of two sides of one review. Specifically, we propose a new bootstrapping mechanism, based on a principle called **dual-view sentiment consensus**. Given an unlabeled instance $\{x_o^u$, $x_a^u\}$, dual view sentiment consensus requires that, the original prediction y_o^u and the antonymous prediction should be opposite: $y_a^u = 1 - y_o^u$. In other words, we only select the instances of which the original prediction is positive/negative, and the same time the antonymous prediction is negative/positive. To increase the degree of sentiment consensus, we further require that the predition y_d^u of h_d should be the same as y_o^u.

We sort all unlabeled instances according to the dual-view predictions in each class, filter the list according to the dual-view sentiment consensus principle, and add the top-ranked s instances in each class to the labeled set. For each selected unlabeled instance, its original view x_o^u is added into $\mathcal{L}_o$ with class label y_o^u; and the antonymous view x_a^u is added into $\mathcal{L}_a$, with an opposite class label $y_a^u = 1 - y_o^u$. When $\mathcal{L}_o$ and $\mathcal{L}_a$ receive the supplemental labeled instances, we update h_o and h_a.

Our bootstrapping mechanism differs from the traditional methods in two major aspects: First, in traditional co-training, given the same instance, the class labels in two views are the same. But in our approach, the class labels in two views need to be opposite. Second, in traditional co-training, the most confidently predicted examples in each view are selected to extend the amount of labeled data. It is dangerous to believe the confident but incorrect predictions. While in our approach, the candidates are further filtered by the principle of dual-view sentiment consensus. In this way, the labeling accuracy and learning efficiency can be improved.

(3) Dual-view testing

Finally, in the testing stage, standard co-training uses a joint set of features in two views to train the classifier. In dual-view testing, we use h_o and h_a to predict the test example in two views, and make the final prediction by considering both sizes of the review.

Given a test example x^{te} with its original view denoted by x_o^{te} and antonymous view denoted by x_a^{te}, let $p_o(\cdot|x_o^{te})$ be the posterior probability predicted by the original-view classifier h_o, and $p_a(\cdot|x_a^{te})$ be the posterior probability predicted by h_a. The dual-view testing process can be formulated as follows:

$$p(+|x^{te}) = p(+|x_o^{te}, x_a^{te}) = \frac{p_o(+|x_o^{te}) + p_a(-|x_a^{te})}{2};$$

$$p(-|x^{te}) = p(-|x_o^{te}, x_a^{te}) = \frac{p_o(-|x_o^{te}) + p_a(+|x_a^{te})}{2}.$$

That is, the final positive score is assigned by measuring not only how positive the original review is, but also how negative the antonymous one is; the negative score is assigned by measuring not only how positive the original review is, but also how negative the antonymous one is.

3.3 Advantages of Dual-view Co-training

Our proposed dual-view co-training approach has the following three advantages.

(1) Effectively address the negation issue

We use the antonymous review as a view to effectively address the negation issue. Let us revisit the example in Section 3.1 and assume that the original review (i.e., "The app doesn't work well on my phone. Disappointing. Do not recommend it.") is an unlabeled sample. Because the traditional

BOW model cannot well represent negative structures, the review is likely to be incorrectly labeled as positive and then added into the labeled set.

In our proposed approach, the antonymous review (i.e., "The app works well on my phone. Satisfactory. Recommend it.") removed all the negative structures, and is thus more suited for the BOW representation. In this example, the antonymous review is also likely to be marked as positive. Hence, in this case, both the original review and its antonymous review will be labeled as positive, which violates the principle of dual-view sentiment consensus as mentioned in Section 3.2. As a result, the unlabeled instance will not be added into the labeled set.

Therefore, our approach can overcome the limitations of the conventional methods in addressing the negation issue and reduce the labeling error rate (caused by the negative structures) during the bootstrapping process.

(2) Automatically learn the associations among antonyms

In semi-supervised sentiment classification, only limited association information between the words and categories can be obtained from a small number of initial labeled data.

For instance, in the above example "disappointing" and "satisfactory" are a pair of antonyms. From the initial labeled data, we may only learn that "disappointing" is derogatory, but we cannot infer that "satisfactory" is commendatory.

During the bootstrapping process in our approach, when constructing the dual view representation, the original view and its antonymous view are required to have opposite class labels. Hence we can automatically infer the relationship between "satisfactory" and "disappointing" (e.g., one is positive and one is negative), thereby improving the learning efficiency of the system.

(3) Better meet two co-training requirements

Compared with traditional methods, our dual-view co-training can better meet the two co-training requirements: 1) sufficient condition (i.e., each view is sufficient for classification); 2) complementary condition (i.e., the two views are conditionally independent).

First, for the sufficient condition, we use a different view construction method. Most traditional methods construct the two views by feature partitioning (i.e., dividing the original feature set into two subsets), while we use data expansion by generating antonymous reviews. We will demonstrate in the experimental section (Section 4.6), that our data expansion method can construct better views than the feature partition method in terms of predicting the class labels from individual views.

Second, as we know, every coin has two sides and the two sides are often complementary. In our proposed approach, the original review and its antonymous review (i.e., two sides of one review) are used as two views for co-training and they can better meet the complementary condition. We will illustrate this point in Section 4.6 by calculating the KL divergence between the two views.

4 Experimental Study

4.1 Datasets and Experimental Settings

We conduct the experiments on the multi-domain sentiment datasets, which were introduced in (Blitzer et al., 2007) and have been widely used in sentiment classification. It consists of four domains (Book, DVD, Electronics, and Kitchen) of reviews extracted from Amazon.com. Each of the four datasets contains 1,000 positive and 1,000 negative reviews. Following the experimental settings used in (Li et al., 2010a), we randomly separate all the reviews in each class into a labeled data set, a unlabeled data set, and a test set, with a proportion of 10%, 70% and 20%, respectively. We report the averaged results of 10-fold cross-validation in terms of classification accuracy.

Note that our approach is a general framework that allows different classification algorithms. Due to the space limitation, we only report the results by using logistic regression[3]. Note the similar conclusions can be obtained by using the other algorithms such as SVMs and naïve Bayes. The LibLinear toolkit[4] is utilized, with a dual L2-regularized factor, and a default tradeoff parameter c. Similar to (Wan , 2009; Li et al., 2010a), we carry out the experiments with the unigram features without feature selection. Presence is used as the term weighting scheme as it was reported in (Pang et al., 2002) that it performed better than TF and TF-IDF. Finally, the paired t-test (Yang and Liu , 1999) is performed to test the significance of the difference be-

[3] Logistic regression is quite similar to Maximum Entropy, and has been proved to be more efficient in sentiment classification than some other classification algorithms including naïve Bayes and SVMs (Pang et al., 2002).

tween two systems, with a default significant level of 0.05.

4.2 Compared Systems

We implement the following nine systems and compare them with our approach:

- **Baseline**, the supervised baseline trained with the initial labeled data only;
- **Expectation Maximization (EM)**, with the naïve Bayes model proposed by Nigam et al. (2000);
- **Label Propagation (LP)**, a graph-based semi-supervised learning method proposed by Zhu and Ghahramani (2002);
- **Transductive SVM (T-SVM)**, an extension of SVM so that it can exploit unlabeled data in semi-supervised learning (Joachims, 1999);
- **Self-Training**, a bootstrapping model that first trains a classifier, uses it to classify the unlabeled data, and adds the most confident data to the labeled set;
- **Self-Reserved**, a variation of self-training proposed in (Liu et al., 2013),with a reserved procedure to incorporate some less confident examples;
- **Co-Static**, the co-training algorithm by using two static partitions of feature set as two views (Blum and Mitchell, 1998);
- **Co-Dynamic**, a variation of co-training that uses dynamic feature space in each loop. It was reported in (Li et al., 2011) that the Co-Dynamic significantly outperforms Co-Static significantly;
- **Co-PI**, another variation of co-training proposed by (Li et al., 2010a), by using personal and impersonal views for co-training.

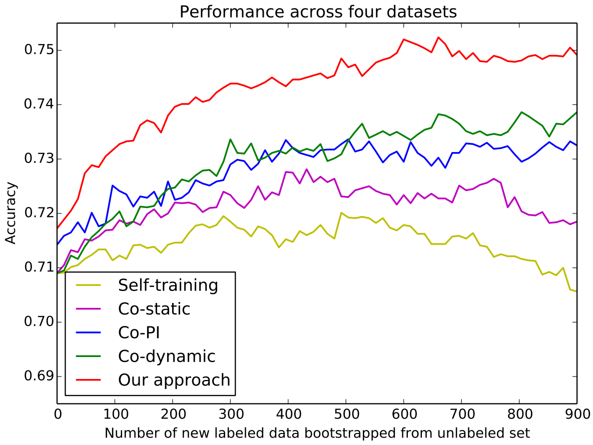

Figure 3: Comparsion of different boostrapping methods.

4.3 Performance Comparison

In table 1, we report the semi-supervised classification accuracy of ten evaluated systems. We report the results with 200 labeled, 1400 unlabeled and 400 test reviews. Note that the similar conclusions can be obtained when the size of the initial labeled data changes. We will discuss its influence later.

As can be seen, trained with only 200 labeled data, the supervised baseline yields an average accuracy of 0.709. Self-training gains an improvement of 1.1%. Self-reserved does not show significant priority against Self-training. Three co-training systems (Co-static, Co-dynamic and Co-PI) get significant improvements. They increase the supervised baseline by 2.0%, 2.8% and 2.4%, respectively.

It is somehow surprising that T-SVM and LP do not outperform the supervised baseline, probably because the supervised baseline is obtained by logistic regression, which was reported to be more effective than SVMs in sentiment classification (the supervised result of SVMs is 0.695).

Our proposed approach significantly outperforms all the other methods. It gains the improvement over the supervised baseline, Self-training, Co-static, Co-dynamic and Co-PI by 4.3%, 3.2%, 2.3%, 1.5% and 1.9%, respectively. All of the improvements are significant according to the paired *t*-test.

4.4 Comparison of Bootstrapping Methods

In Figure 3, we further compare five bootstrapping methods by drawing the accuracy curve dur-

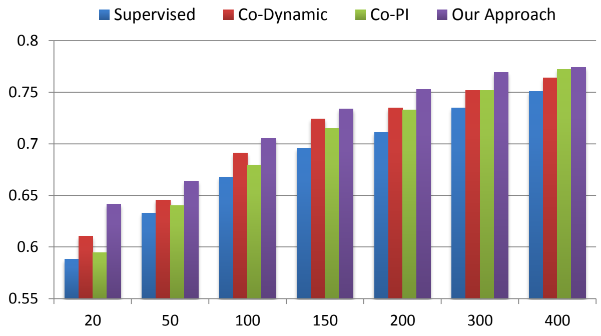

Figure 4: Influence of the size of initial labeled data.

ing the bootstrapping process. The x-axis denotes the number of new labeled data bootstrapped from the unlabeled data.

We can roughly rank five bootstrapping methods as follows: Our approach ≫ Co-dynamic > Co-PI > Co-static ≫ Self-training. Self-training gives the worst performance. Co-static works better but the effect is limited. Co-PI and Co-dynamic are significantly better. Our proposed approach outperforms the other systems robustly, along with the increased number of the new labeled data. It suggests that our approach is very efficient in bootstrapping the class labels from the unlabeled data.

4.5 Influence of the Size of the Initial Labeled Set

The above results are obtained with 200 labeled, 1400 unlabeled and 400 test reviews. We now tune the size of the initial labeled set (from 20 to 400), and report its influence in Figure 4. For all the settings, we fix the size of test set as 400. The x-axis denotes the number of initial labeled set. For example, “20” denotes the setting of 20 labeled and 1580 unlabeled data.

We can observe that our all methods improve as the initial size increases. But the improvements become limited when the size becomes larger. When the initial size is 400, the semi-supervised performance is close to the golden result obtained by the supervised classifier trained with all 1600 labeled data.

Our approach performs consistently the best across different sizes of the initial sizes. The smaller the initial size is, the more improvements our approach can gain, in comparison with the other methods. This confirms our analysis in Section 3.3 that the technique of dual-view construction is very effective to boost the semi-supervised classification performance, especially when the size of the initial labeled set is small.

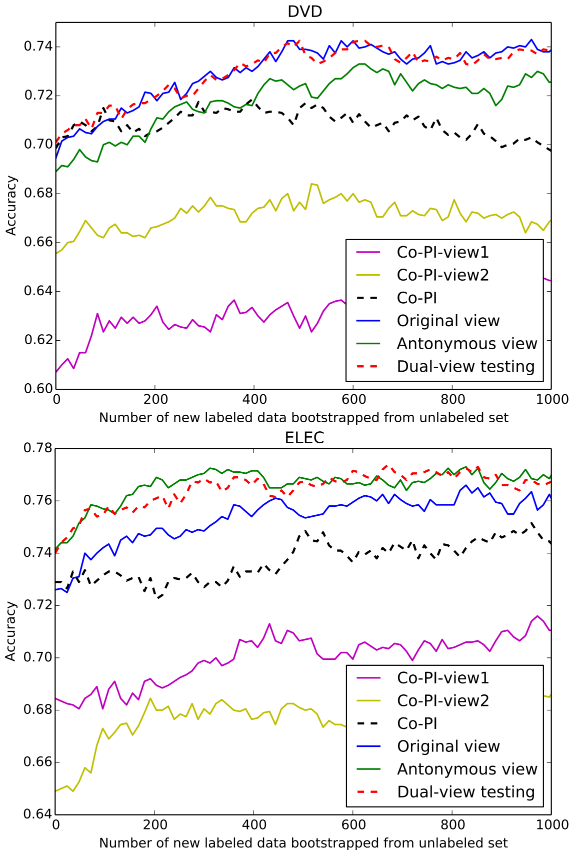

Figure 5: Comparison of different views on the DVD and Electronics datasets.

4.6 Discussion on the Two Co-training Requirements

Ideally, co-training requires that each view is sufficient for classification (sufficient condition) and two views provide complementary information of the instance,(complementary condition).In this section, we answer the following question empirically: whether our approach could meet the two requirements?

(1) Sufficient condition

In Figure 5, we report the classification performance obtained by the classifiers trained with distinct views and compared them with the two views in Co-PI, on the DVD and Electronics datasets. The observation in Book is similar to that in Electronics; the observation in DVD is similar to that in Kitchen.

Seen from Figure 5, the classification performance of both the original-view and antonymous-view classifiers are satisfactory. It shows that in our approach, each individual view is sufficient to predict the sentiment. In comparison with the two views in Co-PI (i.e., the personal and impersonal views), two views in our approach perform significantly better.

As has been mentioned in Section 3.3, in traditional methods, such as Co-PI and Co-dynamic, two views are created by data partition (or feature partition). In comparison, the two views in our approach are constructed in a manner of data expansion. By creating a new antonymous view, our approach can provide more sufficient information of the reviews than traditional methods.

(2) Complementary condition

Since we have not found a direct measure of the complementarity of two views, we instead calculate the Kullback-Leibler (KL) divergence between them, based on an assumption that two views with higher KL divergence can provide more complementary information of the instance.

KL divergence is a widely used metric of statistical distance. We assume that distribution of the review text is multinomial, and calculate the K-L divergence between two views as follows:

$$D_{KL}(p||q) = \sum_{i=1}^{V} p_i \log\left(\frac{p_i}{q_i}\right)$$

where p_i and q_i are the probabilities of word appearing in two views, respectively. In our experiments, we use information gain (IG) to select a set of discriminative words with the dimension $V = 2000$.

In Table 2, we report the results of three different methods: 1) dataset random partition; 2) personal and impersonal views in Co-PI; 3) original and antonymous views in our approach. We can observe from Table 2 that, random partition has the lowest KL divergence. It shows that the distributional distance between two randomly partitioned views is very small. Co-PI is a higher value, but it still does not have significant difference in two views. By contrast, the KL divergence between the original view and the antonymous view is much higher than both random partition and Co-PI. It demonstrates that the distributions of two views in our approach are significantly different. We thereby infer that the two views constructed in our approach can provide more complementary information than traditional methods. It is reasonable since the antonymous view incorporates the antonyms that might have not appeared in the original view (e.g., “satisfactory” in the example in Section 3.2). These features might provide new information about the instance.

	KL divergence
Random Partition	2.43
Co-PI	4.59
Our approach	12.33

Table 2: The average KL divergence between two views across four datasets.

4.7 The Effect of Dual-view Testing

In Figure 5, we can further observe the effect of dual-view testing. On the Electronics dataset, the antonymous view performs better than the original view. This suggests the advantage of the antonymous view, as it removes the negations and thus is more suitable for the BOW representation. On the DVD dataset, the original view is slightly better. This is also reasonablel, because the antonymous review is automatically created and its quality might be limited in some cases. By taking two opposite views into a joint consideration, our dual-view testing technique guarantees a satisfactory classification performance across different datasets.

Note that in the current version, the original-view and antonymous-view classifiers have the same predicting weight. We believe that by learning the tradeoff between two views in different settings may further improve our approach’s performance. For example, if the original view on the Electronics dataset gets a relatively larger weight, dual-view testing might gain more improvements.

5 Conclusions

In this work, a review text is represented by a pair of bags-of-words with opposite views (i.e., the original and antonymous views). By making use of two views in pairs, a dual-view co-training algorithm is proposed for semi-supervised sentiment classification. The dual-view representation is in a good accordance with the two co-training requirements (i.e., sufficient condition and complementary condition). The experimental results demonstrate the effect of our approach, in addressing the negation problem and enhancing the bootstrapping efficiency for semi-supervised sentiment classification.

Abstract

This paper tackles the issue of the detection of user's verbal expressions of likes and dislikes in a human-agent interaction. We present a system grounded on the theoretical framework provided by (Martin and White, 2005) that integrates the interaction context by jointly processing agent's and user's utterances. It is designed as a rule-based and bottom-up process based on a symbolic representation of the structure of the sentence. This article also describes the annotation campaign – carried out through Amazon Mechanical Turk – for the creation of the evaluation dataset. Finally, we present all measures for rating agreement between our system and the human reference and obtain agreement scores that are equal or higher than substantial agreements.

1 Introduction

In the research field of the embodied conversational agents (ECA), detecting sentiment-related phenomena [1] appears as a key task to improve human-agent interactions and to build long-term social relationships (Pecune et al., 2013). Several models and applications have been proposed which mostly take into account non-verbal cues (acoustic features, facial or bodily expressions) to determine the user's emotions (Schuller et al., 2011). The verbal content is more and more integrated but still partially exploited in human-agent interactions. The very infrequent works, integrating the detection of user's sentiments in ECAs based on linguistic cues, concern avatars and visualisation issues rather than face-to-face interaction, (Zhang et al., 2008; Neviarouskaya et al., 2010b). We identify so far two studies that integrate a sentiment detection module for human-agent interaction (Smith et al., 2011; Yildirim et al., 2011).

However, the research field of sentiment analysis and opinion mining provides a set of interesting works dealing with the subjective information conveyed by the verbal content. Three types of approaches are considered: machine-learning, rule-based approaches and hybrid approaches that are a combination of the first two types. Machine learning methods have proven their worth for the positive and negative classification of sentences or texts (Pang and Lee, 2008). Rule-based approaches are grounded on syntactic and semantic analyses of the sentence and provide deeper analyses of sentiment-related phenomena. For example, (Neviarouskaya et al., 2010a) and (Moilanen and Pulman, 2007) provide linguistic rules dealing with the principle of compositionality in order to improve the detection of opinion targets and the resolution of polarity. Similarly, (Shaikh et al., 2009) provide a linguistic adaptation of the OCC model (Ortony, Clore and Collins (Ortony et al., 1990) based on logic and semantic rules. Hybrid approaches also begin to be used for more fine-grained opinion and sentiment analysis (Yang and Cardie, 2013)

Sentiment/opinion detection methods used in human-agent interaction are rare and, when they are employed, they are not different from the ones used in opinion mining: they are consequently not designed for socio-affective interactions. Indeed, the development of a module for the detection of sentiment-related phenomena in face-to-face human-agent interactions requires to tackle

[1] The term *sentiment-related phenomena* is used in (Clavel et al., 2013) to regroup all the phenomena related to sentiment in the literature, from opinion to affect and emotion.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1064–1073,

various scientific issues: the delimitation of the relevant sentiment-phenomenon to detect, the integration of the multi-modal context and the management of the spontaneous and conversational speech.

The present paper tackles two of the issues: the integration of the conversational context and the delimitation of the relevant phenomenon. Regarding the first issue, we propose a system relying on a rule-based method that allows us to model the agent's utterances in order to help the detection of user's sentiment-related phenomena.

Then, we delimit and specify the linguistic phenomenon to detect by focusing on one specific aspect required by ECAs for modelling social relationships: the user's likings that are given by the expressions of user's likes and dislikes in the verbal content.

This paper is organised as follows: first, we present the theoretical model which our system is grounded on (Section 2). Then, we provide a description of the system: each stage of the bottom-up process is described, including the linguistic rules and the patterns used by the system. In Section 4, we introduce the annotation campaign we launched on Amazon Mechanical Turk (AMT) in order to create a data-set for the evaluation of our system. Finally, we present and discuss the results of the system evaluation (Section 5).

2 Theoretical background

The *liking* is one of the key dimensions used for the modelling of social relationships (Pecune et al., 2013). The definition of this concept is grounded on the Heider's *Balance Theory* (Heider, 1958) and is defined as: "the way relations among persons involving some impersonal entity are cognitively experienced by the individual" (Zajonc, 1960). Heider's theory is integrated in social agent computational models by defining scenarios where the agent and the user's likings toward each other are determined by their liking toward other entities (things, process or events). In such scenarios, the analysis of user's verbal content has a key role as a major source of information for determining of the user's likes and dislikes. Therefore, a linguistic description of this phenomenon is required to design a detection system.

In the research field of *Opinion Mining* and *Sentiment Analysis*, the majority of opinion/sentiment detection systems focus on the positive/negative distinction or on the classification of a restricted number of emotion categories. Other in-depth approaches, as (Wiebe et al., 2005; Breck et al., 2007), refer to the Private State Theory, which defines mental states as involving opinions, beliefs, judgements, appraisals and affects. Beside those models, the model proposed by (Martin and White, 2005) is increasingly used in several works (Neviarouskaya et al., 2010a; Bloom et al., 2007; Whitelaw et al., 2005). This model provides a linguistic description and a focus on the verbal expressions of sentiment and opinion and proposes a complex framework, for describing how *attitudes* are expressed in English. It distinguishes affects – which are concerned with emotional reactions – from judgements and appreciations – which relate to evaluations toward people's behaviours and semiotic or natural phenomena. Finally, it models attitudinal expressions as relying on three elements: a source, the person evaluating or experiencing, a target, the entity which is evaluated or which triggers an affect and a linguistic clue expressing the evaluation.

In this model, likes and dislikes can be considered as a subcategory of the *Attitudes*. This subcategory overlaps the three categories (affect, judgment, appreciation) defined by (Martin and White, 2005). For example, the sentence *"This painting makes me sad"* is considered as an affect, while the sentence *"This painting is a master-work"* is considered as an appreciation. But, in both cases, we can consider them as a user's like. However, among the expressions of attitudes where the source is the user, some of them do not refer to a like or dislike. For example, *"I'm very happy"* refers to an affect and does not give any clue regarding a possible like or dislike. Thus, a selection of relevant attitudes have to be done. The rules used for this selection are presented in the next section.

3 A rule-based and symbolic method

On the basis of the Martin and White's model described in the previous section, we design a system able to detect expressions of attitudes corresponding to the user's likes and dislikes. It is grounded on linguistic rules modelling the syntactic and semantic structure of the sentences.

3.1 Integrating the interaction context

The system presented in Figure 1 successively processes each adjacency pair (AP) of the dialogue

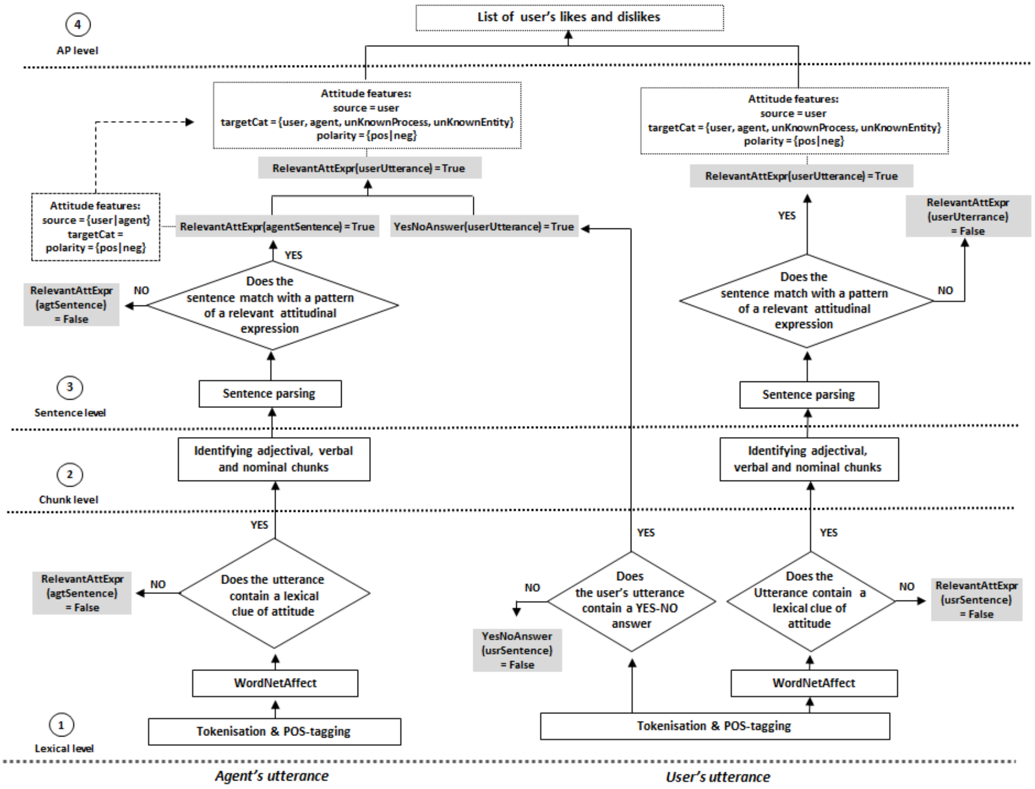

Figure 1: Process overview

(Sacks et al., 1974), i.e. each user's speech turn and the agent's one immediately preceding it. We aim to detect two kinds of user's attitudinal expressions that can occur during the interaction: the first ones which are spontaneous and do not depend on the agent's sentence (Agent: *What did you do today?* User: *I saw a great movie*); and the second ones which are triggered by the agent's sentence (Agent: *Do you like outdoors activities?* User: *Yeah very much*).

In the last case, the detection of the attitude expressed in the agent's sentence appears as a necessary step for the detection of the user's ones. This detection has to be done in an automatic way as, in the agent platform we use (the Greta platform, (Bevacqua et al., 2010), the agent's speech turns are not automatically generated but scripted. Thus, we cannot obtain the linguistic and semantic information about attitude by using the generation data. Furthermore, in order to make the dialogue setting as light as possible, it is not possible to script such values for each agent's sentence.

3.2 A bottom-Up process

The relevant expressions of attitudes are detected by using a bottom-up and rule-based process, which launches successively the different levels of analysis: lexical level, chunk level, sentence level. These three stages comprise formal grammars, which are implemented within the Unitex plateform (Paumier, 2015). During these various stages, values are assigned to the three boolean variables which are finally used to decide whether the user is expressing a like or a dislike: $RelevantAttExpr(agtSentence)$, $RelevantAttExpr(usrSentence)$, $YesNoAnswer(usrSentence)$.

3.2.1 Lexical level

After a tokenisation and a POS-tagging, the system checks whether the sentence (the user or the agent's one) contains lexical clues of attitudinal expressions. Three parts of speech are taken into account: the nouns, the adjectives and the verbs. We use a re-adaptation of the Wordnet-affect lexicon (Valitutti, 2004). In order to adapt this lexicon to our goal, a selection of relevant lexical entries has to be done. Among all the synsets, we select those which can be linked to like and dislike and that belong to the following main categories: *positive-emotion*, *negative-emotion*, *neutral-emotion*. As the lexi-

	SYNTACTIC PATTERNS	ATTITUDE AND POLARITY RULES
		FOR ALL CHUNK: If the chunk conveys a word labelled as a lexical clue of attitude, it is considered as an attitudinal chunk (ex: ''a very good movie'') ChkNoun(att:true) ; ChkAdj(att:true) ; ChkVb(att:true)
Adjectival chunk	ChkAdj → Adv?, Adj	ChkAdj(att:true, pol:pol$_{Adj}$) As no modifier can shift the polarity of the adjective in the adjectival chunk, the polarity of the adjectival chunk is always equal to the adjective one (.
Nominal chunk	ChkNoun → Det?, ChkAdj?, Noun	If Noun(Pol$_{Noun}$) AND ChkAdj(att:true, pol:inv(Pol$_{Noun}$)): **(i)** if the noun and the adjective have an attitudinal value, and if the their polarity differ, the polarity assigned to the nominal chunk is the same as the adjective (ex: ``performance'', positive, ``bad performance'', negative); If Det == neg : ChkNoun(att:true, pol:inv(Pol$_{Noun}$)) **(ii)** if the determiner has a negative value -- *no*, *any*, for example -- the polarity assigned to the nominal chunk is the opposite of the nominal polarity, otherwise the polarity is the same as the noun (ex: ``any good idea'').
Verbal chunk	ChkVb → Aux?, Vb.	If Neg$_{Verb}$ == True OR Neg$_{Aux}$ == True : ChkVerb(att:true, pol:Pol$_{Noun}$) if the verb or one of its auxiliaries convey a negation, the polarity assigned to the verbal chunk is the opposite of the verbal polarity (ex: ``don't like''), otherwise the polarity is the same as the verb (``like'').

Figure 2: Patterns and polarity rules used for the chunk level

con is applied by the Unitex plateform, we turn the Wordnet-Affect lexicon into a unitex dictionary format. Finally, this transformation provides three dictionaries: one for the nouns, one for the adjectives and one for the verbs. If the lexical processing has found one or several lexical clues of attitude, the system continues the analysis and get to the next stage, else $RelevantAttExpr(X) = False$ and the system quits the analysis of the sentence. Regarding the user's sentence, the system also checks if one or several tokens of sentence match with a yes or a no word, by using a short lexicon manually built which comprises less than ten words for each sentence type. If the test succeeds $YesNoAnswer(usrSentence) = True$, else $YesNoAnswer(usrSentence) = False$.

3.2.2 Chunk level

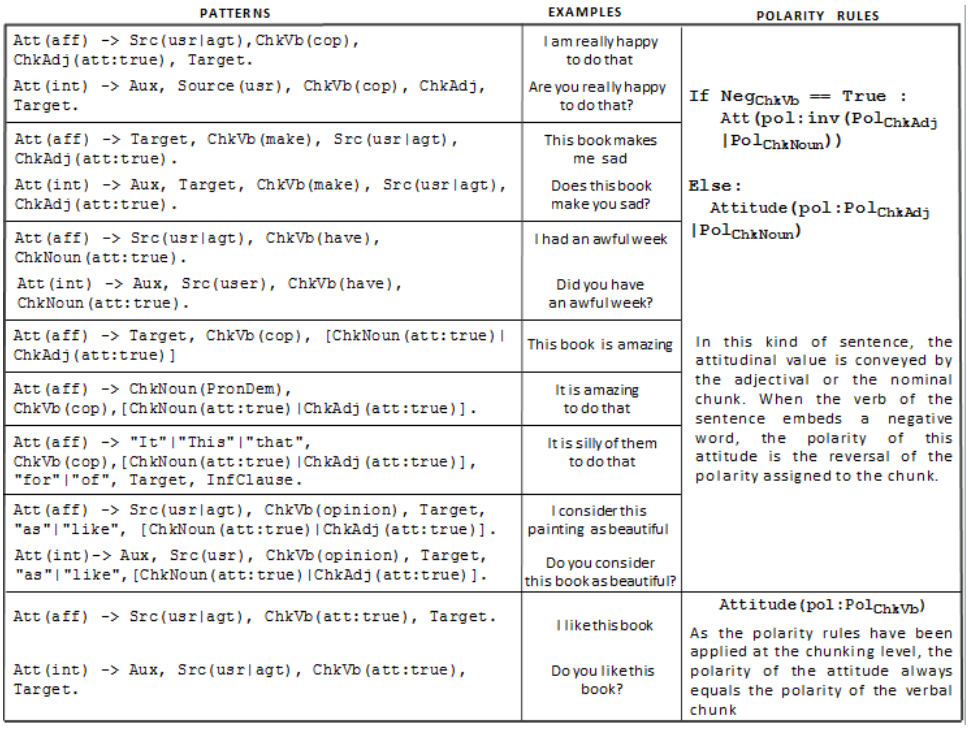
At this level, we design formal grammar – implemented as finite state automatons within the Unitex plateform. Three main chunks are defined: the verbal, the adjectival and the nominal chunks. All these chunks can imply a lexical unit of attitude. In such case, a polarity value is assigned to the entire chunk by applying rules which consider valence shifters and polarity conflict (see Figure 2).

3.2.3 Sentence level

Attitudinal value The system parse of each sentence for checking if the sentence matches with an attitudinal expression, according to its syntactic structure. This parsing phase is grounded on a set of patterns (see Figure 3). Among the attitudinal patterns provided in the literature (Neviarouskaya et al., 2010a; **?**), we selected those expressing a like or dislike according to a previous corpus-based study (Langlet and Clavel, 2014) (development corpus presented in Section 4.1). Depending on the speaker of the processed sentence – the agent or the user – sentence structures can be interrogative or affirmative surface structures. In the agent's sentence, the system looks for both affirmative and interrogative forms, while in the user's sentences, it only takes into account affirmative structures.

Type of the source Simultaneously, the system checks the source of the attitude. The type of a relevant source varies depending on the sentence processed: in the **agent's sentence**, the system aims to detect attitudes able to be validated or invalidated by the user and whose source is either the agent – lexically represented by a first person pronoun ($Src(agt) \rightarrow$ "I"|"me") – or the user – lexically represented by a second person pronoun ($Src(usr) \rightarrow$ "you'); in the **user's sentence**, the system aims to detect only the attitudes whose source is the user – represented by a first person pronoun ($Src(usr) \rightarrow$ "I"|"me").

Target and polarity At this stage, the system is also able to define the polarity of the expression



PATTERNS	EXAMPLES	POLARITY RULES
Att(aff) -> Src(usr|agt),ChkVb(cop), ChkAdj(att:true), Target. Att(int) -> Aux, Source(usr), ChkVb(cop), ChkAdj, Target.	I am really happy to do that Are you really happy to do that?	If Neg$_{ChkVb}$ == True : Att(pol:inv(Pol$_{ChkAdj}$ |Pol$_{ChkNoun}$)) Else: Attitude(pol:Pol$_{ChkAdj}$ |Pol$_{ChkNoun}$) In this kind of sentence, the attitudinal value is conveyed by the adjectival or the nominal chunk. When the verb of the sentence embeds a negative word, the polarity of this attitude is the reversal of the polarity assigned to the chunk.
Att(aff) -> Target, ChkVb(make), Src(usr|agt), ChkAdj(att:true). Att(int) -> Aux, Target, ChkVb(make), Src(usr|agt), ChkAdj(att:true).	This book makes me sad Does this book make you sad?	
Att(aff) -> Src(usr|agt), ChkVb(have), ChkNoun(att:true). Att(int) -> Aux, Src(user), ChkVb(have), ChkNoun(att:true).	I had an awful week Did you have an awful week?	
Att(aff) -> Target, ChkVb(cop), [ChkNoun(att:true)| ChkAdj(att:true)]	This book is amazing	
Att(aff) -> ChkNoun(PronDem), ChkVb(cop),[ChkNoun(att:true)|ChkAdj(att:true)].	It is amazing to do that	
Att(aff) -> "It"|"This"|"that", ChkVb(cop),[ChkNoun(att:true)|ChkAdj(att:true)], "for"|"of", Target, InfClause.	It is silly of them to do that	
Att(aff) -> Src(usr|agt), ChkVb(opinion), Target, "as"|"like", [ChkNoun(att:true)|ChkAdj(att:true)]. Att(int)-> Aux, Src(usr), ChkVb(opinion), Target, "as"|"like",[ChkNoun(att:true)|ChkAdj(att:true)].	I consider this painting as beautiful Do you consider this book as beautiful?	
Att(aff) -> Src(usr|agt), ChkVb(att:true), Target. Att(int) -> Aux, Src(usr|agt), ChkVb(att:true), Target.	I like this book Do you like this book?	Attitude(pol:Pol$_{ChkVb}$) As the polarity rules have been applied at the chunking level, the polarity of the attitude always equals the polarity of the verbal chunk

Figure 3: Patterns and polarity rules used for the sentence level: the second column presents examples of sentences matching with the patterns detailed in the first column. The rules introduced in the third column are applied according to the sentence pattern detected.

by detecting the valence shifters which can modify the polarity of the attitudinal chunk and by applying the appropriate polarity rules described in Figure 3. Regarding the target, the system is only able to assign to the target one of four generic classes. The first two classes concern the two members of the conversation – *agent* and *user*. The third class, called *other*, deals with all entities and processes which are neither the agent or the user. The last one – *unknown* – concerns all the target referring by a pronoun, and whose class – even generic – cannot be known. In a future work, the *other* category could be detailed by using an ontological resource, and *unknown* category by referring to an anaphora resolution.

3.2.4 User's utterance level within the AP

Generating attitude feature set Once the sentence level is done, the $True$ value is assigned to the $relevantAttExpr(usrSentence)$ variable in two steps.

Firstly, the syntactic structure of the user's sentence matches with one of the attitudinal patterns (Figure 3) whose source is the user ($Src(user)$). The feature set of the attitudinal expression is generated according to the information found at the parsing stage: $source \in \{user, agent\}$, $polarity \in \{neg, pos\}$, $targetType \in \{user, agent, other, unknown\}$.

Secondly, if the agent's sentence matches with one of the attitudinal patterns whose source is either the user or the agent ($Src(user|agent)$), then $relevantAttExpr(agtSentence) = True$. In this second case, if $YesNoAnswer(usrSentence) == True$, the user validates or invalidates the attitude. Thus, the system defines $relevantAttExpr(usrSentence) == True$, even if any sentence matching with a relevant pattern has been found in the user's sentence. The feature set associated to the user's attitude is built according to those assigned to the attitudinal expression found is the agent's sentence. Since the user assumes or rejects the attitude expressed by the agent, the system considers that he/she utters an attitudinal expression that he/she is the source. Regarding the polarity, if the user validates the statement expressed by the agent, the polarity of his/her attitude is the same as the agent's one. Otherwise, if the user expresses a no answer, the polarity is the opposite of the agent's one.

Converting attitude into like-dislike The patterns used for the parsing phase refer to attitudes that are good candidates for expressions of like or dislike. When the $relevantAttExpr(usrSentence) == True$, the system converts the attitude into a like or a dislike on the basis of the feature set associated to the expression of attitude: an attitude with a positive polarity ($attitude(pol : pos)$) is considered as a $like$, and an attitude with a negative polarity ($attitude(pol : neg)$) is considered as a $dislike$. The target is the same as the attitudinal expression.

4 Corpus for evaluating the system

4.1 Semaine corpus

In order to evaluate our system, an annotated data set of sentences extracted from the Semaine corpus (McKeown et al., 2011) has been created. This corpus comprises 65 manually-transcribed sessions where a human user interacts with a human operator playing the role of the virtual agent. These interactions are based on a scenario involving four agent characters: Poppy, happy and outgoing, Prudence, sensible and level-headed, Spike, angry and confrontational and Obadiah, depressive and gloomy. Agent's sentences are constrained by a script (however, some deviations to the script occur in the database) aimed at putting the user in the same state as the one of the played character. 30 sessions of the corpus have been used for the development set. The rest of the data has been considered to build the evaluation corpus following the protocol described in the next paragraph.

4.2 Annotation protocol on AMT

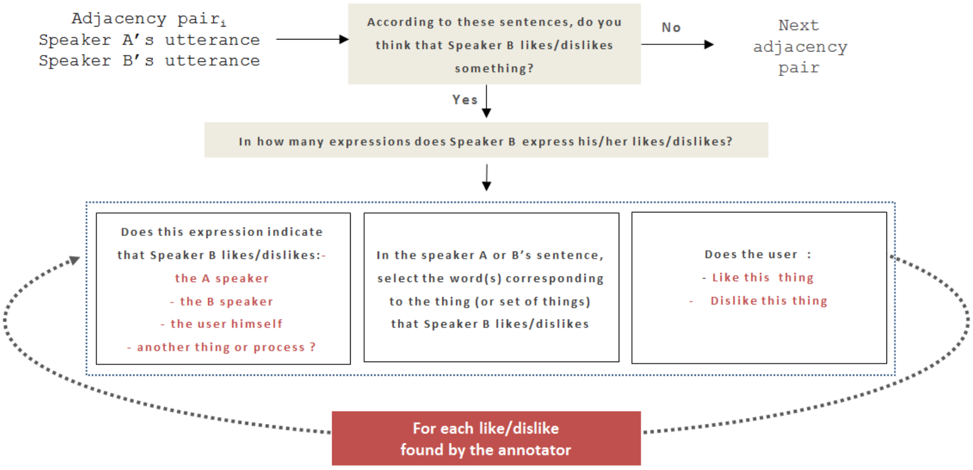
We use AMT platform to carry out the annotation campaign. It allows us to easily recruit a large number of English native speakers. Recent works have shown the reliability of the annotations provided by this platform. For various tasks of language annotation – evaluation of machine translation (Callison-Burch, 2009), affect recognition (Snow et al., 2008), or dictionary validation (Taboada et al., 2011) – they observe a high agreement of non-expert raters with the gold standards.

For our annotation protocol, the recruited annotators are put in the same conditions as the system: each annotator has to label the user's likes and dislikes by only considering the AP (without the whole interaction) and the verbal content (without the audio and video). Among the pairs having less than thirty words in the evaluation corpus, we randomly selected 600 APs – made of an agent's speech turn and a user's one (see Section 3.1). This length of the sentence has been restricted to avoid annotation difficulties.

The dataset is divided in 60 subsets of 10 APs. In order to secure the annotation and to prevent the annotators from doing the annotation task two times, we use TurkGate tool (Goldin and Darlow, 2013). The AMT workers have been selected according to their approval rate – greater than or equal to 99% – and to the number of task approved – greater than or equal to 10000. Each subset of the corpus is randomly assigned to one annotator, and the order in which the AP are presented to each annotator is also randomly defined. A training phase is previously subjected to each annotator in order to familiarise him/her to the annotation principles. Finally, 240 AMT workers have participated to the annotation campaign (4 for each subset).

Questionnaire As the annotation is done by non-expert annotators, we design a simplified and intuitive annotation process: for each pair, the annotators have to answer to a set of questions featured in Figure 4. The goal of the questionnaire is to determine whether the annotator is able to deduce a user's like or dislike from the APs. In order to facilitate the annotation and to make the interpretation of each sentence as spontaneous as possible, the question have been designed without linguistic technical word. In this way, the task is more functional for the annotator and it is easier for him/her to put his/herself to the place of the hearer. Each question of the questionnaire focuses on one of the outputs of the detection system:

- The **first question** examines the presence of an expression of like or dislike and provides a *yes/no* answer.
- the **second question** deals with the multiple occurrences of like/dislike expressions in the same speech turn. We limited the answer to "4" (maximum number of like/dislike expressions observed in the dataset). If the annotator detects more than one expression of like/dislike, the questions 3 to 4 are asked for each expression of like/dislike.
- the **third question** deals with the type of the target. As answers, only the four types –



Adjacency pair$_i$
Speaker A's utterance
Speaker B's utterance
According to these sentences, do you think that Speaker B likes/dislikes something?
No
Next adjacency pair
Yes
In how many expressions does Speaker B express his/her likes/dislikes?
Does this expression indicate that Speaker B likes/dislikes:- the A speaker - the B speaker - the user himself - another thing or process ?
In the speaker A or B's sentence, select the word(s) corresponding to the thing (or set of things) that Speaker B likes/dislikes
Does the user : - Like this thing - Dislike this thing
For each like/dislike found by the annotator

Figure 4: Annotation process on AMT

those the system is able to detect – are proposed.

- The **fourth question** concerns the polarity of the expression: positive (like) or negative (dislike).

4.3 Inter-annotator agreement and consistency

We measure the inter-annotators agreement or consistency at each stage of the questionnaire. All the measures presented in the section have been applied for each subset of the corpus (60 subsets of 10 APs, 4 annotators for each subset).

	Fleiss' Kappa	**Cronbach's alpha**
Max	0.79	0.90
Median	0.32	0.72
Average	0.25	0.59

Table 1: Fleiss' kappa scores and Cronbach's alpha coefficients obtained in on the 60 subsets

Regarding the answer to the first question of the questionnaire, we measure how the annotators are agreeing on the presence of at least one user expression of like or dislike by using the Fleiss' Kappa (Fleiss, 1971) (see Table 1). Second, we measure the consistency on the annotation of the number of user's expressions to each pair by using the Cronbach's alpha coefficient (Cronbach, 1951). As, for labeling the number of likes-dislikes expressed in each pair, the crowd-workers have to select a value on a scale (from 1 to 4), it appears as suitable to measure the relative similarity between ratings rather than the agreement about an exact value. The Cronbach's alpha is designed for evaluating the internal consistency of a scale annotation. In this way, it measures the degree to which different raters or observers make consistent estimates of the same phenomenon.

The obtained scores are encouraging. Regarding the agreement on the presence of an expression of like or dislike, even if the median score is comprised between 0.30 and 0.40, the maximal value equals to 0.79. Moreover, 40% of the subsets has a kappa score comprised between 0.40 and 0.60. The consistency score is also significant: 51% of the annotated sub-corpus has a score equal or higher than 0.7, which is considered as an acceptable level of agreement (George and Mallery, 2010).

For the polarity and the target type, we select the pairs where at least two annotators agree on the presence of an expression of like or dislike, and we consider only the annotations provided by these annotators. After this selection, we obtain a sub-set of ratings with a unfixed set of annotators. As the Fleiss' Kappa must be applied on data with an invariable and fixed set of raters, we consider the percent agreement (Gwet, 2010) as more appropriate. Even though, it seems sometimes difficult for the annotators to agree on the presence of a user's expression of like or dislike, their agreement on the polarity of such expressions appears as more significant: 41% of the sub-corpus has a percentage of agreement between 50% and 75% and 52% of the sub-corpus has a percentage of agreement upper than 75%. The agreement is also significant regarding the target: 61% of the sub-corpus has a percentage of agreement upper than 50%. All these results are quite positive for a system-oriented annotation of a such subjective phenomenon.

5 Evaluation of the system

5.1 Protocol

From the 600 pairs of the previously annotated corpus, we keep 503 pairs for the evaluation of the system by removing the pairs where a consensus can not be found between the 4 annotators – that is that we keep as a reference the majority vote corresponding to the data where at least three annotators agree. We use three different measures to evaluate the system performance relying on the agreement measures presented in Section 4.3: the detection of the presence of a user's expression of like or dislike is evaluated by the Fleiss' kappa between the system output and the reference; the consistency on the number of detected expressions is evaluated by the Cronbach's alpha coefficient; the agreement on the polarity is measured by using the Fleiss' kappa; and the agreement on the target type with the percentage of agreement.

5.2 Results

Table 2 presents the results obtained for each detection task (presence of a like/dislike expression, detection of the correct number of expressions contained in an sentence, and correct classification between like and dislike). The agreement between the system output and the reference is substantial for the detection of the presence of a user expression ($k = 0.61$) and the number of user expressions is also correctly detected by the system (acceptable α largely higher than 0.6). However, the major part of the corpus contains no more than 1 like/dislike expression (98% of the pairs are annotated by the reference and the system as containing 0 or 1 like/dislike expression). 4% of the pairs (25 pairs) is annotated by the system as containing 1 expression, while the referred annotation does not indicate the presence of any like/dislike expression. For 8% of the pairs (43 pairs), it is the opposite phenomenon (1 expression annotated by the reference but not by the system). The Fleiss' kappa score obtained for the polarity is really encouraging since it equals 0.844. Regarding the target type, we obtain a percentage of agreement at 53%. The disagreement frequently concerns a confusion between the *unknown* and *other* categories.

No Expr-Expr	$k = 0.61$
Nb of expressions rated	$\alpha = 0.67$
Polarity	$k = 0.84$
Target type	$p = 53\%$

Table 2: Agreement scores between the system output and the reference

5.3 Discussion

We have carried out an in-depth analysis of the disagreement between the system outputs and the human annotations in order to identify tracks for the improvement of the system. We identified two main types of difficulties.

The first difficulty concerns the processing of spontaneous speech. The Semaine corpus contains a great number of disfluent utterances that disrupt the syntactical structure of the speech turn and thus hinder both the annotation process and the detection system. In the following pair, Agent: *''Oh!"* – User: *''are just very good really good film and read a book"*, the grammatical structure of the user sentence is fuzzy (absence of the subject, presence of repairs) which makes the parsing of the sentence and thus the detection of attitudinal patterns difficult. However, the annotators have here correctly identified the presence of a like and the type of the target ("the film" in the *Others* category), which is not the case for all the annotations of the disfluent utterances. To handle this difficulty, it would be interesting to integrate a system able to automatically label disfluencies, such as the one presented in (Dutrey et al., 2014). The disfluent structure of the sentence could thus be integrated to our syntactic and semantic rules. However, the automatic detection of disfluencies is still an open challenge, in particular in the case of edit disfluencies where the speaker corrects or alters the utterance or abandons it entirely and starts over (Strassel, 2004).

The second difficulty concerns the lack of context provided by some of the APs. Our system offers a first step in the integration of the interaction context by considering jointly the user's utterance and the previous agent's one that allow us to correctly analyse a large scale of expressions. However, the system and the annotators have to focus on the APs without considering the preceding speech turns, which can cause disagreements not only between the system outputs and the human annotations, but also between the human annotators. In the following example, Agent: *"good. ah good"* – User: *"my favourite emotion"*, the source (here, the user) can be easily identified but the information contained in the AP is not sufficient to identify the target. An interesting answer to this issue is to take into account the whole conversation preceding a user's utterance as a significant context for the latter. This will imply the design of new complex rules taking into account a larger interaction context.

6 Conclusion and future works

We have introduced a NLP-based system able to detect user's expressions of likes and dislikes in the conversation with an ECA. This system relies on syntactic and semantic rules integrating the interaction context by analysing the content of the agent's utterances to help the analysis of the user's ones. It is designed as a bottom-up and rule-based process. The system has been evaluated by using an evaluation data set created under AMT platform. This first and pioneering version of the system shows encouraging results for the different tasks performed by the system that concern the detection of relevant like/dislike expressions (substantial agreement with a Fleiss kappa at 0.61), the categorization of the expressions between like and dislike (almost perfect agreement with a Fleiss kappa at 0.84) – polarity assignment – and the identification of the target type (53% of agreement between the reference and the system output). Beyond these quite optimistic results, we have provided some tracks for the system improvement that concerns a deeper integration of the interaction context and the processing of spontaneous speech features.

Acknowledgments

The authors would like to thank the GRETA team for its contributions to the Greta and Vib platforms. This work has been supported by the european project ARIA-VALUSPA, and performed within the Labex SMART (ANR-11-LABX-65) supported by French state funds managed by the ANR within the Investissements d'Avenir programme under reference ANR-11-IDEX-0004-02.

Abstract

We investigate a technique to adapt unsupervised word embeddings to specific applications, when only small and noisy labeled datasets are available. Current methods use pre-trained embeddings to initialize model parameters, and then use the labeled data to tailor them for the intended task. However, this approach is prone to overfitting when the training is performed with scarce and noisy data. To overcome this issue, we use the supervised data to find an embedding subspace that fits the task complexity. All the word representations are adapted through a projection into this task-specific subspace, even if they do not occur on the labeled dataset. This approach was recently used in the SemEval 2015 Twitter sentiment analysis challenge, attaining state-of-the-art results. Here we show results improving those of the challenge, as well as additional experiments in a Twitter Part-Of-Speech tagging task.

1 Introduction

The success of supervised systems largely depends on the amount and quality of the available training data, oftentimes, even more than the particular choice of learning algorithm (Banko and Brill, 2001). Labeled data is, however, expensive to obtain, while unlabeled data is widely available. In order to exploit this fact, semi-supervised learning methods can be used. In particular, it is possible to derive word representations by exploiting word co-occurrence patterns in large samples of unlabeled text. Based on this idea, several methods have been recently proposed to efficiently estimate *word embeddings* from raw text, leveraging neural language models (Huang et al., 2012; Mikolov et al., 2013; Pennington et al., 2014; Ling et al., 2015). These models work by maximizing the probability that words within a given window size are predicted correctly. The resulting embeddings are low-dimensional dense vectors that encode syntactic and semantic properties of words. Using these word representations, Turian et al. (2010) were able to improve near state-of-the-art systems for several tasks, by simply plugging in the learned word representations as additional features. However, because these features are estimated by minimizing the prediction errors made on a generic, unsupervised, task they might be suboptimal for the intended purposes.

Ideally, word features should be adapted to the specific supervised task. One of the reasons for the success of deep learning models for language problems, is the use unsupervised word embeddings to initialize the word projection layer. Then, during training, the errors made in the predictions are backpropagated to update the embeddings, so that they better predict the supervised signal (Collobert et al., 2011; dos Santos and Gatti, 2014a). However, this strategy faces an additional challenge in noisy domains, such as social media. The lexical variation caused by the typos, use of slang and abbreviations leads to a great number of singletons and out-of-vocabulary words. For these words, the embeddings will be poorly re-estimated. Even worse, words not present on the training set will never get their embeddings updated.

In this paper, we describe a strategy to adapt unsupervised word embeddings when dealing with small and noisy labeled datasets. The intuition behind our approach is the following. For a given task, only a subset of all the latent aspects captured by the word embeddings will be useful. Therefore, instead of updating the embeddings directly with the available labeled data, we estimate a projection of these embeddings into a low dimensional sub-space. This simple method brings two funda-

Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

mental advantages. On the one hand, we obtain low dimensional embeddings fitting the complexity of the target task. On the other hand, we are able to learn new representations for all the words, even if they do not occur in the labeled dataset.

To estimate the low dimensional sub-space, we propose a simple non-linear model equivalent to a neural network with one single hidden layer. The model is trained in supervised fashion on the labeled dataset, learning jointly the sub-space projection and a classifier for the target task. Using this model, we built a system to participate in the SemEval 2015 Twitter sentiment analysis benchmark (Rosenthal et al., 2015). Our submission attained state-of-the-art results without hand-coded features or linguistic resources (Astudillo et al., 2015). Here, we further investigate this approach and compare it against several state-of-the-art systems for Twitter sentiment classification. We also report on additional experiments to assess the adequacy of this strategy in other natural language problems. To this end, we apply the embedding sub-space layer to Ling et al. (2015) deep learning model for part-of-speech tagging. Even though the gains were not as significant as in the sentiment polarity prediction task, the results suggest that our method is indeed generalizable to other problems.

The rest of the paper is organized as follows: the related work is reviewed in Section 2. Section 3, briefly describes the model used to pre-train the word embeddings. In Section 4, we introduce the concept of embedding sub-space, as well as the the non-linear sub-space model for text classification. Section 5, details the experiments performed with the SemEval corpora. Section 6 describes additional experiments applying the embedding sub-space method to a Part-of-Speech tagging model for Twitter data. Finally, Section 7 draws the conclusions.

2 Related Work

NLP systems can benefit from a very large pool of unlabeled data. While raw documents are usually not annotated, they contain structure, which can be leveraged to learn word features. Context is one strong indicator for word similarity, as related words tend to occur in similar contexts (Firth, 1968). Approaches that are based on this concept include, Latent Semantic Analysis, where words are represented as rows in the low-rank approximation of a term co-occurrence matrix (Dumais et al., 1988), word clusters obtained with hierarchical clustering algorithms based on Hidden Markov Models (Brown et al., 1992), and continuous word vectors learned with neural language models (Bengio et al., 2003). The resulting clusters and vectors, can then be used as more generalizable features in supervised tasks, as they also provide representations for words not present in the labeled data (Bespalov et al., 2011; Owoputi et al., 2013; Chen and Manning, 2014).

A great amount of work has been done on the problem of learning better word representations from unsupervised data. However, not many studies have discussed the best ways to use them in supervised tasks. Typically, in these cases, word representations are directly used as features or to initialize the parameters of more complex models. In some tasks, this approach is however prone to overfitting. The work presented here aims to provide a simple approach to overcome this last scenario. It is thus directly related to Labutov and Lipson (2013), where a method to learn task-specific representations from general pre-trained embeddings was presented. In this work, new features were estimated with a convex objective function that combined the log-likelihood of the training data, with regularization penalizing the Frobenius norm of the distortion matrix. That is, the matrix of the differences between the original and the new embeddings. Even though the adapted embeddings performed better than the purely unsupervised features, both were significantly outperformed by a simple bag-of-words baseline.

Most other approaches, simply rely on additional training data to fine tune the embeddings for a given supervised task. In Bansal et al. (2014), better word embeddings for dependency parsing were obtained by using a corpus created to capture dependency context. This technique requires, nevertheless, of a pre-existing dependency parser or, at least a parsed corpus. For some other tasks, it is possible to collect weakly labeled corpora by making strong assumptions about the data. In Go et al. (2009) a corpus for Twitter sentiment analysis was built by assuming that tweets with positive emoticons imply positive sentiment, whereas tweets with negative emoticons imply negative sentiment. Using a similar corpus, Tang et al. (2014b) induced sentiment specific word embeddings, for the Twitter domain. The embeddings were estimated with a neural network that minimized a linear combination of two loss functions, one penalized the errors made at predicting the center word within a sequence of words, while the other penalized mistakes made at deciding the sentiment label. Weakly labeled data has also been used to refine unsupervised embeddings, by retraining them to predict the noisy labels before using the actual task-specific supervised data (Severyn and Moschitti, 2015).

3 Unsupervised Structured Skip-Gram Word Embeddings

Word embeddings are generally trained by optimizing an objective function that can be measured without annotations. One popular approach is to estimate the embeddings by maximizing the probability that the words within a given window size are predicted correctly. Our previous work has compared several such models, namely the skip-gram and CBOW architectures (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and the structured skip-gram approach (Ling et al., 2015), suggesting that they all have comparable capabilities. Thus, in this study we only use embeddings derived with the structured skip-gram approach, a modification of the skip-gram architecture that has been shown to outperform the original model in syntax based tasks such as, part-of-speech tagging and dependency parsing.

Central to the structured skip-gram is a log linear model of word prediction. Let $w = i$ denote that a word at a given position of a sentence is the i-th word on a vocabulary of size v, and let $w^p = j$ denote that the word p positions further in the sentence is the j-th word on the vocabulary. The structured skip-gram models the following probability:

$$p(w^p = j | w = i) \propto \exp\left(\mathbf{C}_j^p \cdot \mathbf{E} \cdot \mathbf{w}^i\right) \qquad (1)$$

Here, $\mathbf{w}^i \in \{1, 0\}^{v \times 1}$ is a one-hot representation of $w = i$. That is, a vector of zeros of the size of the vocabulary v with a 1 on the i-th entry of the vector. The symbol $\cdot$ denotes internal product and $\exp()$ acts element-wise. The log-linear model is parametrized by the following matrices: $\mathbf{E} \in \mathbb{R}^{e \times v}$, is the embedding matrix, transforming the one-hot representation into a compact real valued space of size e, $\mathbf{C}_j^p \in \mathbb{R}^{v \times e}$ is a set of output matrices, one for each relative word position p, projecting the real-valued representation to a vector with the size of the vocabulary v. By learning a different matrix $\mathbf{C}^p$ for each relative word position, the model captures word order information, unlike the original skip-gram approach that uses only one output matrix. Finally, a distribution over all possible words is attained by exponentiating and normalizing over the v possible options. In practice, negative sampling is used to avoid having to normalize over the whole vocabulary (Goldberg and Levy, 2014).

As most other neural network models, the structured skip-gram is trained with gradient-based methods. After a model has been trained, the low dimensional embedding $\mathbf{E} \cdot \mathbf{w}_i \in \mathbb{R}^{e \times 1}$ encapsulates the information about each word $\mathbf{w}_i$ and its surrounding contexts. This embbeding can thus be used as input to other learning algorithms to further enhance performance.

4 Adapting Embeddings with Sub-space Projections

As detailed in the introduction and related work, word embeddings are a useful unsupervised technique to attain initial model values or features prior to supervised training. These models can be then retrained using the available labeled data. However, even if the embeddings provide a compact real valued representation of each word in a vocabulary, the total number of parameters in the model can be rather high. If, as it is often the case, only a small amount of supervised data is available, this can lead to severe overfitting. Even if regularization is used to reduce the overfitting risk, only a reduced subset of the words will actually be present in the labeled dataset. Words not seen during training will never get their embeddings updated. Furthermore, rare words will receive very few updates, and thus their embeddings will be poorly adapted for the intended task. We propose a simple solution to avoid this problem.

4.1 Embedding Sub-space

Let $\mathbf{E} \in \mathbb{R}^{e \times v}$ denote the original embedding matrix obtained, e.g. with the structured skip-gram model described in Equation 1. We define the adapted embedding matrix as the factorization $\mathbf{S} \cdot \mathbf{E}$, where $\mathbf{S} \in \mathbb{R}^{s \times e}$, with $s \ll e$. We estimate the parameters of the matrix $\mathbf{S}$ using the labeled dataset, while $\mathbf{E}$ is kept fixed. In other words, we determine the optimal projection of the embedding matrix $\mathbf{E}$ into a sub-space of dimension s.

The idea of embedding sub-space rests on two fundamental principles:

1. With dimensionality reduction of the embeddings, the model can better fit the complexity of the task at hand or the amount of available data.

2. Using a projection, all the embeddings are indirectly updated, not only those of words present in the labeled dataset.

One question that arises from this approach, is if the estimated projection is also optimal for the words not present in the labeled dataset. We assume that the words on the labeled dataset are, to some extent, representative of the words found in the unlabeled corpus. This is a reasonable assumption since both datasets can be seen as samples drawn from the same power-law distribution. If this holds, for every *unknown* word, there will be some other word sufficiently close it in the embedding space. Consequently, the projection matrix $\mathbf{S}$ will also be approximately valid for those unseen words. It is often the case that a relatively small number of words of the labeled dataset are not present on the unlabeled corpus. These words are not represented in $\mathbf{E}$. One way to deal with this case, is to simply set the embeddings of unknown words to zero. But in this case, the embeddings will not be adapted during training. Random initializations of the embeddings seems to be helpful for tasks that have a higher penalty for missing words, although it remains unclear if better initialization strategies exist.

4.2 Non-Linear Embedding Sub-space Model

The concept of embedding sub-space can be applied to log-linear classifiers or any deep learning architecture that uses embeddings. We now describe an application of this method for short text classification tasks. In what follows, we will refer to this approach as Non-Linear Sub-space Embedding (NLSE) model. The NLSE can be interpreted as a simple feed-forward neural network model (Rumelhart et al., 1985) with one single hidden layer utilizing the embedding sub-space approach, as depicted in Fig. 1. Let

$$\mathbf{m} = [\mathbf{w}_1 \cdots \mathbf{w}_n] \qquad (2)$$

denote a message of n words. Each column $\mathbf{w} \in \{0,1\}^{v\times 1}$ of $\mathbf{m}$ represents a word in one-hot form, as described in Section 3. Let y denote a categorical random variable over K classes. The NLSE model, estimates thus the probability of each possible category $y = k \in K$ given a message $\mathbf{m}$ as

$$p(y = k|\mathbf{m}) \propto \exp\left(\mathbf{Y}_k \cdot \mathbf{h} \cdot \mathbf{1}\right). \qquad (3)$$

Here, $\mathbf{h} \in \{0,1\}^{e\times n}$ are the activations of the hidden layer for each word, given by

$$\mathbf{h} = \sigma\left(\mathbf{S} \cdot \mathbf{E} \cdot \mathbf{m}\right) \qquad (4)$$

where $\sigma()$ is a sigmoid function acting on each element of the matrix. The matrix $\mathbf{Y} \in \mathbb{R}^{3\times s}$ maps the embedding sub-space to the classification space and $\mathbf{1} \in 1^{n\times 1}$ is a matrix of ones that sums the scores for all words together, prior to normalization. This is equivalent to a bag-of-words assumption. Finally, the model computes a probability distribution over the K classes, using the *softmax* function.

Compared to a conventional feed-forward network employing embeddings for natural language classification tasks, two main differences arise. First, the input layer is factorized into two components, the embeddings attained in unsupervised form, $\mathbf{E}$, and the projection matrix $\mathbf{S}$. Second, the size of the sub-space, in which the embeddings are projected, is much smaller than that of the original embeddings with typical reductions above one order of magnitude. As usual in this kind of models, all the parameters can be trained with gradient methods, using the backpropagation update rule.

5 NLSE for Twitter Sentiment Analysis

In this section, we apply the NLSE model to the message polarity classification task proposed by SemEval, for their well-known Twitter sentiment analysis challenge (Nakov et al., 2013). Given a message, the goal is to decide whether it expresses a positive, negative, or neutral sentiment. Most of the top performing systems that participated in this challenge, relied on linear classification models and the bag-of-words assumption, representing messages as sparse vectors of the size of the vocabulary. In the case of social media, this approach is particularly inefficient, due to the large vocabularies necessary to account for all the lexical variation found in this domain. Thus, these models

need to be enriched with additional hand-crafted features that try to capture more discriminative aspects of the content, most of which require external tools (e.g., part-of-speech taggers and parsers) or linguistic resources (e.g., dictionaries and sentiment lexicons) (Miura et al., 2014; Kiritchenko et al., 2014). With the embedding sub-space approach, however, we are able to attain state-of-the-art performance while requiring only minimal processing of the data and few hyperparameters. To make our results comparable to other systems for this task, we adopted the guidelines from the benchmark. Our system was trained and tuned using only the development data. The evaluation was performed on the test sets, shown in Table 1, and we report the results in terms of the average F-measure for the positive and negative classes.

5.1 Experimental Setup

The first step of our approach requires a corpus of raw text for the unsupervised pre-training of the embedding matrix **E**. We resorted to the corpus of 52 million tweets used in (Owoputi et al., 2013) and the tokenizer described in the same work. The messages were previously pre-processed as follows: lower-casing, replacing Twitter user mentions and URLs with special tokens and reducing any character repetition to at most 3 characters. Words occurring less than 40 times in the corpus were discarded, resulting in a vocabulary of around 210,000 types. Then, a modified version of the `word2vec` tool[1] was used to compute the word embeddings, as described in Section 3. The window size and negative sampling rate were set to 5 and 25 words, respectively, and embeddings of 50, 200, 400 and 600 dimensions were built.

Our system accepts as input a sentence represented as a matrix, obtained by concatenating the *one-hot* vectors that represent each individual word. Therefore, we first performed the aforementioned normalization and tokenization steps and then, converted each tweet into this representation. The development set was split into 80% for parameter learning and 20% for model evaluation and selection, maintaining the original relative class proportions in each set. All the weights were initialized uniformly at random, as proposed in (Glorot and Bengio, 2010). The model was trained with conventional Stochastic Gradient Descent (Rumelhart et al., 1985) with a fixed learning rate of 0.01, and the weights were updated after each message was processed. Variations of learning rate to smaller values, e.g. 0.005, were considered but did not lead to a clear pattern. We explored different configurations of the hyperparameters e (embedding size) and s (sub-space size). Model selection was done by early stopping, i.e., we kept the configuration with best F-measure on the evaluation set after 5-8 iterations.

5.2 Results

In general, the NLSE model showed consistent and fast convergence towards the optimum in very few iterations. Despite using class log-likelihood as training criterion, it showed good performance in terms of the average F-measure for positive and negative sentiments. We found that all embedding sizes yield comparable performances, al-

[1] `https://github.com/wlin12/wang2vec`

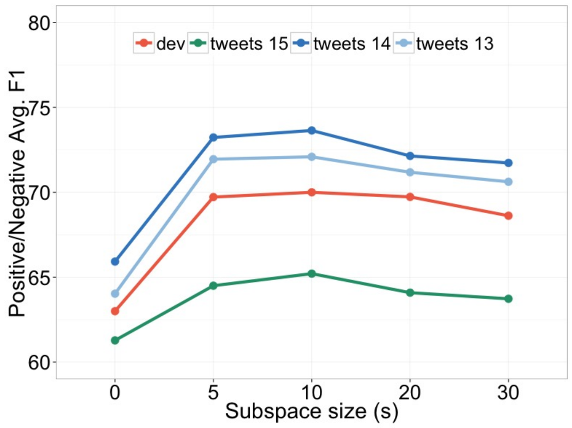

Figure 2: Average F-measure on the SemEval test sets varying with embedding sub-space size s. Sub-space size 0 used to denote the baseline (log-linear model).

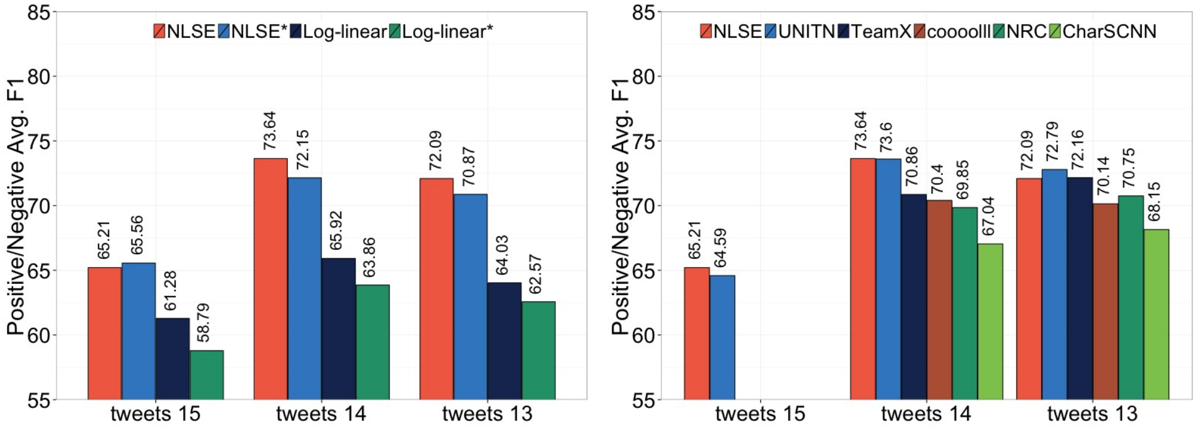
though larger embeddings tend to perform better. Therefore, we only report results obtained with the 600 dimensional vectors. In Figure 2, we show the variation of system performance with sub-space size s. The baseline is a log-linear using the embeddings in $\mathbf{E}$ as features. As it can be seen, the performance is sharply improved when the embedding sub-spaces are used. By choosing different values of s, we can adjust the model to the complexity of the task and the amount of labeled data available. Given the small size of the training set, the best results were attained with the use of smaller sub-spaces, in the range of 5-10 dimensions.

Figure 3, presents the main results of the experimental evaluation. As baselines, we considered two simple approaches: LOG-LINEAR, which uses the unsupervised embeddings directly as features in a log-linear classifier, and LOG-LINEAR*, also using the unsupervised embeddings as features in a log-linear classifier, but updating the embeddings with the training data. These baselines, were compared against two variations of the non-linear sub-space embedding model: NLSE, where we only train the $\mathbf{S}$ and $\mathbf{Y}$ weights while the embeddings are kept fixed, and NLSE*, where we also update the embedding matrix during training. For these experiments, we set $s = 10$. The results in Figure 3a, show that our model largely outperforms the simpler baselines. Furthermore, we observe that updating the embeddings always leads to inferior results. This suggests that pre-computed embeddings should be kept fixed, when little labeled data is available to re-train them.

Comparison with the state-of-the-art

We now compare the NLSE model with state-of-the-art systems, including the best submissions to previous SemEval benchmarks. We also include two other approaches that are related to the one here proposed, where a neural network initialized with pre-trained word embeddings is used to learn relevant features. Specifically, we compare the following systems:

- NRC (Kiritchenko et al., 2014), a support vector machine classifier with a large set of hand-crafted features, including word and character n-grams, brown clusters, POS tags, morphological features, and a set of features based on five sentiment lexicons. Most of the performance was due to the combination of these lexicons. This was the top system in the 2013 edition of SemEval.
- TEAMX (Miura et al., 2014), a logistic regression classifier using a similar set of features. Additional features based on two different POS taggers and a word sense disambiguator were also included in the model. This approach attained the highest ranking in the 2014 edition.
- CHARSCNN (dos Santos and Gatti, 2014b), a deep learning architecture with two convolutional layers that exploit character-level and word-level information. The features are extracted by converting a sentence into a sequence of word embeddings, and the individual words into sequences of character embeddings. Convolution filters followed by max pooling are applied to these sequences, to produce fixed size vectors. These vectors are then combined and transfered to a set of non-linear activation functions, to generate more complex representations of the input. The predictions, based on these learned features are computed with a $softmax$ classifier.
- COOOOLLL (Tang et al., 2014a), a support vector machine classifier that leverages the sentiment specific word embeddings, discussed in Section 2. The embeddings are also processed with a convolution filter, but the output of this operation is used to produce three representations obtained with different strategies, namely with max, min and



(a) Comparison of two baselines with two variations of the NLSE model

(b) Performance of state-of-the-art systems for Twitter sentiment prediction

Figure 3: Average F-measure on the SemEval test sets

$average$ pooling. The final feature vector is obtained by concatenating these representations and Kiritchenko et al. (2014) feature set.

- UNITN (Severyn and Moschitti, 2015), another deep convolutional neural network that jointly learns internal representations and a $softmax$ classifier. The network is trained in three steps: (i) unsupervised pre-training of embeddings, (ii) refinement of the embeddings using a weakly labeled corpus, and (iii) fine tuning the model with the labeled data from SemEval. It should be noted that the system was trained with a labeled corpus 65% larger than ours[2]. This system made the best submission on the 2015 edition of the benchmark.

The results in Figure 3b, show that despite being simpler and requiring less resources and labeled data, the NLSE model is extremely competitive, even outperforming most other systems, in predicting the sentiment polarity of Twitter messages.

6 Generalization to Other Tasks

While the embedding sub-space method works well for the sentiment prediction task, we would like to know its impact in other settings that are known to benefit from unsupervised embeddings. Thus, we decided to replicate the part-of-speech tagging work in (Ling et al., 2015), where pre-training embeddings have been shown to improve the quality of the results significantly.

6.1 Sub-space Window Model

Part-of-speech tagging is a word labeling task, where each word is to be labeled with its syntactic function in the sentence. More formally, given an input sentence $w_1, \ldots, w_n$ of n words, we wish to predict a sequence of labels $y_1, \ldots, y_n$, which are the POS tags of each of the words. This task is scored by the ratio between the number of correct labels and the number of words to be labeled.

We modified (Collobert et al., 2011) window model, to include the sub-space matrix $\mathbf{S}$. The probability of labeling the word w_t with the POS tag k is given by

$$p(y = k|\mathbf{m}_{t-p}^{t+p}) \propto \exp\left(\mathbf{Y}_k \cdot \mathbf{h}_t + \mathbf{b}\right), \qquad (5)$$

where

$$\mathbf{m}_{t-p}^{t+p} = [\mathbf{w}_{t-p} \cdots \mathbf{w}_t \cdots \mathbf{w}_{t+p}] \qquad (6)$$

denotes a context window of words around the t-th word, with a total span of $2p + 1$ words. $\mathbf{h}_t$ denotes the activations of a hidden layer given by

$$\mathbf{h}_t = \tanh\left(\mathbf{H} \cdot \begin{bmatrix} \mathbf{S} \cdot \mathbf{E} \cdot \mathbf{w}_{t+p} \\ \cdots \\ \mathbf{S} \cdot \mathbf{E} \cdot \mathbf{w}_t \\ \cdots \\ \mathbf{S} \cdot \mathbf{E} \cdot \mathbf{w}_{t-p} \end{bmatrix}\right). \qquad (7)$$

Here $\tanh$ denotes the hyperbolic tangent, acting element-wise. Aside from embedding $\mathbf{E}$ and

[2] The UNITN system was trained with around 11,400 labeled examples, whereas we used only 6,900.

sub-space $\mathbf{S}$ matrices, the model is parametrized by the weights $\mathbf{H} \in \mathbb{R}^{h \times ps}$ and $\mathbf{Y} \in \mathbb{R}^{v \times h}$ as well as a bias $\mathbf{b} \in \mathbb{R}^{v \times 1}$.

Note that if $\mathbf{S}$ is set to the identity matrix, this would be equivalent to the original Collobert et al. (2011) model.

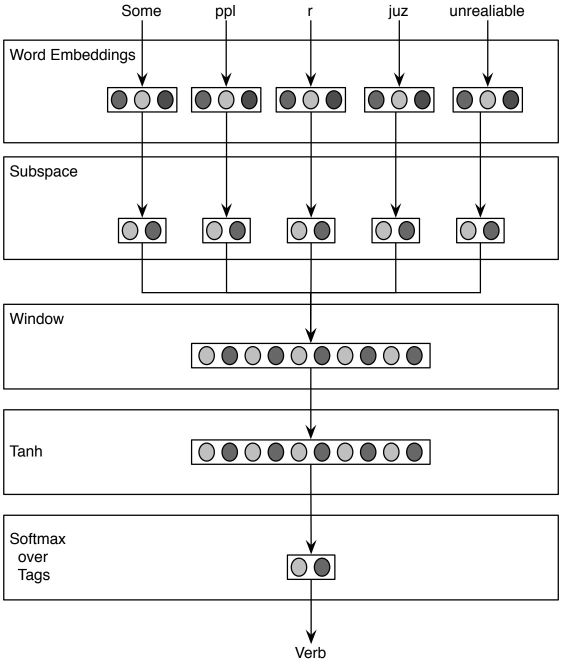


Figure 4: Illustration of the window model by (Collobert et al., 2011) using a sub-space layer.

6.2 Experiments

Tests were performed in Gimpel et al. (2011) Twitter POS dataset, which uses the universal POS tag set composed by 25 different labels (Petrov et al., 2012). The dataset contains 1000 annotated tweets for training, 327 tweets for tuning and 500 tweets for testing. The number of word tokens in these sets are 15000, 5000 and 7000, respectively. There are 5000, 2000 and 3000 word types.

Once again, we initialized the embeddings with unsupervised pre-training using the structured skip-gram approach. As for the hyperparameters of the model, we used embeddings with $e = 50$ dimensions, a hidden layer with $h = 200$ dimensions and a context of $p = 2$ as used in (Ling et al., 2015). Training employed mini-batch gradient descent, with mini batches of 100 sentences and a momentum of 0.95. The learning rate was set to 0.2. Finally, we used early stopping by choosing the epoch with the highest accuracy in the tuning set. As for the sub-space layer size, we tried three different hyperparameterizations: 10, 30 and 50 dimensions.

6.3 Results

Figure 5 displays the results. Using the setup that led to the best results in the sentiment prediction task (FIX), that is, fixing $\mathbf{E}$ and updating $\mathbf{S}$, leads to lower accuracies than the baseline (TRAIN-ALL, $s = 0$). We also see that different values of s do not have a very strong impact in the final results.

Sentiment polarity prediction and POS tagging differ in multiple aspects and there may be more than one reason for this poorer performance. One particularly relevant aspect, in our opinion, is the way words that have no pre-trained embedding are treated. In the case of sentiment prediction, these words were set to having and embedding of zero. This fits the use of the bag-of-words assumption and the fact that only one label is produced per message, as there are many other words to draw evidence from. In the case of POS tagging a hypothesis must be drawn for each word, using a shorter context. Thus, ignoring a word means that context is used instead, which is a frequent cause of errors.

One way around this problem would be to update the parameters of $\mathbf{S}$ and $\mathbf{E}$, but this leads to results similar to the experiment without the sub-space projections (TRAIN-ALL). This is expected as the sub-space layer was designed to work on fixed word embeddings, if these are updated its benefits are lost. Thus, we solve this problem by fixing all the embeddings, except for the word types not found in the pre-training corpus. That is, instead of leaving the unknown words as the zero vector, we use the labeled data to learn a better representation. Using this setup (TRAIN-OOV), we can obtain a small but consistent improvement over the baseline. While these improvements are not significant, as this task is not as prone to overfitting as in sentiment analysis, this is a good check of the validity of our method.

7 Conclusions

We presented a new approach to use unsupervised word embeddings based on the idea of finding a sub-space projection of the embeddings for a given task. This approach offers two main advantages. On the one hand, it allows to indirectly update embeddings unseen during training. On the other

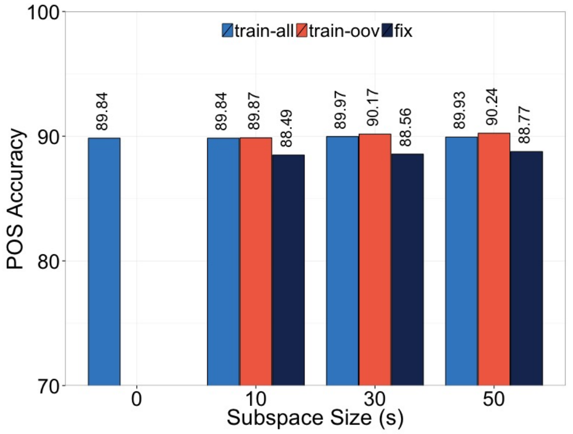

Figure 5: Results for the part-of-speech task on the ARK POS dataset, for different strategies to update the embeddings and with variations of the sub-space size. Sub-space size 0 used to denote the baseline (window model).

hand, it reduces the number of model parameters to fit the complexity of the task. These properties make this method particularly useful for the cases where only small amounts of noisy data are available to train the model.

Experiments on the SemEval challenge corpora validated these ideas, showing that such a simple approach can attain state-of-the-art results comparable with the best systems of past SemEval editions and often outperforming them in all datasets. It should be noted that this is attained while keeping the original embedding matrix **E** fixed and only learning the projection **S** with the supervised data. Additional experiments on the Twitter POS tagging task indicate however that, the technique is not always as effective as in the sentiment classification task. One possible explanation for the different behavior is the use of embeddings of zeros for words without pre-trained embedding. It is plausible that this has a stronger effect on the POS tagging task. Another aspect to be taken into account is the fact that both tasks could have a different complexity which would explain why adapting **E** in the POS taks yields better results. Optimality of the embeddings for each of the tasks might also come into play here.

The implementation of the proposed method and our Twitter Sentiment Analysis system has been made publicly available[3].

Abstract

In this paper, we address the problem of evaluating spontaneous speech using a combination of machine learning and crowdsourcing. Machine learning techniques inadequately solve the stated problem because automatic speaker-independent speech transcription is inaccurate. The features derived from it are also inaccurate and so is the machine learning model developed for speech evaluation. To address this, we post the task of speech transcription to a large community of online workers (crowd). We also get spoken English grades from the crowd. We achieve 95% transcription accuracy by combining transcriptions from multiple crowd workers. Speech and prosody features are derived by force aligning the speech samples on these highly accurate transcriptions. Additionally, we derive surface and semantic level features directly from the transcription. To demonstrate the efficacy of our approach we performed experiments on an expert–graded speech sample of 319 adult non–native speakers. Using these features in a regression model, we are able achieve a Pearson correlation of 0.76 with expert grades, an accuracy much higher than any previously reported machine learning approach. Our approach has an accuracy that rivals that of expert agreement. This work is timely given the huge requirement of spoken English training and assessment.

1 Introduction

Automatic evaluation of spoken English has been of keen interest for more than two decades (Zechner et al., 2007; Neumeyer et al., 1996; Franco et al., 2000; Cucchiarini et al., 1997). It can help learners get feedback in a scalable manner, help build better English training software and also help companies and institutions filter and select prospective employees more effectively. The problem acquires significance given the evidence that better English leads to better employment outcome, wages and promotions (Guven and Islam, 2013).

There has been a considerable success in automatically scoring spoken English, when the spoken text is known a priori (Cucchiarini et al., 2000; Franco et al., 2000). In these cases, the candidate is asked to either read a given text or listen to some speech and repeat it. For these tasks, the scores generated by an automatic system on parameters such as pronunciation and fluency closely mimic those given by human experts. The primary approach behind a majority of these systems is to force align the speech sample on the known text using an HMM–based acoustic model. Features such as likelihood, posterior probability and fluency related features are derived from the aligned speech and a machine learning model is used to predict expert grades (Neumeyer et al., 1996; Franco et al., 2000; Cucchiarini et al., 1997). Some approaches additionally use prosody and energy related features (Dong et al., 2004). More recently, this research has moved towards the assessment of higher granularity metrics like the mispronunciation of particular phonemes (Li et al., 2009; Ito et al., 2006; Koniaris and Engwall, 2011).

In spontaneous speech evaluation, the candidate is asked to speak on a topic or answer a question and what he/she speaks isn't known priori. Evaluation of spontaneous speech is the ultimate test of a candidate's proficiency in speaking a language (Hagley, 2010; Halleck, 1995). While scores from the evaluation of read/repeat speech do correlate with spontaneous speech evaluation, there remains

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1085–1094,
Beijing, China, July 26-31, 2015.

an unexplained variance in the spontaneous speech scores (see Section 5). Generally, candidates who score high on spontaneous speech also score high on read speech and not vice versa.

Given the primacy of spontaneous speech evaluation in judging a person's language capability, there is considerable interest in doing it automatically (Cucchiarini et al., 1997; Dong et al., 2004). Automated approaches for the same have not worked well (Powers et al., 2002; Cucchiarini et al., 2000) primarily because speaker-independent speech recognition is a tough computer science problem. This is exacerbated when the speakers are not proficient in the language or are non-natives (Powers et al., 2002). Given that speech to text conversion for such candidates has a low accuracy, force alignment of the speech on this inaccurate text makes the features and the model inaccurate.

We present a semi-automated approach to grade short duration (45 seconds) spontaneous speech. We accurately predict a holistic score which is based on the pronunciation, fluency, content characteristics and grammar of the speech sample, as determined by experts. Multiple previous studies in language acquisition and second language research conclusively show that proficiency in a second language can be characterized by these factors (Bhat et al., 2014). Being able to provide a holistic score is of high interest in both educational testing (Zechner et al., 2009) and job related testing (Streeter et al., 2011). Institutions and firms look for a holistic score, say based on CEFR, a standard to describe spoken English assessment (Little, 2006; Little, 2007), to make an accept or reject decision on candidates. Currently, an expert based assessment is used for these purposes.

Our method involves combining machine learning with a crowdsourcing layer. Crowdsourcing (Estellés-Arolas and González-Ladrón-de Guevara, 2012) is the process of getting *human intelligence* tasks performed by a large community of online workers (crowd) as opposed to traditional employees.[1] The responses from the human intelligence tasks are then used to create relevant features for machine learning. Human intelligence tasks are defined as those which most humans find easy, but are hard for machines. For instance, a classic example is the task of finding a particular object in an image. There is a large research community that uses crowdsourcing and has demonstrated that it can help perform tasks inexpensively, in large volumes and within reasonable time (Howe, 2006; Whitla, 2009).

Our system design for evaluation of spontaneous speech is illustrated in Figure 1. We post the task[2] of speech transcription to the crowd. We get a final accurate transcription by combining the transcriptions from more than one crowd worker for the same speech sample. Once we have this accurate transcription, we force-align (Erling and Seargeant, 2013; Sjölander, 2003) the speech of the candidate on this text to derive various features which go into a machine learning engine. We also collect spoken English grades of the speech from the crowd (Lejk and Wyvill, 2001), which are used as additional features. With these accurately identified features and crowd grades, machine learning is able to grade spontaneous speech with high accuracy. We found that this approach does much better than a pure machine learning approach.

Crowdsourcing has been used for almost a decade in various problems in speech analysis, grading and language learning (Kunath and Weinberger, 2010; Peabody, 2011; Wang et al., 2014). Within assessment of speech, currently all such approaches use the crowd to directly grade certain parts of the speech (Wang and Meng, 2012). Our work is uniquely positioned where we use the crowd to do accurate transcription, a human intelligence task, and use it in a machine learning based algorithm.[3] We show that such a system provides an accuracy rivaling that of experts.

In this paper, we solve a hitherto unsolved problem of spontaneous speech evaluation (Zechner et al., 2009). The paper makes the following contributions:

- We show that spoken English can be graded with accuracy by combining machine learning and crowdsourcing higher than a pure machine learning approach.

[1] Our approach is different from peer grading (Lejk and Wyvill, 2001) or crowd grading (Van Houdnos, 2011; Tetreault et al., 2010; Madnani et al., 2011) approaches. These approaches directly ask the crowd to grade the response. The primary feature of our technique is using the crowd in the feature extraction step of machine learning.

[2] Even though speaker-independent speech recognition is a hard problem for machines, it is fairly easy for a native speaker or anyone with reasonable command over the language.

[3] Again, speech transcription has been done previously using crowdsourcing (Zaidan and Callison-Burch, 2011), but not used for a grading purpose or combined with machine learning.

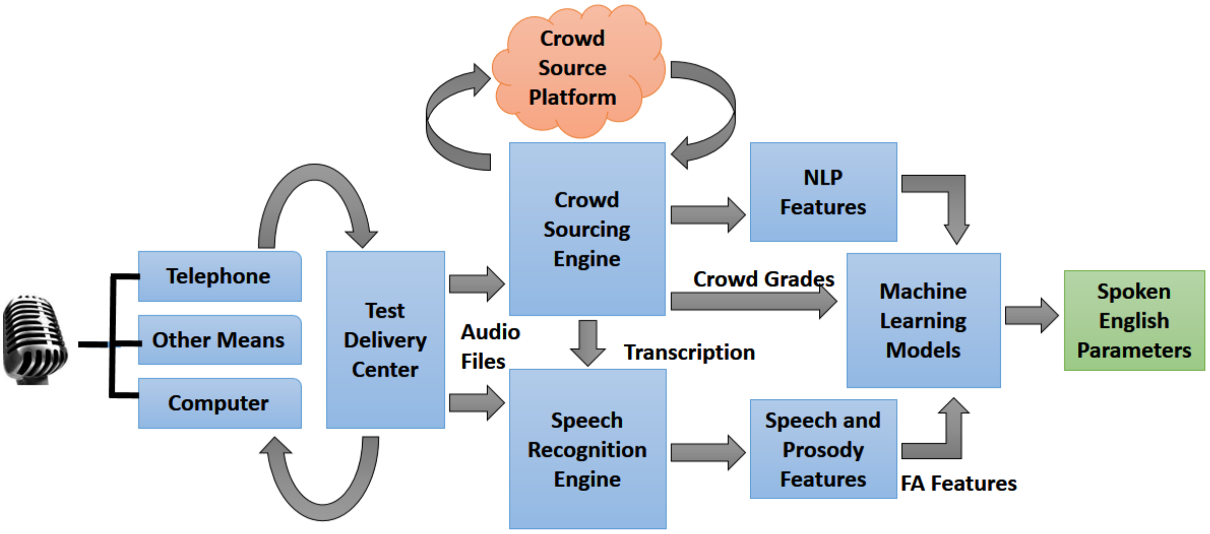

Figure 1: System Design

- We show that the features derived from crowdsourced transcriptions perform as well as crowd grades in predicting expert grades. However, crowd grades add additional predictive value.
- We propose a scalable and accurate way to perform evaluation of spontaneous speech, a huge requirement in the industry and elsewhere.

The paper is organized as follows– Section 2 describes the procedure and aim of the speech assessment task; Section 3 describes the feature classes used in the prediction algorithm; Section 4 describes the crowdsourcing framework which is used as an input to machine learning methods; Section 5 demonstrates how this framework is used with machine learning techniques to predict a composite spoken English score; Section 6 discusses the future work and concludes the paper.

2 Grading Task

We want to assess the quality of spoken English of candidates based on their spontaneous speech samples. The speech samples of the candidates were collected using Aspiring Minds' automated speech assessment tool– SVAR (SVAR, 2014). SVAR is conducted over phone as well as on a computer. The test has multiple sections where the candidate is required to: read sentences aloud, listen and repeat sentences, listen to a passage or conversation and answer multiple choice questions and finally spontaneously speak on a given topic. In the spontaneous speech section, the candidates[4] are provided with a topic and given 30 seconds[5] to think, take notes and then speak on the topic for 45 seconds. The topic is repeated to ensure task clarity. The complete test takes 16-20 minutes to complete, depending on the test version.

Currently, SVAR evaluates speech samples from the read and repeat sections with high accuracy (SVAR, 2014). Our goal in this paper is to evaluate the spontaneous speech of the candidate and provide a composite score based on it.

A 5 point rubric for the composite score, similar to CEFR (Examinations, 2011), was prepared with the help of experts. This score is a function of the pronunciation, fluency, content organization and grammar quality of the speech sample. Broadly speaking, Pronunciation (Dobson, 1957) refers to the correctness in the utterance of the phonemes of a word by the students as per neutral accent. Fluency (Brumfit and Brumfit, 1984) refers to a desired rate of speech along with the absence of hesitations, false starts and stops etc. Content organization (Stalnaker, 1999) measures the candidate's ability to structure the information disposition and present it coherently. Grammar (Brazil, 1995) measures how well the syntax of the language was followed by the candidate.

[4] The subjects of our study use English as their second language and hail from various backgrounds, dialects and educational qualifications.

[5] This is as per global standards of spoken English assessment. High stake tests such as TOEFL provide the candidate 15-30 seconds to think before responding to a spontaneous speech task.

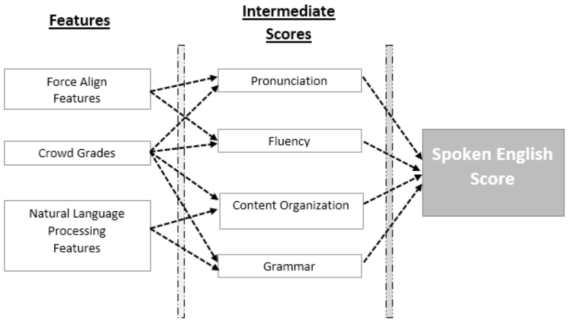

Figure 2: Our intuition of how different features predict the holistic score.

In the next section we discuss the features which are used in the prediction algorithm.

3 Features

We use three classes of features– Crowd Grades (CG), Force Alignment features (FA) and Natural Language Processing features (NLP). The spoken English samples are posted to the crowd to get the transcription and spoken English grades (Figure 1). Each task was completed by three workers. The crowd grades become one set of features. A second set, i.e., FA features, are derived by aligning (Erling and Seargeant, 2013; Sjölander, 2003) the speech sample on the crowdsourced transcriptions. A third set, i.e., NLP features, are also derived from the crowdsourced text. These are explained in the succeeding paragraphs.

- *Crowd Grades:* The crowd transcribes the speech in addition to providing scores on each of the following– pronunciation, fluency, content organization and grammar. These grades are combined to form a composite score per worker per candidate. These are further averaged across workers to give a final score.[6]

- *FA features:* The speech sample is forced aligned (Erling and Seargeant, 2013; Sjölander, 2003) on the crowdsourced transcription using the HTK speech recognizer (Young et al., 2006). We used an acoustic model based on TIMIT (Garofolo et al., 1993) for our experiments. TIMIT is a corpus of phonemically and lexically transcribed speech of American English speakers of different sexes and dialects.

  A number of speech quality features are derived, which include– rate of speech, position and length of pauses, log likelihood of recognition, posterior probability, hesitations and repetitions etc. These features are well known in literature and may be referred from (Neumeyer et al., 1996; Zechner et al., 2009; Cucchiarini et al., 2000). These features are predictive of the pronunciation and fluency of the candidate.

- *NLP features:* These features predict the content quality and grammar of the spoken content[7]. They were derived using standard NLP packages (LightSide, 2013; AfterTheDeadline, 2014) on the crowdsourced transcription. The package calculates surface level features such as the number of words, complexity or difficulty of words and the number of common words used. It also calculates semantic features like the coherency in text, context of the words spoken, sentiment of the text and grammar correctness. In the current system, we do not use any prompt specific features such as occurrence of specific words or phrases. These features are predictive of the grammar and content organization of the sample.

All the features described above were obtained for the spontaneous speech sample. We also derived features similar to FA features for the candidate's read and repeat speech samples collected during his/her SVAR test. The speech and prosody features are calculated by force aligning the speech on the known text. One of the models (RS/LR) in our experiments is based on these features and has been included for comparison. These features do not have any bearing on our final model for spontaneous speech evaluation.

4 Crowdsourcing

The spoken English sample was given to the crowd to transcribe and provide grades. The task was posted on a popular crowdsourcing platform– Amazon Mechanical Turk (AMT) (Paolacci et al.,

[6] Advanced Expectation-Maximization techniques (Hosseini et al., 2012) may also be used for an aggregation strategy, once the number of tasks done by every individual worker increases. In our current experiments, this number wasn't very high.

[7] We were looking at prompt independent features only, at this point.

2010). AMT is a popular crowdsourcing marketplace. It is inspired by the famous 18th century automated chess playing machine, running on the intelligence of a hidden human operator. It has more than $500,000$ online workers from 190 countries (Turk, 2014). One can post tasks on the platform online and offer fixed remuneration for their completion.

A clean and simple interface was provided to the worker with standard features needed for transcription. Additionally, an advanced audio player was embedded with the ability to play the speech sample in repeat mode, rewind and forward, apart from standard play/pause functionality to help the worker. The different transcriptions were combined using the ROVER algorithm (Fiscus, 1997). ROVER is a sophisticated voting algorithm to combine multiple transcriptions with errors, to obtain the best estimate of the correct transcription. It is reported to lead to an error reduction of 20-25%. ROVER proceeds in two stages: first the outputs are aligned and a single word transcription network (WTN) is built. The second stage consists of selecting the best scoring word (with the highest number of votes) at each node.

Several methods have been used in the past for increasing the reliability of the grades given by the crowd by identifying and correcting any biases and removing non-serious/low quality workers (Aker et al., 2012). One of the key techniques for this involves inserting gold standard tasks with known answers to get an estimate of the worker's ability (Nguyen et al., 2013). The gold standard tasks are similar to real tasks and the workers have no way to distinguish between the two. Our tasks took workers a reasonable amount of time (8-10 minutes). It wasn't hence feasible to insert a gold standard task, as done typically, with every task to be completed.

To overcome this problem, we propose an innovative approach where a risk is assigned to a worker based on his/her performance on the gold standard tasks. We conceptualized this system as a state machine that determines the risk level of a worker and proposes actions based on it (Refer to Figure 3). All workers started with an initial risk level of 0.2. Gold standard tasks were probabilistically inserted among real tasks based on the worker's risk level. Workers with a higher risk level saw more gold standard tasks. Also, the risk level of the worker was updated based on his/her performance on the gold standard tasks. Workers who consistently performed poorly on gold standard tasks were allocated a higher risk level and a notification was sent to them with a corrective course of action. Beyond a certain level, the worker was barred from attempting future work. We did not do any retrospective correction of the barred worker's completed tasks and simply stopped him/her from attempting newer tasks. This approach allowed us to control for the quality of workers, provide feedback, remove unsuitable workers and also adaptively control the balance between real and gold standard tasks.[8]

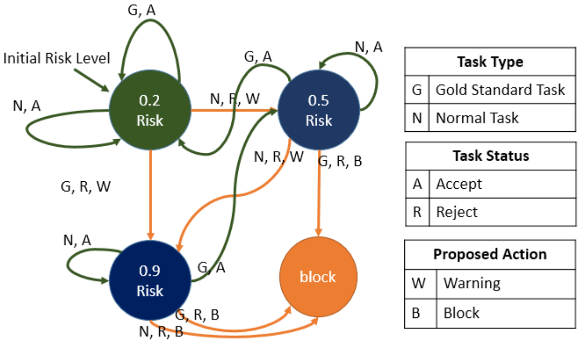

Figure 3: Risk Level State Diagram: In the above figure, each node corresponds to a risk level associated with a worker. The values range between 0 (min) - 1 (max). The worker is either assigned a gold standard task (G) or a normal task (N) on the basis of his/her present risk level. The risk level changes every time a task is Accepted (A) or Rejected (R). Additionally worker may be warned (W) or blocked (B) in case of rejection.

We describe the experimental setup and the results in the next section.

5 Experiments

We conducted the experiments to answer the following questions:

- Can read/repeat features predict spontaneous speech grades accurately?
- How accurate is a pure machine learning approach (without crowdsourced transcription) in predicting grades as compared to grades given by human experts?
- How much better is the ML-CS approach in

[8] Specific details of the implementation are beyond the scope of the paper.

predicting grades as compared to a pure ML approach and to using Crowd Grades only?

- Do Crowd Grades add additional value in predicting grades over and above the features derived from the crowdsourced transcription?

We conducted the experiments on 319 spontaneous speech samples which were graded by expert assessors. To answer the questions stated above, we used different sets of features to develop models and compared their accuracy. The models were built against expert grades using supervised learning techniques. We experimented with three machine learning techniques– Ridge Regression, SVMs and Neural Networks with different features selection algorithms. The data set used in the experiments is discussed in the next section.

5.1 Data Set

Our data set contains 319 spontaneous speech responses. The speech samples were from seniors (non–native English speakers in final year of undergraduate education) pursuing bachelor's degree in India. The candidates were asked to describe one of the following scenes: *a hospital, flood, a crowded market* and *a school playground.* The candidates were given 30 seconds to think and take notes and were then asked to speak for the next 45 seconds. The responses were collected on the phone during the SVAR test (SVAR, 2014). Apart from the spontaneous speech response, each candidate was asked to read 12 given sentences and repeat 9 given sentences immediately after listening to each of them. Empty or very noisy responses (not humanly discernible) were not included in the final 319 sample set.

These responses were graded by two experts who had more than fifteen years of experience in grading spoken English responses. There were two set of scores. The first was a holistic score on the spontaneous speech samples based on its pronunciation, fluency, content characteristics and grammar. The second was a score on the pronunciation and fluency quality of the read/repeat sentences. The correlation between grades given by the two experts was 0.86 and 0.83 respectively for the two cases. For each of the two scores, the average of the scores by the two expert grades was used for further purposes.

The correlation between the expert scores on spontaneous speech and read/repeat speech was 0.54. This shows that there is a considerable unexplained variance (70%) in the spontaneous speech score, not addressed by the read/repeat scores. This could be due to a difference in the pronunciation quality and fluency of the candidates in reading/repeating text vs. speaking spontaneously and also due to the additional parameters of grammar and content characteristics in the spontaneous speech score. Thus, an automatic score mimicking the read/repeat expert grades, which is a solved problem, is inadequate for our task.

The first score is used for all subsequent discussion and development of models.

5.2 Crowdsourced Tasks

The 319 speech sample assessment task was posted on Amazon Mechanical Turk (AMT). Each task was completed by three workers. In total, 71 unique workers completed the tasks. The majority of workers (90%) belonged to USA and India.

The task took on an average 8–9 minutes to complete and a worker was paid between 6–10 cents per task including a bonus which was paid on completion of every 4 tasks. We also got the speech transcribed by experts to find the accuracy we could get from turks. The average transcription accuracy for a worker was 82.4%[9]. This significantly improved to 95.4% when the transcriptions of the three workers were combined using the ROVER algorithm. In comparison, the average automatic transcription of a speech recognition engine was 59.8%.

5.3 Regression Modeling

The data set was split into two sets: train and validation. The train-set had 75% of the sample points whereas the validation set had 25%. The split was done randomly making sure that the grade distribution in both the sets was similar. While learning the model, a 4-fold cross validation was performed on the train sample.

Linear ridge regression, Neural Networks and SVM regression with different kernels were used to build the models. The least cross-validation error was used to select the models. We used some simple techniques for feature selection including forward feature selection and the algorithm which removes all but the k highest correlating features.

Regression parameters: For linear regression with regularization, optimal ridge coefficient λ,

[9] PHP similar_text function was used as similarity metric.

Table 1: Regression Results

Technique	Model Code	Feature Type	Train r	Validation r
Ridge Regression	RR-1	RS/LR	0.51	0.47
	RR-2	Pure ML	0.54	0.47
	RR-3	Crowd Grades	0.63	0.57
	RR-4	ML-CS	0.55	0.60
	RR-5	All	0.76	0.76
SVM	SVM-1	RS/LR	0.50	0.46

between 1 and 1000, was selected based on the the least RMS error in cross-validation. For support vector machines we tested two kernels: linear and radial basis function. In order to select the optimal SVM model, we varied the penalty factor C, parameters γ and ϵ, the SVM kernel and the selected set of values that gave us the lowest RMS error in cross-validation. The Neural Networks model had one hidden layer and 5 to 10 neurons.

Feature sets used: The experiments were carried out on five sets of features:

- RS/LR: A set of features generated by force aligning read/repeated by candidates.
- Pure ML: Features generated by automatic speech transcription of spontaneous speech using a speech recognizer.
- Crowd Grades: A set of features pertaining to grades given by the crowd.
- ML–CS: NLP and FA features generated by force aligning free speech on crowdsourced transcription.
- All: NLP and FA features from crowdsourced transcription and Crowd Grades.

Here, the first set, RS/LR, helps us to know how well we can predict spontaneous speech grades by simply using the read/speak speech of the candidate and without using his/her spontaneous speech sample. This provides a comparison baseline. The second approach evaluates how well we can grade spontaneous speech of the candidate using machine learning approaches only. The third feature shows the efficacy of directly using grades given by crowd, while the fourth finds how well machine learning can do if it has a fairly accurate transcription of the speech by the crowd. The final fifth set tests what happens if we combine the third and fourth set of features, i.e. make use of both the crowdsourced transcription and the crowd grades.

In the following subsection, the features pertaining to ML-CS approach are referred to as ML-CS, those pertaining to natural language processing on crowdsourced transcription are referred to as NLP features while the one pertaining to crowd grades are referred to as Crowd Grades.

5.4 Observations

The results of the experiments are tabulated in Table 1. We report the Pearson coefficient of correlation (r) for the different models against the expert grades. These are the results for the models selected according to least cross-validation error. The best cross-validation error in case of SVMs was obtained for the linear kernel.

All the following observations are based on the validation error. All three techniques perform similarly with Neural Networks doing slightly worse in some cases. The broad trends across feature–sets remain similar across different modeling techniques. We will be referring to the ridge regression results for further discussion.

Firstly, it is observed that the read/repeat features predict the spontaneous speech score with low accuracy ($r = 0.47$). This implies that read-/repeat speech and derived features are inadequate to grade a person's spontaneous speech, the ultimate test of a person's spoken language skills.

The second observation is that the ML-only approach using spontaneous speech features (Model RR-2) is also inadequate to grade spontaneous speech and does worse than approaches that uses features from crowdsourced transcription (Model RR-4). This clearly shows the value of getting accurate transcription from workers towards better features and model.

Further, among the crowdsourcing approaches, we find that the crowd-grades (Model RR-3) does equivalently well (and sometimes worse) than the model using features derived from the crowdsourced speech (Model RR-4). However, when we combine all the features from crowdsourcing including the crowd grades, we find much better prediction accuracy ($r = 0.76$). This shows that the crowd grades feature provides some orthogonal information as compared to the features from the crowdsourced transcription, towards predicting the grade given by experts.

The validation r for Model RR-5 is 0.76. We find that the expert agreement on the validation sample is 0.78. Thus, our predicted score rivals the agreement of experts. This shows great promise for the technique to be used in a high-stake test setting.

In summary, we show the following:

- Read/repeat speech features are inadequate to predict spontaneous speech scores.
- ML only approach based on spontaneous speech samples is also inadequate for the purpose.
- Features derived from crowdsourced transcription (or even crowd grades) do better than a ML only approach.
- When considering features from crowdsourced transcription and crowd grades together, we can predict spontaneous speech scores as well as those done by experts.

6 Conclusions

We addressed the problem of evaluating spontaneous speech using a combination of machine learning and crowdsourcing. To achieve this, we post the task of speech transcription to the crowd. Additionally, we also get spoken English grades from the crowd. We are able to derive accurate features by force aligning the speech sample on the crowdsourced text. We experimented our technique on expert–graded speech samples of adult non–native speakers. Using these features in a regression model, we are able to predict expert grades with much higher accuracy than a machine learning only approach. These features also predict equivalent or better than crowd grades and a combination of these two outperforms all other approaches. Our approach shows an accuracy that rivals that of expert agreement.

Our technique has a promise of higher accuracy but has some trade-offs compared to fully automated approaches. First, there is a cost for every assessment done and the scalability depends on the number of non-expert workers available. Though these drawbacks exist, we were able get tasks done inexpensively. We recently had the crowd rate a hundred samples in a day without any challenge. Second, our approach doesn't provide instant grades. This works fine in many scenarios, but doesn't cater well to providing real-time feedback. Real time crowdsourcing has been an active area of research (Bernstein et al., 2011; Lasecki et al., 2013) and is an area for future work for us as well.

Abstract

ROVER is a widely used method to combine the output of multiple automatic speech recognition (ASR) systems. Though effective, the basic approach and its variants suffer from potential drawbacks: *i)* their results depend on the order in which the hypotheses are used to feed the combination process, *ii)* when applied to combine long hypotheses, they disregard possible differences in transcription quality at local level, *iii)* they often rely on word confidence information. We address these issues by proposing a segment-based ROVER in which hypothesis ranking is obtained from a confidence-independent ASR quality estimation method. Our results on English data from the IWSLT2012 and IWSLT2013 evaluation campaigns significantly outperform standard ROVER and approximate two strong oracles.

1 Introduction

In automatic speech recognition (ASR), the combination of transcription hypotheses produced by multiple systems usually leads to significant word error rate (WER) reductions compared to the output of each individual system. Systems' diversity and complementarity have been exploited in different ways to synthetically obtain more accurate transcriptions. Recognizer output voting error reduction – ROVER (Fiscus, 1997), the most widely used method, performs hypothesis fusion in two steps. First, the 1-best transcriptions from multiple systems are aligned by means of dynamic programming to build a single, minimal word transition network. Then, the resulting network is searched to select the best scoring word at each node. The final hypothesis is constructed via a majority voting mechanism and, if available, by using word confidence measures.

This general strategy has been improved in several ways but, despite their proven effectiveness, ROVER and its variants have three potential drawbacks. The first one is intrinsic to their implementation: the fusion process starts from one of the input hypotheses, which is used as "skeleton" for the greedy alignment of the others. The order in which the hypotheses are used to feed the process can hence determine significant variations in the WER of the resulting combination. **This calls for automatic methods for *ranking* the hypotheses to initialise and carry on the fusion process**.

The second drawback is inherent to the way ROVER is usually run: the fusion process is typically fed with transcriptions of entire audio recordings (lasting up to hours). With this level of granularity, the skeleton used as basis for the alignment may consist of long transcriptions whose quality can considerably vary at local level. For instance, the worst transcription of an entire audio recording (globally) could be the best one for some passages (locally). **This calls for solutions capable to operate at higher granularity levels (*e.g. segments* lasting up to few seconds) to better exploit the local diversity of the combined transcriptions.**

The third drawback relates to the applicability of ROVER-like fusion methods: their common trait is the reliance on information about the inner workings of the combined systems. Indeed, the standard voting scheme with confidence scores is usually much more reliable than the simpler frequency-based voting. The access to confidence scores, however, is a too rigid constraint in application scenarios where the hypotheses to be combined come from unknown ("black-box") systems.[1] **This calls for *confidence-independent* fusion methods.**

[1] One example, among the many possible ones, is the scenario in which an array of microphones (*e.g.* in a room or a vehicle) sends input to one or more commercial ASR systems which do not provide confidence information.

	L3	L4	L5	L6	L7	L8
SysO	12.2	**11.7**	11.8	11.9	12.1	12.1
InSysO	19.8	16.6	15.1	13.9	13.4	13.3
SegO	**10.5**	11.0	11.4	11.6	11.7	11.7
InSegO	22.9	19.6	17.4	15.8	14.4	13.0

Table 1: Motivation: the influence of hypothesis order and granularity on standard ROVER results.

The impact of the first two issues is evident from the figures provided in Table 1. The results refer to the WER achieved by different "oracles" obtained from the output of eight ASR systems that participated in the IWSLT2013 campaign (Cettolo et al., 2013).[2] Such oracles combine:

- Different numbers of transcriptions (from *three* – L3 to *eight* – L8);
- At different granularity levels (*whole utterance* – SysO and *segment* – SegO);
- In different orders (*best to worst* – SysO, SegO and *inverse* – InSysO, InSegO).

As shown in the table, the gap between utterance-based (SysO) and segment-based (SegO) is evident at all levels: WER differences vary from 0.3 (11.9 vs. 11.6 at L6) to 1.7 points (12.2 vs. 10.5 at L3). Another gap is evident between best-to-worst and inverse rankings, with WER differences up to 7.6 points at whole utterance level (SysO vs. InSysO at L3) and 12.4 points at segment level (SegO vs. InSegO at L3). Another interesting observation is that top results (*i.e.* lower WER) are obtained when combining a subset of the outputs (respectively four at utterance level and three at segment level). Referring to this analysis, the goal of computing ROVER based on hypothesis ranking at higher granularity levels is well motivated.

A crucial need to achieve this goal is the availability of a confidence-independent method to predict the quality of ASR transcriptions at segment level. This "quality estimation" (QE) task has been recently addressed in (Negri et al., 2014; C. de Souza et al., 2015) as a supervised regression problem in which transcriptions' WER is predicted without having access to reference transcripts.[3] Different feature sets have been evaluated, showing that even with those extracted only from the signal and the transcription (*i.e.* disregarding information about the decoding process) the prediction error is sufficiently low to open to real applications. However, though promising, experimental results stem from an intrinsic evaluation in which QE is only addressed in isolation.

By applying it to inform ROVER, we propose for the first time an application-oriented *extrinsic* evaluation of ASR QE (our first contribution). To this aim, we extend previous ASR QE methods with new features (second contribution), and report significant improvements over standard ROVER on a shared dataset (third contribution). For the sake of brevity, our comparison is performed only against standard ROVER and in "black-box" conditions. However it's worth remarking that our approach can be straightforwardly applied to any ROVER-like variant and, if available, by exploiting confidence features.

2 Related work

This paper gathers three main research strands together: ASR system combination, ASR quality estimation and machine-learned ranking.

Fiscus (1997) proposed ROVER as an approach to produce a composite ASR output. The basic approach has been extended in several ways. N-Best ROVER (Stolcke et al., 2000) improves the original method by combining multiple alternatives from each combined system. Schwenk and Gauvain (2000) exploit a secondary language model to rescore the final n-best hypotheses generated by ROVER. *i*ROVER (Hillard et al., 2007) exploits a classifier to choose the system that is most likely to be correct at each word location. *c*ROVER (Abida et al., 2011) integrates a semantic pre-filtering step in which the word transition network is scanned to flag and eliminate erroneous words to facilitate the voting. Other approaches to ASR system combination make use of word lattices or confusion networks (Mangu, 2000; Li et al., 2002; Evermann and Woodland, 2000; Hoffmeister et al., 2006; Bougares et al., 2013, inter alia). Note that all these combination methods require to have access to the inner structure of the ASR decoder, while ASR systems, especially the commercial ones, often do not provide this information.

ASR quality estimation allows us to overcome this problem and obtain confidence-independent estimates of ASR output quality. Based on the positive intrinsic evaluation results reported in

[2] Details about this dataset will be provided in Section 6.1.

[3] This formulation is very similar to the machine translation counterpart of the task (Specia et al., 2009; Mehdad et al., 2012; Turchi et al., 2014; C. de Souza et al., 2014).

(Negri et al., 2014; C. de Souza et al., 2015), here we extend the approach with new features and perform an extrinsic evaluation in a real application scenario. Our new features are inspired by research on ASR error detection at word level (Goldwater et al., 2010; Pellegrini and Trancoso, 2010).

Machine-learned ranking (MLR) or learning to rank (Hang, 2011) is widely used in information retrieval to order the answers to a user's query (Cao et al., 2007; McFee and Lanckriet, 2010; McSherry and Najork, 2008). We use it to order the transcription hypotheses produced by multiple ASR systems and feed ROVER with the resulting ranked lists.

3 Method

Given an utterance and a set of *M* transcription hypotheses produced by *M* different (possibly unknown) ASR systems, our goal is to:

1. Split the utterance into segments (ideally at sentence level);
2. For each segment, automatically estimate the quality (*e.g.* in terms of WER) of the corresponding *M* (segment-level) hypotheses;
3. Use the estimates to rank the hypotheses and feed ROVER based on the ranking;
4. Reconstruct the entire utterance transcription by concatenating the combined segment-level transcriptions produced by ROVER;
5. Measure the overall WER differences against standard ROVER and other oracles.

Step 1 is performed by a start-end point detection module based on signal energy, which is followed by a segment classification module based on Gaussian Mixture Models similar to (Cettolo and Federico, 2000). Although the comparison with alternative splitting methods might lead to different results, this is not the main focus of the paper and is left as future work. Steps 2–4, instead, represent the core of our contribution and are described in the following sections.

4 Segment-based QE-informed ROVER

ROVER uses iterative dynamic programming to build a word transition network (WTN) from multiple ASR output hypotheses. The resulting WTN can be seen as a confusion network with an equal number of word arc hypotheses (one for each ASR system entering the combination) in each correspondence slot. The best word sequence is determined from the WTN via majority voting among the words in each slot. Most of the extensions of ROVER, such as *i*ROVER (Hillard et al., 2007), *c*ROVER (Abida et al., 2011) and the one described in (Zhang and Rudnicky, 2006), aim to learn a scoring function that allows improving the reordering of words inside each slot. In particular, *i*ROVER reorders the words in each slot by means of a classifier trained with features that characterize the individual ASR systems. This approach, however, needs first to properly normalize the word lattices generated by each system, in order to exhibit the same vocabulary and similar densities, and to generate a unified segmentation for joining the lattices.

In a similar way, motivated by the analysis shown in Table 1, our method applies reordering of the ASR hypotheses at *segment level*. However, differently from *i*ROVER, it does not require to access the inner components of the decoders (*e.g.* word lattices or word confidences), nor to apply pre-processing steps that can distort the outputs of individual ASR components.

Figure 1: Segment-based ROVER

Figure 1 illustrates the difference between standard ROVER (*RV*, shown at the rightmost vertical) which works at the utterance level (lasting up to few hours) and the segment-based ROVER (*SRV*, shown at the bottom horizontal) that works at the segment level (lasting up to few seconds). *RV* keeps the order of the systems static along the whole utterance ($A \preceq B \preceq C$, *i.e.* system A has generated a better transcription than system B which, in turn is better than system C) for all the segments $RV(T^A_{1..n}, T^B_{1..n}, T^C_{1..n})$. *SRV*, instead, dynamically changes the system order from one segment to the other. For example, the system order for the first segment is $A \preceq B \preceq C$, while for the next segment it is $A \preceq C \preceq B$. Our hypothesis is that, with a proper segment-based ranking, SRV will result in lower WER scores than RV.

Note that, as depicted in Figure 1, segment-based ROVER requires that all the ASR systems share a common segmentation. This is easy to obtain by force-aligning the transcriptions of each system with a given segmentation (*e.g.* one randomly chosen among those employed by each ASR system).

In this paper we approach segment-level ASR QE as a supervised learning task, by comparing two alternative strategies: ranking by regression (Section 4.1) and machine-learned ranking (Section 4.2). Both methods rely on the features used in (Negri et al., 2014), extended with a new set of word-level features described in Section 5.

4.1 Ranking by regression (RR)

The first ranking strategy is based on training a regressor on a set of (*signal*, *transcription*, *WER*) triples, and use it to predict the WER score for new, unseen (*signal*, *transcription*) test instances. Then, based on the predicted WERs, a ranked list is produced for each segment to feed ROVER.

To train the regressor, we are given N segments ($S_i, 1 \leq i \leq N$), their automatic transcriptions ($\{T_i^1 \dots T_i^M\}_{i=1}^{i=N}$) produced by M ASR systems, and manual references from which the true WERs ($\{TW_i^1 \dots TW_i^M\}_{i=1}^{i=N}$) can be computed for each segment i. The whole set of training data is hence represented by instances: $I = \{(S_i, T_i^j, TW_i^j), 1 \leq j \leq M, 1 \leq i \leq N\}$. Training is performed with two alternative strategies, which differ in the amount of training data used. The first one, **RR1**, employs the whole training set I. The second one, **RR2**, uses only one transcription for each segment, randomly chosen from the M available. In this case, the training set becomes: $I' = \{(S_i, T_i^j, TW_i^j), 1 \leq i \leq N, j = rnd(M)\}$ where $rnd(M)$ is a random number between 1 to M. In practice, *RR2* learns from a smaller but more diverse training set compared to *RR1*. On the one side, in fact, *RR1* deals with a larger number of training instances (M times more), but the feature vectors will share the same values for the features extracted from the signal of each utterance. On the other side, *RR2* reduces the size of the training set I' down to $\frac{1}{M}$ of I, but only one feature vector is extracted for each utterance. The unpredictable effect of such differences on QE results motivates experiments with both methods.

4.2 Machine-learned ranking (MLR)

The second strategy relies on directly training a ranking model from a set of instances $I = \{(S_i, T_i^j, TR_i^j), 1 \leq i \leq N, 1 \leq j \leq M\}$, where S_i and T_i^j respectively represent segments and transcriptions, and TR_i^j represents "true ranks" computed from the corresponding reference WER values TW_i^j. That is, given two transcriptions, T_i^j and T_i^k and the true WERs, then $TR_i^j \preceq TR_i^k$, if $TW_i^j \leq TW_i^k$.

It is worth to note that MLR, differently from the two regression methods described above, performs a pairwise comparison between the segment candidates. That is, for each pair of segment transcriptions, the algorithm processes their corresponding feature vectors against each other and decides to place one transcription ahead of the other, as long as returning a score for this decision. Based on this score, the algorithm is then able to rank more than two candidates.

5 Features

We use two sets of features. One consists of the basic features described in (Negri et al., 2014); the other includes several word-based features specifically introduced for our ranking task.

5.1 Basic features

Basic features can be further divided in three groups:

Signal features (16 in total) aim to capture the difficulty to transcribe a given input by looking at the signal as a whole. They are obtained by analyzing the audio waveform with a window of 20ms at a frame rate of 10ms. For each analysed window, 12 Mel Frequency Cepstral Coefficients (MFCCs) are evaluated (MFCC of order 0 is discarded) plus log energy. Then, to form the signal feature vector for each given segment, we compute the mean/min/max values of raw energy, as well as the mean MFCCs values and total segment duration.

Hybrid features (26) provide a more fine-grained way to capture the difficulty of transcribing the signal. They are computed based on the forced alignment between the M given automatic transcriptions of each segment and the corresponding acoustic observations obtained from raw features. For each transcription hypothesis hybrid features are: signal to noise ratio (SNR), mean/min/max noise energy, mean/min/max word energy, (max word - min noise) energy, number of silences (#sil), #sil per second, number of words (#wrd) per second, $\frac{\#sil}{\#wrd}$, total duration of words (D_{wrd}), total duration of silences (D_{sil}), mean duration of words, mean duration of silences, $\frac{D_{sil}}{D_{wrd}}$, $D_{wrd} - D_{sil}$, standard deviation (std) of word duration, std of silence duration, mean/std/min/max of pitch[4], number of hesitations, frequency of hesitations.

Textual features (10) aim to capture the plausibility (*i.e.* the fluency) of a transcription. For each hypothesis textual features are: number of words, LM log probability, LM log probability of part of speech (POS), log perplexity, LM log perplexity of POS, percentage (%) of numbers, % of tokens which do not contain only "[a-z]", % of content words, % of nouns, % of verbs.

5.2 Word-based features

To compensate the absence of ASR confidence information, we also designed a set of "word-based" features inspired by previous approaches to ASR error detection (Chieu and Ng, 2002; Pellegrini and Trancoso, 2010; Goldwater et al., 2010; Tam et al., 2014). They aim to capture words' pronunciation difficulty, which is determined by the number of lexical neighbors (similar pronunciations) and the types of phonemes that form the words. From the ASR error detection field we also borrow additional language model features based on recurrent neural network language model (RNNLM) probability (Mikolov et al., 2010).

Word-based features (22) are: POS tag and score of the previous/current/next words (6), RNNLM probabilities (2) given by models trained on in-domain and out-of-domain data, in-domain/out-of-domain 4-gram LM probability (2), number of phoneme classes (including fricatives, liquids, nasals, stops and vowels) (5), number of homophones (1), number of lexical neighbors (1) and binary features answering the three questions: "is stop word?" (1), "is before/after repetition?" (2), "is before/after silence?" (2). Since the ASR hypotheses of a given segment might contain different numbers of words, we average the values of the word-based features for each hypothesis.

Dataset	duration	sent	token	voc	talks

6 Experimental setup

In this section we illustrate the audio data used in our experiments, the methods used to inform and run ROVER, the evaluation metric and the significance testing method applied.

6.1 Data

We experiment with two sets of speech recordings collected from English TED talks and used for the 2012 (IWSLT2012) and 2013 (IWSLT2013) editions of the International Workshop on Spoken Language Translation (Federico et al., 2012; Cettolo et al., 2013). Statistics for both datasets are shown in Table 2. Six teams participated in the 2012 evaluation: FBK, KIT, MITLL, NICT, RWTH and UEDIN. Two more competitors, NAIST and PRKE, took part in the 2013 edition of the campaign. The related WERs are reported in Table 3. For detailed system descriptions we refer the reader to the IWSLT2012[5] and IWSLT2013[6] proceedings.

In the experiments, we used *tst2012* for training with 4-fold cross-validation, and *tst2013* for testing purposes. Note that cross-validation was applied ensuring that a given speaker does not ap-

[4] Pitch features have been computed with the Praat software tool (Boersma and Weenink, 2005).

[5] `http://workshop2012.iwslt.org`

[6] `http://workshop2013.iwslt.org`

pear simultaneously both in the training and validation sets. The same condition holds for the test set: speakers in *tst2012* do not occur in *tst2013*. These conditions, and the use of two different sets of talks (acquired in different IWSLT editions and transcribed by different sets of ASR systems), make our task particularly difficult and guarantee the congruence with real-life scenarios in which training and test data are totally independent.

As previously mentioned, a common segmentation needs to be shared among the various ASR components. To do this we decided to use the one provided by our internal ASR system, and to force-align to it all the other ones.

6.2 Terms of comparison

We compare our segment-based QE-informed ROVER against three methods that differ in the granularity of the combined hypotheses and in the way they are ranked:

Random ROVER. It is obtained by averaging the results of 100 runs of standard, system-level ROVER (*i.e.* the WTN is obtained by combining transcriptions of the whole utterance) in which the systems to be combined are ranked randomly. Note that this is the only possible way to run ROVER in absence of information about the reliability of the combined systems. Random ROVER is the standard fusion method adopted in IWSLT2013 to produce the final transcriptions that are sent to the machine translation phase.

System-based Oracle (SysO). It is obtained by computing the standard, system-level ROVER based on the true system ranking (*i.e.* the actual ranking of the IWSLT2013 participants). We consider it as an oracle since the true ranking represents prior knowledge about systems' reliability which is not available in real testing conditions.

Segment-based Oracle (SegO). It is obtained by computing ROVER at segment-level, using the true system ranking for each segment. Also this oracle relies on information about systems' ranking (at a higher granularity level), which is not available in real testing conditions. As shown in Table 1, this is the strongest term of comparison and actually represents out upper bound.

6.3 Evaluation metric and significance test

As usually done in ASR evaluation, performance results are measured in terms of WER.[7] Our segment-based, QE-informed ROVER is hence compared against the other methods based on the WER computed on the test set (*tst2013*).

To measure if two methods produce statistically different results, we run the matched-pairs significance test (Gillick and Cox, 1989). It is based on averaging the differences between the number of errors (insertions, deletions and substitutions) produced by the two approaches for the individual segments. If the average falls in the [-0.05,+0.05] interval, then the global WER difference between the two methods is not statistically significant.

In terms of results' significance tests, our success criteria are: *i)* a statistically significant improvement over random ROVER, and *ii)* non-significant differences with respect to the two strong oracles. For the sake of comparison, we define three symbols for the evaluation results reported in Table 4:

1. "†" indicates that the corresponding WER score is not significantly different from random ROVER (a negative result);
2. "•" indicates that the WER score is not significantly different from the system-based ROVER oracle (a positive result);
3. "⋆" indicates that the WER score is not significantly different from the segment-based ROVER oracle (the best result).

6.4 Ranking Models

Ranking by regression (see Section 4.1) is performed using the implementation of the extremely randomized trees algorithm (Geurts et al., 2006) provided by the Scikit-learn package (Pedregosa et al., 2011). Extra-trees are a tree-based ensemble method for supervised classification and regression, which we successfully used in the past both for MT (de Souza et al., 2013) and ASR quality estimation (Negri et al., 2014). The model used for machine learned ranking (see Section 4.2) is based on the implementation of the random forest

[7] The word error rate is the minimum edit distance between an hypothesis and the reference transcription. Edit distance is calculated as the number of edits (word insertions, deletions, substitutions) divided by the number of words in the reference. Lower WERs (↓) indicate better transcriptions.

method-number of combined systems	L3	L4	L5	L6	L7	L8
Random ROVER	14.6	13.7	13.2	12.8	12.7	12.4

Table 4: WER[%] (↓) of random, oracle and QE-informed ROVERs. The symbols assigned to some scores indicate their statistical significance ($p \leq 0.05$ computed with the matched-pairs test). In particular: "†" = the result is not statistically different from random ROVER; "•" = the result is not statistically different from SysO; "⋆" the result is not statistically different from SegO.

ensemble method (Breiman, 2001) provided in the RankLib library.[8]

As mentioned in Section 6.1, all the ranking models are trained in 4-fold cross validation. *RR1* uses all the instances in *tst2012* (*i.e.* 1,124 segments transcribed by 6 ASR systems, which results in a total of 6,744 training instances). *RR2* uses only one instance per segment, which is randomly selected among the 6 automatic transcriptions available in *tst2012* (resulting in a total of 1,124 training instances). Similar to *RR1*, *MLR* uses all the instances in *tst2012* (6,744 in total). The learning parameters of each model (number of bags, number of trees per bag, number of leaves per tree and minimum number of instances per leaf) are tuned by maximising Mean Average Precision as the objective function (Hang, 2011).

All the models are trained using the basic features (*+Basic*), the word-based ones (*+WordBased*) and their combination (*+Basic+WordBased*).

7 Results and discussion

Table 4 reports the WER results obtained on *tst2013* by ROVER methods fed with: different numbers of hypotheses (from 3 to 8), at different granularity levels (whole utterance vs. segment), ranked with different models (random, RR1, RR2 and MLR) trained with different sets of features (Basic, WordBased, Basic+WordBased).

The first three rows present the results achieved by our terms of comparison: random ROVER, the segment-based oracle (SegO) and the system-based oracle (SysO). As anticipated when motivating our work (see Table 1), the WER achieved by SegO is always lower than the scores achieved by SysO. Note also that the performance of SegO decreases as the number of combined hypotheses increases, due to the introduction in the input of progressively worse transcripts. Instead, SysO exhibits a less coherent behaviour, with close WER values at all levels, and a minimum in correspondence of column L4 (the combination of four transcriptions of the whole utterance). We interpret these results as a further motivation for our work: feeding ROVER with a good ranking that exploits local (segment-level) differences between the combined hypotheses seems to be more reliable than relying on system-level ranks based on global WER scores. A theoretical analysis of the relation between the diversity of the combined hypotheses and ROVER results is presented in (Audhkhasi et al., 2014). In light of this analysis, our results open an interesting issue concerning the trade-offs between optimal hypothesis ranking and their (local) diversity. We initially explore this problem in Section 7.1, but leave for future work a more systematic investigation.

Rows 4-6 show the results achieved by **RR1** (ranking by regression, trained with all the tran-

[8] http://sourceforge.net/p/lemur/wiki/RankLib/

scriptions for each input segment). When trained only with basic features, it always outperforms random ROVER. At L8 the gain is not statistically significant but, at the same time, also the WER difference with SysO is not significant. Note that, proceeding from L3 to L8, the WER difference between RR1+Basic and random ROVER decreases from 0.7 to 0.1. This can be explained by the fact that when the number of candidates increases, then the role of majority voting dominates the role of hypothesis ranking. Similar trends are shown by all other approaches, including the oracles. RR1+WordBased slightly improves over RR1+Basic, indicating the possible usefulness of this new set of features. However, when used in combination (RR1+Basic+WordBased), the two feature sets do not yield further WER reductions. Nevertheless, what is worth to remark is that at L7 and L8 the distance from Sys0 is not statistically significant (a positive result).

As shown in rows 7-9, the situation changes with **RR2** (ranking by regression, trained with one transcription per segment). When trained with the combined feature sets (RR2+Basic+WordBased), the model always leads to slight WER reductions over RR2+Basic. Also in this case, the gains over random ROVER are consistent (they range from 0.9 at L3 to 0.2 at L8), and the difference with respect to SysO is not statistically significant at L7 and L8 (a positive result).

As shown in rows 10-12, results are further improved by **MLR**. Except for L8, the improvement over random ROVER is statistically significant, large and consistent with all feature sets. The WER reduction obtained by MLR+Basic varies from 1.7 to 0.2 WER points, indicating a higher effectiveness of machine-learned ranking compared to ranking by regression. MLR+WordBased produces further WER reductions, with differences with SysO that become statistically not-significant at four levels (L3, L6, L7 and L8). Finally, when trained with the combined feature sets, the ranking model leads to the lowest WER scores. Noticeably, such results are not only on par with SysO (the difference is statistically significant only at L4), but in one case (L6) they even reach those of SegO, the strongest competitor (best result).

Overall, as evidenced by the L8 column, when the number of input components becomes large our QE-informed approaches are not significantly better than random ROVER and SysO. This raises the need of a stopping criterion to avoid entering useless inputs into the ROVER combination. Together with the trade-off between ranking performance and hypotheses' diversity, this represents an interesting topic for future work.

7.1 The role of hypotheses' diversity

To gain further insights on our results, and as a first step along the research directions previously outlined, we analysed the relation between ROVER results and hypotheses' diversity. To this aim, Figure 2 plots the WER of our best method (MLR+Basic+WordBased) and the two oracles as a function of hypotheses' diversity at L6, for which we obtain the best results.

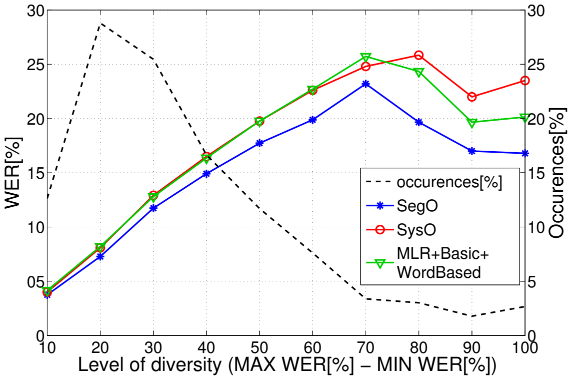

Figure 2: Results on *tst2013* of the oracles and our best model, as functions of hypotheses' diversity.

Diversity is measured by computing the difference between the maximum and the minimum WERs of the input transcriptions. All the segments are then grouped with regard to this difference. For example 10 on the x-axis refers to the group of segments whose diversities lay in the interval of [0,10); 20 refers to the segments whose diversities are in [10,20) and consequently, 100 represents the segments whose diversities lay in [90,100]. This latter means that for each segment there is at least one transcription that is perfect or close to perfection, and one that is (almost completely) wrong.

For segments with diversity smaller than 70, the performance of the system-based oracle (line with circle marks) and our segment-level QE-informed ROVER (line with triangle marks) is almost identical. Instead, for segments with a "high" level of diversity (in the interval [70,100]), our method significantly outperforms the system-based oracle. With a maximum gain larger than 3 WER points, it approaches the strong segment-based oracle (line with asterisk marks). Remarkably, for diversity values in the interval [90,100], our method is able to halve the distance that separates the two oracles.

The considerable WER reductions observed for diversity values larger than 70 shed new light on the global results reported in Table 4. The fact that such performance gains are hidden in the global scores can be explained by looking at the dashed line in Figure 2, which shows the percentage of segments belonging to each diversity level. As it can be observed, the vast majority of the segments (∼95%) falls in diversity bins in the interval [10,70). The large WER reductions obtained on the few remaining segments are definitely not enough to boost global results. Overall, this finding suggests that our segment-level QE-informed ROVER can fully unfold its potential in application scenarios featuring high diversity among the transcriptions.

7.2 Prediction of overall ranks

Since our results strongly depend on the reliability of hypothesis ranking, our final analysis focuses on the correlation between QE-based ranking methods and the "true" ranks used as prior knowledge by the system-based oracle (the official ranking of the IWSLT2013 participants). In order to predict the overall IWSLT2013 ranking, we first run our QE models on each segment. Systems are then ordered based on the average ranking score received by their transcriptions. Finally, the alternative QE-based methods (RR1, RR2 and MLR) are compared by measuring their Spearman correlation with the TRUE systems' order.

Table 5 reports the resulting rankings and the corresponding correlation with the true, official one. Among all the possible combinations (8 factorial), our two best methods (RR2 and MLR) result in a systems' ordering with high correlation with the official IWSLT2013 ranking. In particular, MLR achieves correlation of 0.905 with three out of eight systems (1, 2 and 8) that are correctly positioned. The correlation values of the different approaches reflect the performance reported in Table 4, in which the WER achieved by using MLR is usually better than the ones obtained from RR1 and RR2. It is interesting to note in the last column of Table 5 that the ranking errors are represented by switches between systems with similar WERs, while it seems easier to discriminate between systems with more distant WER values. This consideration is in line with the findings of Section 7.1 concerning the higher potential of segment-level QE-informed ROVER in scenarios featuring a higher diversity between the combined systems.

8 Conclusions

We presented a novel approach to improve the combination of multiple automatic transcription hypotheses using ROVER. Our method is based on informing the fusion process with accurate word error rate predictions obtained from ASR quality estimation models. First, to exploit the possible local diversity among the combined hypotheses, it performs quality prediction and ranking at segment level. Then, the predicted ranks for each segment are used to feed ROVER. Finally, the combined hypotheses are concatenated to reconstruct the entire utterance transcription. To rank predictions, we compared two different regression models with a machine-learned ranking method. We carried out experiments on a set of English TED talks collected for two editions of the IWSLT ASR evaluation campaign. Results show that our segment-level QE-informed ROVER outperforms the standard random ROVER and performs on par (differences are not statistically significant) with a system-based ROVER oracle that exploits prior knowledge about systems' reliability. Moreover, compared to a very strong segment-based ROVER oracle, in one case the performance of our method is not statistically different. These results are particularly encouraging, especially in light of the fact that our approach does not exploit confidence information related to the internal behaviour of the ASR decoders. Overall, this represents the first confirmation, obtained in an extrinsic evaluation setting, of the good potential of reference-free and system-agnostic ASR quality estimation.

Abstract

Natural language generation of coherent long texts like paragraphs or longer documents is a challenging problem for recurrent networks models. In this paper, we explore an important step toward this generation task: training an LSTM (Long-short term memory) auto-encoder to preserve and reconstruct multi-sentence paragraphs. We introduce an LSTM model that hierarchically builds an embedding for a paragraph from embeddings for sentences and words, then decodes this embedding to reconstruct the original paragraph. We evaluate the reconstructed paragraph using standard metrics like ROUGE and Entity Grid, showing that neural models are able to encode texts in a way that preserve syntactic, semantic, and discourse coherence. While only a first step toward generating coherent text units from neural models, our work has the potential to significantly impact natural language generation and summarization[1].

1 Introduction

Generating coherent text is a central task in natural language processing. A wide variety of theories exist for representing relationships between text units, such as Rhetorical Structure Theory (Mann and Thompson, 1988) or Discourse Representation Theory (Lascarides and Asher, 1991), for extracting these relations from text units (Marcu, 2000; LeThanh et al., 2004; Hernault et al., 2010; Feng and Hirst, 2012, inter alia), and for extracting other coherence properties characterizing the role each text unit plays with others in a discourse (Barzilay and Lapata, 2008; Barzilay and Lee, 2004; Elsner and Charniak, 2008; Li and Hovy, 2014, inter alia). However, applying these to text generation remains difficult. To understand how discourse units are connected, one has to understand the communicative function of each unit, and the role it plays within the context that encapsulates it, recursively all the way up for the entire text. Identifying increasingly sophisticated human-developed features may be insufficient for capturing these patterns. But developing neural-based alternatives has also been difficult. Although neural representations for sentences can capture aspects of coherent sentence structure (Ji and Eisenstein, 2014; Li et al., 2014; Li and Hovy, 2014), it's not clear how they could help in generating more broadly coherent text.

Recent LSTM models (Hochreiter and Schmidhuber, 1997) have shown powerful results on generating meaningful and grammatical sentences in sequence generation tasks like machine translation (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015) or parsing (Vinyals et al., 2014). This performance is at least partially attributable to the ability of these systems to capture local compositionally: the way neighboring words are combined semantically and syntactically to form meanings that they wish to express.

Could these models be extended to deal with generation of larger structures like paragraphs or even entire documents? In standard sequence-to-sequence generation tasks, an input sequence is mapped to a vector embedding that represents the sequence, and then to an output string of words. Multi-text generation tasks like summarization could work in a similar way: the system reads a collection of input sentences, and is then asked to generate meaningful texts with certain properties (such as—for summarization—being succinct and conclusive). Just as the local semantic and syntactic compositionally of words can be captured by LSTM models, can the com-

[1] Code for models described in this paper are available at `www.stanford.edu/~jiweil/`.

and the 7th International Joint Conference on Natural Language Processing, pages 1106–1115,
Beijing, China, July 26-31, 2015.

positionally of discourse releations of higher-level text units (e.g., clauses, sentences, paragraphs, and documents) be captured in a similar way, with clues about how text units connect with each another stored in the neural compositional matrices?

In this paper we explore a first step toward this task of neural natural language generation. We focus on the component task of training a paragraph (document)-to-paragraph (document) autoencoder to reconstruct the input text sequence from a compressed vector representation from a deep learning model. We develop hierarchical LSTM models that arranges tokens, sentences and paragraphs in a hierarchical structure, with different levels of LSTMs capturing compositionality at the token-token and sentence-to-sentence levels.

We offer in the following section to a brief description of sequence-to-sequence LSTM models. The proposed hierarchical LSTM models are then described in Section 3, followed by experimental results in Section 4, and then a brief conclusion.

2 Long-Short Term Memory (LSTM)

In this section we give a quick overview of LSTM models. LSTM models (Hochreiter and Schmidhuber, 1997) are defined as follows: given a sequence of inputs $X = \{x_1, x_2, ..., x_{n_X}\}$, an LSTM associates each timestep with an input, memory and output gate, respectively denoted as i_t, f_t and o_t. For notations, we disambiguate e and h where e_t denote the vector for individual text unite (e.g., word or sentence) at time step t while h_t denotes the vector computed by LSTM model at time t by combining e_t and h_{t-1}. σ denotes the sigmoid function. The vector representation h_t for each time-step t is given by:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \text{tanh} \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t \end{bmatrix} \tag{1}$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \tag{2}$$

$$h_t^s = o_t \cdot c_t \tag{3}$$

where $W \in \mathbb{R}^{4K \times 2K}$ In sequence-to-sequence generation tasks, each input X is paired with a sequence of outputs to predict: $Y = \{y_1, y_2, ..., y_{n_Y}\}$. An LSTM defines a distribution over outputs and sequentially predicts tokens using a softmax function:

$$\begin{aligned} & P(Y|X) \\ & = \prod_{t \in [1, n_y]} p(y_t | x_1, x_2, ..., x_t, y_1, y_2, ..., y_{t-1}) \\ & = \prod_{t \in [1, n_y]} \frac{\exp(f(h_{t-1}, e_{y_t}))}{\sum_{y'} \exp(f(h_{t-1}, e_{y'}))} \end{aligned} \tag{4}$$

$f(h_{t-1}, e_{y_t})$ denotes the activation function between e_{h-1} and e_{y_t}, where h_{t-1} is the representation outputted from the LSTM at time $t-1$. Note that each sentence ends up with a special end-of-sentence symbol <end>. Commonly, the input and output use two different LSTMs with different sets of convolutional parameters for capturing different compositional patterns.

In the decoding procedure, the algorithm terminates when an <end> token is predicted. At each timestep, either a greedy approach or beam search can be adopted for word prediction. Greedy search selects the token with the largest conditional probability, the embedding of which is then combined with preceding output for next step token prediction. For beam search, (Sutskever et al., 2014) discovered that a beam size of 2 suffices to provide most of benefits of beam search.

3 Paragraph Autoencoder

In this section, we introduce our proposed hierarchical LSTM model for the autoencoder.

3.1 Notation

Let D denote a paragraph or a document, which is comprised of a sequence of N_D sentences, $D = \{s^1, s^2, ..., s^{N_D}, end_D\}$. An additional "$end_D$" token is appended to each document. Each sentence s is comprised of a sequence of tokens $s = \{w^1, w^2, ..., w^{N_s}\}$ where N_s denotes the length of the sentence, each sentence ending with an "end_s" token. The word w is associated with a K-dimensional embedding e_w, $e_w = \{e_w^1, e_w^2, ..., e_w^K\}$. Let V denote vocabulary size. Each sentence s is associated with a K-dimensional representation e_s.

An autoencoder is a neural model where output units are directly connected with or identical to input units. Typically, inputs are compressed into a representation using neural models (encoding), which is then used to reconstruct it back (decoding). For a paragraph autoencoder, both the input X and output Y are the same document D. The autoencoder first compresses D into a vector representation e_D and then reconstructs D based on e_D.

For simplicity, we define $LSTM(h_{t-1}, e_t)$ to be the LSTM operation on vectors h_{t-1} and e_t to achieve h_t as in Equ.1 and 2. For clarification, we first describe the following notations used in encoder and decoder:

- h_t^w and h_t^s denote hidden vectors from LSTM models, the subscripts of which indicate timestep t, the superscripts of which indicate operations at word level (w) or sequence level (s). $h_t^s(\text{enc})$ specifies encoding stage and $h_t^s(\text{dec})$ specifies decoding stage.

- e_t^w and e_t^s denotes word-level and sentence-level embedding for word and sentence at position t in terms of its residing sentence or document.

3.2 Model 1: Standard LSTM

The whole input and output are treated as one sequence of tokens. Following Sutskever et al. (2014) and Bahdanau et al. (2014), we trained an autoencoder that first maps input documents into vector representations from a $LSTM_{\text{encode}}$ and then reconstructs inputs by predicting tokens within the document sequentially from a $LSTM_{\text{decode}}$. Two separate LSTMs are implemented for encoding and decoding with no sentence structures considered. Illustration is shown in Figure 1.

3.3 Model 2: Hierarchical LSTM

The hierarchical model draws on the intuition that just as the juxtaposition of words creates a joint meaning of a sentence, the juxtaposition of sentences also creates a joint meaning of a paragraph or a document.

Encoder We first obtain representation vectors at the sentence level by putting one layer of LSTM (denoted as $LSTM_{\text{encode}}^{\text{word}}$) on top of its containing words:

$$h_t^w(\text{enc}) = LSTM_{\text{encode}}^{\text{word}}(e_t^w, h_{t-1}^w(\text{enc})) \quad (5)$$

The vector output at the ending time-step is used to represent the entire sentence as

$$e_s = h_{end_s}^w$$

To build representation e_D for the current document/paragraph D, another layer of LSTM (denoted as $LSTM_{\text{encode}}^{\text{sentence}}$) is placed on top of all sentences, computing representations sequentially for each timestep:

$$h_t^s(\text{enc}) = LSTM_{\text{encode}}^{\text{sentence}}(e_t^s, h_{t-1}^s(\text{enc})) \quad (6)$$

Representation $e_{end_D}^s$ computed at the final time step is used to represent the entire document: $e_D = h_{end_D}^s$.

Thus one LSTM operates at the token level, leading to the acquisition of sentence-level representations that are then used as inputs into the second LSTM that acquires document-level representations, in a hierarchical structure.

Decoder As with encoding, the decoding algorithm operates on a hierarchical structure with two layers of LSTMs. LSTM outputs at sentence level for time step t are obtained by:

$$h_t^s(\text{dec}) = LSTM_{\text{decode}}^{\text{sentence}}(e_t^s, h_{t-1}^s(\text{dec})) \quad (7)$$

The initial time step $h_0^s(d) = e_D$, the end-to-end output from the encoding procedure. $h_t^s(d)$ is used as the original input into $LSTM_{\text{decode}}^{word}$ for subsequently predicting tokens within sentence $t + 1$. $LSTM_{\text{decode}}^{word}$ predicts tokens at each position sequentially, the embedding of which is then combined with earlier hidden vectors for the next timestep prediction until the end_s token is predicted. The procedure can be summarized as follows:

$$h_t^w(\text{dec}) = LSTM_{\text{decode}}^{\text{sentence}}(e_t^w, h_{t-1}^w(\text{dec})) \quad (8)$$

$$p(w|\cdot) = \text{softmax}(e_w, h_{t-1}^w(\text{dec})) \quad (9)$$

During decoding, $LSTM_{\text{decode}}^{word}$ generates each word token w sequentially and combines it with earlier LSTM-outputted hidden vectors. The LSTM hidden vector computed at the final time step is used to represent the current sentence.

This is passed to $LSTM_{\text{decode}}^{sentence}$, combined with h_t^s for the acquisition of h_{t+1}, and outputted to the next time step in sentence decoding.

For each timestep t, $LSTM_{\text{decode}}^{sentence}$ has to first decide whether decoding should proceed or come to a full stop: we add an additional token end$_D$ to the vocabulary. Decoding terminates when token end$_D$ is predicted. Details are shown in Figure 2.

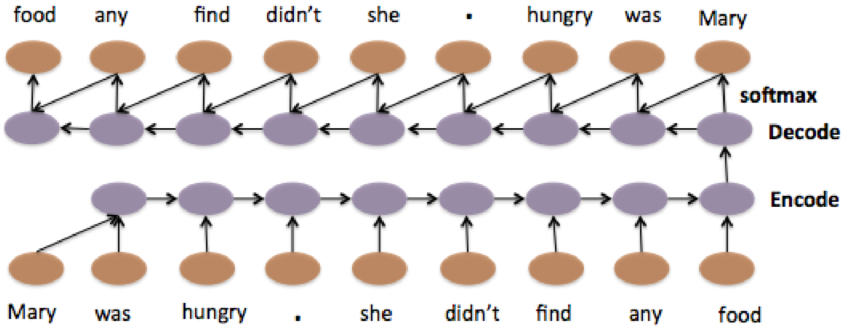

Figure 1: Standard Sequence to Sequence Model.

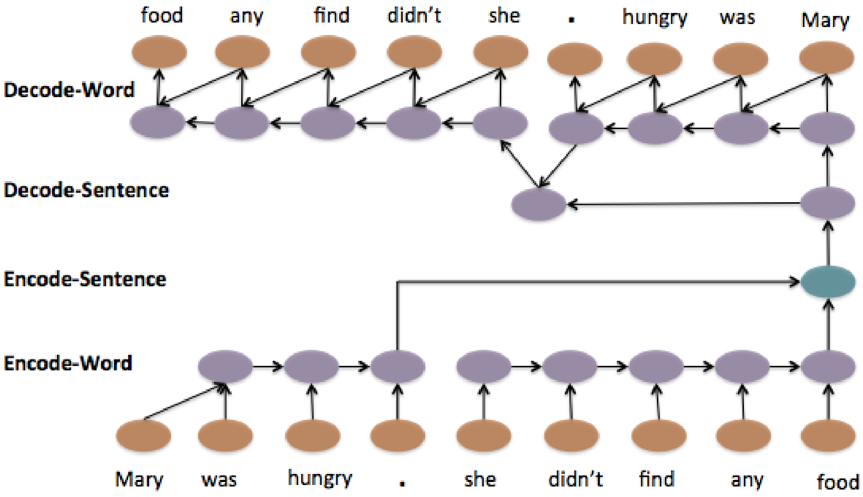

Figure 2: Hierarchical Sequence to Sequence Model.

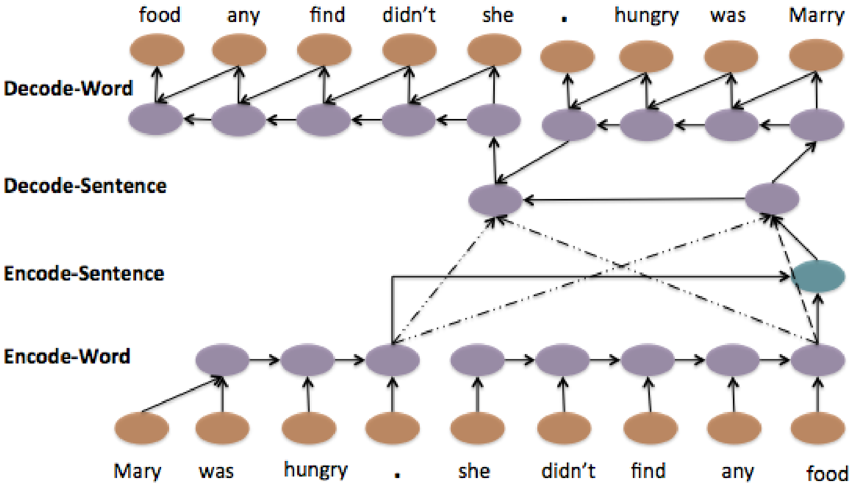

Figure 3: Hierarchical Sequence to Sequence Model with Attention.

3.4 Model 3: Hierarchical LSTM with Attention

Attention models adopt a look-back strategy by linking the current decoding stage with input sentences in an attempt to consider which part of the input is most responsible for the current decoding state. This attention version of hierarchical model is inspired by similar work in image caption generation and machine translation (Xu et al., 2015; Bahdanau et al., 2014).

Let $H = \{h_1^s(e), h_2^s(e), ..., h_N^s(e)\}$ be the collection of sentence-level hidden vectors for each sentence from the inputs, outputted from $LSTM_{\text{encode}}^{\text{Sentence}}$. Each element in H contains information about input sequences with a strong focus on the parts surrounding each specific sentence (time-step). During decoding, suppose that e_t^s denotes the sentence-level embedding at current step and that $h_{t-1}^s(\text{dec})$ denotes the hidden vector outputted from $LSTM_{decode}^{sentence}$ at previous time step $t-1$. Attention models would first link the current-step decoding information, i.e., $h_{t-1}^s(\text{dec})$ which is outputted from $LSTM_{dec}^{sentence}$ with each of the input sentences $i \in [1, N]$, characterized by a strength indicator v_i:

$$v_i = U^T f(W_1 \cdot h_{t-1}^s(\text{dec}) + W_2 \cdot h_i^s(\text{enc})) \quad (10)$$

$W_1, W_2 \in \mathbb{R}^{K \times K}$, $U \in \mathbb{R}^{K \times 1}$. v_i is then normalized:

$$a_i = \frac{\exp(v_i)}{\sum_{i'} \exp(v_i')} \quad (11)$$

The attention vector is then created by averaging weights over all input sentences:

$$m_t = \sum_{i \in [1, N_D]} a_i h_i^s(\text{enc}) \quad (12)$$

LSTM hidden vectors for current step is then achieved by combining c_t, e_t^s and $h_{t-1}^s(\text{dec})$:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \text{tanh} \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1}^s(\text{dec}) \\ e_t^s \\ m_t \end{bmatrix} \quad (13)$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \quad (14)$$

$$h_t^s = o_t \cdot c_t \quad (15)$$

where $W \in \mathbb{R}^{4K \times 3K}$. h_t is then used for word predicting as in the vanilla version of the hierarchical model.

3.5 Training and Testing

Parameters are estimated by maximizing likelihood of outputs given inputs, similar to standard sequence-to-sequence models. A softmax function is adopted for predicting each token within output documents, the error of which is first back-propagated through $LSTM_{\text{decode}}^{word}$ to sentences, then through $LSTM_{\text{decode}}^{sentence}$ to document representation e_D, and last through $LSTM_{\text{encode}}^{sentence}$ and $LSTM_{\text{encode}}^{word}$ to inputs. Stochastic gradient descent with minibatches is adopted.

dataset	S per D	W per D	W per S
Hotel-Review	8.8	124.8	14.1
Wikipedia	8.4	132.9	14.8

Table 1: Statistics for the Datasets. W, S and D respectively represent number of words, number of sentences, and number of documents/paragraphs. For example, "S per D" denotes average number of sentences per document.

For testing, we adopt a greedy strategy with no beam search. For a given document D, e_D is first obtained given already learned $\text{LSTM}_{\text{encode}}$ parameters and word embeddings. Then in decoding, $LSTM_{\text{decode}}^{\text{sentence}}$ computes embeddings at each sentence-level time-step, which is first fed into the binary classifier to decide whether sentence decoding terminates and then into $LSTM_{\text{decode}}^{\text{word}}$ for word decoding.

4 Experiments

4.1 Dataset

We implement the proposed autoencoder on two datasets, a highly domain specific dataset consisting of hotel reviews and a general dataset extracted from Wkipedia.

Hotel Reviews We use a subset of hotel reviews crawled from TripAdvisor. We consider only reviews consisting sentences ranging from 50 to 250 words; the model has problems dealing with extremely long sentences, as we will discuss later. We keep a vocabulary set consisting of the 25,000 most frequent words. A special "<unk>" token is used to denote all the remaining less frequent tokens. Reviews that consist of more than 2 percent of unknown words are discarded. Our training dataset is comprised of roughly 340,000 reviews; the testing set is comprised of 40,000 reviews. Dataset details are shown in Table 1.

Wikipedia We extracted paragraphs from Wikipedia corpus that meet the aforementioned length requirements. We keep a top frequent vocabulary list of 120,000 words. Paragraphs with larger than 4 percent of unknown words are discarded. The training dataset is comprised of roughly 500,000 paragraphs and testing contains roughly 50,000.

4.2 Training Details and Implementation

Previous research has shown that deep LSTMs work better than shallow ones for sequence-to-sequence tasks (Vinyals et al., 2014; Sutskever et al., 2014). We adopt a LSTM structure with four layer for encoding and four layer for decoding, each of which is comprised of a different set of parameters. Each LSTM layer consists of 1,000 hidden neurons and the dimensionality of word embeddings is set to 1,000. Other training details are given below, some of which follow Sutskever et al. (2014).

- Input documents are reversed.
- LSTM parameters and word embeddings are initialized from a uniform distribution between [-0.08, 0.08].
- Stochastic gradient decent is implemented without momentum using a fixed learning rate of 0.1. We stated halving the learning rate every half epoch after 5 epochs. We trained our models for a total of 7 epochs.
- Batch size is set to 32 (32 documents).
- Decoding algorithm allows generating at most 1.5 times the number of words in inputs.
- 0.2 dropout rate.
- Gradient clipping is adopted by scaling gradients when the norm exceeded a threshold of 5.

Our implementation on a single GPU[2] processes a speed of approximately 600-1,200 tokens per second. We trained our models for a total of 7 iterations.

4.3 Evaluations

We need to measure the closeness of the output (candidate) to the input (reference). We first adopt two standard evaluation metrics, ROUGE (Lin, 2004; Lin and Hovy, 2003) and BLEU (Papineni et al., 2002).

ROUGE is a recall-oriented measure widely used in the summarization literature. It measures the n-gram recall between the candidate text and the reference text(s). In this work, we only have one reference document (the input document) and ROUGE score is therefore given by:

$$\mathrm{ROUGE}_n = \frac{\sum_{\mathrm{gram}_n \in \mathrm{input}} \mathrm{count}_{\mathrm{match}}(\mathrm{gram}_n)}{\sum_{\mathrm{gram}_n \in \mathrm{input}} \mathrm{count}(\mathrm{gram}_n)} \tag{16}$$

where $\mathrm{count}_{\mathrm{match}}$ denotes the number of n-grams co-occurring in the input and output. We report ROUGE-1, 2 and W (based on weighted longest common subsequence).

BLEU Purely measuring recall will inappropriately reward long outputs. BLEU is designed to address such an issue by emphasizing precision. n-gram precision scores for our situation are given by:

$$\mathrm{precision}_n = \frac{\sum_{\mathrm{gram}_n \in \mathrm{output}} \mathrm{count}_{\mathrm{match}}(\mathrm{gram}_n)}{\sum_{\mathrm{gram}_n \in \mathrm{output}} \mathrm{count}(\mathrm{gram}_n)} \tag{17}$$

BLEU then combines the average logarithm of precision scores with exceeded length penalization. For details, see Papineni et al. (2002).

Coherence Evaluation Neither BLEU nor ROUGE attempts to evaluate true coherence. There is no generally accepted and readily available coherence evaluation metric.[3] Because of the difficulty of developing a universal coherence evaluation metric, we proposed here only a tailored metric specific to our case. Based on the assumption that human-generated texts (i.e., input documents in our tasks) are coherent (Barzilay and Lapata, 2008), we compare generated outputs with input documents in terms of how much original text order is preserved.

We develop a grid evaluation metric similar to the entity transition algorithms in (Barzilay and Lee, 2004; Lapata and Barzilay, 2005). The key idea of Barzilay and Lapata's models is to first identify grammatical roles (i.e., object and subject) that entities play and then model the transition probability over entities and roles across sentences. We represent each sentence as a feature-vector consisting of verbs and nouns in the sentence. Next we align sentences from output documents to input sentences based on sentence-to-sentence F1 scores (precision and recall are computed similarly to ROUGE and BLEU but at sentence level) using feature vectors. Note that multiple output sentences can be matched to one input

[2] Tesla K40m, 1 Kepler GK110B, 2880 Cuda cores.

[3] Wolf and Gibson (2005) and Lin et al. (2011) proposed metrics based on discourse relations, but these are hard to apply widely since identifying discourse relations is a difficult problem. Indeed sophisticated coherence evaluation metrics are seldom adopted in real-world applications, and summarization researchers tend to use simple approximations like number of overlapped tokens or topic distribution similarity (e.g., (Yan et al., 2011b; Yan et al., 2011a; Celikyilmaz and Hakkani-Tür, 2011)).

Input-Wiki	washington was unanimously elected President by the electors in both the 1788 – 1789 and 1792 elections . he oversaw the creation of a strong, well-financed national government that maintained neutrality in the french revolutionary wars , suppressed the whiskey rebellion , and won acceptance among Americans of all types . washington established many forms in government still used today , such as the cabinet system and inaugural address . his retirement after two terms and the peaceful transition from his presidency to that of john adams established a tradition that continued up until franklin d . roosevelt was elected to a third term . washington has been widely hailed as the " father of his country " even during his lifetime.

Table 2: A few examples produced by the hierarchical LSTM alongside the inputs.

sentence. Assume that sentence s^{i}_{output} is aligned with sentence $s^{i'}_{\text{input}}$, where i and i' denote position index for a output sentence and its aligned input. The penalization score L is then given by:

$$L = \frac{2}{N_{\text{output}} \cdot (N_{\text{output}} - 1)} \times \sum_{i \in [1, N_{\text{output}} - 1]} \sum_{j \in [i+1, N_{\text{output}}]} |(j - i) - (j' - i')| \tag{18}$$

Equ. 18 can be interpreted as follows: $(j - i)$ denotes the distance in terms of position index between two outputted sentences indexed by j and i, and $(j' - i')$ denotes the distance between their mirrors in inputs. As we wish to penalize the degree of permutation in terms of text order, we penalize the absolute difference between the two computed distances. This metric is also relevant to the overall performance of prediction and recall: an irrelevant output will be aligned to a random input, thus being heavily penalized. The deficiency of the proposed metric is that it concerns itself only with a semantic perspective on coherence, barely considering syntactical issues.

4.4 Results

A summary of our experimental results is given in Table 3. We observe better performances for the hotel-review dataset than the open domain Wikipedia dataset, for the intuitive reason that

Model	Dataset	BLEU	ROUGE-1	ROUGE-2	Coherence(L)
Standard	Hotel Review	0.241	0.571	0.302	1.92
Hierarchical	Hotel Review	0.267	0.590	0.330	1.71
Hierarchical+Attention	Hotel Review	0.285	0.624	0.355	1.57
Standard	Wikipedia	0.178	0.502	0.228	2.75
Hierarchical	Wikipedia	0.202	0.529	0.250	2.30
Hierarchical+Attention	Wikipedia	0.220	0.544	0.291	2.04

Table 3: Results for three models on two datasets. As with coherence score L, smaller values signifies better performances.

documents and sentences are written in a more fixed format and easy to predict for hotel reviews.

The hierarchical model that considers sentence-level structure outperforms standard sequence-to-sequence models. Attention models at the sentence level introduce performance boost over vanilla hierarchical models.

With respect to the coherence evaluation, the original sentence order is mostly preserved: the hierarchical model with attention achieves $L = 1.57$ on the hotel-review dataset, equivalent to the fact that the relative position of two input sentences are permuted by an average degree of 1.57. Even for the Wikipedia dataset where more poor-quality sentences are observed, the original text order can still be adequately maintained with $L = 2.04$.

5 Discussion and Future Work

In this paper, we extended recent sequence-to-sequence LSTM models to the task of multi-sentence generation. We trained an autoencoder to see how well LSTM models can reconstruct input documents of many sentences. We find that the proposed hierarchical LSTM models can partially preserve the semantic and syntactic integrity of multi-text units and generate meaningful and grammatical sentences in coherent order. Our model performs better than standard sequence-to-sequence models which do not consider the intrinsic hierarchical discourse structure of texts.

While our work on auto-encoding for larger texts is only a preliminary effort toward allowing neural models to deal with discourse, it nonetheless suggests that neural models are capable of encoding complex clues about how coherent texts are connected .

The performance on this autoencoder task could certainly also benefit from more sophisticated neural models. For example one extension might align the sentence currently being generated with the original input sentence (similar to sequence-to-sequence translation in (Bahdanau et al., 2014)), and later transform the original task to sentence-to-sentence generation. However our long-term goal here is not on perfecting this basic multi-text generation scenario of reconstructing input documents, but rather on extending it to more important applications.

That is, the autoencoder described in this work, where input sequence X is identical to output Y, is only the most basic instance of the family of document (paragraph)-to-document (paragraph) generation tasks. We hope the ideas proposed in this paper can play some role in enabling such more sophisticated generation tasks like summarization, where the inputs are original documents and outputs are summaries or question answering, where inputs are questions and outputs are the actual wording of answers. Sophisticated generation tasks like summarization or dialogue systems could extend this paradigm, and could themselves benefit from task-specific adaptations. In summarization, sentences to generate at each timestep might be pre-pointed to or pre-aligned to specific aspects, topics, or pieces of texts to be summarized. Dialogue systems could incorporate information about the user or the time course of the dialogue. In any case, we look forward to more sophi4d applications of neural models to the important task of natural language generation.

Joint Dependency Parsing and Multiword Expression Tokenisation

Abstract

Complex conjunctions and determiners are often considered as pretokenized units in parsing. This is not always realistic, since they can be ambiguous. We propose a model for joint dependency parsing and multiword expressions identification, in which complex function words are represented as individual tokens linked with morphological dependencies. Our graph-based parser includes standard second-order features and verbal subcategorization features derived from a syntactic lexicon.We train it on a modified version of the French Treebank enriched with morphological dependencies. It recognizes 81.79% of ADV+*que* conjunctions with 91.57% precision, and 82.74% of *de*+DET determiners with 86.70% precision.

1 Introduction

Standard NLP tool suites for text analysis are often made of several processes that are organized as a pipeline, in which the input of a process is the output of the preceding one. Among these processes, one commonly finds a tokenizer, which segments a sentence into words, a part-of-speech (POS) tagger, which associates to every word a part-of-speech tag, and a syntactic parser, which builds a parse tree for the sentence[1]. These three processes correspond to three formal operations on the string: *segmentation* into linguistically relevant units (words), *tagging* the words with POS tags and *linking* the (word, POS) pairs by means of syntactic dependencies.

This setup is clearly not ideal, as some decisions are made too early in the pipeline (Branco and Silva, 2003). More specifically, some tokenization and tagging choices are difficult to make without taking syntax into account. To avoid the pitfall of premature decisions, probabilistic tokenizers and taggers can produce several solutions in the form of lattices (Green and Manning, 2010; Goldberg and Elhadad, 2011). Such approaches usually lead to severe computational overhead due to the huge search space in which the parser looks for the optimal parse tree. Besides, the parser might be biased towards short solutions, as it compares scores of trees associated to sequences of different lengths (De La Clergerie, 2013).

This problem is particularly hard when parsing *multiword expressions* (MWEs), that is, groups of tokens that must be treated as single units (Baldwin and Kim, 2010). The solution we present in this paper is different from the usual pipeline. We propose to jointly parse and tokenize MWEs, transforming segmentation decisions into linking decisions. Our experiments concentrate on two difficult tokenization cases. Hence, it is the parser that will choose, in such cases, whether to group or not several tokens.

Our first target phenomenon is the family of ADV+*que* constructions, a type of complex conjunction in French. They are formed by adverbs like *bien* (*well*) or *ainsi* (*likewise*) followed by the subordinative conjunction *que* (*that*). They function like English complex conjunctions *so that* and *now that*. Due to their structure, ADV+*que* constructions are generally ambiguous, like in the following examples:

1. *Je mange* **bien que** *je n'aie pas faim*
   I eat **although** *I am not hungry*
2. *Je pense* **bien** **que** *je n'ai pas faim*
   I think **indeed that** *I am not hungry*

In example 1, the sequence *bien que* forms a complex conjunction (*although*) whereas in example 2, the adverb *bien* (*indeed*) modifies the verb *pense* (*think*), and the conjunction *que* (*that*) introduces the sentential complement *je n'ai pas faim*

[1] This paper considers dependency syntactic structures.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1116–1126,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

(*I am not hungry*). In treebanks, the different readings are represented through the use of words-with-spaces in the case of complex conjunctions.

Our second target phenomenon is the family of partitive articles which are made of the preposition *de* (*of*) followed by the definite determiner *le*, *la*, *l'* or *les*[2] (*the*). These *de*+DET constructions are ambiguous, as shown in the following examples:

3. *Il boit* **de la** *bière*
   He drinks **some** *beer*
4. *Il parle* **de la** *bière*
   I talks **about the** *beer*

In example 3, the sequence *de la* forms a determiner (*some*) whereas in example 4, *de* is a preposition (*about*) and *la* is the determiner (*the*) of the noun *bière* (*bière*).

We focus on these constructions for two reasons. First, because they are extremely frequent. For instance, in the frWaC corpus, from a total of 54.8M sentences, 1.15M sentences (2.1%) contain one or more occurrences of our target ADV+*que* constructions and 26.7M sentences (48.6%) contain a *de*+DET construction (see Tables 1 and 2). Moreover, in a corpus of 370 M words in French,[3] *des* is the 7^{th} most frequent word. Second, because they are perfect examples of phenomena which are difficult to process by a tokenizer. In order to decide, in example 1, that *bien que* is a complex subordinate conjunction, non-trivial morphological, lexical and syntactic clues must be taken into account, such as the subcategorization frame of the verb of the principal clause and the mood of the subordinate clause. All these clues are difficult to take into account during tokenization, where the syntactic structure of the sentence is not yet explicit.

Ask the parser to perform tokenization will not always solve the problem. Even state-of-the-art parsers can fail to predict the right structure for the cases we are dealing with. The main reason is that they are trained on treebanks of limited size, and some lexico-syntactic phenomena cannot be well modeled. This brings us to the second topic of this paper, which is the integration of external linguistic resources in a treebank-trained probabilistic parser. We show that, in order to correctly solve the two problems at hand, the parser must have access to lexico-syntactic information that can be found in a syntactic lexicon. We propose a simple way to introduce such information in the parser by defining new linguistic features that blend smoothly with treebank features used by the parser when looking for the optimal parse tree.

The paper is organized as follows: Section 2 describes related work on MWE parsing. Section 3 proposes a way to represent multiword units by means of syntactic dependencies. In Section 4, we briefly describe the parser that has been used in this work, and in Section 5, we propose a way to integrate a syntactic lexicon into the parser. Section 6 describes the data sets used for the experiments, which results are presented and discussed in Section 7. Section 8 concludes the paper.

2 Related Work

The famous "pain-in-the-neck" article by Sag et al. (2002) discusses MWEs in parsers, contrasting two representation alternatives in the LinGO ERG HPSG grammar of English: compositional rules and words-with-spaces. The addition of compositional rules for flexible MWEs has been tested in a small-scale experiment which showed significant coverage improvements in HPSG parsing by the addition of 21 new MWEs to the grammar (Villavicencio et al., 2007).

It has been demonstrated that pre-grouping MWEs as words-with-spaces can improve the performance of shallow parsing for English (Korkontzelos and Manandhar, 2010). Nivre and Nilsson (2004) obtained similar results for dependency parsing of Swedish. They compare models trained on two representations: one where MWEs are linked by a special ID dependency, and another one based on gold pre-tokenization. Their results show that the former model can recognize MWEs with F1=71.1%, while the latter can significantly improve parsing accuracy and robustness in general. However, the authors admit that "it remains to be seen how much of theoretically possible improvement can be realized when using automatic methods for MWU recognition".

Several methods of increasing complexity have been proposed for fully automatic MWE tokenization: simple lexicon projection onto a corpus (Kulkarni and Finlayson, 2011), synchronous lexicon lookup and parsing (Wehrli et al., 2010; Seretan, 2011), token-based classifiers trained using

[2] Sequences *de le* and *de les* do not appear as such in French. They have undergone a morpho-phonetic process known as *amalgamation* and are represented as tokens *du* and *des*. In our pipeline, they are artificially *detokenized*.

[3] Newspaper *Le Monde* from 1986 to 2002.

association measures and other contextual features (Vincze et al., 2013a), or contextual sequence models like conditional random fields (Constant and Sigogne, 2011; Constant et al., 2013b; Vincze et al., 2013b) and structured perceptron (Schneider et al., 2014). In theory, compound function words like ADV+*que* and *de*+DET allow no internal variability, thus they should be represented as words-with-spaces. However, to date no satisfactory solution has been proposed for automatically tokenizing *ambiguous* MWEs.

Green et al. (2013) propose a constituency parsing model which, as a by-product, performs MWE identification. They propose a flat representation for contiguous expressions in which all elements are attached to a special node, and then they compare several parsing models, including an original factored-lexicon PCFG and a tree substitution grammar. These generic parsing models can be used for parsing in general, but they have interesting memorization properties which favor MWE identification. Their experiments on French and Arabic show that the proposed models beat the baseline in MWE identification while producing acceptable general parsing results.

Candito and Constant (2014) and Vincze et al. (2013c) present experiments on dependency parsing for MWE identification which are the closest to our settings. Vincze et al. (2013c) focus on light verb constructions in Hungarian. They propose distinguishing regular verbal dependencies from light verbs and their complements through four special labels prefixed by LCV-. Then, they train the Bohnet parser (Bohnet, 2010) using standard parameters and features, and evaluate on a gold test set. They report no significant changes in attachment scores, whereas F1 for light verb identification is 75.63%, significantly higher than the baseline methods of lexicon projection (21.25%) and classification (74.45%).

Candito and Constant (2014) compare several architectures for dependency parsing and MWE identification in French. For regular MWEs like noun compounds, they use regular expressions to automatically generate an internal syntactic structure, combining standard and MWE-dedicated dependency labels. Irregular expressions like complex conjunctions are represented as separate tokens, with a special DEP_CPD dependency that links all tokens to the first MWE word (Constant et al., 2013a). They compare different architectures for MWE identification before, during and after parsing, showing that the best architecture depends on whether the target MWEs are regular or irregular.

Similarly to these two papers, we use a special dependency to model MWEs and evaluate parsing and identification accuracy. Our work departs from theirs on three important aspects. First, we concentrate on syntactically irregular compounds, that we represent with a new kind of dependency. Second, we integrate into the parser a syntactic lexicon in order to help disambiguate ADV+*que* and *de*+DET constructions. Third, we built a specific evaluation corpus to get a better estimation of the performances of our model on ADV+*que* and *de*+DET constructions.

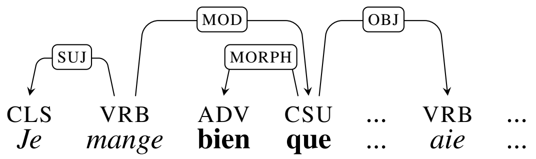
3 The MORPH Dependency

In order to let the parser take the tokenization decisions, we propose *not* to group sequences of tokens of the form ADV+*que* and *de*+DET at tokenization time. Instead, we transform the task of segmentation decision into a parsing decision task.

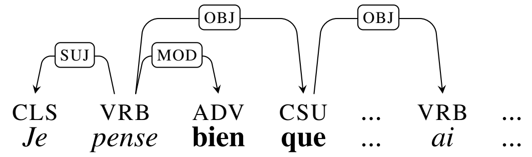
We associate a syntactic structure to ADV+*que* and *de*+DET constructions by introducing a new type of dependency that we call MORPH. It is not a standard syntactic dependency, but a reminiscent of the morphological dependencies of Mel'čuk (1988), similar to the DEP_CPD label proposed by Candito and Constant (2014) or the ID dependency of Nivre and Nilsson (2004), except that we focus on syntactically-motivated MWEs, proposing a regular structure for them.

The syntactic structures of examples 1 and 2, introduced in Section 1, are represented below[4].

Example 1.



Example 2.

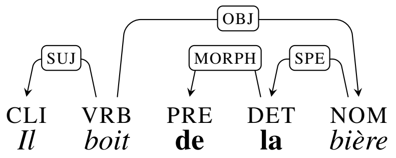


[4] In the examples, parts of speech CLS, VRB, ADV and CSU respectively stand for subject clitic pronoun, verb, adverb and subordinating conjunction. Syntactic labels SUJ, MOD, OBJ, DE-OBJ and SPE stand for subject, modifier, object, indirect object introduced by the preposition *de* and specifier.

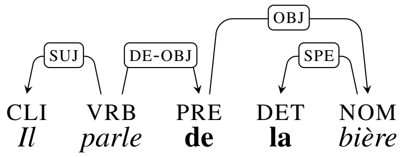
In example 1, the complex conjunction *bien que* is represented by the presence of the MORPH dependency, whereas, in example 2, the adverb *bien* modifies the verb *pense* and *que* introduces its object. From an NLP perspective, the two readings are treated the same way by the tokenizer and the tagger. It is only at parsing time that the presence of the complex conjunction is predicted.

The syntactic structures of examples 3 and 4 are represented below. In example 3, the partitive article *de la* is represented by means of the MORPH dependency. Example 4 exhibits a standard prepositional phrase structure.

Example 3.



Example 4.



4 Parsing

The parser used in this study is a second-order graph-based parser (Kübler et al., 2009). Given a sentence $W = w_1 \dots w_l$, the parser looks for the dependency tree $\hat{T}$ of W that maximizes the score s:

$$\hat{T} = \operatorname*{arg\,max}_{T \in \mathcal{T}(W)} \sum_{F \in \mathcal{F}(T)} s(F)$$

where $\mathcal{T}(W)$ is the set of all possible dependency trees for sentence W and $\mathcal{F}(T)$ is the set of all relevant subparts, called *factors*, of tree T and $s(F)$ is the score of factor F. The values of these scores are parameters estimated during training.

We can define different models of increasing complexity depending on the decomposition of the tree into factors. The most simple one is the *arc-factored* or *first-order model*, which simply decomposes a tree into single dependencies and assigns them a score, independently of their context. We used a second-order parser which decomposes a tree into factors of three types:

1. *first-order factors*, made of one dependency;
2. *sibling factors*, made of two dependencies sharing a common governor;
3. *grandchildren factors*, made of two dependencies where the dependent of one of them is the governor of the other one.

5 Integration with a Syntactic Lexicon

Although this kind of parsers achieve state-of-the-art performances (Bohnet, 2010), their predictions are limited to the phenomena that occur in the treebanks they are trained on. In particular, they often fail at correctly distinguishing elements that are subcategorized by a verb (henceforth *complements*) from others (*modifiers*). This is due to the fact that the nature and number of the complements is specific to each verb. If the verb did not occur, or did not occur often enough, in the treebank, the nature and number of its complements will not be correctly modeled by the parser.

A precise description of verb complements plays an important role in the task of predicting the MORPH dependency, as we illustrate in example 1. In this example, the verb *manger* (*eat*) does not accept an object introduced by the subordinate conjunction *que* (*that*) . This is a vital information in order to predict the correct syntactic structure of the sentence. If the parser cannot link the conjunction *que* to the verb *manger* with an OBJ dependency, then it has to link it with a MOD dependency (it has no other reasonable solution). But *que* by itself cannot be a MOD of the verb unless it is a complex conjunction. The parser has therefore no other choice than linking *que* with the adverb using a MORPH dependency.

In order to help the parser build the right solution in such cases, we have introduced information derived from a syntactic lexicon in the parser. The syntactic lexicon associates, each verb lemma, the features +/-QUE and +/-DE, that indicate respectively if the verb accepts an object introduced by the subordinating conjunction *que* and by the preposition *de*. The verbs of our examples would have the following values:

manger	-QUE	-DE
penser	+QUE	-DE
boire	-QUE	-DE
parler	-QUE	+DE

We will call such features *subcat features* (SFs). The semantics of positive feature values are quite different from the semantics of negative ones. The former indicates that a verb *may* (but does not need to) license a complement introduced by the conjunction *que* or the preposition *de*, whereas the latter indicates that the verb *cannot* license such a complement. Negative feature values have, therefore, a higher predictive power.

Every verbal lemma occurrence in the treebank is enriched with subcat features and three new factor templates have been defined in the parser in order to model the co-occurrence of subcat features and some syntactic configurations. These templates are represented in Figure 1. The first one is a first-order template and the others are grandchildren templates. In the template description, G, D and GD stand respectively for governor, dependent and grand-dependent. SF, POS, FCT and LEM respectively stand for subcat feature, part of speech, syntactic function and lemma.

1	G.SF	G.POS	D.FCT	D.POS	
2	G.SF	G.POS	D.FCT	D.POS	GD.POS
3	G.SF	G.POS	D.FCT	D.LEM	GD.POS

Figure 1: Factor templates modeling the co-occurrence of subcat features and syntactic configurations.

Two factors, of the types 1 and 3, have been represented in Figure 2. The first one models the co-occurrence of subcat feature -QUE and an object introduced by a subordinating conjunction. Such feature will receive a negative score at the end of training, since a verb having the -QUE feature should not license a direct object introduced by a subordinating conjunction. The second feature models the co-occurrence of the feature -QUE and a modifier introduced by the subordinating conjunction QUE and having an adverb as a dependent. Such a feature will receive a positive score.

1	-QUE	VRB	OBJ	CSU	
3	-QUE	VRB	MOD	QUE	ADV

Figure 2: Two factors modeling the co-occurrence of subcat features and syntactic configurations.

6 Experimental Setup

We test the proposed model to verify the linguistic plausibility and computational feasibility of using MORPH links to represent syntactically idiosyncratic MWEs in a dependency parser enriched with subcat features. Therefore, we train a probabilistic dependency parsing model on modified treebank, representing ADV+*que* and *de*+DET constructions using this special syntactic relation instead of pretokenization. Furthermore, in addition to regular features learned from the treebank, we also introduce and evaluate subcat features based on a lexicon of verbal valency, which helps identifying subordinative clauses and *de* prepositional phrases (see Section 5). We evaluate parsing precision and MWE identification on a test treebank and, more importantly, on a dataset built specifically to study the representation of our target constructions. All experiments used the NLP tool suite MACAON[5], which comprises a second-order graph-based parser.

6.1 Data Sets and Resources

French Treebank (FTB) The parser was trained on the French Treebank, a syntactically annotated corpus of news articles from *Le Monde* (Abeillé et al., 2003). We used the version which was transformed into dependency trees by Candito et al. (2009), and which was also used by Candito and Constant (2014) for experiments on MWE parsing. We used a standard split of 9,881 sentences (278K words) for training and 1,235 sentences for test (36K words). We applied simple rules to transform the flat representation of ADV+*que* and *de*+DET constructions into MORPH-linked individual tokens. All other MWEs are kept unchanged in training and test data. They are represented as single tokens, not decomposed into individual words.

MORPH **Dataset** The test portion of the FTB contains relatively few instances of our target constructions (see Tables 4 and 6). Thus, we have created two specific data sets to evaluate the prediction of MORPH links. As for ADV+*que* constructions, we manually selected the 7 most potentially ambiguous combinations from the top-20 most frequent combinations in the French Web as Corpus – frWaC (Baroni and Bernardini, 2006).[6] As for *de*+DET constructions, we selected all 4 possible combinations. For each target ADV+*que* and *de*+DET construction, we randomly selected 1,000 sentences from the frWaC based on two criteria: (1) sentences should contain only one occurrence of the target construction and (2) sentences should have between 10 and 20 words, to avoid distracting the annotators while still providing enough context. Additionally, for *de*+DET we selected only sentences in which a verb preceded the construction, in order to minimize the occur-

l'	136	16.9	83.1	8,204,687
Total	539	36.5	63.5	59,058,977

Table 2: Annotations for *de*+DET combinations MORPH dataset: number of annotated sentences, proportion (%) of complex determiner uses (MORPH) and other uses, number of occurrences in frWaC.

rence of nominal complements (*président de la république - president of the republic*) and focus on the determiner/preposition ambiguity. Two expert French native speakers annotated around 100 sentences per construction. Malformed or ambiguous sentences were discarded. Disagreements were either discussed and resolved or the sentence was discarded.[7]

We can see in Table 1 that ADV+*que* constructions are highly ambiguous, with 56.4% of the cases being complex conjunctions. However, they also present high variability: even though they share identical syntactic behavior, some of them tend to form complex conjunctions very often (*alors*) while others occur more often in other syntactic configurations (*tant* and *encore*). As one can see in Table 2, *de*+DET sequences tend to function as prepositions followed by a determiner with the notable exception of *de les*. The reason is that *de les* (actually the amalgame *des*) is actually the plural of the indefinite article (*un*), used with any plural noun, while the other determiners are partitives that tend to be used only with massive nouns. The last column of these tables shows the number of occurrences of each construction in the frWaC corpus. We can see that they are very recurrent combinations, specially *de*+DET constructions, which account for 3.7% of the total number of bigrams in the corpus. This underlines the importance of correctly predicting their syntactic structure in a parser.

DicoValence Lexicon DicoValence (van den Eynde and Mertens, 2003) is a lexical resource which lists the subcategorization frames of more than $3,700$ French verbs.[8] It describes more specifically the number and nature of the verbs' complements. Dicovalence gives a more fine-grained description of the complements than what is needed in our feature templates. We have only kept, as described in Section 5, the subcat features -QUE, +QUE, -DE and +DE of each verb. Table 3 below shows the number of verbal entries having each of our four subcat features. Although the number of verbs described in DicoValence is moderate, its coverage is high on our data sets. It is equal to 97.82% on the FTB test set and is equal to 95.48% on the MORPH dataset.

-QUE	+QUE	-DE	+DE
3,814	356	3,450	720

Table 3: Number of verbs in DicoValence per value of subcat feature.

6.2 Evaluation

We evaluate our models on two aspects: parsing quality and MWE identification (Nivre and Nilsson, 2004; Vincze et al., 2013c; Candito and Constant, 2014). First, we use standard *parsing attachment scores* to verify whether our models impact parsing performance in general. We compare the generated dependency trees with the reference in the test portion of the FTB, reporting the proportion of matched links, both in terms of structure – unlabeled attachment score (UAS) – and of labeled links – labeled attachment score (LAS).

Since our focus is on MWE parsing, we are also

[7] The dataset is available at `http://pageperso.lif.univ-mrs.fr/%7Ecarlos.ramisch/?page=downloads/morph`

[8] `http://bach.arts.kuleuven.be/dicovalence/`

interested in *MWE identification metrics*. We focus on words whose dependency label is MORPH and calculate the proportion of correctly predicted MORPH links among those in the parser output (precision), among those in the reference (recall) and the F1 average. Since some of the phenomena are quite rare in the FTB test portion, we focus on the MORPH dataset, which contains around 100 instances of each target construction.

We compare our approach with two simple baselines. The first one consists in pretokenizing ADV+*que* systematically as a single token, while *de*+DET is systematically left as two separate tokens. This baseline emulates the behavior of most parsing pipelines, which deal with functional complex words during tokenization. This corresponds to choosing the majority classes in the last row of Tables 1 and 2. For ADV+*que*, the precision of the baseline is 56.4%. If we assume recall is 100%, this yields an F1 score of 72.2%. For *de*+DET, however, recall is 0% since no MORPH link is predicted at all. Therefore, we only look at the baseline's precision of 63.5%. A second, slightly more sophisticated baseline, consists in choosing the majority class for each individual construction and average precisions over the constructions. In this case, the average precision is 75.3% for ADV+*que* and 76.6% for *de*+DET.

We compare our model to the one proposed by Green et al. (2013). We used the pretrained model available as part of the Stanford parser[9]. Their model outputs constituent trees, which were automatically converted to unlabeled dependency structures. We ignore the nature of the dependency link, only checking whether the target construction elements are linked in the correct order.

Our experiments use the MACAON tool suite. For the FTB, gold POS and gold lemmas are given as input to the parser. In the case of the MORPH dataset, for which we do not have gold POS and lemmas, they are predicted by MACAON. The first best prediction is given as input to the parser.

7 Evaluation Results

7.1 ADV+*que* Constructions

Table 4 reports the performances of the parser[10] on the test set of FTB. The rows of the table respectively display the results obtained without and with the use of subcat features (SF). The second and third columns represent standard attachment metrics, column four displays the number of ADV+*que* conjunctions present in the FTB test set FTB and the two last columns show the precision and recall of the MORPH dependency prediction. The table shows that the number of occurrences of ADV+*que* conjunctions is very small (27). It is therefore difficult draw clear conclusions concerning the task of predicting the MORPH dependency. The precision and recall have nevertheless been reported. The recall is perfect (all MORPH dependencies have been predicted) and the the precision is reasonable (the parser overpredicts a little). The table also shows that the use of subcat features is not beneficial, as attachment scores as well as precision decrease. The decrease of precision is misleading, though, due to the small number of occurrences it has been computed on.

SF	LAS	UAS	MORPH	Prec.	Rec.
no	88.98	90.63	27	87.10	100
yes	88.96	90.56	27	81.81	100

Table 4: Attachment scores, count, precision and recall of the MORPH dependency for ADV+*que* in FTB test, without and with subcat features (SF).

Table 5 displays the precision, recall and F1 of the prediction of the MORPH dependency on the 730 ADV+*que* sentences of the MORPH dataset, without and with the use of subcat features. The scores obtained are lower than the same experiments on the FTB.Precision is higher than recall, which indicates that the parser has a tendency to underpredict. We also present the precision of the two baselines described in Section 6.2. Only in two cases the per-construction majority baseline (indiv.) outperforms our parser without subcat features. These two constructions do not tend to form complex conjunctions, that is, the parser overgenerates MORPH dependencies. Here, subcat features help increasing precision, systematically outperforming the baselines.

The introduction of subcat features has a beneficial but limited impact on the results, increasing precision and lowering a bit recall, augmenting the tendency of the parser to under predict MORPH dependencies. Overall, our models are more precise than the Stanford parser at predicting MORPH links, specially for *bien que* and *en-*

core que. However, this is not verified for all individual ADV+*que* constructions. The table also shows an important variety among the seven complex conjunctions studied. Some of them are very well predicted (F1 = 93.5) while others are poorly predicted (F1 = 75.67). This is partly due to the tendency of some ADV+*que* sequences to be part of larger frozen or semi-frozen constructions and to be used with a different semantico-syntactic behavior. An error analysis performed on the *tant que* sequence revealed that 40% of the errors were due to the occurrence of *tant que* as part of the larger *en tant que* expression, while 20% of the errors were due to the usage of *tant que* as a comparative expression.

7.2 *de*+DET Constructions

SF	**LAS**	**UAS**	MORPH	**Prec.**	**Rec.**
no	89.02	90.23	145	85.85	81.12
yes	88.37	89.67	145	86.52	83.92

Table 6: Attachment scores, count, precision and recall of the MORPH dependency for *de*+DET in FTB test, without and with subcat features (SF).

Table 6 reports the results of the same experiments on *de*+DET constructions. It shows that the frequency of *de*+DET constructions is higher than ADV+*que* constructions. It also shows that the introduction of subcat features has a positive impact on the prediction of the MORPH dependency, but a negative effect on the attachment scores.

Table 7 reveals that the prediction of the correct structure of *de*+DET constructions is more difficult than that of ADV+*que* constructions for the parser. Here, not only the majority class is the non-MWE analysis (63.5%), but also there is higher ambiguity because of nominal and adverbial complements that have the same structure. This impacts the performance of the Stanford parser, which overgenerates MORPH links, achieving the lowest precision for all constructions except for *des*. Results also show that the introduction of subcat features has an important impact on the quality of the prediction (F1 jumps from 75% to 84.67%). The use of subcat features slightly improves the identification of *de les*, which is a determiner most of the time. On the other hand, it greatly improves F1 for other constructions, which appear less often as determiners. We believe that the higher impact of subcat frames on *de*+DET is mainly due to the fact that the number of verbs licensing complements introduced by the preposition *de* is higher than the number of verbs licensing complements introduced by the conjunction *que* (see Table 3). Therefore, the parser trained without subcat features can only rely on the examples present in the FTB which are proportionally smaller in the first case than in the second.

8 Conclusions

This paper introduced and evaluated a joint parsing and MWE identification model that can effectively detect and represent ambiguous complex function words. The difficulty of processing such expressions is underestimated because of their limited variability. They often are pregrouped as words-with-spaces in many parsing architectures (Sag et al., 2002). However, we did not use gold tokenization, unrealistic for ambiguous MWEs (Nivre and Nilsson, 2004; Korkontze-

los and Manandhar, 2010).

We proposed to deal with these constructions during parsing, when the required syntactic information to disambiguate them is available. Thus, we trained a graph-based dependency parser on a modified treebank where complex function words were linked with a MORPH dependency. Our results demonstrate that a standard parsing model can correctly learn such special links and predict them for unseen constructions. Nonetheless, the model is more accurate when we integrate external information from a syntactic lexicon. This improved precision for ADV+*que* and specially *de*+DET constructions. For the latter, F1 improved in almost 10%, going from 75% to 84.61%.

This study raised several linguistic and computational questions. Some complex function words include more than two elements, like *si bien que* (*so much that*) and *d'autant (plus) que* (*especially as*). Moreover, they may contain nested expressions with different meanings and structures, e.g. *tant que* (*as long as*) is a conjunction but *en tant que* (*as*) is a preposition. The same applies for quantified partitive determiners, like *beaucoup de* (*much*) and *un (petit) peu de* (*a (little) bit of*). Their identification and representation is planned as a future extension to this work.

We also would like to compare our approach to sequence models (Schneider et al., 2014). Careful error analysis could help us understand in which cases syntactic features can help. Moreover, different variants of the syntactic features and more sophisticated representation for syntactic lexicons can help improve MWE parsing further. For instance, we represent the subcat features of pronominal verbs and their simple versions with the same features, but they should be distinguished, e.g. *se rappeler* (*remember*) is +DE but *rappeler* (*remind*) is -DE.

End-to-end Learning of Semantic Role Labeling Using Recurrent Neural Networks

Jie Zhou and Wei Xu
Baidu Research
{zhoujie01,wei.xu}@baidu.com

Abstract

Semantic role labeling (SRL) is one of the basic natural language processing (NLP) problems. To this date, most of the successful SRL systems were built on top of some form of parsing results (Koomen et al., 2005; Palmer et al., 2010; Pradhan et al., 2013), where pre-defined feature templates over the syntactic structure are used. The attempts of building an end-to-end SRL learning system without using parsing were less successful (Collobert et al., 2011). In this work, we propose to use deep bi-directional recurrent network as an end-to-end system for SRL. We take only original text information as input feature, without using any syntactic knowledge. The proposed algorithm for semantic role labeling was mainly evaluated on CoNLL-2005 shared task and achieved F_1 score of 81.07. This result outperforms the previous state-of-the-art system from the combination of different parsing trees or models. We also obtained the same conclusion with $F_1 = 81.27$ on CoNLL-2012 shared task. As a result of simplicity, our model is also computationally efficient that the parsing speed is 6.7k tokens per second. Our analysis shows that our model is better at handling longer sentences than traditional models. And the latent variables of our model implicitly capture the syntactic structure of a sentence.

1 Introduction

Semantic role labeling (SRL) is a form of shallow semantic parsing whose goal is to discover the predicate-argument structure of each predicate in a given input sentence. Given a sentence, for each target verb (predicate) all the constituents in the sentence which fill a semantic role of the verb have to be recognized. Typical semantic arguments include Agent, Patient, Instrument, etc., and also adjuncts such as Locative, Temporal, Manner, Cause, etc.. SRL is useful as an intermediate step in a wide range of natural language processing (NLP) tasks, such as information extraction (Bastianelli et al., 2013), automatic document categorization (Persson et al., 2009) and question-answering (Dan and Lapata, 2007; Surdeanu et al., 2003; Moschitti et al., 2003).

SRL is considered as a supervised machine learning problem. In traditional methods, linear classifier such as SVM is often employed to perform this task based on features extracted from the training corpus. Actually, people often treat this problem as a multi-step classification task. First, whether an argument is related to the predicate is determined; next the detail relation type was decided(Palmer et al., 2010).

Syntactic information is considered to play an essential role in solving this problem (Punyakanok et al., 2008a). The location of an argument on syntactic tree provides an intermediate tag for improving the performance. However, building this syntactic tree also introduces the prediction risk inevitably. The analysis in (Pradhan et al., 2005) found that the major source of the incorrect predictions was the syntactic parser. Combination of different syntactic parsers was proposed to address this problem, from both feature level and model level (Surdeanu et al., 2007; Koomen et al., 2005; Pradhan et al., 2005).

Besides, feature templates in this classification task strongly rely on the expert experience. They need iterative modification after analyzing how the system performs on development data. When the corpus and data distribution are changed, or when people move to another language, the feature templates have to be re-designed.

To address the above issues, (Collobert et al.,

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1127–1137,
Beijing, China, July 26-31, 2015.

2011) proposed a unified neural network architecture using word embedding and convolution. They applied their architecture on four standard NLP tasks: Part-Of-Speech tagging (POS), chunking (CHUNK), Named Entity Recognition (NER) and Semantic Role Labeling (SRL). They were able to reach the previous state-of-the-art performance on all these tasks except for SRL. They had to resort to parsing features in order to make the system competitive with state-of-the-art performance.

In this work, we propose an end-to-end system using deep bi-directional long short-term memory (DB-LSTM) model to address the above difficulties. We take only original text as the input features, without any intermediate tag such as syntactic information. The input features are processed by the following 8 layers of LSTM bidirectionally. At the top locates the conditional random field (CRF) model for tag sequence prediction. We achieve the state-of-the-art performance of f-score $F_1 = 81.07$ on CoNLL-2005 shared task and $F_1 = 81.27$ on CoNLL-2012 shared task. At last, we find the traditional syntactic information can also be inferred from the learned representations.

2 Related Work

People solve SRL problems in two major ways. The first one follows the traditional spirit widely used in NLP basic problems. A linear classifier is employed with feature templates. Most efforts focus on how to extract the feature templates that can best describe the text properties from training corpus. One of the most important features is from syntactic parsing, although syntactic parsing is also considered as a difficult problem. Thus system combination appear to be the general solution.

In the work of (Pradhan et al., 2005), the syntactic tags are produced by Charniak parser (Charniak, 2000; Charniak and Johnson, 2005) and Collins parser (Collins, 2003) respectively. Based on this, different systems are built to generate SRL tags. These SRL tags are used to extend the original feature templates, along with flat syntactic chunking results. At last another classifier learns the final SRL tag from the above results. In their analysis, the combination of three different syntactic view brings large improvement for the system.

Similarly, Koomen et al. (Koomen et al., 2005) combined the system in another way. They built multiple classifiers and then all outputs are combined through an optimization problem. Surdeanu et al. fully discussed the combination strategy in (Surdeanu et al., 2007).

Beyond the above traditional methods, the second way try to solve this problem without feature engineering. Collobert et al. (Collobert et al., 2011) introduced a neural network model consists of word embedding layer, convolution layers and CRF layer. This pipeline addressed the data sparsity by initializing the model with word embeddings which is trained from large unlabeled text corpus. However, the convolution layer is not the best way to model long distance dependency since it only includes words within limited context. So they processed the whole sequence for each given pair of argument and predicate. This results in the computational complexity of $O(n_pL^2)$, with L denoting the sequence length and n_p the number of predicate, while the complexity of our model is linear ($O(n_pL)$). Moreover, in order to catch up with the performance of traditional methods, they had to incorporate the syntactic features by using parse trees of Charniak parser (Charniak, 2000) which still provides the major contribution.

At the inference stage, structural constraints often lead to improved results (Punyakanok et al., 2008b). The constraints comes from annotation conventions of the task and other linguistic considerations. With dynamic programming, (Täckström et al., 2015) enhance the inference efficiency further. But designation of the constraints depends much on the linguistic knowledge.

Nevertheless, the attempts of building end-to-end systems for NLP become popular in recent years. Inspired by the work in computer vision, people hierarchically organized a window of words through convolution layers in deep form to account for the higher level of organization to solve the document classification task (Kim, 2014; Zhang and LeCun, 2015). Step further, people have also achieved success in directly mapping the sequence to sequence level target as the work in dependency parsing and machine translation (Vinyals et al., 2014; Sutskever et al., 2014).

3 Approaches

In this paper, we propose an end-to-end system based on recurrent topology. Recurrent neural network (RNN) has natural advantage in modeling sequence problems. The past information is built up through the recurrent layer when model consumes the sequence word by word as shown in Eq. 1. x and y are the input and output of the recurrent layer with (t) denoting the time step, w_f^m and w_i^m are the matrix from input or recurrent layer to hidden layer. σ is the activation function. Without $y^{(t-1)}$ term, the rnn model returns to the feed forward form.

$$y_m^{(t)} = \sigma(\sum_f w_f^m x_f^{(t)} + \sum_i w_i^m y_i^{(t-1)}) \qquad (1)$$

However, people often met with two difficulties. First, information of the current word strongly depends on distant words, rather than its neighborhood. Second, gradient parameters may explode or vanish especially in processing long sequences (Bengio et al., 1994). Thus long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) was proposed to address the above difficulties.

In the following part, we will first give a brief introduction about the LSTM and then demonstrate how to build up a network based on LSTM to solve a typical sequence tagging problem: semantic role labeling.

3.1 Long Short-Term Memory (LSTM)

Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997; Graves et al., 2009) is an RNN architecture specifically designed to address the vanishing gradient and exploding gradient problems. The hidden neural units are replaced by a number of memory blocks. Each memory block contains several cells, whose activations are controlled by three multiplicative gates: the input gate, forget gate and output gate. With the above change, the original rnn model is improved to be:

$$\begin{aligned} y_m^{(t)} &= \sigma(s_{c,m}^{(t)}) \cdot \pi_m^{(t)} && (2) \\ &= \sigma(n_m^{(t)} \rho_m^{(t)} + \phi_m^{(t)} s_{c,m}^{(t-1)}) \cdot \pi_m^{(t)} && (3) \end{aligned}$$

Now y is the memory block output. n is equivalent to the original hidden value y in rnn model. ρ, ϕ and π are the input, forget and output gates value. $s_{c,m}$ is state value of cell c in block m and c is fixed to be 1 and omitted in common work. The computation of three multiplicative gates comes from input value, recurrent value and cell state value with different activations σ respectively as shown in the following and Fig. 1:

$$\begin{aligned} n_m^{(t)} &: \sigma_n(\sum_f w_{f,n}^m x_f^{(t)} + \sum_i w_{i,n}^m y_i^{(t-1)}) \qquad (4) \\ \rho_m^{(t)} &: \sigma_\rho(\sum_f w_{f,\rho}^m x_f^{(t)} + \sum_i w_{i,\rho}^m y_i^{(t-1)} + w_\rho^m s_m^{(t-1)}) \\ \phi_m^{(t)} &: \sigma_\phi(\sum_f w_{f,\phi}^m x_f^{(t)} + \sum_i w_{i,\phi}^m y_i^{(t-1)} + w_\phi^m s_m^{(t-1)}) \\ \pi_m^{(t)} &: \sigma_\pi(\sum_f w_{f,\pi}^m x_f^{(t)} + \sum_i w_{i,\pi}^m y_i^{(t-1)} + w_\pi^m s_m^{(t)}) \end{aligned}$$

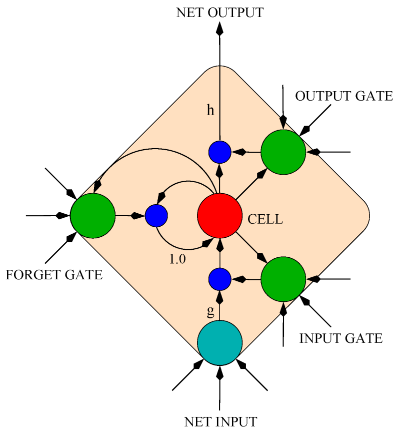

Figure 1: LSTM memory block with a single cell. (Graves et al., 2009)

The effect of the gates is to allow the cells to store and access information over long periods of time. When the input gate is closed, the new coming input information will not affect the previous cell state. Forget gate is used to remove the historical information stored in the cells. The rest of the network can access the stored value of a cell only when its output gate is open.

In language related problems, the structural knowledge can be extracted out by processing sequences both forward and backward so that the complementary information from the past and the future can be integrated for inference. Thus bi-directional LSTM (B-LSTM) containing two hidden layers were proposed(Schuster and Paliwal, 1997). Both hidden layers connect to the same input layer and output layer, processing the same sequence in two directions respectively (A. Graves, 2013).

In this work, we utilize the bi-directional information in another way. First a standard LSTM processes the sequence in forward direction. The output of this LSTM layer is taken by the next

LSTM layer as input, processed in reversed direction. These two standard LSTM layers compose a pair of LSTM. Then we stack LSTM layers pair after pair to obtain the deep LSTM model. We call this topology as deep bi-directional LSTM (DB-LSTM) network. Our experiments show that this architecture is critical to achieve good performance.

3.2 Pipeline

We process the sequence word by word. Two input features play an essential role in this pipeline: predicate (pred) and argument (argu), with argument describing the word under processing. The output for this pair of words is their semantic role. If a sequence has n_p predicates, we will process this sequence n_p times.

We also introduce two other features, predicate context (ctx-p) and region mark (m_r). Since a single predicate word can not exactly describe the predicate information, especially when the same words appear more than one times in a sentence. With the expanded context, the ambiguity can be largely eliminated. Similarly, we use region mark $m_r = 1$ to denote the argument position if it locates in the predicate context region, or $m_r = 0$ if not. These four simple features are all we need for our SRL system. In Tab. 1 we give an example sequence with the labels for each word. We do not use other types of features such as part of speech (POS), syntactic parsing, etc..

time	argu	pred	ctx-p	m_r	label
1	A	set	been set .	0	B-A1
2	record	set	been set .	0	I-A1
3	date	set	been set .	0	I-A1
4	has	set	been set .	0	O
5	n't	set	been set .	0	B-AM-NEG
6	been	set	been set .	1	O
7	set	set	been set .	1	B-V
8	.	set	been set .	1	O

Table 1: An example sequence with 4 input features: argument, predicate, predicate context (context length is 3) , region mark. "IOB" tagging scheme is used (Collobert et al., 2011).

Because the large number of parameters associated with the argument words, similar to (Collobert et al., 2011), the pre-trained word representations are employed to address the data sparsity issue. We used a large unlabeled text corpus to train a neural language model (NLM) (Bengio et al., 2006; Bengio et al., 2003) and then initialized the argument and predicate word representations with parameters from the NLM representations. There are various ways of obtaining good word representations (Mikolov et al., 2013; Collobert and Weston, 2008; Mnih and Kavukcuoglu, 2013; Yu et al., 2014). A systematic comparison of them on the task of SRL is beyond the scope of this work.

The above four features are concatenated to be the input representation at this time step for the following LSTM layers. As described in Sec. 3.1, we use DB-LSTM topology to learn the sequence knowledge and we build up to 8 layers of DB-LSTM in our work.

As in traditional methods, we employ CRF (Lafferty et al., 2001) on top of the network for the final prediction. It takes the representations provided by the last LSTM layer as input to model the strong dependance among adjacent tags.

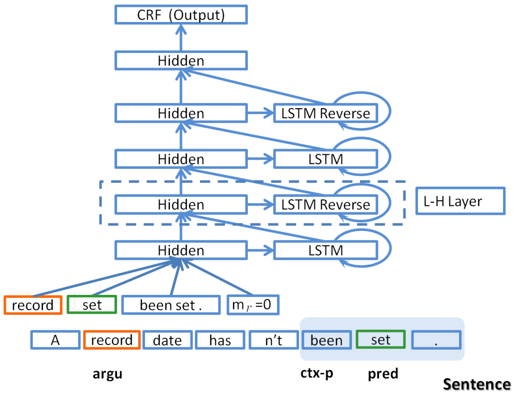

Figure 2: DB-LSTM network.Shadow part denote the predicate context within length 1.

The complete model with 4 LSTM layers is illustrated in Fig. 2. At the bottom of the graph locates the word sequence in Tab. 1. For a given time step (step 2 as an example), argument and predicate are specified with different color. We use the shadowed region to denote the predicate context. The temporal expanded version of the model is shown in Fig. 3. L-H denotes the LSTM hidden layer.

We use the stochastic gradient descent (SGD) algorithm as the training technique for the whole pipeline (Lecun et al., 1998). For a given sequence, we look up the embedding of each word and process this vector with the following LSTM layers for the high level representation. After having finished the whole sequence, we take the representations of all time steps as the input features

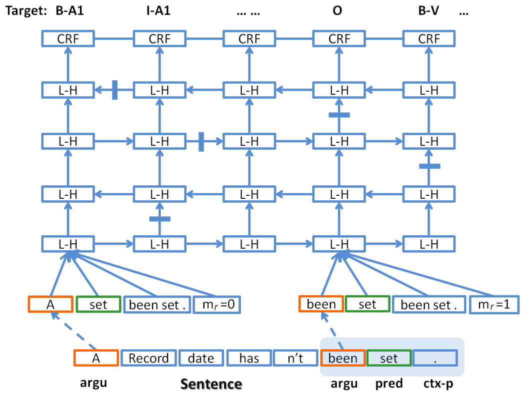

Figure 3: Temporal expanded DB-LSTM network. Bars denote that the connections are blocked by the closed gates. Shadow part denotes the predicate context.

for CRF to perform the sequence tagging task. The traditional viterbi decoding is used for inference. The gradient of the log-likelihood of the tag sequence with respect to the input of the CRF is calculated and back-propagated to all the DB-LSTM layers to get the gradient of the parameters (Collobert et al., 2011).

4 Experiments

We mainly evaluated and analyzed our system on the commonly used CoNLL-2005 shared task data set and the conclusions are also validated on CoNLL-2012 shared task.

4.1 Data set

CoNLL-2005 data set takes section 2-21 of Wall Street Journal (WSJ) data as training set, and section 24 as development set. The test set consists of section 23 of WSJ concatenated with 3 sections from Brown corpus (Carreras and Màrquez, 2005). CoNLL-2012 data set is extracted from OntoNotes v5.0 corpus. The description and separation of train, development and test data set can be found in (Pradhan et al., 2013).

4.2 Word embedding

We trained word embeddings with English Wikipedia (Ewk) corpus using NLM (Bengio et al., 2006). The corpus contains 995 million tokens. We transformed all the words into their lowercase and the vocabulary size is 4.9 million. About 5% words in CoNLL 2005 data set can not be found in Ewk dictionary and are marked as <unk>. In all experiments, we use the same word embedding with dimension 32.

4.3 Network topology

In this part, we will analyze the performance of two different networks, the CNN and LSTM network. Although at last we find CNN can not provide the results as good as that from LSTM, the analysis still help us to gain a deep insight of this problem. In CNN, we add argument context as the fifth feature and the other four features are the same as that used in LSTM. In order to have good understanding of the contribution from each modeling decision, we started from a simple model and add more units step by step.

4.3.1 Convolutional neural network

Using CNN to solve SRL problem has been introduced in (Collobert et al., 2011). Since we only focus on the analysis of features, a simplified version is used here.

Our feature set consists of five parts as described above. The representation of argument and predicate can be obtained by looking up the Emb(Ewk) dictionary. And the representation of argument context and predicate context can be obtained by concatenating the embedding of each word in the context. For each of the above four parts, we add a hidden layer. Then all these four hidden layers together with region mark are projected onto the next hidden layer. At last we use a CRF layer for prediction (See Fig. 4). With above set up, the computational complexity is $O(n_p L)$.

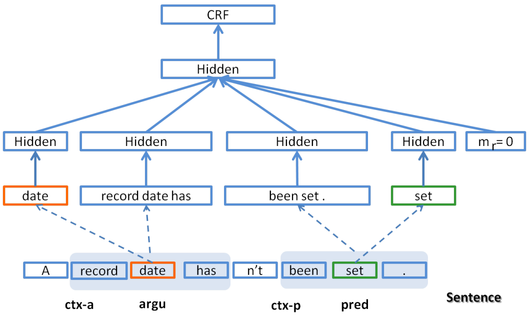

Figure 4: CNN Pipeline. Shadow parts denote the argument context and predicate context respectively

The size of hidden layers connected to argument or predicate is set to be $h_{1w} = 32$. The size of the other two hidden layers connected to context embedding is set to be $h_{1c} = 128$ since the corresponding inputs are larger. To simplify the parameter setting and results comparison, we use the same learning rate $l = 1 \times 10^{-3}$ for each layer and keep this rate a constant during model training. The second hidden layer dimension h_2 is also 128. All hidden layer activation function is $tanh$.

In Tab. 2, it is shown that longer argument and predicate context result in better performance, since longer context brings more information. We observe the same trends in other NLP experiments, such as NER, POS tagging. The difference is that we do not need to use the context length up to 11. This is because most of the useful information for NER and POS tagging is local respect the label position, while in SRL there exists long distance relationship. So in traditional methods for SRL, syntactic trees are often introduced to account for such relation. In order to see whether the improvement from CNN-2 to CNN-3 is due to longer context or larger model size, we tested a model CNN-6 with same context length but more model parameters. As we can see from the result of CoNLL-2005 data set (Tab. 2), larger model does not improve the result.

name	h_{1c}	ctx-a	ctx-p	m_r	F_1(dev)	F_1
CNN-1	128	1	5	y	41.22	41.24
CNN-2	128	5	5	y	51.83	52.09
CNN-3	128	11	5	y	52.81	53.07
CNN-4	128	11	1	y	49.69	50.70
CNN-5	128	11	5	n	36.40	37.50
CNN-6	256	5	5	y	51.60	51.91

Table 2: F_1 of CNN method on development set and test set of CoNLL-2005 data set.

Without using region mark (m_r) feature, the F_1 drops from the 53.07 of CNN-3 to the 37.50 of CNN-5. Since it is generally believed that words near the predicate are more likely to be related to the predicate.

SRL is a typical problem with long distance dependency, while the convolution operation can only learn the knowledge from the limited neighborhood. This is why we have to introduce long context. However, the language information can not be expressed just by linearly expanding the context as what we did in CNN pipeline. In order to better summarize the sequence structure, we turn to LSTM network.

4.3.2 LSTM network

Here the feature set consists of four parts. Argument and predicate are necessary parts in this problem. In recurrent model, argument context (ctx-a) is no longer needed and we only expand the predicate context. We also need the region mark defined in the same way as in CNN. The architecture has been shown in Fig. 2 and described in Sec. 3.2.

Since it is difficult to propagate the error from the top to the bottom layers, we use two learning rates. At the bottom, $i.e.$ from embeddings to the first LSTM layer, we use $l_b = 1 \times 10^{-2}$ for model depth $d <= 4$ and $l_b = 2 \times 10^{-2}$ for $d > 4$. For the other LSTM layers and CRF layer, we set learning rate $l = l_b \times 10^{-3}$. We kept all learning rates constant during training. The model size can be enlarged by increasing the number of LSTM layers (d) or the dimension of hidden layers (h). L2 weight decay in SGD is used for model regularization and we set its strength $r_2 = 8 \times 10^{-4}$:

$$w \leftarrow w - l \cdot (g + r_2 \cdot w) \tag{5}$$

where w denotes the parameter, g the gradient of the log likelihood of the label with respect to the parameter.

We started on CoNLL-2005 dataset from a small model with only one LSTM layer and $h = 32$. All word embeddings were randomly initialized. Predicate context length was 1. Region mark is not used. With this model, we obtained $F_1 = 49.44$ (Tab. 3), better than that of CNN without using argument context (41.24) or region mark (37.50). This result suggests that, the recurrent structure can extract sequential information more effectively than CNN.

By adding predicate context with length 5, F_1 is improved from 49.44 to 56.85 (Tab. 3). This is because we only recurrently process the argument word, so we still need predicate context for more detail. Further more, F_1 rises to 58.71 with region mark feature. The reason is the same as we explained in CNN pipeline.

Next we change the random initialization of word representation to the pre-trained word representation from Emb(Ewk). This representation is fixed in the training process. F_1 rises to 65.11 (See Tab. 3).

So far, we have shown the effect from each part of features in LSTM network. The conclusion is consistent with what we found in CNN network. Besides, LSTM exhibits better abilities to learn the sequence structure. Next, we gradually increase the model size to further enhance the performance.

Emb	d	ctx-p	m_r	h	F_1(dev)	F_1

Table 3: F_1 with LSTM method on development set and test set of CoNLL-2005 data set and CoNLL-2012 data set. Emb: the type of embedding. d: the number of LSTM layers. ctx-p: predicate context length. m_r: region mark feature. h: hidden layer size.

We find that the critical improvement comes from increasing the depth of LSTM network. After adding a reversed LSTM layer, F_1 is improved from 65.11 to 72.56. And the F_1 of the system with $d = 4, 6, 8$ are $75.74, 78.02$ and 78.28 respectively. With 6-layer network, we have outperformed the CoNLL-2005 shared task winner system with $F_1 = 77.92$ (Koomen et al., 2005). Our experiment results also show that the further performance gain by increasing the depth from 6 to 8 is relative small.

Another way to increase the model size is to increase the hidden layer dimension h. We gradually increase the dimension from 32 to $64, 128$, and the corresponding results are listed in Tab. 3. The best F_1 we obtained is 80.28 with $h = 128$. We also show the result $F_1 = 80.70$ on CoNLL-2012 dataset in Tab. 3 with exactly the same setup.

In the above experiments, learning rate and weight decay rate are fixed for the sake of simplicity in comparing different models. To further improve the model, we perform a fine tuning step to adjust the parameters based on previously trained model. This includes the relaxation of weight decay and decrease of learning rate. We set $r_2 = 4 \times 10^{-4}$ and $l_b = 1 \times 10^{-2}$, and obtain $F_1 = 81.07$ as the final result of CoNLL-2005 data set and $F_1 = 81.27$ of CoNLL-2012 data set.

Table 4: Comparison with previous methods.

In Tab. 4, we compare the performance of other works. On CoNLL-2005 shared task, merging syntactic tree at feature level instead of model level exhibits the similar performance with $F_1 = 77.30$ (Pradhan et al., 2005). After further investigation on model combination, Surdeanu et al. obtained a better system (Surdeanu et al., 2007). We also list the results from (Toutanova et al., 2008) and (Täckström et al., 2015) of the joint model with additional considerations of standard linguistic assumptions. For convolution based methods (Collobert et al., 2011), the best F_1 is 76.06, in which syntactic parser plays an essential role. The result without using parser drops down to 74.15. On Brown set, we observe the better performance from the work of (Surdeanu et al., 2007) and (Täckström et al., 2015). We hypothesize that DB-LSTM is a data-driven method that can not performs well on out-domain dataset.

On CoNLL-2012 data set, the traditional method gives $F_1 = 75.53$ (Pradhan et al., 2013) and a dynamic programming algorithm for efficient constrained inference in SRL gives $F_1 = 79.4$ (Täckström et al., 2015) , both of them also rely on syntax trees.

Since the input feature size is much smaller then the traditional sparse feature templates, the inference stage is very efficient that the model can process 6.7k tokens per second on average.

4.4 Analysis

We analyze our results on CoNLL-2005 data set. First we list the details including the performance on each sub-classes in Tab. 5. The results of CoNLL-2005 shared task winner system (Koomen et al., 2005) are also shown for comparison. Their

Table 5: F_1 on each sub sets and classes (CoNLL-2005). (We remove the classes with low statistics.)

final system is the combination of the results of 5 parsing trees from two different parsers. They also reported the scores of each single system on development set and we list the best one of them (dev(s)).

We observe the improvement of F_1 on development set and test set are 2.20 and 3.15 respectively. For single system, the improvement is 4.79 on development set. We also notice that our model show improvement on both WSJ and Brown test set. The advantage of our model is even more significant when comparing with the previous effort of end-to-end training of SRL model (Collobert et al., 2011). Without using linguistic features from parse tree, the F_1 of Collobert's model is 74.15, which is 6.92 lower than our model.

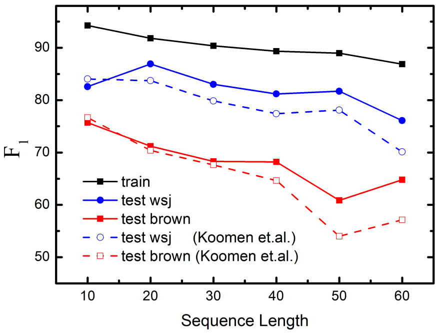

Figure 5: F_1 $vs.$ sentence length (CoNLL-2005).

In order to analyze the performance of our model on the sentences with different lengths, we split the data into 6 bins according to the sentence length, with bin width being 10 words and the last bin includes sequences with $L > 50$ because of insufficient data for longer sentences. Fig. 5 shows F_1 scores at different sequence lengths on WSJ test data and Brown test data for our model and Koomen's model (baseline) (Koomen et al., 2005). In all curves, performance degrades with increased sentence length. However, the performance gain of our model over the baseline model is larger for longer sentences.

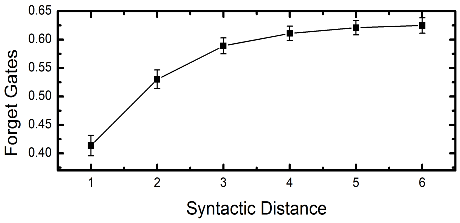

Figure 7: Averaged Forget gates value $vs.$ Syntactic distance (CoNLL-2005). The last point includes instances with syntactic distance $d_s \geq 6$.

Since we do not use any syntactic information as input feature, we are curious about whether this information can be extracted out from the system parameters. In LSTM, forget gates are used to control the use of historical information. We compute the average value v_{fg} of forget gates of the 7^{th} LSTM layer at word position for a given sentence. We also introduce a variable named syntactic distance d_s to represent the number of edges between argument word and predicate word in the dependency parsing tree. Four example sentences are shown in Fig. 6. For each figure, the bottom axis denotes an example sentence. At the top of each graph is the corresponding dependency tree built from gold dependency parsing tag. At the bottom, v_{fg} and d_s are shown in black and red line. Noticed that the higher forget gates values means "Remember" and smaller values "Forget". Smaller d_s means that it is easy to make prediction that long history is unnecessary. On the contrary, large d_s results in a difficult prediction that long historical information is needed. We also computed the average v_{fg} over instances and found it monotonously increases with d_s(Fig. 7). The coincidence of v_{fg} and d_s suggests that the model implicitly captures some syntactic structure.

5 Conclusion and Future work

We investigate a traditional NLP problem SRL with DB-LSTM network. With this model, we are

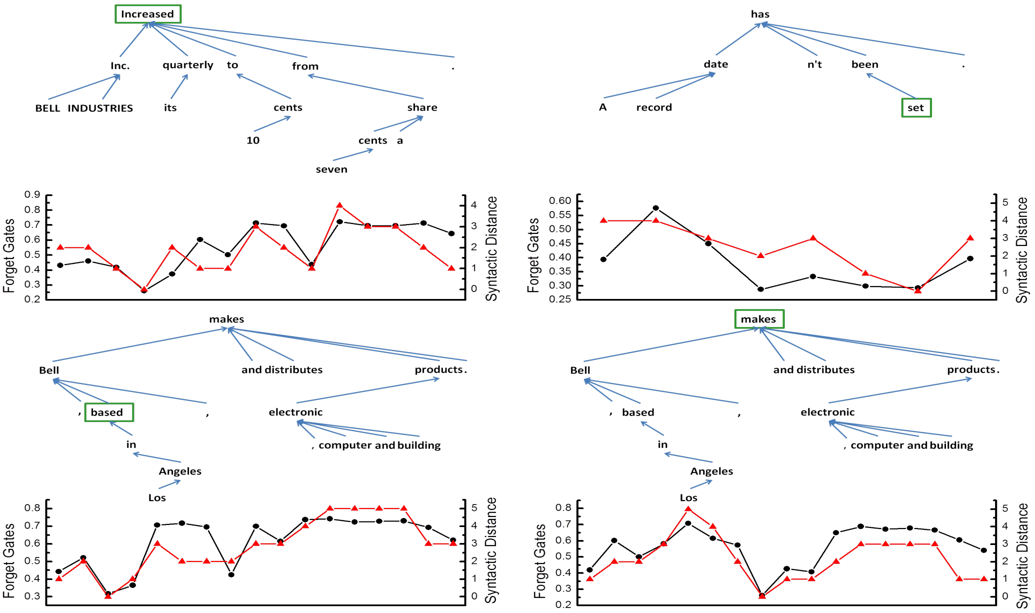

Figure 6: Forget gates value $vs.$ Syntactic distance on four example sentences. Top: dependency parsing tree from gold tag. Green square word: predicate word. Bottom black solid lines: forget gates value at each time step. Bottom red empty square lines: gold syntactic distance between the current argument and predicate.

able to bypass the traditional steps for extracting the intermediate NLP features such as POS and syntactic parsing and avoid human engineering the feature templates. The model is trained to predict the SRL tag directly from the original word sequence with four simple features without any explicit linguistic knowledge. Our model achieves F_1 score of 81.07 on CoNLL-2005 shared task and 81.27 on CoNLL-2012 shared task, both outperforming the previous systems based on parsing results and feature engineering, which heavily rely on the linguistic knowledge from expert. Furthermore, the simplified feature templates results in high inference efficiency with $6.7k$ tokens per second.

In our experiments, increasing the model depth is the major contribution to the final improvement. With deep model, we achieve strong ability of learning semantic rules without worrying about over-fitting even on such limited training set. It also outperforms the convolution method with large context length. Moreover, with more sophisticatedly designed network and training technique based on LSTM, such as the attempt to integrate the parse tree concept into LSTM framework (Tai et al., 2015), we believe the better performance can be achieved.

We show in our analysis that for long sequences our model has even larger advantage over the traditional models. On one hand, LSTM network is capable of capturing the long distance dependency especially in its deep form. On the other hand, the traditional feature templates are only good at describing the properties in neighborhood and a small mistake in syntactic tree will results in large deviation in SRL tagging. Moreover, from the analysis of the internal states of the deep network, we see that the model implicitly learn to capture some syntactic structure similar to the dependency parsing tree.

It is encouraging to see that deep learning models with end-to-end training can outperform traditional models on tasks which are previously believed to heavily depend on syntactic parsing (Koomen et al., 2005; Pradhan et al., 2013). However, we recognize that semantic role labeling itself is an intermediate step towards the language problems we really care about, such as question answering, information extraction etc. We believe that end-to-end training with some suitable deep structure yet to be invented might be proven to be effective to solving these problems. And we are seeing some recent active research exploring this possibility (Weston et al., 2014; Weston et al., 2015; Graves et al., 2014).

Abstract

The performance of discriminative constituent parsing relies crucially on feature engineering, and effective features usually have to be carefully selected through a painful manual process. In this paper, we propose to automatically learn a set of effective features via neural networks. Specifically, we build a feedforward neural network model, which takes as input a few primitive units (words, POS tags and certain contextual tokens) from the local context, induces the feature representation in the hidden layer and makes parsing predictions in the output layer. The network simultaneously learns the feature representation and the prediction model parameters using a back propagation algorithm. By pre-training the model on a large amount of automatically parsed data, and then fine-tuning on the manually annotated Treebank data, our parser achieves the highest F_1 score at 86.6% on Chinese Treebank 5.1, and a competitive F_1 score at 90.7% on English Treebank. More importantly, our parser generalizes well on cross-domain test sets, where we significantly outperform Berkeley parser by 3.4 points on average for Chinese and 2.5 points for English.

1 Introduction

Constituent parsing seeks to uncover the phrase structure representation of sentences that can be used in a variety of natural language applications such as machine translation, information extraction and question answering (Jurafsky and Martin, 2008). One of the major challenges for this task is that constituent parsers require an inference algorithm of high computational complexity in order to search over their large structural space, which makes it very hard to efficiently train discriminative models. So, for a long time, the task was mainly solved with generative models (Collins, 1999; Charniak, 2000; Petrov et al., 2006). In the last few years, however, with the use of effective parsing strategies, approximate inference algorithms, and more efficient training methods, discriminative models began to surpass the generative models (Carreras et al., 2008; Zhu et al., 2013; Wang and Xue, 2014).

Just like other NLP tasks, the performance of discriminative constituent parsing crucially relies on feature engineering. If the feature set is too small, it might underfit the model and leads to low performance. On the other hand, too many features may result in an overfitting problem. Usually, an effective set of features have to be designed manually and selected through repeated experiments (Sagae and Lavie, 2005; Wang et al., 2006; Zhang and Clark, 2009). Not only does this procedure require a lot of expertise, but it is also tedious and time-consuming. Even after this painstaking process, it is still hard to say whether the selected feature set is complete or optimal to obtain the best possible results. A more desirable alternative is to learn features automatically with machine learning algorithms. Lei et al. (2014) proposed to learn features by representing the cross-products of some primitive units with low-rank tensors for dependency parsing. However, to achieve competitive performance, they had to combine the learned features with the traditional hand-crafted features. For constituent parsing, Henderson (2003) employed a recurrent neural network to induce features from an unbounded parsing history. However, the final performance was below the state of the art.

In this work, we design a much simpler neural network to automatically induce features from just the local context for constituent parsing. Con-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics

Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

cretely, we choose the shift-reduce parsing strategy to build the constituent structure of a sentence, and train a feedforward neural network model to jointly learn feature representations and make parsing predictions. The input layer of the network takes as input a few primitive units (words, POS tags and certain contextual tokens) from the local context, the hidden layer aims to induce a distributed feature representation by combining all the primitive units with different weights, and the output layer attempts to make parsing predictions based on the feature representation. During the training process, the model simultaneously learns the feature representation and prediction model parameters using a backpropagation algorithm. Theoretically, the learned feature representation is optimal (or at least locally optimal) for the parsing predictions. In practice, however, our model does not work well if it is only trained on the manually annotated Treebank data sets. However, when pre-trained on a large amount of automatically parsed data and then fine-tuned on the Treebank data sets, our model achieves a fairly large improvement in performance. We evaluated our model on both Chinese and English. On standard data sets, our model reaches $F_1 = 86.6\%$ for Chinese and outperforms all the state-of-the-art systems, and for English our final performance is $F_1 = 90.7\%$ and this result surpasses that of all the previous neural network based models and is comparable to the state-of-the-art systems. On cross-domain data sets, our model outperforms the Berkeley Parser [1] by 3.4 percentage points for Chinese and 2.5 percentage points for English.

The remainder of this paper is organized as follows: Section 2 introduces the shift-reduce constituent parsing approach. Section 3 describes our feature optimization model and some parameter estimation techniques. We discuss and analyze our experimental results in Section 4. Section 5 discusses related work. Finally, we conclude this paper in Section 6.

2 Shift-Reduce Constituent Parsing

Shift-reduce constituent parsing utilizes a series of shift-reduce decisions to construct syntactic trees. Formally, the shift-reduce system is a quadruple $C = (S, T, s_0, S_t)$, where S is a set of parser *states* (sometimes called *configurations*), T is a finite set of *actions*, s_0 is an initialization function

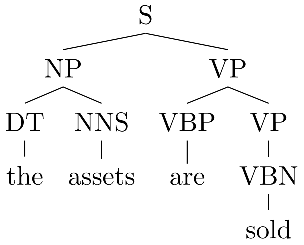

Figure 1: An example of constituent tree.

to map each input sentence into a unique *initial state*, and $S_t \in S$ is a set of *terminal states*. Each action $t \in T$ is a transition function that maps a state into a new state. A parser state $s \in S$ is defined as a tuple $s = (\sigma, \beta)$, where σ is a *stack* which is maintained to hold partial subtrees that are already constructed, and β is a *queue* which is used for storing remaining unprocessed words. In particular, the initial state has an empty stack σ and a queue β containing the entire input sentence, and the terminal states have an empty queue β and a stack σ containing only one complete parse tree. The task of parsing is to scan the input sentence from left to right and perform a sequence of shift-reduce actions to transform the initial state into a terminal state.

In order to jointly assign POS tags and construct a constituent structure for an input sentence, we define the following actions for the action set T, following Wang and Xue (2014):

- SHIFT-X (`sh-x`): remove the first word from β, assign a POS tag X to the word and push it onto the top of σ;

- REDUCE-UNARY-X (`ru-x`): pop the top subtree from σ, construct a new unary node labeled with X for the subtree, then push the new subtree back onto σ. The head of the new subtree is inherited from its child;

- REDUCE-BINARY-{L/R}-X (`rl`/`rr-x`): pop the top two subtrees from σ, combine them into a new tree with a node labeled with X, then push the new subtree back onto σ. The left (L) and right (R) versions of the action indicate whether the head of the new subtree is inherited from its left or right child.

With these actions, our parser can process trees with unary and binary branches easily. For example, in Figure 1, for the sentence "the assets are sold", our parser can construct the

[1] https://code.google.com/p/berkeleyparser/

parse tree by performing the action sequence {sh-DT, sh-NNS, rr-NP, sh-VBP, sh-VBN, ru-VP, rr-VP, rr-S}. To process multi-branch trees, we employ binarization and debinarization processes described in Zhang and Clark (2009) to transform multi-branch trees into binary trees and restore the generated binary trees back to their original forms. For inference, we employ the beam search decoding algorithm (Zhang and Clark, 2009) to balance the tradeoff between accuracy and efficiency.

3 Feature Optimization Model

3.1 Model

To determine which action $t \in T$ should be performed at a given state $s \in S$, we need a model to score each possible $\langle s, t \rangle$ combination. In previous approaches (Sagae and Lavie, 2005; Wang et al., 2006; Zhang and Clark, 2009), the model is usually defined as a linear model $Score(s, t) = \overrightarrow{w} \cdot \Phi(s, t)$, where $\Phi(s, t)$ is a vector of hand-crafted features for each state-action pair and $\overrightarrow{w}$ is the weight vector for these features. The hand-crafted features are usually constructed by compounding primitive units according to some feature templates. For example, almost all the previous work employed the list of primitive units in Table 1(a), and constructed hand-crafted features by concatenating these primitive units according to the feature templates in Table 1(b). Obviously, these feature templates are only a small subset of the cross products of all the primitive units. This feature set is the result of a large number of experiments through trial and error from previous work. Still we cannot say for sure that this is the optimal subset of features for the parsing task.

To cope with this problem, we propose to simultaneously optimize feature representation and parsing accuracy via a neural network model. Figure 2 illustrates the architecture of our model. Our model consists of input, projection, hidden and output layers. First, in the input layer, all primitive units (shown in Table 1(a)) are imported to the network. We also import the suffixes and prefixes of the first word in the queue, because these units have been shown to be very effective for predicting POS tags (Ratnaparkhi, 1996). Then, in the projection layer, each primitive unit is projected into a vector. Specifically, word-type units are represented as word embeddings, and other units are transformed into one-hot representations. The vectors of all primitive units are concatenated to form a holistic vector for the projection layer. The hidden layer corresponds to the feature representation we want to learn. Each dimension in the hidden layer can be seen as an abstract factor of all primitive units, and it calculates a weighted sum of all nodes from the projection layer and applies a non-linear *activation function* to yield its activation. We choose the *logistic sigmoid* function for the hidden layer. The output layer is used for making parsing predictions. Each node in the output layer corresponds to a shift-reduce action. We want to interpret the activation of the output layer as a probability distribution over all possible shift-reduce actions, therefore we normalize the output activations (weighted summations of all nodes from the hidden layer) with the *softmax* function.

(b) Feature Templates

Table 1: Primitive units (a) and feature templates (b) for shift-reduce constituent parsing, where p_i represents the i_{th} subtree in the stack and q_i denotes the i_{th} word in the queue. w refers to the head word, t refers to the head POS, and c refers to the constituent label. p_{il} and p_{ir} refer to the left and right child for a binary subtree p_i, and p_{iu} refers to the child of a unary subtree p_i.

3.2 Parameter Estimation

Our model consists of three groups of parameters: (1) the word embedding for each word type unit,

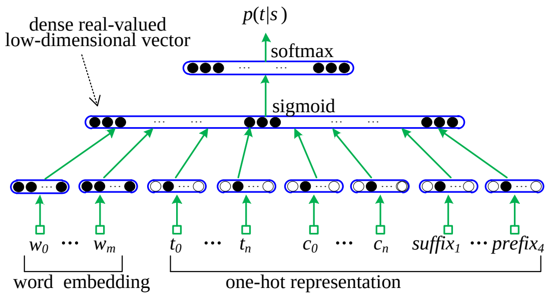

Figure 2: Neural network architecture for constituent parsing, where w_i denotes word type unit, t_i denotes POS tag unit, c_i denotes constituent label unit, $suffix_i$ and $prefix_i$ $(1 \leq i \leq 4)$ denotes i-character word suffix or prefix for the first word in the queue.

(2) the connections between the projection layer and the hidden layer which are used for learning an optimal feature representation and (3) the connections between the hidden layer and the output layer which are used for making accurate parsing predictions. We decided to learn word embeddings separately, so that we can take advantage of a large amount of unlabeled data. The remaining two groups of parameters can be trained simultaneously by the back propagation algorithm (Rumelhart et al., 1988) to maximize the likelihood over the training data.

We also employ three crucial techniques to seek more effective parameters. First, we utilize mini-batched AdaGrad (Duchi et al., 2011), in which the learning rate is adapted differently for different parameters at different training steps. With this technique, we can start with a very large learning rate which decreases during training, and can thus perform a far more thorough search within the parameter space. In our experiments, we got a much faster convergence rate with slightly better accuracy by using the learning rate $\alpha = 1$ instead of the commonly-used $\alpha = 0.01$. Second, we initialize the model parameters by pre-training. Unsupervised pre-training has demonstrated its effectiveness as a way of initializing neural network models (Erhan et al., 2010). Since our model requires many run-time primitive units (POS tags and constituent labels), we employ an in-house shift-reduce parser to parse a large amount of unlabeled sentences, and pre-train the model with the automatically parsed data. Third, we utilize the Dropout strategy to address the overfitting problem. However, different from Hinton et al. (2012), we only use Dropout during testing, because we found that using Dropout during training did not improve the parsing performance (on the dev set) while greatly slowing down the training process.

4 Experiment

4.1 Experimental Setting

We conducted experiments on the Penn Chinese Treebank (CTB) version 5.1 (Xue et al., 2005) and the Wall Street Journal (WSJ) portion of Penn English Treebank (Marcus et al., 1993). To fairly compare with other work, we follow the standard data division. For Chinese, we allocated Articles 001-270 and 400-1151 as the training set, Articles 301-325 as the development set, and Articles 271-300 as the testing set. For English, we use sections 2-21 for training, section 22 for developing and section 23 for testing.

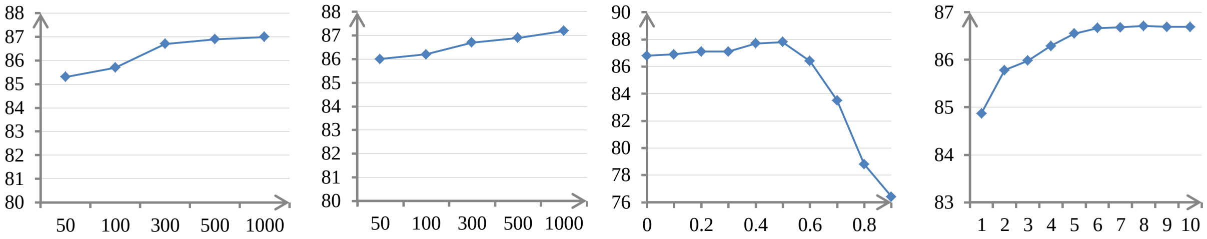
We also utilized some unlabeled corpora and used the word2vec[2] toolkit to train word embeddings. For Chinese, we used the unlabeled Chinese Gigaword (LDC2003T09) and performed Chinese word segmentation using our in-house segmenter. For English, we randomly selected 9 million sentences from our in-house newswire corpus, which has no overlap with our training, testing and development sets. We use Evalb[3] toolkit to evaluate parsing performance.

4.2 Characteristics of Our Model

There are several hyper-parameters in our model, e.g., the word embedding dimension ($wordDim$), the hidden layer node size ($hiddenSize$), the Dropout ratio ($dropRatio$) and the beam size for inference ($beamSize$). The choice of these hyper-parameters may affect the final performance. In this subsection, we present some experiments to demonstrate the characteristics of our model, and select a group of proper hyper-parameters that we use to evaluate our final model. All the experiments in this subsection were performed on Chinese data and the evaluation is performed on Chinese development set.

First, we evaluated the effectiveness of various primitive units. We set $wordDim = 300$, $hiddenSize = 300$, $beamSize = 8$, and did not apply Dropout ($dropRatio = 0$). Table 2 presents the results. By comparing numbers in other rows

[2] https://code.google.com/p/word2vec/
[3] http://nlp.cs.nyu.edu/evalb/



(a) word embedding dimension (b) hidden layer size (c) Dropout ratio (d) beam size

Figure 3: Influence of hyper-parameters.

with row “All Units”, we found that ablating the Prefix and Suffix units (“w/o Prefix & Suffix”) significantly hurts both POS tagging and parsing performance. Ablating POS units (“w/o POS”) or constituent label units (“w/o NT”) has little effect on POS tagging accuracy, but hurts parsing performance. When only keeping the word type units (“Only Word”), both the POS tagging and parsing accuracy drops drastically. So the Prefix and Suffix units are crucial for POS tagging, and POS units and constituent label units are helpful for parsing performance. All these primitive units are indispensable to better performance.

Second, we uncovered the effect of the dimension of word embedding. We set $hiddenSize = 300$, $beamSize = 8$, $dropRatio = 0$ and varied $wordDim$ among {50, 100, 300, 500, 1000}. Figure 3(a) draws the parsing performance curve. When increasing $wordDim$ from 50 to 300, parsing performance improves more than 1.5 percentage points. After that, the curve flattens out, and parsing performance only gets marginal improvement. Therefore, in the following experiments, we fixed $wordDim = 300$.

Third, we tested the effect of hidden layer node size. We varied $hiddenSize$ among {50, 100, 300, 500, 1000}. Figure 3(b) draws the parsing performance curve. We found increasing $hiddenSize$ is helpful for parsing performance. However, higher $hiddenSize$ would greatly increase the amount of computation. To keep the efficiency of our model, we fixed $hiddenSize = 300$ in the following experiments.

Fourth, we applied Dropout and tuned the Dropout ratio through experiments. Figure 3(c) shows the results. We found that the peak performance occurred at $dropRatio = 0.5$, which brought about an improvement of more than 1 percentage point over the model without Dropout ($dropRatio = 0$). Therefore, we fixed $dropRatio = 0.5$.

Primitive Units	F_1	POS
All Units	86.7	96.7
w/o Prefix & Suffix	85.7	95.4
w/o POS	86.0	96.7
w/o NT	86.2	96.6
Only Word	82.7	95.2

Table 2: Influence of primitive units.

Finally, we investigated the effect of beam size. Figure 3(d) shows the curve. We found increasing $beamSize$ greatly improves the performance initially, but no further improvement is observed after $beamSize$ is greater than 8. Therefore, we fixed $beamSize = 8$ in the following experiments.

4.3 Semi-supervised Training

In this subsection, we investigated whether we can train more effective models using automatically parsed data. We randomly selected 200K sentences from our unlabeled data sets for both Chinese and English. Then, we used an in-house shift-reduce parser[4] to parse these selected sentences. The size of the automatically parsed data set may have an impact on the final model. So we trained many models with varying amounts of automatically parsed data. We also designed two strategies to exploit the automatically parsed data. The first strategy (Mix-Train) is to directly add the automatically parsed data to the hand-annotated training set and train models with the mixed data set. The second strategy (Pre-Train) is to first pretrain models with the automatically parsed data, and then fine-tune models with the hand-annotated training set.

Table 3 shows results of different experimental configurations for Chinese. For the Mix-Train

[4] Its performance is F_1 =83.9 on Chinese and F_1 =90.8% on English.

	Mix-Train		Pre-Train	
# Auto Sent	F_1	POS	F_1	POS
0	87.8	97.0	—	—
50K	87.2	96.8	88.4	97.1
100K	88.7	96.9	89.5	97.1
200K	89.2	97.2	89.5	97.4

Table 3: Semi-supervised training for Chinese.

	Mix-Train		Pre-Train	
# Auto Sent	F_1	POS	F_1	POS
0	89.7	96.6	—	—
50K	89.4	96.1	90.2	96.4
100K	89.5	96.0	90.4	96.5
200K	89.2	95.8	90.8	96.7

Table 4: Semi-supervised training for English.

strategy, when we only use 50K automatically parsed sentences, the performance drops in comparison with the model trained without using any automatically parsed data. When we increase the automatically parsed data to 100K sentences, the parsing performance improves about 1 percent but the POS tagging accuracy drops slightly. When we further increase the automatically parsed data to 200K sentences, both the parsing performance and POS tagging accuracy improve. For the Pre-Train strategy, the performance of all three configurations improves performance against the model that does not use any automatically parsed data. The Pre-Train strategy consistently outperforms the Mix-Train strategy when the same amount of automatically parsed data is used. Therefore, for Chinese, the Pre-Train strategy is much more helpful, and the more automatically parsed data we use the better performance we get.

Table 4 presents results of different experimental configurations for English. The performance trend for the Mix-Train strategy is different from that of Chinese. Here, no matter how much automatically parsed data we use, there is a consistent degradation in performance against the model that does not use any automatically parsed data at all. And the more automatically parsed data we use, the larger the drop in accuracy. For the Pre-Train strategy, the trend is similar to Chinese. The parsing performance of the Pre-Train setting consistently improves as the size of automatically parsed data increases.

4.4 Comparing With State-of-the-art Systems

In this subsection, we present the performance of our models on the testing sets. We trained two systems. The first system ("Supervised") is trained only with the hand-annotated training set, and the second system ("Pretrain-Finetune") is trained with the Pre-Train strategy described in subsection 4.3 using additional automatically parsed data. The best parameters for the two systems are set based on their performance on the development set. To further illustrate the effectiveness of our systems, we also compare them with some state-of-the-art systems. We group parsing systems into three categories: supervised single systems (SI), semi-supervised single systems (SE) and reranking systems (RE). Both of our two models belong to semi-supervised single systems, because our "Supervised" system utilized word embeddings in its input layer.

Table 5 lists the performance of our systems as well as the state-of-the-art systems on Chinese test set. Comparing the performance of our two systems, we see that our "Pretrain-Finetune" system shows a fairly large gain over the "Supervised" system. One explanation is that our neural network model is a non-linear model, so the back propagation algorithm can only reach a local optimum. In our "Supervised" system the starting points are randomly initialized in the parameter space, so it only reaches local optimum. In comparison, our "Pretrain-Finetune" system gets to see large amount of automatically parsed data, and initializes the starting points with the pre-trained

Type	System	F_1
Ours	Supervised*‡	89.4
	Pretrain-Finetune*‡	90.7
SI	Collins (1999)	88.2
	Charniak (2000)	89.5
	Henderson (2003)*	88.8
	Petrov and Klein (2007)	90.1
	Carreras et al. (2008)	91.1
	Zhu et al. (2013)‡	90.4
SE	Huang et al. (2010)	91.6

	Huang (2008)	91.7
	Socher et al. (2013)*	90.4

Table 6: Comparing with the state-of-the-art systems on English test set. * marks neural network based systems. ‡ marks shift-reduce parsing systems.

parameters. So it finds a much better local optimum than the "Supervised" system. Comparing our "Pretrain-Finetune" system with all the state-of-the-art systems, we see our system surpass all the other systems. Although our system only utilizes some basic primitive units (in Table 1(a)), it still outperforms Wang and Xue (2014)'s shift-reduce parsing system which uses more complex structural features and semi-supervised word cluster features. Therefore, our model can simultaneously learn an effective feature representation and make accurate parsing predictions for Chinese.

Table 6 presents the performance of our systems as well as the state-of-the-art systems on the English test set. Our "Pretrain-Finetune" system still achieves much better performance than the "Supervised" system, although the gap is smaller than that of Chinese. Our "Pretrain-Finetune" system also outperforms all other neural network based systems (systems marked with *). Although our system does not outperform all the state-of-the-art systems, the performance is comparable to most of them. So our model is also effective for English parsing.

4.5 Cross Domain Evaluation

In this subsection, we examined the robustness of our model by evaluating it on data sets from various domains. We use the Berkeley Parser as our baseline parser, and trained it on our training set.

For Chinese, we performed our experiments on the cross domain data sets from Chinese Treebank 8.0 (Xue et al., 2013). It consists of six domains: newswire (nw), magazine articles (mz), broadcast news (bn), broadcast conversation (bc), weblogs (wb) and discussion forums (df). Since all of the mz domain data is already included in our training set, we only selected sample sentences from the other five domains as the test sets [5], and made sure these test sets had no overlap with our treebank training, development and test sets. Note that we did not use any data from these five domains for training or development. The models are still the ones described in the previous subsection. The results are presented in Table 7. Although our "Supervised" model got slightly worse performance than the Berkeley Parser (Petrov and Klein, 2007), as shown in Table 5, it outperformed the Berkeley Parser on the cross-domain data sets. This suggests that the learned features can better adapt to cross-domain situations. Compared with the Berkeley Parser, on average our "Pretrain-Finetune" model is 3.4 percentage points better in terms of parsing accuracy, and 3.2 percentage points better in terms of POS tagging accuracy. We also presented the performance of our pre-trained model ("Only-Pretrain"). We found the "Only-Pretrain" model performs poorly on this cross-domain data sets. But even pretraining based on this less than competitive model, our "Pretrain-Finetune" model achieves significant improvement over the "Supervised" model. So the Pre-Train strategy is crucial to our model.

For English, we performed our experiments on the cross-domain data sets from OntoNote 5.0 (Weischedel et al., 2013), which consists of nw, mz, bn, bc, wb, df and telephone conversations (tc). We also performed experiments on the SMS domain, using data annotated by the LDC for the DARPA BOLT Program. We randomly selected 300 sentences for each domain as the test sets [5]. Table 8 presents our experimental results. To save space, we only presented the results of our "Pretrain-Finetune" model and the Berkeley

[5] The selected sentences can be downloaded from http://www.cs.brandeis.edu/ xuen/publications.html

	Only-Pretrain		Supervised		Pretrain-Finetune		BerkeleyParser	
domain	F_1	POS	F_1	POS	F_1	POS	F_1	POS
bc	61.6	81.1	72.9	90.2	74.9	91.2	68.2	86.4
bn	—	—	78.2	93.2	80.8	94.2	78.3	91.2
df	65.6	84.5	76.2	91.7	78.5	92.6	75.9	90.3
nw	72.0	86.1	82.1	95.2	85.0	95.8	82.9	93.6

average	66.2	83.3	76.8	92.0	79.2	92.8	75.8	89.6

Table 7: Cross-domain performance for Chinese. The “Only-Pretrain” model cannot successfully parse some sentences in bn domain, so we didn’t give the numbers.

	Pretrain-Finetune		BerkeleyParser	
Domain	F_1	POS	F_1	POS
bc	77.7	92.2	76.0	91.1
bn	88.1	95.4	88.2	95.0
df	82.5	93.3	79.4	92.4
nw	89.6	95.3	86.2	94.6
wb	83.3	93.1	82.0	91.2
sms	79.2	85.8	74.6	85.3
tc	74.2	88.0	71.1	87.6
average	82.1	91.9	79.6	91.0

Table 8: Cross-domain performance for English.

Parser. Except for the slightly worse performance on the bn domain, our model outperformed the Berkeley Parser on all the other domains. While our model is only 0.6 percentage point better than the Berkeley Parser (Petrov and Klein, 2007) when evaluated on the standard Penn TreeBank test set (Table 6), our parser is 2.5 percentage points better on average on the cross domain data sets. So our parser is also very robust for English on cross-domain data sets.

5 Related Work

There has been some work on feature optimization in dependency parsing, but most prior work in this area is limited to selecting an optimal subset of features from a set of candidate features (Nilsson and Nugues, 2010; Ballesteros and Bohnet, 2014). Lei et al. (2014) proposed to learn features for dependency parsing automatically. They first represented all possible features with a multi-way tensor, and then transformed it into a low-rank tensor as the final features that are actually used by their system. However, to obtain competitive performance, they had to combine the learned features with traditional hand-crafted features. Chen and Manning (2014) proposed to learn a dense feature vector for transition-based dependency parsing via neural networks. Their model had to learn POS tag embeddings and dependency label embeddings first, and then induced the dense feature vector based on these embeddings. Comparing with their method, our model is much simpler. Our model learned features directly based on the original form of primitive units.

There have also been some attempts to use neural networks for constituent parsing. Henderson (2003) presented the first neural network for broad coverage parsing. Later, he also proposed to rerank k-best parse trees with a neural network model which achieved state-of-the-art performance (Henderson, 2004). Collobert (2011) designed a recurrent neural network model to construct parse tree by stacks of sequences labeling, but its final performance is significantly lower than the state-of-the-art performance. Socher et al. (2013) built a recursive neural network for constituent parsing. However, rather than performing full inference, their model can only score parse candidates generated from another parser. Our model also requires a parser to generate training samples for pre-training. However, our system is different in that, during testing, our model performs full inference with no need of other parsers. Vinyals et al. (2014) employed a Long Short-Term Memory (LSTM) neural network for parsing. By training on a much larger hand-annotated data set, their performance reached 91.6% for English.

6 Conclusion

In this paper, we proposed to learn features via a neural network model. By taking as input the primitive units, our neural network model learns feature representations in the hidden layer and made parsing predictions based on the learned features in the output layer. By employing the backpropagation algorithm, our model simultaneously induced features and learned prediction model parameters. We show that our model achieved significant improvement from pretraining on a substantial amount of pre-parsed data. Evaluated on standard data sets, our model outperformed all state-of-the-art parsers on Chinese and all neural network based models on English. We also show that our model is particularly effective on cross-domain tasks for both Chinese and English.

Identifying Cascading Errors using Constraints in Dependency Parsing

Dominick Ng and **James R. Curran**

ə-lab, School of Information Technologies
University of Sydney

{dominick.ng,james.r.curran}@sydney.edu.au

Abstract

Dependency parsers are usually evaluated on attachment accuracy. Whilst easily interpreted, the metric does not illustrate the cascading impact of errors, where the parser chooses an incorrect arc, and is subsequently forced to choose further incorrect arcs elsewhere in the parse.

We apply arc-level constraints to MSTparser and ZPar, enforcing the correct analysis of specific error classes, whilst otherwise continuing with decoding. We investigate the direct and indirect impact of applying constraints to the parser. Erroneous NP and punctuation attachments cause the most cascading errors, while incorrect PP and coordination attachments are frequent but less influential. Punctuation is especially challenging, as it has long been ignored in parsing, and serves a variety of disparate syntactic roles.

1 Introduction

Dependency parsers are evaluated using word-level attachment accuracy. Whilst comparable across systems, this does not provide insight into why the parser makes certain errors, or whether certain misattachments are caused by other errors. For example, incorrectly identifying a modifier head may only introduce a single attachment error, while misplacing the root of a sentence will create substantially more errors elsewhere. In projective dependency parsing, erroneous arcs can also force the parser to select other incorrect arcs.

Kummerfeld et al. (2012) propose a static post-parsing analysis to categorise groups of bracket errors in constituency parsing into higher level error classes such as clause attachment. However, this cannot account for cascading changes resulting from repairing errors, or limitations which may prevent the parser from applying a repair. It is unclear whether the parser will apply the repair operation in its entirety, or if it will introduce other changes in response to the repairs.

We develop an evaluation procedure to evaluate the influence of each error class in dependency parsing without making assumptions about how the parser will behave. We define error classes based on dependency labels, and use the dependencies in each class as *arc constraints* specifying the correct head and label for particular words in each sentence. We adapt parsers to apply these constraints, whilst otherwise proceeding with decoding under their grammar and model. By evaluating performance with and without constraints, we can directly observe the cascading impact of each error class on each the parser.

We implement our procedure for the graph-based MSTparser (McDonald and Pereira, 2006) and the transition-based ZPar (Zhang and Clark, 2011) using basic Stanford dependencies over the OntoNotes 4.0 release of the WSJ Penn Treebank data. Our results show that erroneously attaching NPs, PPs, modifiers, and punctuation have the largest overall impact on UAS. Of those, NPs and punctuation have the most substantial cascading impact, indicating that these errors have the most effect on the remainder of the parse. Enforcing correct punctuation arcs has a particularly large impact on accuracy, even though most evaluation scripts ignore punctuation. We find that punctuation arcs are commonly misplaced by large distances in the final parse, crossing over and forcing other arcs to be incorrect in the process.

We will make our source code available, and

Figure 1: MSTparser output (top) and the gold parse (bottom) for a WSJ 22 sentence. MSTparser produces two independent errors: an NP bracketing error (red, dotted), and an incorrect root (blue, dashed).

Parser	UAS	LAS	usent	lsent
MSTparser	91.3	87.5	41.3	26.1
ZPar	91.7	89.3	45.1	35.9

Table 1: Baseline UAS and LAS scores on Stanford dependencies over WSJ 22.

hope that our findings will drive efforts addressing the remaining dependency parsing errors.

2 Motivation

Table 1 summarises the performance of MSTparser and ZPar on Stanford dependencies over OntoNotes 4 WSJ 22. ZPar performs slightly better than MSTparser on UAS, and substantially better on LAS. However, these numbers do not show what types of errors are being made by each parser, what errors remain to be addressed, or hint at what underlying problems cause each error.

Figure 1 depicts a WSJ 22 sentence as parsed by MSTparser, and the gold parse. The UAS is 47.1%, with 8 of 17 arcs correct. By contrast, ZPar (parse not shown) scores 94.1%, with the sole attachment error being on *LME* (as with MSTparser). While there are nine incorrect arcs overall, MSTparser seems to have made only two underlying errors:

- *LME* attached to *decline* rather than *stocks* (NP internal). Correcting this repairs one error;
- *expected* being chosen as the root rather than *was*. Correcting the root and moving all attachments to it from the old root repairs the remaining eight errors.

Intuitively, it seems that the impact of the NP error is limited. By contrast, the root selection error has a substantial impact on the second half of the sentence, causing a misplaced subject, misattached punctuation, and incorrect coordination. These cascaded errors appear to be *caused by* the incorrect root.

What we do not know is whether these intuitions actually hold. Many dependency parsers, including MSTparser and ZPar, construct trees by repeatedly combining fragments together until a spanning analysis is found, using a small window of information to make each arc decision. An error in one part of the tree may have no influence on a different part of the tree. Alternatively, errors may exert long-range influence — particularly if there are higher-order features or algorithmic constraints such as projectivity over the tree. As parsing algorithms are complex, we wish to repair various error types in isolation without otherwise making assumptions regarding the subsequent actions of the parser.

3 Applying Constraints

We investigate how each parser behaves when certain errors in the tree are corrected. We force each parser to select the correct head and label for specific words, but otherwise allow it to construct its best parse. Given a set of *constraints*, each of which lists a word with the head and label to which it must be attached, we investigate two measures:

1. errors *directly corrected* by the constraints, called the *constrained accuracy impact*;
2. the *indirect impact of the constraints*, including errors *indirectly corrected*, and correct

arcs *indirectly destroyed*, together called the *cascaded accuracy impact*.

The constrained accuracy impact tells us how often the parser makes errors in the set of words covered by the constraints. The cascaded accuracy impact is less predictable, as it describes what effect the errors made over the constrained set of arcs have over the rest of the sentence. It is the *influence* of the set of constraints over the other attachments, which may be mediated through projectivity requirements, or changes in the context used for other parsing decisions.

The core of our procedure is adapting each parser to accept a set of constraints. Following Kummerfeld et al. (2012), we define meaningful error classes grouped with the operations that repair them. In dependency parsing, error classes are groups of Stanford dependency labels, rather than groups of node repair operations. The Stanford labels provide a rich distinction in NP internal structure, clauses, and modifiers, and map well to the error categories of Kummerfeld et al. (2012), allowing us to avoid excessive heuristics in the mapping process. Our technique can be applied to other dependency schemes such as LTH (Johansson and Nugues, 2007) by defining new mappings from labels to error types.

The difficulty of the mapping task depends on the intricacies of each formalism. The major challenge with LTH dependencies is the enormous skew towards the nominal modifier NMOD label. This label occurs 11,335 times in WSJ 22, more than twice as frequently as the next most frequent punctuation P. By contrast, the most common Stanford label is punctuation, at 4,731 occurrences. The NMOD label is split into many smaller, but more informative nominal labels in the Stanford scheme, making it better suited for our goal of error analysis.

The label grouping was performed with reference to the Stanford dependencies manual v2.04 (de Marneffe and Manning, 2008, updated 2012). For each error class, we generate a set of constraints over WSJ 22 for all words with a gold-standard label in the set associated with the class. Our types are defined as follows:

NP attachment: any label specifically attaching an NP, includes `appos`, `dobj`, `iobj`, `nsubj`, `nsubjpass`, `pobj`, and `xsubj`.

NP internal: any label marking nominal structure (not including adjectival modifiers), includes `abbrev`, `det`, `nn`, `number`, `poss`, `possessive`, and `predet`.

PP attachment: any label attaching a prepositional phrase, includes `prep`. Also includes `pcomp` if the POS of the word is `TO` or `IN`.

Clause attachment: any label attaching a clause, includes `advcl`, `ccomp`, `csubj`, `csubjpass`, `purpcl`, `rcmod`, and `xcomp`. Also includes `pcomp` if the POS of the word is not `TO` or `IN`.

Modifier attachment: any label attaching an adverbial or adjectival modifier, includes `advmod`, `amod`, `infmod`, `npadvmod`, `num`, `partmod`, `quantmod`, and `tmod`.

Coordination attachment: `conj`, `cc`, and `preconj`.

Root attachment: the `root` label.

Punctuation attachment: the `punct` label.

Other attachment: all other Stanford labels, specifically `acomp`, `attr`, `aux`, `auxpass`, `complm`, `cop`, `dep`, `expl`, `mark`, `mwe`, `neg`, `parataxis`, `prt`, `ref`, and `rel`.

For example, Root constraints specify sentence roots, while PP constraints specify heads of prepositional phrases.

One deficiency of our implementation is that we apply constraints to all arcs of a particular error type in each sentence, and do not isolate multiple instances of the same error class in a sentence. We do this since applying single constraints to a sentence at a time would require substantial modifications to the standard evaluation regime.

3.1 MSTparser implementation

MSTparser is a graph-based, second-order parser that uses Eisner (1996)'s algorithm for projective decoding (McDonald and Pereira, 2006).[1] Eisner's algorithm constructs and caches subtrees which span progressively larger sections of the sentence. These spans are marked either as *complete*, consisting of a head, a dependent, and all of the descendants of that head to one side, or *incomplete*, consisting of a head, a dependent, and an unfilled region where additional tokens may be attached. Dependencies are formed between the head and dependent in each complete span, while label assignment occurs as a separate process.

We enforce constraints by allowing complete spans to be formed only from constrained tokens

[1] As the variant of Stanford dependencies we use are projective, we did not use non-projective decoding.

to their correct heads with the correct labels. Any complete span between an incorrect head and the constrained token is forbidden. The algorithm is forced to choose the constrained spans as it builds the parse; these constraints have no impact on the parser's coverage as all possible head selections are considered.

3.2 ZPar implementation

ZPar is an arc-eager transition-based parser (Zhang and Clark, 2011) that uses an incremental process with a stack storing partial parse *states* (Nivre et al., 2004). Each state represents tokens that may accept further arcs. The tokens of a sentence are initially stored in a buffer, and at each point during parsing, the parser decides whether or not to create an arc between the *front* token of the buffer and the *top* token on the stack.

We apply constraints in a similar way to Nivre et al. (2014). Arc creation actions are factored on the dependency label to be assigned to the arc. ZPar scores each possible action using a perceptron model over features from the front of the buffer and the top of the stack (as well as some additional context features which refer to previously created states). The highest scoring actions and their resulting states are kept in a beam; during parsing, ZPar finds the optimal action for all items in the beam, and retains the highest scoring new states at each step.

We disallow any arc creation action that would create an arc that conflicts with any constraints. Due to the use of beam search, it is possible for all of the partial states containing the constrained arcs to be evicted from the beam if they score lower under the model than other states. When this happens, the parser will fail to find an analysis for the sentence, as no head will exist in the beam for the constrained token. We have deliberately chosen to not address this issue as any solution (e.g. increasing the beam size from its default of 64) would change the decisions of the parser and model.

We verified that our modifications were working correctly for both parsers by passing in zero constraints (checking that the output matched the baseline performance), and every possible constraint (checking that the output scored 100%).

4 Related Work

Kummerfeld et al. (2012) perform a comprehensive classification of constituency bracket errors and their cascading impact, and their work is philosophically similar to ours. They associate groups of bracket errors in the parse with abstract error classes, and identify the tree operations that repair these error types, such as the insertion, deletion, or substitution of nodes in the parse tree. The error classes in a particular parser's output are identified through a heuristic procedure that repeatedly applies the operation repairing the largest number of bracket errors. This approach differs from our methodology as it is a static post-process that assumes the parser would respond perfectly to each repair, when it is possible that the parser may not perform the repair in full, or even be incapable of constructing the repaired tree.

McDonald and Nivre (2011) perform an in-depth comparison of the graph-based MSTparser and transition-based MaltParser. However, MaltParser uses support vector machines to deterministically predict the next transition, rather than storing the most probable options in a beam like ZPar. Additionally, they do not focus on the cascading impact of errors, and instead concentrate on higher-level error classification (e.g. by POS tag, labels and dependency lengths) in lieu of examining how the parsers respond to forced corrections.

Nivre et al. (2014) describe several uses for arc-level constraints in transition-based parsing. However, these applications focus on improving parsing accuracy when constraints can be readily identified, e.g. imperatives at the beginning of a sentence are likely to be the root. We focus our constraints on evaluation, attempting to identify important sources of error in dependency parsers.

Our constraint-based approach shares similarities to oracle training and decoding methods, where an external source of truth is used to verify parser decisions. An oracle source of parser actions is a necessary component for training transition-based parsers (Nivre, 2009). Oracle decoding, where a system is forced to produce correct output if possible, can be used to assess its upper performance bounds (Ng and Curran, 2012).

Constraining the parser's internal search space is akin to an optimal pruning operation. Charniak and Johnson (2005) use a coarse-to-fine, iterative pruning approach for efficiently generating high-quality n-best parses for a discriminative reranker. Rush and Petrov (2012) use a similar coarse-to-fine algorithm with vine grammars (Eisner and Smith, 2005) to accelerate graph-based de-

pendency parsing, achieving parsing speeds close to linear-time transition parsers despite encoding more complex features. Supertagging (Clark and Curran, 2007) and chart pruning (Zhang et al., 2010) have been used to constrain the search space of a CCG parser, and to remove unlikely or forbidden spans from repeated consideration. In our work, we use pruning not for parsing speed, but evaluation, and so we prune items based on gold-standard constraints rather than heuristics.

5 Evaluation

We use the training (sections 2-21) and development (section 22) data from the OntoNotes 4.0 release of the Penn Treebank WSJ data (Marcus et al., 1993), as supplied by the SANCL 2012 Shared Task on Parsing the Web (Petrov and McDonald, 2012). OntoNotes annotates enriched NP structure compared to the Penn Treebank (Weischedel et al., 2011), meaning that determining NP attachments is less trivial. We changed all marker tokens in the corpus (e.g. `-LRB-` and `-LCB-`) to their equivalent unescaped punctuation marks to ensure correct evaluation. The corpus has been converted to basic Stanford dependencies using the Stanford Parser v2.0,[2] and part-of-speech tagged using MXPOST (Ratnaparkhi, 1996). A model trained on WSJ sections 2-21 was used to tag the development set, and 10-fold jackknife training was used to tag the training data.

We implement a custom evaluation script to facilitate a straightforward comparative analysis between the unconstrained and constrained output. The script is based on and produces identical scores to `eval06.pl`, the official evaluation for the CoNLL-X Shared Task on Multilingual Dependency Parsing (Buchholz and Marsi, 2006). We ignore punctuation as defined by `eval06.pl` in our evaluation; experiments with constraints over punctuation tokens constrain those tokens in the parse, but ignore them during evaluation.

We run the modified parsers over WSJ 22 with and without each set of constraints. We examine the overall unlabeled and labeled attachment scores (UAS and LAS), as well as identifying the contribution to the overall UAS improvement from directly (constrained) and indirectly corrected arcs.

MSTparser uses coarse-grained tags and fine-grained POS tags in its features, both of which were provided by the CoNLL-X Shared Task. We approximate the coarse-grained POS tags by taking the first character of the MXPOST-assigned POS tag, a technique also used by Bansal et al. (2014)[3].

6 Results

Figure 2 and Table 2 show the impact of applying constraints on tokens with various labels to MSTparser for the sentence in Figure 1. Enforcing the gold `nn` arc between *decline* and *LME* repairs that noun phrase error, but does not affect any of the other errors. Conversely, enforcing the gold `root` arc does not affect the noun phrase error, but repairs nearly every other error in the parse. Unfortunately, the constrained `root` arc introduces

two new errors, with the parser incorrectly attaching the clausal complement headed by *expected* and the modifier headed by *about*. In fact, correcting the `ccomp` arc in isolation rather than the `root` arc leads to MSTparser producing the full correct analysis for the second half of the sentence (though again, it does not repair the separate noun phrase error). This example highlights why we have chosen to implement our evaluation as a set of constraints in the parser, rather than Kummerfeld et al. (2012)'s post-processing approach, as we cannot know that the parser will react as we expect it to when repairing errors.

Tables 3 and 4 summarise our results on MSTparser and ZPar, calculated over the sentences covered by ZPar in WSJ 22. Results over the full WSJ 22 for MSTparser were consistent with these figures. We focus on discussing UAS results in this paper, since LAS results are consistent.

The UAS of constrained arcs in each experiment is the expected 100%. Effective constraints repair an error in the baseline, and the effective constraint percentage is this figure expressed as a percentage, i.e. the *error rate*. Error displacement is the average number of words that effective constraints moved an attachment point. The overall ΔUAS improvement is divided into Δc, the constrained impact, and Δu, the cascaded impact.

It is important to note that a parser may make a substantial number of mistakes on a particular error class (large effective constraint percentage), but correcting those mistakes may have very little cascading impact (small Δc), limiting the overall ΔUAS improvement. Conversely, there may be a class with a small effective constraint percentage, but a large ΔUAS due to a large cascading impact from the corrections, or simply because the class contains more constraints.

6.1 Overall Parser Comparison

When applying all constraints, ZPar has a 8.8% effective constraint percentage compared to 9.3% for MSTparser. This is directly related to the UAS difference between the parsers. Aside from coordination, where the parsers made a nearly identical number of errors, ZPar is more accurate across the board. It makes substantially fewer mistakes on clause attachments, punctuation dependencies, and NP attachments, whilst maintaining a small advantage across all of the other categories.

The relative rank of the effective constraint percentage per error category is similar across the parsers, with PP attachment, punctuation, modifiers, and coordination recording the largest number of effective constraints, and thus the most errors. This illustrates that the behaviour of both parsers is very consistent, despite one considering every possible attachment point, and the other using a linear transition-based beam search. ZPar is able to make fewer mistakes across each error category, suggesting that the beam search pruning is maintaining more desired states than the graph-based parser is able to rank during its search.

ZPar's coverage is 98.5% when applying all constraints. However, as the number of constraints is reduced, coverage also drops. This seems counter-intuitive, but applying more constraints eliminates more undesired states, leaving more space in the beam for satisfying states. Reducing the number of constraints permits more states which do not yet violate a constraint, but only yield undesired states later.

Punctuation constraints have the largest impact on coverage, reducing it to 93.2%. NP attachments, clauses, and modifier attachments also incur substantial coverage reductions. This suggests that ZPar's performance will degrade substantially over the sentences which it cannot cover, as they must contain constructions which are dispreferred by the model and fall out of the beam. Constraints with the smallest effect on coverage include root attachments, which only occur once per sentence and are rarely incorrect, and NP internal and PP attachments. For the latter two, the small displacements suggest that alternate attachment points often lie within the same projective span.

6.2 Noun phrases

Applying NP attachment constraints causes a 4.4% drop in coverage for ZPar, and the effective constraint percentage is below 5% for both parsers. However, these constraints still result in the largest ΔUAS for both parsers, at 2.6% for MSTparser and 2.2% for ZPar. This reflects the prevalence of NP attachments in the corpus.

ΔUAS is split evenly between correcting constrained (1.4%) and cascaded arcs (1.2%) for MSTparser, while it skews towards cascaded arcs for ZPar (1.0% and 1.4%). Most error classes skew in the other direction, while repairing one NP attachment error typically repairs another non-NP attachment error.

For NP internal attachments, both parsers have a similar error rate, with 206 effective constraints for MSTparser and 197 for ZPar. Although this is the second largest class, applying these constraints gives the second smallest Δu for both parsers. This implies that determining NP internal structure is a strength, even with the more complex OntoNotes 4 NP structure. Δc is also small for both parsers, reinforcing the limited displacement and cascading impact of NP internal errors.

Despite fewer effective constraints (i.e. less errors to fix), ZPar exhibits more cascading repair than MSTparser using both NP and NP internal constraints. This will be a common theme through this evaluation: the transition-based ZPar is better at propagating effective constraints into cascaded impact than the graph-based MSTparser, even though ZPar almost always begins with fewer effective constraints due to its better baseline performance. One possibility to explain this is that the beam is actually pruning away other erroneous states, while the graph-based MSTparser must still consider all of them.

Table 5 summarises the error classes of corrected cascaded arcs for the two NP constraint types, which are closely related. NP attachment constraints directly identify the head of the NP as well as its correct attachment, providing strong cues for determining the internal structure. NP internal constraints implicitly identify the head of an NP. We can see that for both types of constraints, many of the cascaded corrections come from the other NP error class.

Table 5 also shows that, compared to MSTparser, ZPar repairs nearly twice as many NP internal and coordination errors when using NP attachment constraints, and vice versa when using NP internal constraints. This suggests that ZPar has more difficulty identifying the correct heads for

	NP attachment		NP internal	
Error class	MSTparser	ZPar	MSTparser	ZPar
NP attachment	-	-	45	69
NP internal	43	80	-	-
Modifier attachment	65	68	24	30
PP attachment	26	36	2	10
Coordination attachment	37	67	20	41
Clause attachment	59	65	1	1
Root attachment	24	21	2	1
Punctuation attachment	79	80	26	41
Other attachment	68	76	7	11
Total	401	493	127	204

Table 5: The number of unconstrained errors repaired per error class when enforcing NP attachment and NP internal constraints for MSTparser and ZPar over WSJ 22.

nominal coordination, and often chooses a word which should be a nominal modifier instead.

6.3 Coordination, Modifiers and PPs

These categories are large error classes for both parsers, with constraints leading to UAS improvements of 1.3 to 1.7%.

PPs and coordination have high effective constraint percentages relative to the other error classes for both parsers. However, they are also amongst the most isolated errors, with only 0.3% and 0.4% Δu for MSTparser and ZPar respectively. These errors also have minimal impact on ZPar's coverage. Both classes seem to have relatively contained attachment options within a limited projective span. The small error displacements reinforce this idea.

Modifiers are relatively isolated errors for MSTparser (0.5% Δu), but less so for ZPar (0.7% Δu). There are substantially more modifier constraints than PP or coordination, despite all yielding a similar UAS increase. This suggests that modifiers are actually relatively well analysed by both parsers, but there are so many of them that they form a large source of error.

6.4 Clause attachment

MSTparser performs substantially worse than ZPar on clause attachments, with an effective constraint percentage of 17.9% compared to 13.0%, and Δc of 0.9% compared with 0.6%. MSTparser's error rate is the worst of any error class on clause attachments, while it is second to coordination attachments for ZPar. Attaching clauses is very challenging for dependency parsers, particularly considering the small size of the class.

ZPar again achieves a slightly larger cascaded impact than MSTparser (0.6% to 0.5%), despite having far fewer effective constraints. This implies that the additional clause errors being made by MSTparser are largely self-contained, as they have not triggered a corresponding increase in Δu.

6.5 Root attachment

Both parsers make few root attachment errors, though MSTparser is less accurate than ZPar. However, root constraints provide the largest UAS improvement per number of constraints for both parsers. Root errors are also the most displaced of any error class, at 9.3 words for MSTparser and 9.9 for ZPar. When the root is incorrect, it is often very far from its correct location, and causes substantial cascading errors.

6.6 Punctuation

Despite ignoring punctuation dependencies in evaluation, applying punctuation constraints led to substantial UAS improvements. On MSTparser, Δu is 0.1% (due to some punctuation not being excluded from evaluation), but Δc is 1.7%. On ZPar, the equivalent metrics are 0.2% and 1.5%. Enforcing correct punctuation has a disproportionate impact on the remainder of the parse.

For both parsers, punctuation errors occur more frequently than any other error type, with 469 and 430 effective constraints respectively (though the majority of these corrected errors are on non-evaluated arcs). ZPar's coverage is worst of all when enforcing punctuation constraints, suggesting that the remaining uncovered sentences will

Error class	MSTparser	ZPar
NP attachment	75	51
NP internal	25	27
Modifier attachment	33	43
PP attachment	45	55
Coordination attachment	87	106
Clause attachment	66	48
Root attachment	59	27
Other attachment	65	69
Total	455	426

Table 6: The number of unconstrained errors repaired per error class when enforcing punctuation constraints for MSTparser and ZPar.

contain even more punctuation errors.

Incorrect punctuation heads are displaced from their correct locations by 7.4 words for MSTparser and 7.3 words for ZPar on average, second only to root attachments. Given that we are using projective parsers and a projective grammar, the large average displacement caused by errors indicates that punctuation affects and is in turn affected by the requirement for non-crossing arcs.

Table 6 summarises the error classes of the repaired cascaded arcs when punctuation constraints are applied. MSTparser has a more even distribution of repairs, while ZPar's repairs are concentrated in coordination attachment. This shows that MSTparser is relatively better at coordination as a proportion of its overall performance compared to ZPar. It also indicates that the majority of punctuation errors in both parsers (and especially ZPar) stem from incorrectly identified coordination markers such as commas.

Punctuation is commonly ignored in dependency parser evaluation (Yamada and Matsumoto, 2003; Buchholz and Marsi, 2006), and they are inconsistently treated across different grammars. Our results show that enforcing the correct punctuation attachments in a sentence has a substantial cascading impact, suggesting that punctuation errors are highly correlated with errors elsewhere in the analysis. Given the broad similarities between Stanford dependencies and other dependency schemes commonly used in parsing (Søgaard, 2013), we anticipate that the problems with roots and punctuation will carry across different treebanks and schemes.

Punctuation is often placed at phrasal boundaries and serves to split sentences into smaller sections within a projective parser. Graph-based and transition-based parsers, both of which use a limited local context to make parsing decisions, are equally prone to the cascading impact of erroneous punctuation. Removing the confounding presence of punctuation from parsing and treating attachment as a global post-process may help to alleviate these issues. Alternatively, more punctuation-specific features to account for its myriad roles in syntax could serve to improve performance.

7 Conclusion

We have developed a procedure to classify the importance of errors in dependency parsers without any assumptions on how the parser will respond to attachment repairs. Our approach constrains the parser to allow only correct arcs for certain tokens, whilst allowing it to otherwise form the parse that it thinks is best. Compared to Kummerfeld et al. (2012), we can observe exactly how the parser responds to the parse repairs, though at the cost of requiring modifications to the parser itself.

Our results show that noun phrases remain challenging for dependency parsers, both in choosing the correct head, and in determining the internal structure. Punctuation, despite being commonly ignored in parsers and evaluation, causes substantial cascading errors when misattached.

We are extending our work to other popular dependency parsers and non-projective parsing algorithms, and hope to develop features to improve and mitigate the cascading impact of punctuation attachment errors in parsing. Given that constituency parsers perform strongly when converted to dependencies (Cer et al., 2010; Petrov and McDonald, 2012), it would also be interesting to investigate how they perform on our metrics.

We implement a robust procedure to identify the cascading impact of dependency parser errors. Our results provide insights into which errors are most damaging in parsing, and will drive further improvements in parsing accuracy.

Abstract

In this work, we address the problem to model all the nodes (words or phrases) in a dependency tree with the dense representations. We propose a recursive convolutional neural network (RCNN) architecture to capture syntactic and compositional-semantic representations of phrases and words in a dependency tree. Different with the original recursive neural network, we introduce the convolution and pooling layers, which can model a variety of compositions by the feature maps and choose the most informative compositions by the pooling layers. Based on RCNN, we use a discriminative model to re-rank a k-best list of candidate dependency parsing trees. The experiments show that RCNN is very effective to improve the state-of-the-art dependency parsing on both English and Chinese datasets.

1 Introduction

Feature-based discriminative supervised models have achieved much progress in dependency parsing (Nivre, 2004; Yamada and Matsumoto, 2003; McDonald et al., 2005), which typically use millions of discrete binary features generated from a limited size training data. However, the ability of these models is restricted by the design of features. The number of features could be so large that the result models are too complicated for practical use and prone to overfit on training corpus due to data sparseness.

Recently, many methods are proposed to learn various distributed representations on both syntax and semantics levels. These distributed representations have been extensively applied on many natural language processing (NLP) tasks, such as syntax (Turian et al., 2010; Mikolov et al., 2010; Collobert et al., 2011; Chen and Manning, 2014) and semantics (Huang et al., 2012; Mikolov et al., 2013). Distributed representations are to represent words (or phrase) by the dense, low-dimensional and real-valued vectors, which help address the curse of dimensionality and have better generalization than discrete representations.

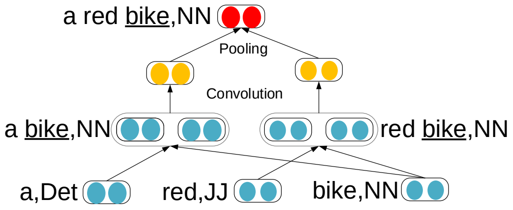

Figure 1: Illustration of a RCNN unit.

For dependency parsing, Chen et al. (2014) and Bansal et al. (2014) used the dense vectors (embeddings) to represent words or features and found these representations are complementary to the traditional discrete feature representation. However, these two methods only focus on the dense representations (embeddings) of words or features. These embeddings are pre-trained and keep unchanged in the training phase of parsing model, which cannot be optimized for the specific tasks.

Besides, it is also important to represent the (unseen) phrases with dense vector in dependency parsing. Since the dependency tree is also in recursive structure, it is intuitive to use the recursive neural network (RNN), which is used for constituent parsing (Socher et al., 2013a). However, recursive neural network can only process the binary combination and is not suitable for dependency parsing, since a parent node may have two or more child nodes in dependency tree.

In this work, we address the problem to rep-

resent all level nodes (words or phrases) with dense representations in a dependency tree. We propose a recursive convolutional neural network (RCNN) architecture to capture syntactic and compositional-semantic representations of phrases and words. RCNN is a general architecture and can deal with k-ary parsing tree, therefore it is very suitable for dependency parsing. For each node in a given dependency tree, we first use a RCNN unit to model the interactions between it and each of its children and choose the most informative features by a pooling layer. Thus, we can apply the RCNN unit recursively to get the vector representation of the whole dependency tree. The output of each RCNN unit is used as the input of the RCNN unit of its parent node, until it outputs a single fixed-length vector at root node. Figure 1 illustrates an example how a RCNN unit represents the phrases "a red bike" as continuous vectors.

The contributions of this paper can be summarized as follows.

- RCNN is a general architecture to model the distributed representations of a phrase or sentence with its dependency tree. Although RCNN is just used for the re-ranking of the dependency parser in this paper, it can be regarded as semantic modelling of text sequences and handle the input sequences of varying length into a fixed-length vector. The parameters in RCNN can be learned jointly with some other NLP tasks, such as text classification.

- Each RCNN unit can model the complicated interactions of the head word and its children. Combined with a specific task, RCNN can capture the most useful semantic and structure information by the convolution and pooling layers.

- When applied to the re-ranking model for parsing, RCNN improve the accuracy of base parser to make accurate parsing decisions. The experiments on two benchmark datasets show that RCNN outperforms the state-of-the-art models.

2 Recursive Neural Network

In this section, we briefly describe the recursive neural network architecture of (Socher et al., 2013a).

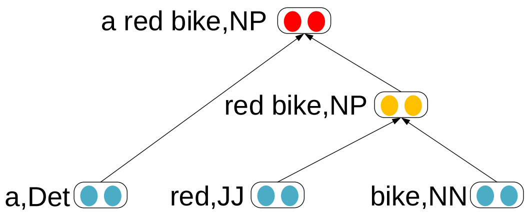

Figure 2: Illustration of a RNN unit.

The idea of recursive neural networks (RNN) for natural language processing (NLP) is to train a deep learning model that can be applied to phrases and sentences, which have a grammatical structure (Pollack, 1990; Socher et al., 2013c). RNN can be also regarded as a general structure to model sentence. At every node in the tree, the contexts at the left and right children of the node are combined by a classical layer. The weights of the layer are shared across all nodes in the tree. The layer computed at the top node gives a representation for the whole sentence.

Following the binary tree structure, RNN can assign a fixed-length vector to each word at the leaves of the tree, and combine word and phrase pairs recursively to create intermediate node vectors of the same length, eventually having one final vector representing the whole sentence. Multiple recursive combination functions have been explored, from linear transformation matrices to tensor products (Socher et al., 2013c). Figure 2 illustrates the architecture of RNN.

The binary tree can be represented in the form of branching triplets ($p \rightarrow c_1 c_2$). Each such triplet denotes that a parent node p has two children and each c_k can be either a word or a non-terminal node in the tree.

Given a labeled binary parse tree, $((p_2 \rightarrow ap_1), (p_1 \rightarrow bc))$, the node representations are computed by

$$\mathbf{p}_1 = f(\mathbf{W}\begin{bmatrix}\mathbf{b}\\\mathbf{c}\end{bmatrix}), \mathbf{p}_2 = f(\mathbf{W}\begin{bmatrix}\mathbf{a}\\\mathbf{p}_1\end{bmatrix}), \quad (1)$$

where $(\mathbf{p}_1, \mathbf{p}_2, \mathbf{a}, \mathbf{b}, \mathbf{c})$ are the vector representation of (p_1, p_2, a, b, c) respectively, which are denoted by lowercase bold font letters; $\mathbf{W}$ is a matrix of parameters of the RNN.

Based on RNN, Socher et al. (2013a) introduced a compositional vector grammar, which uses the syntactically untied weights $\mathbf{W}$ to learn the syntactic-semantic, compositional vector representations. In order to compute the score of how plausible of a syntactic constituent a parent is, RNN uses a single-unit linear layer for all p_i:

$$s(p_i) = \mathbf{v} \cdot \mathbf{p}_i, \quad (2)$$

where $\mathbf{v}$ is a vector of parameters that need to be trained. This score will be used to find the highest scoring tree. For more details on how standard RNN can be used for parsing, see (Socher et al., 2011).

Costa et al. (2003) applied recursive neural networks to re-rank possible phrase attachments in an incremental constituency parser. Their work is the first to show that RNNs can capture enough information to make the correct parsing decisions. Menchetti et al. (2005) used RNNs to re-rank different constituency parses. For their results on full sentence parsing, they re-ranked candidate trees created by the Collins parser (Collins, 2003).

3 Recursive Convolutional Neural Network

The dependency grammar is a widely used syntactic structure, which directly reflects relationships among the words in a sentence. In a dependency tree, all nodes are terminal (words) and each node may have more than two children. Therefore, the standard RNN architecture is not suitable for dependency grammar since it is based on the binary tree. In this section, we propose a more general architecture, called **recursive convolutional neural network** (RCNN), which borrows the idea of convolutional neural network (CNN) and can deal with to k-ary tree.

3.1 RCNN Unit

For ease of exposition, we first describe the basic unit of RCNN. A RCNN unit is to model a head word and its children. Different from the constituent tree, the dependency tree does not have non-terminal nodes. Each node consists of a word and its POS tags. Each node should have a different interaction with its head node.

Word Embeddings Given a word dictionary $\mathcal{W}$, each word $w \in \mathcal{W}$ is represented as a real-valued vector (word embedding) $\mathbf{w} \in \mathbb{R}^m$ where m is the dimensionality of the vector space. The word embeddings are then stacked into a embedding matrix $M \in \mathbb{R}^{m|\mathcal{W}|}$. For a word $w \in \mathcal{W}$, its corresponding word embedding $Embed(w) \in \mathbb{R}^m$ is retrieved by the lookup table layer. The matrix M is initialized with pre-training embeddings and updated by back-propagation.

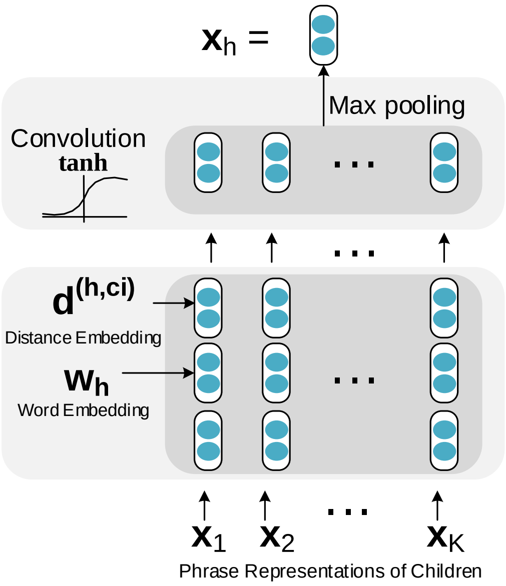

Figure 3: Architecture of a RCNN unit.

Distance Embeddings Besides word embeddings, we also use distributed vector to represent the relative distance of a head word h and one of its children c. For example, as shown in Figure 1, the relative distances of “bike” to “a” and “red” are -2 and -1, respectively. The relative distances also are mapped to a vector of dimension m_d (a hyperparameter); this vector is randomly initialized. Distance embedding is a usual way to encode the distance information in neural model, which has been proven effectively in several tasks. Our experimental results also show that the distance embedding gives more benefits than the traditional representation. The relative distance can encode the structure information of a subtree.

Convolution The word and distance embeddings are subsequently fed into the convolution component to model the interactions between two linked nodes.

Different with standard RNN, there are no non-terminal nodes in dependency tree. Each node h in dependency tree has two associated distributed representations:

1. word embedding $\mathbf{w}_h \in \mathbb{R}^m$, which is denoted as its own information according to its word form;

2. phrase representation $\mathbf{x}_h \in \mathbb{R}^m$, which is denoted as the joint representation of the whole subtree rooted at h. In particular, when h is leaf node, $\mathbf{x}_h = \mathbf{w}_h$.

Given a subtree rooted at h in dependency tree, we define $c_i, 0 < i \leq L$ as the i-th child node of h, where L represents the number of children.

For each pair (h, c_i), we use a convolutional hidden layer to compute their combination representation $\mathbf{z}_i$.

$$\mathbf{z}_i = \tanh(\mathbf{W}^{(h,c_i)}\mathbf{p}_i), 0 < i \leq K, \qquad (3)$$

where $\mathbf{W}^{(h,c_i)} \in \mathbb{R}^{m \times n}$ is the linear **composition matrix**, which depends on the POS tags of h and c_i; $\mathbf{p}_i \in \mathbb{R}^n$ is the concatenated representation of h and the i-th child, which consists of the head word embeddings $\mathbf{w}_h$, the child phrase representation $\mathbf{x}_{c_i}$ and the distance embeddings $\mathbf{d}^{h,c_i}$ of h and c_i,

$$\mathbf{p}_i = \mathbf{x}_h \oplus \mathbf{x}_{c_i} \oplus \mathbf{d}^{(h,c_i)}, \qquad (4)$$

where $\oplus$ represents the concatenation operation.

The distances d_{h,c_i} is the relative distance of h and c_i in a given sentence. Then, the relative distances also are mapped to m-dimensional vectors. Different from constituent tree, the combination should consider the order or position of each child in dependency tree.

In our model, we do not use the POS tags embeddings directly. Since the composition matrix varies on the different pair of POS tags of h and c_i, it can capture the different syntactic combinations. For example, the combination of adjective and noun should be different with that of verb and noun.

After the composition operations, we use **tanh** as the non-linear activation function to get a hidden representation $\mathbf{z}$.

Max Pooling After convolution, we get $\mathbf{Z}^{(h)} = [\mathbf{z}_1, \mathbf{z}_2, \cdots, \mathbf{z}_K]$, where K is dynamic and depends on the number of children of h. To transform $\mathbf{Z}$ to a fixed length and determine the most useful semantic and structure information, we perform a max pooling operation to $\mathbf{Z}$ on rows.

$$\mathbf{x}_j^{(h)} = \max_i \mathbf{Z}_{j,i}^{(h)}, 0 < j \leq m. \qquad (5)$$

Thus, we obtain the vector representation $\mathbf{x}_h \in \mathbb{R}^m$ of the whole subtree rooted at node h.

Figure 3 shows the architecture of our proposed RCNN unit.

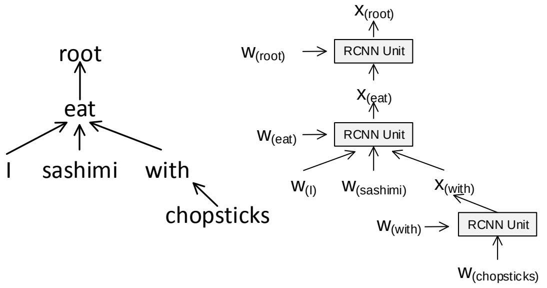

Figure 4: Example of a RCNN unit

Given a whole dependency tree, we can apply the RCNN unit recursively to get the vector representation of the whole sentence. The output of each RCNN unit is used as the input of the RCNN unit of its parent node.

Thus, RCNN can be used to model the distributed representations of a phrase or sentence with its dependency tree and applied to many NLP tasks. The parameters in RCNN can be learned jointly with the specific NLP tasks. Each RCNN unit can model the complicated interactions of the head word and its children. Combined with a specific task, RCNN can select the useful semantic and structure information by the convolution and max pooling layers.

Figure 4 shows an example of RCNN to model the sentence "*I eat sashimi with chopsitcks*".

4 Parsing

In order to measure the plausibility of a subtree rooted at h in dependency tree, we use a single-unit linear layer neural network to compute the score of its RCNN unit.

For constituent parsing, the representation of a non-terminal node only depends on its two children. The combination is relative simple and its correctness can be measured with the final representation of the non-terminal node (Socher et al., 2013a).

However for dependency parsing, all combinations of the head h and its children $c_i (0 < i \leq K)$ are important to measure the correctness of the subtree. Therefore, our score function $s(h)$ is computed on all of hidden layers $\mathbf{z}_i (0 < i \leq K)$:

$$s(h) = \sum_{i=1}^{K} \mathbf{v}^{(h,c_i)} \cdot \mathbf{z}_i, \qquad (6)$$

where $\mathbf{v}^{(h,c_i)} \in \mathbb{R}^{m \times 1}$ is the **score vector**, which also depends on the POS tags of h and c_i.

Given a sentence x and its dependency tree y, the goodness of a complete tree is measured by summing the scores of all the RCNN units.

$$s(x, y, \Theta) = \sum_{h \in y} s(h), \tag{7}$$

where $h \in y$ is the node in tree y; $\Theta = \{\Theta_{\mathbf{W}}, \Theta_{\mathbf{v}}, \Theta_{\mathbf{w}}, \Theta_{\mathbf{d}}\}$ including the combination matrix set $\Theta_{\mathbf{W}}$, the score vector set $\Theta_{\mathbf{v}}$, the word embeddings $\Theta_{\mathbf{w}}$ and distance embeddings $\Theta_{\mathbf{d}}$.

Finally, we can predict dependency tree $\hat{y}$ with highest score for sentence x.

$$\hat{y} = \arg\max_{y \in \mathbf{gen}(x)} s(x, y, \Theta), \tag{8}$$

where $\mathbf{gen}(x)$ is defined as the set of all possible trees for sentence x. When applied in re-ranking, $\mathbf{gen}(x)$ is the set of the k-best outputs of a base parser.

5 Training

For a given training instance (x_i, y_i), we use the max-margin criterion to train our model. We first predict the dependency tree $\hat{y_i}$ with the highest score for each x_i and define a structured margin loss $\Delta(y_i, \hat{y_i})$ between the predicted tree $\hat{y_i}$ and the given correct tree y_i. $\Delta(y_i, \hat{y_i})$ is measured by counting the number of nodes y_i with an incorrect span (or label) in the proposed tree (Goodman, 1998).

$$\Delta(y_i, \hat{y_i}) = \sum_{d \in \hat{y_i}} \kappa \mathbf{1}\{d \notin y_i\} \tag{9}$$

where κ is a discount parameter and d represents the nodes in trees.

Given a set of training dependency parses $\mathcal{D}$, the final training objective is to minimize the loss function $J(\Theta)$, plus a l_2-regulation term:

$$J(\Theta) = \frac{1}{|\mathcal{D}|} \sum_{(x_i, y_i) \in \mathcal{D}} r_i(\Theta) + \frac{\lambda}{2} \|\Theta\|_2^2, \tag{10}$$

where

$$r_i(\Theta) = \max_{\hat{y_i} \in Y(x_i)} (\ 0, s_t(x_i, \hat{y_i}, \Theta) + \Delta(y_i, \hat{y_i}) - s_t(x_i, y_i, \Theta)\ ). \tag{11}$$

By minimizing this object, the score of the correct tree y_i is increased and the score of the highest scoring incorrect tree $\hat{y_i}$ is decreased.

We use a generalization of gradient descent called subgradient method (Ratliff et al., 2007) which computes a gradient-like direction. The subgradient of equation is:

$$\frac{\partial J}{\partial \Theta} = \frac{1}{|\mathcal{D}|} \sum_{(x_i, y_i) \in \mathcal{D}} \left(\frac{\partial s_t(x_i, \hat{y_i}, \Theta)}{\partial \Theta} - \frac{\partial s_t(x_i, y_i, \Theta)}{\partial \Theta} \right) + \lambda \Theta. \tag{12}$$

To minimize the objective, we use the diagonal variant of AdaGrad (Duchi et al., 2011). The parameter update for the i-th parameter $\Theta_{t,i}$ at time step t is as follows:

$$\Theta_{t,i} = \Theta_{t-1,i} - \frac{\rho}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i}, \tag{13}$$

where ρ is the initial learning rate and $g_\tau \in \mathbb{R}^{|\theta_i|}$ is the subgradient at time step τ for parameter θ_i.

6 Re-rankers

Re-ranking k-best lists was introduced by Collins and Koo (2005) and Charniak and Johnson (2005). They used discriminative methods to re-rank the constituent parsing. In the dependency parsing, Sangati et al. (2009) used a third-order generative model for re-ranking k-best lists of base parser. Hayashi et al. (2013) used a discriminative forest re-ranking algorithm for dependency parsing. These re-ranking models achieved a substantial raise on the parsing performances.

Given $\mathcal{T}(x)$, the set of k-best trees of a sentence x from a base parser, we use the popular mixture re-ranking strategy (Hayashi et al., 2013; Le and Mikolov, 2014), which is a combination of the our model and the base parser.

$$\hat{y_i} = \arg\max_{y \in \mathcal{T}(x_i)} \alpha s_t(x_i, y, \Theta) + (1 - \alpha) s_b(x_i, y) \tag{14}$$

where $\alpha \in [0, 1]$ is a hyperparameter; $s_t(x_i, y, \Theta)$ and $s_b(x_i, y)$ are the scores given by RCNN and the base parser respectively.

To apply RCNN into re-ranking model, we first get the k-best outputs of all sentences in train set with a base parser. Thus, we can train the RCNN in a discriminative way and optimize the re-ranking strategy for a particular base parser.

Note that the role of RCNN is not fully valued when applied in re-ranking model since that the $\mathbf{gen}(x)$ in Eq.(8) is just the k-best outputs of a base parser, not the set of all possible trees for sentence x. The parameters of RCNN could overfit to k-best outputs of training set.

7 Experiments

7.1 Datasets

To empirically demonstrate the effectiveness of our approach, we use two datasets in different languages (English and Chinese) in our experimental evaluation and compare our model against the other state-of-the-art methods using the unlabeled attachment score (UAS) metric ignoring punctuation.

English For English dataset, we follow the standard splits of Penn Treebank (PTB), using sections 2-21 for training, section 22 as development set and section 23 as test set. We tag the development and test sets using an automatic POS tagger (at 97.2% accuracy), and tag the training set using four-way jackknifing similar to (Collins and Koo, 2005).

Chinese For Chinese dataset, we follow the same split of the Penn Chinese Treeban (CTB5) as described in (Zhang and Clark, 2008) and use sections 001-815, 1001-1136 as training set, sections 886-931, 1148- 1151 as development set, and sections 816-885, 1137-1147 as test set. Dependencies are converted by using the Penn2Malt tool with the head-finding rules of (Zhang and Clark, 2008). And following (Zhang and Clark, 2008) (Zhang and Nivre, 2011), we use gold segmentation and POS tags for the input.

We use the linear-time incremental parser (Huang and Sagae, 2010) as our base parser and calculate the 64-best parses at the top cell of the chart. Note that we optimize the training settings for base parser and the results are slightly improved on (Huang and Sagae, 2010). Then we use max-margin criterion to train RCNN. Finally, we use the mixture strategy to re-rank the top 64-best parses.

For initialization of parameters, we train word2vec embeddings (Mikolov et al., 2013) on Wikipedia corpus for English and Chinese respectively. For the combination matrices and score vectors, we use the random initialization within $(0.01, 0.01)$. The parameters which achieve the best unlabeled attachment score on the development set will be chosen for the final evaluation.

7.2 English Dataset

We first evaluate the performances of the RCNN and re-ranker (Eq. (14)) on the development set. Figure 5 shows UASs of different models with varying k. The base parser achieves 92.45%. When $k = 64$, the oracle best of base parser achieves 97.34%, while the oracle worst achieves 73.30% (-19.15%) . RCNN achieves the maximum improvement of 93.00%(+0.55%) when $k = 6$. When $k > 6$, the performance of RCNN declines with the increase of k but is still higher than baseline (92.45%). The reason behind this is that RCNN could require more negative samples to avoid overfitting when k is large. Since the negative samples are limited in the k-best outputs of a base parser, the learnt parameters could easily overfits to the training set.

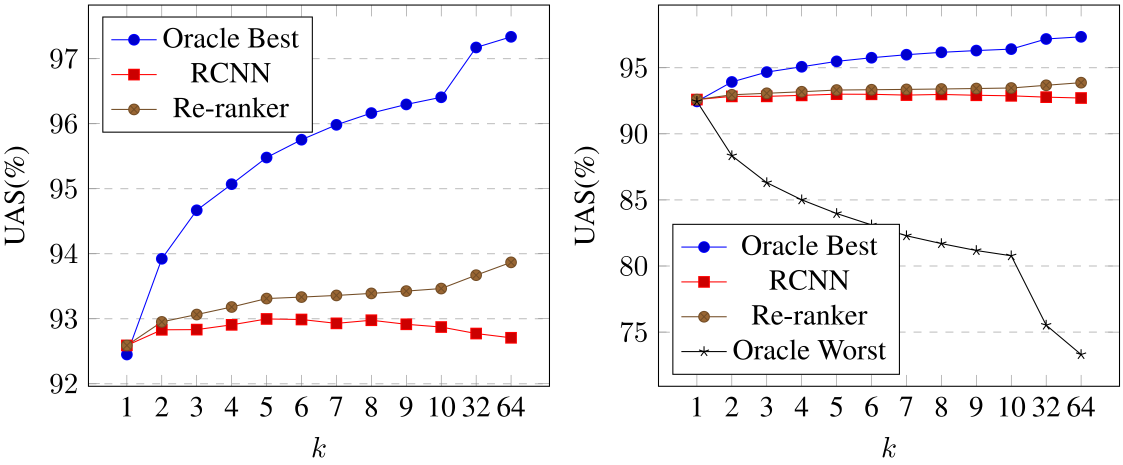
The mixture re-ranker achieves the maximum improvement of 93.50%(+1.05%) when $k = 64$. In mixture re-ranker, α is optimised by searching with the step-size 0.005.

Therefore, we use the mixture re-ranker in the following experiments since it can take the advantages of both the RCNN and base models.

Figure 6 shows the accuracies on the top ten POS tags of the modifier words with the largest improvements. We can see that our re-ranker can improve the accuracies of *CC* and *IN*, and therefore may indirectly result in rising the the well-known coordinating conjunction and PP-attachment problems.

The final experimental results on test set are shown in Table 1. The hyperparameters of our model are set as in Table 2. Our re-ranker achieves the maximum improvement of 93.83%(+1.48%) on test set. Our system performs slightly better than many state-of-the-art systems such as Zhang and Clark (2008) and Huang and Sagae (2010). It outperforms Hayashi et al. (2013) and Le and Zuidema (2014), which also use the mixture reranking strategy.

Since the result of ranker is conditioned to k-best results of base parser, we also do an experiment to avoid this limitation by adding the oracle to k-best candidates. With including oracle, the re-ranker can achieve 94.16% on UAS, which is shown in the last line ("our re-ranker (with oracle)") of Table 1.



(a) without the oracle worst result

(b) with the oracle worst result

Figure 5: UAS with varying k on the development set. Oracle best: always choosing the best result in the k-best of base parser; Oracle worst: always choosing the worst result in the k-best of base parser; RCNN: choosing the most probable candidate according to the score of RCNN; Re-ranker: a combination of the RCNN and base parser.

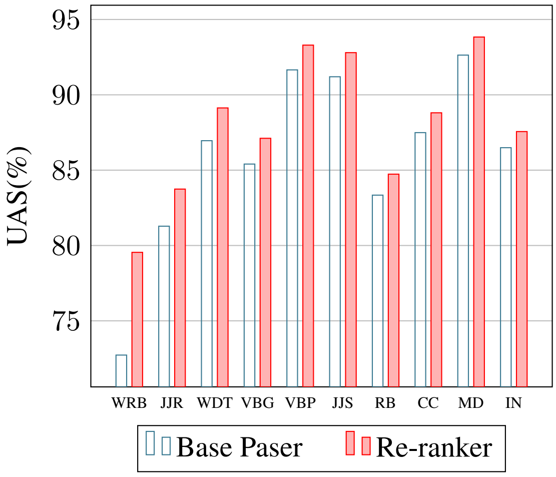


Figure 6: Accuracies on the top ten POS tags of the modifier words with the largest improvements on the development set.

7.3 Chinese Dataset

We also make experiments on the Penn Chinese Treebank (CTB5). The hyperparameters is the same as the previous experiment on English except that α is optimised by searching with the step-size 0.005.

The final experimental results on the test set are shown in Table 3. Our re-ranker achieves the performance of 85.71%(+0.25%) on the test set, which also outperforms the previous state-of-the-art methods. With adding oracle, the re-ranker can achieve 87.43% on UAS, which is shown in the last line ("our re-ranker (with oracle)") of Table 3.

	UAS

Le and Zuidema (2014)	93.12
Our baseline	92.35
Our re-ranker	93.83(+1.48)
Our re-ranker (with oracle)	94.16

Table 1: Accuracy on English test set. Our baseline is the result of base parser; our re-ranker uses the mixture strategy on the 64-best outputs of base parser; our re-ranker(with oracle) is to add the oracle to k-best outputs of base parser.

Compared with the re-ranking model of Hayashi et al. (2013), that use a large number of handcrafted features, our model can achieve a competitive performance with the minimal feature engineering.

7.4 Discussions

The performance of the re-ranking model is affected by the base parser. The small divergence of the dependency trees in the output list also results to overfitting in training phase. Although our re-

ranker outperforms the state-of-the-art methods, it can also benefit from improving the quality of the candidate results. It was also reported in other reranking works that a larger k (eg. $k > 64$) results the worse performance. We think the reason is that the oracle best increases when k is larger, but the oracle worst decrease with larger degree. The error types increase greatly. The re-ranking model requires more negative samples to avoid overfitting. When k is larger, the number of negative samples also needs to multiply increase for training. However, we just can obtain at most k negative samples from the k-best outputs of the base parser.

The experiments also show that the our model can achieves significant improvements by adding the oracles into the output lists of the base parser. This indicates that our model can be boosted by a better set of the candidate results, which can be implemented by combining the RCNN in the decoding algorithm.

8 Related Work

There have been several works to use neural networks and distributed representation for dependency parsing.

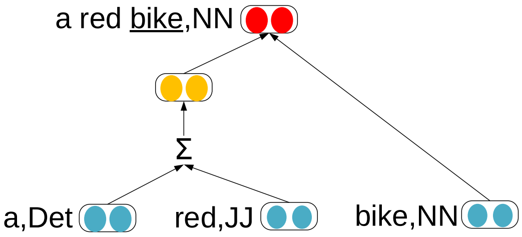

Figure 7: Example of a DT-RNN unit

Stenetorp (2013) attempted to build recursive neural networks for transition-based dependency parsing, however the empirical performance of his model is still unsatisfactory. Chen and Manning (2014) improved the transition-based dependency parsing by representing all words, POS tags and arc labels as dense vectors, and modeled their interactions with neural network to make predictions of actions. Their methods aim to transition-based parsing and can not model the sentence in semantic vector space for other NLP tasks.

Socher et al. (2013b) proposed a compositional vectors computed by dependency tree RNN (DT-RNN) to map sentences and images into a common embedding space. However, there are two major differences as follows. 1) They first summed up all child nodes into a dense vector $\mathbf{v}_c$ and then composed subtree representation from $\mathbf{v}_c$ and vector parent node. In contrast, our model first combine the parent and each child and then choose the most informative features with a pooling layer. 2) We represent the relative position of each child and its parent with distributed representation (position embeddings), which is very useful for convolutional layer. Figure 7 shows an example of DTRNN to illustrates how RCNN represents phrases as continuous vectors.

Specific to the re-ranking model, Le and Zuidema (2014) proposed a generative re-ranking model with Inside-Outside Recursive Neural Network (IORNN), which can process trees both bottom-up and top-down. However, IORNN works in generative way and just estimates the probability of a given tree, so IORNN cannot fully utilize the incorrect trees in k-best candidate results. Besides, IORNN treats dependency tree as a sequence, which can be regarded as a generalization of simple recurrent neural network (SRNN) (Elman, 1990). Unlike IORNN, our proposed RCNN is a discriminative model and can optimize the re-ranking strategy for a particular base parser. Another difference is that RCNN computes the score of tree in a recursive way, which is more natural for the hierarchical structure of natural language. Besides, the RCNN can not only be used for the re-ranking, but also be regarded as general model to represent sentence with its dependency tree.

9 Conclusion

In this work, we address the problem to represent all level nodes (words or phrases) with dense representations in a dependency tree. We propose a recursive convolutional neural network (RCNN) architecture to capture the syntactic and compositional-semantic representations of phrases and words. RCNN is a general architecture and can deal with k-ary parsing tree, therefore RCNN is very suitable for many NLP tasks to minimize the effort in feature engineering with a external dependency parser. Although RCNN is just used for the re-ranking of the dependency parser in this paper, it can be regarded as semantic modelling of text sequences and handle the input sequences of varying length into a fixed-length vector. The parameters in RCNN can be learned jointly with some other NLP tasks, such as text classification.

For the future research, we will develop an integrated parser to combine RCNN with a decoding algorithm. We believe that the integrated parser can achieve better performance without the limitation of base parser. Moreover, we also wish to investigate the ability of our model for other NLP tasks.

Abstract

Constituent parsing is typically modeled by a chart-based algorithm under probabilistic context-free grammars or by a transition-based algorithm with rich features. Previous models rely heavily on richer syntactic information through lexicalizing rules, splitting categories, or memorizing long histories. However enriched models incur numerous parameters and sparsity issues, and are insufficient for capturing various syntactic phenomena. We propose a neural network structure that explicitly models the unbounded history of actions performed on the stack and queue employed in transition-based parsing, in addition to the representations of partially parsed tree structure. Our transition-based neural constituent parsing achieves performance comparable to the state-of-the-art parsers, demonstrating F1 score of 90.68% for English and 84.33% for Chinese, without reranking, feature templates or additional data to train model parameters.

1 Introduction

A popular parsing algorithm is a cubic time chart-based dynamic programming algorithm that uses probabilistic context-free grammars (PCFGs). However, PCFGs learned from treebanks are too coarse to represent the syntactic structures of texts. To address this problem, various contexts are incorporated into the grammars through lexicalization (Collins, 2003; Charniak, 2000) or category splitting either manually (Klein and Manning, 2003) or automatically (Matsuzaki et al., 2005; Petrov et al., 2006). Recently a rich feature set was introduced to capture the lexical contexts in each span without extra annotations in grammars (Hall et al., 2014).

Alternatively, transition-based algorithms run in linear time by taking a series of shift-reduce actions with richer lexicalized features considering histories; however, the accuracies did not match with the state-of-the-art methods until recently (Sagae and Lavie, 2005; Zhang and Clark, 2009). Zhu et al. (2013) show that the use of better transition actions considering unaries and a set of non-local features can compete with the accuracies of chart-based parsing. The features employed in a transition-based algorithm usually require part of speech (POS) annotation in the input, but the delayed feature technique allows joint POS inference (Wang and Xue, 2014).

In both frameworks, the richer models require that more parameters be estimated during training which can easily result in the data sparseness problems. Furthermore, the enriched models are still insufficient to capture various syntactic relations in texts due to the limited contexts represented in latent annotations or non-local features. Recently Socher et al. (2013) introduced compositional vector grammar (CVG) to address the above limitations. However, they employ reranking over a forest generated by a baseline parser for efficient search, because CVG is built on cubic time chart-based parsing.

In this paper, we propose a neural network-based parser — *transition-based neural constituent parsing (TNCP)* — which can guarantee efficient search naturally. TNCP explicitly models the actions performed on the stack and queue employed in transition-based parsing. More specifically, the queue is modeled by recurrent neural network (RNN) or Elman network (Elman, 1990) in backward direction (Henderson, 2004). The stack structure is also modeled similarly to RNNs, and its top item is updated using the previously constructed hidden representations saved in the

stack. The representations from both the stack and queue are combined with the representations propagated from the partially parsed tree structure inspired by the recursive neural networks of CVGs. Parameters are estimated efficiently by a variant of max-violation (Huang et al., 2012) which considers the worst mistakes found during search and updates parameters based on the expected mistake.

Under similar settings, TCNP performs comparably to state-of-the-art parsers. Experimental results obtained using the Wall Street Journal corpus of the English Penn Treebank achieved a labeled F1 score of 90.68%, and the result for the Penn Chinese Treebank was 84.33%. Our parser performs no reranking with computationally expensive models, employs no templates for feature engineering, and requires no additional monolingual data for reliable parameter estimation. The source code and models will be made public[1].

2 Related Work

Our study is largely inspired by recursive neural networks for parsing, first pioneered by Costa et al. (2003), in which parsing is treated as a ranking problem of finding phrasal attachment. Such network structures have been used successfully as a reranker for k-best parses from a baseline parser (Menchetti et al., 2005) or parse forests (Socher et al., 2013), and have achieved gains on large data. Stenetorp (2013) showed that the recursive neural networks are comparable to the state-of-the-art system with a rich feature set under dependency parsing. Our model is not a reranking model, but a discriminative parsing model, which incorporates the representations of stacks and queues employed in the transition-based parsing framework, in addition to the representations of the tree structures. The use of representations outside of the partial parsed trees is very similar to the recently proposed inside-outside recursive neural networks (Le and Zuidema, 2014) which can assign probabilities in a top-down manner, in the same way as PCFGs.

Henderson (2003) was the first to demonstrate the successful use of neural networks to represent derivation histories under large-scale parsing experiments. He employed synchrony networks, i.e., feed-forward style networks, to assign a probability for each step in the left-corner parsing conditioning on all parsing steps. Henderson (2004) later employed a discriminative model and showed further gains by conditioning on the representation of the future input in addition to the history of parsing steps. Similar feed-forward style networks are successfully applied for transition-based dependency parsing in which limited contexts are considered in the feature representation (Chen and Manning, 2014). Our model is very similar in that the score of each action is computed by conditioning on all previous actions and future input in the queue.

The use of neural networks for transition-based shift-reduce parsing was first presented by Mayberry and Miikkulainen (1999) in which the stack representation was treated as a hidden state of an RNN. In their study, the hidden state is updated recurrently by either a shift or reduce action, and its corresponding parse tree is decoded recursively from the hidden state (Berg, 1992) using recursive auto-associative memories (Pollack, 1990). We apply the idea of representing a stack in a continuous vector; however, our method differs in that it memorizes all hidden states pushed to the stack and performs push/pop operations. In this manner, we can represent the local contexts saved in the stack explicitly and use them to construct new hidden states.

3 Transition-based Constituent Parsing

Our transition-based parser is based on a study by Zhu et al. (2013), which adopts the shift-reduce parsing of Sagae and Lavie (2005) and Zhang and Clark (2009). However, our parser differs in that we do not differentiate left or right head words. In addition, POS tags are jointly induced during parsing in the same manner as Wang and Xue (2014). Given an input sentence $w_0, \cdots, w_{n-1}$, the transition-based parser employs a stack of partially constructed constituent tree structures and a queue of input words. In each step, a transition action is applied to a state $\langle i, f, S\rangle$, where i is the next input word position in the queue w_i, f is a flag indicating the completion of parsing, i.e., whether the *ROOT* of a constituent tree covering all the input words is reached, and S represents a stack of tree elements, $s_0, s_1, \cdots$.

The parser consists of five actions:

shift-*X* consumes the next input word, w_i, from the queue and pushes a non-terminal symbol (or a POS label) as a tree of $X \rightarrow w_i$.

\end{array}
$$

Figure 1: Deduction system for shift-reduce parsing, where j is a step size and ρ is a score.

reduce-X pops the top two items s_0 and s_1 out of the stack and combines them as a partial tree with the constituent label X as its root, and with s_0 and s_1 as right and left antecedents, respectively ($X \rightarrow s_1 s_0$). The newly created tree is then pushed into the stack.

unary-X is similar to reduce-X; however, it consumes only the top most item s_0 from the stack and pushes a new tree of $X \rightarrow s_0$.

finish indicates the completion of parsing, i.e., reaching the $ROOT$.

idle preserves completion until the goal is reached.

The whole procedure is summarized as a deduction system in Figure 1. We employ beam search which starts from an axiom consisting of a stack with a special symbol ⟨eps⟩, and ends when we reach a goal item (Zhang and Clark, 2009). A set of agenda $\boldsymbol{B} = B_0, B_1, \cdots$ maintains the k-best states for each step j at B_j, which is first initialized by inserting the axiom in B_0. Then, at each step $j = 0, 1, \cdots$, every state in the agenda B_j is extended by applying one of the actions and the new states are inserted into the agenda B_{j+1} for the next step, which retains only the k-best states.

We limit the maximum number of consecutive unary actions to u (Sagae and Lavie, 2005; Zhang and Clark, 2009) and the maximum number of unary actions in a single derivation to $u \times n$. Thus, the process is repeated until we reach the final step of $(2+u)n$, which keeps the completed states. The idle action is inspired by the padding method of Zhu et al. (2013), such that the states in an agenda are comparable in terms of score even if differences exist in the number of unary actions. Unlike Zhu et al. (2013) we do not terminate parsing even if all the states in an agenda are completed ($f =$ true).

The score of a state is computed by summing the scores of all the actions leading to the state. In Figure 1, ρ_{sh}, ρ_{re}, ρ_{un}, ρ_{fi} and ρ_{id} are the scores of shift-X, reduce-X, unary-X, finish and idle actions, respectively, which are computed on the basis of the history of actions.

4 Neural Constituent Parsing

The score of a state is defined formally as the total score of transition actions, or a (partial) derivation $\boldsymbol{d} = d_0, d_1, \cdots$ leading to the state as follows:

$$\rho(\boldsymbol{d}) = \sum_{j=0}^{|\boldsymbol{d}|-1} \rho(d_j | d_0^{j-1}). \tag{1}$$

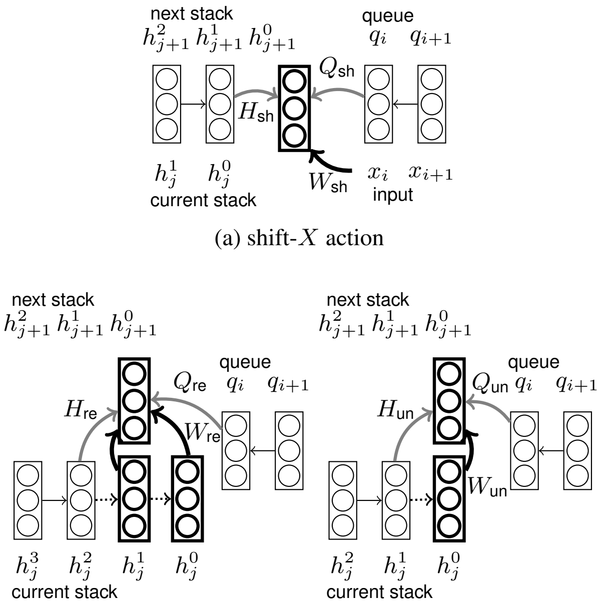
Note that the score of each action is dependent on all previous actions. In previous studies, the score is computed by a linear model, i.e., a weighted sum of feature values derived from limited histories, such as those that consider two adjacent constituent trees in a stack (Sagae and Lavie, 2005; Zhang and Clark, 2009; Zhu et al., 2013). Our method employs an RNN or Elman network (Elman, 1990) to represent an unlimited stack and queue history.

Formally, we use an m-dimensional vector for each hidden state unless otherwise stated. Here, let $x_i \in \mathbb{R}^{m' \times 1}$ be an m'-dimensional vector representing the input word w_i and the dimension may not match with the hidden state size m. $q_i \in \mathbb{R}^{m \times 1}$ denotes the hidden state for the input word w_i in a queue. Following the RNN in backward direction (Henderson, 2004), the hidden state for each word w_i is computed right-to-left, q_{n-1} to q_0, beginning from a constant q_n:

$$q_i = \tau \left(H_{\mathsf{qu}} q_{i+1} + W_{\mathsf{qu}} x_i + b_{\mathsf{qu}} \right), \tag{2}$$

where $H_{\mathsf{qu}} \in \mathbb{R}^{m \times m}$, $W_{\mathsf{qu}} \in \mathbb{R}^{m \times m'}$, $b_{\mathsf{qu}} \in \mathbb{R}^{m \times 1}$ and $\tau(x)$ is hard-tanh applied element-wise[2].

[2] $\tau(x) = -1$ for $x < 1$, 1 for $x > 1$ otherwise x.



(a) shift-X action

(b) reduce-X action

(c) unary-X action

Figure 2: Example neural network for constituent parsing. The thick arrows indicate the context of tree structures, and the gray arrows represent interactions from the stack and queue. The dotted arrows denote popped states.

Shift: Now, let $h^l_j \in \mathbb{R}^{m \times 1}$ represent a hidden state associated with the lth stack item for the jth action. We define the score of a shift action:

$$h^0_{j+1} = \tau\left(H^X_{\text{sh}} h^0_j + Q^X_{\text{sh}} q_i + W^X_{\text{sh}} x_i + b^X_{\text{sh}}\right) \quad (3)$$

$$\rho(d_j = \text{shift-}X | d_0^{j-1}) = V^X_{\text{sh}} h^0_{j+1} + v^X_{\text{sh}} \quad (4)$$

where $H^X_{\text{sh}} \in \mathbb{R}^{m \times m}$, $Q^X_{\text{sh}} \in \mathbb{R}^{m \times m}$, $W^X_{\text{sh}} \in \mathbb{R}^{m \times m'}$ and $b^X_{\text{sh}} \in \mathbb{R}^{m \times 1}$. Figure 2(a) shows the network structure for Equation 3. H^X_{sh} represents an RNN-style architecture that propagates the previous context in the stack. Q^X_{sh} can reflect the queue context q_i, or the future input sequence from w_i through w_{n-1}, while W^X_{sh} directly expresses the leaf of a tree structure using the shifted input word representation x_i for w_i. The hidden state h^0_{j+1} is used to compute the score of a derivation $\rho(d_j | d_0^{j-1})$ in Equation 4, which is based on the matrix $V^X_{\text{sh}} \in \mathbb{R}^{1 \times m}$ and the bias term $v^X_{\text{sh}} \in \mathbb{R}$. Note that $h^l_{j+1} = h^{l-1}_j$ for $l = 1, 2, \cdots$ because the stack is updated by the newly created partial tree label X associated with the new hidden state h^0_{j+1}.

Inspired by CVG (Socher et al., 2013), we differentiate the matrices for each non-terminal (or POS) label X rather than using shared parameters. However, our model differs in that the parameters are untied on the basis of the left hand side of a rule, rather than the right hand side, because our model assigns a score discriminatively for each action with the left hand side label X unlike a generative model derived from PCFGs.

Reduce: Similarly, the score for a reduce action is obtained as follows:

$$h^0_{j+1} = \tau\left(H^X_{\text{re}} h^2_j + Q^X_{\text{re}} q_i + W^X_{\text{re}} h^{[0:1]}_j + b^X_{\text{re}}\right) \quad (5)$$

$$\rho(d_j = \text{reduce-}X | d_0^{j-1}) = V^X_{\text{re}} h^0_{j+1} + v^X_{\text{re}}, \quad (6)$$

where $H^X_{\text{re}} \in \mathbb{R}^{m \times m}$, $Q^X_{\text{re}} \in \mathbb{R}^{m \times m}$, $W^X_{\text{re}} \in \mathbb{R}^{m \times 2m}$, $b^X_{\text{re}} \in \mathbb{R}^{m \times 1}$, and $h^{[l:l']}$ denotes the vertical matrix concatenation of hidden states from h^l to $h^{l'}$.

Note that the reduce-X action pops top two items in the stack that correspond to the two hidden states of $h^{[0:1]}_j$ as represented by Figure 2(b). By pushing a newly created tree with the constituent X, its corresponding hidden state h^0_{j+1} is pushed to the stack with each remaining hidden state $h^l_{j+1} = h^{l+1}_j$ for $l = 1, 2, \cdots$. The hidden state of the top stack item h^0_j is a representation of the right antecedent of a newly created binary tree with h^0_{j+1} as a root, while the hidden state of the next top stack item h^1_j corresponds to the left antecedent of the binary tree. Thus, the two hidden states capture the recursive neural network-like structure (Costa et al., 2003), while $h^2_j = h^1_{j+1}$ represents the RNN-like linear history in the stack.

Unary: In the same manner as the reduce action, the unary action is defined by simply reducing a single item from a stack and by pushing a new item (Figure 2(c)):

$$h^0_{j+1} = \tau\left(H^X_{\text{un}} h^1_j + Q^X_{\text{un}} q_i + W^X_{\text{un}} h^0_j + b^X_{\text{un}}\right) \quad (7)$$

$$\rho(d_j = \text{unary-}X | d_0^{j-1}) = V^X_{\text{un}} h^0_{j+1} + v^X_{\text{un}}, \quad (8)$$

where $H^X_{\text{un}} \in \mathbb{R}^{m \times m}$, $Q^X_{\text{un}} \in \mathbb{R}^{m \times m}$, $W^X_{\text{un}} \in \mathbb{R}^{m \times m}$ and $b^X_{\text{un}} \in \mathbb{R}^{m \times 1}$. Note that $h^l_{j+1} = h^l_j$ for $l = 1, 2, \cdots$, because only the top item is updated in the stack by creating a partial tree with h^0_j together with the stack history h^1_j.

In summary, the number of model parameters for the three actions is $9 \times m^2 + m \times m' + 6 \times m + 3$ for each non-terminal label X. The scores for a finish action and an idle action are defined analogous to the unary-X action with special labels for X, $\langle$finish$\rangle$ and $\langle$idle$\rangle$, respectively[3].

5 Parameter Estimation

Let $\boldsymbol{\theta} = \left\{H_{\mathsf{sh}}^X, Q_{\mathsf{sh}}^X, \cdots\right\} \in \mathbb{R}^M$ be an M-dimensional vector of all model parameters. The parameters are initialized randomly by following Glorot and Bengio (2010), in which the random value range is determined by the size of the input/output layers. The bias parameters are initialized to zeros.

We employ a variant of max-violation (Huang et al., 2012) as our training objective, in which parameters are updated based on the worst mistake found during search, rather than the first mistake as performed in the early update perceptron algorithm (Collins and Roark, 2004). Specifically, given a training instance $(\boldsymbol{w}, \boldsymbol{y})$ where $\boldsymbol{w}$ is an input sentence and $\boldsymbol{y}$ is its gold derivation, i.e., a sequence of actions representing the gold parse tree for $\boldsymbol{w}$, we seek for the step j^* where the difference of the scores is the largest:

$$j^* = \arg\min_j \left\{\rho_{\boldsymbol{\theta}}(y_0^j) - \max_{\boldsymbol{d} \in B_j} \rho_{\boldsymbol{\theta}}(\boldsymbol{d})\right\}. \quad (9)$$

Then, we define the following hinge-loss function:

$$L(\boldsymbol{w}, \boldsymbol{y}; \boldsymbol{B}, \boldsymbol{\theta}) = \max\left\{0, 1 - \rho_{\boldsymbol{\theta}}(y_0^{j^*}) + \mathbb{E}_{\tilde{B}_{j^*}}[\rho_{\boldsymbol{\theta}}]\right\}, \quad (10)$$

wherein we consider the subset of sub-derivations $\tilde{B}_{j^*} \subset B_{j^*}$ consisting of those scored higher than $\rho_{\boldsymbol{\theta}}(y_0^{j^*})$:

$$\tilde{B}_{j^*} = \left\{\boldsymbol{d} \in B_{j^*} \middle| \rho_{\boldsymbol{\theta}}(\boldsymbol{d}) > \rho_{\boldsymbol{\theta}}(y_0^{j^*})\right\} \quad (11)$$

$$p_{\boldsymbol{\theta}}(\boldsymbol{d}) = \frac{\exp(\rho_{\boldsymbol{\theta}}(\boldsymbol{d}))}{\sum_{\boldsymbol{d}' \in \tilde{B}_{j^*}} \exp(\rho_{\boldsymbol{\theta}}(\boldsymbol{d}'))} \quad (12)$$

$$\mathbb{E}_{\tilde{B}_{j^*}}[\rho_{\boldsymbol{\theta}}] = \sum_{\boldsymbol{d} \in \tilde{B}_{j^*}} p_{\boldsymbol{\theta}}(\boldsymbol{d}) \rho_{\boldsymbol{\theta}}(\boldsymbol{d}). \quad (13)$$

Unlike Huang et al. (2012) and inspired by Tamura et al. (2014), we consider all incorrect sub-derivations found in $\tilde{B}_{j^*}$ through the expected score $\mathbb{E}_{\tilde{B}_{j^*}}[\rho_{\boldsymbol{\theta}}]$[4]. The loss function in Equation 10 can be intuitively considered an expected mistake suffered at the maximum violated step j^*, which is measured by the Viterbi violation in Equation 9. Note that if we replace $\mathbb{E}_{\tilde{B}_{j^*}}[\rho_{\boldsymbol{\theta}}]$ with $\max_{\boldsymbol{d} \in B_{j^*}} \rho_{\boldsymbol{\theta}}(\boldsymbol{d})$ in Equation 10, it is exactly the same as the max-violation objective (Huang et al., 2012)[5].

To minimize the loss function, we use a diagonal version of AdaDec (Senior et al., 2013) — a variant of diagonal AdaGrad (Duchi et al., 2011) — under mini-batch settings. Given the sub-gradient $\boldsymbol{g}_t \in \mathbb{R}^M$ of Equation 10 at time t computed by the back-propagation through structure (Goller and Küchler, 1996), we maintain additional parameters $\boldsymbol{G}_t \in \mathbb{R}^M$:

$$\boldsymbol{G}_t \leftarrow \gamma \boldsymbol{G}_{t-1} + \boldsymbol{g}_t \odot \boldsymbol{g}_t, \quad (14)$$

where $\odot$ is the Hadamard product (or the element-wise product). $\boldsymbol{\theta}_{t-1}$ is updated using the element specific learning rate $\boldsymbol{\eta}_t \in \mathbb{R}^M$ derived from $\boldsymbol{G}_t$ and a constant $\eta_0 > 0$:

$$\boldsymbol{\eta}_t \leftarrow \eta_0 \left(\boldsymbol{G}_t + \epsilon\right)^{-\frac{1}{2}} \quad (15)$$

$$\boldsymbol{\theta}_{t-\frac{1}{2}} \leftarrow \boldsymbol{\theta}_{t-1} - \boldsymbol{\eta}_t \odot \boldsymbol{g}_t \quad (16)$$

$$\boldsymbol{\theta}_t \leftarrow \arg\min_{\boldsymbol{\theta}} \frac{1}{2} \|\boldsymbol{\theta} - \boldsymbol{\theta}_{t-\frac{1}{2}}\|_2^2 + \lambda \boldsymbol{\eta}_t^\top \operatorname{abs}(\boldsymbol{\theta}). \quad (17)$$

Compared with AdaGrad, the squared sum of the sub-gradients decays over time using a constant $0 < \gamma \leq 1$ in Equation 14. The learning rate in Equation 15 is computed element-wise and bounded by a constant $\epsilon \geq 0$, and if we set $\epsilon \geq \eta_0^2$, it is always decayed[6]. In our preliminary studies, AdaGrad eventually becomes very conservative to update parameters when training longer iterations. AdaDec fixes the problem by ignoring older histories of sub-gradients in $\boldsymbol{G}$, which is reflected in the learning rate $\boldsymbol{\eta}$. In each update, we employ ℓ_1 regularization through FOBOS (Duchi and Singer, 2009) using a hyperparameter $\lambda \geq 0$ to control the fitness in Equation 16 and 17. For testing, we found that taking the average of the parameters over period $\frac{1}{T+1}\sum_{t=0}^{T} \boldsymbol{\theta}_t$ under training iterations T was very effective as demonstrated by Hashimoto et al. (2013).

Parameter estimation is performed in parallel by distributing training instances asynchronously

[3] Since h_j^1 and q_n are constants for the finish and idle actions, we enforce $H_{\mathsf{un}}^X = 0$ and $Q_{\mathsf{un}}^X = 0$ for those special actions.

[4] We can use all the sub-derivations in B_{j^*}; however, our preliminary studies indicated that the use of $\tilde{B}_{j^*}$ was better.

[5] Or, setting $p_{\boldsymbol{\theta}}(\boldsymbol{d}^*) = 1$ for the Viterbi derivation $\boldsymbol{d}^* = \arg\max_{\boldsymbol{d} \in \tilde{B}_{j^*}} \rho_{\boldsymbol{\theta}}(\boldsymbol{d})$ and zero otherwise.

[6] Note that AdaGrad is a special case of AdaDec with $\gamma = 1$ and $\epsilon = 0$.

in each shard and by updating locally copied parameters using the sub-gradients computed from the distributed mini-batches (Dean et al., 2012). The sub-gradients are broadcast asynchronously to other shards to reflect the updates in one shard. Unlike Dean et al. (2012), we do not keep a central storage for model parameters; the replicated parameters are synchronized in each iteration by choosing the model parameters from one of the shards with respect to the minimum of ℓ_1 norm[7]. Note that we synchronize $\boldsymbol{\theta}$, but $\boldsymbol{G}$ is maintained as shard local parameters.

6 Experiments

6.1 Settings

We conducted experiments for transition-based neural constituent parsing (TNCP) for two languages — English and Chinese. English data were derived from the Wall Street Journal (WSJ) of the Penn Treebank (Marcus et al., 1993), from which sections 2-21 were used for training, 22 for development and 23 for testing. Chinese data were extracted from the Penn Chinese Treebank (CTB) (Xue et al., 2005); articles 001-270 and 440-1151 were used for training, 301-325 for development, and 271-300 for testing. Inspired by jack-knifing (Collins and Koo, 2005), we reassigned POS tags for training data using the Stanford tagger (Toutanova et al., 2003)[8]. The treebank trees were normalized by removing empty nodes and unary rules with X over X (or $X \rightarrow X$), then binarized in a left-branched manner.

The possible actions taken for our shift-reduce parsing, e.g., $X \rightarrow w$ in shift-X, were learned from the normalized treebank trees. The words that occurred twice or less were handled differently in order to consider OOVs for testing: They were simply mapped to a special token ⟨unk⟩ when looking up their corresponding word representation vector. Similarly, when assigning possible POS tags in shift actions, they fell back to their corresponding "word signature" in the same manner as the Berkeley parser[9]. A maximum number of consecutive unary actions was set to $u = 3$ for WSJ and $u = 4$ for CTB, as determined by the treebanks.

Table 1: Comparison of various state/word representation dimension size measured by labeled F1(%). "-32" denotes the hidden state size $m = 32$. The numbers in bold indicate the best results for each hidden state dimension.

Parameter estimation was performed on 16 cores of a Xeon E5-2680 2.7GHz CPU. It took approximately one day for 100 training iterations with $m = 32$ and $m' = 128$ under a mini-batch size of 4 and a beam size of 32. Doubling either one of m or m' incurred approximately double training time. We chose the following hyperparameters by tuning toward the development data in our preliminary experiments[10]: $\eta_0 = 10^{-2}$, $\gamma = 0.9$, $\epsilon = 1$. The choice of λ from $\{10^{-5}, 10^{-6}, 10^{-7}\}$ and the number of training iterations were very important for different training objectives and models in order to avoid overfitting. Thus, they were determined by the performance on the development data for each different training objective and/or network configuration, e.g., the dimension for a hidden state. The word representations were initialized by a tool developed in-house for an RNN language model (Mikolov et al., 2010) trained by noise contrastive estimation (Mnih and Teh, 2012). Note that the word representations for initialization were learned from the given training data, not from additional unannotated data as done by Chen and Manning (2014).

Testing was performed using a beam size of 64 with a Xeon X5550 2.67GHz CPU. All results were measured by the labeled bracketing metric PARSEVAL (Black et al., 1991) using EVALB[11] after debinarization.

6.2 Results

Table 1 shows the impact of dimensions on the parsing performance. We varied the hid-

[7] We also tried averaging among shards. However we observed no gains likely because we performed averaging for testing.

[8] `http://nlp.stanford.edu/software/tagger.shtml`

[9] `https://code.google.com/p/berkeleyparser/`

[10] We confirmed that this hyperparameter setting was appropriate for different models experimented in Section 6.2 through our preliminary studies.

den vector size $m = \{32, 64\}$ and the word representation (embedding) vector size $m' = \{32, 64, 128, 256, 512, 1024\}$[12]. As can be seen, the greater word representation dimensions are generally helpful for both WSJ and CTB on the closed development data (*dev*), which may match with our intuition that the richer syntactic and semantic knowledge representation for each word is required for parsing. However, overfitting was observed when using a 32-dimension hidden vector in both tasks, i.e., drops of performance on the open test data (*test*) when $m' = 1024$, probably caused by the limited generalization capability in the smaller hidden state size. In the rest of this paper, we show the results with $m = 64$ and $m' = 1024$ as determined by the performance on the development data, wherein we achieved 91.11% and 85.77% labeled F1 for WSJ and CTB, respectively. The total number of parameters were approximately 28.3M and 22.0M for WSJ and CTB, respectively, among which 17.8M and 13.4M were occupied for word representations, respectively.

Table 2 differentiated the network structure. The *tree* model computes the new hidden state h^0_{j+1} using only the recursively constructed network by ignoring parameters from the stack and queue, e.g., by enforcing $H^X_{\mathsf{sh}} = 0$ and $Q^X_{\mathsf{sh}} = 0$ in Equation 3, which is essentially similar to the CVG approach (Socher et al., 2013). Adding the context from the stack in *+stack* boosts the performance significantly. Further gains are observed when the queue context *+queue* is incorporated in the model. These results clearly indicate that explicit representations of the stack and queue are very important when applying a recursive neural network model for transition-based parsing.

We then compared the expected mistake with the Viterbi mistake (Huang et al., 2012) as our training objective by replacing $\mathbb{E}_{\tilde{B}_{j*}}[\rho_{\boldsymbol{\theta}}]$ with $\max_{\boldsymbol{d} \in B_{j*}} \rho_{\boldsymbol{\theta}}(\boldsymbol{d})$ in Equation 10. Table 3 shows that the use of the expected mistake (*expected*) as a loss function is significantly better than that of the Viterbi mistake (*Viterbi*) by considering all the incorrect sub-derivations at maximum violated steps during search. Figure 3 and 4 plot the training curves for WSJ and CTB, respectively. The plots clearly demonstrate that the use of the expected mistake is faster in convergence and stabler in learning when compared with that of the Viterbi mistake[13].

Next, we compare our parser, TNCP, with other parsers listed in Table 4 for WSJ and Table 5 for CTB on the test data. The Collins parser (Collins, 1997) and the Berkeley parser (Petrov and Klein, 2007) are chart-based parsers with rich states, either through lexicalization or latent annotation. SSN is a left-corner parser (Henderson, 2004), and CVG is a compositional vector grammar-based parser (Socher et al., 2013)[14]. Both parsers rely on neural networks to represent rich contexts, similar to our work; however they differ in that they essentially perform reranking from either the k-best parses or parse forests[15]. The word representa-

[12] We experimented larger dimensions in Appendix A.

[13] The labeled F1 on those plots are slightly different from EVALB in that all the syntactic labels are considered when computing bracket matching. Further, the scores on the training data are approximation since they were obtained as a by-product of online learning.

[14] `http://nlp.stanford.edu/software/lex-parser.shtml`

[15] Strictly speaking, SSN can work as a standalone parser; Table 4 shows the result after reranking (Henderson, 2004).

ZPar (Zhu et al., 2013)	90.4
CVG (Socher et al., 2013)	90.4
Charniak-R (Charniak and Johnson, 2005)	**91.0**
This work: TNCP	90.7

Table 4: Comparison of different parsers on the WSJ test data measured by labeled F1(%).

tion in CVG was learned from large monolingual data (Turian et al., 2010), but our parser learns word representation from only the provided training data. Charniak-R is a discriminative reranking parser with non-local features (Charniak and Johnson, 2005). ZPar is a transition-based shift-reduce parser (Zhu et al., 2013)[16] that influences the deduction system in Figure 1, but differs in that scores are computed by a large number of features and POS tagging is performed separately. The results shown in Table 4 and 5 come from the feature set without extra data, i.e., semi-supervised features. Joint is the joint POS tagging and transition-based parsing with non-local features (Wang and Xue, 2014). Similar to ZPar, we present the result without cluster features learned from extra unannotated data.

Finally, we measured the speed for parsing by varying beam size and hidden dimension (Table 6). When testing, we applied a pre-computation technique for layers involving word representation vectors (Devlin et al., 2014), i.e., W_{qu} in Equation 2 and W^{X}_{sh} in Equation 3. Thus, the parsing speed was influenced by only the hidden state size m. It is clear that the enlarged beam size improves performance by trading off run time in most cases. Note that Berkeley, CVG and ZPar took 4.74, 1.54 and 37.92 sentences/sec, respectively, with WSJ. Although it is more difficult to compare with other parsers, our parser implemented in C++ is on par with Java implementations of Berkeley and CVG. The large run time difference with the C++ implemented ZPar may come from the network computation and joint POS inference in our model which impact parsing speed significantly.

6.3 Error Analysis

To assess parser error types, we used the tool proposed by Kummerfeld et al. (2012)[17]. The average number of errors per sentence is listed in Table 7 for each error type on the WSJ test data. Generally, our parser results in errors that are comparable to the state-of-the-art parsers; however, greater reductions are observed for various attachments errors. One of the largest gains comes from the clause attachment, i.e., 0.12 reduction in average errors from Berkeley and 0.05 from CVG. The average number of errors is also reduced by 0.09 from Berkeley and 0.06 from CVG for the PP attachment. We also observed large reductions in coordination and unary rule errors.

7 Conclusion

We have introduced transition-based neural constituent parsing — a neural network architecture that encodes each state explicitly — as a continuous vector by considering the recurrent se-

Table 7: Comparison of different parsers on the WSJ test data measured by average number of errors per sentence; the numbers in bold indicate the least errors in each error type.

quences of the stack and queue in the transition-based parsing framework in addition to recursively constructed partial trees. Our parser works in a standalone fashion without reranking and does not rely on an external POS tagger or additional monolingual data for reliable estimates of syntactic and/or semantic representations of words. The parser achieves performance that is comparable to state-of-the-art systems.

In the future, we plan to apply our neural network structure to dependency parsing. We are also interested in using long short-term memory neural networks (Hochreiter and Schmidhuber, 1997) to better model the locality of propagated information from the stack and queue. The parameter estimation under semi-supervised setting will be investigated further.

A Additional Results

We conducted additional experiments by enlarging the word representation vector size m' in Table 8. In general, we observed further gains with richer word representation, but suffered overfitting effects when setting $m' = 4096$. The results with $m = 64$ and $m' = 4096$ achieved the best performance on the development data, 91.36% and 86.94% labeled F1 for WSJ and CTB, respectively, wherein we observed the accuracies of 90.94% and 84.38% on the test data, respectively. Note that it took approximately one week to train the model when $m' = 4096$ under WSJ, which was impractical to analyze the results further, e.g. comparison with other training objectives.

Feature Selection in Kernel Space: A Case Study on Dependency Parsing

{qx,yangl}@hlt.utdallas.edu

Abstract

Given a set of basic binary features, we propose a new L_1 norm SVM based feature selection method that explicitly selects the features in their polynomial or tree kernel spaces. The efficiency comes from the anti-monotone property of the subgradients: the subgradient with respect to a combined feature can be bounded by the subgradient with respect to each of its component features, and a feature can be pruned safely without further consideration if its corresponding subgradient is not steep enough. We conduct experiments on the English dependency parsing task with a third order graph-based parser. Benefiting from the rich features selected in the tree kernel space, our model achieved the best reported unlabeled attachment score of 93.72 without using any additional resource.

1 Introduction

In Natural Language Processing (NLP) domain, existing linear models typically adopt exhaustive search to generate tons of features such that the important features are included. However, the brute-force approach will guickly run out of memory when the feature space is extremely large. Unlike linear models, kernel methods provide a powerful and unified framework for learning a large or even infinite number of features implicitly using limited memory. However, many kernel methods scale quadratically in the number of training samples, and can hardly reap the benefits of learning a large dataset. For example, the popular Penn Tree Bank (PTB) corpus for training an English part of speech (POS) tagger has approximately $1M$ words, thus it takes $1M^2$ time to compute the kernel matrix, which is unacceptable using current hardwares.

In this paper, we propose a new feature selection method that can efficiently select representative features in the kernel space to improve the quality of linear models. Specifically, given a limited number of basic features such as the commonly used unigrams and bigrams, our method performs feature selection in the space of their combinations, e.g, the concatenation of these n-grams. A sparse discriminative model is produced by training L_1 norm SVMs using subgradient methods. Different from traditional training procedures, we divide the feature vector into a number of segments, and sort them in a coarse-to-fine order: the first segment includes the basic features, the second segment includes the combined features composed of two basic features, and so on. In each iteration, we calculate the subgradient segment by segment. A combined feature and all its further combinations in the following segments can be safely pruned if the absolute value of its corresponding subgradient is not sufficiently large. The algorithm stops until all features are pruned. Besides, two simple yet effective pruning strategies are proposed to filter the combinations.

We conduct experiments on English dependency parsing task. Millions of deep, high order features derived by concatenating contextual words, POS tags, directions and distances of dependencies are selected in the polynomial kernel and tree kernel spaces. The result is promising: these features significantly improved a state-of-the-art third order dependency parser, yielding the best reported unlabeled attachment score of 93.72 without using any additional resource.

2 Related Works

There are two solutions for learning in ultra high dimensional feature space: kernel method and feature selection.

Fast kernel methods have been intensively studied in the past few years. Recently, randomized methods have attracted more attention due to its theoretical and empirical success, such as the Nyström method (Williams and Seeger, 2001) and random projection (Lu et al., 2014). In NLP domain, previous studies mainly focused on polynomial kernels, such as the splitSVM and approximate polynomial kernel (Wu et al., 2007).

In feature selection domain, there has been plenty of work focusing on fast computation, while feature selection in extremely high dimensional feature space is relatively less studied. Zhang et al. (2006) proposed a progressive feature selection framework that splits the feature space into tractable disjoint sub-spaces such that a feature selection algorithm can be performed on each one of them, and then merges the selected features from different sub-spaces. The search space they studied contained more than 20 million features. Tan et al. (2012) proposed adaptive feature scaling (AFS) scheme for ultra-high dimensional feature selection. The dimensionality of the features in their experiments is up to 30 millions.

Previous studies on feature selection in kernel space typically used mining based approaches to prune feature candidates. The key idea for efficient pruning is to estimate the upper bound of statistics of features without explicit calculation. The simplest example is frequent mining where for any n-gram feature, its frequency is bounded by any of its substrings.

Suzuki et al. (Suzuki et al., 2004) proposed to select features in convolution kernel space based on their chi-squared values. They derived a concise form to estimate the upper bound of chi-square values, and used PrefixScan algorithm to enumerates all the significant sub-sequences of features efficiently.

Okanohara and Tsujii (Okanohara and Tsujii, 2009) further combined the pruning technique with L_1 regularization. They showed the connection between L_1 regularization and frequent mining: the L_1 regularizer provides a minimum support threshold to prune the gradients of parameters. They selected the combination features in a coarse-to-fine order, the gradient value for a combination feature can be bounded by each of its component feature, hence may be pruned without explicit calculation. They also sorted the features to tighten the bound. Our idea is similar with theirs, the difference is that our search space is much larger: we did not restrict the number of component features. We recursively pruned the feature set and in each recursion we selected feature in a batch manner. We further adopted an efficient data structure, spectral bloom filter, to estimate the gradients for the candidate features without generating them.

3 The Proposed Method

3.1 Basic Idea

Given n training samples $x_1 \dots x_n$ with labels $y_1 \dots y_n \in \mathcal{Y}$, we extend the kernel over the input space to the joint input and output space by simply defining $\mathbf{f}^T(x_i, y)\mathbf{f}(x_i, y') = K(x_i, x_j)I(y == y')$, which is the same as Taskar's (see (Taskar, 2004), Page 68), where $\mathbf{f}$ is the explicit feature map for the kernel, and $I(\cdot,\cdot)$ is the indicator function.

Our task is to select a subset of representative elements in the feature vector $\mathbf{f}$. Unlike previously studied feature selection problems, the dimension of $\mathbf{f}$ could be extremely high. It is impossible to store the feature vector in the memory or even on the disk.

For easy illustration, we describe our method for the polynomial kernel, and it can be easily extended to the tree kernel space.

The R degree polynomial kernel space is established by a set of basic features $\mathcal{B} = \{b_0 = 1, b_1, \dots, b_{|\mathcal{B}|}\}$ and their combinations. In other words, each feature is the product of at most R basic features $f_j = b_{j_1} * b_{j_2} * \dots * b_{j_r}$, $r \leq R$. As we assume that all features are binary [1], f_j can be rewritten as the minimum of these basic features: $f_j = \min\{b_{j_1}, b_{j_2}, \dots, b_{j_r}\}$. We use $\mathcal{B}_j = \{b_{j_1}, b_{j_2}, \dots, b_{j_r}\}$ to denote the set of component basic features for f_j. r is called the order of feature f_j. For two features f_j, f_k, we say f_k is an extension of f_j if $\mathcal{B}_j \subset \mathcal{B}_k$.

Take the document classification task as an example, the basic features could be word n-grams, and the quadratic kernel (degree=2) space includes the combinated features composed of two

[1] Binary features are often used in NLP.

n-grams, a second order feature is true if both n-grams appear in the document, it is an extension of any of its component n-grams (first order features).

We use L_1 norm SVMs for feature selection. Traditionally, the L_1 norm SVMs can be trained using subgradient descent and generate a sparse weight vector $\mathbf{w}$ for feature $\mathbf{f}$. Due to the high dimensionality in our case, we divide $\mathbf{f}$ into a number of segments according to the order of the feature, the k-th segment includes the k-order features. In each iteration, we update the weights of features segment by segment. When updating the weight of feature f_j in the k-th segment, we estimate the subgradients with respective to f_j's extensions in the rest $k+1, k+2, \dots$ segments and keep their weights at zero if the subgradients are not sufficiently steep. In this way, we could ignore these features without explicit calculation.

3.2 L_1 Norm SVMs

Specifically, the objective function for learning L_1 norm SVMs is:

$$\min_{\mathbf{w}} \mathcal{O}(\mathbf{w}) = C\|\mathbf{w}\|_1 + \sum_i loss(i)$$

where

$$loss(i) = \max_{y\in\mathcal{Y}}\{\mathbf{w}^T\Delta\mathbf{f}(x_i, y) + \delta(y_i, y)\}$$

is the hinge loss function for the i-th sample. $\Delta\mathbf{f}(x_i, y) = \mathbf{f}(x_i, y_i) - \mathbf{f}(x_i, y)$ is the residual feature vector, $\delta(a, b) = 0$ if $a = b$, otherwise $\delta(a, b) = 1$. Regularization parameter C controls the sparsity of $\mathbf{w}$. With higher C, more zero elements are generated. We call a feature is fired if its value is 1.

The objective function is a sum of piecewise linear functions, hence is convex. Subgradient descent algorithm is one poplar approach for minimizing non-differentiable convex functions, it updates $\mathbf{w}$ using

$$\mathbf{w}^{new} = \mathbf{w} - \mathbf{g}\alpha^t$$

where $\mathbf{g}$ is the subgradient of $\mathbf{w}$, α^t is the step size in the t-th iteration. Subgradient algorithm converges if the step size sequence is properly selected (Boyd and Mutapcic, 2006).

We are interested in the non-differentiable point $w_j = 0$. Let $y_i^* = \max_y\{\mathbf{w}^T\Delta\mathbf{f}(x_i, y) + \delta(y_i, y)\}$, the prediction of the current model. According to the definition of subgradient, we have, for each sample x_i, $\Delta\mathbf{f}(x_i, y_i^*)$ is a subgradient of $loss(i)$, thus, $\sum_i \Delta\mathbf{f}(x_i, y_i^*)$ is a subgradient of $\sum_i loss(i)$.

Adding the penalty term $C\|\mathbf{w}\|_1$, we get the subset of subgradients at $w_j = 0$ for the objective function

$$\sum_i \Delta f_j(x_i, y_i^*) - C \le g_j \le \sum_i \Delta f_j(x_i, y_i^*) + C$$

We can pick any g_j to update w_j. Remind that our purpose is to keep the model sparse, and we would like to pick $g_j = 0$ if possible. That is, we can keep $w_j = 0$ if $|\sum_i \Delta f_j(x_i, y_i^*)| \le C$.

Obviously, for any j, we have $|\sum_i \Delta f_j(x_i, y_i^*)| \le \sum_i\sum_y f_j(x_i, y) = \#f_j$, i.e., the frequency of feature f_j. Thus, we have

Proposition 1 *Let C be the threshold of the frequency, the model generated by the subgradient method is sparser than frequent mining.*

3.3 Feature Selection Using Gradient Mining

Now the problem is how to estimate $|\sum_i \Delta f_j(x_i, y_i^*)|$ without explicit calculation for each f_j.

In the following, we mix the terminology gradient and subgradient without loss of clarity. We define the positive gradient and negative gradient for w_j

$$\#f_j^+ = \sum_{i, y_i \neq y_i^*} f_j(x_i, y_i)$$
$$\#f_j^- = \sum_{i, y_i \neq y_i^*} f_j(x_i, y_i^*)$$

We have

$$\begin{aligned}\sum_i \Delta f_j(x_i, y_i^*) &= \sum_{i, y_i^* \neq y_i} \Delta f_j(x_i, y_i^*) \\ &= \#f_j^+ - \#f_j^-\end{aligned}$$

The estimation problem turns out to be a counting problem: we collect all the incorrectly predicted samples, and count $\#f_j^+$, the frequency of f_j fired by the gold labels, and $\#f_j^-$ the frequency of f_j fired by the predictions.

As mentioned above, each feature in polynomial kernel space is defined as $f_j = \min\{b \in \mathcal{B}_j\} = \min\{b_{j1}, \dots, b_{j_r}\}$. Equivalently, we can define f_j in a recursive way, which is more frequently used in the rest of the paper. That is, $f_j =$

$\min\{\min\{b_{j_2},\dots,b_{j_r}\},\min\{b_{j_1},b_{j_3},\dots,b_{j_r}\},\dots\}$, which is the mimum of r features of order $r-1$. Formally, denote $\mathcal{B}_j^{-i}$ as the subset of $\mathcal{B}_j$ by removing its i-th element, then the r-order feature, we have $f_j = \min\{h_1,\dots,h_r\}$, where $h_k = \min\{b \in \mathcal{B}_j^{-k}\}, 1 \le k \le r$.

We have the following anti-monotone property, which is the basis of our method

$$\begin{aligned} \#f_j^+ &\le \#h_k^+ \quad \forall k \\ \#f_j^- &\le \#h_k^- \quad \forall k \end{aligned}$$

If there exists a k, such that $\#h_k^+ \le C$ and $\#h_k^- \le C$, we have

$$\begin{aligned} & |\sum_i \Delta f_j(x_i, y_i^*)| \\ = \; & |\#f_j^+ - \#f_j^-| \\ \le \; & \max\{\#f_j^+, \#f_j^-\} \\ \le \; & \max\{\min_k\{\#h_k^+\}, \min_k\{\#h_k^-\}\} \\ \le \; & \min_k\{\max\{\#h_k^+, \#h_k^-\}\} \\ \le \; & C \end{aligned}$$

The third inequality comes from the well known min-max inequality: $\max_i \min_j\{a_{ij}\} \le \min_j \max_i\{a_{ij}\}$. Thus, we could prune f_j without calculating its corresponding gradient.

This is a chain rule, which means that any feature that has f_j as its component can also be pruned safely. To see this, suppose $\phi = \min\{\dots, f_j, \dots\}$ is such a combined feature, we have

$$\begin{aligned} |\#\phi^+ - \#\phi^-| &\le \max\{\#\phi^+, \#\phi^-\} \\ &\le \max\{\#f_j^+, \#f_j^-\} \\ &\le C \end{aligned}$$

Based on this, we present the gradient mining based feature selection framework in Algorithm 1.

4 Prune the Candidate Set

In practice, Algorithm 1 is far from efficient because Line 17 may generate large amounts of candidate features that quickly consume the memory. In this section, we introduce two pruning strategies that could greatly reduce the size of candidates.

Algorithm 1 Feature Selection Using Gradient Mining

```
Require: Samples $X = \{x_1,\dots,x_n\}$ with labels $\{y_1,\dots,y_n\}$, basic features $\mathcal{B} = \{b_1,\dots,b_{|\mathcal{B}|}\}$, threshold $C > 0$, max iteration number $M$, degree of polynomial kernel $R$, sequence of learning step $\{\alpha^t\}$.
Ensure: Set of selected features $\mathcal{S} = \{f_j\}$, where $f_j = \min\{b \in \mathcal{B}_j\}, \mathcal{B}_j \subseteq \mathcal{B}, |\mathcal{B}_j| \le R$.
 1: $\mathcal{S}_r = \emptyset, r = 1,\dots,R$ {$\mathcal{S}_r$ denotes the selected $r$-order features}
 2: for $t = 1 \to M$ do
 3:   Set $\mathcal{S} = \bigcup_{r=1}^R \mathcal{S}_r$, $\mathbf{f}$ = the vector of features in $\mathcal{S}$.
 4:   Calculate $y_i^* = \max_y\{\mathbf{w}^T\mathbf{f}(x_i,y) + \delta(y_i,y)\}, \forall i$.
 5:   Initialize candidate set $\mathcal{A} = \mathcal{B}$
 6:   for $r = 1 \to R$ do
 7:     for all $f_j \in \mathcal{A}$ do
 8:       Calculate $\#f_j^+ = \sum_{i,y_i \ne y_i^*} f_j(x_i,y_i)$ and $\#f_j^- = \sum_{i,y_i \ne y_i^*} f_j(x_i,y_i^*)$
 9:       if $\#f_j^+, \#f_j^- \le C$ and $w_j = 0$ then
10:         Remove $f_j$ from $\mathcal{A}$
11:       else
12:         $w_j = w_j + (\#f_j^+ - \#f_j^- + C\text{sign}(w_j))\alpha^t$
13:       end if
14:     end for
15:     $\mathcal{S}_r = \mathcal{A}$
16:     if $r < R$ then
17:       Generate order-$r+1$ candidates: $\mathcal{A} = \mathcal{S}_{r+1} \bigcup \{h | h = \min\{f_1,\dots f_r \in \mathcal{S}_r\}$, order of $h$ is $r+1\}$
18:     end if
19:   end for
20: end for
```

4.1 Pre-Training

Usually, the weights of features are initialized with 0 in the training procedure. However, this will select too many features in the first iteration, because all samples are mis-classified in Line 4, the gradients $\#f_j^+$ and $\#f_j^-$ equal to the frequencies of the features, and many of them could be larger than C. Luckily, due to the convexity of piecewise linear function, the optimality of subgradient method is irrelevant with the initial point. So we can start with a well trained model using a small subset of features such as the set of lower order features so that the prediction is more accurate and the gradients $\#f^+$ and $\#f^-$ are much lower.

4.2 Bloom Filter

The second strategy is to use bloom filter to reduce candidates before putting them into the candidate set $\mathcal{A}$.

A bloom filter (Bloom, 1970) is a space efficient probabilistic data structure designed to rapidly check whether an element is present in a set. In this paper, we use one of its extension, spectral bloom filter (Cohen and Matias, 2003), which can efficiently calculate the upper bound of the frequencies of elements.

The base data structure of a spectral bloom filter is a vector of L counters, where all counters are initialized with 0. The spectral bloom filter uses m hash functions, $h_1, \ldots, h_m$, that map the elements to the range $\{1, \ldots L\}$. When adding an element f to the bloom filter, we hash it using the m hash functions, and get the hash codes $h_1(f), \ldots, h_m(f)$, then we check the counters at positions $h_1(f), \ldots, h_m(f)$, and get the counts $\{c_1, \ldots, c_m\}$. Let c^* be the minimal count among these counts: $c^* = \min\{c_1, \ldots, c_m\}$, we increase only the counters whose counts are c^*, while keeping other counters unchanged.

To check the frequency of an element, we hash the element and check the counters in the same way. The minimum count c^* provides the upper bound of the frequency. In other words, when pruning elements with frequencies no greater than a predefined threshold θ, we could safely prune the element if $c^* \leq \theta$.

In our case, we use the spectral bloom filter to eliminate the low-frequency candidates.

To estimate the gradients of newly generated $r + 1$-order candidates, we run Line 17 twice. In the first round, we estimate the upper bound of $\#h^+$ for each candidate and add the candidate to $\mathcal{A}$ if its upper bound is greater than a predefined threshold θ. The second round is similar, we add the candidates using the upper bound of h^-. We did not estimate $\#h^+$ and $\#h^-$ simultaneously, because this needs two bloom filters for positive and negative gradients respectively, which consumes too much memory.

Specifically, in the first round, we initialize the spectral bloom filter so that all counters are set to zero. Then for each incorrectly predicted sample x_i, we generate $r + 1$-order candidates by combining r-order candidates that are fired by the gold label i.e., $f(x_i, y_i) = 1$. Once a new candidate is generated, we hash it and check its corresponding m counters in the spectral bloom filter. If the minimal count $c^* = \theta$, we know that its positive gradient $\#f^+$ may be greater than θ. So we keep all counts unchanged, and add the candidate to $\mathcal{A}$. Otherwise, we increase the counts by 1 using the method described above. The second round is similar.

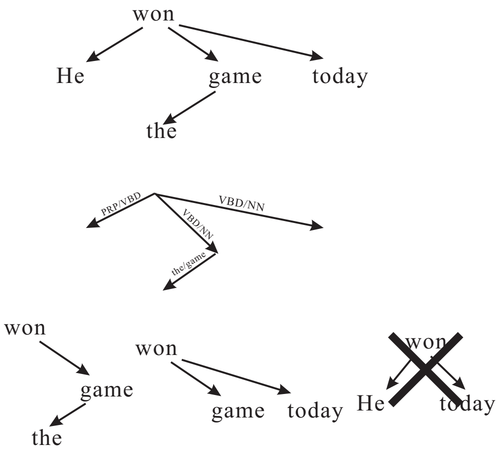

Figure 1: A dependency parse tree (top), one of its feature trees (middle) and some of its subtrees (bottom). *He* ← *won* → *today* is not a subtree because *He* and *today* are not adjacent siblings.

5 Efficient Candidate Generation

5.1 Polynomial Kernel

As mentioned above, we generate the $r + 1$-order candidates by combining the candidates of order r. An efficient feature generation algorithm should be carefully designed to avoid duplicates, otherwise $\#f^+$ and $\#f^-$ may be over counted.

The candidate generation algorithm is kernel dependent. For polynomial kernel, we just combine any two r-order candidates and remove the combined feature if its order is not $r + 1$. This method requires square running time for each example.

5.2 Dependency Tree Kernel

5.2.1 Definition

Collins and Duffy (2002) proposed tree kernels for constituent parsing which includes the all-subtree features. Similarly, we define dependency tree kernel for dependency parsing. For compatibility with the previously studied subtree features for dependency parsing, we propose a new dependency tree kernel that is different from Culotta and Sorensen's (Culotta and Sorensen, 2004). Given a dependency parse tree T composed of L words, $L - 1$ arcs, each arc has several basic features, such as the concatenation of the head word and the modifier word, the concatenation of the word left to the head and the lower case of the word right to the modifier, the distance of the arc, the direction of the arc, the concatenation of the POS tags of the head and the modifier, etc.

A feature tree of T is a tree that has the same structure as T, while each arc is replaced by any of its basic features. For a parse tree that has $L-1$ arcs, and each arc has d basic features, the number of the feature trees is d^{L-1}. For example, the dependency parse tree for sentence *He won the game today* is shown in Figure 1. Suppose each arc has two basic features: word pair and POS tag pair. Then there are 2^4 feature trees, because each arc can be replaced by either word pair or POS tag pair.

A subtree of a tree is a connected fragment in the tree. In this paper, to reduce computational cost, we restrict that adjacent siblings in the subtrees must be adjacent in the original tree. For example *He* ← *won* → *game* is a subtree, but *He* ← *won* → *today* is not a subtree. The motivation of the restriction is to reduce the number of subtrees, for a node having k children, there are $k^(k-1)/2$ subtrees, but without the restriction the number of subtrees is exponential: 2^k.

A sub feature tree of a dependency tree T is a feature tree of any of its subtrees. For example, the dependency tree in Figure 1 has 12 subtrees including four arcs, four arc pairs, the three arc triples and the full feature tree, and each subtree having s arcs has 2^s sub feature trees. Thus the dependency tree has $2*4+4*2^2+3*2^3+2^4 = 64$ sub feature trees.

Given two dependency trees T_1 and T_2, the dependency tree kernel is defined as the number of common sub feature trees of T_1 and T_2. Formally, the kernel function is defined as

$$K(T_1, T_2) = \sum_{n_1 \in T_1, n_2 \in T_2} \Delta(n_1, n_2)$$

where $\Delta(n_1, n_2)$ denotes the number of common sub feature trees rooted in n_1 and n_2 nodes.

Like tree kernel, we can calculate $\Delta(n_1, n_2)$ recursively. Let c_i and c'_j denote the i-th child of n_1 and j-th child of n_2 respectively, let $ST_{p,l}(n_1)$ denote the set of the sub feature trees rooted in node n_1 and the children of the root are $c_p, c_{p+1}, \ldots, c_{p+l-1}$, we denote $ST_{q,l}(n_2)$ similarly. Then we define

$$\Delta_{p,q,l}(n_1, n_2) = \sum_{p,q} |ST_{p,l}(n_1) \bigcap ST_{q,l}(n_2)|$$

the number of common sub feature trees in $ST_{p,l}(n_1)$ and $ST_{q,l}(n_2)$.

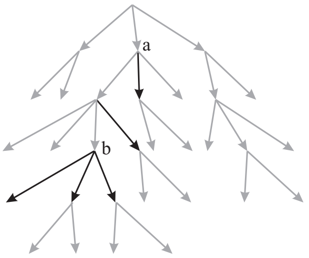

Figure 2: For any subtree rooted in a with the rightmost leaf b, we could extend the subtree by any arc below or right to the path from a to b (shown in black)

To calculate $\Delta_{p,q,l}(n_1, n_2)$, we first consider the sub feature trees with only two levels, i.e., sub feature trees that are composed of n_1, n_2 and some of their children. We initialize $\Delta_{p,q,1}(n_1, n_2)$ with number of the common features of arcs $n_1 \to c_p$ and $n_2 \to c'_q$. Then we calculate $\Delta_{p,q,l}(n_1, n_2)$ recursively using

$$\begin{aligned}&\Delta_{p,q,l}(n_1, n_2)\\ =&\Delta_{p,q,l-1}(n_1, n_2) * \Delta_{p+l,q+l,1}(n_1, n_2)\end{aligned}$$

And $\Delta(n_1, n_2) = \sum_{p,q,l} \Delta_{p,q,l}(n_1, n_2)$

Next we consider all the sub feature trees, we have

$$\begin{aligned}&\Delta_{p,q,l}(n_1, n_2)\\ =&\Delta_{p,q,l-1}(n_1, n_2) * \big(1 + \Delta(c_{p+l-1}, c'_{q+l-1})\big)\end{aligned}$$

Computing the dependency tree kernel for two parse trees requires $|T_1|^2 * |T_2|^2 * \min\{|T_1|, |T_2|\}$ running time in the worst case, as we need to enumerate p, q, l and n_1, n_2.

One way to incorporate the dependency tree kernel for parsing is to rerank the K best candidate parse trees generated by a simple linear model. Suppose there are n training samples, the size of the kernel matrix is $(K * n)^2$, which is unacceptable for large datasets.

5.2.2 Candidate Generation

For constituent parsing, Kudo et al. showed such an all-subtrees representation is extremely redundant and a comparable accuracy can be achieved using just a small set of subtrees (Kudo et al., 2005). Suzuki et al. even showed that the over-fitting problem often arises when convolution kernels are used in NLP tasks (Suzuki et al., 2004). Now we attempt to select representative sub feature trees in the kernel space using Algorithm 1. The r-order features in dependency tree kernel space are the sub feature trees with r arcs. The candidate feature generation in Line 17 has two steps: first we generate the subtrees with r arcs, then we generate the sub feature trees for each subtree.

The simplest way for subtree generation is to enumerate the combinations of $r + 2$ words in the sentence, and check if these words form a subtree.

We can speed up the generation by using the results of the subtrees with $r + 1$ words (r arcs). For each subtree S_r with r arcs, we can add an extra word to S_r and generate S_{r+1} if the words form a subtree.

This method has three issues: first, the time complexity is exponential in the length of the sentence, as there are 2^L combinations of words, L is the sentence length; second, it may generate duplicated subtrees, and over counts the gradients. For example, there are two ways to generate the subtree *He won the game* in Figure 1: we can either add word *He* to the subtree *won the game*, or add word *the* to the subtree *He won game*; third, checking a fragment requires $O(L)$ time.

These issues can be solved using the well known rightmost-extension method (Zaki, 2002; Asai et al., 2002; Kudo et al., 2005) which enumerates all subtrees from a given tree efficiently. This method starts with a set of trees consisting of single nodes, and then expands each subtree attaching a new node.

Specifically, it first indexes the words in the pre-order of the parse tree. When generating S_{r+1}, only the words whose indices are larger than the greatest index of the words in S_r are considered. In this way, each subtree is generated only once. Thus, we only need to consider two types of words: (i) the children of the rightmost leaf of S_r, (ii) the adjacent right sibling of the any node in S_r, as shown in Figure 2.

The total number of subtrees is no greater than L^3, because the level of a subtree is less than L, and for the children of each node, there are at most L^2 subsequences of siblings. Therefore the time complexity for subtree extraction is $O(L^3)$.

6 Experiments

6.1 Experimental Results on English Dataset

6.1.1 Settings

First we used the English Penn Tree Bank (PTB) with standard train/develop/test for evaluation. Sections 2-21 (around 40K sentences) were used as training data, section 22 was used as the development set and section 23 was used as the final test set.

We extracted dependencies using Joakim Nivre's Penn2Malt tool with Yamada and Matsumoto's rules (Yamada and Matsumoto, 2003). Unlabeled attachment score (UAS) ignoring punctuation is used to evaluate parsing quality.

We apply our technique to rerank the parse trees generated by a third order parser (Koo and Collins, 2010) trained using 10 best MIRA algorithm with 10 iterations. We generate the top 10 best candidate parse trees using 10 fold cross validation for each sentence in the training data. The gold parse tree is added if it is not in the candidate list. Then we learn a reranking model using these candidate trees. During testing, the score for a parse tree T is a linear combination of the two models:

$$score(T) = \beta score^{O3}(T) + score^{rerank}(T)$$

where the meta-parameter $\beta = 5$ is tuned by grid search using the development dataset. $score^{O3}(T)$ and $score^{rerank}(T)$ are the outputs of the third order parser and the reranking classifier respectively.

For comparison, we implement the following reranking models:

- Perceptron with Polynomial kernels $K(\mathbf{a}, \mathbf{b}) = (\mathbf{a}^T\mathbf{b} + 1)^d$, $d = 2, 4, 8$
- Perceptron with Dependency tree kernel.
- Perceptron with features generated by templates, including all siblings and fourth order features.
- Perceptron with the features selected in polynomial and tree kernel spaces, where threshold $C = 3$.

The basic features to establish the kernel spaces include the combinations of contextual words or POS tags of head and modifier, the length and

$w_h w_m, p_h p_m, w_h p_m, p_h w_m$
$p_{h-1} p_m, p_{h-1} w_m, p_h p_{m-1}, w_h p_{m-1}$
$p_{h+1} p_m, p_{h+1} w_m, p_h p_{m+1}, w_h p_{m+1}$
$p_{h-1} p_h p_m, p_h p_{h+1} p_m, p_h p_{m-1} p_m, p_h p_m p_{m+1}$
Concatenate features above with length and direction
$p_h p_b p_m$

Table 1: Basic features in polynomial and dependency tree kernel spaces, w_h: the word of head node, w_m denotes the word of modifier node, p_h: the POS of head node, p_m denotes the POS of modifier node, p_{h+1}: POS to the right of head node, p_{h-1}: POS to the left of modifier node, p_{m+1}: POS to the right of head node, p_{m-1}: POS to the left of modifier node, p_b: POS of a word in between head and modifier nodes.

direction of the arcs, and the POS tags of the words lying between the head and modifier, as shown in Table 1. The POS tags are automatically generated by 10 fold cross validation during training, and a POS tagger trained using the full training data during testing which has an accuracy of 96.9% on the development data and 97.3% on the test data.

As kernel methods are not scalable for large datasets, we applied the strategy proposed by Collins and Duffy (2002), to break the training set into 10 chunks of roughly equal size, and trained 10 separate kernel perceptrons on these data sets. The outputs from the 10 runs on test examples were combined through the voting procedure.

For feature selection, we set the maximum iteration number $M = 100$. We use the first order and second order features for pre-training. We choose the constant step size $\alpha^t = 1$ because we find this could quickly reduce the prediction error in very few iterations.

We use the SHA-1 hash function to generate the hash codes for the spectral bloom filter. The SHA-1 hash function produces a 160-bit hash code for each candidate feature. The hash code is then segmented into 5 segments, in this way we get five hash codes $h_1, \ldots, h_5$. Each code has 32 bits. Then we create 2^{32}(4G) counters. The threshold θ is set to 3, thus each counter requires 2 bits to store the counts. The spectral bloom filter costs $1G$ memory in total.

Furthermore, to reduce memory cost, we save the local data structure such as the selected features in Step 15 of Algorithm 1 whenever possible, and load them into the memory when needed.

After feature selection, we did not use the L_1 SVM for testing, instead, we trained an averaged perceptron with the selected features. Because we find that the averaged perceptron significantly outperforms L_1 SVM.

Table 2: Comparison between our system and the state-of-art systems on English dataset. LM is short for Linear Model, hrs, mins are short for hours and minutes respectively

6.1.2 Results

Experimental results are listed in Table 2, all systems run on a 64 bit Fedora operation system with a single Intel core i7 3.40GHz and 32G memory. We also include results of representative state-of-the art systems.

It is clear that the use of kernels or the deep features in kernel spaces significantly improves the baseline third order parser and outperforms the reranking model with shallow, template-generated features. Besides, our feature selection outperforms kernel methods in both efficiency and accuracy.

It is unsurprising that the dependency tree kernel outperforms polynomial kernels, because it captures the structured information. For example, polynomial kernels can not distinguish the grand-child feature or sibling feature from the combination of two separated arc features.

When no additional resource is available, our parser achieved the best reported performance 93.72% UAS on English PTB dataset. It is

C	#Feat	#Template	Hours	Mem(G)	UAS
1	$0.34G$	N/A	stalled	OOM	N/A
2	$0.34G$	N/A	stalled	OOM	N/A
3	$33.1M$	$11.4K$	36	4.0	93.72
5	$6.32M$	$2.1K$	20	2.2	93.55
10	$2.10M$	$1.6K$	5	1.4	93.40

Table 3: Feature selection in dependency kernel space with different threshold C.

worth pointing that our method is orthogonal to other reported systems that benefit from advanced inference algorthms, such as cube pruning (Zhang and McDonald, 2014), AD^3 (Martins et al., 2013), etc. We believe that combining our techniques with others' will achieve further improvement.

Reranking the candidate parse trees of 2416 testing sentences takes 67 seconds, about 36 sentences per second.

To further understand the complexity of our algorithm, we perform feature selection in dependency tree kernel space with different thresholds C and record the number of selected features and feature templates, the speed and memory cost. Table 3 shows the results. We can see that our algorithm works efficiently when $C \geq 3$, but for $C < 3$, the number of selected features grows drastically, and the program runs out of memory (OOM).

6.2 Experimental Results on CoNLL 2009 Dataset

Now we looked at the impact of our system on non-English treebanks. We evaluate our system on six other languages from the CoNLL 2009 shared-task. We used the best setting in the previous experiment: reranking model is trained using the features selected in the dependency tree kernel space. For POS tag features we used the predicted tags.

As the third order parser can not handle non-projective parse trees, we used the graph transformation techniques to produce non-projective structures (Nivre and Nilsson, 2005). First, the training data for the parser is projectivized by applying a number of lifting operations (Kahane et al., 1998) and encoding information about these lifts in arc labels. We used the path encoding scheme where the label of each arc is concatenated with two binary tags, one indicates if the arc is lifted, the other indicates if the arc is along the lifting path from the syntactic to the linear head. Then we train a projective parser on the transformed data without arc label information and a classifier to predict the arc labels based on the projectivized gold parse tree structure. During testing, we run the parser and the classifier in a pipeline to generate a labeled parse tree. Labeled syntactic accuracy is reported for comparison.

Language	Ours	Official Best
Chinese	76.77	**79.17**
Japanese	**92.68**	92.57
German	87.40	**87.48**
Spanish	**87.82**	87.64
Czech	**80.51**	80.38
Catalan	86.98	**87.86**

Table 4: Experimental Results on CoNLL 2009 non-English datasets.

Comparison results are listed in Table 4. We achieved the best reported results on three languages, Japanese, Spanish and Czech. Note that CoNLL 2009 also provide the semantic labeling annotation which we did not used in our system. While some official systems benefit from jointly learning parsing and semantic role labeling models.

7 Conclusion

In this paper we proposed a new feature selection algorithm that selects features in kernel spaces in a coarse to fine order. Like frequent mining, the efficiency of our approach comes from the anti-monotone property of the subgradients. Experimental results on the English dependency parsing task show that our approach outperforms standard kernel methods. In the future, we would like to extend our technique to other real valued kernels such as the string kernels and tagging kernels.

Semantic Role Labeling Improves Incremental Parsing

Ioannis Konstas and Frank Keller
Institute for Language, Cognition and Computation

{ikonstas,keller}@inf.ed.ac.uk

Abstract

Incremental parsing is the task of assigning a syntactic structure to an input sentence as it unfolds word by word. Incremental parsing is more difficult than full-sentence parsing, as incomplete input increases ambiguity. Intuitively, an incremental parser that has access to semantic information should be able to reduce ambiguity by ruling out semantically implausible analyses, even for incomplete input. In this paper, we test this hypothesis by combining an incremental TAG parser with an incremental semantic role labeler in a discriminative framework. We show a substantial improvement in parsing performance compared to the baseline parser, both in full-sentence F-score and in incremental F-score.

1 Introduction

When humans listen to speech, the input becomes available gradually as the speech signal unfolds. Reading happens in a similarly gradual manner when the eyes scan a text. There is good evidence that the human language processor is adapted to this and works incrementally, i.e., computes an interpretation for an incoming sentence on a word-by-word basis (Tanenhaus et al., 1995; Altmann and Kamide, 1999). Also language processing systems often deal with speech as it is spoken, or text as it is typed. A dialogue system should start interpreting a sentence while it is spoken, and an information retrieval system should start retrieving results while the user is typing.

Incremental processing is therefore essential both for realistic models of human language processing and for NLP applications that react to user input in real time. In response to this, a number of incremental parsers have been developed, which use context-free grammar (Roark, 2001; Schuler et al., 2010), dependency grammar (Chelba and Jelinek, 2000; Nivre, 2007; Huang and Sagae, 2010), or tree-substitution grammars (Sangati and Keller, 2013). Typical applications of incremental parsers include speech recognition (Chelba and Jelinek, 2000; Roark, 2001; Xu et al., 2002), machine translation (Schwartz et al., 2011; Tan et al., 2011), reading time modeling (Demberg and Keller, 2008), or dialogue systems (Stoness et al., 2004).

Incremental parsing, however, is considerably harder than full-sentence parsing: when processing the n-th word in a sentence, a_n, the parser only has access to the left context (words $a_1 \ldots a_{n-1}$); the right context (words $a_{n+1} \ldots a_N$) is not known yet. This can lead to **local ambiguity,** i.e., produce additional syntactic analyses that are valid for the sentence prefix, but become invalid as the right context is processed. As an example consider the sentence prefix in (1):

(1) The athlete realized her goals ...
  a. at the competition
  b. were out of reach

The prefix could continue as in (1-a), i.e., as a main clause structure. Or the next words could be as in (1-b), in which case *her goals* is part of a subordinate clause.

Intuitively, an incremental parser that has access to semantic information would be able to decide which of these two analyses is likely to be correct, even without knowing the rest of the sentence. If the NP *her goals* is a likely ARG1 of *realized* the parser should prefer the main clause structure. On the other hand, if the NP is a likely ARG0 of an (as yet unseen) embedded verb, then the parser should go for the subordinate clause structure. This is illustrated in Figure 2. Note that the preference can easily be reversed: if the prefix was *the athlete realized her shoes*, then *her shoes* is very likely to be an ARG0 rather than an ARG1.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1191–1201,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

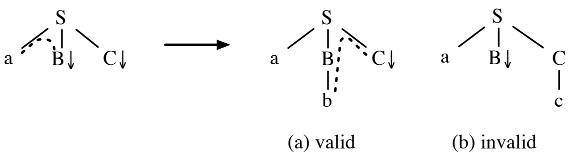
The basis of this paper is the hypothesis that semantic information can aid incremental parsing. To test this hypothesis, we combine an incremental TAG parser with an **incremental semantic role labeling** (iSRL) system. The iSRL system takes prefix trees and computes their most likely semantic role assignments. We show that these role assignments can be used to re-rank the output of the incremental parser, leading to substantial improvements in parsing performance compared to the baseline parser, both in full-sentence F-score and in incremental F-score.

2 Incremental Semantic Role Labeling

The current work builds on an existing incremental parser, the Psycholinguistically Motivated Tree Adjoining Grammar (PLTAG) parser of Demberg et al. (2013). The distinguishing feature of this parser is that it builds fully connected structures (no words are left unattached during incremental parsing); this requires it to make predictions about the right context, which are verified as more of the input becomes available. Konstas et al. (2014) show that semantic information can be attached to PLTAG structures, making it possible to assign semantic roles incrementally. In the present paper, we use these semantic roles to re-rank the output of the PLTAG parser.

2.1 Psycholinguistically Motivated TAG

PLTAG extends standard TAG (Joshi and Schabes, 1992) in order to enable incremental parsing. Standard TAG assumes a lexicon of **elementary trees,** each of which contains at least one lexical item as an anchor and at most one leaf node as a **foot node,** marked with $A*$. All other leaves are marked with $A\downarrow$ and are called **substitution nodes.** To derive a TAG parse for a sentence, we start with the elementary tree of the head of the sentence and integrate the elementary trees of the other lexical items of the sentence using two operations: **adjunction** at an internal node and **substitution** at a substitution node (the node at which the operation applies is the **integration point**). Standard TAG derivations are not guaranteed to be incremental, as adjunction can happen anywhere in a sentence, possibly violating left-to-right processing order. PLTAG addresses this limitation by introducing **prediction trees,** elementary trees without a lexical anchor. These are used to predict syntactic structure anchored by words that appears later in an incremental derivation. This ensures that fully connected prefix trees can be built for every prefix of the input.



(a) valid (b) invalid

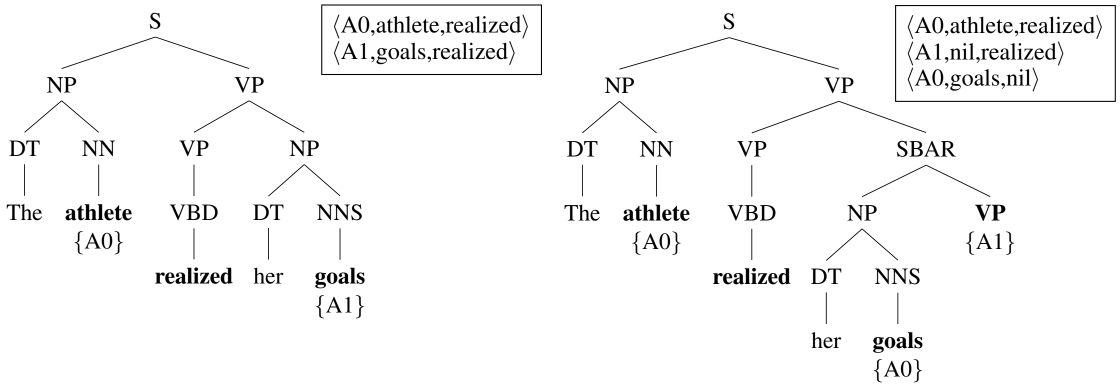
Figure 1: The current fringe (dashed line) indicates where valid substitutions can occur. Other substitutions result in an invalid prefix tree.

In order to efficiently parse PLTAG, Demberg et al. (2013) introduce the concept of **fringes.** Fringes capture the fact that in an incremental derivation, a prefix tree can only be combined with an elementary tree at a limited set of nodes. For instance, the prefix tree in Figure 1 has two substitution nodes, for *B* and *C*. However, only substitution into *B* leads to a valid new prefix tree; if we substitute into *C*, we obtain the tree in Figure 1b, which is not a valid prefix tree (i.e., it represents a non-incremental derivation).

2.2 Incremental Role Propagation

The output of a semantic role labeler is a set of semantic dependency triples $\langle l, r, p \rangle$, where l is a semantic role label (e.g., ARG0, ARG1, ARGM in Propbank), and r and p are the words (argument and predicate) to which the role applies. An *incremental* semantic role labeler assigns semantic dependency triples to a prefix of the input sentence. Note that not every word is an argument to a predicate, therefore the set of triples will not necessarily change at every input word. Also, triples can be incomplete, as either the predicate or the argument may not have been observed yet.

Konstas et al. (2014) propose an iSRL system based on a PLTAG parser with a semantically augmented lexicon. They parse an input sentence incrementally, applying their incremental role propagation algorithm (IRPA) to the resulting prefix trees. This creates new semantic triples (or updates existing, incomplete ones) whenever an elementary or prediction tree that carries semantic role information is attached to the prefix tree. As soon as a triple is completed a two-stage classification process is applied, that first identifies whether the predicate/argument pair is a good candidate, and then disambiguates the role label (often multiple roles are possible for a lexical entry). Figure 2 shows the incremental role assignment for the two readings of the prefix *the athlete realized her goals*



(a)

(b)

Figure 2: Incremental Role Propagation Algorithm application for two different prefix trees of the sentence prefix *the athlete realized her goals*. In (a) the parser builds a main clause, so IRPA assigns an A1 to *goals* with *realized* as predicate. In (b) the parser predicts an embedded clause, so IRPA delays the assignment of the A1 to *realized*, and instead introduces two incomplete triples: the first one is predicate-incomplete, with the argument *goals* assigned an A0, waiting to be attached to a predicate. The second one is argument-incomplete with predicate *realized* assigned an A1, waiting for an argument to follow.

(see Section 1). Note the use of incomplete semantic role triples in Figure 2b.

3 Model

We use a discriminative model in order to re-rank the output of the baseline PLTAG parser based on semantic roles assigned by the iSRL system.

3.1 Problem Formulation

Our overall approach is closely related to the discriminative incremental parsing framework of Collins and Roark (2004). The goal is to learn a mapping from input sentences $x \in \mathcal{X}$ to parse trees $y \in \mathcal{Y}$. For a given set of training pairs of sentences and gold-standard parse trees $(x,y) \in \mathcal{X} \times \mathcal{Y}$, the output $\hat{y}$ can be defined as:

$$\hat{y} = \underset{y \in GEN(x)}{\operatorname{argmax}} \Phi(x,y) \cdot \bar{w} \tag{1}$$

where $GEN(x)$ is a function that enumerates candidate parse trees for a given input x, Φ is a representation that maps each training example (x,y) to a feature vector $\Phi(x,y) \in \mathbb{R}^d$, and $\bar{w} \in \mathbb{R}^d$ is a vector of feature weights.

During training, the task is to estimate $\bar{w}$ given the training examples. In terms of efficiency, a crucial part of Equation (1) is the search strategy over parses produced by *GEN* and, to a smaller degree, the dimensionality of $\bar{w}$. One common decoding technique is to implement a dynamic program, thus avoiding the explicit enumeration of all analyses for a given timestamp (Huang, 2008). However, central to the discriminative approach is the exploration of features that cannot be straightforwardly embedded into the parser using a dynamic program. These include arbitrarily long-range dependencies contained in a parse tree, and more importantly non-isomorphic representations of the input sentence such as its semantic frame, i.e., the set of all semantic roles tripes that pertain to the same predicate. In order to accommodate these, we decode via beam search over candidate parses. We keep a list of the *k*-best analyses and prune those whose score $scr(x) = \Phi(x,y) \cdot \bar{w}$ falls below a threshold.

3.2 Incremental *k*-best Parsing

What we described in the previous section could equally apply to *k*-best re-ranking for full-sentence parsing (e.g., Charniak and Johnson, 2005). For incremental parsing, in addition to outputting $\hat{y}$ for the full sentence, we need to output **prefix trees** $\hat{y}_n$ for every prefix of length $n \in \{1 \dots N\}$ of sentence $x = a_1 \dots a_N$ with length N. Let $\langle x_n, \hat{y}_n, n \rangle$, be the state of our model after we have parsed the first n words of sentence x, resulting in analysis $\hat{y}_n$. The initial state is defined as $\langle x_0, \emptyset, 0 \rangle$, where $\emptyset$ is the empty analysis, and the final state is $\langle x, \hat{y}, N \rangle$, which represents a full analysis for the input sentence. We need a function *ADV* that transitions from a state at word a_n to a set of states at word

a_{n+1} by combining the prefix tree $\hat{y}_n$ with a_{n+1}:

$$\begin{aligned} ADV\big(\langle x_n,\hat{y}_n,n\rangle\big) &= \langle x_n,\hat{y}_n,n\rangle \otimes a_{n+1} \\ &= \{\langle x_{n+1},\hat{y}_{n+1},n+1\rangle\} \end{aligned}$$

Next, we define the set of states representing prefix trees as π, with $\pi_0 = \{\langle x_0,\emptyset,0\rangle\}$, and $\pi_n = \cup_{\pi' \in \pi_{n-1}} ADV(\pi')$. We can now redefine $GEN(x_n) = \pi_n$, for any prefix of length n.

We enumerate prefix trees (function *GEN*) with the incremental parser of Demberg et al. (2013). The states of the model are stored in a chart; each cell holds the top-k prefix trees. The transition to the next state (function *ADV*) is performed by combining each prefix tree with a set of candidate of elementary (and prediction) trees via adjunction and substitution, subject to restrictions imposed by incrementallity (see Figure 2). In order to efficiently compute all combinations, the PLTAG parser computes only the fringes (see Section 2) of the prefix tree, and the candidate elementary trees and matches these two; this avoids the computation of the prefix tree entirely.[1]

Each prefix tree is weighted using a probability model estimated over PLTAG operations and the lexicon. This probability is used as a feature in Φ. In addition, we define a set of features of increasing sophistication, which include features specific to PLTAG, standard tree-based features, and, crucially, features extracted from the semantic role triples produced incrementally by the iSRL system of Konstas et al. (2014). The features are computed for each prefix tree y_n, so Φ can be rewritten as $\Phi(x_n,y_n)$, and therefore Equation (1) becomes:

$$\hat{y}_n = \underset{y_n \in \pi_n}{\operatorname{argmax}}\, \Phi(x_n,y_n) \cdot \bar{w} \qquad (2)$$

Our goal now becomes to learn mappings between sentence *prefixes* x_n and *prefix* trees $\hat{y}_n$. In contrast to models that estimate features weights on full sentence parses (Collins and Roark, 2004; Charniak and Johnson, 2005), we do not observe gold-standard prefix trees during training. However, we can use gold-standard lexicon entries when parsing the training data with the PLTAG parser, which gives an approximation of gold-standard prefix trees y_n^+. Finally, during testing, given an unseen sentence x and a trained set of feature weights $\bar{w}$, our model generates prefix trees y_n for every sentence prefix of size n.

4 Reranking Features

This section describes the features used for reranking the prefix trees generated by the incremental parser. We include three different classes of features, based on local information from PLTAG elementary trees, based on global and structural information from prefix trees, and based on semantic information provided by iSRL triples. In contrast to work on discriminative full-sentence parsing (e.g., Charniak and Johnson, 2005; Collins and Koo, 2005), we can only use features extracted from the prefix trees being constructed incrementally as the sentence is parsed. The right context of the current word cannot be used, as this would violate incrementality. Every feature combination we try also includes the following baseline features:

Prefix Tree Probability is the log probability of the prefix tree as scored by the probability model of the baseline parser. The score is normalized by prefix length, to avoid getting larger negative log probability scores for longer prefixes.

Elementary Tree Probability is the log probability of the elementary tree corresponding to the word just added to the prefix tree according to the probability model of the baseline parser.

4.1 PLTAG Features

The baseline generative model of the PLTAG parser employs features based on parsing actions, the elementary trees used at each timestamp, and the previous word and PoS tag. In the discriminative model, we extend the locality of these features, as well as addressing sparsity issues arising from rare elementary trees. In all cases, both lexicalized and unlexicalized versions of the elementary trees are used.

Unigram Trees is a family of binary features that record the local elementary trees chosen by the parser for the n-th word, i.e., current word for $n = 1$ and previous word for $n = 2$.

Parent-Unigram Trees is a variation of the previous feature, where we encode the elementary tree of the current word along with the category of the node it attaches to in the prefix tree. This captures the attachment decisions the parser makes.

Bigram Trees are pairs of elementary trees for adjacent words (i.e., the elementary tree currently added to the prefix tree and the previous one). This extends the history the parser has access to,

[1] As in a chart parser, the prefix tree can be re-constructed by following backpointers in the chart. This is done only for evaluation at the end of the sentence or incrementally on demand.

and captures pairs of elementary trees that are frequently chosen together, e.g., a verb-headed tree with a PP foot node, followed by an NP-headed prepositional tree.

4.2 Tree Features

The following features are inspired by Charniak and Johnson (2005) and attempt to encode properties of the prefix tree, as well as capture regularities for specific syntactic construction such as coordination. Even though the PLTAG parser builds fully connected structures and predicts upcoming context, some constituents in a given prefix tree may be incomplete. We therefore compute the features in this group only for those constituents that have been completed in the current prefix tree (i.e., constituents that are complete at word a_n, but were incomplete at word a_{n-1}). This ensures each of the features is only counted once per constituent. For example, the coordination parallelism feature (see below) should be computed only after all the words in the yield of the CC non-terminal have been observed.

Right Branch encodes the number of nodes on the longest path from the root of the prefix tree to the rightmost pre-terminal. We also include the symmetrical feature which records the number of the remaining nodes in the prefix tree. This feature allows the parser to prefer right-branching trees, commonly found in English syntax.

Coordination Parallelism records whether the two sibling subtrees of a coordination node are identical in terms of structure and node categories up to depth l. We encode identity in a bit mask, and set $l = 4$ (e.g., 1100 means the subtrees have identical children and grandchildren).

Coordination Parallelism Length indicates the binned difference in size between the yields of each sibling subtree under a coordination node. It also stores whether the second subtree is at the end of the sentence.

Heavy stores the category of each node in a completed constituent, along with the binned length of its yield and whether it is at the end of the sentence. This feature captures the tendency of larger constituents to occur towards the end of the sentence.

Neighbors encodes the category of each node in the completed constituent, the binned yield size, and the PoS tags of the l preceding words, were $l = 1$ or 2.

Word stores the current word along with the categories of its l immediate ancestor nodes (excluding pre-terminals); $l = 2$ or 3.

4.3 SRL Features

The features in this group are extracted from the output of iSRL system of Konstas et al. (2014), which annotates prefix trees with semantic roles. The setup proposed in the current paper makes it possible to feed the semantic information back to the PLTAG parser by using it to re-rank the k-best prefix trees generated by the parser. (The re-ranked prefix trees could then also result in better iSRL performance, an issue we will return to in Section 6.3.)

Recall that the SRL information comes in the form of triples $\langle l, r, p\rangle$, where l is a semantic role label and r and p are the words to which the role applies (see Figure 2 for examples). For each feature, we also compute an unlexicalized version by replacing the argument and predicates in the triples with their PoS tags.

Complete SRL Triples stores the complete triples (if any) generated by the current word. The word can be the predicate or the argument in one or more dependency relations involving previous words.

Semantic Frame records all the arguments of a predicate (if present) for frequent semantic labels, i.e., A0, A1 and A2, as well as the presence of a modifier (e.g., AM-TMP, AM-LOC, etc.). This feature usually fires when a verb is added to the prefix tree and generates several complete SRL triples. The feature captures the semantic frame of a verb as a whole (while the previous feature just records it as a collection of triples).

Back-off SRL Triples are generated by removing either the argument, or the predicate, or the role label, from a complete triple. This provides a way of generalizing between triples that share some information without being completely identical.

Predicate/Argument/Role encodes the elements of a complete SRL triple individually (argument, predicate, or role). This allows for further generalization and reduces sparsity.

5 Feature Weight Estimation

We estimate the vector of feature weights $\bar{w}$ in Equation (2) using the averaged structured perceptron algorithm of Collins (2002); we give the pseudocode in Algorithm 1. The perceptron makes T passes over L training examples. In each iteration, for each sentence prefix/prefix tree pair (x_n, y_n), it computes the best scoring prefix tree $\hat{y}_n$ among the candidate prefix trees, given the current feature weights $\bar{w}$. In line 7, the algorithm updates $\bar{w}$ with the difference (if any) between the feature representations of the best scoring prefix tree $\hat{y}_n$ and the approximate gold-standard prefix tree y_n^+ (see Section 3.2). Note that since we use a constant beam during decoding with the PLTAG parser in order to enumerate the set of prefix trees π_n, there is no guarantee that the argmax in line 5 will find the highest scoring (in terms of F-score) prefix tree $y_n^* \neq \hat{y}_n$. Search errors due to the best analysis falling out of the beam at a given prefix length will create errors both when decoding unseen sentences at test time, and when learning the feature weights with the perceptron algorithm. The final weight vector $\bar{w}$ is the average of the weight vectors over T iterations, L examples and N words. The averaging avoids overfitting and produces more stable results (Collins, 2002).

Note that features are computed for every prefix of the input sentence. Recall that the parser avoids the explicit computation of the prefix trees in π_n through the use of the fringes (see Sections 2.1 and 3.2). This is sufficient for the computation of PLTAG and SRL features, but we need to explicitly calculate every prefix tree y_n for the computation of the tree features (see Section 4.2). This is an expensive operation if we are parsing the whole training corpus. To overcome this time bottleneck, we compute features only for those analyses of every input sentence prefix that belongs to the k-best analyses at the end of the sentence. In other words, π_n is the set of only those prefix trees that are used by the k-best analyses at the end of the sentence. This results in a much smaller number of prefix trees that need to be computed for each word. However, during testing, given the trained $\bar{w}$ and an unseen sentence, we compute all features for each prefix length of the sentence, hence calculate all prefix trees in π_n and incrementally re-rank the chart entries of the parser on the fly.

Algorithm 1: Averaged Structured Perceptron

```
  Input: Training Examples: $(x,y)_{i=1}^{L}, x_i = a_1 \dots a_N$
1 $\bar{w} \leftarrow 0$
2 for $t \leftarrow 1 \dots T$ do
3     for $i \leftarrow 1 \dots L$ do
4         for $n \leftarrow 1 \dots N$ do
5             $\hat{y}_n = \mathrm{argmax}_{y_n \in \pi_n} \Phi(x_n, y_n) \cdot \bar{w}$
6             if $y_n^+ \neq \hat{y}_n$ then
7                 $\bar{w} \leftarrow \bar{w} + \Phi(x_n, y_n^+) - \Phi(x_n, y_n)$
8 return $\frac{1}{T}\sum_{t=1}^{T} \frac{1}{L}\sum_{i=1}^{L} \sum_{n=1}^{N} \frac{1}{N} w_{t,i,n}$
```

6 Experiments

6.1 Setup

We use the PLTAG parser of Demberg et al. (2013) to enumerate prefix trees y_n and to compute the prefix tree and word probability scores which we use as features. We also use the iSRL system of Konstas et al. (2014) to generate incremental SRL triples. Their system includes a semantically-enriched lexicon extracted from the Wall Street Journal (WSJ) part of the Penn Treebank corpus (Marcus et al., 1993), converted to PLTAG format. Semantic role annotation is sourced from Propbank. We trained the probability model of the parser and the identification and labeling classifiers of the iSRL system using the intersection of Sections 2–21 of WSJ and the English portion of the CoNLL 2009 Shared Task (Hajič et al., 2009). We learn the weight vector $\bar{w}$ by training the perceptron algorithm also on Sections 2–21 of WSJ (see Section 5 for details). We use the PoS tags predicted by the parser, rather than gold standard PoS tags. Testing is performed on section 23 of WSJ, for sentences up to 40 words.

6.2 Evaluation

In addition to standard full-sentence labeled bracket score, we evaluate our model incrementally, by scoring the prefix trees generated for each sentence prefix (Sangati and Keller, 2013). For each prefix of the input sentence (two words or more), we compute the labeled bracket score for the minimal structure spanning that prefix. The minimal structure is defined as the subtree rooted in the lowest common ancestor of the prefix nodes, while removing any leftover intermediate nodes on the right edge of the subtree that do not have a word in the prefix as their yield.

Although not the main focus of this paper, we also report full-sentence combined SRL accuracy (counting verb-predicates only). This score is obtained by re-applying the iSRL system to the syn-

System	Prec	Rec	F	AUC	SRL
BASELINE	75.51	76.93	76.21	71.49	69.43
TREE	75.99	77.52	76.75	73.02	68.80
SRL	75.99	77.65	76.81	73.97	69.96
TREE+PLTAG	76.67	78.27	77.47	72.27	70.27
TREE+PLTAG +SRL	77.00	78.57	77.77	74.97	70.00

Table 1: Full-sentence parsing results[2], area under the curve (AUC) for the incremental parsing results of Figure 3, and combined SRL score across different groups of features.

tactic parses output by our re-ranker. (In contrast, Konstas et al. (2014) work with gold-standard syntactic parses.)

We evaluate four variants of our model (see Section 4 for an explanation of the different groups of features):

TREE is the model that uses tree features only; this essentially simulates standard parse reranking approaches such as the one of Charniak and Johnson (2005).

SRL uses only features based on iSRL triples; it provides a proof-of-concept, demonstrating that the semantic information encoded in SRL triples can help the parser building better syntactic trees.

TREE+PLTAG adds PLTAG Features to the TREE model, taking advantage of local information specific to elementary PLTAG trees; TREE+PLTAG essentially provides a strong syntax-only baseline.

TREE+PLTAG+SRL combines SRL features and syntactic features.

Finally, our baseline is the PLTAG parser of Demberg et al. (2013), using the original probability model without any re-ranking. A comparison with other incremental parsers would be desirable, but is not trivial to achieve. This is because the PLTAG parser is trained and evaluated on a version of the Penn Treebank that was converted to PLTAG format. This renders our results not directly comparable to parsers that reproduce the Penn Treebank bracketing. For example, the PLTAG parser produces deeper tree structures informed by Propbank and the noun phrase annotation of Vadas and Curran (2007).

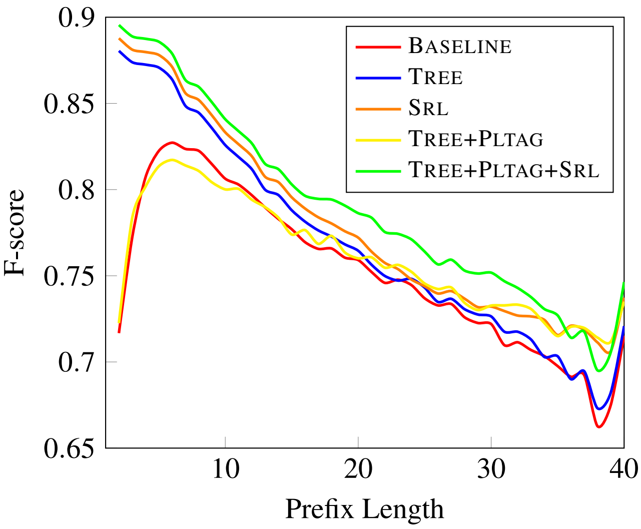


Figure 3: Incremental parsing F-score for increasing sentence prefixes, up to 40 words.

6.3 Results

Figure 3 gives the results of evaluating incremental parsing performance. The x-axis shows prefix length, and the y-axis shows incremental F-score computed as suggested by Sangati and Keller (2013). Each point is averaged over all prefixes of a given length in the test set. To quantify the trends shown in this figure, we also compute the area under the curve (AUC) for each feature combination; this is given in Table 1.

We find that TREE performs consistently better than the baseline for short prefixes (up to the first 20 words), and then is very close to the baseline. This is expected given that tree features add structure-specific information (e.g., about coordination) to the baseline model, and is consistent with results obtained using similar features in the literature (Charniak and Johnson, 2005). Adding PLTAG features (TREE+PLTAG) hurts incremental performance for short prefixes (up to about 20 words), but then performance gradually increases over the baseline and over TREE alone. It seems that the PLTAG features, which are specific to the grammar formalism used, are able to help with longer and more complex prefixes, but introduce noise in smaller prefixes.

The SRL feature set, on the other hand, results in a consistent increase in performance compared

[2] Note that the baseline score is lower than the published F = 77.41 of Demberg et al. (2013). This is expected, since we use a semantically-enriched lexicon, which increases the size of the lexicon, resulting in higher ambiguity per word as well as increased sparsity in the probability model.

to the baseline, across all prefix lengths. SRL provides semantic knowledge, while TREE provides syntactic knowledge, but the performance of both feature sets is very close to each other, up to a prefix length of about 30 words, after which SRL has a clear advantage. SRL features seem to filter out local ambiguity caused by creating prefix trees incrementally and result in correct parses closer to the end of sentence, even without the use of the syntactic information contained in the TREE+PLTAG feature set. Recall that SRL uses information provided by the semantic frame, something that a syntax-only model does not have access to. It seems that this makes it possible for SRL to (partially) compensate for mistakes made by the parser. The AUC of SRL is higher by 0.95 and 1.7 points compared to TREE and TREE+PLTAG, respectively.

We observe an additional boost in performance when using all features together in the TREE+PLTAG+SRL configuration, which outperforms SRL alone by 1.0 points in AUC. Recall that SRL features do not apply to every word; they fire only when semantic information is introduced to the parser via the semantically-enriched lexicon. Hence by adding tree and PLTAG features, which normally apply for every new word, we are able to perform effective re-ranking for all sentence prefixes, which explains the boost in performance. Note that for all variants of our model we observe a dip in performance at around 38 words. This is probably due to noise, caused by the small number of sentences of this length. The upward trend seen around word 40 is probably the effect of observing the end of the sentence, which boosts parsing accuracy.

Turning to full sentence evaluation (Table 1), we observe a similar trend. Both TREE and SRL beat the baseline by about 0.55 points in F-score. Progressively adding features increases performance, with the greatest gain of 1.56 points attained by the combination of all features in TREE+PLTAG+SRL.

We also report combined SRL F-score computed on the re-ranked syntactic trees (rightmost column of Table 1). We find that compared to the baseline, only a small improvement of 0.55 points is achieved by TREE+PLTAG+SRL, while TREE+PLTAG improves by 0.84 points. The syntax-only variant therefore outperforms the full model, but only by a small margin.

7 Related Work

The most similar approach in the literature is Collins and Roark's (2004) re-ranking model for incremental parsing. They learn the syntactic features of Roark (2001) using the perceptron model of Collins (2002). Similar to us, they use the incremental parser to search over candidate parses. However, they limited themselves to local derivation features (akin to our PLTAG features), and do not explore global syntactic feature (tree features) or SRL features. Even though they re-rank the output of an incremental parser, they only evaluate full sentence parsing performance. Other re-ranking approaches to syntactic parsing make use of an extensive set of global features, but apply it on the *k*-best list of full sentence parses (Charniak and Johnson, 2005; Collins and Koo, 2005) or the *k*-best list of derivations of a packed forest (Huang, 2008), i.e., these approaches are not incremental.

Based on the CoNLL Shared Tasks (e.g., Hajič et al., 2009), a number of systems exist that perform syntactic parsing and semantic role labeling jointly. Toutanova et al. (2008), Sutton and McCallum (2005) and Li et al. (2010) combine the scores of two separate models, i.e., a syntactic parser and a semantic role labeler, and re-rank the combination using features from each domain. Titov et al. (2009) and Gesmundo et al. (2009), instead of combining models, create a common search space for syntactic parsing and SRL, using a shift reduce-style technique (Nivre, 2007) and learn a latent variable model (Incremental Sigmoid Belief Networks) that optimizes over both tasks at the same time. Volokh and Neumann (2008) use a variant of Nivre's (2007) incremental shift-reduce parser and rely only on the current word and previous content to output partial dependency trees; then they output role labels given the full parser output. In contrast to all the joint approaches, we perform *both* parsing and semantic role labeling strictly incrementally, without having access to the whole sentence, outputting prefix trees and iSRL triples for every sentence prefix. Our approach creates a feedback loop, i.e., we generate a prefix tree using the baseline model, give it as input to iSRL, then re-rank it using a set of syntactic and SRL features. The resulting new prefix tree can then be fed back into iSRL, etc.

8 Conclusions

We started from the observation that human parsing uses semantic knowledge to rule out parses that lead to implausible interpretations. Based on this, we hypothesized that also in NLP, an incremental syntactic parser should benefit from semantic information. To test this hypothesis, we combined an incremental TAG parser with an incremental semantic role labeler. We used the output of the iSRL system to derive features that can be used to re-rank the prefix trees generated by the incremental parser. We found that SRL features, both in isolation and together with standard syntactic features, improve parsing performance, both when measured using full-sentence F-score, and in terms of incremental F-score.

In future work, we plan to combine our incremental parsing/role labeling approach with a compositional model of semantics, which would have to be modified to take semantic role triples as input (rather than words or word pairs). The resulting plausibility estimates could then be used as another source of semantic information for the parser, or employed in down-stream tasks.

Discontinuous Incremental Shift-Reduce Parsing

Wolfgang Maier

Universitätsstr. 1, 40225 Düsseldorf, Germany
maierw@hhu.de

Abstract

We present an extension to incremental shift-reduce parsing that handles discontinuous constituents, using a linear classifier and beam search. We achieve very high parsing speeds (up to 640 sent./sec.) and accurate results (up to 79.52 F_1 on TiGer).

1 Introduction

Discontinuous constituents consist of more than one continuous block of tokens. They arise through phenomena which traditionally in linguistics would be analyzed as being the result of some kind of "movement", such as extraposition or topicalization. The occurrence of discontinuous constituents does not necessarily depend on the degree of freedom in word order that a language allows for. They can be found, e.g., in almost equal proportions in English and German treebank data (Evang and Kallmeyer, 2011).

Generally, discontinuous constituents are accounted for in treebank annotation. One annotation method consists of using trace nodes that denote the source of a movement and are co-indexed with the moved constituent. Another method is to annotate discontinuities directly by allowing for crossing branches. Fig. 1 shows an example for the latter approach with which we are concerned in this paper, namely, the annotation of (1). The tree contains a discontinuous VP due to the fact that the fronted pronoun is directly attached.

(1) Das wollen wir umkehren
That want we reverse
"This is what we want to reverse"

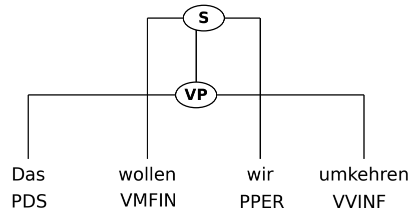

Figure 1: Example annotation with discontinuous constituents from TiGer

Several methods have been proposed for parsing such structures. Trace recovery can been framed as a separate pre-, post- or in-processing task to PCFG parsing (Johnson, 2002; Dienes and Dubey, 2003; Jijkoun, 2003; Levy and Manning, 2004; Schmid, 2006; Cai et al., 2011, among others); see particularly Schmid (2006) for more details. Directly annotated discontinuous constituents can be parsed with a dependency parser, given a reversible transformation from discontinuous constituency trees to non-projective dependency structures. Transformations have been proposed by Hall and Nivre (2008), who use complex edge labels that encode paths between lexical heads, and recently by Fernández-González and Martins (2015), who use edge labels to encode the attachment order of modifiers to heads.

Direct parsing of discontinuous constituents can be done with Linear Context-Free Rewriting System (LCFRS), an extension of CFG which allows its non-terminals to cover more than one continuous block (Vijay-Shanker et al., 1987). LCFRS parsing is expensive: CYK chart parsing with a binarized grammar can be done in $\mathcal{O}(n^{3k})$ where k is the *block degree*, the maximal number of continuous blocks a non-terminal can cover (Seki et al., 1991). For a typical treebank LCFRS (Maier and Søgaard, 2008), $k \approx 3$, instead of $k = 1$ for PCFG. In order to improve on otherwise impractical parsing times, LCFRS chart parsers employ different strategies to speed up search: Kallmeyer

and the 7th International Joint Conference on Natural Language Processing*, pages 1202–1212,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

and Maier (2013) use A* search; van Cranenburgh (2012) and van Cranenburgh and Bod (2013) use a coarse-to-fine strategy in combination with Data-Oriented Parsing; Angelov and Ljunglöf (2014) use a novel cost estimation to rank parser items. Maier et al. (2012) apply a treebank transformation which limits the block degree and therewith also the parsing complexity.

Recently Versley (2014) achieved a breakthrough with a *EaFi*, a classifier-based parser that uses an “easy-first” approach in the style of Goldberg and Elhadad (2010). In order to obtain discontinuous constituents, the parser uses a strategy known from non-projective dependency parsing (Nivre, 2009; Nivre et al., 2009): For every non-projective dependency tree, there is a projective dependency tree which can be obtained by reordering the input words. Non-projective dependency parsing can therefore be viewed as projective dependency parsing with an additional reordering of the input words. The reordering can be done online during parsing with a “swap” operation that allows to process input words out of order. This idea can be transferred, because also for every discontinuous constituency tree, one can find a continuous tree by reordering the terminals. Versley (2014) uses an adaptive gradient method to train his parser. He reports a parsing speed of 40-55 sent./sec. and results that surpass those reported for the above mentioned chart parsers.

In (continuous) constituency parsing, incremental shift-reduce parsing using the structured perceptron is an established technique. While the structured perceptron for parsing has first been used by Collins and Roark (2004), classifier-based incremental shift-reduce parsing has been taken up by Sagae and Lavie (2005). A general formulation for the application of the perceptron algorithm to various problems, including shift-reduce constituency parsing, has been introduced by Zhang and Clark (2011b). Improvements have followed (Zhu et al., 2012; Zhu et al., 2013). A similar strategy has been shown to work well for CCG parsing (Zhang and Clark, 2011a), too.

In this paper, we contribute a perceptron-based shift-reduce parsing architecture with beam search (following Zhu et al. (2013) and Bauer (2014)) and extend it such that it can create trees with crossing branches (following Versley (2014)). We present strategies to improve performance on discontinuous structures, such as a new feature set. Our parser is very fast (up to 640 sent./sec.), and produces accurate results. In our evaluation, where we pay particular attention to the parser performance on discontinuous structures, we show among other things that surprisingly, a grammar-based parser has an edge over a shift-reduce approach concerning the reconstruction of discontinuous constituents.

The remainder of the paper is structured as follows. In subsection 2.1, we introduce the general parser architecture; the subsections 2.2 and 2.3 introduce the features we use and our strategy for handling discontinuous structures. Section 3 presents and discusses the experimental results, section 4 concludes the article.

2 Discontinuous Shift-Reduce Parsing

Our parser architecture follows previous work, particularly Zhu et al. (2013) and Bauer (2014).

2.1 Shift-reduce parsing with perceptron training

An *item* in our parser consists of a *queue* q of token/POS-pairs to be processed, and a *stack* s, which holds completed constituents.[1] The parser uses different transitions: SHIFT shifts a terminal from the queue on to the stack. UNARY-X reduces the first element on the stack to a new constituent labeled *X*. BINARY-X-L and BINARY-X-R reduce the first two elements on the stack to a new *X* constituent, with the lexical head coming from the left or the right child, respectively. FINISH removes the last element from the stack. We additionally use an IDLE transition, which can be applied any number of times after FINISH, to improve the comparability of analyses of different lengths (Zhu et al., 2013).

The application of a transition is subject to restrictions. UNARY-X, e.g., can only be applied when there is at least a single item on the stack. We implement all restrictions listed in the appendix of Zhang and Clark (2009), and add additional restrictions that block transitions involving the root label when not having arrived at the end of a derivation. We do not use an underlying grammar to filter out transitions which have not been seen during training.

For decoding, we use beam search (Zhang and Clark, 2011b). Decoding is started by putting the

[1] As in other shift-reduce approaches, we assume that POS tagging is done outside of the parser.

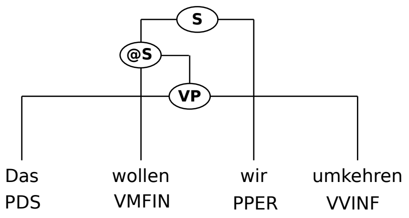

Figure 2: Binarization example

start item (empty stack, full queue) on the beam. Then, repeatedly, a candidate list is filled with all items that result from applying legal transitions to the items on the beam, followed by putting the highest scoring n of them back on the beam (given a beam size of n). Parsing is finished if the highest scoring item on the beam is a final item (stack holds one item labeled with the root label, queue is empty), which can be popped. Item scores are computed as in Zhang and Clark (2011b): The score of the $i+1$th item is computed as the sum of the score of the ith item and the dot product of a global feature weight vector and the local weight vector resulting from the changes induced by the corresponding transition to the $i+1$th item. The start item has score 0. We train the global weight vector with an averaged Perceptron with early update (Collins and Roark, 2004).

Parsing relies on binary trees. As in previous work, we binarize the incoming trees head-outward with binary top and bottom productions. Given a constituent X which is to be binarized, all intermediate nodes which are introduced will be labeled $@X$. Lexical heads are marked with Collins-style head rules. As an example, Fig. 2 shows the binarized version of the tree of Fig. 1.

Finally, since we are learning a sparse model, we also exploit the work of Goldberg and Elhadad (2011) who propose to include a feature in the calculation of a score only if it has been observed $\geq$ MINUPDATE times.

2.2 Features

Features are generated by applying templates to parser items. They reflect different configurations of stack and queue. As BASELINE features, we use the feature set from Zhang and Clark (2009) without the bracketing features (as used in Zhu et al. (2013)). We furthermore experiment with features that reflect the presence of separating punctuation ",", ":", ";" (SEPARATOR) (Zhang and Clark, 2009), and with the EXTENDED features of Zhu et al. (2013), which look deeper into the trees on the stack, i.e., up to the grand-children instead of only to children.

Figure 3: Feature templates

Fig. 3 shows all the feature templates. Note that s_i and q_i stands for the ith stack and queue item, w stands for the head word, t for the head tag and c for the constituent label (w, t and c are identical on POS-level). l and r (ll and rr) represent the left and right children (grand-children) of the element on the stack; u handles the unary case. Concerning the separator features, p is a unique separator punctuation between the head words of s_0 and s_1, q is the count of any separator punctuation between s_0 and s_1.

2.3 Handling Discontinuities

In order to handle discontinuities, we use two variants of a swap transition which are similar to *swap-eager* and *swap-lazy* from Nivre (2009) and Nivre et al. (2009). The first variant, SINGLESWAP, swaps the second item of the stack back on the queue. The second variant COMPOUNDSWAP$_i$ bundles a maximal number of adjacent swaps. It swaps i items starting from the second item on the stack, with $1 \leq i < |s|$. Both swap operations can only be applied if

1. the item has not yet been FINISHed and the last transition has not been a transition with the root category,
2. the queue is not empty,
3. all elements to be swapped are pre-terminals, and

4. if the first item of the stack has a lower index than the second (this inhibits swap loops).

SingleSwap can only been applied if there are at least two items on the stack. For CompoundSwap$_i$, there must be at least $i + 1$ items.

Transition sequences are extracted from treebank trees with an algorithm that traverses the tree bottom-up and collects the transitions. For a given tree τ, intuitively, the algorithm works as follows. We start out with a queue t containing the preterminals of τ, a stack σ that receives finished constituents, a counter s that keeps track of the number of terminals to be swapped, and an empty sequence r that holds the result. First, the first element of t is pushed on σ and removed from t.

While $|\sigma| > 0$ or $|t| > 0$, we repeat the following two steps.

1. Repeat while transitions can be added:
   (a) if the top two elements on σ, l and r, have the same parent p labeled X and *l*/*r* is the head of p, add Binary-X-*l*/*r* to r, pop two elements from σ and push p;
   (b) if the top element on σ is the only child of its parent p labeled X, add Unary-X, pop an element of σ and push p.
2. If $|t| > 0$, while the first element of t is not equal to the leftmost pre-terminal dominated by the right child of the parent of the top element on σ (i.e., while there are terminals that must be swapped), add Shift to r, increment s, push the first element of t on σ and remove it from t. Finally, add another Shift to r, push first element of t to σ and remove it from t (this will contribute to the next reduction). If $s > 0$, we must swap. Either we add s many Swap transitions or one CompoundSwap$_s$ to r. Then we move s many elements from σ to the front of t, starting with the second element of σ. Finally we set $s = 0$.

As an example, consider the transition sequence we would extract from the tree in Fig. 2. Using SingleSwap, we would obtain Shift, Shift, Shift, Shift, SingleSwap, SingleSwap, Binary-VP-R, Shift, Binary-@S-R, Shift, Binary-S-L, Finish. Using CompoundSwap$_i$, instead of two SingleSwaps, we would just obtain a single CompoundSwap$_2$.

Figure 4: Features for discontinuous structures

We explore two methods which improve the performance on discontinuous structures. Even though almost a third of all sentences in the German NeGra and TiGer treebanks contains at least one discontinuous constituent, among all constituents, the discontinuous ones are rare, making up only around 2%. The first, simple method addresses this sparseness by raising the importance of the features that model the actual discontinuities by counting all feature occurrences at a gold swap transition twice (Importance).

Secondly, we use a new feature set (Disco) with bigram and unigram features that conveys information about discontinuities. The features condition the possible occurrence of a gap on previous gaps and their properties.[2] The feature templates are shown in Fig. 4. x denotes the gap type of a tree on the stack. There are three possible values, either “none” (tree is fully continuous), “pass” (there is a gap at the root, i.e., this gap must be filled later further up in the tree), or “gap” (the root of this tree fills a gap, i.e., its children have gaps, but the root does not). Finally, y is the sum of all gap lengths.

3 Experiments

3.1 Data

We use the TiGer treebank release 2.2 (TiGer), and the NeGra treebank (NeGra). For TiGer, we use the first half of the last 10,000 sentences for development and the second half for testing.[3] We also recreate the split of Hall and Nivre (2008) (TiGerHN), for which we split TiGer in 10 parts, assigning sentence i to part $imod10$. The first of those parts is used for testing, the concatenation of the rest for training.

[2] See Maier and Lichte (2011) for a formal account on gaps in treebanks.

[3] This split, which corresponds to the split used in the SPMRL 2013 shared task (Seddah et al., 2013), was proposed in Farkas and Schmid (2012). We exclude sentences 46,234 and 50,224, because of annotation errors. Both contain nodes with more than one parent node.

From NeGra, we exclude all sentences longer than 30 words (in order to make a comparison with `rparse` possible, see below), and split off the last 10% of the treebank for testing, as well as the previous 10% for development. As a preprocessing step, in both treebanks we remove spurious discontinuities that are caused by material which is attached to the virtual root node (mainly punctuation). All such elements are attached to the least common ancestor node of their left and right terminal neighbors (as proposed by Levy (2005), p. 163). We furthermore create a continuous variant NeGraCF of NeGra with the method usually used for PCFG parsing: For all maximal continuous parts of a discontinuous constituent, a separate node is introduced (Boyd, 2007). Subsequently, all nodes that do not cover the head child of the discontinuous constituent are removed.

No further preprocessing or cleanup is applied.

3.2 Experimental Setup

Our parser is implemented in Java. We run all our experiments with Java 8 on an Intel Core i5, allocating 15 GB per experiment. All experiments are carried out with gold POS tags, as in previous work on shift-reduce constituency parsing (Zhang and Clark, 2009). Grammatical function labels are discarded.

For the evaluation, we use the corresponding module of *discodop*.[4] We report several metrics (as implemented in *discodop*):

- Extended labeled bracketing, in which a bracket for a single node consists of its label and a set of pairs of indices, delimiting the continuous blocks it covers. We do not include the root node in the evaluation and ignore punctuation. We report labeled precision, recall and F_1, as well as exact match (all brackets correct).

- Leaf-ancestor (Sampson and Babarczy, 2003), for which we consider all paths from leaves to the root.

- Tree edit distance (Emms, 2008), which consists of the minimum edit distance between gold tree and parser output.

Aside from a full evaluation, we also evaluate only the constituents that are discontinuous.

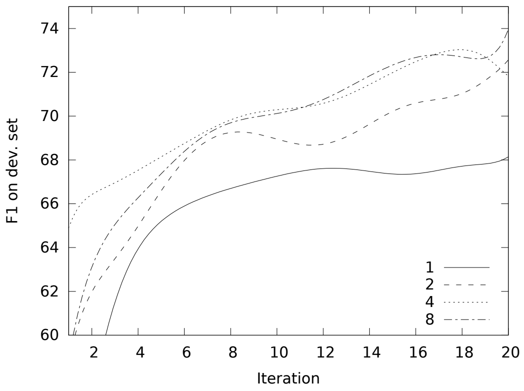

Figure 5: NeGra dev results (F_1) for different beam sizes

We perform 20 training iterations unless indicated otherwise. When training stops, we average the model (as in Daumé III (2006)).

We run further experiments with *rparse*[5] (Kallmeyer and Maier, 2013) to facilitate a comparison with a grammar-based parser.

3.3 Results

We start with discontinuous parsing experiments on NeGra and TiGer, followed by continuous parsing experiments, and a comparison to grammar-based parsing.

3.3.1 Discontinuous Parsing

NeGra The first goal is to determine the effect of different beam sizes with Baseline features and the CompoundSwap$_i$ operation. We run experiments with beam sizes 1, 2, 4 and 8; Fig. 5 shows the results obtained on the dev set after each iteration. Fig. 6 shows the average decoding speed during each iteration for each beam size (both smoothed).

Tracking two items instead of one results in a large improvement. Raising the beam size from 2 to 4 results in a smaller improvement. The improvement obtained by augmenting the beam size from 4 to 8 is even smaller. This behavior is mirrored by the parsing speeds during training: The differences in parsing speed roughly align with the result differences. Note that fast parsing during training means that the parser does not perform well (yet) and that therefore, early update is done more often. Note finally that the average parsing speeds on the test set after the last training iteration

range from 640 sent./sec. (greedy) to 80 sent./sec. (beam size 8).

For further experiments on NeGra, we choose a beam size of 8. Tab. 1 shows the bracketing scores for various parser setups. In Tab. 2, the corresponding TED and Leaf-Ancestor scores are shown.

In the first block of the tables, we compare Swap with CompoundSwap$_i$. On all constituents, the latter beats the former by 0.8 (F$_1$). On discontinuous constituents, using CompoundSwap$_i$ gives an improvement of more than four points in precision and of about 0.8 points in recall. A manual analysis confirms that as expected, particularly discontinuous constituents with large gaps profit from bundling swap transitions.

Table 2: Results NeGra TED and Leaf-Ancestor

In the second block, we run the Baseline features with CompoundSwap$_i$ combined with Separator, Extended and Disco. The Separator features were not as successful as they were for Zhang and Clark (2009). All scores for discontinuous constituents drop (compared to the baseline). The Extended features are more effective and give an improvement of about half a point F$_1$ on all constituents, as well as the highest exact match among all experiments. On discontinuous constituents, precision raises slightly but we loose about 1.4% in recall (compared to the baseline). The latter seems to be due to the fact that in comparison to the baseline, with Extended, more sentences get erroneously analyzed as not containing any crossing branches. This effect can be explained with data sparseness and is less pronounced when more training data is available (see below). Similarly to Extended, the new Disco features lead to a slight gain over the baseline (on all constituents). As with Extended, on discontinuous constituents, we again gain precision (3%) but loose recall (0.5%), because more sentences wrongly analyzed as not having discontinuities than in the Baseline. A category-based evaluation of discontinuous constituents reveals that Extended has an advantage over Disco when considering all constituents. However, we can also see that the Disco features yield better results than

EXTENDED particularly on the frequent discontinuous categories (NP, VP, AP, PP), which indicates that the information about gap type and gap length is useful for the recovery of discontinuities. IMPORTANCE (see Sec. 2.3) is not very successful, yielding results which lie in the vicinity of those of the BASELINE.

In the third block of the tables, we test the performance of the DISCO features in combination with other techniques, i.e., we use the BASELINE and DISCO features with COMPOUNDSWAP$_i$ and combine it with EXTENDED and SEPARATOR features as well as with the IMPORTANCE strategy. All experiments beat the BASELINE/DISCO combination in terms of F_1. EXTENDED and DISCO give a cumulative advantage, resulting in an increase of precision of almost 4%, resp. over 6% on discontinuous constituents, compared to the use of DISCO, resp. EXTENDED alone. Adding the SEPARATOR features to this combination does not bring an advantage. The IMPORTANCE strategy is the most successful one in combination with DISCO, causing a boost of almost 10% on precision of discontinuous constituents, leading to the highest overall discontinuous F_1 of 29.41 (notably more than 12 points higher than the baseline); also on all constituents we obtain the third-highest F_1. Combining DISCO with IMPORTANCE and EXTENDED leads to the highest overall F_1 on all constituents of 76.95, however, the results on discontinuous constituents are slightly lower than for IMPORTANCE alone. This confirms the previously observed behavior: The EXTENDED features help when considering all constituents, but they do not seem to be effective for the recovery of discontinuities in particular.

In the TED and LA scores (Tab. 2), we see much less variation than in the bracketing scores. As reported in the literature (e.g., Rehbein and van Genabith (2007)), this is because of the fact that with bracketing evaluation, a single wrong attachment can "break" brackets which otherwise would be counted as correct. Nevertheless, the trends from bracketing evaluation repeat.

To sum up, the COMPOUNDSWAP$_i$ operation works better than SWAP because the latter misses long gaps. The most useful feature sets were EXTENDED and DISCO, both when used independently and when used together. DISCO was particularly useful for discontinuous constituents. SEPARATOR yielded no usable improvements. IMPORTANCE has also proven to be effective, yielding the best results on discontinuous constituents (in combination with DISCO). Over almost all experiments, a common error is that on root level, CS and S get confused, indicating that the present features do not provide sufficient information for disambiguation of those categories. We can also confirm the tendency that discontinuous VPs in relatively short sentences are recognized correctly, as reported by Versley (2014).

TiGer We now repeat the most successful experiments on TIGER. Tab. 3 shows the parsing results for the test set.

Some of the trends seen on the experiments with NEGRA are repeated. EXTENDED and DISCO yields an improvement on all constituents. However, now not only DISCO, but also EXTENDED lead to improved scores on discontinuous constituents. As mentioned above, this can be explained with the fact that for the EXTENDED features to be effective, the amount of training data available in NEGRA was not enough. Other than in NEGRA, the DISCO features are now more effective when used alone, leading to the highest overall F_1 on discontinuous constituents of 19.45. They are, however, less effective in combination with EXTENDED. This is partially remedied by giving the swap transitions more IMPORTANCE, which leads to the highest overall F_1 on all constituents of 74.71.

The models we learn are sparse, therefore, as mentioned above, we can exploit the work of Goldberg and Elhadad (2011). They propose to only include the weight of a feature in the computation of a score if it has been seen more than MINUPDATE times. We repeat the BASELINE experiment with two different MINUPDATE settings (see Tab. 3). As expected, the MINUPDATE models are much smaller. The final model with the baseline experiment uses 8.3m features (parsing speed on test set 73 sent./sec.), with MINUPDATE 5 3.3m features (121 sent./sec.) and with MINUPDATE 10 1.8m features (124 sent./sec.). With MINUPDATE 10, the results do degrade. However, with MINUPDATE 5 in addition to the faster parsing we consistently improve over the baseline.

Finally, in order to check the convergence, we run a further experiment in which we limit training iterations to 40 instead of 20, together with beam size 4. We use the BASELINE features with COMPOUNDSWAP$_i$ combined with DISCO, EX-

tended, and Importance. The parsing speed on the test set drops to around 39 sentences per second. However, we achieve 75.10 F$_1$, i.e., a slight improvement over the experiments in Tab. 3 that confirms the tendencies visible in Fig. 5.

3.3.2 Continuous Parsing

We investigate the impact of the swap transitions on both speed and parsing results by running an experiment with NeGraCF using the Baseline and Extended features. The corresponding results are shown in Tab. 4.

Particularly high frequency categories (NP, VP, S) are much easier to find in the continuous case and show large improvements. This explains why without the swap transition, F$_1$ with Baseline features is 6.9 points higher than the F$_1$ on discontinuous constituents (with CompoundSwap$_i$). With the Extended features, we obtain a small improvement.

Note that with the shift-reduce approach, the difference between the computational cost of producing discontinuous constituents vs. the cost of producing continuous constituents is much lower than for a grammar-based approach. When producing continuous constituents, parsing is only 20% faster than with the swap transition, namely 97 instead of 81 sentences per second.

In order to give a different perspective on the role of discontinuous constituents, we perform two further evaluations. First, we remove the discontinuities from the output of the discontinuous baseline parser using the procedure described in Sec. 3.1 and evaluate the result against the continuous gold data. We obtain an F$_1$ of 76.70, 5.5 points lower than the continuous baseline. Secondly, we evaluate the output of the continuous baseline parser against the discontinuous gold data. This leads to an F$_1$ 78.89, 2.9 point more than the discontinuous baseline. Both evaluations confirm the intuition that parsing is much easier when discontinuities (i.e., in our case the swap transition) do not have to be considered.

3.3.3 Comparison with other Parsers

rparse In order to compare our parser with a grammar-based approach, we now parse NeGra with *rparse*, with the same training and test sets as before (i.e., we do not use the development set). We employ markovization with $v = 1$, $h = 2$ and head driven binarization with binary top and bottom productions.

The first thing to notice is that *rparse* is much slower than our parser. The average parsing speed is about 0.3 sent./sec.; very long sentences require over a minute to be parsed. The parsing results are shown in Tab. 5. They are about 5 points worse than those reported by Kallmeyer and Maier (2013). This is due to the fact that they train on the first 90% of the treebank, and not on the first 80% as we do, which leads to an increased number of unparsed sentences. In comparison to the baseline setting of the shift-reduce parser with beam size 8, the results are around 10 points worse. However, *rparse* reaches an F$_1$ of 26.61 on discontinuous constituents, which is 5.9 points more than we achieved with the best setting with our parser.

In order to investigate why the grammar-based approach outperforms our parser on discontinuous constituents, we count the frequency of LCFRS productions of a certain gap degree in the binarized grammar used in the *rparse* experiment. The

	LF_1	E
Versley (2014)	74.23	37.32
this work	79.52	44.32
H&N (2008)	79.93	37.78
F&M (2015)	**85.53**	**51.21**

Table 6: Results TiGerHN, sentence length ≤ 40

average occurrence count of rules with gap degree 0 is 12.18. Discontinuous rules have a much lower frequency, the average count of productions with one, two and three gaps being 3.09, 2.09, and 1.06, respectively. In PCFG parsing, excluding low frequency productions does not have a large effect (Charniak, 1996); however, this does not hold for LCFRS parsing, where they have a major influence (cf. Maier (2013, p. 205)): This means that removing low frequency productions has a negative impact on the parser performance particularly concerning discontinuous structures; however, it also means that low frequency discontinuous productions get triggered reliably. This hypothesis is confirmed by the fact that the our parser performs much worse on discontinuous constituents with a very low frequency (such as CS, making up only 0.62% of all discontinuous constituents) than it performs on those with a high frequency (such as VP, making up 60.65% of all discontinuous constituents), while *rparse* performs well on the low frequency constituents.

EaFi and Dependency Parsers We run an experiment with 40 iterations on TiGerHN, using Disco, Extended and Importance. Tab. 6 lists the results, together with the corresponding results of Versley (2014), Hall and Nivre (2008) (H&N) and Fernández-González and Martins (2015) (F&M).

Our results exceed those of EaFi[6] and the exact match score of H&N. We are outperformed by the F&M parser. Note, that particularly the comparison to *EaFi* must be handled with care, since Versley (2014) uses additional preprocessing: PP-internal NPs are annotated explicitly, and the parenthetical sentences are changed to be embedded by their enclosing sentence (instead of vice versa).

We postpone a thorough comparison with both EaFi and the dependency parsers to future work.

3.4 Discussion

To our knowledge, surprisingly, numerical scores for discontinuous constituents have not been reported anywhere in previous work. The relatively low overall performance with both grammar-based and shift-reduce based parsing, along with the fact that the grammar-based approach outperforms the shift-reduce approach, is striking. We have shown that it is possible to push the precision on discontinuous constituents, but not the recall, to the level of what can be achieved with a grammar-based approach.

Particularly the outcome of the experiments involving the Extended features and Importance drives us to the conclusion that the major problem when parsing discontinuous constituents is data sparseness. More features cannot be the only solution: A more reliable recognition of discontinuous constituents requires a more robust learning from larger amounts of data.

4 Conclusion

We have presented a shift-reduce parser for discontinuous constituents which combines previous work in shift-reduce parsing for continuous constituents with recent work in easy-first parsing of discontinuous constituents. Our experiments confirm that an incremental shift-reduce architecture with a swap transition can indeed be used to parse discontinuous constituents. The swap transition is associated with a low computational cost. We have obtained a speed-up of up to 2,000% in comparison to the grammar-based *rparse*, and we have shown that we obtain better results than with the grammar-based parser, even though the grammar-based strategy does better at the reconstruction of discontinuous constituents.

In future work, we will concentrate on methods that could remedy the data sparseness concerning discontinuous constituents, such as self-training. Furthermore, we will experiment with larger feature sets that add lexical information. An formal investigation of the expressivity of our parsing model is currently under way.

Acknowledgments

I wish to thank Miriam Kaeshammer for enlightening discussions and the three anonymous reviewers for helpful comments and suggestions. This work was partially funded by Deutsche Forschungsgemeinschaft (DFG).

[6] Note that Versley (2014) reports a parsing speed of 40-55 sent./sec.; depending on the beam size and the training set size, per second, our parser parses 39-640 sentences.

Abstract

Neural probabilistic parsers are attractive for their capability of automatic feature combination and small data sizes. A transition-based greedy neural parser has given better accuracies over its linear counterpart. We propose a neural probabilistic structured-prediction model for transition-based dependency parsing, which integrates search and learning. Beam search is used for decoding, and contrastive learning is performed for maximizing the sentence-level log-likelihood. In standard Penn Treebank experiments, the structured neural parser achieves a 1.8% accuracy improvement upon a competitive greedy neural parser baseline, giving performance comparable to the best linear parser.

1 Introduction

Transition-based methods have given competitive accuracies and efficiencies for dependency parsing (Yamada and Matsumoto, 2003; Nivre and Scholz, 2004; Zhang and Clark, 2008; Huang and Sagae, 2010; Zhang and Nivre, 2011; Goldberg and Nivre, 2013). These parsers construct dependency trees by using a sequence of transition actions, such as SHIFT and REDUCE, over input sentences. High accuracies are achieved by using a linear model and millions of binary indicator features. Recently, Chen and Manning (2014) propose an alternative dependency parser using a neural network, which represents atomic features as dense vectors, and obtains feature combination automatically other than devising high-order features manually.

The greedy neural parser of Chen and Manning (2014) gives higher accuracies compared to the greedy linear MaltParser (Nivre and Scholz, 2004), but lags behind state-of-the-art linear systems with sparse features (Zhang and Nivre, 2011), which adopt global learning and beam search decoding (Zhang and Nivre, 2012). The key difference is that Chen and Manning (2014) is a *local classifier* that greedily optimizes each action. In contrast, Zhang and Nivre (2011) leverage a *structured-prediction* model to optimize whole sequences of actions, which correspond to tree structures.

In this paper, we propose a novel framework for *structured* neural probabilistic dependency parsing, which maximizes the likelihood of action sequences instead of individual actions. Following Zhang and Clark (2011), beam search is applied to decoding, and global structured learning is integrated with beam search using early-update (Collins and Roark, 2004). Designing such a framework is challenging for two main reasons:

First, applying global structured learning to transition-based neural parsing is non-trivial. A direct adaptation of the framework of Zhang and Clark (2011) under the neural probabilistic model setting does not yield good results. The main reason is that the parameter space of a neural network is much denser compared to that of a linear model such as the structured perceptron (Collins, 2002). Due to the dense parameter space, for neural models, the scores of actions in a sequence are relatively more dependent than that in the linear models. As a result, the log probability of an action sequence can not be modeled just as the sum of log probabilities of each action in the sequence, which is the case of structured linear model. We address the challenge by using a *softmax* function to directly model the distribution of action sequences.

Second, for the structured model above, maximum-likelihood training is computationally intractable, requiring summing over all possible action sequences, which is difficult for transition-

based parsing. To address this challenge, we take a contrastive learning approach (Hinton, 2002; LeCun and Huang, 2005; Liang and Jordan, 2008; Vickrey et al., 2010; Liu and Sun, 2014). Using the sum of log probabilities over the action sequences in the beam to approximate that over all possible action sequences.

In standard PennTreebank (Marcus et al., 1993) evaluations, our parser achieves a significant accuracy improvement (+1.8%) over the greedy neural parser of Chen and Manning (2014), and gives the best reported accuracy by shift-reduce parsers. The incremental neural probabilistic framework with global contrastive learning and beam search could be used in other structured prediction tasks.

2 Background

2.1 Arc-standard Parsing

Transition-based dependency parsers scan an input sentence from left to right, and perform a sequence of transition actions to predict its parse tree (Nivre, 2008). In this paper, we employ the **arc-standard** system (Nivre et al., 2007), which maintains partially-constructed outputs using a *stack*, and orders the incoming words in the input sentence in a *queue*. Parsing starts with an empty stack and a queue consisting of the whole input sentence. At each step, a *transition action* is taken to consume the input and construct the output. The process repeats until the input queue is empty and stack contains only one dependency tree.

Formally, a parsing state is denoted as $\langle j, S, L\rangle$, where S is a stack of subtrees $[\ldots s_2,\ s_1,\ s_0]$, j is the head of the queue (i.e. $[\ q_0 = w_j,\ q_1 = w_{j+1} \cdots]$), and L is a set of dependency arcs. At each step, the parser chooses one of the following actions:

- SHIFT: move the front word w_j from the queue onto the stacks.

- LEFT-ARC(l): add an arc with label l between the top two trees on the stack ($s_1 \leftarrow s_0$), and remove s_1 from the stack.

- RIGHT-ARC(l): add an arc with label l between the top two trees on the stack ($s_1 \rightarrow s_0$), and remove s_0 from the stack.

input : $w_0 \ldots w_{n-1}$
axiom : $0 : \langle 0, \phi, \phi, 0\rangle$
goal : $2n-1 : \langle n, s_0, L\rangle$

$$\text{SHIFT} \quad \frac{k : \langle j, S, L\rangle}{k+1 : \langle j+1, S|w_j, L\rangle}$$

$$\text{LEFT-ARC}(l) \quad \frac{k : \langle j, S|s_1|s_0, L\rangle}{k+1 : \langle j, S|s_0, L \cup \{s_1 \xleftarrow{l} s_0\}\rangle}$$

$$\text{RIGHT-ARC}(l) \quad \frac{k : \langle j, S|s_1|s_0, L\rangle}{k+1 : \langle j, S|s_1, L \cup \{s_1 \xrightarrow{l} s_0\}\rangle}$$

Figure 1: The deductive system for arc-standard dependency parsing.

The arc-standard parser can be summarized as the deductive system in Figure 1, where k denotes the current parsing step. For a sentence with size n, parsing stops after performing exactly $2n-1$ actions.

MaltParser uses an SVM classifier for deterministic arc-standard parsing. At each step, MaltParser generates a set of successor states according to the current state, and deterministically selects the highest-scored one as the next state.

2.2 Global Learning and Beam Search

The drawback of deterministic parsing is error propagation. An incorrect action will have a negative influence to its subsequent actions, leading to an incorrect output parse tree.

To address this issue, global learning and beam search (Zhang and Clark, 2011; Bohnet and Nivre, 2012; Choi and McCallum, 2013) are used. Given an input x, the goal of decoding is to find the highest-scored action sequence *globally*.

$$y = \underset{y' \in \text{GEN}(x)}{\arg\max}\ score(y') \tag{1}$$

Where GEN(x) denotes all possible action sequences on x, which correspond to all possible parse trees. The score of an action sequence y is:

$$score(y) = \sum_{a \in y} \theta \cdot \Phi(a) \tag{2}$$

Here a is an action in the action sequence y, Φ is a feature function for a, and θ is the parameter vector of the linear model. The score of an action sequence is the linear sum of the scores of each action. During training, action sequence scores are globally learned.

The parser of Zhang and Nivre (2011) is developed using this framework. The structured perceptron (Collins, 2002) with early update (Collins and Roark, 2004) is applied for training. By utilizing rich manual features, it gives state-of-the-art accuracies in standard Penn Treebank evaluation. We take this method as one baseline.

2.3 Greedy Neural Network Model

Chen and Manning (2014) build a greedy neural arc-standard parser. The model can be regarded as an alternative implementation of MaltParser, using a feedforward neural network to replace the SVM classifier for deterministic parsing.

2.3.1 Model

The greedy neural model extracts n atomic features from a parsing state, which consists of words, POS-tags and dependency labels from the stack ans queue. *Embeddings* are used to represent word, POS and dependency label atomic features. Each embedding is represented as a d-dimensional vector $e_i \in \mathbb{R}$. Therefore, the full embedding matrix is $E \in \mathbb{R}^{d \times V}$, where V is the number of distinct features. A *projection layer* is used to concatenate the n input embeddings into a vector $x = [e_1; e_2 \ldots e_n]$, where $x \in \mathbb{R}^{d \cdot n}$. The purpose of this layer is to fine-tune the embedding features. Then x is mapped to a d_h-dimensional *hidden layer* by a mapping matrix $W_1 \in \mathbb{R}^{d_h \times d \cdot n}$ and a cube activation function:

$$h = (W_1 x + b_1)^3 \tag{3}$$

Finally, h is mapped into a *softmax output layer* for modeling the probabilistic distribution of candidate shift-reduce actions:

$$p = softmax(o) \tag{4}$$

where

$$o = W_2 h \tag{5}$$

$W_2 \in \mathbb{R}^{d_o \times d_h}$ and d_o is the number of shift-reduce actions.

2.3.2 Features

One advantage of Chen and Manning (2014) is that the neural network parser achieves feature combination automatically. Their atomic features are defined by following Zhang and Nivre (2011). As shown in Table 1, the features are categorized into three types: F^w, F^t, F^l, which represents word features, POS-tag features and dependency label features, respectively.

	Templates
F^w	$s_0w, s_2w, q_0w, q_1w, q_2w, lc_1(s_0)w, lc_2(s_0)w$ $s_1w, rc_2(s_0)w, lc_1(s_1)w, lc_2(s_1)w, rc_2(s_1)w$ $rc_1(s_0)w, rc_1(s_1)w, lc_1(lc_1(s_0))w, lc_1(lc_1(s_1))w$ $rc_1(rc_1(s_1))w, rc_1(rc_1(s_0))w$
F^t	$s_0t, q_0t, q_1t, q_2t, rc_1(s_0)t, lc_1(s_0)t, lc_2(s_0)t$ $s_1t, s_2t, lc_1(s_1)t, lc_2(s_1)t, rc_1(s_1)t, rc_2(s_0)t$ $rc_2(s_1)t, lc_1(lc_1(s_0))t, lc_1(lc_1(s_1))t$ $rc_1(rc_1(s_0))t, rc_1(rc_1(s_1))t$
F^l	$rc_1(s_0)l, lc_1(s_0)l, lc_2(s_0)l, lc_1(s_1)l, lc_2(s_1)l$ $rc_1(s_1)l, rc_2(s_0)l, rc_2(s_1)l, lc_1(lc_1(s_0))l$ $lc_1(lc_1(s_1))l, rc_1(rc_1(s_0))l, rc_1(rc_1(s_1))l$

Table 1: Feature templates.

For example, s_0w and q_0w represent the first word on the stack and queue, respectively; $lc_1(s_0)w$ and $rc_1(s_0)w$ represent the leftmost and rightmost child of s_0, respectively. Similarly, $lc_1(s_0)t$ and $lc_1(s_0)l$ represent the POS-tag and dependency label of the leftmost child of s_0, respectively.

Chen and Manning (2014) find that the cube activation function in Equation (3) is highly effective in capturing feature interaction, which is a novel contribution of their work. The cube function achieves linear combination between atomic word, POS and label features via the product of three element combinations. Empirically, it works better compared to a sigmoid activation function.

2.4 Training

Given a set of training examples, the training objective of the greedy neural parser is to minimize the cross-entropy loss, plus a l_2-regularization term:

$$L(\theta) = -\sum_{i \in A} \log p_i + \frac{\lambda}{2} \parallel \theta \parallel^2 \tag{6}$$

θ is the set of all parameters (i.e. W_1, W_2, b, E), and A is the set of all gold actions in the training data. AdaGrad (Duchi et al., 2011) with minibatch is adopted for optimization. We take the greedy neural parser of Chen and Manning (2014) as a second baseline.

3 Structured Neural Network Model

We propose a neural structured-prediction model that scores whole sequences of transition actions, rather than individual actions. As shown in Table 2, the model can be seen as a neural probabilistic alternative of Zhang and Nivre (2011),

	local classifier	structured prediction
linear sparse	Section 2.1 (Nivre et al., 2007)	Section 2.2 (Zhang and Nivre, 2011)
neural dense	Section 2.3 (Chen and Manning, 2014)	this work

Table 2: Correlation between different parsers.

or a structured-prediction alternative of Chen and Manning (2014). It combines the advantages of both Zhang and Nivre (2011) and Chen and Manning (2014) over the greedy linear MaltParser.

3.1 Neural Probabilistic Ranking

Given the baseline system in Section 2.2, the most intuitive structured neural dependency parser is to replace the linear scoring model with a neural probabilistic model. Following Equation 1, the score of an action sequence y, which corresponds to its log probability, is sum of log probability scores of each action in the sequence.

$$s(y) = \sum_{a \in y} \log p_a \tag{7}$$

where p_a is defined by the baseline neural model of Section 2.3 (Equation 4). The training objective is to maximize the score margin between the gold action sequences (y_g) and these of incorrectly predicated action sequences (y_p):

$$L(\theta) = max(0, \delta - s(y_g) + s(y_p)) + \frac{\lambda}{2} \parallel \theta \parallel^2 \tag{8}$$

With this ranking model, beam search and early-update are used. Given a training instance, the negative example is the incorrectly predicted output with largest score (Zhang and Nivre, 2011).

However, we find that the ranking model works poorly. One explanation is that the actions in a sequence is probabilistically dependent on each other, and therefore using the total log probabilities of each action to compute the log probability of an action sequence (Equation 7) is inaccurate. Linear models do not suffer from this problem, because the parameter space of linear models is much more sparse than that of neural models. For neural networks, the dense parameter space is shared by all the actions in a sequence. Increasing the likelihood of a gold action may also change the likelihood of incorrect actions through the shared parameters. As a result, increasing the scores of a gold action sequence and simultaneously reducing the scores of an incorrect action sequence does not work well for neural models.

3.2 Sentence-Level Log-Likelihood

To overcome the above limitation, we try to directly model the probabilistic distribution of whole action sequences. Given a sentence x and neural networks parameter θ, the probability of the action sequence y_i is given by the *softmax* function:

$$p(y_i \mid x, \theta) = \frac{e^{f(x,\, \theta)_i}}{\sum\limits_{y_j \in \mathrm{GEN}(x)} e^{f(x,\, \theta)_j}} \tag{9}$$

where

$$f(x,\, \theta)_i = \sum_{a_k \in y_i} o(x,\, y_i,\, k,\, a_k) \tag{10}$$

Here $\mathrm{GEN}(s)$ is the set of all possible valid action sequences for a sentence x; $o(x,\, y_i,\, k,\, a_k)$ denotes the neural network score for the action a_k given x and y_i. We use the same sub network as Chen and Manning (2014) to calculate $o(x,\, y_i,\, k,\, a_k)$ (Equation 5). The same features in Table 1 are used.

Given the training data as $(X,\, Y)$, our training objective is to minimize the negative log-likelihood:

$$\begin{aligned} L(\theta) &= - \sum_{(x_i,\, y_i) \in (X, Y)} \log p(y_i \mid x_i, \theta) && (11) \\ &= - \sum_{(x_i,\, y_i) \in (X, Y)} \log \frac{e^{f(x_i, \theta)_i}}{Z(x_i, \theta)} && (12) \\ &= \sum_{(x_i,\, y_i) \in (X, Y)} \log Z(x_i, \theta) - f(x_i, \theta)_i && (13) \end{aligned}$$

where

$$Z(x, \theta) = \sum_{y_j \in \mathrm{GEN}(x)} e^{f(x,\, \theta)_j} \tag{14}$$

Here, $Z(x, \theta)$ is called the *partition function*. Following Chen and Manning(2014), we apply l_2-regularization for training.

For optimization, we need to compute gradients for $L(\theta)$, which includes gradients of exponential numbers of negative examples in *partition function* $Z(x, \theta)$. However, beam search is used for transition-based parsing, and no efficient optimal dynamic program is available to estimate $Z(x, \theta)$ accurately. We adopt a novel contrastive learning approach to approximately compute $Z(x, \theta)$.

3.3 Contrastive Learning

As an alternative to maximize the likelihood on some observed data, contrastive learning (Hinton, 2002; LeCun and Huang, 2005; Liang and Jordan, 2008; Vickrey et al., 2010; Liu and Sun, 2014) is an approach that assigns higher probabilities to observed data and lower probabilities to noisy data.

We adopt the contrastive learning approach, assigning higher probabilities to the gold action sequence compared to incorrect action sequences in the beam. Intuitively, this method only penalizes incorrect action sequences with high probabilities. Our new training objective is approximated as:

$$L'(\theta) = -\sum_{(x_i, y_i) \in (X,Y)} \log p'(y_i \mid x_i, \theta) \qquad (15)$$

$$= -\sum_{(x_i, y_i) \in (X,Y)} \log \frac{e^{f(x_i, \theta)_i}}{Z'(x_i, \theta)} \qquad (16)$$

$$= \sum_{(x_i, y_i) \in (X,Y)} \log Z'(x_i, \theta) - f(x_i, \theta)_i \qquad (17)$$

where

$$Z'(x, \theta) = \sum_{y_j \in \mathrm{BEAM}(x)} e^{f(x,\, \theta)_j} \qquad (18)$$

$p'(y_i \mid x, \theta)$ is the relative probability of the action sequence y_i, computed over only the action sequences in the beam. $Z'(x, \theta)$ is the contrastive approximation of $Z(x, \theta)$. $\mathrm{BEAM}(x)$ returns the predicated action sequences in the beam and the gold action sequence.

We assume that the probability mass concentrates on a relatively small number of action sequences, which allows the use of a limited number of probable sequences to approximate the full set of action sequences. The concentration may be enlarged dramatically with an exponential activation function of the neural network (i.e. $a > b \Rightarrow e^a \gg e^b$).

3.4 The Neural Probabilistic Structured-Prediction Framework

We follow Zhang and Clark (2011) to integrate search and learning. Our search and learning framework for dependency parsing is shown as Algorithm 1. In every training iteration i, we randomly sample the training instances, and perform online learning with early update (Collins and Roark, 2004). In particular, given a training example, we use beam-search to decode the sentence. At any step, if the gold action sequence falls out of the beam, we take all the incorrect action sequences in the beam as negative examples, and the current gold sequence as a positive example for parameter update, using the training algorithm of Section 3.3. AdaGrad algorithm (Duchi et al., 2011) with mini-batch is adopted for optimization.

Algorithm 1: Training Algorithm for Structured Neural Parsing

```
Input: training examples (X, Y)
Output: $\theta$
$\theta \leftarrow$ pretrained embedding
for $i \leftarrow 1$ to $N$ do
    x, y = RandomSample(X, Y)
    $\delta$ = 0
    foreach $x_j, y_j \in$ x, y do
        $beam$ = $\phi$
        $goldState$ = null
        $terminate$ = false
        $beamGold$ = true
        while $beamGold$ and not $terminate$ do
            $beam$ = DECODE($beam$, $x_j$, $y_j$)
            $goldState$ = GOLDMove($goldState$, $x_j$, $y_j$)
            if not isGold(beam) then
                $beamGold$ = false
            if ITEMSCOMPLETE(beam) then
                $terminate$ = true;
        $\delta$ = $\delta$ + UPDATE($goldState$, $beam$)
    $\theta$ = $\theta$ + $delta$
```

In this way, the distribution of ot only full action sequences (i.e. complete parse trees), but also partial action sequences (i.e. partial outputs) are modeled, which makes training more challenging. The advantage of early update is that training is used to guide search, minimizing search errors.

4 Experiments

4.1 Set-up

Our experiments are performed using the English Penn Treebank (PTB; Marcus et al., (1993)). We follow the standard splits of PTB3, using sections 2-21 for training, section 22 for development testing and section 23 for final testing. For comparison with previous work, we use Penn2Malt[1] to convert constituent trees to dependency trees. We use the POS-tagger of Collins (2002) to assign POS automatically. 10-fold jackknifing is performed for tagging the training data.

We follow Chen and Manning (2014), and use the set of pre-trained word embeddings[2] from Collobert et al. (2011) with a dictionary size of 13,000. The word embeddings were trained on the entire English Wikipedia, which contains about 631 million words.

4.2 WSJ Experiments

4.2.1 Development experiments

We set the following hyper-parameters according to the baseline greedy neural parser (Chen and Manning, 2014): embedding size d = 50, hidden layer size d_h = 200, regularization parameter λ = 10^{-8}, initial learning rate of Adagrad α = 0.01. For the structured neural parser, beam size and mini-batch size are important to the parsing performance. We tune them on the development set.

Beam size. Beam search enlarges the search space. More importantly, the larger the beam is, the more accurate our training algorithm is. the Contrastive learning approximates the exact probabilities over exponential many action sequences by computing the relative probabilities over action sequences in the beam (Equation 18). Therefore, the larger the beam is, the more accurate the relative probability is.

The first column of Table 3 shows the accuracies of the structured neural parser on the development set with different beam sizes, which improves as the beam size increases. We set the final beam size as 100 according to the accuracies on development set.

Description	UAS	
Baseline	91.63	
	structured	greedy
beam = 1	74.90	91.63
beam = 4	84.64	91.92
beam = 16	91.53	91.90
beam = 64	93.12	91.84
beam = 100	93.23	91.81

Table 3: Accuracies of structured neural parsing and local neural classification parsing with different beam sizes.

Description	UAS
greedy neural parser	91.47
ranking model	89.08
beam contrastive learning	93.28

Table 4: Comparison between sentence-level log-likelihood and ranking model.

The effect of integrating search and learning. We also conduct experiments on the parser of Chen and Manning (2014) with beam search decoding. The score of a whole action sequence is computed by the sum of log action probabilities (Equation 7). As shown in the second column of Table 3, beam search can improve parsing slightly. When the beam size increases beyond 16, however, accuracy improvements stop. In contrast, by integrating beam search and global learning, our parsing performance benefits from large beam sizes much more significantly. With a beam size as 16, the structured neural parser gives an accuracy close to that of baseline greedy parser[3]. When the beam size is 100, the structured neural parser outperforms baseline by 1.6%.

Zhang and Nivre (2012) find that global learning and beam search should be used jointly for improving parsing using a *linear* transition-based model. In particular, increasing the beam size, the accuracy of ZPar (Zhang and Nivre, 2011) increases significantly, but that of MaltParser does not. For structured *neural* parsing, our finding is similar: integrating search and learning is much more effective than using beam search only in decoding.

Our results in Table 3 are obtained by using the same beam sizes for both training and testing. Zhang and Nivre (2012) also find that for their lin-

[3] Our baseline accuracy is a little lower than accuracy reported in baseline paper (Chen and Manning, 2014), because we use Penn2Malt to convert the Penn Treebank, and they use LTH Conversion.

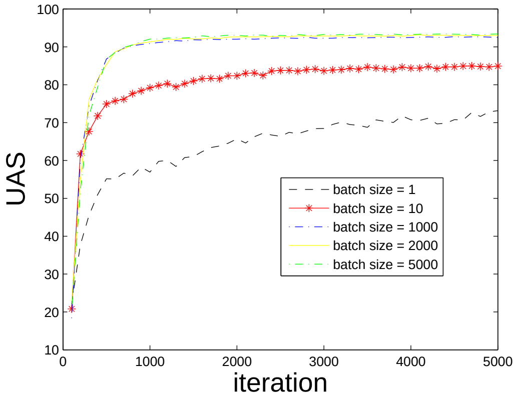

Figure 2: Parsing performance with different training batch sizes.

ear model, the best results are achieved by using the same beam sizes during training and testing. We find that this observation does not apply to our neural parser. In our case, a large training beam always leads to better results. This is likely because a large beam improves contrastive learning. As a result, our training beam size is set to 100 for the final test.

Batch size. Parsing performance using neural networks is highly sensitive to the batch size of training. In greedy neural parsing (Chen and Manning, 2014), the accuracy on the development data improves from 85% to 91% by setting the batch size to 10 and 100000, respectively. In structured neural parsing, we fix the beam size as 100 and draw the accuracies on the development set by the training iteration.

As shown in Figure 2, in 5000 training iterations, the parsing accuracies improve as the iteration grows, yet different batch sizes result in different convergence accuracies. With a batch size of 5000, the parsing accuracy is about 25% higher than with a batch size of 1 (i.e. SGD). For the remaining experiments, we set batch size to 5000, which achieves the best accuracies on development testing.

4.2.2 Sentence-level maximum likelihood vs. ranking model

We compare parsing accuracies of the sentence-level log-likelihood + beam contrastive learning (Section 3.2), and the structured neural parser with probabilistic ranking (Section 3.1). As shown in Table 4, performance of global learning with ranking model is weaker than the baseline greedy parser. In contrast, structured neural parsing with sentence-level log-likelihood and contrastive learning gives a 1.8% accuracy improvement upon the baseline greedy parser.

System		UAS	LAS	Speed
baseline greedy parser		91.47	90.43	0.001
Huang and Sagae (2010)		92.10		0.04
Zhang and Nivre (2011)		92.90	91.80	0.03
Choi and McCallum (2013)		92.96	91.93	0.009
Ma et al. (2014)		93.06		
Bohnet and Nivre (2012)†‡		93.67	92.68	0.4
Suzuki et al. (2009)†		93.79		
Koo et al. (2008)†		93.16		
Chen et al. (2014)†		93.77		
beam size				
training	decoding			
100	100	**93.28**	**92.35**	0.07
100	64	93.20	92.27	0.04
100	16	92.40	91.95	0.01

Table 5: Results on WSJ. Speed: sentences per second. †: semi-supervised learning. ‡: joint POS-tagging and dependency parsing models.

As mentioned in Section 3.1, a likely reason for the poor performance of the structured neural ranking model may be that, the likelihoods of action sequences are highly influenced by each other, due to the dense parameter space of neural networks. To maximize likelihood of gold action sequence, we need to decrease the likelihoods of more than one incorrect action sequences.

4.2.3 Final Results

Table 5 shows the results of our final parser and a line of transition-based parsers on the test set. Our structured neural parser achieves an accuracy of 93.28%, 0.38% higher than Zhang and Nivre (2011), which employees millions of high-order binary indicator features in parsing. The model size of ZPar (Zhang and Nivre, 2011) is over 250 MB on disk. In contrast, the model size of our structured neural parser is only 25 MB. To our knowledge, the result is the best reported result achieved by shift-reduce parsers on this data set.

Bohnet and Nivre (2012) obtain an accuracy of 93.67%, which is higher than our parser. However, their parser is a joint model of parsing and POS-tagging, and they use external data in parsing. We also list the result of Chen et al. (2014), Koo et al. (2008) and Suzuki et al. (2009) in Table 5, which make use of large-scale unannotated text to improve parsing accuracies. The input embeddings of our parser are also trained over large raw text, and in this perspective our model is correlated with the semi-supervised models. However, because we fine-tune the word embeddings in supervised training, the embeddings of in-vocabulary words become systematically different from these of out-of-vocabulary words after training, and the effect of pre-trained out-of-vocabulary embeddings become uncertain. In this sense, our model can also be regarded as an almost fully supervised model. The same applies to the models of Chen and Manning (2014).

We also compare the speed of the structured neural parser on an Intel Core i7 3.40GHz CPU with 16GB RAM. The structured neural parser runs about as fast as Zhang and Nivre (Zhang and Nivre, 2011) and Huang and Sagae (Huang and Sagae, 2010). The results show that our parser combines the benefits of structured models and neural probabilistic models, offering high accuracies, fast speed and slim model size.

5 Related Work

Parsing with neural networks. A line of work has been proposed to explore the effect of neural network models for constituent parsing (Henderson, 2004; Mayberry III and Miikkulainen, 2005; Collobert, 2011; Socher et al., 2013; Legrand and Collobert, 2014). Performances of most of these methods are still well below the state-of-the-art, except for Socher et al.(2013), who propose a neural reranker based on a PCFG parser. For transition-based dependency parsing, Stenetorp (2013) applies a compositional vector method (Socher et al., 2013), and Chen and Manning (2014) propose a feed-forward neural parser. The performances of these neural parsers lag behind the state-of-the-art.

More recently, Dyer et al. (2015) propose a greedy transition-based dependency parser, using three stack LSTMs to represent the input, the stack of partial syntactic trees and the history of parse actions, respectively. By modeling more history, the parser gives significant better accuracies compared to the greedy neural parser of Chen and Manning (2014).

Structured neural models. Collobert et al. (2011) presents a unified neural network architecture for various natural language processing (NLP) tasks. They propose to use sentence-level log-likelihood to enhance a neural probabilistic model, which inspires our model. Sequence labeling is used for graph-based decoding. Using the Viterbi algorithm, they can compute the exponential partition function in linear time without approximation. However, with a dynamic programming decoder, their sequence labeling model can only extract local features. In contrast, our integrated approximated search and learning framework allows rich global features.

Weiss et al. (2015) also propose a structured neural transition-based parser by adopting beam search and early updates. Their model is close in spirit to ours in performing structured prediction using a neural network. The main difference is that their structured neural parser uses a greedy parsing process for pre-training, and fine-tunes an additional perceptron layer consisting of the pre-trained hidden and output layers using structured perceptron updates. Their structured neural parser achieves an accuracy of 93.36% on Stanford conversion of the PTB, which is significant higher than the baseline parser of Chen and Manning (2014). Their results are not directly comparable with ours due to different dependency conversions.

6 Conclusion

We built a structured neural dependency parsing model. Compared to the greedy neural parser of Chen and Manning (2014), our parser integrates beam search and global contrastive learning. In standard PTB evaluation, our parser achieved a 1.8% accuracy improvement over the parser of Chen and Manning (2014), which shows the effect of combining search and learning. To our knowledge, the structured neural parser is the first neural parser that outperforms the best linear shift-reduce dependency parsers. The structured neural probabilistic framework can be used in other incremental structured prediction tasks.

Abstract

Treebanks are key resources for developing accurate statistical parsers. However, building treebanks is expensive and time-consuming for humans. For domains requiring deep subject matter expertise such as law and medicine, treebanking is even more difficult. To reduce annotation costs for these domains, we develop methods to improve cross-domain parsing inference using paraphrases. Paraphrases are easier to obtain than full syntactic analyses as they do not require deep linguistic knowledge, only linguistic fluency. A sentence and its paraphrase may have similar syntactic structures, allowing their parses to mutually inform each other. We present several methods to incorporate paraphrase information by jointly parsing a sentence with its paraphrase. These methods are applied to state-of-the-art constituency and dependency parsers and provide significant improvements across multiple domains.

1 Introduction

Parsing is the task of reconstructing the syntactic structure from surface text. Many natural language processing tasks use parse trees as a basis for deeper analysis.

The most effective sources of supervision for training statistical parsers are treebanks. Unfortunately, treebanks are expensive, time-consuming to create, and not available for most domains. Compounding the problem, the accuracy of statistical parsers degrades as the domain shifts away from the supervised training corpora (Gildea, 2001; Bacchiani et al., 2006; McClosky et al., 2006b; Surdeanu et al., 2008). Furthermore, for domains requiring subject matter experts, e.g., law and medicine, it may not be feasible to produce large scale treebanks since subject matter experts generally don't have the necessary linguistic background. It is natural to look for resources that are more easily obtained. In this work, we explore using paraphrases. Unlike parse trees, paraphrases can be produced quickly by humans and don't require extensive linguistic training. While paraphrases are not parse trees, a sentence and its paraphrase may have similar syntactic structures for portions where they can be aligned.

We can improve parsers by jointly parsing a sentence with its paraphrase and encouraging certain types of overlaps in their syntactic structures. As a simple example, consider replacing an unknown word in a sentence with a synonym found in the training data. This may help disambiguate the sentence without changing its parse tree. More disruptive forms of paraphrasing (e.g., topicalization) can also be handled by not requiring strict agreement between the parses.

In this paper, we use paraphrases to improve parsing inference within and across domains. We develop methods using dual-decomposition (where the parses of both sentences from a dependency parser are encouraged to agree, Section 3.2) and pair-finding (which can be applied to any n-best parser, Section 3.3). Some paraphrases significantly disrupt syntactic structure. To counter this, we examine relaxing agreement constraints and building classifiers to predict when joint parsing won't be beneficial (Section 3.4). We show that paraphrases can be exploited to improve cross-domain parser inference for two state-of-the-art parsers, especially on domains where they perform poorly.

2 Related Work

Many constituency parsers can parse English newswire text with high accuracy (Collins, 2000;

[*] Work performed during an IBM internship.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1223–1233,
Beijing, China, July 26-31, 2015.

Charniak and Johnson, 2005; Petrov et al., 2006; Socher et al., 2013; Coppola and Steedman, 2013). Likewise, dependency parsers have rapidly improved their accuracy on a variety of languages (Eisner, 1996; McDonald et al., 2005; Nivre et al., 2007; Koo and Collins, 2010; Zhang and McDonald, 2014; Lei et al., 2014). There are many approaches tackling the problem of improving parsing accuracy both within and across domains, including self-training/uptraining (McClosky et al., 2006b; Petrov et al., 2010), reranking (Collins, 2000; McClosky et al., 2006b), incorporating word clusters (Koo et al., 2008), model combination (Petrov, 2010), automatically weighting training data (McClosky et al., 2010), and using n-gram counts from large corpora (Bansal and Klein, 2011). Using paraphrases falls into the semi-supervised category. As we show later, incorporating paraphrases provides complementary benefits to self-training.

2.1 Paraphrases

While paraphrases are difficult to define rigorously (Bhagat and Hovy, 2013), we only require a loose definition in this work: a pair of phrases that mean approximately the same thing. Paraphrases can be constructed in various ways: replacing words with synonyms, reordering clauses, adding relative clauses, using negation and antonyms, etc. Table 1 lists some example paraphrases.

There are a variety of paraphrase resources produced by humans (Dolan and Brockett, 2005) and automatic methods (Ganitkevitch et al., 2013). Recent works have shown that reliable paraphrases can be crowdsourced at low cost (Negri et al., 2012; Burrows et al., 2013; Tschirsich and Hintz, 2013). Paraphrases have been shown to help summarization (Cohn and Lapata, 2013), question answering (Duboue and Chu-Carroll, 2006; Fader et al., 2013), machine translation (Callison-Burch et al., 2006), and semantic parsing (Berant and Liang, 2014). Paraphrases have been applied to syntactic tasks, such as prepositional phrase attachment and noun compounding, where the corpus frequencies of different syntactic constructions (approximated by web searches) are used to help disambiguate (Nakov and Hearst, 2005). One method for transforming constructions is to use paraphrase templates.

How did Bob Marley die? What killed Bob Marley?
How fast does a cheetah run? What is a cheetah's top speed?
He came home unexpectedly. He wasn't expected to arrive home like that.
They were far off and looked tiny. From so far away, they looked tiny.
He turned and bent over the body of the Indian. Turning, he bent over the Indian's body.
No need to dramatize. There is no need to dramatize.

Table 1: Example paraphrases from our dataset.

2.2 Bilingual Parsing

The closest task to ours is bilingual parsing where sentences and their translations are parsed simultaneously (Burkett et al., 2010). While our methods differ from those used in bilingual parsing, the general ideas are the same.[1] Translating and paraphrasing are related transformations since both approximately preserve meaning. While syntax is only partially preserved across these transformations, the overlapping portions can be leveraged with joint inference to mutually disambiguate. Existing bilingual parsing methods typically require parallel treebanks for training and parallel text at runtime while our methods only require parallel text at runtime. Since we do not have a parallel paraphrase treebank for training, we cannot directly compare to these methods.

3 Jointly Parsing Paraphrases

With a small number of exceptions, parsers typically assume that the parse of each sentence is independent. There are good reasons for this independence assumption: it simplifies parsing inference and oftentimes it is not obvious how to relate multiple sentences (though see Rush et al. (2012) for one approach). In this section, we present two methods to jointly parse paraphrases without complicating inference steps. Before going into details, we give a high level picture of how jointly parsing paraphrases can help in Figure 1. With the baseline parser, the parse tree of the target sentence is incorrect but its paraphrase (parsed by the same parser) is parsed correctly. We use rough alignments to map words across sentence pairs.

[1] Applying our methods to bilingual parsing is left as future work.

Note the similar syntactic relations when they are projected across the aligned words.

Our goal is to encourage an appropriate level of agreement between the two parses across alignments. We start by designing "hard" methods which require complete agreement between the parses. However, since parsers are imperfect and alignments approximate, we also develop "soft" methods which allow for disagreements. Additionally, we make procedures to decide whether to use the original (non-joint) parse or the new joint parse for each sentence since joint parses may be worse in cases where the sentences are too different and alignment fails.

3.1 Objective

In a typical parsing setting, given a sentence (x) and its paraphrase (y), parsers find $a^*(x)$ and $b^*(y)$ that satisfy the following equation:[2]

$$\begin{aligned} a^*, b^* &= \operatorname*{argmax}_{a\in T(x), b\in T(y)} f(a) + f(b) \\ &= \operatorname*{argmax}_{a\in T(x)} f(a) + \operatorname*{argmax}_{b\in T(y)} f(b) \end{aligned} \tag{1}$$

where f is a parse-scoring function and T returns all possible trees for a sentence. f can take many forms, e.g., summing the scores of arcs (Eisner, 1996; McDonald et al., 2005) or multiplying probabilities together (Charniak and Johnson, 2005). The argmax over a and b of equation (1) is separable; parsers make two sentence-level decisions. For joint parsing, we modify the objective so that parsers make one global decision:

$$a^*, b^* = \operatorname*{argmax}_{\substack{a\in T(x), b\in T(y) \\ : c(a,b)=0}} f(a) + f(b) \tag{2}$$

where c (defined below) measures the syntactic similarity between the two trees. The smaller $c(a, b)$ is, the more similar a and b are. Intuitively, joint parsers must retrieve the most similar pair of trees with the highest sum of scores.

3.1.1 Constraints

The constraint function, c, ties two trees together using alignments as a proxy for semantic information. An alignment is a pair of words from sentences x and y that approximately mean the same thing. For example, in Figure 1, (help^x, help^y) is one alignment and (pestilence^x, disease^y) is another. To simplify joint parsing, we assume the aligned words play the same syntactic roles (which is obviously not always true and should be revisited in future work). c measures the syntactic similarity by computing how many pairs of alignments have different syntactic head relations. For the two trees in Figure 1, we see two different relations: (help $\xrightarrow{x}$ dying, help $\overset{y}{\not\to}$ dying) and (natives $\overset{x}{\not\to}$ dying, natives $\xrightarrow{y}$ dying). The rest have the same relation so $c(a, b) = 2$. As we'll show in Section 5, the constraints defined above are too restrictive because of this strong assumption. To alleviate the problem, we present ways of appropriately changing constraints later. We now turn to the first method of incorporating constraints into joint parsing.

```
Set $u^0(i,j) = 0$ for all $i, j \in E$
for $k$ = 1 to $K$ do
  $a^k = \operatorname*{argmax}_{a\in T(x)} \Big( f(a) + \sum_{i,j\in E} u^k(i,j)a(i,j) \Big)$
  $b^k = \operatorname*{argmax}_{b\in T(y)} \Big( f(b) - \sum_{i,j\in E} u^k(i,j)b(i,j) \Big)$
  $v, u^{k+1}$ = UPDATE($u^k, \delta^k, a^k, b^k$)
  if $v = 0$ then return $a^k, b^k$
return $a^K, b^K$

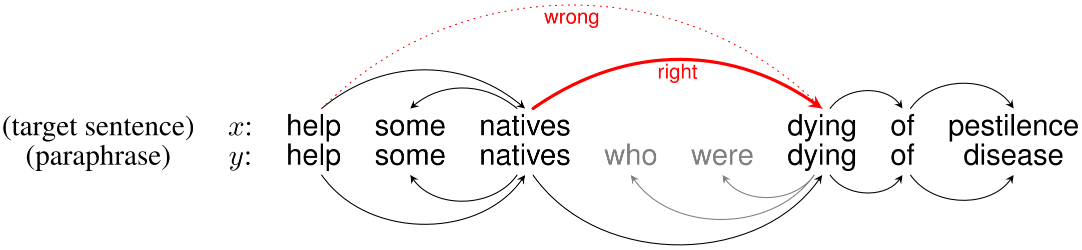
function UPDATE ($u, \delta, a, b$)
  $v = 0, u'(i,j) = 0$ for all $i, j \in E$
  for $i, j \in E$ do
    $u'(i,j) = u(i,j) - \delta(a(i,j) - b(i,j))$
    if $a(i,j) \neq b(i,j)$ then $v = v + 1$
  return $v, u'$
```

Algorithm 1: Dual decomposition for jointly parsing paraphrases pseudocode. E is the set of all possible edges between any pair of aligned words. Given ℓ aligned word pairs, $E = \{1, \ldots, \ell\} \times \{1, \ldots, \ell\}$. $a(i, j)$ is one if the ith aligned word is the head of jth aligned word, zero otherwise. $u(i, j)$ is the dual value of an edge from the ith aligned word to the jth aligned word. δ^k is the step size at kth iteration.

3.2 Constraints via Dual Decomposition

Dual decomposition (Rush and Collins, 2012) is well-suited for finding the MAP assignment to equation (2). When the parse-scoring function f includes an arc-factored component as in McDonald et al. (2005), it is straightforward to incorpo-

[2] When it is clear from context, we omit x and y to simplify notation.



wrong
right
(target sentence) x:
(paraphrase) y:
help some natives dying of pestilence
help some natives who were dying of disease

Figure 1: An illustration of joint parsing a sentence with its paraphrase. Unaligned words are gray. Joint parsing encourages structural similarity and allows the parser to correct the incorrect arc.

rate constraints as shown in Algorithm 1. Essentially, dual decomposition penalizes relations that are different in two trees by adding/subtracting dual values to/from arc scores. When dual decomposition is applied in Figure 1, the arc score of (help $\xrightarrow{x}$ dying) decreases and the score for (natives $\xrightarrow{x}$ dying) increases in the second iteration, which eventually leads the algorithm to favor the latter.

We relax the constraints by employing soft dual decomposition (Anzaroot et al., 2014) and replacing UPDATE in Algorithm 1 with S-UPDATE from Algorithm 2. The problem with the original constraints is they force every pair of alignments to have the same relation even when some aligned words certainly play different syntactic roles. The introduced slack variable lets some alignments have different relations when parsers prefer them. Penalties bounded by the slack tend to help fix incorrect ones and not change correct parses. In this work, we use a single slack variable but it's possible to have a different slack variable for each type of dependency relation.[3]

```
function S-UPDATE ($u, \delta, a, b, s$)
  $v = 0, u'(i,j) = 0$ for all $i, j \in E$
  for $i, j \in E$ do
    $t = \max(u(i,j) - \delta(a(i,j) - b(i,j)), 0)$
    $u'(i,j) = \min(t, s)$
    if $u'(i,j) \neq 0, u'(i,j) \neq s$ then
      $v = v + 1$
  return $v, u'$
```

Algorithm 2: The new UPDATE function of soft dual decomposition for joint parsing. It projects all dual values between 0 and $s \geq 0$. s is a slack variable that allows the algorithm to avoid satisfying some constraints.

3.3 Constraints via Pair-finding

One shortcoming of the dual decomposition approach is that it only applies to parse-scoring functions with an arc-factored component. We introduce another method for estimating equation (2) that applies to all n-best parsers.

Given the n-best parses of x and the m-best parses of y, Algorithm 3 scans through $n \times m$ pairs of trees and chooses the pair that satisfies equation (2). If it finds one pair with $c(a, b) = 0$, then it has found the answer to the equation. Otherwise, it chooses the pair with the smallest $c(a, b)$, breaking ties using the scores of the parses $(f(a) + f(b))$. This algorithm is well suited for finding solutions to the equation but the solutions are not necessarily good trees due to overly hard constraints.

The algorithm often finds bad trees far down the n-best list because it is mainly interested in retrieving pairs of trees that satisfy all constraints. Parsers find such pairs with low scores if they are allowed to search through unrestricted space. To mitigate the problem, we shrink the search space by limiting n. Reducing the search space relies on the fact that higher ranking trees are more likely to be correct than the lower ranking ones. Note that we decrease n because we are interested in recovering the tree of the target sentence, x. m should also be decreased to improve the parse of its paraphrase, y.

3.4 Logistic Regression

One caveat of the previous two proposed methods is that they do not know whether the original or joint parse of x is more accurate. Sometimes they increase agreement between the parses at the cost

[3] We did pilot experiments with multiple slack variables. Since they showed only small improvements and were harder to tune, we stuck with a single slack variable for remaining experiments.

```
function PAIR-FINDING ($a_{1:n}, b_{1:m}$)
  Set $a, b = null, min = \infty, max = -\infty$
  for $i$ = 1 to $n$ do
    for $j$ = 1 to $m$ do
      $v = \text{C}\ (a_i, b_j)$
      $sum = f(a_i) + f(b_j)$
      if $v < min$ then
        $a = a_i, b = b_j$
        $min = v, max = sum$
      else if $v = min, sum > max$ then
        $a = a_i, b = b_j$
        $max = sum$
  return $a, b$

function C ($a, b$)
  $v = 0$
  for $i, j \in E$ do
    if $a(i, j) \neq b(i, j)$ then  $v = v + 1$
  return $v$
```

Algorithm 3: The pair-finding scheme with a constraint function, c. $a_{1:n}$ are the n-best trees of x and $b_{1:m}$ are the m-best of y.

of accuracy. To remedy this problem, we use a classifier (specifically logistic regression) to determine whether a modified tree should be used. The classifier can learn the error patterns produced by each method.

3.4.1 Features

Classifier features use many sources of information: the target sentence x and its paraphrase y, the original and new parses of x (a^0 and a), and the alignments between x and y.

Crossing Edges How many arcs cross when alignments are drawn between paraphrases on a plane divided by the length of x. It roughly measures how many reorderings are needed to change x to y.

Non-projective Edges Whether there are more non-projective arcs in new parse (a) than the original (a^0).

Sentence Lengths Whether the length of x is smaller than that of y. This feature exists because baseline parsers tend to perform better on shorter sentences.

Word Overlaps The number of words in common between x and y normalized by the length of x.

REL	REL + REL$_p$
REL + REL$_p$ + REL$_{gp}$	REL + REL$_{gp}$
CP	CP + CP$_p$
CP + CP$_p$ + CP$_{gp}$	CP + CP$_{gp}$
REL + CP	REL + CP + CP$_p$
REL + CP$_p$ + REL$_{gp}$	

Table 2: Feature templates: REL is the dependency relation between the word and its parent. CP is the coarse part-of-speech tag (first two letters) of a word. p and gp select the parent and grandparent of the word respectively.

Parse Structure Templates The feature generator goes through every word in $\{a^0, a\}$ and sets the appropriate boolean features from Table 2. Features are prefixed by whether they come from a^0 or a.

4 Data and Programs

This section describes our paraphrase dataset, parsers, and other tools used in experiments.

4.1 Paraphrase Dataset

To evaluate the efficacy of the proposed methods of jointly parsing paraphrases, we built a corpus of paraphrases where one sentence in a pair of paraphrases has a gold tree.[4] We randomly sampled 4,000 sentences[5] from four gold treebanks: Brown, British National Corpus (BNC), QuestionBank[6] (QB) and Wall Street Journal (section 24) (Francis and Kučera, 1989; Foster and van Genabith, 2008; Judge et al., 2006; Marcus et al., 1993). A linguist provided a paraphrase for each sampled sentence according to these instructions:

> The paraphrases should more or less convey the same information as the original sentence. That is, the two sentences should logically entail each other. The paraphrases should generally use most of the same words (but not necessarily in the same order). Active/passive transforms, changing words with synonyms, and rephrasings of the same idea are all examples of transformations that paraphrases can use (others can be used too).

[4] The dataset is available upon request.

[5] We use sentences with 6 to 25 tokens to keep the paraphrasing task in the nontrivial to easy range.

[6] With Stanford's updates: http://nlp.stanford.edu/data/QuestionBank-Stanford.shtml

> They can be as simple as just changing a single word in some cases (though, ideally, a variety of paraphrasing techniques would be used).

We also provided 10 pairs of sentences as examples. We evaluate our methods only on the sampled sentences from the gold corpora because the new paraphrases do not include syntactic trees. The data was divided into development and testing sets such that development and testing share the same distribution over the four corpora. Paraphrases were tokenized by the BLLIP tokenizer. See Table 3 for statistics of the dataset.[7]

4.2 Meteor Word Aligner

We use Meteor, a monolingual word aligner developed by Denkowski and Lavie (2014), to find alignments between paraphrases. It uses the exact matches, stems, synonyms, and paraphrases[8] to form these alignments. Because it uses paraphrases, it sometimes aligns multiple words from sentence x to one or more words from sentence y or vice versa. We ignore these multiword alignments because our methods currently only handle single word alignments. In pilot experiments, we also tried using a simple aligner which required exact word matches. Joint parsing with simpler alignments improved parsing accuracy but not as much as Meteor.[9] Thus, all results in Section 5 use Meteor for word alignment. On average across the four corpora, 73% of the tokens are aligned.

4.3 Parsers

We use a dependency and constituency parser for our experiments: RBG and BLLIP. RBG parser (Lei et al., 2014) is a state-of-the-art dependency parser.[10] It is a third-order discriminative dependency parser with low-rank tensors as part of its features. BLLIP (Charniak and Johnson, 2005) is a state-of-the-art constituency parser, which is composed of a generative parser and a discriminative reranker.[11]

To train RBG and BLLIP, we used the standard WSJ training set (sections 2–21, about 40,000 sentences).[12] We also used the self-trained BLLIP parsing model which is trained on an additional two million Gigaword parses generated by the BLLIP parser (McClosky et al., 2006a).

4.4 Logistic Regression

We use the logistic regression implementation from Scikit-learn[13] with hand-crafted features from Section 3.4.1. The classifier decides to whether to keep the parse trees from the joint method. When it decides to disregard them, it returns the parse from the baseline parser. We train a separate classifier for each joint method.

5 Experiments

We ran all tuning and model design experiments on the development set. For the final evaluation, we tuned parameters on the development set and evaluate them on the test set. Constituency trees were converted to basic non-collapsed dependency trees using Stanford Dependencies (De Marneffe et al., 2006).[14] We report unlabeled attachment scores (UAS) for all experiments and labeled attachment scores (LAS) as well in final evaluation, ignoring punctuation. Averages are micro-averages across all sentences.

5.1 Dual Decomposition

Since BLLIP is not arc-factored, these experiments only use RBG. Several parameters need to be fixed beforehand: the slack constant (s), the learning rate (δ), and the maximum number of iterations (K). We set $\delta^0 = 0.1$ and $\delta^k = \frac{\delta^0}{2^t}$ where t is the number of times the dual score has increased (Rush et al., 2010). We choose $K = 20$. These numbers were chosen from pilot studies. The slack variable ($s = 0.5$) was tuned with a grid search on values between 0.1 and 1.5 with interval 0.1. We chose a value that generalizes well across four corpora as opposed to a value that does

[7] The distribution over four corpora is skewed because each corpus has a different number of sentences within length constraints. Samples are collected uniformly over all sentences that satisfy the length criterion.

[8] Here paraphrase means a single/multiword phrase that is semantically similar to another single/multiword.

[9] The pilot was conducted on fewer than 700 sentence pairs before all paraphrases were created. We give Meteor tokenized paraphrases with capitalization. Maximizing accuracy rather than coverage worked better in pilot experiments.

[10] `http://github.com/taolei87/RBGParser`, 'master' version from June 24th, 2014.

[11] `http://github.com/BLLIP/bllip-parser`

[12] RBG parser requires predicted POS tags. We used the Stanford tagger (Toutanova et al., 2003) to tag WSJ and paraphrase datasets. Training data was tagged using 20-fold cross-validation and the paraphrases were tagged by a tagger trained on all of WSJ training.

very well on a single corpus. As shown in Table 4, joint parsing with hard dual decomposition performs worse than independent parsing (RBG). This is expected because hard dual decomposition forces every pair of alignments to form the same relation even when they should not. With relaxed constraints (S-Dual), joint parsing performs significantly better than independent parsing. Soft dual decomposition improves across all domains except for Brown (where it ties).

5.2 Pair-finding

These experiments use the 50-best trees from BLLIP parser. When converting to dependencies, some constituency trees map to the same dependency tree. In this case, trees with lower rankings are dropped. Like joint parsing with hard dual decomposition, joint parsing with unrestricted pair-finding ($n = 50$) allows significantly worse parses to be selected (Table 5). With small n values, pair-finding improves over the baseline BLLIP parser.[15] Experiments with self-trained BLLIP exhibit similar results so we use $n = 2$ for all other experiments. Interestingly, each corpus has a different optimal value for n which suggests we might improve accuracy further if we know the domain of each sentence.

5.3 Logistic Regression

The classifier is trained on sentences where parse scores (UAS) of the proposed methods are higher or lower than those of the baselines[16] from the development set using leave-one-out cross-validation. We use random greedy search to select specific features from the 15 feature templates defined in Section 3.4.1. Features seen fewer than three times in the development are thrown out. Separate regression models are built for three different parsers. The logistic regression classifier uses an L_1 penalty with regularization parameter $C = 1$.

Logistic regression experiments are reported in

[15] Decreasing m did not lead to further improvement and thus we don't report the results of changing m.

[16] We only use sentences with different scores to limit ceiling effects.

Table 6: Effect of using logistic regression on top of each method (UAS). Leave-one-out cross-validation is performed on the development data. +X means augmenting the above system with X.

Table 6. All parsers benefit from employing logistic regression models on top of paraphrase methods. BLLIP experiments show a larger improvement than RBG. This may be because BLLIP cannot use soft constraints so its errors are more pronounced.

5.4 Final Evaluation

We evaluate the three parsers on the test set using the tuned parameters and logistic regression models from above. Joint parsing with paraphrases significantly improves accuracy for all systems (Table 7). Self-trained BLLIP with logistic regression is the most accurate, though RBG with S-Dual provides the most consistent improvements.

Joint parsing without logistic regression (RBG + S-Dual) is more accurate than independent parsing (RBG) overall. With the help of logistic regression, the methods do at least as well as their baseline counterparts on all domains with the exception of self-trained BLLIP on BNC. We believe that the drop on BNC is largely due to noise as our BNC test set is the smallest of the four. As on development, logistic regression does not change the accuracy much over the RBG parser with soft dual decomposition.

Joint parsing provides the largest gains on QuestionBank, the domain with the lowest baseline accuracies. This fits with our goal of using paraphrases for domain adaptation — parsing with paraphrases helps the most on domains furthest from our training data.

5.5 Error analysis

We analyzed the errors from RBG and BLLIP along several dimensions: by dependency label, sentence length, dependency length, alignment status (whether a token was aligned), percentage of tokens aligned in the sentence, and edit distance between the sentence pairs. Most errors are fairly uniformly distributed across these dimensions and indicate general structural improvements when using paraphrases. BLLIP saw a 2.2% improvement for the ROOT relation, though RBG's improvement here was more moderate. For sentence lengths, BLLIP obtains larger boosts for shorter sentences while RBG's are more uniform. RBG gets a 1.4% UAS improvement on longer dependencies (6 or more tokens) while shorter dependencies are more modestly improved by about 0.3-0.5% UAS. Surprisingly, alignment information provides no signal as to whether accuracy improves.

Additionally, we had our annotator label a portion of our dataset with the set of paraphrasing operations employed.[17] While most paraphrasing operations generally improved performance under joint inference, the largest reliable gains came from lexical replacements (e.g., synonyms).

6 Conclusions and Future Work

Our methods of incorporating paraphrases improve parsing across multiple domains for state-of-the-art constituency and dependency parsers. We leverage the fact that paraphrases often express the same semantics with similar syntactic realizations. These provide benefits even on top of self-training, another domain adaptation technique.

Since paraphrases are not available at most times, our methods may seem limited. However, there are several possible use cases. The best case scenario is when users can be directly asked to rephrase a question and provide a paraphrase. For instance, question answering systems can ask users to rephrase questions when an answer is marked as wrong by users. Another option is to use crowdsourcing to quickly create a paraphrase corpus (Negri et al., 2012; Burrows et al., 2013; Tschirsich and Hintz, 2013). As part of future work, we plan to integrate existing larger paraphrase resources, such as WikiAnswers (Fader et al., 2013) and PPDB (Ganitkevitch et al., 2013). WikiAnswers provides rough equivalence classes of questions. PPDB includes phrasal and syntactic alignments which could supplement our existing alignments or be used as proxies for paraphrases.

[17] See the extended version of this paper for more information about this task and its results.

Table 7: Final evaluation on testing data. Numbers are unlabeled attachment score (labeled attachment score). +X indicates extending the above system with X. BLLIP-ST is BLLIP using the self-trained model. Coloring indicates a significant difference over baseline ($p < 0.01$).

While these resources are noisy, the quantity of data may provide additional robustness. Lastly, integrating our methods with paraphrase detection or generation systems could help provide paraphrases on demand.

There are many other ways to extend this work. Poor alignments are one of the larger sources of errors and improving alignments could help dramatically. One simple extension is to use multiple paraphrases and their alignments instead of just one. More difficult would be to learn the alignments jointly while parsing and adaptively learn how alignments affect syntax. Our constraints can only capture certain types of paraphrase transformations currently and should be extended to understand common tree transformations for paraphrases, as in (Heilman and Smith, 2010). Finally, and perhaps most importantly, our methods apply only at inference time. We plan to investigate methods which use paraphrases to augment parsing models created at train time.

Acknowledgments

We would like to thank Eugene Charniak for the idea of using paraphrases to improve parsing, our anonymous reviewers for their valuable feedback, Karen Ingraffea for constructing and classifying the paraphrase corpus, Dave Buchanan and Will Headden for last minute paper reading, the DeepQA team at IBM for feedback and support on the project, and Mohit Bansal and Micha Elsner for helpful discussions.

Abstract

This paper investigates the problem of cross-lingual dependency parsing, aiming at inducing dependency parsers for low-resource languages while using only training data from a resource-rich language (e.g. English). Existing approaches typically don't include lexical features, which are not transferable across languages. In this paper, we bridge the *lexical feature gap* by using distributed feature representations and their composition. We provide two algorithms for inducing cross-lingual distributed representations of words, which map vocabularies from two different languages into a common vector space. Consequently, both lexical features and non-lexical features can be used in our model for cross-lingual transfer.

Furthermore, our framework is able to incorporate additional useful features such as cross-lingual word clusters. Our combined contributions achieve an average relative error reduction of 10.9% in labeled attachment score as compared with the delexicalized parser, trained on English universal treebank and transferred to three other languages. It also significantly outperforms McDonald et al. (2013) augmented with projected cluster features on identical data.

1 Introduction

Dependency Parsing has been one of NLP's longstanding central problems. The majority of work on dependency parsing has been dedicated to resource-rich languages, such as English and Chinese. For these languages, there exist large-scale annotated treebanks that can be used for supervised training of dependency parsers. However, for most of the languages in the world, there are few or even no labeled training data for parsing, and it is labor intensive and time-consuming to manually build treebanks for all languages. This fact has given rise to a number of research on unsupervised methods (Klein and Manning, 2004), annotation projection methods (Hwa et al., 2005), and model transfer methods (McDonald et al., 2011) for predicting linguistic structures. In this study, we focus on the model transfer methods, which attempt to build parsers for low-resource languages by exploiting treebanks from resource-rich languages.

The major obstacle in transferring a parsing system from one language to another is the lexical features, e.g. words, which are not directly transferable across languages. To solve this problem, McDonald et al. (2011) build a delexicalized parser - a parser that only has non-lexical features. A delexicalized parser makes sense in that POS tag features are significantly predictive for unlabeled dependency parsing. However, for labeled dependency parsing, especially for semantic-oriented dependencies like Stanford-type dependencies (De Marneffe et al., 2006; De Marneffe and Manning, 2008), these non-lexical features are not predictive enough. Täckström et al. (2012) propose to learn cross-lingual word clusters from multilingual paralleled unlabeled data through word alignments, and apply these clusters as features for semi-supervised delexicalized parsing. Word clusters can be thought as a kind of coarse-grained representations of words. Thus, this approach partially fills the gap of lexical features in cross-lingual learning of dependency parsing.

This paper proposes a novel approach for cross-lingual dependency parsing that is based on pure distributed feature representations. In contrast to

Beijing, China, July 26-31, 2015.

the discrete lexical features used in traditional dependency parsers, distributed representations map symbolic features into a continuous representation space, that can be shared across languages. Therefore, our model has the ability to utilize both lexical and non-lexical features naturally. Specifically, our framework contains two primary components:

- A neural network-based dependency parser. We expect a non-linear model for dependency parsing in our study, because distributed feature representations are shown to be more effective in non-linear architectures than in linear architectures (Wang and Manning, 2013). Chen and Manning (2014) propose a transition-based dependency parser using a neural network architecture, which is simple but works well on several datasets. Briefly, this model simply replaces the predictor in transition-based dependency parser with a well-designed neural network classifier. We will provide explanations for the merits of this model in Section 3, as well as how we adapt it to the cross-lingual task.

- Cross-lingual word representation learning. The key to filling the *lexical feature gap* is to project the representations of these features from different languages into a common vector space, preserving the translational equivalence. We will study and compare two approaches of learning cross-lingual word representations in Section 4. The first approach is robust projection, and the second approach is based on canonical correlation analysis. Both approaches are simple to implement and are scalable to large data.

We evaluate our model on the universal multilingual treebanks (McDonald et al., 2013). Case studies include transferring from English to German, Spanish and French. Experiments show that by incorporating lexical features, the performance of cross-lingual dependency parsing can be improved significantly. By further embedding cross-lingual cluster features (Täckström et al., 2012), we achieve an average relative error reduction of 10.9% in labeled attachment score (LAS), as compared with the delexicalized parsers. It also significantly outperforms McDonald et al. (2013) augmented with cluster features on identical data. The original major contributions of this paper include:

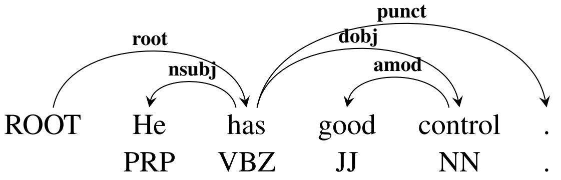

Figure 1: An example labeled dependency tree.

- We propose a novel and flexible cross-lingual learning framework for dependency parsing based on distributed representations, which can effectively incorporate both lexical and non-lexical features.

- We present two novel and effective approaches for inducing cross-lingual word representations, that bridge the *lexical feature gap* in cross-lingual dependency parsing.

- We show that cross-lingual word cluster features can be effectively embedded into our model, leading to significant additive improvements.

2 Background

2.1 Dependency Parsing

Given an input sentence $\mathbf{x} = w_0 w_1 ... w_n$, the goal of dependency parsing is to build a dependency tree (Figure 1), which can be denoted by $\mathbf{d} = \{(h, m, l) : 0 \leq h \leq n; 0 < m \leq n, l \in \mathcal{L}\}$. (h, m, l) indicates a directed arc from the head word w_h to the modifier w_m with a dependency label l, and $\mathcal{L}$ is the label set. The mainstream models that have been proposed for dependency parsing can be described as either graph-based models or transition-based models (McDonald and Nivre, 2007).

Graph-based models view the parsing problem as finding the highest scoring tree from a directed graph. The score of a dependency tree is typically factored into scores of some small structures (e.g. arcs) depending on the order of a model. Transition-based models aim to predict a transition sequence from an initial parser state to some terminal states, depending on the parsing history. This approach has a lot of interest since it is fast (linear time) and can incorporate rich non-local features (Zhang and Nivre, 2011).

It has been considered that simple transition-based parsing using greedy decoding and local training is not as accurate as graph-based parsers or transition-based parsers with beam-search and global training (Zhang and Clark, 2011). Recently, Chen and Manning (2014) show that greedy transition-based parsers can be greatly improved by using a well-designed neural network architecture. This approach can be considered as a new paradigm of parsing, in that it is based on pure distributed feature representations. In this study, we choose Chen and Manning's architecture to build our basic dependency parsing model.

2.2 Distributed Representations for NLP

In recent years, there has been a trend in the NLP research community of learning distributed representations for different natural language units, from morphemes, words and phrases, to sentences and documents. Using distributed representations, these symbolic units are embedded into a low-dimensional and continuous space, thus it is often referred to as *embeddings*.[1]

In general, there are two major ways of applying distributed representations to NLP tasks. First, they can be fed into existing supervised NLP systems as augmented features in a semi-supervised manner. This kind of approach has been adopted in a variety of applications (Turian et al., 2010). Despite its simplicity and effectiveness, it has been shown that the potential of distributed representations cannot be fully exploited in the generalized linear models which are adopted in most of the existing NLP systems (Wang and Manning, 2013). One remedy is to discretize the distributed feature representations, as studied in Guo et al. (2014). However, we believe that a non-linear system, e.g. a neural network, is a more powerful and effective solution. Some decent progress has already been made in this paradigm of NLP on various tasks (Collobert et al., 2011; Chen and Manning, 2014; Sutskever et al., 2014).

3 Transition-based Dependency Parsing: A Neural Network Architecture

In this section, we first briefly describe transition-based dependency parsing and the *arc-standard* parsing algorithm. Then we revisit the neural network architecture for transition-based dependency parsing proposed by Chen and Manning (2014).

As discussed in Section 2.1, transition-based parsing aims to predict a transition sequence from an initial parser state to the terminal state. Each state is conventionally regarded as a *configuration*, which typically consists of a *stack* S, a *buffer* B, and a partially derived forest, i.e. a set of dependency arcs A. Given an input word sequence $\mathbf{x} = w_1 w_2, ..., w_n$, the initial *configuration* can be represented as a tuple: $\langle [w_0]_S, [w_1 w_2, ..., w_n]_B, \varnothing \rangle$, and the terminal *configuration* is $\langle [w_0]_S, []_B, A \rangle$, where w_0 is a pseudo word indicating the *root* of the whole dependency tree. We consider the *arc-standard* algorithm (Nivre, 2004) in this paper, which defines three types of transition actions: LEFT-ARC(l), RIGHT-ARC(l), and SHIFT, l is the dependency label.

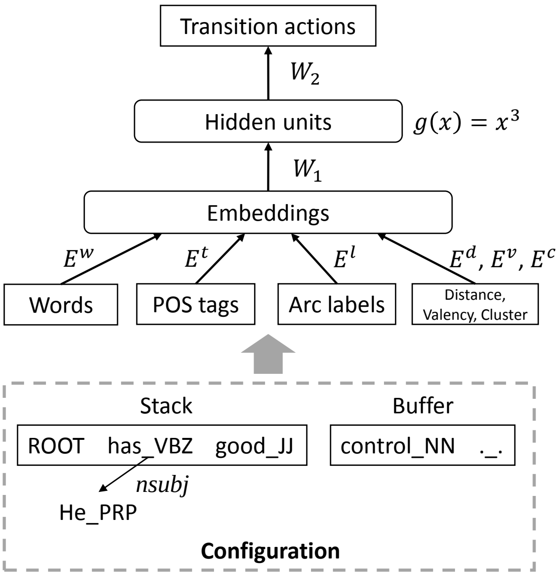

Figure 2: Neural network model for dependency parsing. The *Cluster* features are introduced in Section 5.2.

The typical approach for greedy *arc-standard* parsing is to build a multi-class classifier (e.g., SVM, MaxEnt) of predicting the transition action given a feature vector extracted from a specific *configuration*. While conventional feature engineering suffers from the problem of *sparsity*, *incompleteness* and *expensive feature computation* (Chen and Manning, 2014), the neural network model provides a potential solution.

The architecture of the neural network-based dependency parsing model is illustrated in Figure 2. Primarily, three types of information are extracted from a *configuration* in Chen and Manning's model: word features, POS features and label features respectively. In this study, we add *distance* features indicating the distance between two items, and *valency* features indicating the number of children for a given item (Zhang and Nivre,

[1] In this paper, these two terms are used interchangeably.

Word features
$E^w_{S_i}, E^w_{B_i}, i = 0, 1, 2$
$E^w_{lc1(S_i)}, E^w_{rc1(S_i)}, E^w_{lc2(S_i)}, E^w_{rc2(S_i)}, i = 0, 1$
$E^w_{lc1(lc1(S_i))}, E^w_{rc1(rc1(S_i))}, i = 0, 1$
POS features
$E^t_{S_i}, E^t_{B_i}, i = 0, 1, 2$
$E^t_{lc1(S_i)}, E^t_{rc1(S_i)}, E^t_{lc2(S_i)}, E^t_{rc2(S_i)}, i = 0, 1$
$E^t_{lc1(lc1(S_i))}, E^t_{rc1(rc1(S_i))}, i = 0, 1$
Label features
$E^l_{lc1(S_i)}, E^l_{rc1(S_i)}, E^l_{lc2(S_i)}, E^l_{rc2(S_i)}, i = 0, 1$
$E^l_{lc1(lc1(S_i))}, E^l_{rc1(rc1(S_i))}, i = 0, 1$
Distance: $E^d_{\langle S_0, S_1 \rangle}, E^d_{\langle S_0, B_0 \rangle}$
Valency: $E^{lv}_{S_0}, E^{lv}_{S_1}, E^{rv}_{S_1}$

Table 1: Feature templates of the neural network parsing model. $E^w_p, E^t_p, E^l_p, E^d_p, E^{lv}_p, E^{rv}_p$ indicate the $\{$word, POS, label, distance, left/right valency$\}$ embeddings of the element at position p, correspondingly. $lc1$ / $rc1$ is the first child in the left / right, $lc2$ / $rc2$ is the second child in the left / right. S_i and B_i refer to the i^{th} elements respectively in the *stack* and *buffer*.

2011). All of these features are projected to an embedding layer via corresponding embedding matrices, which will be estimated through the training process. The complete feature templates used in our system are shown in Table 1. Then, feature compositions are performed at the hidden layer via a **cube activation function**: $g(x) = x^3$.

The cube activation function can be viewed as a special case of low-rank tensor. Formally, $g(x)$ can be expanded as:

$$g(w_1 x_1 + ... + w_m x_m + b) =$$
$$\sum_{i,j,k} (w_i w_j w_k) x_i x_j x_k + \sum_{i,j} b(w_i w_j) x_i x_j + ...$$

If we treat the bias term as $b \times x_0$ where $x_0 = 1$, then the weight corresponding to each feature combination $x_i x_j x_k$ is $w_i w_j w_k$, which is exactly the same as a rank-1 component tensor in the low-rank form using CP tensor decomposition (Cao and Khudanpur, 2014). Consequently, the cube activation function implicitly derives full feature combinations. An advantage of the cube activation function is that it is flexible for adding extra features to the input. In fact, we can add as many features as possible to the input layer to improve the parsing accuracy. We will show in Section 5.2 that the Brown cluster features can be readily incorporated into our model.

Cross-lingual Transfer. The idea of cross-lingual transfer using the parser we examined above is straightforward. In contrast to traditional approaches that have to discard rich lexical features (delexicalizing) when transferring models from one language to another, our model can be transferred using the full model trained on the source language side, i.e. English.

Since the non-lexical feature (POS, label, distance, valency) embeddings are directly transferable between languages,[2] the key component of this framework is the cross-lingual learning of lexical feature embeddings, i.e. word embeddings. Once the cross-lingual word embeddings are induced, we first learn a dependency parser at the source language side. After that, the parser will be directly used for parsing target language data.

4 Cross-lingual Word Representation Learning

Prior to introducing our approaches for cross-lingual word representation learning, we briefly review the basic model for learning monolingual word embeddings, which constitutes a subprocedure of the cross-lingual approaches.

4.1 Continuous Bag-of-Words Model

Various approaches have been studied for learning word embeddings from large-scale plain texts. In this study, we consider the Continuous Bag-of-Words (CBOW) model (Mikolov et al., 2013) as implemented in the open-source toolkit word2vec.[3] The basic principle of the CBOW model is to predict each individual word in a sequence given the bag of its context words within a fixed window size as input, using a log-linear classifier. This model avoids the non-linear transformation in hidden layers, and hence can be trained with high efficiency.

With large window size, grouped words using the resulting word embeddings are more topically similar; whereas with small window size, the grouped words will be more syntactically similar. So we set the window size to 1 in our parsing task.

Next, we introduce our approach for inducing bilingual word embeddings. In general, we expect our bilingual word embeddings to preserve translational equivalences. For example, “cooking” (English) should be close to its translation: “kochen” (German) in the embedding space.

[2] POS tags are language-independent here since we use the universal POS tags (Section 5).

[3] `http://code.google.com/p/word2vec/`

4.2 Robust Alignment-based Projection

Our first method for inducing cross-lingual word embeddings has two stages. First, we learn word embeddings from a source language (S) corpora as in the monolingual case, and then project the monolingual word embeddings to a target language (T), based on word alignments.

Given a sentence-aligned parallel corpus $\mathcal{D}$, we first conduct unsupervised bidirectional word alignment, and then collect an alignment dictionary. Specifically, in each word-aligned sentence pair of $\mathcal{D}$, we keep all alignments with conditional alignment probability exceeding a threshold $\delta = 0.95$ and discard the others. Specifically, let $\mathcal{A}^{T|S} = \{(w_i^T, w_j^S, c_{i,j}), i = 1,2,...,N_T; j = 1,2,...,N_S\}$ be the alignment dictionary, where $c_{i,j}$ is the number of times when the i^{th} target word w_i^T is aligned to the j^{th} source word w_j^S. N_S and N_T are vocabulary sizes. We use the shorthand $(i,j) \in \mathcal{A}^{T|S}$ to denote a word pair in $\mathcal{A}^{T|S}$. The projection can be formalized as the weighted average of the embeddings of translation words:

$$v(w_i^T) = \sum_{(i,j)\in\mathcal{A}^{T|S}} \frac{c_{i,j}}{c_{i,\cdot}} \cdot v(w_j^S) \tag{1}$$

where $c_{i,\cdot} = \Sigma_j c_{i,j}$, $v(w)$ is the embedding of w.

Obviously, the simple projection method has one drawback, it only assigns word embeddings for those target language words that occur in the word aligned data, which is typically smaller than the monolingual datasets. Therefore, in order to improve the robustness of projection, we utilize a morphology-inspired mechanism, to propagate embeddings from in-vocabulary words to out-of-vocabulary (OOV) words. Specifically, for each OOV word w_{oov}^T, we extract a list of candidate words that is similar to it in terms of *edit distance*, and then set the averaged vector as the embedding of w_{oov}^T. Formally,

$$\begin{aligned} &v(w_{oov}^T) = \underset{w'\in C}{Avg}(v(w')) \\ &\text{where } C = \{w|EditDist(w_{oov}^T, w) \le \tau\} \end{aligned} \tag{2}$$

To reduce noise, we choose a small *edit distance* threshold $\tau = 1$.

4.3 Canonical Correlation Analysis

The second approach we consider is similar to Faruqui and Dyer (2014), which use CCA to improve monolingual word embeddings with multilingual correlation. CCA is a way of measuring the linear relationship between multidimensional variables. For two multidimensional variables, CCA aims to find two projection matrices to map the original variables to a new basis (lower-dimensional), such that the correlation between the two variables is maximized.

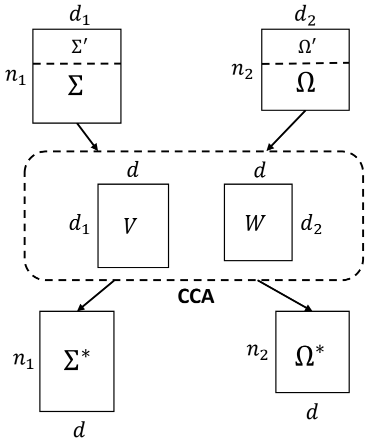

Figure 3: CCA for cross-lingual word representation learning.

Let's treat CCA as a blackbox here, and see how to apply CCA for inducing bilingual word embeddings. Suppose there are already two pre-trained monolingual word embeddings (e.g. English and German): $\Sigma \in \mathbb{R}^{n_1 \times d_1}$ and $\Omega \in \mathbb{R}^{n_2 \times d_2}$. At the first step, we extract a one-to-one alignment dictionary $\mathcal{D} : \Sigma' \leftrightarrow \Omega'$ from the alignment dictionary $\mathcal{A}^{S|T}$.[4] Here, $\Sigma' \subseteq \Sigma$, indicating that every word in Σ' is translated to one word in $\Omega' \subseteq \Omega$, and vice versa.

The process is illustrated in Figure 3. Denoting the dimension of resulting word embeddings by $d \le min(d_1, d_2)$. First, we derive two projection matrices $V \in \mathbb{R}^{d_1 \times d}, W \in \mathbb{R}^{d_2 \times d}$ respectively for Σ' and Ω' using CCA:

$$V, W = CCA(\Sigma', \Omega') \tag{3}$$

Then, V and W are used to project the entire vocabulary Σ and Ω:

$$\Sigma^* = \Sigma V, \quad \Omega^* = \Omega W \tag{4}$$

where $\Sigma^* \in \mathbb{R}^{n_1 \times d}$ and $\Omega^* \in \mathbb{R}^{n_2 \times d}$ are the resulting word embeddings for our cross-lingual task.

Contrary to the projection approach, CCA assigns embeddings for every word in the monolingual vocabulary. However, one potential limitation is that CCA assumes linear transformation of word embeddings, which is difficult to satisfy.

[4] $\mathcal{A}^{T|S}$ is also worth trying, but we observed slight performance degradation in our experimental setting.

Note that both approaches can be generalize to lower-resource languages where parallel bitexts are not available. In that way, the dictionary $\mathcal{A}$ can be readily obtained either using bilingual lexicon induction approaches (Koehn and Knight, 2002; Mann and Yarowsky, 2001; Haghighi et al., 2008), or from resources like Wiktionary[5] and Panlex.[6]

5 Experiments

5.1 Data and Settings

For the pre-training of word embeddings, we use the WMT-2011 monolingual news corpora for English, German and Spanish.[7] For French, we combined the WMT-2011 and WMT-2012 monolingual news corpora.[8] We obtained the word alignment counts using the *fast-align* toolkit in cdec (Dyer et al., 2010) from the parallel news commentary corpora (WMT 2006-10) combined with the Europarl corpus for English-{German, Spanish, French}.[9]

For the training of the neural network dependency parser, we set the number of hidden units to 400. The dimension of embeddings for different features are shown in Table 2.

	Word	POS	Label	Dist.	Val.	Cluster
Dim.	50	50	50	5	5	8

Table 2: Dimensions of feature embeddings.

Adaptive stochastic gradient descent (AdaGrad) (Duchi et al., 2011) is used for optimization. For the CCA approach, we use the implementation of Faruqui and Dyer (2014). The dimensions of the monolingual embeddings (d_1, d_2) and the resulting bilingual embeddings are set to 50 equally.

We employ the universal dependency treebanks proposed by McDonald et al. (2013) for a reliable evaluation of our approach for cross-lingual dependency parsing. The universal multilingual treebanks are annotated using the universal POS tagset (Petrov et al., 2011) which contains 12 POS tags, as well as the universal dependencies which contains 42 relations. We follow the standard split of the treebanks for every language (DE, ES, and FR).[10]

5.2 Baseline Systems

We compare our approach with three systems. For the first baseline, we evaluate the delexicalized transfer of our parser [DELEX], in which we only use non-lexical features.

We also compare our approach with the delexicalized parser in McDonald et al. (2013) [McD13], who used a perceptron-trained transition-based parser with a beam of size 8, along with rich non-local features (Zhang and Nivre, 2011).

Furthermore, we augment cross-lingual word clusters to the perceptron-based delexicalized parser, as proposed in Täckström et al. (2012). We use the same alignment dictionary as described in Section 4 to induce the cross-lingual word clusters. We re-implement the PROJECTED cluster approach in Täckström et al. (2012), which assigns a target word to the cluster with which it is most often aligned:

$$c(w_i^T) = \arg\max_{k} \sum_{(i,j)\in\mathcal{A}^{T|S}} c_{i,j} \cdot \mathbb{1}[c(w_j^S) = k]$$

This method also has the drawback that words that do not occur in the alignment dictionary (OOV) cannot be assigned a cluster. Therefore, we use the same strategy as described in Section 4.2 to find the most likely clusters for the OOV words. Instead of the clustering model of Uszkoreit and Brants (2008), we use Brown clustering (Brown et al., 1992) to induce hierarchical word clusters, where each word is represented as a bit-string. We use the same word cluster feature templates from Täckström et al. (2012), and set the number of Brown clusters to 256.

5.3 Experimental Results

All of the parsing models are trained using the development data from English for early-stopping. Table 3 lists the results of the cross-lingual transfer experiments for dependency parsing. Table 4 further summarizes each of the experimental gains detailed in Table 3.

Our delexicalized system obtains slightly lower performance than those reported in McDonald et al. (2013) (McD13), because we're using

[5] `https://www.wiktionary.org/`

[6] `http://panlex.org/`

[7] `http://www.statmt.org/wmt11/`

[8] `http://www.statmt.org/wmt12/`

[9] `http://www.statmt.org/europarl/`

[10] `http://code.google.com/p/uni-dep-tb/`. Before this dataset was carried out, the CoNLL multilingual dependency treebanks (Buchholz and Marsi, 2006) were often used for evaluation. However, the major problem is that the dependency annotations vary for different languages (e.g. the choice of lexical versus functional head), which makes it impossible to evaluate the LAS.

greedy decoding and local training. Our re-implementation of (McDonald et al., 2013) attains comparable performance with McD13.

For all languages we consider in this study, by using cross-lingual word embeddings either from alignment-based projection or CCA, we obtain statistically significant improvements against the delexicalized system, both in UAS and LAS.

Interestingly, we notice that PROJ consistently performs better than CCA by a significant margin, and is comparable to McD13*+Cluster. We will give further analysis to this observation in Section 5.3.1 and 5.3.2.

Our framework is flexible for incorporating richer features simply by embedding them into continuous vectors. Thus we further embed the cross-lingual word cluster features into our model, together with the proposed cross-lingual word embeddings. The cluster feature template used here is similar to the POS tag feature templates:

Cluster features
$E^c_{S_i}, E^c_{B_i}, i = 0, 1, 2$
$E^c_{lc1(S_i)}, E^c_{rc1(S_i)}, E^c_{lc2(S_i)}, E^c_{rc2(S_i)}, i = 0, 1$
$E^c_{lc1(lc1(S_i))}, E^c_{rc1(rc1(S_i))}, i = 0, 1$

Table 5: Word cluster feature templates.

As shown in Table 3, additive improvements are obtained for both PROJ and CCA. Compared with our delexicalized system, the relative error is reduced by up to 13.1% in UAS, and up to 12.6% in LAS. The combined system further outperforms McD13* augmented with cluster features significantly .

5.3.1 Effect of Robust Projection

Since in both PROJ and the induction of cross-lingual word clusters, we use *edit distance* measure for OOV words, we would like to see how this affects the performance of parsing.

Intuitively, higher coverage of projected words in the test dataset should promote the parsing performance more. To verify this, we further conduct experiments under both settings using the PROJ+Cluster model. Results are shown in Table 6. Improvements are observed for all languages when using robust projection with *edit distance* measure, especially for FR, where the highest coverage gain is obtained by robust projection.

5.3.2 Fine-tuning of Word Embeddings

Another reason for the effectiveness of PROJ over CCA lies in the fine-tuning of word embeddings while training the parser.

		Simple	Robust	Δ
DE	coverage	91.37	94.70	+3.33
	UAS	59.74	60.35	+0.61
	LAS	50.84	51.54	+0.70
ES	coverage	94.51	96.67	+2.16
	UAS	70.97	71.90	+0.93
	LAS	61.34	62.28	+0.94
FR	coverage	90.83	97.60	+6.77
	UAS	71.17	72.93	+1.76
	LAS	61.72	63.12	+1.40

Table 6: Effect of robust projection.

CCA can be viewed as a joint method for inducing cross-lingual word embeddings. When training the source language dependency parser with cross-lingual word embeddings derived from CCA, the EN word embeddings should be fixed. Otherwise, the translational equivalence will be broken. However, for PROJ, there is no such limitation. Word embeddings can be updated as other non-lexical feature embeddings, in order to obtain a more accurate dependency parser. We refer to this procedure as a *fine-tuning* process to the word embeddings. To verify the benefits of *fine-tuning*, we conduct experiments to see relative loss if word embeddings are fixed while training. Results are shown in Table 7, which indicates that *fine-tuning* indeed offers considerable help.

		Fix	Fine-tune	Δ
DE	UAS	59.74	60.07	+0.33
	LAS	49.44	49.94	+0.50
ES	UAS	70.10	71.42	+1.32
	LAS	61.31	61.76	+0.45
FR	UAS	70.65	71.36	+0.71
	LAS	60.69	61.50	+0.81

Table 7: Effect of fine-tuning word embeddings.

5.4 Compare with Existing Bilingual Word Embeddings

In this section, we compare our bilingual embeddings with several previous approaches in the context of dependency parsing. To the best of our knowledge, this is the first work on evaluation of bilingual word embeddings in syntactic tasks. The approaches we consider include the multi-task learning approach (Klementiev et al., 2012) [MTL], the bilingual auto-encoder approach (Chandar et al., 2014) [BIAE], the bilingual compositional vector model (Hermann and Blunsom, 2014) [BICVM], and the bilingual bag-of-words approach (Gouws et al., 2014) [BILBOWA].

For MTL and BIAE, we adopt their released word embeddings directly due to the inefficiency of training.[13] For BICVM and BILBOWA, we rerun their systems on the same dataset as our previous experiments.[14] Results are summarized in Table 8. CCA and PROJ consistently outperforms all other approaches in all languages, and PROJ performs the best. The inferior performance of MTL and BIAE is partly due to the low word coverage. For example, they cover only 31% of words in the universal DE test treebank, whereas the CCA and PROJ covers over 70%. Moreover, BIAE, BICVM and BILBOWA are optimized using semantic-related objectives. So we suggest that they are probably not well fit for syntactic tasks.

It is worth noting that we don't assume/require bilingual parallel data in CCA and PROJ. What we need in practice is a bilingual lexicon for each paired languages. This is especially important for generalizing our approaches to lower-resource languages, where parallel texts are not available.

6 Related Studies

Existing approaches for cross-lingual dependency parsing can be divided into three categories: cross-lingual annotation projection methods, jointly modeling methods and cross-lingual representation learning methods.

The cross-lingual annotation projection method is first proposed in Yarowsky et al. (2001) for shallower NLP tasks (POS tagging, NER, etc.). The central idea is to project the syntactic annotations from a resource-rich language to the target language through word alignments, and then train a supervised parser on the projected noisy annotations (Hwa et al., 2005; Smith and Eisner, 2009; Zhao et al., 2009; Jiang et al., 2011; Tiedemann, 2014; Tiedemann, 2015). Noises and errors introduced by the word alignment and annotation projection processes can be reduced with robust projection methods by using graph-based label propagation (Das and Petrov, 2011; Kim and Lee, 2012), or by incorporating auxiliary resources (Kim et al., 2012; Khapra et al., 2010).

The jointly modeling methods integrates the monolingual grammar induction with bilingually-projected dependency information (Liu et al., 2013), or linguistic constraints via posterior

[13] The MTL embeddings are normalized before training.

[14] BICVM only uses the bilingual parallel dataset.

	DE		ES		FR	
	UAS	LAS	UAS	LAS	UAS	LAS
MTL (Klementiev et al., 2012)‡	57.70	47.13	68.04	58.78	67.66	57.30
BIAE (Chandar et al., 2014)‡	53.74	43.68	58.81	46.66	60.10	49.47
BICVM (Hermann and Blunsom, 2014)	56.30	46.99	67.78	58.08	69.13	58.13
BILBOWA (Gouws et al., 2014)	51.65	41.83	65.02	54.35	63.35	51.65
CCA	59.42	49.32	68.87	59.65	69.58	59.50
PROJ	**60.07**	**49.94**	**71.42**	**61.76**	**71.36**	**61.55**

Table 8: Comparison with existing bilingual word embeddings. ‡For MTL and BIAE, we use their released bilingual word embeddings.

regularization (Ganchev et al., 2009), manually constructed universal dependency parsing rules (Naseem et al., 2010) and manually specified typological features (Naseem et al., 2012). Besides dependency parsing, the joint modeling method has also been applied for other multilingual NLP tasks, including NER (Che et al., 2013; Wang and Manning, 2014), SRL (Zhuang and Zong, 2010; Titov and Klementiev, 2012) and WSD (Guo and Diab, 2010).

The cross-lingual representation learning method aims at building connections across different languages by inducing language-independent feature representations. After that, a parser can be trained at the source-language side within the induced feature space, and directly be applied to the target language. Typical approaches include cross-lingual word clustering (Täckström et al., 2012) which is employed in this paper as a baseline, projection features (Durrett et al., 2012). Xiao and Guo (2014) learns cross-lingual word embeddings and apply them with MSTParser for linguistic transfer, which inspires this work.

It is worth mentioning that remarkable results on the universal dependency treebanks have been achieved by using annotation projection method (Tiedemann, 2014), treebank translation method (Tiedemann and Nivre, 2014), and distribution transferring method (Ma and Xia, 2014). Unlike our approach, all of these methods involve training a parser at the target language side. Parallel bitexts are required in these methods, which limits their scalability to lower-resource languages. That said, these methods have the advantage that they are capable of capturing some language-specific syntactic patterns which our approach cannot.[15] These two kinds of approaches are complementary, and can be integrated to push the performance further.

7 Conclusion

This paper proposes a novel framework based on distributed representations for cross-lingual dependency parsing. Two algorithms are proposed for the induction of cross-lingual word representations: robust projection and CCA, which bridge the *lexical feature gap*.

Experiments show that by using cross-lingual word embeddings derived from either approach, the transferred parsing performance can be improved significantly against the delexicalized system. A notable observation is that our projection method performs significantly better than CCA, a joint method. Additionally, our framework is flexibly able to incorporate the cross-lingual word cluster features, with further significant gains in each use. The combined system significantly outperforms the delexicalized system on all languages, by an average of 10.9% error reduction on LAS, and further significantly outperforms McDonald et al. (2013) augmented with projected cluster features.[16]

Acknowledgments

We are grateful to Manaal Faruqui for providing the bilingual resources. We thank Ryan McDonald for pointing out the evaluation issue in the experiment. We also thank Sharon Busching for the proofreading and the anonymous reviewers for the insightful comments and suggestions. [15] For example, in Spanish and French, adjectives often appears after nouns, thus forming a right-directed arc labeled by *amod*, whereas in English, the *amod* arcs are mostly left-directed.

Can Natural Language Processing Become Natural Language Coaching?

Abstract

How we teach and learn is undergoing a revolution, due to changes in technology and connectivity. Education may be one of the best application areas for advanced NLP techniques, and NLP researchers have much to contribute to this problem, especially in the areas of learning to write, mastery learning, and peer learning. In this paper I consider what happens when we convert natural language processors into natural language coaches.

1 Why Should You Care, NLP Researcher?

There is a revolution in learning underway. Students are taking Massive Open Online Courses as well as online tutorials and paid online courses. Technology and connectivity makes it possible for students to learn from anywhere in the world, at any time, to fit their schedules. And in today's knowledge-based economy, going to school only in one's early years is no longer enough; in future most people are going to need continuous, lifelong education.

Students are changing too — they expect to interact with information and technology. Fortunately, pedagogical research shows significant benefits of active learning over passive methods. The modern view of teaching means students work actively in class, talk with peers, and are coached more than graded by their instructors.

In this new world of education, there is a great need for NLP research to step in and help. I hope in this paper to excite colleagues about the possibilities and suggest a few new ways of looking at them. I do not attempt to cover the field of language and learning comprehensively, nor do I claim there is no work in the field. In fact there is quite a bit, such as a recent special issue on language learning resources (Sharoff et al., 2014), the long running ACL workshops on Building Educational Applications using NLP (Tetreault et al., 2015), and a recent shared task competition on grammatical error detection for second language learners (Ng et al., 2014). But I hope I am casting a few interesting thoughts in this direction for those colleagues who are not focused on this particular topic.

2 How Awkward

Perhaps the least useful feedback that an instructor writes next to a block of prose on a learner's essay is `'awkward'`. We know what this means: something about this text does not read fluently. But this is not helpful feedback; if the student knew how to make the wording flow, he or she would have written it fluently in the first place! Useful feedback is *actionable*: it provides steps to take to make improvements.

A challenge for the field of NLP is how to build writing *tutors* or *coaches* – as opposed to *graders* or *scorers*. There is a vast difference between a tool that performs an assessment of writing and one that coaches students to help them as they are attempting to write.

Current practice uses the output of scorers to give students a target to aim for: revise your essay to get a higher score. An alternative is to design a system that watches alongside a learner as they write an essay, and coaches their work at all levels of construction – phrase level, clause level, sentence level, discourse level, paragraph level, and essay level.

Grammar checking technology has been excellent for years now (Heidorn, 2000), but instead of just showing the right answer as grammar checkers do, a grammar coach should give hints and scaffolding the way a tutor would – not giving the answer explicitly, but showing the path and letting the learner fill in the missing information. When the learner makes incorrect choices, the parser

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1245–1252,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

can teach principles and lessons for the conceptual stage that the learner is currently at. Different grammars could be developed for learners at different competency levels, as well as for different first-second language pairings in the case of second language learning.

This suggests a different approach for building a parser than what is the current standard. I am not claiming that this has not been suggested in the past; for instance Schwind (1988) designed a parser to explain errors to learners. However, because of the renewed interest in technology for teaching, this may be a pivotal time to reconsider how we develop parsing technology: perhaps we should think fundamentally about parsers as coaches rather than parsers as critics.

This inversion can apply to other aspects of NLP technology as well. For instance, Dale and Kilgarriff (2011) have held a series of workshop to produce algorithms to identify errors introduced into texts by non-native writers in the warmly named "Helping Our Own" shared task (Dale et al., 2012). Using the technology developed for tasks like these, the challenge is to go beyond recognizing and correcting the errors to helping the writer understand why the choices they are making are not correct. Another option is to target practice questions tailored for learners based on errors in a fun manner (as described below).

Of course, for decades, the field of Intelligent Tutoring Systems (ITS) (VanLehn, 2011) has developed technology for this purpose, so what is new about what I am suggesting? First, we know as NLP researchers that language analysis requires specific technology beyond standard algorithms, and so advances in Intelligent Tutoring Systems on language problems most likely requires collaboration with experts in NLP. And, apparently such collaborations have not been as robust as they might be (Borin, 2002; Meurers, 2012). So there is an opportunity for new advances at the intersection of these two fields.

And second, the newly expanded interest in online learning and technology makes possible the access of information about student writing behavior on a large scale that was not possible in the past. Imagine thousands of students in cascaded waves, tasked with writing essays on the same topic, and receiving real-time suggestions from different algorithms. The first wave of student responses to the feedback would be used to improve the algorithms and these results would be fed into the next wave of student work, and so on. Students and instructors could be encouraged to give feedback via the user interface. Very rapid cycles of iteration should lead to accelerated improvements in understanding of how the interfaces and the algorithms could be improved. A revolution in understanding of how to coach student writing could result!

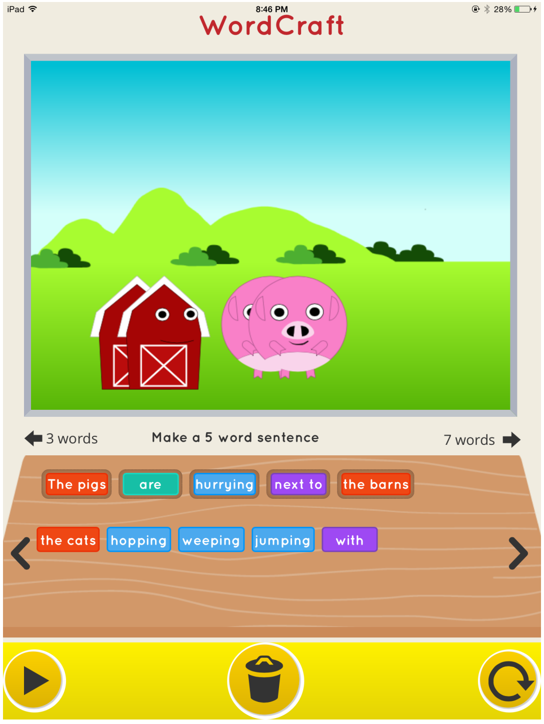

Figure 1: Wordcraft user interface showing a farm scene with four characters, a fully formed sentence, the word tray with candidate additional words colored by part of speech, and tool bar. When the child completes a sentence correctly, the corresponding action is animated.

Algorithms could be designed to give feedback for partially completed work: partially written sentences in the case of a parser; partially completed paragraphs in the case of a discourse writing tool, and so on, rather than only assessing completed work after the fact.

3 Karaoke Anyone?

Beyond learning to write, new technology is changing other aspects of language learning in ways that should excite NLP researchers. In order to write well, a student must have a good vocabulary and must know syntax. Learning words and syntax requires exposure to language in many contexts, both spoken and written, for a student's primary language was well as for learning a second language.

Although computerized vocabulary tools have been around for quite some time, the rise of mobile, connected applications, the serious games movement, and the idea of "microtasks" which are done during interstices of time while out and about during the day, opens the door to new ways to expose students to repetitive learning tasks for acquiring language (Edge et al., 2011). Some of the most innovative approaches for teaching language combine mobile apps with multimedia information.

For example, the Tip Tap Tones project (Edge et al., 2012) attempts to help learners reduce the the challenge of mastering a foreign phonetic system by microtasking with minute-long episodes of mobile gaming. This work focuses in particular on helping learners acquire the tonal sound system of Mandarin Chinese and combines gesture swipes with audio on a smartphone.

The ToneWars app (Head et al., 2014) takes this idea one step farther by linking second language learners with native speakers in real time to play a Tretis-like game against one another to better learn Chinese pronunciation. The second language learner feels especially motivated when they are able to beat the native speaker, and the native speaker contributes their expert tone recordings to the database, fine-tunes their understanding of their own language, and enjoys the benefits of tutoring others in a fun context.

Going beyond phonemes, the DuoLingo second-language learning application (von Ahn, 2013) teaches syntax as well as vocabulary through a game-based interface. For instance, one of Duolingo's games consists of a display of a sentence in one language, and a jumbled list of words in the opposing language presented as cards to be dragged and dropped onto a tray in the correct order to form a sentence. In some cases the user must select between two confounding choices, such as the articles "le" or "la" to modify French nouns.

Our work on a game for children called WordCraft takes this idea one step further (Anand et al., 2015) (see Figure 1). Children manipulate word cards to build sentences which, when grammatically well formed, come to life in a storybook-like animated world to illustrate their meaning. Preliminary studies of the use of Wordcraft found that children between the ages of 4 and 8 were able to observe how different sentence constructions resulted in different meanings and encouraged children to engage in metalinguistic discourse, especially when playing the game with another child.

A karaoke-style video simulation is used by the Engkoo system to teach English to Chinese speakers (Wang et al., 2012). The interface not only generates audio for the English words, but also shows the lip and facial shapes necessary for forming English words using a 3D simulated model lip-syncing the words in a highly realistic manner. To generate a large number of sample sentences, the text was drawn from bilingual sentence pairs from the web.

These technologies have only become feasible recently because of the combination of multimedia, fast audio and image processing, fast network connectivity, and a connected population. NLP researchers may want to let their imaginations consider the possibilities that arise from this new and potent combination.

4 Closing the Cheese Gap

Salman Kahn, the creator of Kahn Academy, talks about the "Swiss cheese" model of learning in which students learn something only partly before they are forced to move on to the next topic, building knowledge on a foundation filled with holes, like the cheese of the same name (Khan, 2012). This is akin to learning to ride a bicycle without perfecting the balancing part. In standard schooling, students are made to move one from one lesson to the next even if they only got 70, 80, 90% correct on the test. By contrast, *mastery learning* requires a deep understanding, working with knowledge and probing it from every angle, trying out the ideas and applying them to solve real problems.

In many cases, mastery learning also requires practicing with dozens, hundreds, or even thousands of different examples, and getting feedback on those examples. Automation can help with mastery learning by generating personalized practice examples that challenge and interest students. Automatically generated examples also reduce the cost of creating new questions for instructors who are concerned about answer sharing among students from previous runs of a course.

Recently, sophisticated techniques developed in the programming languages field have begun to be applied to automate repetitive and structured tasks in education, including problem generation, solution generation, and feedback generation for computer science and logic topics (Gulwani, 2014).

Closer to the subject at hand is the automated generation of mathematical word problems that are organized around themes of interest to kids, such as "School of Wizardry" (Polozov et al., 2015). The method allows the student to specify personal preferences about the world and characters, and then creates mini "plots" for each word problem by enforcing coherence across the sentences using constraints in a logic programming paradigm combined with hand-crafted discourse tropes (constraints on logical graphs) and a natural language generation step. A sample generated word problem is

> Professor Alice assigns Elliot to make a luck potion. He had to spend 9 hours first reading the recipe in the textbook. He spends several hours brewing 11 portions of it. The potion has to be brewed for 3 hours per portion. How many hours did Elliot spend in total?

Results are close in terms of comprehensibility and solubility to those of a textbook. The project's ultimate goal is to have the word problems actually tell a coherent story, but that challenge is still an open one. But the programs can generate an infinite number of problems with solutions. Other work by the same research team generated personalized algebraic equation problems in a game environment and showed that students could achieve mastery learning in 90 minutes or less during an organized educational campaign (Liu et al., 2015).

Another way that NLP can help with mastery learning is to aid instructors in the providing of feedback on short answer test questions. There has been significant work in this space (Kukich, 2000; Hirschman et al., 2000). The standard approach builds on the classic successful model of essay scoring which compares the student's text to model essays using a similarity-based technique such as LSA (Landauer et al., 2000; Mohler and Mihalcea, 2009) or careful authoring of the answer (Leacock and Chodorow, 2003).

Recent techniques pair with learning techniques like Inductive Logic Programming with instructor editing to induce logic rules that describe permissible answers with high accuracy (Willis, 2015). Unfortunately most approaches require quite a large number of students' answers to be marked up manually by the instructor before the feedback is accurate enough to be reliably used for a given question; a recent study found on the order of 500-800 items per question had to be marked up at minimum in order to obtain acceptable correlations with human scorers (Heilman and Madnani, 2015). This high initial cost makes the development of hundreds of practice questions for a given conceptual unit a daunting task for instructors.

Recent research in Learning at Scale has produced some interesting approaches to improving "feedback at scale." One approach (Brooks et al., 2014) uses a variation on hierarchical text clustering in tandem with a custom user interface that allows instructors to rapidly view clusters and determine which contain correct answers, incorrect answers, and partially correct answers. This greatly speeds up the markup time and allows instructors to assign explanations to a large group of answers with a click of a button.

An entirely different approach to providing feedback that is becoming heavily used in Massive Open Online Courses is peer feedback, in which students assign grades or give feedback to other students on their work (Hicks et al., 2015). Researchers have studied how to refine the process of peer feedback to train students to produce reviews that come within a grade point of that of instructors, with the aid of carefully designed rubrics (Kulkarni et al., 2013).

However, to ensure accurate feedback, several peer assessments per assignment are needed in addition to a training exercise, and students sometimes complain about workload. To reduce the effort, Kulkarni et al. (2014) experimented with a workflow that uses machine grading as a first step. After training a machine learning algorithm for a given assignment, assignments are scored by the algorithm. The less confident the algorithm is in its score, the more students are assigned to grade the assignment, but high-confidence assignments may need only one peer grader. This step was found to successfully reduce the amount of feedback needed to be done with a moderate decrease in grading performance. That said, the algorithm did require the instructors to mark up 500 sample assignments, and there is room for improvement in the algorithm in other ways, since only a first pass at NLP techniques was used to date.

Nonetheless, mixing machine and peer grading is a promising technique to explore, as it has been found to be useful in other contexts (Nguyen and Litman, 2014; Kukich, 2000).

5 Are You a FakeBot?

Why is the completion rate of MOOCs so low? This question vexes proponents and opponents of MOOCs alike. Counting the window shopping enrollees of a MOOC who do not complete a course is akin to counting everyone who visits a college campus as a failed graduate of that university; many people are just checking the course out (Jordan, 2014). That said, although the anytime, anywhere aspect of online courses works well for many busy professionals who are self-directed, research shows that most people need to learn in an environment that includes interacting with other people.

Learning with others can refer to instructors and tutors, and online tutoring systems have had success comparable to that of human tutors in some cases (VanLehn, 2011; Aleven et al., 2004). But another important component of learning with others refers to learning with other students. Literally hundreds of research papers show that an effective way to help students learn is to have them talk together in small groups, called structured peer learning, collaborative learning, or cooperative learning (Johnson et al., 1991; Lord, 1998). In the classroom, this consists of activities in which students confer in small groups to discuss conceptual questions and to engage in problem-solving. Studies and meta-analyses show the significant pedagogical benefit of peer learning including improved critical thinking skills, retention of learned information, interest in subject matter, and class morale (Hake, 1998; Millis and Cottell, 1998; Springer et al., 1999; Smith et al., 2009; Deslauriers et al., 2011). Even studies of intelligent tutoring systems find it hard to do better than just having students discuss homework problems in a structured setting online (Kumar et al., 2007).

The reasons for the success of peer learning include: students are at similar levels of understanding that experts can no longer relate to well, people learn material better when they have to explain it to others, and identify the gaps in their current understanding, and the techniques of structured peer learning introduce activities and incentives to help students help one another.

S2	I think E is the right answer
S1	Hi, I think E is right, too
S3	Hi! This seems to be a nurture vs nature question.
S3	Can scent be learned, or only at birth?
S2	Yeah, but answer A supports the author's conclusion
S1	I felt that about A too
S2	But the question was, which statement would weaken the author's conclusion
S3	So I choose A, showing that scent can be learned at not only AT BIRTH.
S2	That's why I think E is right
S3	Are you real, or fake?
S2	real
S1	I didn't think that b or d had anything to do with the statement
S3	Actually what you said makes sense.
S1	So, do we all agree that E was the correct answer?
S2	I think so, yes.
S3	But I'm sticking with A since "no other water could stimulate olfactory sites" abd I suggests that other water could be detected.
S3	*and
S1	I thought about c for awhile but it didn't really seem to have anything to do with the topic of scent
S3	It has to be A or E. Other ones don't have anything do do with the question.
S2	but that "no other water" thing applies equally well to E
S3	E is still about spawing ground water, I think. this is a confusing question.
S1	I thought E contradicted the statement the most
S2	me too
S3	I loving hits with other mturkers

Table 1: Transcript of a conversation among three crowdworkers who discussed the options for a multiple choice question for a GMAT logical reasoning task. Note the meta-discussion about the prevalence of robots on the crowdsourcing platform.

In our MOOCChat research, we were interested in bringing structured peer learning into the MOOC setting. We first tried out the idea on a crowdsourcing platform (Coetzee et al., 2015), showing that when groups of 3 workers discussed challenging problems together, and especially if they were incentivized to help each other arrive at the correct answer, they achieved better results than working alone. (A sample conversation is shown in Table 1.) We also found that providing a *mini-lesson* in which workers consider the principles underlying the tested concept and justify their answers leads to further improvements, and combining the mini-lesson with the discussion of the corresponding multiple-choice question in a group of 3 leads to significant improvements on that question. Crowd workers also expressed positive subjective responses to the peer interactions, suggesting that discussions can improve morale in remote work or learning settings.

When we tested the synchronous small-group discussions in a live MOOC we found that, for those students that were successfully placed into a group of 3 for discussion, they were quite positive about the experience (Lim et al., 2014). However, there are significant challenges in getting students to coordinate synchronously in very large low-cost courses (Kotturi et al., 2015).

There is much NLP research to be done to enhance the online dialogues that are associated with student discussion text beyond the traditional role of intelligent tutoring systems. One idea is to monitor discussions in real time and try to shape the way the group works together (Tausczik and Pennebaker, 2013). Another idea is to automatically assess if students are discussing content at appropriate levels on Bloom's taxonomy of educational objectives (Krathwohl, 2002).

In our MOOCChat work with triad discussions we observed that more workers will change their answer from an incorrect to a correct one if at least one member of the group starts out correct than if no one is correct initially (Hearst et al., 2015). We also noticed that if all group members start out with the same answer — right or wrong — no one is likely to change their answer in any direction. This behavior pattern suggests an interesting idea for large scale online group discussions that are not feasible in in-person environments: dynamically assign students to groups depending on what their initial answers to questions are, and dynamically regroup students according to the misconceptions and correct conceptions they have. Rather than building an intelligent tutoring system to prompt students with just the right statement at just the right time, a more successful strategy might be to mix students with other poeple who for that particular discussion point have the just the right level of conceptual understanding to move the group forward.

6 Conclusions

In this paper I am suggesting inverting the standard mode of our field from that of processing, correcting, identifying, and generating aspects of language to one of recognizing what a person is doing with language: NLP algorithms as coaches rather than critics. I have outlined a number of specific suggestions for research that are currently outside the mainstream of NLP research but which pose challenges that I think some of my colleagues will find interesting. Among these are text analyzers that explain what is wrong with an essay at the clause, sentence, discourse level as the student writes it, promoting mastery learning by generating unlimited practice problems, with answers, in a form that makes practice fun, and using NLP to improve the manner in which peers learning takes place online. The field of learning and education is being disrupted, and NLP researchers should be helping push the frontiers.

Acknowledgements I thank the ACL program chairs Michael Strube and Chengqing Zong for inviting me to write this paper and keynote talk, Lucy Vanderwende for suggested references, and colleagues at NAACL 2015 for discussing these ideas with me. This research is supported in part by a Google Social Interactions Grant.

Abstract

This paper proposes a novel approach for incorporating discourse information into machine comprehension applications. Traditionally, such information is computed using off-the-shelf discourse analyzers. This design provides limited opportunities for guiding the discourse parser based on the requirements of the target task. In contrast, our model induces relations between sentences while optimizing a task-specific objective. This approach enables the model to benefit from discourse information without relying on explicit annotations of discourse structure during training. The model jointly identifies relevant sentences, establishes relations between them and predicts an answer. We implement this idea in a discriminative framework with hidden variables that capture relevant sentences and relations unobserved during training. Our experiments demonstrate that the discourse aware model outperforms state-of-the-art machine comprehension systems.[1]

1 Introduction

The task of machine comprehension concerns the automatic extraction of answers from a given passage. Often, the relevant information required to answer a question is distributed across multiple sentences. Understanding the relation(s) between these sentences is key to finding the correct answer. Consider the example in fig. 1. To answer the question about *why Sally put on her shoes* , we need to infer that *She put on her shoes* and *She went outside to walk* are connected by a causality relation.

Sally liked going outside. She put on her shoes. She went outside to walk. [...] Missy the cat meowed to Sally. Sally waved to Missy the cat. [...] Sally hears her name. ”Sally, Sally, come home”, Sally’s mom calls out. Sally runs home to her Mom. Sally liked going outside.

Why did Sally put on her shoes?
A) To wave to Missy the cat
B) To hear her name
C) *Because she wanted to go outside*
D) To come home

Figure 1: Sample story excerpt from a passage in the MCTest dataset.[2] Correct answer is in italics.

Prior work has demonstrated the value of discourse relations in related applications such as question answering (Jansen et al., 2014). Traditionally, however, these approaches rely on outputs from off-the-shelf discourse analyzers, using them as features for target applications. Such pipeline designs provide limited opportunities for guiding the discourse parser based on the requirements of the end task. Given a wide spectrum of discourse frameworks (Mann and Thompson, 1988; Prasad et al., 2008; Wolf and Gibson, 2005), it is not clear a priori what the optimal set of discourse annotations is for the task. Moreover, a generic discourse parser may introduce additional errors due to the mismatch between its training corpus and a dataset used in an application. In fact, the largest discourse treebanks are based on newspaper corpora (Prasad et al., 2008; Carlson et al., 2002), which differ significantly in style from text used in machine comprehension corpora (Richardson et al., 2013).

In this paper, we propose a novel approach for incorporating discourse structure into machine

comprehension applications. Rather than using a standalone parser that is trained on external supervised data to annotate discourse relations, the model induces relations between sentences while optimizing a task-specific objective. This design biases the model to learn relations at a granularity optimized for the machine comprehension task. In contrast to a generic discourse analyzer, our method can also utilize additional information available in the machine comprehension context. For instance, question types provide valuable cues for determining discourse relations, and thus can facilitate learning.

We implement these ideas in a discriminative log-linear model with hidden variables. The model jointly identifies relevant sentences, establishes relations between them and predicts an answer. Since the same set of sentences can give rise to multiple questions, we do not limit the model to a single discourse relation, but rather model a distribution over possible relations. During training, we only have access to questions and gold answers. Since relevant sentences and their relations are not known, we model them as hidden variables. To guide the model towards linguistically plausible discourse relations, we add a few seed markers that are typical of each relation. The model predicts relations not only based on the sentences, but also incorporates information about the question. By decomposing the dependencies between model components, we can effectively train the model using a standard gradient descent approach.

We evaluate our model using a recently released machine comprehension dataset (Richardson et al., 2013). In this corpus, roughly half of the questions rely on multiple sentences in the passage to generate the correct answer. For baselines, we use the best published results on this dataset. Our results demonstrate that our relation-aware model outperforms the individual baselines by up to 5.7% and rivals the performance of a state-of-the-art combination system. Moreover, we show that the discourse relations it predicts for sentence pairs exhibit considerable overlap with relations identified by human annotators.

2 Related Work

Machine Comprehension Following traditional methods in question answering, most approaches to machine comprehension focus on analyzing the connection between the question, candidate answer and the document. For instance, Richardson et al. (2013) show that using word overlap alone provides a good starting point for the task. Using textual entailment output (Stern and Dagan, 2011) and embedding-based representations (Iyyer et al., 2014) further improves the result. Even though these methods operate at a paragraph level, they do not model relations between sentences. For instance, in their work on factoid question answering using recursive neural networks, Iyyer et al. (2014) average the sentence vectors element-wise when considering more than one sentence.

A notable exception is the approach proposed by Berant et al. (2014). Their approach builds on a semantic representation that encodes a number of inter-event relations, such as *cause* and *enable*. These relations straddle the boundary between discourse and semantic connections, since most of them are specific to the domain of interest. These relations are identified in a supervised fashion using a significant amount of manual annotations. In contrast, we are interested in extracting discourse relations with minimal additional annotation, relying primarily on the available question-answer pairs. As a result, we look at a smaller set of basic relations that can be learned without explicit annotations.

Discourse analysis for Question Answering Prior work has established the value of domain-independent discourse relations in question answering applications (Verberne et al., 2007; Jansen et al., 2014; Chai and Jin, 2004). For instance, Verberne et al. (2007) propose an answer extraction technique that treats question topics and answers as siblings in a Rhetorical Structure Theory (RST) tree, significantly improving performance on *why*-questions. Chai and Jin (2004) argue that incorporating discourse processing can significantly help context question answering, a task in which subsequent questions may refer to entities or concepts in previous questions. Jansen et al. (2014) utilize discourse information to improve reranking of human-written answers for non-factoid questions. They experiment with both shallow discourse markers and deep representations based on RST parsers to rerank answers for *how* and *why*-type questions[3].

While the above approaches vary greatly in

[3] They use data from Yahoo! Answers and a Biology textbook.

terms of their design, they incorporate discourse information in a similar fashion, adding it as features to a supervised model. The discourse information is typically computed using discourse parsers based on frameworks like RST (Feng and Hirst, 2014) or PDTB (Lin et al., 2014), trained using supervised data. In contrast, our goal is to learn discourse relations driven by the task objective. The set of these relations does not capture the richness of discourse representations considered in traditional discourse theories (Mann and Thompson, 1988; Prasad et al., 2008). However, we learn them without explicit annotations of discourse structure, and demonstrate that they improve model performance.

3 Task Description and Approach

We focus on the task of machine comprehension, which involves answering questions based on a passage of text. Concretely, let us consider a passage $p_i = \{\mathcal{Z}_i, \mathcal{Q}_i\}$ to consist of a set of sentences $\mathcal{Z}_i = \{z_{in}\}$ and a set of questions $\mathcal{Q}_i = \{q_{ij}\}$, with each question also having a set of answer choices $\mathcal{A}_{ij} = \{a_{ijk}\}$. We denote the correct answer choice for a question q_{ij} as a^*_{ij}. Given a set of training passages $\mathcal{P}_{train}$ with questions annotated with the correct answer choice, the task is to be able to answer questions accurately in a different set of passages $\mathcal{P}_{test}$.

Figure 1 shows an example of a passage, along with a question and answer choices. The only (weak) source of supervision available is the correct answer choice for each question in training. We do not use any extra annotations during training. We propose joint probabilistic models to address this task, that can learn to identify single or multiple relevant sentences given a question, establish a relation between them and score the answer choices.

We explore three different discriminative models, ranging from a simple one that answers questions using a single sentence in the passage, to one that infers relations between multiple sentences to score answer choices. We defer the description of the features used in our models to section 3.1.

Model 1 In our first model, we assume that each question can be answered using a single sentence from the passage. Treating the sentence as a hidden variable, we define a joint model for a sentence $z \in \mathcal{Z}$ and an answer choice $a \in \mathcal{A}_j$, given a question q_j.

$$P(a, z \mid q_j) = P(z \mid q_j) \cdot P(a \mid z, q_j) \quad (1)$$

We define the joint probability as a product of two distributions. The first is the conditional distribution of sentences in the paragraph given the question. This is to help identify the right sentence required to answer the question. The second component models the conditional probability of an answer given the question q and a sentence z. For both component probabilities, we use distributions from the exponential family with features and associated weights:

$$P(z \mid q) \propto e^{\theta_1 \cdot \phi_1(q,z)}$$
$$P(a \mid z, q) \propto e^{\theta_2 \cdot \phi_2(q,a,z)}$$

where ϕs are the feature functions and θs are the corresponding weight vectors.

We cast the learning problem as estimation of the parameter weights to maximize the likelihood of the correct answers in the training data. We consider soft assignments to z and marginalize over all its values to get the likelihood of an answer choice:

$$P(a_{jk} \mid q_j) = \sum_n P(a_{jk}, z_n | q_j) \quad (3)$$

This results in the following regularized likelihood objective to maximize:

$$L_1(\theta; \mathcal{P}_{train}) = \log \sum_{i=1}^{|\mathcal{P}_{train}|} \sum_{j=1}^{|\mathcal{Q}_i|} P(a^*_{ij} \mid q_{ij}) - \lambda ||\theta||^2 \quad (4)$$

Model 2 We now propose a model for the multi-sentence case where we make use of more than a single relevant sentence pertaining to a question. Considering that a majority of the questions in the dataset can be answered using two sentences, we restrict ourselves to sentence pairs for purposes of computational tractability. We define the new joint model as:

$$P(a, z_1, z_2 \mid q) = P(z_1 \mid q) \cdot P(z_2 \mid z_1, q) \cdot P(a \mid z_1, z_2, q) \quad (5)$$

where the new components are also exponential-family distributions:

$$P(z_2 \mid z_1, q) \propto e^{\theta_3 \cdot \phi_3(q,z_1,z_2)}$$
$$P(a \mid z_1, z_2, q) \propto e^{\theta_2 \cdot \phi_2(q,a,z_1,z_2)}$$

Here, we have three components: the conditional probability of a sentence z_1 given q, of a second sentence z_2 given q and z_1, and of the answer a given q and the sentences.[4] Ideally, we would be able to consider all possible pairs of sentences in a given paragraph. However, to reduce computation costs in practice, we use a sentence window k and consider only sentences that are at most k away from each other.[5] We hence maximize:

$$L_2(\theta; \mathcal{P}_{train}) = \log \sum_{i=1,j=1,m=1}^{|\mathcal{P}_{train}|,|\mathcal{Q}_i|,|\mathcal{Z}_i|} \sum_{n\in[m-k,m+k]} P(a^*_{ij}, z_{im}, z_{in} \mid q_{ij}) - \lambda||\theta||^2 \tag{7}$$

Model 3 In our next model, we aim to capture important relations between sentences. This model has two novel aspects. First, we consider a distribution over relations between sentence pairs as opposed to a single relation. Second, we utilize the cues from the question as context to resolve ambiguities in sentences pairs with multiple plausible relations.

We add in a hidden variable $r \in \mathcal{R}$ to represent the relation type. We incorporate features that tie in the question type with the relation type, and that connect the type of relation to the lexical and syntactic similarities between sentences. Our relation set $\mathcal{R}$ consists of the following relations:

- *Causal* : Causes of events or reasons for facts.
- *Temporal* : Time-ordering of events
- *Explanation* : Predominantly dealing with *how*-type questions.
- *Other* : A relation other than the above[6]

We can now modify the joint probability from (5) by adding in relation type r to get:

$$P(a, r, z_1, z_2 \mid q) = P(z_1 \mid q) \cdot P(r \mid q) \cdot P(z_2 \mid z_1, r, q) \cdot P(a \mid z_1, z_2, r, q) \tag{8}$$

where

$$P(r \mid q) \propto e^{\theta_4 \cdot \phi_4(q,r)} \tag{9a}$$

$$P(z_2 \mid z_1, r, q) \propto e^{\theta_3 \cdot \phi_3(q,r,z_1,z_2)} \tag{9b}$$

$$P(a \mid z_1, z_2, r, q) \propto e^{\theta_2 \cdot \phi_2(q,r,a,z_1,z_2)} \tag{9c}$$

The extra component $P(r \mid q)$ is the conditional distribution of the relation type r depending on the question. This is to encourage the model to learn, for instance, that *why*-questions correspond to the *causal* relation. We also add in extra features to $P(z_2 \mid z_1, r)$, that help select a sentence pair conditioned on a relation. The likelihood objective to maximize is:

$$L_3(\theta; \mathcal{P}_{train}) = \log \sum_{i,j,m,r\in\mathcal{R}} \sum_{n\in[m-k,m+k]} P(a^*_{ij}, z_{im}, z_{in}, r \mid q_{ij}) - \lambda||\theta||^2 \tag{10}$$

We maximize the likelihood objectives using LBFGS-B (Byrd et al., 1995). We compute the gradients required using Automatic Differentiation (Corliss, 2002).

To predict an answer for a test question q_j, we simply marginalize over all the hidden variables and choose the answer that maximizes $P(a_{jk} \mid q_j)$:

$$\hat{a}_j = \underset{k}{argmax}\ P(a_{jk}|q_j)$$

3.1 Features

We use a variety of lexical and syntactic features in our model. We employ the Stanford CoreNLP tool (Manning et al., 2014) to pre-process the data. Other than commonly used features in Q&A systems such as unigram and bigram matches, part-of-speech tags, syntactic features, we also add in features specific to our model.

We first define some terms used in our description. *Entities* are coreference-resolved nouns or pronouns. *Actions* refer to verbs other than auxiliary ones such as *is, are, was* and *were*. An *entity graph* is a graph between entities present in a sentence. We create an entity graph by collapsing nodes in the dependency graph and storing the intermediate nodes between any two entity nodes in the edge between the nodes. We refer to the words in a question q as q-words and similarly to words in an answer a as a-words and those in a sentence z as z-words. Figure 2 shows an example of an entity graph constructed from the dependency graph of a sentence.

We divide the features into 4 sets (ϕ_{1-4}), corresponding to each component probability in (8). Types 1 and 2 are inspired by prior work in question classification/answering (Blunsom et al., 2006; Jansen et al., 2014). Feature types 3 and 4 are specific to our models, primarily dealing with relation types.

[4] Since this component replaces the second component in model 1, we use the same subscript 2 for its feature set ϕ.

[5] Including the case where $z_1 = z_2$.

[6] This includes the no-relation cases

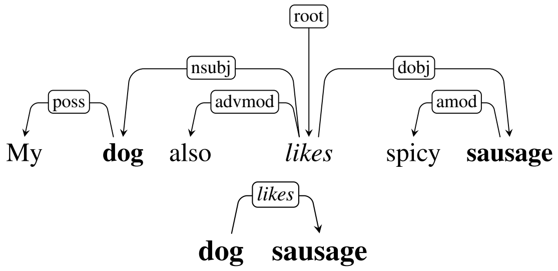

Figure 2: **Top**: Dependency graph, **Bottom**: Entity graph for an example sentence. Entities are in bold, actions are in italics.

Relation	**Word list**
Causal	because, why, due, so
Temporal	when, between, soon, before, after, during, then, finally, now, nowadays, first
Explanation	how, by, using

Table 1: Seed marker words for relations used by the model.

Type 1 (ϕ_1) These features are primarily intended to help the model select the most relevant sentence from the passage for a question. We add commonly used features such as unigram and bigram matches, syntactic root match, entity and action matches, missed entities/actions (in q but absent in z) and fractional coverage of q-words in z. In addition, we use matches between the edges of the entity graph of q and z. We also have second-order features that are a cross of each feature mentioned above with the question word (*how, what, when*, etc.).

Type 2 (ϕ_2) Features in ϕ_2 capture interactions between the answer a, question q and sentence(s) (z_1, z_2 in models 2,3 or z in model 1). For the first-order features, we use ones similar to those in ϕ_1 for lexical, syntactic, entity and action matches/misses between a and z. In addition, we add in a *neighbor match* feature, which checks for matches between the neighborhood of a word from a that occurs in z, and q-words. Another feature we employ is the *joint match* between z-words and the union of a-words and q-words. Finally, we add in a sliding window (*SW*) feature, computing its value as in Richardson et al. (2013).

Type 3 (ϕ_3) The next set of features are specific to only models 2 and 3, used to connect sentences z_1 and z_2 (and a relation r in model 3 only).

Split	**MC160**		**MC500**	
	Passages	**Questions**	**Passages**	**Questions**
Train	70	280	300	1200
Dev	30	120	50	200
Test	60	240	150	600

Table 2: Dataset Statistics

We use features like the inter-sentence distance and the presence of relation-specific markers in the sentences. We also cross the latter features with *entity* and *action* matches between z_1 and z_2. For the relation-specific words for each relation (except *Other*), we use words (see Table 1) derived mainly from Marcu (1997)'s list of discourse markers.

Type 4 (ϕ_4) The final set of features (used only in model 3) are present to help the model learn connections between the words in the question and the relation type r. Specifically, we check if the interrogative word in the question matches the class represented by r. For instance, the word *why* matches the *Causal* relation.

For the match-type features of all four types, we use the match count as the feature value if the count is non-zero. If the count is zero, we instead set a corresponding *zero* feature[7] to 1.

4 Experimental setup

Data and Setup We run our experiments on a recently compiled dataset for machine comprehension: MCTest (Richardson et al., 2013). The data consists of two distinct sets: MC160 and MC500, which are of different sizes. Table 2 gives details on the data splits for each dataset. Each passage has 4 questions, with 4 answer choices each. The questions are also annotated into 2 types: *single*, if the question can be answered using a single sentence in the passage, or *multi* otherwise. We do not use the type information in our learning; we only use it for categorizing accuracy during evaluation. We report final results on all our models trained with $\lambda = 0.1$, tuned using the Dev sets.

Evaluation We report accuracy scores for each model averaged over the questions in the test data. For each question, the system gains 1 point if it scores the correct answer highest and 0 otherwise. In case of ties, we use an inverse weighting

[7] For each match feature, like *Entity-Match*, we have a corresponding *zero* feature, *Entity-Match-Zero*

scheme to assign partial credit. So, if three answers (including the correct one) tie for the highest score, the system gains 1/3 points.

Baselines We use the systems proposed by Richardson et al. (2013) as our baselines. These systems have the best reported scores on this dataset. The first baseline, *SWD*, uses a sliding window to count matches between the passage words and the words in the answer. This is then combined with a score representing the average distance between answer and question words in the passage. The second baseline, *RTE*, uses a *textual entailment* recognizer (Stern and Dagan, 2011) to determine if the answer (turned into a statement along with the question) is entailed by the passage. The third system, *RTE+SWD*, is a weighted combination of the first two baselines and achieves the highest accuracy on the dataset.

5 Results

Comprehension accuracy Table 3 shows that our relation-aware model 3 outperforms individual baselines on both test sets. On the MC160 test set, the model achieves the best performance of 73.23% accuracy, outperforming the *SWD* baseline by 5.7% and the *RTE+SWD* combination by 4.07%. The major gains of model 3, which utilizes inter-sentential relations, over model 1 can be seen in the accuracy of *multi* type questions with a jump of almost 5% absolute in accuracy (statistically significant with $p < 0.05$). On the MC500 test set, we again find that model 3, with a score of 63.75%, provides a gain of 3.5% over *SWD* and is comparable to the performance of *RTE+SWD* (63.33%)

The importance of utilizing multiple relevant sentences to score answers is evident from the higher scores of models 2 and 3 on *multi* type questions in both test sets. However, model 1, which retrieves only a single relevant sentence for each question, achieves the best scores on the *single* type questions up to 83.25% on MC160 test. One reason for this could be the larger search space for model 3 over pairs of sentences compared to just single sentences for model 1.

Table 4 shows the variation of our model's accuracy with the question type. We see that the model deals well with *what, where* and *why* type questions in MC500, achieving almost 67-69% accuracy.[8] The major errors (in MC500) seem to come from the *how*-questions, where the model's accuracy is low (48%). In MC160, the accuracy is even higher for *what*-questions (almost 80%). On the other hand, the model does slightly worse on *why*-questions, with only 60% accuracy.

RST augmented model Further, we experiment with adding in relations extracted by a publicly available RST parser (Feng and Hirst, 2012). The parser extracts a tree with the passage sentences as its leaves and relations as interior nodes in the tree. From this tree, we compute the relation between a pair of sentences as their lowest common ancestor. If one of the sentences is broken down into clauses, we use them all to gather multiple relations. We add in features that combine the RST-predicted relation with the interrogation word of the question, and with entity and action matches between sentence pairs.

We can see from Table 3 that adding in RST features to model 2 (M2+RST) does not give the

[8] Note that *what*-questions may also require causal/temporal/explanation relations to answer.

same performance as model 3. In fact, the model performs slightly worse than model 2, which does not utilize inter-sentential relations. Our analysis of the RST trees reveals that for a vast majority of sentence pairs (77%), the RST algorithm predicts the *elaboration* relation which does not provide an informative distinction.

5.1 Analysis

To gain further insight into the workings of our model, we perform several analyses on model 3 using human judgements. We annotate 240 questions from the test set of MC160 with the most relevant sentences[9] in the passage for each question. In addition, if they chose more than a single relevant sentence, we also asked the annotators to mark the most appropriate relation (from our set of relations used in model 3) between the sentence pairs.[10] We find that 146 question annotations contain a single relevant sentence and 94 contain multiple sentences.[11] We obtain 103 sentence pairs with annotated relations.

Annotation statistics We select a random subset of 134 questions from this data to annotate twice and compute inter-annotator agreement. The second annotator agreed completely with the sentence predictions of the first annotator in 76.11% cases and both annotators agreed on at least one sentence in 94.77% of the questions. The agreement on relations annotated over common sentence pairs is 68.6%, with $\kappa = 0.462$. We find that out of the 103 annotated sentence pairs, 67 are next to each other in the passage while 27 are at a distance of two and 9 pairs are at a distance of three or more.

It has been well documented that identifying discourse relations without explicit markers is significantly harder than with markers (Pitler et al., 2008; Lin et al., 2009; Park and Cardie, 2012). We compute statistics on the presence of discourse markers anywhere in the manually picked sentence(s) for each question. We find that only 33.89% of these pairs have a relevant discourse marker present in either sentence. We consider a discourse marker as relevant if it occurs in our marker list for the annotated relation. Further, if we only consider markers occurring at the beginning or end of the sentences, this number drops to 9.23% of sentences. Since we consider relations between sentence pairs, most explicit markers that could help identify these relations would occur at an extremity of either sentence. We point out that these numbers are an over-estimation since many of the markers occur in syntactic roles as opposed to discourse in the sentences (ex. *so* in *This is so good* compared to *So, he decided to ...*). These statistics reflect the difficulty of the problem since operating over implicit relations is much harder.

Sentence Retrieval We analyze our models' ability to predict relevant sentences given only the question. For each question, we order the pairs scored by a model in descending order of their probability according to $P(z_1, z_2 \mid q)$ and compare them to the annotated pairs, reporting recall at various thresholds.

This is a stringent evaluation primarily due to

[9] The annotators are native English speakers.

[10] If there were more than *two* relevant sentences, we asked them to mark relations between all pairs. This was a very rare occurrence though.

[11] We found that some of the *multiple* questions did not require multiple sentences to answer and conversely, some *single* questions required more than one sentence to answer.

Question Type (#)	R @ 1				R @ 2				R @ 5			
	Freq	M1	M2	M3	Freq	M1	M2	M3	Freq	M1	M2	M3
how (21)	9.67	29.03	32.25	35.48	9.67	32.25	45.16	48.38	19.35	51.61	58.06	64.51

who (28)	2.12	45.45	45.45	42.42	4.25	45.45	60.60	57.57	23.40	63.63	72.72	75.75
why (37)	9.09	34.32	31.34	34.32	2.27	35.82	40.29	40.29	38.63	44.77	53.73	52.23
when (5)	0.0	57.14	57.14	57.14	0.0	57.14	71.42	71.42	25.00	85.71	100.0	85.71
(other) (5)	0.0	42.85	28.57	42.85	0.0	42.85	57.14	57.14	100.0	71.42	71.42	71.42
Single (146)	6.84	56.16	53.42	51.36	11.64	58.21	66.43	63.69	33.56	72.60	80.13	80.82
Multi (94)	3.88	24.27	23.30	25.72	9.70	25.24	34.46	33.98	29.61	39.32	50.00	50.48
Overall (240)	5.11	**37.5**	35.79	36.36	10.51	38.92	**47.72**	46.30	31.25	53.12	62.5	**63.06**

Table 5: Recall (%) of relevant sentence(s) in the ranking by models 1, 2 and 3 compared with a match-frequency baseline (Freq) at various thresholds, for different question types in MC160. Question frequencies are in parentheses. Bold numbers represent best scores.

two reasons. First, we do not use the candidate answers in selecting relevant sentences. Second, on the machine comprehension task, the model predicts answers by *marginalizing* over the sentences/sentence pairs. Hence, the model can score answers correctly even if the relevant sentence(s) are not at the top of its sentence distribution calculated here. We compute the distribution over sentence pairs as:

$$P(z_1, z_2|q) = \sum_{r\in\mathcal{R}} P(z_1 \mid q) \cdot P(r \mid q) \cdot P(z_2|z_1, r, q)$$

For comparison, we add in a baseline (Freq) that orders sentences using the sum of unigram and bigram matches with the question (in descending frequency).

Table 5 shows that our models perform significantly better than the Freq baseline over all question types. For the *single*-question case, we observe that model 3 ranks the annotated sentence at the top of its distribution around 51% of the time and 80% of the time in the top 5. For *multi*-sentences, these recall numbers drop to around 25% (@1) and 50% (@5). We also observe that models 2 and 3 perform better than model 1 on the *multi*-sentence cases. The similar sentence recall of models 2 and 3 also point to the fact that the gains from model 3 on comprehension accuracy are due to its ability to utilize relations between the sentences.

We observe that *where, when* and *who* questions have the highest recalls. This is likely because these questions often have characteristic words occurring in the sentences (such as *here, there, after, before, him, her*). In contrast, questions asking *how, which* and *why* have lower recalls since they often involve reasoning over multiple sentences. *What*-questions are somewhere in between since their complexity varies from question to question.

Relation Retrieval We examine how well our model can predict relations between given sentence pairs. For each annotated pair of sentences, we calculate the relation distribution and compute the relation recall at various thresholds of the ranking by probability. The relation distribution is computed as:

$$P(r|z_1, z_2, q) = \frac{P(r \mid q) \cdot P(z_2|z_1, r, q)}{\sum_{r'\in\mathcal{R}} P(r' \mid q) \cdot P(z_2|z_1, r', q)}$$

From table 6, we observe that our model's top prediction matches the manual annotations (overall) 51% of the time. The model predicts *causal* and *other* relations more accurately than the other two.

Relation (#)	R @ 1	R @ 2
Causal (32)	56.25	75.00
Temporal (11)	27.27	54.54
Explanation (6)	16.66	33.33
Other (54)	57.40	64.81
Overall	51.45	65.04

Table 6: Recall of annotated relations at various thresholds in the ordered relation distribution predicted by model 3. Relation frequencies are in parentheses.

6 Conclusions

In this paper, we propose a new approach for incorporating discourse information into machine comprehension applications. The key idea is to implant discourse analysis into a joint model for comprehension. Our results demonstrate that the discourse-aware model outperforms state-of-the-art standalone systems, and rivals the performance of a system combination. We also find that features derived from an off-the-shelf parser do not improve performance of the model. Our analysis also demonstrates that the model accuracy varies significantly according to the question type. Finally, we show that the predicted discourse relations exhibit considerable overlap with relations identified by human annotators.

Abstract

There is a growing interest in researching *null instantiations*, which are those implicit semantic arguments. Many of these implicit arguments can be linked to referents in context, and their discoveries are of great benefits to semantic processing. We address the issue of automatically identifying and resolving implicit arguments in Chinese discourse. For their resolutions, we present an approach that combines the information about overtly labeled arguments and frame-to-frame relations defined by FrameNet. Experimental results on our created corpus demonstrate the effectiveness of our approach.

1 Introduction

In natural discourse, only a small proportion of the theoretically possible semantic arguments of predicates tend to be locally instantiated. Other locally unrealized semantic roles are called *null instantiations* (NIs). Nevertheless, many of these implicit roles, while linguistically unexpressed, can often be bound to antecedent referents in the discourse context. What's more, capturing such implicit semantic roles and linking them to their antecedents can dramatically help text understanding.

Example (1) shows an analyzed result (Li, 2012) by employing Chinese FrameNet (Liu, 2011), which is a lexical semantic knowledge base based on the frame semantics of Fillmore (1982) and takes Berkeley's FrameNet Project (Baker et al., 1998) as the reference. In Chinese FrameNet, the predicates, called lexical units (LU), evoke frames which roughly correspond to different events or scenarios. Each frame defines a set of arguments called Frame Elements (FE). The set of FEs is further split into core FEs and non-core FEs. Particularly, the core FEs are the essential components of a frame and can be defined by themselves. However, not all core FEs of a frame can be realized simultaneously in a sentence. These non-instantiated FEs are considered as *null instantiations of the frame elements*. Depending on the interpretation type of the omission, Chinese FrameNet divides the NIs into two categories: 1) Indefinite Null Instantiations (INIs), the missing element which can be understood given interpretational conventions and do not need resolution, and 2) Definite Null Instantiations (DNIs), the missing element which is something that can be understood in the linguistic or discourse context, and the fillers need to be inferred from the context through resolutions.

(1) [天葬卫星]$_{Entity}$**也是**$_{\textbf{属于某类}}$ [人造卫星]$_{Category}$，和侦察卫星、通信卫星、气象卫星等同属一类。

[The celestial burial satellite]$_{Entity}$ **is** ***Being_in_category*** [artificial satellite]$_{Category}$, and belongs to the same category with reconnaissance, communications and meteorological satellite.

不同的是用途各异，是专门用来存放骨灰盒的；高度亦不同，一般**发射**$_{\textbf{使位移}}$ [到距地球表面3000多公里处的环球轨道上]$_{Goal}$。[*Theme* DNI] [*Agent* INI]

The purpose is different, specially used for storing the urn; due to the different heights, generally **launched** ***Cause_motion*** into [the orbit over 3000 kilometers away from the surface of earth]$_{Goal}$. [*Theme* DNI] [*Agent* INI]

Particularly, in example (1), lexical unit (or target) *launched*/发射 evokes the semantic frame `Cause_motion`, which has nine core FEs, namely *Agent*, *Theme*, *Source*, *Path*, *Goal*, *Area*, *Cause*, *Result*, *Initial_State*, but only one of them is instantiated, i.e. *Goal*, whose filler is [*the orbit over 3000 kilometers away from the surface of earth*/到距地球表面3000 多公里处的环球轨道上]. For another core FE *Theme*, it is filled by [*The celestial burial satellite*/天葬卫星] that occurs in

the previous sentence.

Clearly, human beings have no problem to infer these uninstantiated roles and find the corresponding fillers based on the relevant context information, but this is beyond the capacity of state-of-the-art semantic role labeling systems.

Next, we formalize the problem as follows: given a discourse $D = \{S_1, S_2, ..., S_n\}$, where $S_k\,(k \in [1, n])$ is the k-th sentence in D. The lexical unit set in S_k is $T_k = \{T_{k1}, T_{k2}, ..., T_{kp}\}$, and $F_k = \{F_{k1}, F_{k2}, ..., F_{kp}\}$ is relevant frame set. For a particular frame $F_{ki}\,(i \in [1, p])$, its core FE set is $E_{ki} = \{e_1, e_2, ..., e_m\}$, but it is possible that only part of core FEs C_{ki} appears in S_k, i.e. $C_{ki} \subseteq E_{ki}$. Apparently the set $E_{ki} - C_{ki}$ includes the uninstantiated core FEs. Thus, we need to determine which elements in $E_{ki} - C_{ki}$ are null instantiations. If e_m $(e_m \in E_{ki} - C_{ki})$ has been identified as a null instantiated FE, we should determine whether e_m is a DNI. If so, we need to find the corresponding antecedent d_m in context.

The major contributions of this paper can be summarized as follows:

(i) We have created a null instantiation (NI) annotations corpus, consisting of 164 Chinese discourses across different fields.

(ii) We use frame-to-frame relations to find antecedents from those explicit semantic roles.

2 Related Work

Among the researches of null instantiation on English, the most representative work is the task "Linking Events and Their Participants in Discourse" shared by the SemEval-2010 (Ruppenhofer et al., 2010). The two systems participated in the NI resolution task, VENSES++ and SEMAFOR, took very different approaches.

Tonelli and Delmonte (2010) develop a knowledge-based system called VENSES++, and describe two strategies depending on the predicate class (either nominal or verbal). For verbal predicates, they try to map the predicate argument structure extracted by VENSES with the valence patterns generated from FrameNet data, to identify missing arguments. And NIs are resolved by reasoning about the semantic similarity between an NI and a potential filler using WordNet. For nominal predicates, they resolve NIs by utilizing a common sense reasoning module that builds on ConceptNet (Liu and Singh, 2004). The final Precision and Recall are 4.62% and 0.86% respectively.

Later on, Tonelli and Delmonte (2011) propose a simpler role linking strategy that based on computing a relevancy score for the nominal head of each potential antecedent. The intuition is that heads which often serve as role fillers and occur close to the target NI are more likely to function as antecedents for the NI. Finally they reported an F-score of 8% for role linking. However, being strongly lexicalized, their trained model seems heavily dependent on the training data.

The second system (Chen et al., 2010) is statistical based and extends an existing semantic role labeler (Das et al., 2010). Resolving DNIs is modeled in the same way as labeling overt arguments, with the search space being extended to nouns, pronouns, and noun phrases from the previous three sentences. When evaluating a potential filler, the syntactic features used in argument labeling of overt arguments are replaced by two semantic features: firstly the system checks whether a potential filler fills the null instantiated role overtly in at least one of the FrameNet sentences and train data, if not, the system calculates the distributional similarity between filler and role. While this system achieved 5% in F-score, data sparseness is a potential limiting factor.

Also closely related studies are as follows. Silberer and Frank (2012) cast NI resolution as a coreference resolution (CR) task, and employ an entity-mention model. They experiment with features of SRL and CR, and automatically expand the training set with examples generated from coreference corpus to avoid data sparseness, ultimately achieving F-score of 7.1%.

Gorinski et al. (2013) present a weakly supervised approach that investigates and combines a number of linguistically motivated strategies, which consist of four basic NI resolvers that exploit different types of linguistic knowledge, and achieve F-score of 12%.

Wang et al. (2013) conduct DNI resolution on SemEval2010 task10 data. They considered the task as a classified problem, by adding new features such as the information of head word and frame to traditional features, proposed a rule to choose the best candidate words set and combination of features, achieving F-score of 14.65% finally.

Laparra and Rigau (2013) present an attempt to apply a set of features that have been traditionally used to model anaphora and coreference resolution tasks to implicit argument resolution, and got the best results: F-score of 18%.

For nominal predicates, Gerber and Chai (2010) investigate the linking of implicit arguments using the PropBank role labeling scheme. In contrast to the SemEval task, which focuses on a verbs and nouns, their system is only applied to nouns and is restricted to 10 predicates with 120 annotated instances per predicate on average. They propose a discriminative model that selects an antecedent for an implicit role from an extended context window. The approach incorporates some aspects relating to CR that go beyond the SRL oriented SemEval systems: A candidate representation includes information about all the candidates' coreferent mentions (determined by automatic CR), in particular their semantic roles (provided by gold annotations) and WordNet synsets. Patterns of semantic associations between filler candidates and implicit roles are learned for all mentions contained in the candidate's entity chain. They achieve an F-score of 42.3%, which is noticeably higher than those obtained on the SemEval data.

And Gerber (2011) presents an extended model that incorporates strategies suggested in Burchardt et al. (2005): using frame relations as well as coreference patterns acquired from large corpora. This model achieves an F-score of 50.3%.

Lei et al. (2013) conduct DNI identification on SemEval2010 task10 data. They adopt the method of combining rules and machine learning. Different from them, we conduct two-level identifying for NI detection and use more features on Chinese data. Wang et al. (2013) take noun phrases and pronoun as candidate words for DNI filler. We use several similar features with them. The differences are that 1) we take the fillers of overt instantiated FE as candidate words and 2) we use Frame-to-Frame relations. And Gerber (2011) also used frame relations. Different from them, we limit relation paths to 2.

3 Null Instantiation Detection

Now, we are ready to address the first subtask, i.e. null instantiation detection.

3.1 Frame element relations

Not all core arguments of all frames can be realized simultaneously. Some frames involve core FEs that are mutually exclusive. In example (2), in the Amalgamation frame, there are four core FEs, namely *Part_1*, *Part_2*, *Parts* and *Whole*, in which the first two FEs are mutually exclusive with *Parts*, thus formed an *Excludes* relation (relation 1). At the same time, *Part_1* and *Part_2* are in a *Requires* relation (relation 2), which means that if one of these two core FEs is present, then the other must occur as well. FE *Whole*, the result of the Amalgamation, is only existentially bound within the discourse, annotated as NI.

CoreSet (relation 3) specifies that *at least* one of the set must be instantiated overtly, though more of them can also be instantiated. As shown in example (3), in the Awareness frame, the two FEs *Content* and *Topic* are in one *CoreSet*. As *Content* is overtly realized, we consider *Topic* is not annotated as NI. The frame owning this relation is complicated. Sometimes, if one FE of this set is explicit, the absence of the other FEs in the set is not annotated as NI, but sometimes it is not true.

(2) [旧体制]$_{Part\_1}$ 和[新体制]$_{Part\_2}$ **结合**$_{结合}$ 在一起。[*Whole* INI]

[The old system]$_{Part\_1}$ and [the new system]$_{Part\_2}$ are **combined** $_{\textit{\textbf{Amalgamation}}}$ together. [*Whole* INI]

(3) [你老板]$_{Cognizer}$ **知道**$_{知道}$ [你的任务]$_{Content}$。

[Your boss]$_{Cognizer}$ is **aware**$_{\textit{\textbf{Awareness}}}$ [of your commitment]$_{Content}$.

3.2 Modeling Null Instantiation detection

As shown in example (1), given a frame F_{ki} (e.g. Cause_motion evoked by *launched*/发射), NI detector needs to determine whether core FEs in $E_{F_{ki}} - subE_{F_{ki}}$ are missing, relying on information about the three types of the relations among core FEs: *CoreSet*$_{F_{ki}}$, *Excludes*$_{F_{ki}}$, *Requires*$_{F_{ki}}$ (as discussed in Section 3.1). In Cause_motion, the core FEs *Initial_State*, *Goal*, *Path*, *Source* and *Result* belong to the same $CoreSet$, and *Goal* is instantiated, thus *Initial_State*, *Path*, *Source* and *Result* are not annotated as NIs. Meanwhile core FEs *Goal* and *Area* are connected by the $Excludes$ relation, so do *Cause* and $Agent$. Therefore, according to the context, *Area* and *Cause* are not annotated as NIs.

Our approach for performing this detection is described as follows. For the first-level of detection, we make full use of the three types of relations, and adopt a rule-based strategy proposed by Lei et al. (2013) to detect NIs. As for *CoreSet* relation, in particular, as long as one of the FEs in this set is expressed overtly, NIs are not annotated for the absence of the other FEs in the set. If none of *CoreSet* is expressed, the contextually most relevant one should be annotated as a NI. However, this is difficult for automatic detector, which inevitably introduces some false detected NIs.

Thus, we conduct a second-level identifying. To be specific, for the current lexical unit, i.e. the target word, we collect its frame element patterns from the training dataset. Frame element patterns are annotated semantic roles, which include the roles annotated as NIs. Taking lexical unit *launched*/发射 as an example, Table 1 shows its frame element patterns in our data. Depending on this kind of patterns, we are able to filter out some false NIs effectively.

Patte1	Time	Agent$_{INI}$	Theme	Goal$_{INI}$
Patte2	Agent	Theme	Goal$_{INI}$	

Table 1: Frame element patterns for the target 发射/*launched* in our data

4 Definite Null Instantiation Identification

In this section, we focus on our second task of definite null instantiation (DNI) identification.

Before performing the implicit argument resolution in discourse, we have to decide which null instantiated frame elements should be selected, i.e. which null instantiations are definite. As shown in example (1) above, assuming one detected null instantiated FE in the previous step is e_m (e.g. *Theme*), we should determine whether e_m needs to be filled or not, that is, we should determine e_m as DNI or INI.

Num	Feature names	Feature Descriptions
T1	Target	Target predicate
T2	Pos	The part of speech of target
T3	Frame	The frame that target evokes
T4	FENI	NI of frame elements
T5	FE	Overtly expressed FEs

Table 2: Features description in DNI Identification

We treat this issue as a classification problem, and build a binary maximum entropy model to predict the null instantiation type of e_m. Table 2 lists all features used for training our models. In addition, we employ some similar features that were used in Lei et al. (2013). Meanwhile, we choose to learn a SVM classifier for comparison purpose.

5 Definite Null Instantiation Resolution

In this section, we tackle the last subtask, namely definite null instantiation resolution.

5.1 Frame-to-Frame Relations

The relations of Frame-to-Frame and FE-to-FE in FrameNet, serve as important information sources, to be leveraged for DNI resolutions.

FrameNet arranges frames into a net by defining frame-to-frame relations, including Inheritance, Inchoative Of, Subframe, Causative Of, Precedes, Using, See_also and Perspective On. In the case of Inheritance relation, it defines two frames, i.e. one more general frame and the other more specific frame. The specific frame `Commerce buy`, for example, is inherited from the general frame `Getting`.

As Figure 1 shows, the inheritance relation allows a general frame (e.g., `Getting`) to be specialized with a particular semantic interpretation (e.g., `Commerce buy`). Also the inheritance relation exists between the *frame elements* of two related frames. Each of the inheriting FEs contains all semantic properties of the inherited general frame elements and also owns its additional private properties.

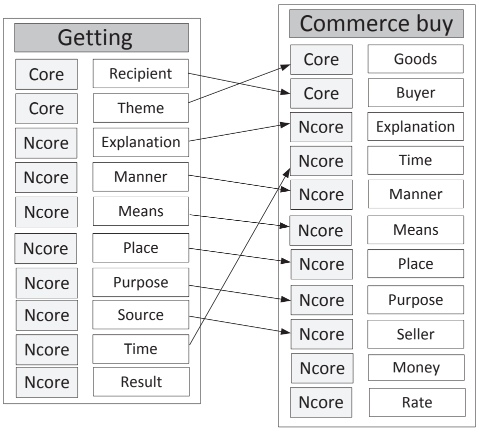

Figure 1: FE-FE relations of frame `Getting` and `Commerce buy`

Number		Features Name	Features Description
T1	F1	DistCT	The number of sentences between candidate FE content and target
	F2	CanFEcon	Candidate frame element content
	F3	CanFEpt	The phrase type or POS of candidate frame element content
T2	F4	Frame	The frame that target predicate evokes
	F5	FEDNI	DNI frame element
	F6	Target	Target predicate
	F7	TargetPOS	The part of speech of target

Table 3: Features description in Overt Frame Elements Based Resolver

5.2 Modeling Definite Null Instantiation Resolution

After accomplishing the previous processes, we can perform DNI resolutions. If the uninstantiated FE e_m (e.g., *Theme* in example (1)) has been identified as DNI previously, we need to find the corresponding antecedent mention d_m (e.g., [*The celestial burial satellite*/天葬卫星] in example (1)). Due to having fine-grained frame semantic role labeled for each sentence, we think the filler of DNI maybe also instantiates the FE of other annotated frames in the context. Therefore, we collect the overt FE content set φ instantiated in the discourse, and this set forms the overall set of candidates for DNI linking. Then, for DNI e_m, a subset of candidates φ_m ($\varphi_m \subseteq \varphi$) is chosen as candidate search space for resolving e_m.

We implement two semantic resolvers based on different methods. For either of these two resolvers, if two or more candidates score equally well, the one closest to the target predicate is chosen.

OvertFE is based on machine learning, and FFR is an inference method. As the inherent difficulty of task, it's difficult to find all fillers for DNIs only using one of them. Thus finally we simultaneously employ OvertFE and FFR to find as many fillers for DNIs as possible.

Overt Frame Elements Based Resolver (OvertFE)

This resolver is based on the assumption that the filler of DNI can be found among the overt FE content set in context. Given a DNI e_m , DNI linking can be treated as a classification problem to judge whether a candidate overt FE content d ($d \in \varphi_m$) could be taken as filler of a DNI. Therefore, we employ a classification method to solve the problem. Clearly, the performance of classifiers largely depends on constructed features. Since corresponding antecedent of DNI is not overtly expressed, it is difficult to get some information from context to describe them. What we take as features is the information of candidate frame element contents and frame information. Table 3 lists all features used for training our models. Some similar features were employed by Wang et al. (2013) where they also considered DNI linking as a classification problem.

Then maximum entropy models, widely used in natural language processing (such as Chinese word segmentation and machine translation), are employed to predict whether a candidate FE content is the filler of DNI.

Frame-to-Frame Relations Based Resolver (F-FR)

Another way of finding the correct filler is through searching Frame-to-Frame relations in a given context window. This is because Frame-to-Frame relations and FE-to-FE relations can provide relevant information for finding DNI filler among candidate frame element contents. Specifically, for one frame f_1 that contains a DNI, firstly we need to find related frame f_2 with it from context. Then, if DNI frame element in f_1 has relation with the frame element (marked with fe_2) of f_2, the filler of fe_2 is the corresponding filler of this DNI. The detailed steps are reported in Algorithm 1.

If frame names are the same, we think they are related, and Figure 2 illustrates this case. As the frames evoked in two sentences are both `Arriving`, we link the antecedent of *Goal* in the second sentence to [*Tiananmen Square*/天安门广场], which is the content of *Goal* in the first sentence.

For other cases, we use the related frames which at most contain two relation paths (e.g., the paths from `Event` to `Process_start` to `Activity_start` in Figure 3). As shown in Figure 3, the target *initiated*/发起 in the first sentence evokes the `Activity_start` frame, in which the two frame elements (*Agent*, *Place*) is expressed in a single constituent [*our country*/我国], i.e. the phenomenon of frame element fusion arises. Frame `Event` is evoked by the target *happened*/出现 in the second sentence, where *Time* and *Event* FEs are expressed overtly, except the core FE *Place*. In the net of FrameNet, frame `Activity_start` inherits from the frame `Process_start` which further inherits from the `Event` frame. These inheritance relationships also hold between the frame elements of the related frames. According to the FE-to-FE relations, the content of FE *Place* in the first sentence, [*our country*/我国], is the corresponding filler of implicit FE *Place* in the second sentence.

Algorithm 1 : Frame-to-Frame Relations Based Resolver

```
Input: The frame set in discourse is $F = \{f_1, f_2, ..., f_n\}$; overt core frame element set
  for frame $f_i$ is $E_i = \{e_1, e_2, ..., e_m\}$, its corresponding filler set is
  $A_i = \{a_1, a_2, ..., a_m\}$; one frame that contains DNI $e^*$ is $f^*$, target $t$ evokes
  the frame $f^*$; $dis\,(a_i, t)$ is the distance between DNI filler $a_i$ and target $t$;
  $relationpath\,(f_i, f^*)$ are the relation paths from $f_i$ to $f^*$; $A^{temp}$ is
  temporary DNI filler set
Output: the filler $a^*$ of DNI $e^*$
  $A^{temp} = \phi$
  for each $f_i \in F$ do
    if $f_i$ has frame relation with $f^*$ AND $relationpath\,(f_i, f^*) \leq 2$ then
      for each $e_i \in E_i$, $a_i \in A_i$ do
        if $e_i$ has relation with $e^*$ then
          $a_i \in A^{temp}$
        end if
      end for
    else if $f_i = f^*$ then
      $a_i \in A^{temp}$
    end if
  end for
  if $A^{temp} \neq \phi$ then
    for $a_i \in A^{temp}$ do
      if $dis\,(a_i, t)$ is minimum then
        $a^* = a_i$
      end if
    end for
  end if
  return $a^*$ ;
```

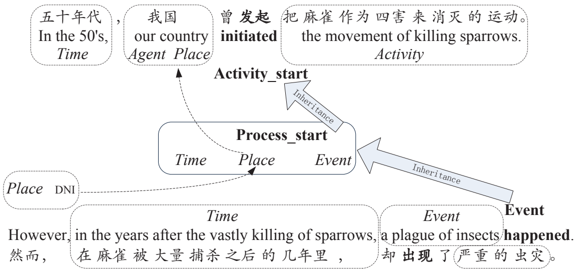

Figure 3: Two consecutive sentences owing related frames. Bold fonts represent lexical units or frames. Dashed boxes represent FEs.

6 Experiments

6.1 Experimental Settings

Data: Experimental data set comes from Semantic Computing and Chinese FrameNet Research Centor of Shanxi University[1]. Because of the current low performance of CFN automatic semantic analysis systems, all discourses are labeled semantic roles manually, and the process is similar with the FrameNet annotation.

First, the ICTCLAS are used for part-of-speech tagging (omitted in examples), and we treat verbs, adjectives and nouns in each sentence as potential targets. As not all potential targets can be annotated, it is necessary to identify those targets which can evoke frames.

Then, we choose corresponding frames for those targets. For one verb target *launched*/发射 in example (1), we find its evoked frame `Cause_motion`.

Then annotate semantic roles for those constituents which share syntactical relations with this target, so the span [*the orbit over 3000 kilometers away from the surface of earth*/到距地球表面3000多公里处的环球轨道上] is annotated as role *Goal*, which is, however, the only one instantiated, out of nine `Cause_motion`'s core frame elements. So according to the context and frame element relations, we need to determine whether each

[1] `http://sccfn.sxu.edu.cn/`

missing frame element should be annotated as DNI or INI.

Next, we generate the XML format for our annotated corpus, which is similar to the data format in SemEval-10 Task 10.

Our 164 discourses had been annotated by one person (to make it consistent), and they consist of 57 discourses from People's Daily and 107 discourses from Chinese reading comprehension, which cover technology, health care, social, geography and other fields. Each discourse contains 10 sentences in average. The data set contains about 37526 words in 1618 sentences; it has 175 frame types, including 2283 annotated frame instances. Table 4 shows the detailed statistics of our data set. we'll share our data in the website(http://sccfn.sxu.edu.cn/).

discourses	sentences	frame inst.	frame types	INIs	DNIs
164	1618	2283	175	213	212

Table 4: Corpus Statistics

Definite Null Instantiation identification and resolution model: Our maximum entropy classification model uses the toolkit from Zhang (2005) with the default parameter values. The SVM classifier for comparison was trained via SVM toolkit LIBSVM with the default parameter values too.

6.2 Experimental Results

Based on the experimental methods described in the previous section, we have systematically evaluated our approach on the constructed Chinese null instantiation corpus. Note all the performances are achieved using 5-fold cross validation.

Null Instantiation Detection

Table 5 gives the performance of NI detection, which achieves 72.71%, 86.12% and 78.84% in precision, recall and F-score, respectively. Here, the relatively lower precision is mainly due to the heuristic rules used to detect NIs. However, it is worth to point out that lower precision and higher recall is highly beneficial, as higher recall means less filtering of true NIs.

	P%	R%	F%
Ours	**72.71**	86.12	**78.84**
Lei et al.	56.18	90.57	69.34

Table 5: Performance of NI Detection

To illustrate the effectiveness of our method, we compare it with the Lei et al.'s method on our data, as shown in the Table 5. The F-score of our method is 78.84%, which is 9% higher than that of Lei et al.'s method. Clearly, these experimental results further prove that our second-level identification is very effective.

Definite Null Instantiation Identification

Table 6 provides the performance of DNI identification on our automatic NI detection results. It shows that DNI identification based on maximum entropy model achieves the performance of 67.86%, 69.93% and 68.88% in terms of precision, recall and F-score respectively, which are better than the results using SVM classifier, as well as the results employing Lei et al.'s method on our data.

We observe, from Table 6, that the performance of DNI identification is not high, possibly due to the poorer results of NI detection in the previous step. Moreover, because of the diversity of NI distribution, the difference of frames, and target words or missing core frame elements, the interpretation of NI types may be quite different. Thus it is difficult to build a suitable and accurate uniform classification model.

	P%	R%	F%
DNI IdenME	**67.86**	**69.93**	**68.88**
DNI IdenSVM	67.25	62.02	64.53
Lei et al.	64.58	67.73	66.12

Table 6: Performance of DNI Identification

Resolution on golden Definite Null Instantiation

In order to select the most effective features for OvertFE resolver and choose the best search space, we assume perfect results for the first two steps, that is, we perform DNI resolution experiment just with the correct DNIs in discourse. After extensive experiments employing different sets of features in different window sizes, we conclude that combining all features can achieve the best performance. Table 7 shows the results on correct DNIs using the best feature set in the window of 2, 3 and 4 sentences containing and before the target predicate (Win2, Win3, Win4 for short).

For OvertFE resolver, it shows that the F-score with Win2 is higher than that in other windows, because the bigger the window size, the more the candidate fillers for DNI, and the more difficult for

	Win2			Win3			Win4		
	P%	R%	F%	P%	R%	F%	P%	R%	F%
OvertFE	45.22	18.20	25.95	43.04	17.64	25.02	38.63	15.23	21.84
FFR	65.56	16.29	26.11	63.50	16.81	26.58	58.53	17.32	26.72
OvertFE+FFR	51.17	31.59	**39.06**	52.41	32.02	**39.75**	45.88	31.10	**37.07**

Table 7: Results on golden DNI

OvertFE classifier to find right fillers.

For FFR resolver, it needs to find related frames, and we find that its resolved DNIs are less than that by OvertFE resolver, thereby resulting in the lower precision of OvertFE than FFR.

Though performances of OvertFE and FFR both are relatively low, FFR can resolve several DNIs that OvertFE can not. Figures 2 and 3 both are such cases. So when combining the two resolvers, the final result of OvertFE+FFR outperforms that of each individual resolver. Meanwhile, as shown in Table 7, for the combined resolver OvertFE+FFR, the F-score is the highest when the window size is 3 (i.e. Win3).

Overall: Null Instantiation Resolution

Table 8 gives the performance of overall null instantiations resolution with automatic NI detection and automatic DNI determination. It shows that our resolver OvertFE+FFR achieves 40.53%, 21.54% and 28.13% in terms of precision, recall and F-score. In comparison with the results (52.41%, 32.02% and 39.75% in P, R and F) in Win3 of Table 7, it shows that the errors caused by automatic NI detection and automatic DNI determination decrease the performance of overall NI resolution by about 11% in terms of F-score.

	P%	R%	F%
OvertFE	33.28	13.78	19.49
FFR	52.95	9.71	16.41
OvertFE+FFR	**40.53**	**21.54**	**28.13**
Wang et al.	31.93	12.76	18.23

Table 8: Performance of NI resolution for our models and comparative systems

For comparison, we also conduct DNI resolution on our constructed corpus employing the method proposed by Wang et al. (2013). Since our corpus does not contain annotation of head words, the results are obtained by using their features without head word information. As the last line of Table 8 shows, the performance behaves similarly with our OvertFE resolver. In addition, we notice current state-of-the-art approach of Laparra and Rigau (2013) employs coreference models, although our corpus does not contain coreference annotation information. As such, we are not able to conduct experiments on our dataset using their method for comparison purpose.

Overall, the relatively low performance of resolution reflects the inherent difficulty of this task, also reveals that further research is needed.

7 Conclusion and Future Work

Apparently, linking implicit participants of a predicate is a challenging problem. We have presented a study for identifying implicit arguments and finding their antecedents in Chinese discourse.

As shown in this paper, we split the difficult task into three subtasks: null instantiation detection, definite null instantiation identification and definite null instantiation resolution. Among the three subtasks, the third is our major focus. For the third subtask, we build two different resolvers: 1) OvertFE resolver, which represents that the filler of a DNI can be found among those overt FE content set in context, by employing classification methods; 2) FFR resolver, which is the frame-related search, leverages rich network of frame-frame relations to find antecedents. We have proved that these two resolvers are very useful for the third subtask, and a combination of two resolvers produced the best results.

In the near future, we plan to create and release a larger null instantiation corpus. As null instantiation detection and definite null instantiation identification are the foundation of resolving definite null instantiation, it is critical to improve the performance of both subtasks. Moreover, as different information sources have been used in our study, we cannot directly compare with some of the existing methods. For our future work, we plan to manually annotate coreference information so that we can compare with more methods. Finally, we hope to exploit some additional knowledge resources, such as HowNet, which could potentially further improve the performance of our proposed method.

Acknowledgments

We would like to thank anonymous reviewers and the mentor Jacob Eisenstein for their valuable comments and suggestions, and Xiaoli Li for helping us polish the paper. Discourse-sensitive Automatic Identification of Generic Expressions

Annemarie Friedrich **Manfred Pinkal**
Department of Computational Linguistics
Saarland University, Saarbrücken, Germany
{afried,pinkal}@coli.uni-saarland.de

Abstract

This paper describes a novel sequence labeling method for identifying generic expressions, which refer to kinds or arbitrary members of a class, in discourse context. The automatic recognition of such expressions is important for any natural language processing task that requires text understanding. Prior work has focused on identifying generic noun phrases; we present a new corpus in which not only subjects but also clauses are annotated for genericity according to an annotation scheme motivated by semantic theory. Our context-aware approach for automatically identifying generic expressions uses conditional random fields and outperforms previous work based on local decisions when evaluated on this corpus and on related data sets (ACE-2 and ACE-2005).

1 Introduction

Distinguishing between statements about particular individuals or situations and generic sentences is an important part of human language understanding. Consider example (1): sentence (a) names characteristic attributes of a kind, which are inherent to every (typical) individual, and sentence (b) describes a specific individual.

(1) *(a) The modern domestic horse has a life expectancy of 25 to 30 years. (**generic**)*

*(a) Old Billy lived to the age of 62. (**non-generic**)*

The above example illustrates that generic and non-generic sentences differ substantially in their semantic impact and entailment properties. It can be inferred from sentence (1a) that a *typical* horse has a life expectancy of 25 to 30 years, and if we know that *Nelly* is a horse, we can infer that its life expectancy is 25 to 30 years. Sentence (1b) has no such properties, it only allows inferences about the particular individual *Old Billy*.

An automatic classifier that recognizes generic expressions would be extremely valuable for various kinds of natural language processing systems: for text understanding and question answering systems, through the improvement of textual entailment methods, and for systems acquiring machine-readable knowledge from text. Machine-readable knowledge bases have different representations for statements corresponding to generic knowledge about kinds and knowledge about specific individuals. The non-generic sentence (1b) roughly speaking provides ABox content for a machine-readable knowledge base, i.e., knowledge about particular instances, e.g, *"A is an instance of B / has property X"*. In contrast, the generic sentence (1a) feeds the TBox, i.e., knowledge of the form *"All B are C / have property X"*. Reiter and Frank (2010) provide a detailed discussion of the relevance of the distinction between classes and instances for automatic ontology construction.

In this paper, we present a new corpus annotated in a linguistically motivated way for genericity, and a context-sensitive computational model for labeling sequences of clauses or noun phrases (NPs) with their genericity status. Both manual annotation and automatic recognition of generic expressions are challenging tasks: virtually all NP types – definites, indefinites and quantified NPs, full NPs, pronouns, and even proper names (e.g. species names such as *Elephas maximus*) – can be found in generic and non-generic uses depending on their clausal context.

In this work, we call clauses generic if they provide a general characterization of entities of a certain kind, and we call mentions of NPs generic if they refer to kinds or arbitrary members of a class. Although genericity on the clause- and NP-level

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1272–1281,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

are strongly interrelated, the concepts do not always coincide. As example (2) shows, sentences describing episodic events can have a generic NP as their subject. Note that references to species are kind-referring / generic on the NP level (following Krifka et al. (1995), see p. 65).

*(2) In September 2013 the blobfish was voted the "World's Ugliest Animal". (subject **generic**, clause **non-generic**)*

Genericity often cannot be annotated without paying attention to the wider discourse context. Clearly, coreference information is needed for the genericity classification of pronouns. Often, even genericity of full NPs or entire clauses cannot be decided in isolation, as illustrated by example (3). Sentence (b) could be part of a particular narrative about a tree, or it could be a generic statement. Only the context given by (a) clarifies that (b) indeed makes reference to any year's new twigs and is to be interpreted as generic.

*(3) (a) Sugar maples also have a tendency to color unevenly in fall. (**generic**)*
*(b) The recent year's growth twigs are green and turn dark brown. (**generic**)*

In computational linguistics, most research on detecting genericity has been done in relation to the ACE corpora (Mitchell et al., 2003; Walker et al., 2006), focusing on assigning genericity labels to noun phrases (Suh et al., 2006; Reiter and Frank, 2010), see Section 2. Our work is based on these approaches, most notably on the work of Reiter and Frank (2010), and extends upon them in the following essential ways.

The major contributions of this work are: (1) We create *a new corpus of Wikipedia articles* annotated with linguistically motivated genericity labels both on the subject- and clause-level (see Section 3). The corpus is balanced with respect to genericity and about 10,000 clauses in size. (2) We present a *discourse-sensitive genericity labeler*. Technically, we use conditional random fields as a sequence labeling method (Section 4). We train and evaluate our method on the Wikipedia dataset and the ACE corpora, evaluating both the tasks of predicting NP genericity and the task of predicting clause-level genericity. Our labeler outperforms the state-of-the-art by a margin of 6.6-11.9% (depending on the data set) in terms of accuracy, at the same time increasing F_1-score. Much of the performance gain is due to the inclusion of discourse information. For the discussion of our experimental results, see Section 5.

In this paper, we do *not* address the following two important aspects of genericity. First, *habitual* sentences form a class of generalizing statements which bear a close relation to generics. As can be seen in example (4), they describe a characterizing property of either a specific entity or a class by generalizing over situations instead of or in addition to entities (Carlson, 2005). We classify habitual sentences with a generic subject as generic, and habitual sentences which describe a specific entity as non-generic, leaving the task of habituality detection for future work.

(4) (a) John smokes after dinner.
(b) Gentlemen smoke after dinner.

Second, generic clauses express regularities within classes of entities, and thus are similar to universally quantified sentences in their truth conditions and entailment properties. However, their truth-conditional interpretation is tricky, since they express typicality, describe stereotypes and allow exceptions, for example *Dutchmen are good sailors* is not false even if most Dutchmen do not sail at all (Carlson, 1977). We concentrate on the decision of whether a clause is generic or not, and leave the truth-conditional interpretation for further work. For a detailed discussion of the semantics of generics expressions see the comprehensive survey by Krifka et al. (1995); a short and instructive overview can be found in the first part of (Reiter and Frank, 2010).

2 Related Work

In this section, we first briefly review previously developed annotation schemes for genericity. We then describe work on automatically predicting the genericity of NPs or different types of clauses.

Annotation. ACE-2 (Mitchell et al., 2003) and ACE-2005 (Walker et al., 2006) are the two most notable annotation projects for labeling genericity of NPs to date. In the ACE-2 corpus, 40106 entity mentions in 520 newswire and broadcast documents are marked with regard to whether they refer to "any member of the set in question" (GEN, generic) rather than "some particular, identifiable member of that set" (SPC, specific/non-generic). The major drawback of ACE-2 is that genericity is basically defined as lack of specificity, which leads to uncertainty and inconsistencies in the annotation process, and to a heterogeneous set of NPs labeled with GEN, including quantificational NPs and NPs in modalized, future, conditional, hypothetical, negated, uncertain, and question contexts. In addition, in both ACE-2 and ACE-2005, predicative and modifier uses of nouns, to which the genericity distinction is not applicable, also receive labels (e.g. *John seems to be a nice person / a subway system*).

In the updated guidelines of ACE-2005, the label USP (underspecified) is introduced for non-generic non-specific reference, including NPs in the various contexts mentioned above that were improperly labeled as generic in ACE-2. The class also contains mentions of an entity whose identity would be 'difficult to locate' (*Officials reported ...*). Moreover, annotators are asked to mark truly ambiguous cases that have both a generic and a non-generic reading as USP. Finally, NEG (negated) marks negatively quantified entities that refer to the empty set of the kind mentioned.

While we agree that in general there are underspecified cases, the guidelines for ACE-2005 mix other phenomena into the USP class, resulting in a high confusion between USP and both of the labels SPC and GEN in the manual annotations (Friedrich et al., 2015). Data from two annotators is available, and we compute an agreement of Cohen's κ = 0.53 over the four labels. The ACE corpora consist only of news data, and the distributions of labels are highly skewed towards specific mentions. For some criticism of the ACE annotation scheme, see also Suh (2006).

Several linguistically motivated annotation studies targeting genericity of noun phrases bear similarity to our annotation scheme (Section 3), but comprise very little data (Poesio, 2004; Herbelot and Copestake, 2009). In the ARRAU corpus (Poesio and Artstein, 2008), about 24321 markables are tagged for genericity.

Nedoluzhko (2013) survey the treatment of genericity phenomena within coreference resolution research; they find a consistent definition of genericity to be lacking. Friedrich and Palmer (2014b) present an annotation scheme for situation types including generic sentences, which they find to be infrequent in their corpus consisting of news, jokes and (fund-raising) letters. Our new WikiGenerics corpus contains more than 10,000 clauses, approximately half of which are generic.

Automatic Identification of Genericity. Suh et al. (2006) propose a rule-based approach, which extracts only bare plurals and singular NPs quantified with *every* or *any* as generic. Reiter and Frank (2010) use a wide range of syntactic and semantic features to train a supervised classifier for identifying generic NPs. We compare to their method (described in detail in Section 5.2) as a highly-competitive baseline.

Palmer et al. (2007) classify clauses into several types of situation entities including states, events, generalizing sentences (habitual utterances referring to specific individuals) and generic sentences. They find that using context by using the labels of preceding clauses as features improves the classification of clause types, but generic sentences are extremely sparse in their data set. Our present approach uses a sequence labeling model that computes the best labeling for an entire sequence.

3 WikiGenerics: Data and Annotations

In order to study generics in a genre other than news (as in ACE), we turn to an encyclopedia, in which we expect many generics. We create our **WikiGenerics** corpus[1] as follows. We aim to create a corpus that is balanced in the sense that it contains many generic and non-generic sentences, and also generics from many different domains. We collect 102 texts about animals, organised crime, ethnic groups, games, sports, medicine, music, politics, religion, scientific disciplines and biographies from Wikipedia. For example, some sentences make statements about a 'natural' kind (*Blobfish are typically shorter than 30 cm*), others express definitions such as the rules of a football game (*The offensive team must line up in a legal formation before they can snap the ball*).

Generic clauses have the typical form of a predicative statement about the sentence topic, which is normally realized as the grammatical subject in English. Intuitions about NP-level genericity and its relation to clause-level genericity are quite reliable for topic NPs of clauses, which also typically occur in subject position in English. Since generics in non-subject positions are less frequent and hard to interpret (see the discussion of "dependent generics" by Link (1995)), we decided to annotate subject NPs only. We are aware that we are missing relevant cases (e.g. the less preferred reading

[1] The WikiGenerics corpus is freely available at: `www.coli.uni-saarland.de/projects/sitent`

of *Cats chase mice*, which attributes to mice the property of being chased by cats), but in this work, we want to study the "easier" subject cases as a first step.

We use the discourse parser SPADE (Soricut and Marcu, 2003) to automatically segment the first 70 sentences of each article into clauses. Each clause is manually annotated with the following information (for more details on the annotation scheme, see (Friedrich et al., 2015)):

- **Task NP**: whether or not the *subject* NP of the clause refers to a class or kind (**generic** vs. **non-generic**);
- **Task Cl**: whether the *clause* is **generic**, defined as a clause that makes a characterizing statement about a class or kind, or **non-generic**.
- **Task Cl+NP**: using the information from Task NP and Cl above, we automatically derive the following classification for each *clause* (compare to the explanation of example (2)).
  - **GEN_gen**: generic clause, subject is generic by definition (*The lion is a predatory cat*);
  - **NON-GEN_non-gen**: non-generic clause with a non-generic subject (*Simba roared*);
  - or **NON-GEN_gen**: episodic clause with a generic subject (*Dinosaurs died out*).
  - **GEN_non-gen** does not exist by definition.

We construct the gold standard for our experiments via majority voting over the labels given by three paid annotators, students of computational linguistics. Annotators were given a written manual and a short training on documents not included in the corpus. They are given the option to indicate segmentation errors, e.g. that two segments should actually be one, or that one segment contains multiple clauses. In the latter case, we ask them to give labels for the first clause in the segment. 10240 (86%) of all pre-segmented clauses received labels for all three tasks from all annotators, who were allowed to skip clauses that do not contain a finite verb. Our gold standard includes an additional 115 segments that did not receive a label by one annotator but were unanimously labeled by the other two. The other segments are disregarded in the experiments. Some of them have expletive subjects, and most others are non-finite verb phrases such as *to*-infinites or headlines that consist of only a NP. Inter-annotator agreement measured as Fleiss' κ (Fleiss, 1971) on the segments labeled by all three annotators is 0.70, 0.73 and 0.69 for Task NP, Task Cl and Task Cl+NP respectively, indicating substantial agreement (Landis and Koch, 1977).

4 A Sequence Labeling Model for Genericity

This section describes our method for identifying generic clauses and NPs in context. We apply the following methods on each of the three different prediction tasks NP, Cl and Cl+NP introduced in Section 3, varying only the type of labels on which we train and test. In contrast to prior work, our computational model integrates not only information from each local instance, but also information about the genericity status of surrounding instances. The final labeling for the sequence of instances of an entire document is optimized with regard to these two types of information, which, as we have argued in Section 1, both play a crucial role in determining genericity. The sequences to be labeled contain all clauses or NPs of a document. We also tried labeling sequences for paragraphs instead of documents, but the performance was similar. A reason might be that paragraphs are quite often linked by mentioning the same entities (Friedrich and Palmer, 2014a).

Computational model. We use linear chain conditional random fields (Lafferty et al., 2001) to label sequences of mentions or sequences of clauses with regard to their genericity. Conditional random fields (CRFs) are well suited for our labeling task as they do not make an independence assumption between the features. CRFs predict the conditional probability of label sequence $\vec{y}$ given an observation sequence $\vec{x}$ as follows:

$$P(\vec{y}|\vec{x}) = \frac{1}{Z(\vec{x})} exp(\sum_{j=1}^{n}\sum_{i=1}^{m} \lambda_i f_i(y_{j-1}, y_j, \vec{x}, j))$$

$Z(\vec{x})$ is a normalization constant, the sum over the scores of all possible label sequences for an observation sequence with the length of $\vec{x}$. The weights λ_i of the feature functions are the parameters to be learned. They do not depend on the current position j in the sequence. The feature functions f_i are in general allowed to look at the current label y_j, the previous label y_{j-1} and the entire observation sequence $\vec{x}$. We use a simple instantiation of a linear chain CRF whose feature functions take two forms, $f_i(y_j, x_j)$ and $f_i(y_{j-1}, y_j)$. We create a linear chain CRF model using the CRF++ toolkit[2], using all the default parameters.

NP-BASED FEATURES	
number	sg, pl
person	1, 2, 3
countability	from *Celex*, e.g. count
noun type	common, proper, pronoun
determiner type	def, indef, demon
part-of-speech	POS of head
bare plural	true, false
WN granularity	number of edges to top node
WN sense $[0-2]$	WN senses (head+hypernyms)
WN senseTop	top sense in hypernym hierarchy
WN lexical filename	person, artifact, event, ...

CLAUSE-BASED FEATURES	
dependency $[0-4]$	dependency relation between head and governor etc.
tense	tense, aspect and voice information, e.g. *pres_perf_active*
coarseTense	pres, past, fut
progressive	true, false
perfective	true, false
passive	true, false
temporal modifier	true, false
number of modifiers	numeric
part-of-speech	POS of head
predicate	lemma of head
adjunct-degree	positive, comparative, superlative
adjunct-pred	lemma of adverbial clauses' head

Table 1: **Features**. WN=WordNet.

Feature functions. We extract the set of features listed in Table 1 for each instance. This set of features is inspired by Reiter and Frank (2010), see also Section 5.2. In the case of the WikiGenerics corpus, the NP features are extracted for the subject of the clause. We parse the data using the Stanford parser (Klein and Manning, 2002) and obtain the subject NPs from the collapsed dependencies. For the ACE data, the NP features are extracted for all mentions in the gold standard and the clause features are extracted from the clause in which the mention appears. Our feature functions $f_i(y_j, x_j)$ are indicator functions combining the current label and one of the feature values of the current mention or clause, for example:

f = if (y_j = GENERIC and x_j.np.person=3)
    return 1 else return 0

We create two versions of the CRF model: the bigram[3] model additionally uses indicator functions $f(y_{j-1}, y_j)$ for each combination of labels, thus taking context into account. The unigram model does not use these feature functions, it is thus similar to a maximum entropy model (with a different normalization). Log-linear models work very well for many NLP tasks, especially if features are correlated as it is the case here, so in order to get a fair estimate of the impact of using the context (via the transition feature functions), we give numbers for this 'unigram' model in addition, rather than simply comparing the bigram-CRF to a Bayesian network, which is used by Reiter and Frank (2010). Using more complex feature functions did not result in significant performance gains, so we chose the simplest model. Note that even though the feature functions only formulate relationships between adjacent labels in the sequence, the optimal labeling is computed for the entire sequence: the choices of labels assigned to non-adjacent clauses *do* influence each other.

Two-step Approach for Task Cl+NP. Task Cl+NP can be regarded as a combination of the two decisions made in Task NP and Task Cl. Therefore, we approach Task Cl+NP in two ways. (a) We train a CRF which directly outputs the three labels. (b) The *two-step* approach combines the output from the labelers trained for Task NP and Task Cl into one label in a rule-based way. This leads to the additional class **GEN_non-gen**, of which no gold instances exist by definition. As we evaluate in terms of F$_1$-score and accuracy for the existing classes, items classified into this artificial class will simply be counted as wrong and lack from the recall counts.

5 Experiments

This section reports on our experiments, which we evaluate in terms of precision (P), recall (R) and F$_1$-measure per class. We compute macro-averages as $P_{macro} = \frac{1}{|c|} * \sum_{i=1}^{|c|} P_i$ etc., where $|c|$ stands for the number of classes. Macro-F$_1$ is the harmonic mean of macro-average P and R. To report on statistical significance of differences in accuracy, we apply McNemar's test with $p < 0.01$.

5.1 Experimental Settings and Data

We report results for cross validation (CV). Because we leverage contextual information by labeling sequences of clauses from entire documents, for all experiments presented in this section, if not indicated otherwise, we put all instances of one document into the same fold as one sequence. Fold sizes differ slightly from each other, but folds are kept constant for all experiments.

On WikiGenerics, we carry out all three prediction tasks as defined in Section 3. On the ACE corpora, we only conduct Task NP because there are

[3] Following CRF++ terminology.

	generic			non-generic			macro-avg			
System	P	R	F1	P	R	F1	P	R	F1	accuracy
Majority class baseline	0.0	0.0	0.0	86.8	100	92.9	43.4	50.0	46.5	86.8

Reimpl. (BayesNet)	38.1	67.7	48.8	94.4	83.3	88.5	66.3	75.5	70.6	81.2

Table 2: Results of **reimplemented baseline** on ACE-2 (original, unbalanced data set), 40106 instances (annotated noun phrases). Weka's stratified 10-fold cross validation, using all features.

no labels corresponding to Task Cl or Task Cl+NP.

For the experiments on WikiGenerics, we use leave-one-document-out CV, i.e., we train on 101 of the 102 documents and test on the remaining document in each fold. The total number of clauses is 10355. From ACE-2005, we use the newswire and broadcast news subsections.[4] Due to low frequency, we omit instances of NEG in our experiments, and apply a three-way classification task (GEN, SPC, USP). We present results for all remaining 40106 mentions and for the subset of 18029 subject mentions, each time using 10-fold CV.

5.2 Baseline: Local Classifier

The system for identifying generic NPs of Reiter and Frank (2010), henceforth R&F, makes use of the English ParGram LFG grammar for the XLE parser (Butt et al., 2002). As this grammar is not publicly available, we implement a similar system using exclusively the Stanford CoreNLP toolsuite (Manning et al., 2014), the Celex database of English nouns (Baayen et al., 1996) and WordNet (Fellbaum, 1999). Our system is based on dkpro (de Castilho and Gurevych, 2014). We extract the features listed in Table 1 based on the POS tags and syntactic dependencies assigned by the Stanford parser (Klein and Manning, 2002). We could not reimplement several tense- and aspect-related ParGram-specific features. In order to compensate for this, we add an additional feature (tense) with finer-grained tense and voice information, using the rules described by Loaiciga et al. (2014). Other additional features did not improve performance, which shows that R&F's set of features captures the syntactic-semantic information relevant to genericity classification quite well. Therefore, we use this feature set also for the sequence labeling model. Using the same feature set allows us to attribute any performance gain to the context-awareness of our model rather than the features.

R&F train a Bayesian network using Weka (Hall et al., 2009). The decisions of this classifier are local to each clause. They report the performance of their system on the ACE-2 corpus: Table 2 shows that the performance of our reimplemented feature set[5] is comparable to the system of R&F.[6] In all other other tables, "BayesNet R&F" refers to our re-implemented system.

R&F present the "Person baseline" as a simple informed baseline (see Table 2). We trained a J48 decision tree on this feature alone, which confirmed that only second-person mentions (the generic "you") are classified as generic, while all other mentions are classified as non-generic.

5.3 Results and Discussion

In this section, we first discuss the results of our experiments in terms of identifying generic NPs or clauses. Then we present some additional experiments testing the influence of the different feature classes and of other discourse-related information.

All tasks, WikiGenerics. The observations described in this paragraph are the same for all three prediction tasks on WikiGenerics. As Tables 3 and 4 show, our CRF models outperform the baseline system of R&F by a large margin both in terms of accuracy and F_1-score on the WikiGenerics corpus. In Task NP and Task Cl, precision and recall are quite balanced (not shown in tables). The performance of the bigram model is significantly better than that of the unigram model, increasing accuracy by about 3%, at the same time increasing F_1. In an oracle experiment, we use the previous gold label instead of the predicted one for $f_i(y_{j-1}, y_j)$, and scores increase by up to 6.6% compared to the unigram model. These results provide strong empirical evidence for our hypoth-

[4] The rest of the data comprise broadcast conversation, weblog and forum texts as well as transcribed conversational telephone, and would require specialized preprocessing.

esis that using context information is useful for identifying the genericity of NPs or clauses.

Task Cl+NP, WikiGenerics. In Task Cl+NP (see Table 4), only about 6% of the instances have the gold label **NON-GEN_gen** (i.e., a non-generic sentence with a generic subject), the other instances are distributed roughly evenly between the other two labels. The difficulty of Task Cl+NP thus consists in identifying this infrequent case. The three-way CRF outperforms the two-step approach both in terms of accuracy and macro-average F_1-score. The precision-recall tradeoff differs: for the **NON-GEN_gen** class, P and R of the CRF are 55.2% and 24.5% and those of the two-step-approach are 23.8% and 35.9%. The two-step approach labels more instances as **NON-GEN_gen** but does so in a less precise way. While the performance of our model leaves room for improvement on Task Cl+NP, especially with regard to the class **NON-GEN_gen**, it is worth noting that the computational model captures something about the nature of this latter class; its instances *do* look different in the feature space. The context-aware CRF using three labels performs best.

Feature set ablation. In this ablation test, shown in Tables 3 and 4, our best model (CRF bigram) uses either the set of clause-based or the set of NP-based features at a time. Clause-based features are more important than the NP-based features for all three classification tasks. An interesting observation is that the NP features alone are not able to separate the infrequent class **NON-GEN_gen** from the other two at all, the F_1-score of 2.5 shows that almost all instances of this class were labeled as one of the other two classes. In sum, this shows that whether an NP is interpreted as generic or not strongly depends on how it is used in the clause.

Task NP, ACE. Both on ACE-2 (see Table 5) and on ACE-2005 (see Table 6), the CRF outperforms the system of Reiter and Frank (2010) in terms of accuracy, and has a higher F_1-score. We give results also for subjects only as this parallels the setting of the WikiGenerics experiments (reasons for the restriction to subjects were given in Section 3). For subjects, the majority class SPC is less frequent (compare the accuracies of the two majority class baselines); only 7% of the subjects are marked as GEN, the rest are labeled as USP. The bigram model does not outperform the unigram model, but our oracle experiments show that context information is indeed useful: accuracy increases significantly and F_1 increases considerably, especially for subjects.

We identify two reasons for the fact that when evaluating on the ACE corpora, oracle information is needed to show the benefit of using bigram feature functions: (a) The frequency of **GEN** mentions in the ACE corpora is low – news contains only little generic information, so the context information is harder to leverage. (b) The ACE annotation guidelines contain some vagueness (see Section 3); this makes it harder for an automatic system to learn about regularities.

Higher-order Markov models. Another research question is whether models incorporating not only the previous label, but more preceding labels would perform even better. We turn to the Mallet toolkit (McCallum, 2002), whose CRF implementation allows for using higher-order models.[7] For example, an order-2 model considers the two previous labels. We use L1-regularization during training. Figure 1 shows that the optimum is reached for order-1 (bigram) models for each of the classification tasks for accuracy, the same tendencies were observed for F_1-score (not shown). It seems sufficient to use bigram feature functions; note that as explained in Section 4, the bigram model does not mean that only adjacent clauses influence each other – context is actually wider.

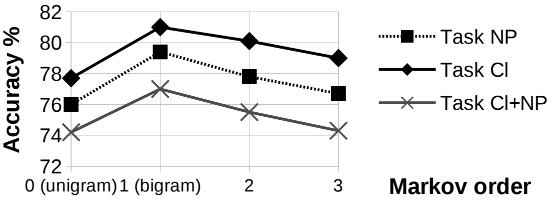

Figure 1: Labeling results for CRF models of various orders on WikiGenerics corpus.

Using coreference information. In our approximately balanced WikiGenerics corpus, 54% of all pronouns are marked as generic and 46% are marked as non-generic, which shows that there is no preference for pronouns to occur with either class. Some of the features (countability, noun type, determiner type, bare plural, and the WordNet related features) are not informative when applied to personal or relative pronouns. Sometimes, it is not even possible to determine number without referring to the antecedent (e.g., in the case of the relative pronoun 'who'). We conduct the following experiment: we automatically resolve coreference using the Stanford coreference resolution system (Raghunathan et al., 2010). We replace the NP features of each pronominal instance with the features of the first link of the coreference chain. We did not obtain a significant performance gain. One reason is that this change of features only applies to about 13% of the data. We observe that any positive changes in the classification go along with some negative changes which were often due to coreference resolution errors. One difficult step in manually annotating, and hence also in automatically resolving coreference is to determine whether a NP is generic or not (Nedoluzhko, 2013). The task of identifying generic NPs and

[7] The CRF++ toolkit, which we use in all other experiments, does not allow for higher-order models. We use CRF++ in the main experiments as it comes with a concise documentation; this helps to make our experiments easily replicable.

coreference resolution are intertwined. We plan to manually annotate at least part of our corpus with coreference information in order to test to what extent the classification of the pronouns' genericity status can profit from including antecedent information.

6 Conclusion

We have presented a novel method for labeling sequences of clauses or their subjects with regard to their genericity, showing that genericity should be treated as a discourse-sensitive phenomenon. Our experiments prove that context information improves automatic labeling results, and that our model outperforms previous approaches by a large margin.

The major contributions of this work include the study of genericity both on the NP- and clause-level, and the study of the interaction of these two levels. Our results of Task Cl+NP show that our model indeed captures the three different types of clauses resulting from the combination of NP-level and clause-level genericity.

During the development of our annotation scheme, we found that it is beneficial to focus on genericity, disentangling it from the issue of specificity. Our work provides a step forward to finding reliable ways to apply semantic theories of genericity in practice, and we also provide a new state-of-the-art system for automatically labeling generic expressions. This in turn lays foundations for natural language processing tasks requiring text understanding.

Future Work. Our present approach for annotating and automatically classifying targets the subjects of each clause. We have not attempted to tackle the task of classifying the genericity status of other dependents, as they are even harder to classify than subjects, and a concise annotation scheme has to be worked out in order achieve an acceptable inter-annotator agreement on this task. Another related distinction is the one between habitual, stative and episodic sentences (Mathew and Katz, 2009), which applies to both what we call generic and non-generic sentences. No large corpora exist to date, but studying the interaction of these phenomena is on our research agenda.

Acknowledgments

We thank the anonymous reviewers, Alexis Palmer, Nils Reiter and Melissa Peate Sørensen for their helpful comments related to this work, and our annotators Christine Bocionek and Kleo-Isidora Mavridou. This research was supported in part by the Cluster of Excellence "Multimodal Computing and Interaction" of the German Excellence Initiative (DFG), and the first author is supported by an IBM PhD Fellowship.

Model-based Word Embeddings from Decompositions of Count Matrices

Karl Stratos **Michael Collins** **Daniel Hsu**

{stratos, mcollins, djhsu}@cs.columbia.edu

Abstract

This work develops a new statistical understanding of word embeddings induced from transformed count data. Using the class of hidden Markov models (HMMs) underlying Brown clustering as a generative model, we demonstrate how canonical correlation analysis (CCA) and certain count transformations permit efficient and effective recovery of model parameters with lexical semantics. We further show in experiments that these techniques empirically outperform existing spectral methods on word similarity and analogy tasks, and are also competitive with other popular methods such as WORD2VEC and GLOVE.

1 Introduction

The recent spike of interest in dense, low-dimensional lexical representations—i.e., word embeddings—is largely due to their ability to capture subtle syntactic and semantic patterns that are useful in a variety of natural language tasks. A successful method for deriving such embeddings is the negative sampling training of the skip-gram model suggested by Mikolov et al. (2013b) and implemented in the popular software WORD2VEC. The form of its training objective was motivated by efficiency considerations, but has subsequently been interpreted by Levy and Goldberg (2014b) as seeking a *low-rank factorization* of a matrix whose entries are word-context co-occurrence counts, scaled and transformed in a certain way. This observation sheds new light on WORD2VEC, yet also raises several new questions about word embeddings based on decomposing count data. What is the right matrix to decompose? Are there rigorous justifications for the choice of matrix and count transformations?

In this paper, we answer some of these questions by investigating the decomposition specified by CCA (Hotelling, 1936), a powerful technique for inducing generic representations whose computation is efficiently and exactly reduced to that of a matrix singular value decomposition (SVD). We build on and strengthen the work of Stratos et al. (2014) which uses CCA for learning the class of HMMs underlying Brown clustering. We show that certain count transformations enhance the accuracy of the estimation method and significantly improve the empirical performance of word representations derived from these model parameters (Table 1).

In addition to providing a rigorous justification for CCA-based word embeddings, we also supply a general template that encompasses a range of spectral methods (algorithms employing SVD) for inducing word embeddings in the literature, including the method of Levy and Goldberg (2014b). In experiments, we demonstrate that CCA combined with the square-root transformation achieves the best result among spectral methods and performs competitively with other popular methods such as WORD2VEC and GLOVE on word similarity and analogy tasks. We additionally demonstrate that CCA embeddings provide the most competitive improvement when used as features in named-entity recognition (NER).

2 Notation

We use $[n]$ to denote the set of integers $\{1, \ldots, n\}$. We denote the $m \times m$ diagonal matrix with values $v_1 \ldots v_m$ along the diagonal by $\mathrm{diag}(v_1 \ldots v_m)$. We write $[a_1 \ldots a_m]$ to denote a matrix whose i-th column is a_i. The expected value of a random variable X is denoted by $\mathbf{E}[X]$. Given a matrix Ω and an exponent a, we distinguish the entrywise power operation $\Omega^{\langle a \rangle}$ (i.e., $\Omega^{\langle a \rangle}_{i,j} = (\Omega_{i,j})^a$) from the matrix power operation Ω^a (defined only for square Ω).

3 Background in CCA

In this section, we review the variational characterization of CCA. This provides a flexible framework for a wide variety of tasks. CCA seeks to maximize a statistical quantity known as the Pearson correlation coefficient between random variables $L, R \in \mathbb{R}$:

$$\text{Cor}(L, R) := \frac{\mathbf{E}[LR] - \mathbf{E}[L]\mathbf{E}[R]}{\sqrt{\mathbf{E}[L^2] - \mathbf{E}[L]^2}\sqrt{\mathbf{E}[R^2] - \mathbf{E}[R]^2}}$$

This is a value in $[-1, 1]$ indicating the degree of linear dependence between L and R.

3.1 CCA objective

Let $X \in \mathbb{R}^n$ and $Y \in \mathbb{R}^{n'}$ be two random vectors. Without loss of generality, we will assume that X and Y have zero mean.[1] Let $m \leq \min(n, n')$. CCA can be cast as finding a set of projection vectors (called canonical directions) $a_1 \dots a_m \in \mathbb{R}^n$ and $b_1 \dots b_m \in \mathbb{R}^{n'}$ such that for $i = 1 \dots m$:

$$\begin{aligned} (a_i, b_i) = \underset{a \in \mathbb{R}^n,\, b \in \mathbb{R}^{n'}}{\arg\max} \quad & \text{Cor}(a^\top X, b^\top Y) \qquad (1) \\ & \text{Cor}(a^\top X, a_j^\top X) = 0 \quad \forall j < i \\ & \text{Cor}(b^\top Y, b_j^\top Y) = 0 \quad \forall j < i \end{aligned}$$

That is, at each i we simultaneously optimize vectors a, b so that the projected random variables $a^\top X, b^\top Y \in \mathbb{R}$ are maximally correlated, subject to the constraint that the projections are uncorrelated to all previous projections.

Let $A := [a_1 \dots a_m]$ and $B := [b_1 \dots b_m]$. Then we can think of the joint projections

$$\underline{X} = A^\top X \qquad \underline{Y} = B^\top Y \qquad (2)$$

as new m-dimensional representations of the original variables that are transformed to be as correlated as possible with each other. Furthermore, often $m \ll \min(n, n')$, leading to a dramatic reduction in dimensionality.

3.2 Exact solution via SVD

Eq. (1) is non-convex due to the terms a and b that interact with each other, so it cannot be solved exactly using a standard optimization technique. However, a method based on SVD provides an efficient and exact solution. See Hardoon et al. (2004) for a detailed discussion.

Lemma 3.1 (Hotelling (1936))**.** *Assume X and Y have zero mean. The solution (A, B) to (1) is given by $A = \boldsymbol{E}[XX^\top]^{-1/2}U$ and $B = \boldsymbol{E}[YY^\top]^{-1/2}V$ where the i-th column of $U \in \mathbb{R}^{n \times m}$ ($V \in \mathbb{R}^{n' \times m}$) is the left (right) singular vector of*

$$\Omega := \boldsymbol{E}[XX^\top]^{-1/2}\boldsymbol{E}[XY^\top]\boldsymbol{E}[YY^\top]^{-1/2} \qquad (3)$$

corresponding to the i-th largest singular value σ_i. Furthermore, $\sigma_i = Cor(a_i^\top X, b_i^\top Y)$.

3.3 Using CCA for word representations

As presented in Section 3.1, CCA is a general framework that operates on a pair of random variables. Adapting CCA specifically to inducing word representations results in a simple recipe for calculating (3).

A natural approach is to set X to represent a word and Y to represent the relevant "context" information about a word. We can use CCA to project X and Y to a low-dimensional space in which they are maximally correlated: see Eq. (2). The projected X can be considered as a new word representation.

Denote the set of distinct word types by $[n]$. We set $X, Y \in \mathbb{R}^n$ to be one-hot encodings of words and their associated context words. We define a context word to be a word occurring within ρ positions to the left and right (excluding the current word). For example, with $\rho = 1$, the following snippet of text where the current word is "souls":

```
Whatever our souls are made of
```

will generate two samples of $X \times Y$: a pair of indicator vectors for "souls" and "our", and a pair of indicator vectors for "souls" and "are".

CCA requires performing SVD on the following matrix $\Omega \in \mathbb{R}^{n \times n}$:

$$\begin{aligned} \Omega = & (\mathbf{E}[XX^\top] - \mathbf{E}[X]\mathbf{E}[X]^\top)^{-1/2} \\ & (\mathbf{E}[XY^\top] - \mathbf{E}[X]\mathbf{E}[Y]^\top) \\ & (\mathbf{E}[YY^\top] - \mathbf{E}[Y]\mathbf{E}[Y]^\top)^{-1/2} \end{aligned}$$

At a quick glance, this expression looks daunting: we need to perform matrix inversion and multiplication on potentially large dense matrices. However, Ω is easily computable with the following observations:

Observation 1. We can ignore the centering operation when the sample size is large (Dhillon et al.,

[1] This can be always achieved through data preprocessing ("centering").

2011). To see why, let $\{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$ be N samples of X and Y. Consider the sample estimate of the term $\mathbf{E}[XY^\top] - \mathbf{E}[X]\mathbf{E}[Y]^\top$:

$$\frac{1}{N}\sum_{i=1}^{N} x^{(i)}(y^{(i)})^\top - \frac{1}{N^2}\left(\sum_{i=1}^{N} x^{(i)}\right)\left(\sum_{i=1}^{N} y^{(i)}\right)^\top$$

The first term dominates the expression when N is large. This is indeed the setting in this task where the number of samples (word-context pairs in a corpus) easily tends to billions.

Observation 2. The (uncentered) covariance matrices $\mathbf{E}[XX^\top]$ and $\mathbf{E}[YY^\top]$ are diagonal. This follows from our definition of the word and context variables as one-hot encodings since $\mathbf{E}[X_w X_{w'}] = 0$ for $w \neq w'$ and $\mathbf{E}[Y_c Y_{c'}] = 0$ for $c \neq c'$.

With these observations and the binary definition of (X, Y), each entry in Ω now has a simple closed-form solution:

$$\Omega_{w,c} = \frac{P(X_w = 1, Y_c = 1)}{\sqrt{P(X_w = 1)P(Y_c = 1)}} \tag{4}$$

which can be readily estimated from a corpus.

4 Using CCA for parameter estimation

In a less well-known interpretation of Eq. (4), CCA is seen as a parameter estimation algorithm for a language model (Stratos et al., 2014). This model is a restricted class of HMMs introduced by Brown et al. (1992), henceforth called the Brown model. In this section, we extend the result of Stratos et al. (2014) and show that its correctness is preserved under certain element-wise data transformations.

4.1 Clustering under a Brown model

A Brown model is a 5-tuple (n, m, π, t, o) for $n, m \in \mathbb{N}$ and functions π, t, o where

- $[n]$ is a set of word types.
- $[m]$ is a set of hidden states.
- $\pi(h)$ is the probability of generating $h \in [m]$ in the first position of a sequence.
- $t(h'|h)$ is the probability of generating $h' \in [m]$ given $h \in [m]$.
- $o(w|h)$ is the probability of generating $w \in [n]$ given $h \in [m]$.

Importantly, the model makes the following additional assumption:

Assumption 4.1 (Brown assumption)**.** *For each word type $w \in [n]$, there is a unique hidden state $\mathcal{H}(w) \in [m]$ such that $o(w|\mathcal{H}(w)) > 0$ and $o(w|h) = 0$ for all $h \neq \mathcal{H}(w)$.*

In other words, this model is an HMM in which observation states are partitioned by hidden states. Thus a sequence of N words $w_1 \ldots w_N \in [n]^N$ has probability $\pi(\mathcal{H}(w_1)) \times \prod_{i=1}^{N} o(w_i|\mathcal{H}(w_i)) \times \prod_{i=1}^{N-1} t(\mathcal{H}(w_{i+1})|\mathcal{H}(w_i))$.

An equivalent definition of a Brown model is given by organizing the parameters in matrix form. Under this definition, a Brown model has parameters (π, T, O) where $\pi \in \mathbb{R}^m$ is a vector and $T \in \mathbb{R}^{m\times m}, O \in \mathbb{R}^{n\times m}$ are matrices whose entries are set to:

$$\begin{aligned} \pi_h &= \pi(h) & h &\in [m] \\ T_{h',h} &= t(h'|h) & h, h' &\in [m] \\ O_{w,h} &= o(w|h) & h &\in [m], w \in [n] \end{aligned}$$

Our main interest is in obtaining some representations of word types that allow us to identify their associated hidden states under the model. For this purpose, representing a word by the corresponding row of O is sufficient. To see this, note that each row of O must have a single nonzero entry by Assumption 4.1. Let $v(w) \in \mathbb{R}^m$ be the w-th row of O normalized to have unit 2-norm: then $v(w) = v(w')$ iff $\mathcal{H}(w) = \mathcal{H}(w')$. See Figure 1(a) for illustration.

A crucial aspect of this representational scheme is that its correctness is *invariant* to scaling and rotation. In particular, clustering the normalized rows of $\text{diag}(s)O^{\langle a\rangle}\text{diag}(s_2)Q^\top$ where $O^{\langle a\rangle}$ is any element-wise power of O with any $a \neq 0$, $Q \in \mathbb{R}^{m\times m}$ is any orthogonal transformation, and $s_1 \in \mathbb{R}^n$ and $s_2 \in \mathbb{R}^m$ are any positive vectors yields the correct clusters under the model. See Figure 1(b) for illustration.

4.2 Spectral estimation

Thus we would like to estimate O and use its rows for representing word types. But the likelihood function under the Brown model is non-convex, making an MLE estimation of the model parameters difficult. However, the hard-clustering assumption (Assumption 4.1) allows for a simple

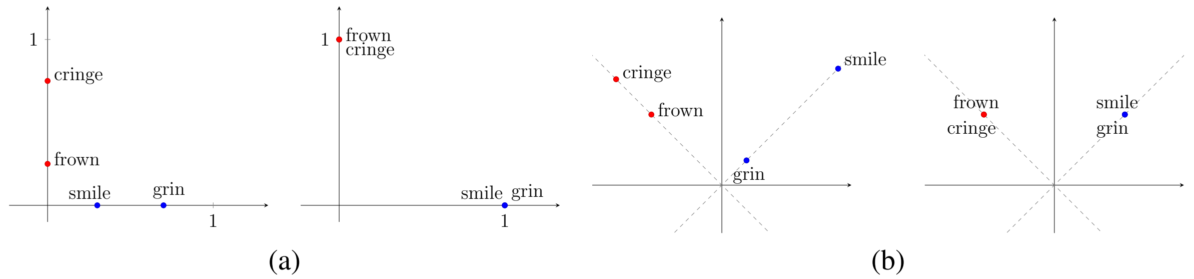

Figure 1: Visualization of the representational scheme under a Brown model with 2 hidden states. (a) Normalizing the original rows of O. (b) Normalizing the scaled and rotated rows of O.

spectral method for consistent parameter estimation of O.

To state the theorem, we define an additional quantity. Let ρ be the number of left/right context words to consider in CCA. Let $(H_1, \ldots, H_N) \in [m]^N$ be a random sequence of hidden states drawn from the Brown model where $N \geq 2\rho + 1$. Independently, pick a position $I \in [\rho + 1, N - \rho]$ uniformly at random. Define $\tilde{\pi} \in \mathbb{R}^m$ where $\tilde{\pi}_h := P(H_I = h)$ for each $h \in [m]$.

Theorem 4.1. *Assume $\tilde{\pi} > 0$ and rank(O) = rank(T) = m. Assume that a Brown model (π, T, O) generates a sequence of words. Let $X, Y \in \mathbb{R}^n$ be one-hot encodings of words and their associated context words. Let $U \in \mathbb{R}^{n \times m}$ be the matrix of m left singular vectors of $\Omega^{\langle a \rangle} \in \mathbb{R}^{n \times n}$ corresponding to nonzero singular values where Ω is defined in Eq. (4) and $a \neq 0$:*

$$\Omega^{\langle a \rangle}_{w,c} = \frac{P(X_w = 1, Y_c = 1)^a}{\sqrt{P(X_w = 1)^a P(Y_c = 1)^a}}$$

Then there exists an orthogonal matrix $Q \in \mathbb{R}^{m \times m}$ and a positive $s \in \mathbb{R}^m$ such that $U = O^{\langle a/2 \rangle}$diag$(s) Q^\top$.

This theorem states that the CCA projection of words in Section 3.3 is the rows of O up to scaling and rotation even if we raise each element of Ω in Eq. (4) to an arbitrary (nonzero) power. The proof is a variant of the proof in Stratos et al. (2014) and is given in Appendix A.

4.3 Choice of data transformation

Given a corpus, the sample estimate of $\Omega^{\langle a \rangle}$ is given by:

$$\hat{\Omega}^{\langle a \rangle}_{w,c} = \frac{\#(w, c)^a}{\sqrt{\#(w)^a \#(c)^a}} \tag{5}$$

where $\#(w, c)$ denotes the co-occurrence count of word w and context c in the corpus, $\#(w) := \sum_c \#(w, c)$, and $\#(c) := \sum_w \#(w, c)$. What choice of a is beneficial and why? We use $a = 1/2$ for the following reason: it stabilizes the variance of the term and thereby gives a more statistically stable solution.

4.3.1 Variance stabilization for word counts

The square-root transformation is a *variance-stabilizing transformation* for Poisson random variables (Bartlett, 1936; Anscombe, 1948). In particular, the square-root of a Poisson variable has variance close to $1/4$, independent of its mean.

Lemma 4.1 (Bartlett (1936))**.** *Let X be a random variable with distribution Poisson$(n \times p)$ for any $p \in (0, 1)$ and positive integer n. Define $Y := \sqrt{X}$. Then the variance of Y approaches $1/4$ as $n \to \infty$.*

This transformation is relevant for word counts because they can be naturally modeled as Poisson variables. Indeed, if word counts in a corpus of length N are drawn from a multinomial distribution over $[n]$ with N observations, then these counts have the same distribution as n independent Poisson variables (whose rate parameters are related to the multinomial probabilities), conditioned on their sum equaling N (Steel, 1953). Empirically, the peaky concentration of a Poisson distribution is well-suited for modeling word occurrences.

4.3.2 Variance-weighted squared-error minimization

At the heart of CCA is computing the SVD of the $\Omega^{\langle a \rangle}$ matrix: this can be interpreted as solving the following (non-convex) squared-error minimization problem:

$$\min_{u_w, v_c \in \mathbb{R}^m} \sum_{w,c} \left(\Omega^{\langle a \rangle}_{w,c} - u_w^\top v_c \right)^2$$

But we note that minimizing *unweighted* squared-error objectives is generally suboptimal when the target values are heteroscedastic. For instance, in linear regression, it is well-known that a *weighted least squares* estimator dominates ordinary least squares in terms of statistical efficiency (Aitken, 1936; Lehmann and Casella, 1998). For our setting, the analogous weighted least squares optimization is:

$$\min_{u_w, v_c \in \mathbb{R}^m} \sum_{w,c} \frac{1}{\mathrm{Var}\left(\Omega^{\langle a \rangle}_{w,c}\right)} \left(\Omega^{\langle a \rangle}_{w,c} - u_w^\top v_c\right)^2 \quad (6)$$

where $\mathrm{Var}(X) := \mathbf{E}[X^2] - \mathbf{E}[X]^2$. This optimization is, unfortunately, generally intractable (Srebro et al., 2003). The square-root transformation, nevertheless, obviates the variance-based weighting since the target values have approximately the same variance of 1/4.

5 A template for spectral methods

Figure 2 gives a generic template that encompasses a range of spectral methods for deriving word embeddings. All of them operate on co-occurrence counts $\#(w, c)$ and share the low-rank SVD step, but they can differ in the data transformation method (t) and the definition of the matrix of scaled counts for SVD (s).

We introduce two additional parameters $\alpha, \beta \leq 1$ to account for the following details. Mikolov et al. (2013b) proposed smoothing the empirical context distribution as $\hat{p}_\alpha(c) := \#(c)^\alpha / \sum_c \#(c)^\alpha$ and found $\alpha = 0.75$ to work well in practice. We also found that setting $\alpha = 0.75$ gave a small but consistent improvement over setting $\alpha = 1$. Note that the choice of α only affects methods that make use of the context distribution ($s \in \{\text{ppmi}, \text{cca}\}$).

The parameter β controls the role of singular values in word embeddings. This is always 0 for CCA as it does not require singular values. But for other methods, one can consider setting $\beta > 0$ since the best-fit subspace for the rows of Ω is given by $U\Sigma$. For example, Deerwester et al. (1990) use $\beta = 1$ and Levy and Goldberg (2014b) use $\beta = 0.5$. However, it has been found by many (including ourselves) that setting $\beta = 1$ yields substantially worse representations than setting $\beta \in \{0, 0.5\}$ (Levy et al., 2015).

Different combinations of these aspects reproduce various spectral embeddings explored in the literature. We enumerate some meaningful combinations:

SPECTRAL-TEMPLATE
Input: word-context co-occurrence counts $\#(w, c)$, dimension m, transformation method t, scaling method s, context smoothing exponent $\alpha \leq 1$, singular value exponent $\beta \leq 1$
Output: vector $v(w) \in \mathbb{R}^m$ for each word $w \in [n]$
Definitions: $\#(w) := \sum_c \#(w, c)$, $\#(c) := \sum_w \#(w, c)$, $N(\alpha) := \sum_c \#(c)^\alpha$

1. Transform all $\#(w, c)$, $\#(w)$, and $\#(c)$:

$$\#(\cdot) \leftarrow \begin{cases} \#(\cdot) & \text{if } t = \text{—} \\ \log(1 + \#(\cdot)) & \text{if } t = \text{log} \\ \#(\cdot)^{2/3} & \text{if } t = \text{two-thirds} \\ \sqrt{\#(\cdot)} & \text{if } t = \text{sqrt} \end{cases}$$

2. Scale statistics to construct a matrix $\Omega \in \mathbb{R}^{n \times n}$:

$$\Omega_{w,c} \leftarrow \begin{cases} \#(w, c) & \text{if } s = \text{—} \\ \frac{\#(w,c)}{\#(w)} & \text{if } s = \text{reg} \\ \max\left(\log \frac{\#(w,c)N(\alpha)}{\#(w)\#(c)^\alpha}, 0\right) & \text{if } s = \text{ppmi} \\ \frac{\#(w,c)}{\sqrt{\#(w)\#(c)^\alpha}} \sqrt{\frac{N(\alpha)}{N(1)}} & \text{if } s = \text{cca} \end{cases}$$

3. Perform rank-m SVD on $\Omega \approx U \Sigma V^\top$ where $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_m)$ is a diagonal matrix of ordered singular values $\sigma_1 \geq \cdots \geq \sigma_m \geq 0$.

4. Define $v(w) \in \mathbb{R}^m$ to be the w-th row of $U\Sigma^\beta$ normalized to have unit 2-norm.

Figure 2: A template for spectral word embedding methods.

No scaling $\left[t \in \{\text{—}, \text{log}, \text{sqrt}\},\ s = \text{—}\right]$. This is a commonly considered setting (e.g., in Pennington et al. (2014)) where no scaling is applied to the co-occurrence counts. It is however typically accompanied with some kind of data transformation.

Positive point-wise mutual information (PPMI) $\left[t = \text{—},\ s = \text{ppmi}\right]$. Mutual information is a popular metric in many natural language tasks (Brown et al., 1992; Pantel and Lin, 2002). In this setting, each term in the matrix for SVD is set as the point-wise mutual information between word w and context c:

$$\log \frac{\hat{p}(w, c)}{\hat{p}(w)\hat{p}_\alpha(c)} = \log \frac{\#(w, c) \sum_c \#(c)^\alpha}{\#(w)\#(c)^\alpha}$$

Typically negative values are thresholded to 0 to keep Ω sparse. Levy and Goldberg (2014b) observed that the negative sampling objective of the skip-gram model of Mikolov et al. (2013b) is implicitly factorizing a shifted version of this matrix.[2]

[2] This is not equivalent to applying SVD on this matrix, however, since the loss function is different.

Regression $\big[t \in \{\text{—}, \text{sqrt}\},\ \ s = \text{reg}\big]$. Another novelty of our work is considering a low-rank approximation of a linear regressor that predicts the context from words. Denoting the word sample matrix by $\mathcal{X} \in \mathbb{R}^{N\times n}$ and the context sample matrix by $\mathcal{Y} \in \mathbb{R}^{N\times n}$, we seek $U^* = \arg\min_{U\in\mathbb{R}^{n\times n}} ||\mathcal{Y} - \mathcal{X}U||^2$ whose closed-from solution is given by:

$$U^* = (\mathcal{X}^\top\mathcal{X})^{-1}\mathcal{X}^\top\mathcal{Y} \tag{7}$$

Thus we aim to compute a low-rank approximation of U^* with SVD. This is inspired by other predictive models in the representation learning literature (Ando and Zhang, 2005; Mikolov et al., 2013a). We consider applying the square-root transformation for the same variance stabilizing effect discussed in Section 4.3.

CCA $\big[t \in \{\text{—}, \text{two-thirds}, \text{sqrt}\},\ \ s = \text{cca}\big]$. This is the focus of our work. As shown in Theorem 4.1, we can take the element-wise power transformation on counts (such as the power of $1, 2/3, 1/2$ in this template) while preserving the representational meaning of word embeddings under the Brown model interpretation. If there is no data transformation ($t =$ —), then we recover the original spectral algorithm of Stratos et al. (2014).

6 Related work

We make a few remarks on related works not already discussed earlier. Dhillon et al. (2011) and (2012) propose novel modifications of CCA (LR-MVL and two-step CCA) to derive word embeddings, but do not establish any explicit connection to learning HMM parameters or justify the square-root transformation. Pennington et al. (2014) propose a weighted factorization of log-transformed co-occurrence counts, which is generally an intractable problem (Srebro et al., 2003). In contrast, our method requires only efficiently computable matrix decompositions. Finally, word embeddings have also been used as features to improve performance in a variety of supervised tasks such as sequence labeling (Dhillon et al., 2011; Collobert et al., 2011) and dependency parsing (Lei et al., 2014; Chen and Manning, 2014). Here, we focus on understanding word embeddings in the context of a generative word class model, as well as in empirical tasks that directly evaluate the word embeddings themselves.

7 Experiments

7.1 Word similarity and analogy

We first consider word similarity and analogy tasks for evaluating the quality of word embeddings. Word similarity measures the Spearman's correlation coefficient between the human scores and the embeddings' cosine similarities for word pairs. Word analogy measures the accuracy on syntactic and semantic analogy questions. We refer to Levy and Goldberg (2014a) for a detailed description of these tasks. We use the multiplicative technique of Levy and Goldberg (2014a) for answering analogy questions.

For the choice of corpus, we use a preprocessed English Wikipedia dump (`http://dumps.wikimedia.org/`). The corpus contains around 1.4 billion words. We only preserve word types that appear more than 100 times and replace all others with a special symbol, resulting in a vocabulary of size around 188k. We define context words to be 5 words to the left/right for all considered methods.

We use three word similarity datasets each containing 353, 3000, and 2034 word pairs.[3] We report the average similarity score across these datasets under the label AVG-SIM. We use two word analogy datasets that we call SYN (8000 syntactic analogy questions) and MIXED (19544 syntactic and semantic analogy questions).[4]

We implemented the template in Figure 2 in C++.[5] We compared against the public implementation of WORD2VEC by Mikolov et al. (2013b) and GLOVE by Pennington et al. (2014). These external implementations have numerous hyperparameters that are not part of the core algorithm, such as random subsampling in WORD2VEC and the word-context averaging in GLOVE. We refer to Levy et al. (2015) for a discussion of the effect of these features. In our experiments, we enable all these features with the recommended default settings.

We reserve a half of each dataset (by category)

as a held-out portion for development and use the other half for final evaluation.

7.1.1 Effect of data transformation for CCA

We first look at the effect of different data transformations on the performance of CCA. Table 1 shows the result on the development portion with 1000-dimensional embeddings. We see that without any transformation, the performance can be quite bad—especially in word analogy. But there is a marked improvement upon transforming the data. Moreover, the square-root transformation gives the best result, improving the accuracy on the two analogy datasets by 25.46% and 20.06% in absolute magnitude. This aligns with the discussion in Section 4.3.

7.1.2 Comparison among different spectral embeddings

Next, we look at the performance of various combinations in the template in Figure 2. We smooth the context distribution with $\alpha = 0.75$ for PPMI and CCA. We use $\beta = 0.5$ for PPMI (which has a minor improvement over $\beta = 0$) and $\beta = 0$ for all other methods. We generally find that using $\beta = 0$ is critical to obtaining good performance for $s \in \{—, \text{reg}\}$.

Table 2 shows the result on the development portion for both 500 and 1000 dimensions. Even without any scaling, SVD performs reasonably well with the square-root and log transformations. The regression scaling performs very poorly without data transformation, but once the square-root transformation is applied it performs quite well (especially in analogy questions). The PPMI scaling achieves good performance in word similarity but not in word analogy. The CCA scaling, combined with the square-root transformation, gives the best overall performance. In particular, it performs better than all other methods in mixed analogy questions by a significant margin.

7.1.3 Comparison with other embedding methods

We compare spectral embedding methods against WORD2VEC and GLOVE on the test portion. We use the following combinations based on their performance on the development portion:

- LOG: log transform, — scaling
- REG: sqrt transform, reg scaling
- PPMI: — transform, ppmi scaling
- CCA: sqrt transform, cca scaling

For WORD2VEC, there are two model options: continuous bag-of-words (CBOW) and skip-gram (SKIP). Table 3 shows the result for both 500 and 1000 dimensions.

In word similarity, spectral methods generally excel, with CCA consistently performing the best. SKIP is the only external package that performs comparably, with GLOVE and CBOW falling behind. In word analogy, REG and CCA are significantly better than other spectral methods. They are also competitive to GLOVE and CBOW, but SKIP does perform the best among all compared methods on (especially syntactic) analogy questions.

Method		500 dimensions			1000 dimensions		
		AVG-SIM	SYN	MIXED	AVG-SIM	SYN	MIXED
Spectral	LOG	0.652	59.52	67.27	0.635	56.53	68.67
	REG	0.602	65.51	67.88	0.609	66.47	70.48
	PPMI	0.628	43.81	58.38	0.637	48.99	63.82
	CCA	**0.655**	68.38	74.17	**0.650**	66.08	76.38
Others	GLOVE	0.576	68.30	78.08	0.586	67.40	78.73
	CBOW	0.597	75.79	73.60	0.509	70.97	60.12

Table 3: Performance of different word embedding methods on the test portion of data. See the main text for the configuration details of spectral methods.

7.2 As features in a supervised task

Finally, we use word embeddings as features in NER and compare the subsequent improvements between various embedding methods. The experimental setting is identical to that of Stratos et al. (2014). We use the Reuters RCV1 corpus which contains 205 million words. With frequency thresholding, we end up with a vocabulary of size around 301k. We derive LOG, REG, PPMI, and CCA embeddings as described in Section 7.1.3, and GLOVE, CBOW, and SKIP embeddings again with the recommended default settings. The number of left/right contexts is 2 for all methods. For comparison, we also derived 1000 Brown clusters (BROWN) on the same vocabulary and used the resulting bit strings as features (Brown et al., 1992).

Table 4 shows the result for both 30 and 50 dimensions. In general, using any of these lexical features provides substantial improvements over the baseline.[6] In particular, the 30-dimensional CCA embeddings improve the F1 score by 2.84 on the development portion and by 4.88 on the test portion. All spectral methods perform competitively with external packages, with CCA and SKIP consistently delivering the biggest improvements on the development portion.

Features	30 dimensions		50 dimensions

8 Conclusion

In this work, we revisited SVD-based methods for inducing word embeddings. We examined a framework provided by CCA and showed that the resulting word embeddings can be viewed as cluster-revealing parameters of a certain model and that this result is robust to data transformation. Our proposed method gives the best result among spectral methods and is competitive to other popular word embedding techniques.

This work suggests many directions for future work. Past spectral methods that involved CCA without data transformation (e.g., Cohen et al. (2013)) may be revisited with the square-root transformation. Using CCA to induce representations other than word embeddings is another important future work. It would also be interesting to formally investigate the theoretical merits and algorithmic possibility of solving the variance-weighted objective in Eq. (6). Even though the objective is hard to optimize in the worst case, it may be tractable under natural conditions.

Acknowledgments

We thank Omer Levy, Yoav Goldberg, and David Belanger for helpful discussions. This work was made possible by a research grant from Bloomberg's Knowledge Engineering team.

[6] We mention that the well-known dev/test discrepancy in the CoNLL 2003 dataset makes the results on the test portion less reliable.

A Proof of Theorem 4.1

We first define some random variables. Let ρ be the number of left/right context words to consider in CCA. Let $(W_1, \ldots, W_N) \in [n]^N$ be a random sequence of words drawn from the Brown model where $N \geq 2\rho + 1$, along with the corresponding sequence of hidden states $(H_1, \ldots, H_N) \in [m]^N$. Independently, pick a position $I \in [\rho + 1, N - \rho]$ uniformly at random; pick an integer $J \in [-\rho, \rho] \backslash \{0\}$ uniformly at random. Define $B \in \mathbb{R}^{n \times n}$, $u, v \in \mathbb{R}^n$, $\tilde{\pi} \in \mathbb{R}^m$, and $\tilde{T} \in \mathbb{R}^{m \times m}$ as follows:

$$\begin{aligned} B_{w,c} &:= P(W_I = w, W_{I+J} = c) && \forall w, c \in [n] \\ u_w &:= P(W_I = w) && \forall w \in [n] \\ v_c &:= P(W_{I+J} = c) && \forall c \in [n] \\ \tilde{\pi}_h &:= P(H_I = h) && \forall h \in [m] \\ \tilde{T}_{h',h} &:= P(H_{I+J} = h' | H_I = h) && \forall h, h' \in [m] \end{aligned}$$

First, we show that $\Omega^{\langle a \rangle}$ has a particular structure under the Brown assumption. For the choice of positive vector $s \in \mathbb{R}^m$ in the theorem, we define $s_h := (\sum_w o(w|h)^a)^{-1/2}$ for all $h \in [m]$.

Lemma A.1. *$\Omega^{\langle a \rangle} = A\Theta^\top$ where $\Theta \in \mathbb{R}^{n \times m}$ has rank m and $A \in \mathbb{R}^{n \times m}$ is defined as:*

$$A := diag(O\tilde{\pi})^{-a/2} O^{\langle a \rangle} diag(\tilde{\pi})^{a/2} diag(s)$$

Proof. Let $\tilde{O} := O\tilde{T}$. It can be algebraically verified that $B = O\text{diag}(\tilde{\pi})\tilde{O}^\top$, $u = O\tilde{\pi}$, and $v = \tilde{O}\tilde{\pi}$. By Assumption 4.1, each entry of $B^{\langle a \rangle}$ has the form

$$\begin{aligned} B^{\langle a \rangle}_{w,c} &= \left(\sum_{h \in [m]} O_{w,h} \times \tilde{\pi}_h \times \tilde{O}_{c,h} \right)^a \\ &= \left(O_{w,\mathcal{H}(w)} \times \tilde{\pi}_{\mathcal{H}(w)} \times \tilde{O}_{c,\mathcal{H}(w)} \right)^a \\ &= O^a_{w,\mathcal{H}(w)} \times \tilde{\pi}^a_{\mathcal{H}(w)} \times \tilde{O}^a_{c,\mathcal{H}(w)} \\ &= \sum_{h \in [m]} O^a_{w,h} \times \tilde{\pi}^a_h \times \tilde{O}^a_{c,h} \end{aligned}$$

Thus $B^{\langle a \rangle} = O^{\langle a \rangle}\text{diag}(\tilde{\pi})^a(\tilde{O}^{\langle a \rangle})^\top$. Therefore,

$$\begin{aligned} \Omega^{\langle a \rangle} &= \left(\text{diag}(u)^{-1/2} B \text{diag}(v)^{-1/2} \right)^{\langle a \rangle} \\ &= \text{diag}(u)^{-a/2} B^{\langle a \rangle} \text{diag}(v)^{-a/2} \\ &= \text{diag}(O\tilde{\pi})^{-a/2} O^{\langle a \rangle} \text{diag}(\tilde{\pi})^{a/2} \text{diag}(s) \\ &\quad \text{diag}(s)^{-1} \text{diag}(\tilde{\pi})^{a/2} (\tilde{O}^{\langle a \rangle})^\top \text{diag}(\tilde{O}\tilde{\pi})^{-a/2} \end{aligned}$$

This gives the desired result. □

Next, we show that the left component of $\Omega^{\langle a \rangle}$ is in fact the emission matrix O up to (nonzero) scaling and is furthermore orthonormal.

Lemma A.2. *The matrix A in Lemma A.1 has the expression $A = O^{\langle a/2 \rangle} diag(s)$ and has orthonormal columns.*

Proof. By Assumption 4.1, each entry of A is simplified as follows:

$$\begin{aligned} A_{w,h} &= \frac{o(w|h)^a \times \tilde{\pi}_h^{a/2} \times s_h}{o(w|\mathcal{H}(w))^{a/2} \times \tilde{\pi}^{a/2}_{\mathcal{H}(w)}} \\ &= o(w|h)^{a/2} \times s_h \end{aligned}$$

This proves the first part of the lemma. Note that:

$$[A^\top A]_{h,h'} = \begin{cases} s_h^2 \times \sum_w o(w|h)^a & \text{if } h = h' \\ 0 & \text{otherwise} \end{cases}$$

Thus our choice of s gives $A^\top A = \mathcal{I}_{m \times m}$. □

Proof of Theorem 4.1. With Lemma A.1 and A.2, the proof is similar to the proof of Theorem 5.1 in Stratos et al. (2014). □

Abstract

Existing distributed representations are limited in utilizing structured knowledge to improve semantic relatedness modeling. We propose a principled framework of embedding entities that integrates hierarchical information from large-scale knowledge bases. The novel embedding model associates each category node of the hierarchy with a distance metric. To capture structured semantics, the entity similarity of context prediction are measured under the aggregated metrics of relevant categories along all inter-entity paths. We show that both the entity vectors and category distance metrics encode meaningful semantics. Experiments in entity linking and entity search show superiority of the proposed method.

1 Introduction

There has been a growing interest in distributed representation that learns compact vectors (a.k.a embedding) for words (Mikolov et al., 2013a), phrases (Passos et al., 2014), and concepts (Hill and Korhonen, 2014), etc. The induced vectors are expected to capture semantic relatedness of the linguistic items, and are widely used in sentiment analysis (Tang et al., 2014), machine translation (Zhang et al., 2014), and information retrieval (Clinchant and Perronnin, 2013), to name a few.

Despite the impressive success, existing work is still limited in utilizing structured knowledge to enhance the representation. For instance, word and phrase embeddings are largely induced from plain text. Though recent knowledge graph embeddings (Lin et al., 2015; Wang et al., 2014) integrate the relational structure among entities, they primarily target at link prediction and lack an explicit relatedness measure.

In this paper, we propose to improve the distributed representations of entities by integrating hierarchical information from large-scale knowledge bases (KBs). An entity hierarchy groups entities into categories which are further organized to form a taxonomy. It provides rich structured knowledge on entity relatedness (Resnik, 1995). Our work goes beyond the previous heuristic use of entity hierarchy which relies on hand-crafted features (Kaptein and Kamps, 2013; Ponzetto and Strube, 2007), and develops a principled optimization-based framework. We learn a *distance metric* for each category node, and measure entity-context similarity under the aggregated metrics of all relevant categories. The metric aggregation encodes the hierarchical property that nearby entities tend to share common semantic features. We further provide a highly-efficient implementation in order to handle large complex hierarchies.

We train a distributed representation for the whole entity hierarchy of Wikipedia. Both the entity vectors and the category distance metrics capture meaningful semantics. We deploy the embedding in both entity linking (Han and Sun, 2012) and entity search (Demartini et al., 2010) tasks. Hierarchy embedding significantly outperforms that without structural knowledge. Our methods also show superiority over existing competitors.

To the best of our knowledge, this is the first work to learn distributed representations that incorporates hierarchical knowledge in a principled framework. Our model that encodes hierarchy by distance metric learning and aggregation provides a potentially important and general scheme for utilizing hierarchical knowledge.

The rest of the paper is organized as follows: §2 describes the proposed embedding model; §3 presents the application of the learned embedding; §4 evaluates the approach; §5 reviews related work; and finally, §6 concludes the paper.

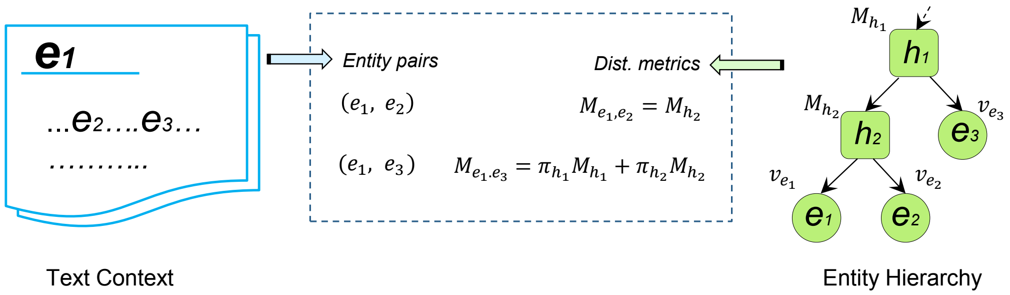

Figure 1: The model architecture. The text context of an entity is based on its KB encyclopedia article. The entity hierarchical structure is incorporated through distance metric learning and aggregation.

2 Entity Hierarchy Embedding

The objective of the embedding model is to find a representation for each entity that is useful for predicting other entities occurring in its *context*. We build entity's context upon KB encyclopedia articles, where entity annotations are readily available. We further incorporate the entity hierarchical structure in the context prediction through distance metric learning and aggregation, which encodes the rich structured knowledge in the induced representations. Our method is flexible and efficient to model large complex DAG-structured hierarchies. Figure 1 shows an overview of the model architecture.

2.1 Model Architecture

Our architecture builds on the skip-gram word embedding framework (Mikolov et al., 2013b). In the skip-gram model, a set of (target, context) word pairs are extracted by sliding a fixed-length context window over a text corpus, and the word vectors are learned such that the similarity of the target- and context-word vectors is maximized. We generalize both the context definition and the similarity measure for entity hierarchy embedding.

Unlike words that can be directly extracted from plain text, entities are hidden semantics underlying their surface forms. In order to avoid manual annotation cost, we exploit the text corpora from KBs where the referent entities of surface text are readily annotated. Moreover, since a KB encyclopedia article typically focuses on describing one entity, we naturally extend the entity's context as its whole article, and obtain a set of entity pairs $\mathcal{D} = \{(e_T, e_C)\}$, where e_T denotes the target-entity and e_C denotes the context-entity occurring in entity e_T's context.

Let $\mathcal{E}$ be the set of entities. For each entity $e \in \mathcal{E}$, the model learns both a "target vector" $v_e \in \mathbb{R}^n$ and "context vector" $\bar{v}_e \in \mathbb{R}^n$, by maximizing the training objective

$$\mathcal{L} = \frac{1}{|\mathcal{D}|} \sum\nolimits_{(e_T,e_C)\in\mathcal{D}} \log p(e_C|e_T), \tag{1}$$

where the prediction probability is defined as a softmax:

$$p(e_C|e_T) = \frac{\exp\{-d(e_T, e_C)\}}{\sum_{e\in\mathcal{E}} \exp\{-d(e_T, e)\}}. \tag{2}$$

Here $d(e, e')$ is the distance between the target vector of e (i.e., v_e) and the context vector of e' (i.e., $\bar{v}_{e'}$). We present the design in the following.

2.2 Hierarchical Extension

An entity hierarchy takes entities as leaf nodes and categories as internal nodes, which provides key knowledge sources on semantic relatedness that 1) far-away entities in the hierarchy tend to be semantically distant, and 2) nearby entities tend to share common semantic features. We aim to encode this knowledge in our representations. As KB hierarchies are large complex DAG structures, we develop a highly-efficient scheme to enable practical training.

Specifically, we associate a separate *distance metric* $M_h \in \mathbb{R}^{n\times n}$ with each category h in the hierarchy. A distance metric is a positive semidefinite (PSD) matrix. We then measure the distance between two entities under some *aggregated* distance metric as detailed below. The local metrics thus not only serve to capture the characteristics of individual categories, but also make it possible to share the representation across entities through metric aggregation of relevant categories.

Metric aggregation Given two entities e and e', let $\mathcal{P}_{e,e'}$ be the path between them. One obvious way to define the aggregated metric $M_{e,e'} \in \mathbb{R}^{n\times n}$ is through a combination of the metrics on the

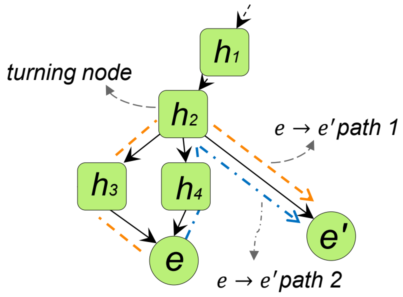

Figure 2: Paths in a DAG-structured hierarchy. A path P is defined as a sequence of non-duplicated nodes with the property that there exists a *turning node* $t \in P$ such that any two consecutive nodes before t are (child, parent) pairs, while consecutive nodes after t are (parent, child) pairs. Thus a turning node is necessarily a common ancestor.

path: $\sum_{h \in \mathcal{P}_{e,e'}} M_h$, leading to a nice property that the more nodes a path has, the more distant the entities tend to be (as M_h is PSD). This simple strategy, however, can be problematic when the hierarchy has a complex DAG structure, in that there can be multiple paths between two entities (Figure 2). Though the shortest path can be selected, it ignores other related category nodes and loses rich information. In contrast, an ideal scheme should not only mirror the distance in the hierarchy, but also take into account all possible paths in order to capture the full aspects of relatedness.

However, hierarchies in large KBs can be complex and contains combinationally many paths between any two entities. We propose an efficient approach that avoids enumerating paths and instead models the underlying nodes directly. In particular, we extend $\mathcal{P}_{e,e'}$ as the set of all category nodes included in any of the $e \rightarrow e'$ paths, and define the aggregate metric as

$$M_{e,e'} = \gamma_{e,e'} \sum\nolimits_{h \in \mathcal{P}_{e,e'}} \pi_{ee',h} M_h, \tag{3}$$

where $\{\pi_{ee',h}\}$ are the relative weights of the categories such that $\sum_{h \in \mathcal{P}_{e,e'}} \pi_{ee',h} = 1$. This serves to balance the size of $\mathcal{P}$ across different entity pairs. We set $\pi_{ee',h} \propto (\frac{1}{s_{h \downarrow e}} + \frac{1}{s_{h \downarrow e'}})$ with $s_{h \downarrow e}$ being the average #steps going down from node h to node e in the hierarchy (infinite if h is not an ancestor of e). This implements the intuition that an entity (e.g., "Iphone") is more relevant to its immediate categories (e.g., "Mobile phones") than to farther and more generic ancestors (e.g., "Technology"). The scaling factor $\gamma_{e,e'}$ encodes the distance of the entities in the hierarchy and can be of various choices. We set $\gamma_{e,e'} = \min_h\{s_{h \downarrow e} + s_{h \downarrow e'}\}$ to mirror the least common ancestor.

In Figure 2, $\mathcal{P}_{e,e'} = \{h_2, h_3, h_4\}$, and the relative weights of the categories are $\pi_{ee',h_2} \propto 3/2$ and $\pi_{ee',h_3} = \pi_{ee',h_4} \propto 1$. Category h_2 is the least common ancestor and $\gamma_{e,e'} = 3$.

Based on the aggregated metric, the distance between a target entity e_T and a context entity e_C can then be measured as

$$d(e_T, e_C) = (v_{e_T} - \tilde{v}_{e_C})^\top M_{e_T, e_C} (v_{e_T} - \tilde{v}_{e_C}). \tag{4}$$

Note that nearby entities in the hierarchy tend to share a large proportion of local metrics in Eq 3, and hence can exhibit common semantic features when measuring distance with others.

Complexity of aggregation As computing distance is a frequent operation in both training and application stages, a highly efficient aggregation algorithm is necessary in order to handle complex large entity hierarchies (with millions of nodes). Our formulation (Eq 3) avoids exhaustive enumeration over all paths by modeling the relevant nodes directly. We show that this allows linear complexity in *the number of children of two entities' common ancestors*, which is efficient in practice.

The most costly operation is to find $\mathcal{P}_{e,e'}$, i.e., the set of all category nodes that can occur in any of $e \rightarrow e'$ paths. We use a two-step procedure that (1) finds all common ancestors of entity e and e' that are *turning nodes* of any $e \rightarrow e'$ paths (e.g., h_2 in Figure 2), denoted as $\mathcal{Q}_{e,e'}$; (2) expands from $\mathcal{Q}_{e,e'}$ to construct the full $\mathcal{P}_{e,e'}$. For the first step, the following theorem shows each common ancestor can be efficiently assessed by testing only its children nodes. For the second step, it is straightforward to see that $\mathcal{P}_{e,e'}$ can be constructed by expanding $\mathcal{Q}_{e,e'}$ with its descendants that are ancestors of either e or e'. Other parameters ($\boldsymbol{\pi}_{ee'}$ and $\gamma_{e,e'}$) of aggregation can be computed during the above process.

We next provide the theorem for the first step. Let $\mathcal{A}_e$ be the ancestor nodes of entity e (including e itself). For a node $h \in \mathcal{A}_e \cup \mathcal{A}_{e'}$, we define its *critical* node t_h as the nearest (w.r.t the length of the shortest path) descendant of h (including h itself) that is in $\mathcal{Q}_{e,e'} \cup \{e, e'\}$. E.g., in Figure 2, $t_{h_1} = h_2; t_{h_2} = h_2; t_{h_3} = e$. Let $\mathcal{C}_h$ be the set of immediate child nodes of h.

Theorem 1. *$\forall h \in \mathcal{A}_e \cap \mathcal{A}_{e'}$, $h \in \mathcal{Q}_{e,e'}$ iff it satisfies the two conditions: (1) $|\mathcal{C}_h \cap (\mathcal{A}_e \cup \mathcal{A}_{e'})| \geq 2$; (2) $\exists a, b \in \mathcal{C}_h$ s.t. $t_a \neq t_b$.*

Proof. We outline the proof here, and provide the details in the appendix.

Sufficiency: Note that $e, e' \notin Q_{e,e'}$. We prove the sufficiency by enumerating possible situations: (i) $t_a = e, t_b = e'$; (ii) $t_a = e, t_b \in Q_{e,e'}$; (iii) $t_a, t_b \in Q_{e,e'}$. For (i): as $t_a = e$, there exists a path $e \to \cdots \to a \to h$ where any two consecutive nodes is a (child, parent) pair. Similarly, there is a path $h \to b \to \cdots \to e'$ where any two consecutive nodes is a (parent, child) pair. It is provable that the two paths intersect only at h, and thus can be combined to form an $e \to e'$ path: $e \to \cdots \to a \to h \to b \to \cdots \to e'$, yielding h as a turning node. The cases (ii) and (iii) can be proved similarly.

Necessity: We prove by contradiction. Suppose that $\forall a, b \in \mathcal{C}_h \cap (\mathcal{A}_e \cup \mathcal{A}_{e'})$ we have $t_a = t_b$. W.l.o.g. we consider two cases: (i) $t_a = t_b = e$, and (ii) $t_a = t_b \in Q_{e,e'}$. It is provable that both cases will lead to contradiction. □

Therefore, by checking common ancestors from the bottom up, we can construct $\mathcal{Q}_{e,e'}$ with time complexity linear to the number of all ancestors' children.

2.3 Learning

For efficiency, we use negative sampling to reformulate the training objective, which is then optimized through coordinate gradient ascent.

Specifically, given the training data $\{(e_T, e_C)\}$ extracted from KB corpora, the representation learning is formulated as maximizing the objective in Eq 1, subject to PSD constraints on distance metrics $M_h \succeq 0$, and $\|v_e\|_2 = \|\bar{v}_e\|_2 = 1$ to avoid scale ambiguity.

The likelihood of each data sample is defined as a softmax in Eq 2, which iterates over all entities in the denominator and is thus computationally prohibitive. We apply the negative sampling technique as in conventional skip-gram model, by replacing each log probability $\log p(e_C|e_T)$ with

$$\log \sigma(-d\left(e_T, e_C\right)) + \sum\nolimits_{i=1}^{k} \mathbb{E}_{e_i \sim P(e)}\left[\log \sigma(-d\left(e_T, e_i\right))\right],$$

where $\sigma(x) = 1/(1 + \exp(-x))$ is the sigmoid function; and for each data sample we draw k negative samples from the noise distribution $P(e) \propto U(e)^{3/4}$ with $U(e)$ being the unigram distribution (Mikolov et al., 2013b).

The negative sampling objective is optimized using coordinate gradient ascent, as shown in Algorithm 1. To avoid overfitting and improve efficiency, in practice we restrict the distance metrics M_h to be diagonal (Xing et al., 2002). Thus the PSD project of M_h (line 17) is simply taking the positive part for each diagonal elements.

Algorithm 1 Entity Hierarchy Embedding

```
Input: The training data $\mathcal{D} = \{(e_T, e_C)\}$,
       Entity hierarchy,
       Parameters: $n$ – dimension of the embedding
                   $k$ – number of negative samples
                   $\eta$ – gradient learning rate
                   $B$ – minibatch size
 1: Initialize $\boldsymbol{v}, \bar{\boldsymbol{v}}, \boldsymbol{M}$ randomly such that $\|v\|_2 = \|\bar{v}\|_2 = 1$
    and $M \succeq 0$.
 2: repeat
 3:   Sample a batch $\mathcal{B} = \{(e_T, e_C)_i\}_{i=1}^{B}$ from $\mathcal{D}$
 4:   for all $(e_T, e_C) \in \mathcal{B}$ do
 5:     Compute $\{\mathcal{P}, \boldsymbol{\pi}, \gamma\}_{e_T, e_C}$ for metric aggregation
 6:     Sample negative pairs $\{(e_T, e_i)\}_{i=1}^{k}$
 7:     Compute $\{\{\mathcal{P}, \boldsymbol{\pi}, \gamma\}_{e_T, e_i}\}_{i=1}^{k}$ for metric aggregation
 8:   end for
 9:   repeat
10:     for all $e \in \mathcal{E}$ included in $\mathcal{B}$ do
11:       $v_e = v_e + \eta \frac{\partial \mathcal{L}}{\partial v_e}$
12:       $\bar{v}_e = \bar{v}_e + \eta \frac{\partial \mathcal{L}}{\partial \bar{v}_e}$
13:       $v_e, \bar{v}_e = \text{Project\_to\_unit\_sphere}(v_e, \bar{v}_e)$
14:     end for
15:   until convergence
16:   repeat
17:     for all $h$ included in $\mathcal{B}$ do
18:       $M_h = M_h + \eta \frac{\partial \mathcal{L}}{\partial M_h}$
19:       $M_h = \text{Project\_to\_PSD}(M_h)$
20:     end for
21:   until convergence
22: until convergence
Output: Entity vectors $\boldsymbol{v}, \bar{\boldsymbol{v}}$, and category dist. metrics $\boldsymbol{M}$
```

3 Applications

One primary goal of learning semantic embedding is to improve NLP tasks. The compact representations are easy to work with because they enable efficient computation of semantic relatedness. Compared to word embedding, entity embedding is particularly suitable for various language understanding applications that extract underlying semantics of surface text. Incorporating entity hierarchies further enriches the embedding with structured knowledge.

In this section, we demonstrate how the learned entity hierarchy embedding can be utilized in two important tasks, i.e., *entity linking* and *entity search*. In both tasks, we measure the semantic relatedness between entities as the reciprocal distance defined in Eq 4. This greatly simplifies previous methods which have used various hand-crafted features, and leads to improved performance as shown in our experiments.

3.1 Entity Linking

The entity linking task is to link surface forms (mentions) of entities in a document to entities in a reference KB. It is an essential first step for downstream tasks such as semantic search and KB construction. The quality of entity relatedness measure is critical for entity linking performance, because of the key observation that entities in a document tend to be semantically coherent. For example, in sentence "Apple released an operating system Lion", The mentions "Apple" and "Lion" refer to Apple Inc. and Mac OS X Lion, respectively, as is more coherent than other configurations like (fruit apple, animal lion).

Our algorithm finds the optimal configuration for the mentions of a document by maximizing the overall relatedness among assigned entities, together with the local mention-to-entity compatibility. Specifically, we first construct a mention-to-entity dictionary based on Wikipedia annotations. For each mention m, the dictionary contains a set of candidate entities and for each candidate entity e a compatibility score $P(e|m)$ which is proportional to the frequency that m refers to e. For efficiency we only consider the top-5 candidate entities according to $P(e|m)$. Given a set of mentions $\mathcal{M} = \{m_i\}_{i=1}^M$ in a document, let $\mathcal{A} = \{e_{m_i}\}_{i=1}^M$ be a configuration of its entity assignments. The score of $\mathcal{A}$ is formulated as probability

$$P(\mathcal{A}|\mathcal{M}) \propto \prod\nolimits_{i=1}^{M} P(e_{m_i}|m_i) \sum\nolimits_{\substack{j=1\\ j\neq i}}^{M} \frac{1}{d\left(e_{m_i}, e_{m_j}\right) + \epsilon},$$

where for each entity assignment we define its global relatedness to other entity assignments as the sum of the reciprocal distances ($\epsilon = 0.01$ is a constant used to avoid divide-by-zero). Direct enumeration of all potential configurations is computationally prohibitive, we therefore use simulated annealing to search for an optimal solution.

3.2 Entity Search

Entity search has attracted a growing interest (Chen et al., 2014b; Balog et al., 2011). Unlike conventional web search that finds unorganized web pages, entity search retrieves knowledge directly by generating a list of relevant entities in response to a search request. The input of the entity search task is a natural language question $\mathcal{Q}$ along with one or more desired entity categories $\mathcal{C}$. For example, a query can be $\mathcal{Q} =$"films directed by Akira Kurosawa" and $\mathcal{C} =$\{Japanese films\}.

Previous methods typically score candidate entities by measuring both the similarity between entity content and the query question $\mathcal{Q}$ (text matching), and the similarity between categories of entities and the query categories $\mathcal{C}$ (category matching).

We apply a similar category matching strategy as in previous work (Chen et al., 2014b) that assesses lexical (e.g., head words) similarity between category names, while replacing the text matching with entity relatedness measure. Specifically, we first extract the underlying entities mentioned in $\mathcal{Q}$ through entity linking, then score each candidate entity by its average relatedness to the entities in $\mathcal{Q}$. For instance, the entity Rashomon will obtain a high score in the above example as it is highly related with the entity Akira Kurosawa in the query. This scheme not only avoids complex document processing (e.g., topic modeling) in text matching, but also implicitly augments the short query text with background knowledge, and thus improves the accuracy and robustness.

4 Experiments

We validate the quality of our entity representation by evaluating its applications of entity linking and entity search on public benchmarks. In the entity linking task, our approach improves the F1 score by 10% over state-of-the-art results. We also validate the advantage of incorporating hierarchical structure. In the entity search task, our simple algorithm shows competitive performance. We further qualitatively analyze the entity vectors and category metrics, both of which capture meaningful semantics, and can potentially open up a wide rage of other applications.

Knowledge base We use the Wikipedia snapshot from Jan 12nd, 2015 as our training data and KB. After pruning administrative information we obtain an entity hierarchy including about 4.1M entities and 0.8M categories organized into 12 layers. Loops in the original hierarchy are removed by deleting bottom-up edges, yielding a DAG structure. We extract a set of 87.6M entity pairs from the wiki links on Wikipedia articles.

We train 100-dimensional vector representations for the entities and distance metrics (100×100 diagonal matrixes) for the categories (we would study the impact of dimensionality in the future). We set the batch size $B = 500$, the initial learning rate $\eta = 0.1$ and decrease it by a factor of 5 whenever the objective value does not increase, and the negative sample size $k = 5$. The model is trained on a Linux machine with 128G RAM and 16 cores. It takes 5 days to converge.

4.1 Entity Linking

4.1.1 Setup

Dataset As our entities based on English Wikipedia include not only named entities (e.g., persons, organizations) but also general concepts (e.g., "computer" and "human"), we use a standard entity linking dataset IITB[1] where mentions of Wikipedia entities are manually annotated exhaustively. The dataset contains about 100 documents and 17K mentions in total. As in the baseline work, we use only the mentions whose referent entities are contained in Wikipedia.

Criteria We adopt the common criteria, *precision*, *recall*, and *F1*. Let $\mathcal{A}^*$ be the golden standard entity annotations, and $\mathcal{A}$ be the annotations by entity linking model, then

$$precision = \frac{|\mathcal{A}^* \cap \mathcal{A}|}{|\mathcal{A}|} \qquad recall = \frac{|\mathcal{A}^* \cap \mathcal{A}|}{|\mathcal{A}^*|}.$$

The F1 score is then computed based on the average precision and recall across all documents.

Baselines We compare our algorithm with the following approaches. All the competitors are designed to be able to link general concept mentions to Wikipedia.

CSAW (Kulkarni et al., 2009) has a similar framework as our algorithm. It measures entity relatedness using a variation of Jaccard similarity on Wikipedia page incoming links.

Entity-TM (Han and Sun, 2012) models an entity as a distribution over mentions and words, and sets up a probabilistic generative process for the observed text.

Ours-NoH. To validate the advantage of incorporating hierarchical structure, we design a baseline that relies on entity embedding without entity hierarchy. That is, we obtain entity vectors by fixing the distance metric in Eq 4 as an identity matrix.

4.1.2 Results

Table 1 shows the performance of the competitors. Our algorithm using the entity hierarchy embedding gets 21% to 10% improvement in F1, and over 6% and 14% improvements in Precision and Recall, respectively. The CSAW model devises a set of entity features based on text content and link structures of Wikipedia pages, and combines them to measure relatedness. Compared to these hand-crafted features which are essentially heuristic and hard to verify, our embedding model induces semantic representations by optimizing a single well-defined objective. Note that the embedding actually also encodes the Wikipedia interpage network, as we train on the entity-context pairs which are extracted from wiki links.

Methods	Precision	Recall	F1
CSAW	0.65	0.74	0.69
Entity-TM	0.81	0.80	0.80
Ours-NoH	0.78	0.85	0.81
Ours	**0.87**	**0.94**	**0.90**

Table 1: Entity linking performance

The Entity-TM model learns a representation for each entity as a word distribution. However, as noted in (Baroni et al., 2014), the counting-based distributional model usually shows inferior performance than context-predicting methods as ours. Moreover, in addition to the text context, our model integrates the entity hierarchical structure which provides rich knowledge of semantic relatedness. The comparison between *Ours* and *Ours-NoH* further reveals the effect of integrating the hierarchy in learning entity vectors. With entity hierarchy, we obtain more semantically meaningful representations that achieve 9% F1 improvement over entity vectors without hierarchical knowledge.

4.2 Entity Search

4.2.1 Setup

Dataset We use the dataset from INEX 2009 entity ranking track[2], which contains 55 queries. The golden standard results of each query contains a set of relevant entities each of which corresponds to a Wikipedia page.

Criteria We use the common criteria of precision@k, i.e., the percentage of relevant entities in the top-k results (we set $k = 10$), as well as precision@R where R is the number of golden standard entities for a query.

[1] http://www.cse.iitb.ac.in/soumen/doc/CSAW/Annot

[2] http://www.inex.otago.ac.nz/tracks/entity-ranking/entity-ranking.asp

Baselines We compare our algorithm with the following recent competitors.

Balog (Balog et al., 2011) develops a probabilistic generative model which represents entities, as well as the query, as distributions over both words and categories. Entities are then ranked based on the KL-divergence between the distributions.

K&K (Kaptein and Kamps, 2013) exploits Wikipedia entity hierarchy to derive the content of each category, which is in turn used to measure relatedness with the query categories. It further incorporates inter-entity links for relevance propagation.

Chen (Chen et al., 2014b) creates for each entity a context profile leveraging both the whole document (long-range) and sentences around entity (short-range) context, and models query text by a generative model. Categories are weighted based on the head words and other features. Our algorithm exploits a similar method for category matching.

Methods	Precision@10	Precision@R
Balog	0.18	0.16
K&K	0.31	0.28
Chen	0.55	0.42
Ours	**0.57**	**0.46**

Table 2: Entity search performance.

4.2.2 Results

Table 2 lists the entity search results of the competitors. Our algorithm shows superiority over the previous best performing methods. Balog constructs representations for each entity merely by counting (and smoothing) its co-occurrence between words and categories, which is inadequate to capture relatedness accurately. K&K leverages the rich resources in Wikipedia such as text, hierarchy, and link structures. However, the handcrafted features are still suboptimal compared with our learned representations.

Chen performs well by combining both long- and short-context of entities, as well as category lexical similarity. Our algorithm replaces its text matching component with a semantic enrichment step, i.e., grounding entity mentions in the query text onto KB entities. This augments the short query with rich background knowledge, facilitating accurate relatedness measure based on our high-quality entity embedding.

4.3 Qualitative Analysis

We qualitatively inspect the learned representations of the entity hierarchy. The results show that both the entity vectors and the category distance metrics capture meaningful semantics, and can potentially boost a wide range of applications such as recommendation and knowledge base completion.

Entity vectors Table 3 shows a list of target entities, and their top-4 nearest entities in the whole entity set or subsets belonging to given categories. Measuring under the whole set (column 2) results in nearest neighbors that are strongly related with the target entity. For instance, the nearest entities for "black hole" are "faster-than-light", "event horizon", "white hole", and "time dilation", all of which are concepts from physical cosmology and the theory of relativity. Similar results can be observed from other 3 examples.

Even more interesting is to specify a category and search for the most related entities under the category. The third column of Table 3 shows several examples. E.g., our model found that the most related Chinese websites to Youtube are "Tudou", "56.com", "Youku" (three top video hosting services in China), and "YinYueTai" (a major MV sharing site in China). The high-quality results show that our embedding model is able to discover meaningful relationships between entities from the complex entity hierarchy and plain text. This can be a useful feature in a wide range of applications such as semantic search (e.g., looking for movies about black hole), recommendation (e.g., suggesting TV series of specific genre for kids), and knowledge base completion (e.g., extracting relations between persons), to name a few.

Target entity	Most related entities	
black hole	**overall:** faster-than-light event horizon white hole time dilation	**American films:** Hidden Universe 3D Hubble (film) Quantum Quest Particle Fever
Youtube	**overall:** Instagram Twitter Facebook Dipdive	**Chinese websites:** Tudou 56.com Youku YinYueTai
Harvard University	**overall:** Yale University University of Pennsylvania Princeton University Swarthmore College	**businesspeople in software:** Jack Dangermond Bill Gates Scott McNealy Marc Chardon
X-Men: Days of Future Past (film)	**overall:** Marvel Studios X-Men: The Last Stand X2 (film) Man of Steel (film)	**children's television series:** Ben 10: Race Against Time Kim Possible: A Sitch in Time Ben 10: Alien Force Star Wars: The Clone Wars

Table 3: Most related entities under specific categories. "Overall" represents the most general category that includes all the entities.

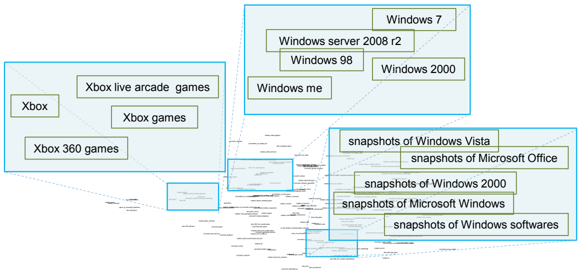

Figure 3: Distance metric visualization for the subcategories of the category "Microsoft". The t-SNE (Van der Maaten and Hinton, 2008) algorithm is used to map the high-dimensional (diagonal) matrixes into the 2D space.

Category distance metrics In addition to learning vector representations of entities, we also associate with each category a local distance metric to capture the features of individual category. As we restrict the distance metrics to be diagonal matrixes, the magnitude of each diagonal value can be viewed as how much a category is characterized by the corresponding dimension. Categories with close semantic meanings are expected to have similar metrics.

Figure 3 visualizes the metrics of all subcategories under the category "Microsoft", where we amplify some parts of the figure to showcase the clustering of semantically relevant categories. For instance, the categories of Microsoft Windows operating systems, and those of the Xbox games, are embedded close to each other, respectively. The results validate that our hierarchy embedding model can not only encode relatedness between leaf entities, but also capture semantic similarity of the internal categories. This can be helpful in taxonomy refinement and relation discovery.

5 Related Work

Distributed representation There has been a growing interest in distributed representation of words. Skip-gram model (Mikolov et al., 2013a) is one of the most popular methods to learn word representations. The model aims to find a representation for each word that is useful for predicting its context words. Word-context similarity is measured by simple inner product. A set of recent works generalizing the basic skip-gram to incorporate dependency context (Levy and Goldberg, 2014), word senses (Chen et al., 2014a), and multi-modal data (Hill and Korhonen, 2014). However, these work leverages limited structured knowledge. Our proposed method goes beyond skip-gram significantly such that we measures entity-context similarity under aggregated distance metrics of hierarchical category nodes. This effectively captures the structured knowledge. Another research line learn knowledge graph embedding (Lin et al., 2015; Wang et al., 2014; Bordes et al., 2013), which models entities as vectors and relations as some operations on the vector space (e.g., translation). These works aim at relation prediction for knowledge graph completion, and can be viewed as a supplement to the above that extracts semantics from plain text.

Utilizing hierarchical knowledge Semantic hierarchies are key sources of knowledge. Previous works (Ponzetto and Strube, 2007; Leacock and Chodorow, 1998) use KB hierarchies to define relatedness between concepts, typically based on path-length measure. Recent works (Yogatama et al., 2015; Zhao et al., 2011) learn representations through hierarchical sparse coding that enforces similar sparse patterns between nearby nodes. Category hierarchies have also been widely used in classification (Xiao et al., 2011; Weinberger and Chapelle, 2009). E.g., in (Verma et al., 2012) category nodes are endowed with discriminative power by learning distance metrics. Our approach differs in terms of entity vector learning and metric aggregation on DAG hierarchy.

6 Conclusion

In this paper, we proposed to learn entity hierarchy embedding to boost semantic NLP tasks. A principled framework was developed to incorporate both text context and entity hierarchical structure from large-scale knowledge bases. We learn a distance metric for each category node, and measure entity vector similarity under aggregated metrics. A flexible and efficient metric aggregation scheme was also developed to model large-scale hierarchies. Experiments in both entity linking and entity search tasks show superiority of our approach.

The qualitative analysis indicates that our model can be potentially useful in a wide range of other applications such as knowledge base completion and ontology refinement. Another interesting aspect of future work is to incorporate other sources of knowledge to further enrich the semantics.

Abstract

A recent distributional approach to word-analogy problems (Mikolov et al., 2013b) exploits interesting regularities in the structure of the space of representations. Investigating further, we find that performance on this task can be related to orthogonality within the space. Explicitly designing such structure into a neural network model results in representations that decompose into orthogonal semantic and syntactic subspaces. We demonstrate that learning from word-order and morphological structure within English Wikipedia text to enable this decomposition can produce substantial improvements on semantic-similarity, pos-induction and word-analogy tasks.

1 Introduction

Distributional methods have become widely used across computational linguistics. Recent applications include predicate clustering for question answering (Lewis and Steedman, 2013), bilingual embeddings for machine translation (Zou et al., 2013) and enhancing the coverage of POS tagging (Huang et al., 2013). The popularity of these methods, stemming from their conceptual simplicity and wide applicability, motivates a deeper analysis of the structure of the representations they produce.

Commonly, these representations are made in a single vector space with similarity being the main structure of interest. However, recent work by Mikolov et al. (2013b) on a word-analogy task suggests that such spaces may have further useful internal regularities. They found that semantic differences, such as between big and $small$, and also syntactic differences, as between big and $bigger$, were encoded consistently across their space. In particular, they solved the word-analogy problems by exploiting the fact that equivalent relations tended to correspond to parallel vector-differences.

In this paper, we investigate orthogonality between relations rather than parallelism. While parallelism serves to ensure that the same relation is encoded consistently, our hypothesis is that orthogonality serves to ensure that distinct relations are clearly differentiable. We focus specifically on semantic and syntactic relations as these are probably the most distinct classes of properties encoded in distributional spaces.

Empirically, we demonstrate that orthogonality predicts performance on the word-analogy task for three existing approaches to constructing word vectors. We also attempt to enhance the weakest of these three models by imposing an orthogonal structure in its construction. In these extensions, word representations decompose into orthogonal semantic and syntactic spaces, and we use word-order and morphology to drive this separation. This decomposition also allows us to define a novel approach to solving the word-analogy problems and our extended models become competitive with the other two original models. In addition, we show that the separate semantic and syntactic sub-spaces gain improved performance on semantic-similarity and POS-induction tasks respectively.

Our experiments here are based on models that construct vector-representations within a model that predicts the occurence of words in context. In particular we focus on the CBOW and Skip-gram models of Mikolov etal. (2013b) and Pennington et al.'s (2014) GloVe model. These models share the property of producing a single general representation for each word, which can be utilized in a variety of tasks, from POS tagging to semantic role labelling. In contrast, here we attempt to decompose the representations into separate seman-

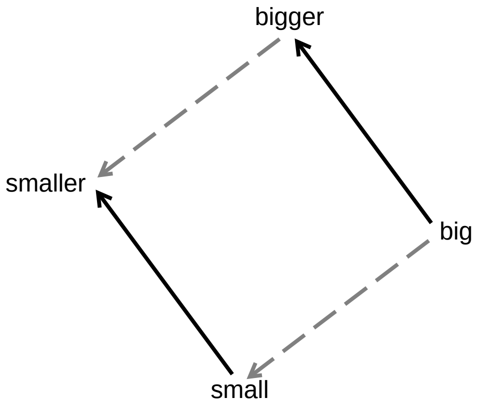

Figure 1: Geometric relationships between $small$, $smaller$, big and $bigger$.

tic and syntactic components.

To motivate this decomposition, consider the analogical reasoning task that Mikolov et al. (2013b) apply neural embeddings to. In this task, given vectors for the words big, $bigger$ and $small$, we try to predict the vector for $smaller$. They find that in practice $smaller \approx small + bigger - big$ produces an estimate that is frequently closer to the actual representation of $smaller$ than any other word vector. We can think of the vector $bigger - big$ as representing the syntactic relation that holds between an adjective and its comparative. Adding this syntactic structure to $small$ thus ends up at, or near, the relevant comparative, $smaller$. Alternatively, we could think of the vector $small - big$ as representing the semantic difference between small and big, and adding this relation to $bigger$ produces a semantic transformation to $smaller$.

Mikolov et al. (2013b) represent these sort of relations in terms of a diagram similar to Figure 1. The image places the four words in a 2D space and represents the relations between them in terms of arrows. The solid black arrows represent the syntactic relations $smaller - small$ and $bigger - big$, while the gray dashed arrows represent the semantic differences $smaller - bigger$ and $small - big$. Their solution to the analogy problem exploits the fact that these pairs of relations are approximately parallel to each other, i.e. that we can approximate $smaller - small$ with $bigger - big$, or $smaller - bigger$ with $small - big$. However, knowing that opposite sides of the square in Figure 1 are parallel to each other still leaves open the question of what happens at the corners. In other words, what is the relationship between the semantic differences, e.g. $smaller - bigger$, and the syntactic differences, e.g. $smaller - small$?

In this paper we explore the idea that such semantic and syntactic relations ought to be orthogonal to each other. This hypothesis arises both from the intuition that such distinct types of information ought to be represented distinctly within our space and also from the observation that solving the word-analogy task requires that words can be uniquely identified by combining these vector differences and so $small - big$ ought to be easily differentiable from $bigger - big$ as these relations point to different end results starting from big. Essentially, orthogonality will make better use of the volume within the space, spreading words with different semantic or syntactic characteristics further from each other.

In terms of predicting $smaller$ from big, $bigger$ and $small$, orthogonality of the relationship between $smaller - bigger$ and $smaller - small$ can be expressed in terms of their dot product:

$$(smaller - bigger) \cdot (smaller - small) = 0 \quad (1)$$

If all semantic relations were genuinely orthogonal to all syntactic relations, then their space would be decomposable into two orthogonal subspaces: one semantic, the other syntactic. Any word representation, $\mathbf{v}$, would then be the combination of a unique semantic vector, $\mathbf{b}$, within the semantic subspace and a unique syntactic vector, $\mathbf{s}$, within the syntactic subspace. If $\mathbf{b}$ were given a representation in terms of e components, and $\mathbf{s}$ in terms of f components, then $\mathbf{v}$ would have a representation in terms of $d = e + f$ components which would just be the concatenation of the two sets of components, which we will represent in terms of the operator $\oplus$.

$$\mathbf{v} = \mathbf{b} \oplus \mathbf{s} \quad (2)$$

Achieving this differentiation within the representations requires that the model have a means of differentiating semantic and syntactic information in the raw text. We consider two very simple approaches for this purpose, based on morphological and word order features. Both these types of features have been previously employed in simple word co-occurrence models (e.g., McDonald and Lowe, 1998; Clark, 2003), with bag-of-words and

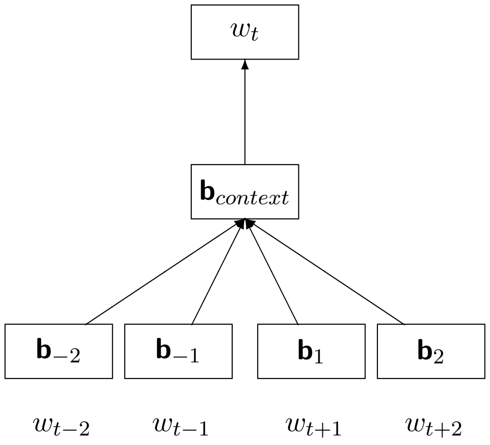

Figure 2: CBOW model predicting w_t from of a bag-of-words representation, $\mathbf{b}_{context}$, of a 4-word window around it.

lemmatization being good for semantic applications, while sequential order and suffixes is more useful for syntax. More recently, Mitchell (2013) demonstrated that word order could be used to separate syntactic from semantic structure, but only within a simple bigram language model, rather than a neural network model, and without exploiting morphology.

Our enhanced models are based on Mikolov et al.'s (2013a) CBOW architecture, which is described in Section 2. The novel extensions to it, employing a semantic-syntactic decomposition, are proposed in Section 3. We then describe our evaluation tasks and provide their results in Sections 5 and 6 respectively. These evaluations are based on the word-analogy dataset of Mikolov et al. (2013b), a noun-verb similarity task (Mitchell, 2013) and a POS clustering task.

2 Continuous Bag-of-Words Model (CBOW)

In the original CBOW model, the probability of a central target word, w_t, is predicted from a bag-of-words representation of the context it occurs in, as illustrated in Figure 2. This context representation, $\mathbf{b}_{context}$, is a simple sum of the CBOW vectors, $\mathbf{b}_i$, that represent each item, w_{t+i}, in a k-word window either side of the target.

$$\mathbf{b}_{context} = \sum_{i=-k, i \neq 0}^{k} \mathbf{b}_i \tag{3}$$

For speed, the output layer uses a hierarchical softmax function (Morin and Bengio, 2005). Each word is given a Huffman code corresponding to a path through a binary tree, and the output predicts the binary choices on nodes of the tree as independent variables. In comparison to the computational cost of doing the full softmax over the whole vocabulary, this hierarchical approach is much more efficient.

Each node is associated with a vector, $\mathbf{n}$, and the output at that node, given a context vector, $\mathbf{b}_{context}$, is:

$$p = logistic(\mathbf{n} \cdot \mathbf{b}_{context}) \tag{4}$$

Here, p is the probability of choosing 1 over 0 at this node of the tree, or equivalently finding a 1 in the Huffman code of w_t at the relevant position.

The objective function is the negative log-likelihood of the data given the model.

$$O = \sum -\log(p) \tag{5}$$

Where the sum is over tokens in the training corpus and the relevant nodes in the tree. Training is then based on stochastic gradient descent, with a decreasing learning rate.

3 Extensions

3.1 Continuous Sequence of Words (CSOW)

A major feature of the CBOW model is its use of a bag-of-words representation of the context and this is achieved by summing over the vectors representing words in the input. Although the model does seem to produce representations that are effective on both semantic and syntactic tasks, we want to be able to exploit word order information to separate these two characteristics. We therefore need to consider models which do not reduce the context to a structureless bag-of-words. Modifying the original model to retain the sequential information in the input is relatively straightforward. Instead of summing the input representations, we simply leave them as an ordered sequence of vectors, $\mathbf{s}_i$.

Then in the output layer, we require a vector for every input position, i, on every node. In this way, the output of the network depends on which context word is in which position, rather than just the set of words, irrespective of position in the input.

The network still learns a single representation for each word independently of position, but the output function has more parameters.

$$p = logistic(\sum_{i=-k,i\neq 0}^{k} \mathbf{n}_i \cdot \mathbf{s}_i) \quad (6)$$

Here each node of the tree is associated with one vector, $\mathbf{n}_i$, for each position, i, in the input context, giving $2k$ vectors in total at each node.

3.2 Continuous Bag and Sequence of Words (CBSOW)

Having introduced a sequential version of the CBOW model, what is really desired is a model that combines both bag and sequence components. Each word will have both an e-dimensional bag-vector $\mathbf{b}$ and an f-dimensional sequence-vector $\mathbf{s}$. The full representation of a word, $\mathbf{v}$, is then the concatenation of the components of $\mathbf{b}$ and $\mathbf{s}$.

Given this structure, the representation of a context of $2k$ words will be made up of the sum, $\mathbf{b}_{context}$, of their bag vectors, $\mathbf{b}_i$, as in the CBOW model given by Equation 3, along with the ordered sequence vectors, $\mathbf{s}_i$, as in the CSOW model. Each node in the tree then requires both a bag vector, $\mathbf{n}^b$, to handle the bag context, and $2k$ sequence vectors, $\mathbf{n}_i^s$, to handle the sequence context vectors, with probabilities given by:

$$p = logistic(\mathbf{n}^b \cdot \mathbf{b}_{context} + \sum_{i=-k,i\neq 0}^{k} \mathbf{n}_i^s \cdot \mathbf{s}_i) \quad (7)$$

3.3 Continuous Bag of Morphemes (CBOM)

A second source of information which might be used to differentiate semantic from syntactic representations is morphology. Specifically, English has the useful characteristic that the written words themselves can often be broken into a semantic stem on the left and a syntactic ending on the right. For example, *dancing* = *dance* + *ing* and *swimmer* = *swim* + *er*. In fact, stemming or lemmatization is commonly used in constructing distributional vectors precisely because throwing away the syntactic information helps to enhance their semantic content. Here, we want to use both the left and right halves separately to enhance both the semantic and syntactic components of the representations.

Our starting point is to break each word into a left-hand stem and a right-hand ending using CELEX (Baayen et al., 1995), as explained in more detail in Section 4.1.

The simplest model is then to represent each of these with its own vector, $\mathbf{l}_i$ and $\mathbf{r}_i$ respectively, and sum these vectors to form context representations of words in the input.

$$\mathbf{l}_{context} = \sum_{i=-k,i\neq 0}^{k} \mathbf{l}_i \quad (8)$$

$$\mathbf{r}_{context} = \sum_{i=-k,i\neq 0}^{k} \mathbf{r}_i \quad (9)$$

The output function takes much the same form as the original model but now each node needs both a left and a right vector, corresponding to the two context representations.

$$p = logistic(\mathbf{n}^l \cdot \mathbf{l}_{context} + \mathbf{n}^r \cdot \mathbf{r}_{context}) \quad (10)$$

3.4 Continuous Bag and Sequence of Words and Morphemes (CBSOWM)

Finally, we want to incorporate all these elements in a single model, with the morphological and word order elements of the model working in harmony. In particular, we want the sequential part of the model to be guided by morphological information without being constrained to give all words with same ending the same representation. Our solution is to add a constraint term to the objective function, which penalizes sequence vectors that stray far from the relevant morphological representation. The bag vectors, in contrast, are determined directly by the left hand stems, with all words having the same stem then sharing the same bag vector, $\mathbf{b} = \mathbf{l}$.

The main structure of the model remains as in the CBSOW model, with the context being represented by the sum of bag vectors alongside the ordered sequence vectors. Output probabilities are as given by Equation 7, and we add a morphological penalty, m, to the objective function.

$$m = \sum_{i=-k,i\neq 0}^{k} \frac{1}{2}\lambda|\mathbf{s}_i - \mathbf{r}_i|^2 \quad (11)$$

The morphological representations $\mathbf{r}$ enter into the model only through the penalty term, and they adapt during training solely in terms of this interaction with the sequence vectors. Gradient descent results in the $\mathbf{r}$ vectors moving towards the centre of the corresponding $\mathbf{s}$ vectors, and the $\mathbf{s}$ vectors in turn being drawn towards that centre.

The result is to elastically connect all the $\mathbf{s}$ vectors corresponding to a single morphological element through their $\mathbf{r}$ vectors, so that they are drawn together, but can still develop idiosyncratically if there is sufficient evidence in the data.

3.5 Application to the Word-Analogy Task

Decomposition of representations into separate semantic and syntactic spaces enables us to utilise a new approach to solving the word-analogy problems. Rather than using vector differences to predict a vector, we can instead construct it by copying the relevant bag and sequence vectors. So, since $small$ and $smaller$ share very similar semantic content, we can use the bag vector of $small$ as the bag vector of $smaller$, since that is where the semantic content is mainly represented: $\mathbf{b}_{smaller} \approx \mathbf{b}_{small}$. Similarly, we can use the sequence vector of $bigger$ as the sequence vector for $smaller$, since these words share common syntactic behaviour: $\mathbf{s}_{smaller} \approx \mathbf{s}_{bigger}$.

The predicted representation of $smaller$ is then given by the concatenation of the components.

$$\mathbf{v}_{smaller} \approx \mathbf{b}_{small} \oplus \mathbf{s}_{bigger} \qquad (12)$$

We find that this gives the best performance on the models that use word-order features (CBSOW and CBSOWM).

4 Training

Our experiments are based on the publicly available word2vec[1] and GloVe[2] packages. We modified the original CBOW code to incorporate the CBSOW, CBOM and CBSOWM extensions described above, and trained models on three English Wikipedia corpora of varying sizes, including the enwik8 and enwik9 files[3] suggested in the word2vec documentation, containing the first 10^8 and 10^9 characters of a 2006 download, and also a full download from 2009. On the smallest 17M word corpus we explored a range of vector dimensionalities from 10 to 1000. On the larger 120M and 1.6B word corpus, we trained extended models with a 200-dimensional semantic component and a 100-dimensional syntactic component comparing to 300-dimensional CBOW, Skip-gram and GloVe models. The parameter, λ, in Equation 11 was set to 0.1 and the recommended window sizes of 5, 10 and 15 words either side of the central word were used as context for the CBOW, Skip-gram and GloVe models respectively.

4.1 CELEX

We attempted to split all the words in the training data into a left hand and a right hand using CELEX (Baayen et al., 1995), an electronic dictionary containing morphological structure. In the cases of words that were not found in the dictionary and also those that were found but had no morphological substructure, the left hand was just the whole word and the right hand was a $-NULL-$ token. For the remaining words, we treated short suffixes as being syntactic inflections and stripped all these off to leave a left hand 'semantic' component. The 'syntactic' component was then rightmost of these suffixes, with any additional suffixes being ignored.

5 Evaluation

The hypothesis that orthogonality is useful to word vector representations is investigated empirically in two ways. Firstly, we attempt to quantify the orthogonality that is already implicitly present in the original CBOW, Skip-gram and GloVe representations and relate that to their success in the word-analogy task. Secondly, the extensions described above are evaluated on a number of tasks in order to evaluate the benefits of their explicit orthogonality between components.

5.1 Orthogonality within the Original Models

Equation 1 relates orthogonality of vector differences to their dot product being zero, which corresponds to the fact the cosine of $90°$ is zero. Thus, we can use the cosine as a quantification of how close to orthogonal the vector differences are and then relate that to performance on the word-analogy dataset distributed with the word2vec toolkit.

That task involves predicting a word vector given vectors for other related words. So, for example, given vectors for big, $bigger$ and $small$, we would try to predict a vector for $smaller$. We then judge the success of this prediction in terms of whether the predicted vector is in fact closer to $smaller$'s actual word vector than any other word vector. The dataset contains 19,544 items, broken down into 14 subtasks (e.g. capitals of common countries or adjective to adverb conversion).

[1] https://code.google.com/p/word2vec/

[2] http://nlp.stanford.edu/projects/glove/

[3] http://mattmahoney.net/dc/text.html

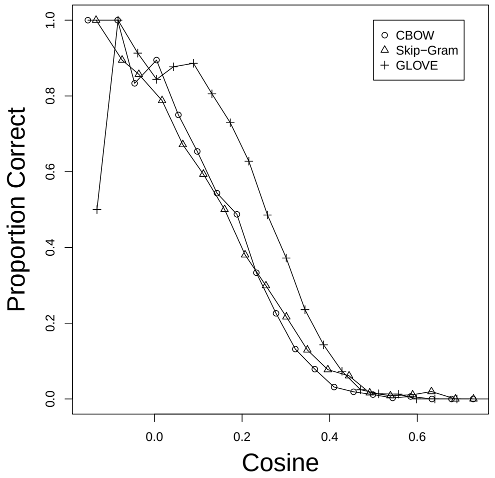

Figure 3: Proportion Correct against Average Cosine.

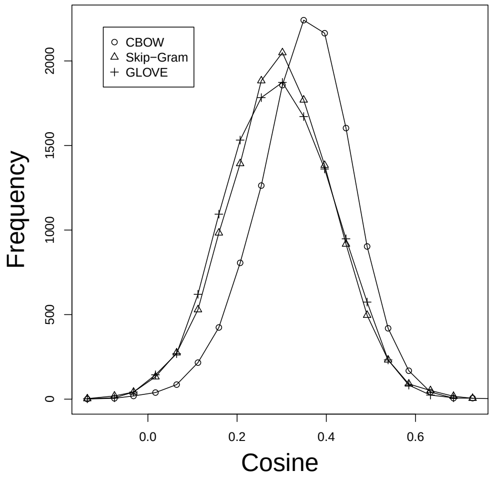

Figure 4: Frequency against Cosine.

For each item, we measure the cosine of the angle between the vector differences for the word we are trying to predict (e.g. $smaller - small$ and $smaller - bigger$) and analyze these values in terms of the success of the model's prediction, with smaller cosine values corresponding to angles that are closer to orthogonal.

5.2 CBOW Extensions

We evaluate the extensions on three tasks. Alongside the word-analogy problems, we also evaluate the separate semantic and syntactic sub-spaces on their own individual tasks. The semantic task correlates predicted semantic similarities with the noun-verb similarity ratings gathered by Mitchell (2013), and the remaining task clusters the syntactic representations and evaluates these clusters in relation to the POS classes found in the Penn Treebank.

On the word-analogy problem we compare to the original CBOW, Skip-gram and GloVe models. In the case of these original models and also the CBOM model, we follow Mikolov et al.'s (2013b) method for making the word-analogy predictions in terms of addition and subtraction: $smaller \approx bigger - big + small$. However, in the case of the CBSOW and CBSOWM models, we use the novel approach described in Section 3.5: $\mathbf{v}_{smaller} \approx \mathbf{b}_{small} \oplus \mathbf{s}_{bigger}$. Similarity is then based on the cosine measure for all types of representation.

The noun-verb similarity task is based on correlating the model's predicted semantic similarity for words with human ratings gathered in an online experiment. Such evaluations have been commonly used to evaluate distributional representations, with higher correlations indicating a model which is more effective at forming vectors whose relations to each other mirror human notions of semantic similarity. Mitchell (2013) argued that predicting semantic similarity relations across syntactic categories provided a measure of the extent to which word representations succeed in separating semantic from syntactic content, and gathered a dataset of similarities for noun-verb pairs. Each rated item consists of a noun paired with a verb, and the pairs are constucted to range from high semantic similarity, e.g. *disappearance* - *vanish*, to low, e.g. *transmitter* - *grieve*. The dataset contains ratings for 108 different pairs, each of which was rated by 20 participants. For the CBOW model, we predict similarities in terms of the cosine measure for the two word vectors. For the other models, we predict similarities from cosine applied to just the bag or left-hand vectors.

The syntactic component of the representations is evaluated by clustering the vectors and then comparing the induced classes to the POS classes found in the Penn Treebank. We use the many-to-one measure (Christodoulopoulos et al., 2010; Yatbaz et al., 2012) to determine the extent to which the clusters agree with the POS classes. Each cluster is mapped to its most frequent gold tag and the reported score is the proportion of word tokens correctly tagged using this mapping. The clustering itself is a form of k-means clustering, where similarity is measured in terms of the cosine measure. Each vector is assigned to a clus-

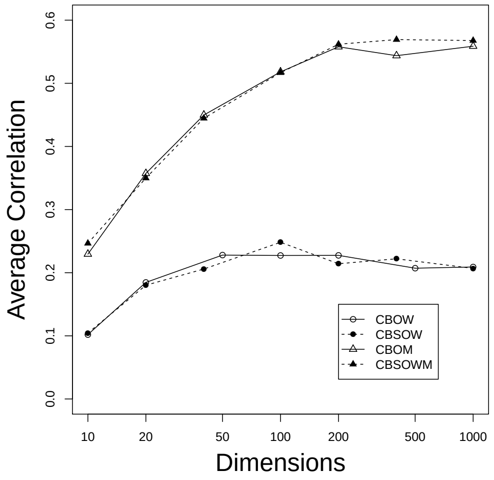

Figure 5: Average Correlation on Noun-Verb Evaluation Task against Size of Representations.

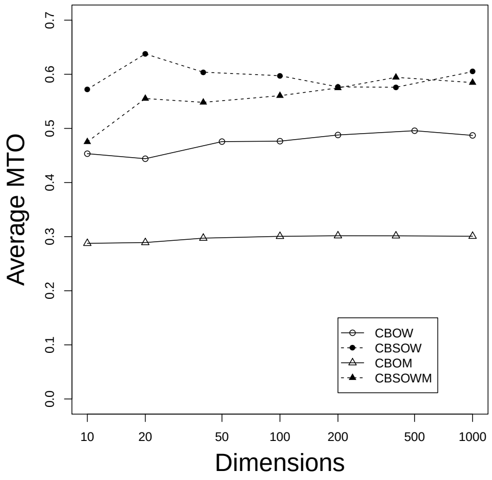

Figure 6: Average Many-To-One Evaluation against Size of Representations.

ter based on which cluster centroid it is most similar to and then the cluster centroids are updated given the new cluster assignments and the process repeats. This clustering was applied to either the sequence or right-hand vectors in the case of the CBSOW, CBOM and CBSOWM models, and to the whole vectors in the case of CBOW. We randomly initialized 45 clusters and then evaluated after 100 iterations of the k-means algorithm.

6 Results

6.1 Original Models

Figure 3 is a plot of the proportion of correct predictions made by 100-dimensional CBOW, Skip-Gram and GloVe models on the word-analogy task against cosine of the angle between the vector differences. The range of the cosine distribution was broken into twenty intervals and the plotted values were derived by calculating the proportion correct and average cosine value within each interval. It is clear from the resulting curves that cosine is a fairly strong predictor for all models of whether the model gets a word-analogy item correct, with higher rates of success for smaller cosine values - i.e. angles closer to orthogonality. This is confirmed by a significant ($p < 0.001$) result from a logistic regression of correctness against cosine value. Similar results are found for both the semantic subtasks (e.g. capitals of common countries) and syntactic subtasks (e.g. adjective to adverb conversion) considered separately.

The actual distribution of cosine values for each type of model is given in Figure 4. This analysis reveals that while the Skip-Gram and GloVe models have fairly similar cosine distributions, the CBOW model's distribution is shifted to the right, with more angles further from othogonality. This begs the question of what the effect on performance would be if we managed to push more of the CBOW distribution towards zero, and in the next section we examine the extensions that implement this idea.

6.2 CBOW Extensions

We first consider the models trained on the smaller 17M word corpus, and the evaluations of these models on the noun-verb similarity and POS clustering tasks are presented in Figures 5 and 6 respectively. These graphs depict the performance as the representations grow in size. For the CBOW model, this is just the dimension of the induced vectors. For the other models, we consider models with equal sizes of semantic and syntactic subspaces and report performance against the total dimensionality of the combined representation. For both these tasks, the results were averaged over ten repetitions of training with random initializations.

On the noun-verb similarity task, morphology produces the largest performance gains, with the CBOM model substantially outperforming the CBOW model. Word order structure has no clear impact.

On the syntactic task, in contrast, it is word order that produces reliable gains, with the CBSOW model clearly improving on the CBOW model. The simplistic use of morphology in the CBOM model results in a degradation of performance in

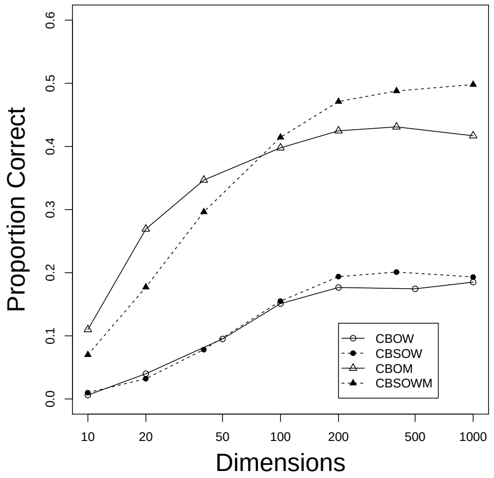

Figure 7: Proportion Correct on the Analogy Task against Size of Representations.

	Training Words		
Model	17M	120M	1.6B
GloVe	29.53%	58.18%	**72.54%**
Skip-Gram	30.03%	52.67%	62.34%
CBOW	18.47%	38.48%	54.17%
CBSOW	20.83%	42.00%	59.41%
CBOM	44.29%	53.60%	61.87%
CBSOWM	**48.92%**	**63.19%**	68.32%

Table 1: Performance of 300-Dimensional Models on the Word-Analogy Task

comparison to the CBOW model, but the CBSOWM model's performance is comparable to that of the CBSOW for larger representations.

Thus for these two tasks, the CBSOWM results appear to show a reasonable integration of morphology and word order information giving good performance on both semantic and syntactic tasks. This conclusion is borne out the results of the word-analogy tasks in Figure 7, where the CBSOWM model outperforms all the other models. Here, morphology gives the greatest benefit on its own, as evidenced in the differences between the CBOW and CBOM models. Nonetheless, word order still produces noticeable improvements, with the CBSOW result beating the CBOW results, and the CBSOWM beating the CBOM at larger dimensions. There is considerable variation in the effects on performance among the various analogy subtasks, but even a task such as capitals of common countries (e.g. predicting Iraq as having Baghdad as its capital, given that Greece has Athens) appears to benefit from decomposition of representations, despite not obviously involving syntactic structure.

Table 1 compares 300-dimensional models across different sizes of training data. In the case of the CBSOW, CBOM and CBSOWM models we use representations with 200 semantic and 100 syntactic dimensions and compare these to CBOW, Skip-gram and GloVe models of the same total size. It is clear for all quantities of training data that all the extensions outperform the basic CBOW model, with morphology giving greater gains than word order, and the combined CBSOWM model outperforming both. This performance advantage of the CBOM over CBSOW appears to weaken as the training data grows, which is probably the effect of both the lack of morphological information for rare words encountered in the larger datasets and also the diminishing returns on that information as more data provides better supervision of the training process. The sequential information, in contrast, is internal to the training data and seems to provide the same, or greater, performance boost as the training set grows.

Comparing the results of our extended models to the Skip-gram and GloVe models, we can see that on the two smaller corpora CBSOWM outperforms both these models, while on the largest corpus, it only beats the Skip-gram results and GloVe achieves the best performance. Of course, neither the Skip-gram nor GloVe models has access to the morphological information that the CBSOWM model uses, but the results demonstrate that the performance of the CBOW model can be substantially boosted by exploiting a representational structure that decomposes into semantic and syntactic sub-spaces. Similar methods could in principle be applied to most word embedding models, including Skip-gram and GloVe.

We can also examine the distribution of cosine values for the new models. Figure 8 compares the distribution of cosine values for CBOW, CBSOW, CBOM and CBSOWM models. Although, in comparison to the original CBOW model, each of the extended models shifts the distribution towards zero, i.e. towards orthogonality, this shift for the CBSOW model is marginal. In contrast, the CBOM model has a large number of instances where the cosine is exactly zero, corresponding to cases where all of the relevant morphological information is found in CELEX. The remainder

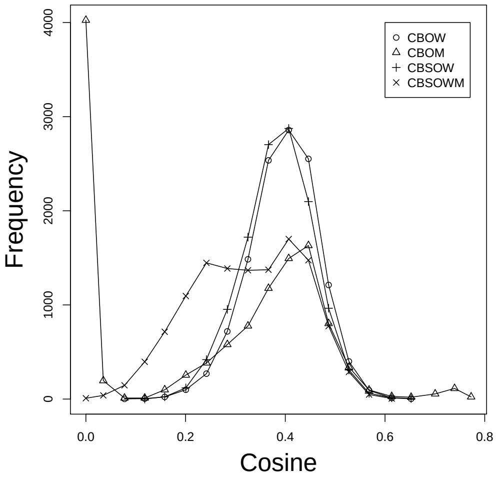

Figure 8: Frequency against Cosine.

of the data, however, seems to be less orthogonal than the original CBOW distribution, suggesting that words without a morphological analysis need a more sophisticated treatment. The shift in the CBSOWM distribution, in comparison, is less radically bimodal, with more continuity between those words with and without morphology. This reflects the difference in these models handling of suffixes, with the CBSOWM model's greater flexibility resulting in gains over the CBOM model on the POS induction and word analogy tasks.

7 Conclusions

Our experiments demonstrate the utility of orthogonality within vector-space representations in a number of ways. In terms of existing models, we find that the cosines of vector-differences is a strong predictor of the performance of CBOW, Skip-gram and GloVe representations on the word analogy task, with smaller cosine values - corresponding to angles closer to orthogonality - being associated with a greater proportion of correct predictions. With regard to developing new models, this orthogonality of relationships inspired three models which used word-order and morphology to separate semantic and syntactic representations. These separate sub-spaces were shown to have enhanced performance in semantic similarity and POS-induction tasks and the combined representations showed enhanced performance on the word-analogy task, using a novel approach to solving this problem that exploits the decomposable structure of the representations.

Both Botha and Blunsom (2014) and Luong et al. (2013) take a more sophisticated approach to morphology[4], constructing a word's embedding by recursively combining representations of all its morphemes, though only within a single non-decomposed space. Future work ought to pursue models in which all morphemes contribute both semantic and syntactic content to the word representations.

It would also be desirable to explore more practical applications of these representations than the limited evaluations presented here. It seems feasible that our decomposition of representations could benefit tasks that need to differentiate their treatment of semantic and syntactic content. In particular, applications of word embeddings that mainly involve syntax, such as POS tagging (e.g., Tsuboi, 2014) or supertagging for parsing (e.g., Lewis and Steedman, 2014), may be a reasonable starting point.

Abstract

We consider the problem of building scalable semantic parsers for Freebase, and present a new approach for learning to do partial analyses that ground as much of the input text as possible without requiring that all content words be mapped to Freebase concepts. We study this problem on two newly introduced large-scale noun phrase datasets, and present a new semantic parsing model and semi-supervised learning approach for reasoning with partial ontological support. Experiments demonstrate strong performance on two tasks: referring expression resolution and entity attribute extraction. In both cases, the partial analyses allow us to improve precision over strong baselines, while parsing many phrases that would be ignored by existing techniques.

1 Introduction

Recently, significant progress has been made in learning semantic parsers for large knowledge bases (KBs) such as Freebase (FB) (Cai and Yates, 2013; Berant et al., 2013; Kwiatkowski et al., 2013; Reddy et al., 2014). Although these methods can build general purpose meaning representations, they are typically evaluated on question answering tasks and are designed to only parse questions that have complete ontological coverage, in the sense that there exists a logical form that can be executed against Freebase to get the correct answer.[1] In this paper, we instead consider the problem of learning semantic parsers for open domain text containing concepts that may or may not be representable using the Freebase ontology.

Even very large knowledge bases have two types of incompleteness that provide challenges for semantic parsing algorithms. They (1) have partial ontologies that cannot represent the meaning of many English phrases and (2) are typically missing many facts. For example, consider the phrases in Figure 1. They include subjective or otherwise unmodeled phrases such as “relaxed” and “quake-hit.” Freebase, despite being large-scale, contains a limited set of concepts that cannot represent the meaning of these phrases. They also refer to entities that may be missing key facts. For example, a recent study (West et al., 2014) showed that over 70% of people in FB have no birth place, and 99% have no ethnicity. In our work, we introduce a new semantic parsing approach that explicitly models ontological incompleteness and is robust to missing facts, with the goal of recovering as much of a sentence’s meaning as the ontology supports. We argue that this will enable the application of semantic parsers to a range of new tasks, such as information extraction (IE), where phrases rarely have full ontological support and new facts must be added to the KB.

Because existing semantic parsing datasets have been filtered to limit incompleteness, we introduce two new corpora that pair complex noun phrases with one or more entities that they describe. The

Figure 2: Examples of noun phrases x, from the Wikipedia category and apposition datasets, paired with the set of entities $\mathbf{e}$ they describe, their underspecified logical form l_0, and their final logical form y.

first new dataset contains 365,000 Wikipedia category labels (Figure 1, top), each paired with the list of the associated Wikipedia entity pages. The second has 67,000 noun phrases paired with a single named entity, extracted from the appositive constructions in KBP 2009 newswire text (Figure 1, bottom).[2] This new data is both large scale, and unique in the focus on noun phrases. Noun phrases contain a number of challenging compositional phenomena, including implicit relations and noun-noun modifiers (e.g. see Gerber and Chai (2010)).

To better model text with only partial ontological support, we present a new semantic parser that builds logical forms with concepts from a target ontology and *open* concepts that are introduced when there is no appropriate concept match in the target ontology. Figure 2 shows examples of the meanings that we extract. Only the first of these examples can be fully represented using Freebase, all other examples require explicit modeling of open concepts. To build these logical forms, we follow recent work for Combinatory Categorical Grammar (CCG) semantic parsing with Freebase (Kwiatkowski et al., 2013), extended to model when open concepts should be used. We develop a two-stage learning algorithm: we first compute broad coverage lexical statistics over all of the data, which are then incorporated as features in a full parsing model. The parsing model is tuned on a hand-labeled data set with gold analyses.

Experiments demonstrate the benefits of the new approach. It significantly outperforms strong baselines on both a referring expression resolution task, where much like in the QA setting we directly evaluate if we recover the correct logical form for each input noun phrase, and on entity attribute extraction, where individual facts are extracted from the groundable part of the logical form. We also see that modeling incompleteness significantly boosts precision; we are able to more effectively determine which words should not be mapped to KB concepts. When run on all of the Wikipedia category data, we estimate that the learned model would discover 12 million new facts that could be added to Freebase with 72% precision.

2 Overview

Semantic Parsing with Open Concepts Our goal is to learn to map noun phrase referring expressions x to logical forms y that describe their meaning. In this work, y is built using both concepts from a knowledge base $\mathcal{K}$ and *open concepts* that lie outside of the scope of $\mathcal{K}$. For example, in Figure 2 the phrase "Defunct Korean football clubs" is modeled using a logical form y that contains the $\mathcal{K}$ concept $\texttt{football\_clubs}(\texttt{x})$ as well as the open concepts $\texttt{OpenType}[\texttt{defunct}](\texttt{x})$.

In this paper we describe a new method for learning the mapping from x to y from corpora of referring expression noun phrases, paired with a sets of entities e that these referring expressions describe. Figure 2 shows examples of these data drawn from two sources.

Tasks We introduce two new datasets (Sec. 3) that pair referring noun phrases x with one or more

[2] All new data is available on the authors' websites.

entities **e** that they describe. These data support evaluation for two tasks: referring expression resolution and information extraction.

In referring expression resolution, the parser is given x and is used to predict the referring expression logical form y that describes **e**. Since the majority of our data cannot be fully modeled with Freebase, we evaluate each y against a hand labeled gold standard instead of trying to extract **e** from $\mathcal{K}$.

The entity attribute extraction task also involves mapping phrases x to logical forms y, with the goal of adding new facts to the knowledge base $\mathcal{K}$. To do this, we assume each x is additionally paired with an set of entities **e**. We also define an *entity attribute* to be a literal in y that uses only concepts from $\mathcal{K}$. Finally, we extract, for each entity in **e**, all of the attributes listed in y. For example, the first logical form y in Figure 2 has two entity attributes: $\texttt{composer}(\texttt{JeanSibelius}, \texttt{x})$ and $\texttt{composition.form}(\texttt{x}, \texttt{Symphonic\_poems})$ which can be added to $\mathcal{K}$ for the entities $\{\texttt{TheBard}, \texttt{Finlandia}\}$.

Model and Learning Our approach extends the two-stage semantic parser introduced by Kwiatkowski et al (2013). We use CCG to build domain-independent logical forms l_0 and then introduce a new method for reasoning about how to map this intermediary representation onto both open concepts and $\mathcal{K}$ concepts (Sec. 4).

To learn this model, we assume access to data with two different types of annotations. The first contains noun phrase descriptions x and described entity sets e (as in Figure 2), which can be easily gathered at scale with no manual data labeling effort. However, this data, in general, has significant amount of knowledge base incompleteness; many described concepts and entity attributes will be missing from $\mathcal{K}$ (see Sec. 3 for more details). Therefore, to support effective learning, we will also use a small hand-labeled dataset containing x, **e**, a gold logical form y, an intermediary CCG logical form l_0, and a mapping from words in x to constants in $\mathcal{K}$ and open concepts. Our full learning approach (Sec. 5) estimates a linear model on the small labeled dataset, with broad coverage features derived from the larger dataset.

3 Data

We gathered two new datasets that pair complex noun phrases with one or more Freebase entities.

The Wikipedia category dataset contains 365,504 Wikipedia category names paired with the list of entities in that category. [3] Table 1 shows the details of this dataset and examples are given in Figure 2. For each development and test data, we randomly select 500 categories consisted of 3-10 words and describing fewer than 100 entities.

The apposition dataset is a large set of complex noun phrases paired with named entities, extracted from appositive constructions such as "Gustav Bayer, a former Olympic gymnast for Norway." For this example, we extract the entity "Gustav Bayer" and pair it with the noun phrase "a former Olympic gymnast for Norway." To identify appositive constructions, we ran the Stanford dependency parser on the newswire section of the KBP 2009 source corpus,[4] and selected noun phrases composed of 3 to 10 words, starting with an article, and paired with a named entity that is in Freebase.

This procedure of identifying complex entity descriptions allows for information extraction from a wide range of sources. However, it is also noisy and challenging. The dependency parser makes errors, for example "the next day against the United States, Spain" is falsely detected as an apposition. Furthermore, addressing context and co-reference is often necessary. For example, "Puerto Montt, a city south of the capital" or "the company's parent, Shenhua Group" requires reference resolution. We gathered 67 thousand appositions, which will be released to support future work, and randomly selected 300 for testing.

Measuring Incompleteness To study the amount of incompleteness in this data, we hand labeled logical forms for 500 Wikipedia categories in the development set. Examples of annotations are given in the rows labeled y in Figure 2. We use these to measure the schema and fact coverage of Freebase. Many of the entities in this dataset do not have the Freebase attributes described by the category phrases. When a concept is not in Freebase, we annotate it as `OpenType` or `OpenRel`, as shown in Figure 2. On average, each Wikipedia category name describes 2.58 Freebase attributes, and 0.39 concepts that cannot be mapped to FB. Overall, 27.2% of the phrases contain concepts that do not exist in the Freebase schema.

# unique words	25,472	817
# words per apposition	5.73	5.93

Table 2: Appositive data statistics.

Each category may have multiple correct logical forms. For example, “Hotels” can be mapped to: $\mathtt{hotel(x)}$, $\mathtt{accomodation.type(x, hotel)}$, or $\mathtt{building\_function(x, hotel)}$. There are also genuine ambiguities in meaning. For example, “People from Bordeaux” can be interpreted as $\mathtt{people(x)} \wedge \mathtt{place\_lived(x, Bordeaux)}$ or $\mathtt{people(x)} \wedge \mathtt{place\_of\_birth(x, Bordeaux)}$. We made a best effort attempt to gather as many correct logical forms as possible, finding on average 1.8 logical forms per noun phrase. There were 97 unique binary relations, and 247 unique unary attributes in the annotation.

Given these logical forms, we also measured factual coverage. For the 72.8% of phrases that can be completely represented using Freebase, we executed the logical forms and compared the result to the labeled entity set. In total, 56% of the queries returned no entities and those that did return results have on average 15% overlap with the Wikipedia entity set. We also measured how often attributes from the labeled logical forms were assigned to the Wikipedia entities in FB, finding that only 33.6% were present. Given this rate, we estimate that it is possible to add 12 million new facts into FB from the 7 million entity-category pairs.

4 Mapping Text to Meaning

We adopt a two-stage semantic parsing approach (Kwiatkowski et al., 2013). We first use a CCG parser to define a set $\textsc{ccg}(x)$ of possible logical forms l_0. Then we will choose the logical form l_0 that closely matches the linguistic structure of the input text x, according to a learned linear model, and use an ontological match step that defines a set of transformations $\textsc{ont}(l_0, \mathcal{K})$ to map this meaning to a Freebase query y. Figure 2 shows examples of x, l_0 and y. In this section we describe our approach with the more detailed example derivation in Figure 3. We also describe the parameterization of a linear model that scores each derivation.

CCG parsing We use a CCG (Steedman, 1996) semantic parser (Kwiatkowski et al., 2013) to generate an underspecified logical form l_0. Figure 3a shows an example parse. The constants $Former$, $Municipalities$, in, $Brandenburgh$ in l_0 are not tied to the target knowledge base, causing the logical form to be underspecified. They can be replaced with Freebase constants in the later ontology matching step.

Ontological Matching The ontological match step has *structural match* and *constant match* components. Structural match operators can collapse or expand sub-expressions in the logical forms to match equivalent typed concepts in the target knowledge base. We adopt existing structural match operators (Kwiatkowski et al., 2013) and refer readers to that work for details.

Constant match operators replace underspecified constants in the underspecified logical form l_0 with concepts from the target knowledge base. There are four constant match operations used in Figure 3. The first two constant matches, shown below, match underspecified constants with constants of the same type from Freebase.

$$in \rightarrow \mathtt{location.containedby}$$
$$Brandenburgh \rightarrow \mathtt{BRANDENBURGH}$$

However, because we are modeling the semantics of phrases that are not covered by the Freebase schema, we also require the following two constant matches:

$$Former(x) \rightarrow \mathtt{OpenType}$$
$$municipalities(x) \rightarrow \mathtt{OpenRel(x, Municipality)}$$

Here, the word ‘former’ has been associated with a placeholder typing predicate since Freebase has no way of expressing end dates of administrative divisions. There is also no Freebase type representing the concept ‘municipalities.’ However, this word is associated with an entity in Freebase. Since there is no suitable linking predicate for the entity $\mathtt{Municipality}$, we introduce a placeholder linking predicate $\mathtt{OpenRel}$ in the step from $l_2 \rightarrow l_3$. Our constant match operators can also introduce placeholder entities $\mathtt{OpenEntity}$ when there is no good match in Freebase.

(a) **CCG parse** builds an underspecified semantic representation of the sentence.

$$\begin{array}{cccc} \text{Former} & \text{municipalities} & \text{in} & \text{Brandenburgh} \\ \hline N/N & N & N\backslash N/NP & NP \\ \lambda f \lambda x.f(x) \wedge former(x) & \lambda x.municipalities(x) & \lambda f \lambda x \lambda y.f(y) \wedge in(y,x) & Brandenburg \end{array}$$

$$\xrightarrow{\quad\quad\quad\quad\quad} {>} \qquad\qquad \xrightarrow{\quad\quad\quad\quad\quad} {>}$$

$$\begin{array}{cc} N & N\backslash N \\ \lambda x.former(x) \wedge municipalities(x) & \lambda f \lambda y.f(y) \wedge in(y, Brandenburg) \end{array}$$

$$\xrightarrow{\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad} {<}$$

$$\begin{array}{c} N \\ l_0 = \lambda x.former(x) \wedge municipalities(x) \wedge in(x, Brandenburg) \end{array}$$

(b) **Constant matches** replace underspecified constants with Freebase concepts

$\mathbf{l_0} = \lambda x.former(x) \wedge municipalities(x) \wedge in(x, Brandenburg)$

$\mathbf{l_1} = \lambda x.former(x) \wedge municipalities(x) \wedge in(x, \texttt{Brandenburg})$

$\mathbf{l_2} = \lambda x.former(x) \wedge municipalities(x) \wedge \texttt{location.containedby}(x, \texttt{Brandenburg})$

$\mathbf{l_3} = \lambda x.former(x) \wedge \texttt{OpenRel}(x, \texttt{Municipality}) \wedge \texttt{location.containedby}(x, \texttt{Brandenburg})$

$\mathbf{l_4} = \lambda x.\texttt{OpenType}(x) \wedge \texttt{OpenRel}(x, \texttt{Municipality}) \wedge \texttt{location.containedby}(x, \texttt{Brandenburg})$

Figure 3: Derivation of the analysis for “Former municipalities in Brandenburgh”. This analysis contains a placeholder type and a placeholder relation as described in Section 4.

We also allow the creation of typing predicates from matched entities through the introduction of linking predicates. For example, there is no native type associated with the word ‘actor’ in Freebase. Instead we create a typing predicate by matching the word to a Freebase entity Actor using Freebase API and allowing the introduction of linked predicates such as person.profession :

$$actor(x) \rightarrow \texttt{person.profession(x, Actor)}$$

Scoring Full Parses Our goal in this paper is to learn a function from the phrase x to the correct analysis y. We score each parse using a linear model with features that signal attributes of the underspecified parse ϕ_p and those that signal attributes of the ontological match ϕ_{ont}. Since the model factors over the two stages of parser, we split the prediction problem similarly. First, we select the maximum scoring underspecified logical form:

$$l^* = \arg \max_{l \in \text{CCG}(x)} (\theta_p \cdot \phi_p(l))$$

and then we select the highest scoring Freebase analysis y^* that can be built from l^*:

$$y^* = \arg \max_{r \in \text{ONT}(l^*, \mathcal{K})} (\theta_{ont} \cdot \phi_{ont}(r))$$

We describe an approach to learning the parameter vectors θ_p and θ_{ont} below.

5 Learning

We introduce a learning approach that first collates aggregate statistics from the 7 million Wikipedia entity-category pairs and existing facts in FB, and then uses a small labeled training set to tune the weights for features that incorporate these statistics.

Wikipedia Category	
Wars involving the Grand Duchy of Lituania	
Entity	Attribute
BattleOfGrunwald	type(x, military.conflict)
GollubWar	type(x, military.conflict)
BattleOfGrunwald	time.event.loc(x, Grunwald)
...	...
Entity	Relation
BattleOfGrunwald	military_conflict.combatants
GollubWar	time.event.start_time
BattleOfGrunwald	military_conflict.commanders
...	...

Figure 4: Labeled entities are associated with attributes and relations.

Broad Coverage Lexical Statistics Each Wikipedia category is associated with a number of entities, most of which exist in FB. We use these entities to extract relations and attributes in FB associated with that category. For example, in Figure 4 the category ‘Wars involving the Grand Duchy of Lithuania’ is associated with the relation military_conflict.combatants and the attribute type(x, military.conflict) multiple times, because they are present in many of the category’s entities. For each of the sub-phrases in the category name we count these associations over the entire Wikipedia category set.

We use these counts to calculate Pointwise Mutual Information (PMI) between words and Freebase attributes or relations. We choose PMI to avoid overcompensating common words, attributes, or relations. For example, the word ‘Wars’ is seen with the incorrect analysis type(x, time.event) more frequently than the correct analysis type(x, military.conflict). However, PMI penalizes the attribute type(x, time.event) for its popularity and the correct analysis is preferred. As PMI has a tendency to emphasize rare counts, we chose PMI squared, which takes the squared value of the co-occurence count (PMI^2(a, b) = $\log\frac{count(a \wedge b)^2}{count(a) * count(b)}$), as a feature.

Structural KB Statistics Existing semantic parsers typically make use of type constraints to limit the space of possible logical forms. These strong type constraints are not feasible when the knowledge base is incomplete. For example, in Freebase the relation military_conflict.combatants expects an entity of type military_conflict.combatant as its object. However, many countries that have been involved in wars are not assigned this type.

We instead calculate type overlap statistics for all Freebase entities, to find likely missing types. For example, including the fact that the object of military_conflict.combatants is very often of type location.country.

Learning from Labeled Data We train each half of the prediction problem separately, as defined in Section 4, using the labeled training data introduced in Section 3. We use structured max-margin perceptrons to learn feature weights for both the underspecified parse and the ontological match step following (Kwiatkowski et al., 2013). The aggregate statistics collected from 7 million category-entity pairs produce very useful lexical features. We integrate these statistics into our linear model by summing their values for each derivation and treating them as a feature. All of the other features described in Section 6 are not word specific and are therefore far less sparse.

6 Features

We include a number of features that enable soft type checking on the output logical form, described first below, along with other features that measure different aspects of the analysis.

Coherency features For example, consider the phrase "The UK home city of the Queen," with Freebase logical form $y = \lambda x.\mathtt{home}(\mathtt{QEII}, \mathtt{x}) \wedge \mathtt{in}(\mathtt{x}, \mathtt{UK}) \wedge \mathtt{city}(\mathtt{x})$. Each of the relations has expected types for their argument: the relation $\langle$home$\rangle$ expects a subject of type $\langle$person$\rangle$ and an object of type $\langle$location$\rangle$. Each type in Freebase lives in a hierarchy, so the type city implies $\{$location, administrative_division, $\ldots\}$. The next four features test agreement of these types on different parts of the output logical form.

Relation arguments trigger a feature if their type is in the set of types expected by the relation. QEII is a person so this feature is triggered for the relation-argument application in home(QEII, x).

Relation-relation pairs can share variable arguments. For example, the variable x is the object of $\langle$home$\rangle$ and the subject of $\langle$in$\rangle$. Each relation expects a set of types of x. We have features to signal if: these sets are disjoint; one set subsumes the other; and the PMI between the highest level expected type (described in Section 5) if the sets are disjoint. In the example given here, the type $\langle$location$\rangle$ expected by $\langle$in$\rangle$ subsumes the type $\langle$city$\rangle$ expected by $\langle$home$\rangle$ so the second feature fires. We treat types such as city(x) as unary relations and include them in this feature set.

Type domain measures compatibility among domains in Freebase. Freebase is split into high-level domains and some of these are relevant, such as 'football' and 'sports'. We identify those by counting their co-occurrences. This becomes an indicator feature that signals their co-occurrence in y.

Named entity type features test if the entity e that we are extracting attributes for have Freebase type "person", "location" or "organization". If it does, we have a feature indicating if y defines a set of the same type. This features is not used in the referring expression task presented in Section 7 since we cannot assume access to the entities that are described.

CCG parse feature signals which lexical items were used in the CCG parse. Another feature fires if capitalized words map to named entities.

String similarity features signal exact string match, stemmed string match, and length weighted string edit distance between a phrase in the sentence and the name of the Freebase element it was matched on. We also use the Freebase search API to generate scores for phrase, entity pairs and include the log of this score as a features.

Lexical PMI feature includes the lexical Pointwise Mutual Information described in Section 5.

Freebase constant features signal the use of linking predicates, as defined in Section 4, and the log frequency count of the Freebase attributes across all entities in the Wikipedia category set.

Other features indicate the use of OpenRel, OpenEntity, OpenType in y and count repetitions of Freebase concepts in y.

7 Experimental Setup

Knowledge base We use the Jan. 26, 2014 Freebase dump. After pruning binary predicates taking numeric values, it contains 9351 binary predicates, 2754 unary predicates, and 1.2 billion assertions.

Pruning and Feature Initialization We perform beam search at each semantic parsing stage, using the Freebase search API to determine candidate named entities (10 per phrase), binary predicates (300 per phrase), and unary predicates (500 per phrase). The ontology matching stage considers the highest scored underspecified parse.

The features are initialized to prefer well-typed logical forms. Type checking features are initially set to -2 for mismatch. Features signalling incompatible topic domains and repetition are initialized as -10. All other initial feature weights are set to 1.

Datasets and Annotation We evaluate on the Wikipedia category and appositive datasets introduced in Sec. 3. On the Wikipedia development data, we annotated 500 logical forms, underspecified logical forms and constant mappings for ontology matching. The Wikipedia test data is composed of 500 unseen categories. We did not train on the appositive dataset, as it contains challenges such as co-reference and parsing errors as described in Sec. 3. Instead, we chose 300 randomly selected examples for evaluation, and ran on the model trained on the Wikipedia development data.

Evaluation Metrics We report five-fold cross validation for development but ran the final model once on the test data, manually scoring the output.

For evaluation on the referring expression resolution performance (as defined in Sec. 2), we include accuracy for the final logical form (*Exact Match*). We also evaluate precision and recall for predicting individual literals in this logical form on the development set. To control for missing facts, we did not evaluate the set of returned entities.

To evaluate entity attribute extraction performance (as defined in Sec. 2), we identified three classes of predictions. Extractions can be correct, benign, or false. Correct attributes are actually described in the phrase, benign extraction may not have been described but are still true, and false extractions are not true. For example, if the phrase "the capital of the communist-ruled nation" is mapped to the pair of attributes capital_of_administrative_division(x) , location(x), the first is correct and the second is benign. Other incorrect facts would be false.

System	Exact	Partial Match		
	Match	P	R	F1
KCAZ13	1.4	9.6	6.3	7.0
IE Baseline	6.8	37.0	23.3	28.6
NoPMI	11.0	23.7	20.8	21.6
NoOpenSchema	13.7	35.8	30.0	31.1
NoTyping	9.6	37.6	29.3	31.8
Our Approach	15.9	39.3	33.5	35.1
with Gold NE	20.8	46.6	40.5	42.3

Table 3: Referring expression resolution performance on the development set on gold references.

Data	System	Exact Match Accuracy
Wikipedia	IE Baseline	21.8%
	Our Approach	28.4%
Appos	IE Baseline	0.0%
	Our Approach	4.7%

Table 4: Manual evaluation for referring expression resolution on the test sets.

On the development set, we report precision and recall against the union of the FB attributes in our annotations without adjusting for benign extractions or the fact that the annotations are not complete. For the test sets, we computed precision (P) where benign extractions are considered to be wrong, as well as an adjusted precision metric (P*) where benign extractions are counted as correct. As we do not have full test set annotations, we cannot report recall. Finally, we report the average number of facts extracted per noun phrase (fact #).

Comparison Systems We compare performance to a number of ablated versions of the full system, where we have removed the open-constant ontology matching operators (NoOpenSchema), the PMI features (NoPMI), or the type checking features (NoTyping). For the referring expression resolution task, we excluded the named entity type feature, as this assumes typing information about the entity we are extracting attributes for.

We report results without the PMI features and the open schema matching operators (KCAZ13), which is a reimplementation of a recent Freebase QA model (Kwiatkowski et al., 2013). We also learn with gold named entity linking (Gold NE).

For the entity attribute extraction, we built a supervised learning baseline that combines the output of two discrete SVMs, one for predicting unary relations and one for binary relations. Each classifier

System	Top n	P	R	F1	fact #
IE Baseline	-	37.3	26.5	30.6	1.6
Our Approach	1	44.2	32.8	37.7	1.9
	2	36.9	38.0	37.5	2.6
	3	30.7	42.7	35.7	3.6
	4	27.0	44.7	33.6	4.2
	5	23.7	47.2	31.6	5.1
	10	15.9	52.0	24.3	8.5

Table 5: Entity attribute extraction performance on the Wikipedia category development set.

Data	System	P	P*	fact #
Wikipedia	IE Baseline	56.7	58.7	1.6
	Our Approach	61.2	72.6	2.0
Appos	IE Baseline	4.9	13.9	1.3
	Our Approach	33.2	61.4	0.9

Table 6: Manual evaluation for entity attribute extraction on the test sets.

is trained using the annotated Wikipedia categories. This dataset contains hundreds of unary and binary relations, which the IE baseline can predict. Each classifier is further anchored on a specific word, and includes n-gram and POS context features around that word, following features from Mintz et al (2009). To predict binary relations, we used named entities as anchors. For unary attributes we anchored on all possible nouns and adjectives. The final logical form includes the best relation predicted by each classifier. We use the Stanford CoreNLP[5] toolkit for tokenization, named entity recognition, and part-of-speech tagging.

8 Results

Tables 3 and 4 show performance on the referring expression resolution task. Tables 5 and 6 show performance on the extraction task. Reported precision is lower on the labeled development set than on the test set, where predicted logical forms are manually evaluated. This reflects the fact that, despite our best attempts, the development set labels are incomplete, as discussed in Section 3.

Referring expression resolution The systems retrieve the full meaning with 28.4% accuracy on the Wikipedia test set, and 15.9% on the development set. The gold named entity input improves performance by modest amounts. This suggests that the errors stem from ontology mismatches, as we will describe in more detail later in the qualitative analysis. We also see that all of the ablations hurt performance, and that the KCAZ13 model performs extremely poorly. The independent classifier baseline performs well at the sub-clause level, but fails to form a full logical form of the referring expression. Partial grounding and broad-coverage data statistics are essential for this problem.

Entity attribute extraction In the two test sets, the approach achieves high benign precision levels (P*) of 72.6 and 61.4. However, the appositives data is significantly more challenging, and the model misses many of the true facts that could be extracted. Many errors comes in the early stages of the pipeline, which can be attributed at least in part to both (1) the higher levels of noise in the input data (see Section 3), and (2) the fact that the CCG parser was developed on the Wikipedia category labels. While the IE baseline performs reasonably on the Wikipedia test data, its performance degrades significantly on appositions. As it is trained to predict pre-determined relations, it does not generalize to different domains.

For the development set, Table 5 also shows the precision-recall trade off for the set of Freebase attributes that appear in the top-n predicted logical forms. Precision drops quickly but recall can be improved significantly, showing that the model can produce many of the labeled facts.

Qualitative evaluation We sampled 100 errors from the Wikipedia test set for qualitative analysis. 10% came from entity linking. About 30% come from choosing a superset or subset of the desired meaning, for example by mapping "novel" to `book`. About 10% of the errors are from domain ambiguity, such as mapping "stage actor" to `film.film_actor`. 10% of the cases are from spurious string similarity, such as mapping "Hungarian expatriates" to `nationality(x,Hungary)`. 15% of the failures were due to incorrect underspecified logical forms and, finally, about 10% of the errors were because the typing features encouraged compound nouns to be split into separate attributes. On the apposition dataset, 65% of errors stems from parsing, either in apposition detection or CCG parsing. Better modeling the complex attachment decisions for the noun phrases in the apposition dataset remains an area for future work.

One advantage of our approach, especially in comparison to classifier based models like the IE baseline, is the ability to predict previously unseen relations. Counting only the correctly predicted

[5] http://nlp.stanford.edu/software/corenlp.html

triples, we see that over 40% of the unique relations we predict is not in the development set; our model learns to generalize based on the learned PMI features and other lexical cues.

Finally, our approach extracted 2.0 entity attributes per Wikipedia phrase and 0.9 per apposition on average. This matches our intuition that the apposition dataset contains many more words that cannot be modeled with concepts in Freebase.

9 Related Work

Recent work has begun to study the problem of knowledge base incompleteness and reasoning with open concepts. Joshi et al. (2014) describes an approach for mapping short search queries to a single Freebase relation, that benefits from modeling schema incompleteness. Additionally, Krishnamurthy et al. (2012; 2014) present a semantic parser that builds partial meaning representations with Freebase for information extraction applications. This is similar in spirit to the approach we present here, however they focus on a small, fixed, set of binary relations while we aim to represent as much of the text as possible using the entire Freebase ontology. Krishnamurthy and Mitchell (2015) have also studied semantic parsing with open concepts via matrix factorization. They use Freebase entities but do not include Freebase concepts.

The problem of building complete sentence analyses using all of the Freebase ontology has recently received attention within the context of question answering systems (Cai and Yates, 2013; Kwiatkowski et al., 2013; Berant et al., 2013; Berant and Liang, 2014; Reddy et al., 2014). Since they do not model KB incompleteness, these models will not work well on data that cannot be fully modeled by Freebase. In section 7, we report results using one of these systems to provide a reference point for our approach. There has also been other work on Freebase question answering (Yao and Van Durme, 2014; Bordes et al., 2014; Wang et al., 2014) that directly searches the facts in the KB to find answers without explicitly modeling compositional semantic structure. Therefore, these methods will suffer when facts are missing.

The syntactic and semantic structure of noun phrases has been extensively studied. For example, work on NomBank (Meyers et al., 2004; Gerber and Chai, 2010) focus on the challenge of modeling implicit arguments introduced by nominal predicates. In a manual study, we discovered that the 65% of our noun phrases contain implicit relations. We build on insights from Vadas and Curran (2008), who studied how to model the syntactic structure of noun phrases in CCGBank. While we are, to the best of our knowledge, the first to study compound noun phrases for semantic parsing to knowledge-bases, semantic parsers for noun phrase referring expressions have been built for visual referring expression (FitzGerald et al., 2013).

There has been little work on IE from compound noun phrases. Most existing IE algorithms extract a single relation, usually represented as a verb that holds between a pair of named entities, for example with supervised learning techniques (Freitag, 1998) or via distant supervision (Mintz et al., 2009; Riedel et al., 2013; Hoffmann et al., 2011). We aim to go beyond relations between entity pairs, and to retrieve full semantics of noun phrases, extracting unary and binary relations for a single entity. A notable exception to this trend is the ReNoun system (Yahya et al., 2014) which models noun phrase structure for open information extraction. They report that 97% of the attributes in Freebase are commonly expressed as noun phrases. However, unlike our work, they considered open information extraction and did not ground the extractions in an external KB.

10 Conclusion

In this paper, we present a semantic parsing approach with knowledge base incompleteness, applied to the problem of information extraction from noun phrases. When run on all of the Wikipedia category data, the approach would extract up to 12 million new Freebase facts at 72% precision.

There is significant potential for improving the parsing models, as well as better optimizing the precision recall trade-off for the extracted facts. It would also be interesting to gather data with compositional phenomena, such as negation and disjunction, and study its impact on the performance of the semantic parser.

Abstract

We propose a novel semantic parsing framework for question answering using a knowledge base. We define a *query graph* that resembles subgraphs of the knowledge base and can be directly mapped to a logical form. Semantic parsing is reduced to query graph generation, formulated as a staged search problem. Unlike traditional approaches, our method leverages the knowledge base in an early stage to prune the search space and thus simplifies the semantic matching problem. By applying an advanced entity linking system and a deep convolutional neural network model that matches questions and predicate sequences, our system outperforms previous methods substantially, and achieves an F_1 measure of 52.5% on the WEBQUESTIONS dataset.

1 Introduction

Organizing the world's facts and storing them in a structured database, large-scale knowledge bases (KB) like DBPedia (Auer et al., 2007) and Freebase (Bollacker et al., 2008) have become important resources for supporting open-domain question answering (QA). Most state-of-the-art approaches to KB-QA are based on semantic parsing, where a question (utterance) is mapped to its formal meaning representation (e.g., logical form) and then translated to a KB query. The answers to the question can then be retrieved simply by executing the query. The semantic parse also provides a deeper understanding of the question, which can be used to justify the answer to users, as well as to provide easily interpretable information to developers for error analysis.

However, most traditional approaches for semantic parsing are largely decoupled from the knowledge base, and thus are faced with several challenges when adapted to applications like QA. For instance, a generic meaning representation may have the ontology matching problem when the logical form uses predicates that differ from those defined in the KB (Kwiatkowski et al., 2013). Even when the representation language is closely related to the knowledge base schema, finding the correct predicates from the large vocabulary in the KB to relations described in the utterance remains a difficult problem (Berant and Liang, 2014).

Inspired by (Yao and Van Durme, 2014; Bao et al., 2014), we propose a semantic parsing framework that leverages the knowledge base more tightly when forming the parse for an input question. We first define a *query graph* that can be straightforwardly mapped to a logical form in λ-calculus and is semantically closely related to λ-DCS (Liang, 2013). Semantic parsing is then reduced to query graph generation, formulated as a search problem with staged states and actions. Each state is a candidate parse in the query graph representation and each action defines a way to *grow* the graph. The representation power of the semantic parse is thus controlled by the set of legitimate actions applicable to each state. In particular, we stage the actions into three main steps: locating the *topic entity* in the question, finding the main *relationship* between the answer and the topic entity, and expanding the query graph with additional *constraints* that describe properties the answer needs to have, or relationships between the answer and other entities in the question.

One key advantage of this staged design is that through grounding partially the utterance to some entities and predicates in the KB, we make the search far more efficient by focusing on the promising areas in the space that most likely lead to the correct query graph, before the full parse is determined. For example, after linking "Fam-

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1321–1331,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

ily Guy” in the question “Who first voiced Meg on Family Guy?” to `FamilyGuy` (the TV show) in the knowledge base, the procedure needs only to examine the predicates that can be applied to `FamilyGuy` instead of all the predicates in the KB. Resolving other entities also becomes easy, as given the context, it is clear that Meg refers to `MegGriffin` (the character in Family Guy). Our design divides this particular semantic parsing problem into several sub-problems, such as entity linking and relation matching. With this integrated framework, best solutions to each subproblem can be easily combined and help produce the correct semantic parse. For instance, an advanced entity linking system that we employ outputs candidate entities for each question with both high precision and recall. In addition, by leveraging a recently developed semantic matching framework based on convolutional networks, we present better relation matching models using continuous-space representations instead of pure lexical matching. Our semantic parsing approach improves the state-of-the-art result on the WebQuestions dataset (Berant et al., 2013) to 52.5% in F_1, a 7.2% absolute gain compared to the best existing method.

The rest of this paper is structured as follows. Sec. 2 introduces the basic notion of the graph knowledge base and the design of our query graph. Sec. 3 presents our search-based approach for generating the query graph. The experimental results are shown in Sec. 4, and the discussion of our approach and the comparisons to related work are in Sec. 5. Finally, Sec. 6 concludes the paper.

2 Background

In this work, we aim to learn a semantic parser that maps a natural language question to a logical form query q, which can be executed against a knowledge base $\mathcal{K}$ to retrieve the answers. Our approach takes a graphical view of both $\mathcal{K}$ and q, and reduces semantic parsing to mapping questions to *query graphs*. We describe the basic design below.

2.1 Knowledge base

The knowledge base $\mathcal{K}$ considered in this work is a collection of subject-predicate-object triples (e_1, p, e_2), where $e_1, e_2 \in \mathcal{E}$ are the entities (e.g., `FamilyGuy` or `MegGriffin`) and $p \in \mathcal{P}$ is a binary predicate like `character`. A knowledge base in this form is often called a *knowledge graph*

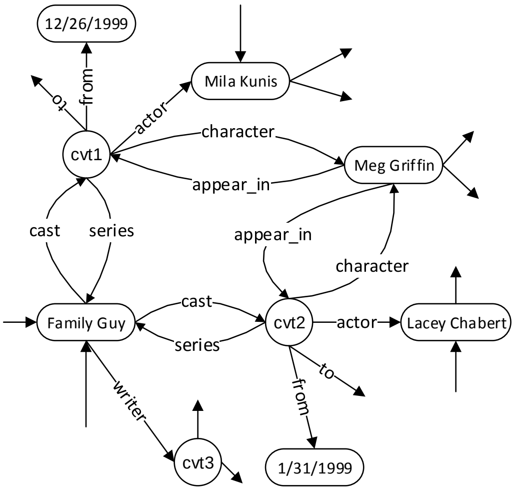

Figure 1: Freebase subgraph of Family Guy

because of its straightforward graphical representation – each entity is a node and two related entities are linked by a directed edge labeled by the predicate, from the subject to the object entity.

To compare our approach to existing methods, we use Freebase, which is a large database with more than 46 million topics and 2.6 billion facts. In Freebase’s design, there is a special entity category called *compound value type* (CVT), which is not a real-world entity, but is used to collect multiple fields of an event or a special relationship.

Fig. 1 shows a small subgraph of Freebase related to the TV show *Family Guy*. Nodes are the entities, including some dates and special CVT entities[1]. A directed edge describes the relation between two entities, labeled by the predicate.

2.2 Query graph

Given the knowledge graph, executing a logical-form query is equivalent to finding a subgraph that can be mapped to the query and then resolving the binding of the variables. To capture this intuition, we describe a restricted subset of λ-calculus in a graph representation as our *query graph*.

Our query graph consists of four types of nodes: *grounded entity* (rounded rectangle), *existential variable* (circle), *lambda variable* (shaded circle), *aggregation function* (diamond). Grounded entities are existing entities in the knowledge base $\mathcal{K}$. Existential variables and lambda variables are un-

[1] In the rest of the paper, we use the term *entity* for both real-world and CVT entities, as well as properties like date or height. The distinction is not essential to our approach.

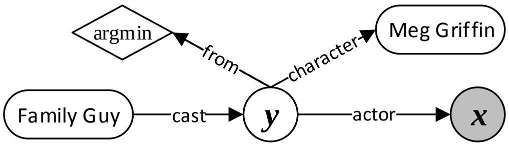

Figure 2: Query graph that represents the question "Who first voiced Meg on Family Guy?"

grounded entities. In particular, we would like to retrieve all the entities that can map to the lambda variables in the end as the answers. Aggregation function is designed to operate on a specific entity, which typically captures some numerical properties. Just like in the knowledge graph, related nodes in the query graph are connected by directed edges, labeled with predicates in $\mathcal{K}$.

To demonstrate this design, Fig. 2 shows one possible query graph for the question "Who first voiced Meg on Family Guy?" using Freebase. The two entities, MegGriffin and FamilyGuy are represented by two rounded rectangle nodes. The circle node y means that there should exist an entity describing some casting relations like the character, actor and the time she started the role[2]. The shaded circle node x is also called the answer node, and is used to map entities retrieved by the query. The diamond node $\arg\min$ constrains that the answer needs to be the earliest actor for this role. Equivalently, the logical form query in λ-calculus without the aggregation function is: $\lambda x.\exists y.\texttt{cast}(\texttt{FamilyGuy}, y) \wedge \texttt{actor}(y, x) \wedge \texttt{character}(y, \texttt{MegGriffin})$ Running this query graph against $\mathcal{K}$ as in Fig. 1 will match both LaceyChabert and MilaKunis before applying the aggregation function, but only LaceyChabert is the correct answer as she started this role earlier (by checking the from property of the grounded CVT node).

Our query graph design is inspired by (Reddy et al., 2014), but with some key differences. The nodes and edges in our query graph closely resemble the exact entities and predicates from the knowledge base. As a result, the graph can be straightforwardly translated to a logical form query that is directly executable. In contrast, the query graph in (Reddy et al., 2014) is mapped from the CCG parse of the question, and needs further transformations before mapping to subgraphs of the target knowledge base to retrieve answers.

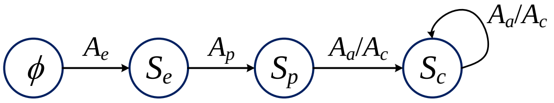

Figure 3: The legitimate actions to *grow* a query graph. See text for detail.

Semantically, our query graph is more related to simple λ-DCS (Berant et al., 2013; Liang, 2013), which is a syntactic simplification of λ-calculus when applied to graph databases. A query graph can be viewed as the tree-like graph pattern of a logical form in λ-DCS. For instance, the path from the answer node to an entity node can be described using a series of *join* operations in λ-DCS. Different paths of the tree graph are combined via the *intersection* operators.

3 Staged Query Graph Generation

We focus on generating query graphs with the following properties. First, the tree graph consists of one entity node as the root, referred as the *topic entity*. Second, there exists only one lambda variable x as the answer node, with a directed path from the root to it, and has zero or more existential variables in-between. We call this path the *core inferential chain* of the graph, as it describes the main relationship between the answer and topic entity. Variables can only occur in this chain, and the chain only has variable nodes except the root. Finally, zero or more entity or aggregation nodes can be attached to each variable node, including the answer node. These branches are the additional *constraints* that the answers need to satisfy. For example, in Fig. 2, FamilyGuy is the root and FamilyGuy $\rightarrow y \rightarrow x$ is the core inferential chain. The branch $y \rightarrow$ MegGriffin specifies the character and $y \rightarrow \arg\min$ constrains that the answer needs to be the earliest actor for this role.

Given a question, we formalize the query graph generation process as a search problem, with *staged* states and actions. Let $\mathcal{S} = \bigcup\{\phi, \mathcal{S}_e, \mathcal{S}_p, \mathcal{S}_c\}$ be the set of states, where each state could be an empty graph (ϕ), a single-node graph with the topic entity ($\mathcal{S}_e$), a core inferential chain ($\mathcal{S}_p$), or a more complex query graph with additional constraints ($\mathcal{S}_c$). Let $\mathcal{A} = \bigcup\{\mathcal{A}_e, \mathcal{A}_p, \mathcal{A}_c, \mathcal{A}_a\}$ be the set of actions. An action grows a given graph by adding some edges

[2] y should be grounded to a CVT entity in this case.

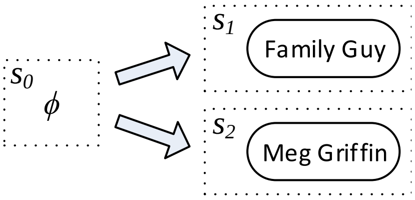

Figure 4: Two possible topic entity linking actions applied to an empty graph, for question "Who first voiced [Meg] on [Family Guy]?"

and nodes. In particular, $\mathcal{A}_e$ picks an entity node; $\mathcal{A}_p$ determines the core inferential chain; $\mathcal{A}_c$ and $\mathcal{A}_a$ add constraints and aggregation nodes, respectively. Given a state, the valid action set can be defined by the finite state diagram in Fig. 3. Notice that the order of possible actions is chosen for the convenience of implementation. In principle, we could choose a different order, such as matching the core inferential chain first and then resolving the topic entity linking. However, since we will consider multiple hypotheses during search, the order of the staged actions can simply be viewed as a different way to prune the search space or to bias the exploration order.

We define the reward function on the state space using a log-linear model. The reward basically estimates the likelihood that a query graph correctly parses the question. Search is done using the best-first strategy with a priority queue, which is formally defined in Appendix A. In the following subsections, we use a running example of finding the semantic parse of question q_{ex} = "Who first voiced Meg of Family Guy?" to describe the sequence of actions.

3.1 Linking Topic Entity

Starting from the initial state s_0, the valid actions are to create a single-node graph that corresponds to the topic entity found in the given question. For instance, possible topic entities in q_{ex} can either be `FamilyGuy` or `MegGriffin`, shown in Fig. 4.

We use an entity linking system that is designed for short and noisy text (Yang and Chang, 2015). For each entity e in the knowledge base, the system first prepares a surface-form lexicon that lists all possible ways that e can be mentioned in text. This lexicon is created using various data sources, such as names and aliases of the entities, the anchor text in Web documents and the Wikipedia redirect table. Given a question, it considers all the consecutive word sequences that have occurred in the lexicon as possible mentions, paired with their possible entities. Each pair is then scored by a statistical model based on its frequency counts in the surface-form lexicon. To tolerate potential mistakes of the entity linking system, as well as exploring more possible query graphs, up to 10 top-ranked entities are considered as the topic entity. The linking score will also be used as a feature for the reward function.

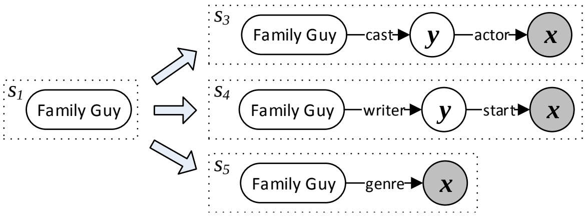

Figure 5: Candidate core inferential chains start from the entity `FamilyGuy`.

3.2 Identifying Core Inferential Chain

Given a state s that corresponds to a single-node graph with the topic entity e, valid actions to extend this graph is to identify the *core inferential chain*; namely, the relationship between the topic entity and the answer. For example, Fig. 5 shows three possible chains that expand the single-node graph in s_1. Because the topic entity e is given, we only need to explore legitimate predicate sequences that can start from e. Specifically, to restrict the search space, we explore all paths of length 2 when the middle existential variable can be grounded to a CVT node and paths of length 1 if not. We also consider longer predicate sequences if the combinations are observed in training data[3].

Analogous to the entity linking problem, where the goal is to find the mapping of mentions to entities in $\mathcal{K}$, identifying the core inferential chain is to map the natural utterance of the question to the correct predicate sequence. For question "*Who* first voiced Meg on [Family Guy]?" we need to measure the likelihood that each of the sequences in {`cast-actor`, `writer-start`, `genre`} correctly captures the relationship between *Family Guy* and *Who*. We reduce this problem to measuring semantic similarity using neural networks.

[3] Decomposing relations in the utterance can be done using decoding methods (e.g., (Bao et al., 2014)). However, similar to ontology mismatch, the relation in text may not have a corresponding single predicate, such as *grandparent* needs to be mapped to `parent-parent` in Freebase.

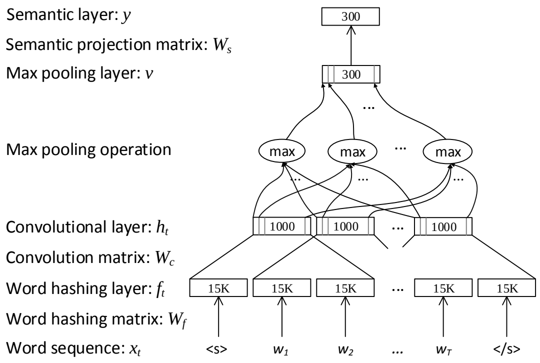

Figure 6: The architecture of the convolutional neural networks (CNN) used in this work. The CNN model maps a variable-length word sequence (e.g., a pattern or predicate sequence) to a low-dimensional vector in a latent semantic space. See text for the description of each layer.

3.2.1 Deep Convolutional Neural Networks

To handle the huge variety of the semantically equivalent ways of stating the same question, as well as the mismatch of the natural language utterances and predicates in the knowledge base, we propose using Siamese neural networks (Bromley et al., 1993) for identifying the core inferential chain. For instance, one of our constructions maps the question to a *pattern* by replacing the entity mention with a generic symbol <e> and then compares it with a candidate chain, such as "who first voiced meg on <e>" vs. `cast-actor`. The model consists of two neural networks, one for the pattern and the other for the inferential chain. Both are mapped to k-dimensional vectors as the output of the networks. Their semantic similarity is then computed using some distance function, such as *cosine*. This continuous-space representation approach has been proposed recently for semantic parsing and question answering (Bordes et al., 2014a; Yih et al., 2014) and has shown better results compared to lexical matching approaches (e.g., word-alignment models). In this work, we adapt a convolutional neural network (CNN) framework (Shen et al., 2014b; Shen et al., 2014a; Gao et al., 2014) to this matching problem. The network architecture is illustrated in Fig. 6.

The CNN model first applies a word hashing technique (Huang et al., 2013) that breaks a word into a vector of letter-trigrams ($x_t \rightarrow f_t$ in Fig. 6). For example, the bag of letter-trigrams of the word "who" are #-w-h, w-h-o, h-o-# after adding the word boundary symbol #. Then, it uses a convolutional layer to project the letter-trigram vectors of words within a context window of 3 words to a local contextual feature vector ($f_t \rightarrow h_t$), followed by a max pooling layer that extracts the most salient local features to form a fixed-length global feature vector (v). The global feature vector is then fed to feed-forward neural network layers to output the final non-linear semantic features (y), as the vector representation of either the pattern or the inferential chain.

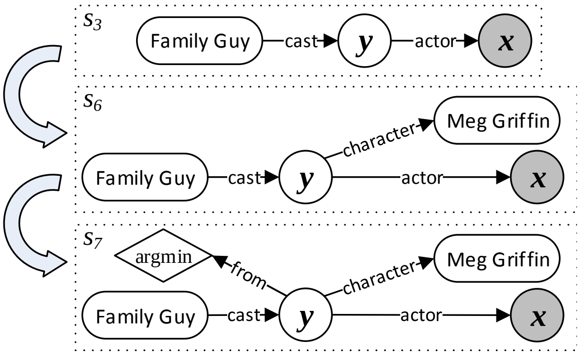

Figure 7: Extending an inferential chain with constraints and aggregation functions.

Training the model needs positive pairs, such as a pattern like "who first voiced meg on <e>" and an inferential chain like `cast-actor`. These pairs can be extracted from the full semantic parses when provided in the training data. If the correct semantic parses are latent and only the pairs of questions and answers are available, such as the case in the WEBQUESTIONS dataset, we can still hypothesize possible inferential chains by traversing the paths in the knowledge base that connect the topic entity and the answer. Sec. 4.1 will illustrate this data generation process in detail.

Our model has two advantages over the embedding approach (Bordes et al., 2014a). First, the word hashing layer helps control the dimensionality of the input space and can easily scale to large vocabulary. The letter-trigrams also capture some sub-word semantics (e.g., words with minor typos have almost identical letter-trigram vectors), which makes it especially suitable for questions from real-world users, such as those issued to a search engine. Second, it uses a deeper architecture with convolution and max-pooling layers, which has more representation power.

3.3 Augmenting Constraints & Aggregations

A graph with just the inferential chain forms the simplest legitimate query graph and can be executed against the knowledge base $\mathcal{K}$ to retrieve the answers; namely, all the entities that x can be grounded to. For instance, the graph in s_3 in Fig. 7 will retrieve all the actors who have been on FamilyGuy. Although this set of entities obviously contains the correct answer to the question (assuming the topic entity FamilyGuy is correct), it also includes incorrect entities that do not satisfy additional constraints implicitly or explicitly mentioned in the question.

To further restrict the set of answer entities, the graph with only the core inferential chain can be expanded by two types of actions: $\mathcal{A}_c$ and $\mathcal{A}_a$. $\mathcal{A}_c$ is the set of possible ways to attach an entity to a variable node, where the edge denotes one of the valid predicates that can link the variable to the entity. For instance, in Fig. 7, s_6 is created by attaching MegGriffin to y with the predicate character. This is equivalent to the last conjunctive term in the corresponding λ-expression: $\lambda x.\exists y.\texttt{cast}(\texttt{FamilyGuy}, y) \wedge \texttt{actor}(y, x) \wedge \texttt{character}(y, \texttt{MegGriffin})$. Sometimes, the constraints are described over the entire answer set through the aggregation function, such as the word “first” in our example question q_{ex}. This is handled similarly by actions $\mathcal{A}_a$, which attach an aggregation node on a variable node. For example, the $\arg\min$ node of s_7 in Fig. 7 chooses the grounding with the smallest from attribute of y.

The full possible constraint set can be derived by first issuing the core inferential chain as a query to the knowledge base to find the bindings of variables y’s and x, and then enumerating all neighboring nodes of these entities. This, however, often results in an unnecessarily large constraint pool. In this work, we employ simple rules to retain only the nodes that have some possibility to be legitimate constraints. For instance, a constraint node can be an entity that also appears in the question (detected by our entity linking component), or an aggregation constraint can only be added if certain keywords like “first” or “latest” occur in the question. The complete set of these rules can be found in Appendix B.

3.4 Learning the reward function

Given a state s, the reward function $\gamma(s)$ basically judges whether the query graph represented by s is the correct semantic parse of the input question q. We use a log-linear model to learn the reward function. Below we describe the features and the learning process.

3.4.1 Features

The features we designed essentially match specific portions of the graph to the question, and generally correspond to the staged actions described previously, including:

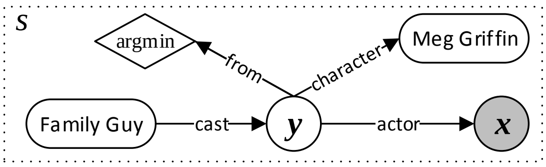
Topic Entity The score returned by the entity linking system is directly used as a feature.

Core Inferential Chain We use similarity scores of different CNN models described in Sec. 3.2.1 to measure the quality of the core inferential chain. **PatChain** compares the pattern (replacing the topic entity with an entity symbol) and the predicate sequence. **QuesEP** concatenates the canonical name of the topic entity and the predicate sequence, and compares it with the question. This feature conceptually tries to verify the entity linking suggestion. These two CNN models are learned using pairs of the question and the inferential chain of the parse in the training data. In addition to the *in-domain* similarity features, we also train a **ClueWeb** model using the Freebase annotation of ClueWeb corpora (Gabrilovich et al., 2013). For two entities in a sentence that can be linked by one or two predicates, we pair the sentences and predicates to form a parallel corpus to train the CNN model.

Constraints & Aggregations When a constraint node is present in the graph, we use some simple features to check whether there are words in the question that can be associated with the constraint entity or property. Examples of such features include whether a mention in the question can be linked to this entity, and the percentage of the words in the name of the constraint entity appear in the question. Similarly, we check the existence of some keywords in a pre-compiled list, such as “first”, “current” or “latest” as features for aggregation nodes such as $\arg\min$. The complete list of these simple word matching features can also be found in Appendix B.

Overall The number of the answer entities retrieved when issuing the query to the knowledge base and the number of nodes in the query graph are both included as features.

q = “Who first voiced Meg on Family Guy?”



(1) EntityLinkingScore(FamilyGuy, “Family Guy”) = 0.9
(2) PatChain(“who first voiced meg on <e>”, cast-actor) = 0.7
(3) QuesEP(q, “family guy cast-actor”) = 0.6
(4) ClueWeb(“who first voiced meg on <e>”, cast-actor) = 0.2
(5) ConstraintEntityWord(“Meg Griffin”, q) = 0.5
(6) ConstraintEntityInQ(“Meg Griffin”, q) = 1
(7) AggregationKeyword(argmin, q) = 1
(8) NumNodes(s) = 5
(9) NumAns(s) = 1

Figure 8: Active features of a query graph s. (1) is the entity linking score of the topic entity. (2)-(4) are different model scores of the core chain. (5) indicates 50% of the words in “Meg Griffin” appear in the question q. (6) is 1 when the mention “Meg” in q is correctly linked to `MegGriffin` by the entity linking component. (8) is the number of nodes in s. The knowledge base returns only 1 entity when issuing this query, so (9) is 1.

To illustrate our feature design, Fig. 8 presents the active features of an example query graph.

3.4.2 Learning

In principle, once the features are extracted, the model can be trained using any standard off-the-shelf learning algorithm. Instead of treating it as a binary classification problem, where only the correct query graphs are labeled as positive, we view it as a ranking problem. Suppose we have several candidate query graphs for each question[4]. Let g_a and g_b be the query graphs described in states s_a and s_b for the same question q, and the entity sets A_a and A_b be those retrieved by executing g_a and g_b, respectively. Suppose that A is the labeled answers to q. We first compute the precision, recall and F_1 score of A_a and A_b, compared with the gold answer set A. We then rank s_a and s_b by their F_1 scores[5]. The intuition behind is that even if a query is not completely correct, it is still preferred than some other totally incorrect queries. In this work, we use a one-layer neural network model based on lambda-rank (Burges, 2010) for training the ranker.

4 Experiments

We first introduce the dataset and evaluation metric, followed by the main experimental results and some analysis.

4.1 Data & evaluation metric

We use the WEBQUESTIONS dataset (Berant et al., 2013), which consists of 5,810 question/answer pairs. These questions were collected using Google Suggest API and the answers were obtained from Freebase with the help of Amazon MTurk. The questions are split into training and testing sets, which contain 3,778 questions (65%) and 2,032 questions (35%), respectively. This dataset has several unique properties that make it appealing and was used in several recent papers on semantic parsing and question answering. For instance, although the questions are not directly sampled from search query logs, the selection process was still biased to commonly asked questions on a search engine. The distribution of this question set is thus closer to the “real” information need of search users than that of a small number of human editors. The system performance is basically measured by the ratio of questions that are answered correctly. Because there can be more than one answer to a question, *precision*, *recall* and F_1 are computed based on the system output for each individual question. The average F_1 score is reported as the main evaluation metric[6].

Because this dataset contains only question and answer pairs, we use essentially the same search procedure to *simulate* the semantic parses for training the CNN models and the overall reward function. Candidate topic entities are first generated using the same entity linking system for each question in the training data. Paths on the Freebase knowledge graph that connect a candidate entity to at least one answer entity are identified as the core inferential chains[7]. If an inferential-chain query returns more entities than the correct answers, we explore adding constraint and aggregation nodes, until the entities retrieved by the query graph are identical to the labeled answers, or the F_1 score cannot be increased further. Negative examples are sampled from of the incorrect candidate graphs generated during the search process.

[4] We will discuss how to create these candidate query graphs from question/answer pairs in Sec. 4.1.

[5] We use F_1 partially because it is the evaluation metric used in the experiments.

[6] We used the *official* evaluation script from `http://www-nlp.stanford.edu/software/sempre/`.

[7] We restrict the path length to 2. In principle, parses of shorter chains can be used to train the initial reward function, for exploring longer paths using the same search procedure.

Method	Prec.	Rec.	F_1
(Berant et al., 2013)	48.0	41.3	35.7
(Bordes et al., 2014b)	-	-	29.7
(Yao and Van Durme, 2014)	-	-	33.0
(Berant and Liang, 2014)	40.5	46.6	39.9
(Bao et al., 2014)	-	-	37.5
(Bordes et al., 2014a)	-	-	39.2
(Yang et al., 2014)	-	-	41.3
(Wang et al., 2014)	-	-	45.3
Our approach – STAGG	52.8	60.7	**52.5**

Table 1: The results of our approach compared to existing work. The numbers of other systems are either from the original papers or derived from the evaluation script, when the output is available.

In the end, we produce 17,277 query graphs with none-zero F_1 scores from the training set questions and about 1.7M completely incorrect ones.

For training the CNN models to identify the core inferential chain (Sec. 3.2.1), we only use 4,058 chain-only query graphs that achieve $\mathrm{F}_1 = 0.5$ to form the parallel question and predicate sequence pairs. The hyper-parameters in CNN, such as the learning rate and the numbers of hidden nodes at the convolutional and semantic layers were chosen via cross-validation. We reserved 684 pairs of patterns and inference-chains from the whole training examples as the held-out set, and the rest as the initial training set. The optimal hyper-parameters were determined by the performance of models trained on the initial training set when applied to the held-out data. We then fixed the hyper-parameters and retrained the CNN models using the whole training set. The performance of CNN is insensitive to the hyper-parameters as long as they are in a reasonable range (e.g., 1000 ± 200 nodes in the convolutional layer, 300 ± 100 nodes in the semantic layer, and learning rate $0.05 \sim 0.005$) and the training process often converges after ~ 800 epochs.

When training the reward function, we created up to 4,000 examples for each question that contain all the positive query graphs and randomly selected negative examples. The model is trained as a ranker, where example query graphs are ranked by their F_1 scores.

4.2 Results

Tab. 1 shows the results of our system, STAGG (Staged query graph generation), compared to existing work[8]. As can be seen from the table, our system outperforms the previous state-of-the-art method by a large margin – 7.2% absolute gain.

Method	#Entities	# Covered Ques.	# Labeled Ent.
Freebase API	19,485	3,734 (98.8%)	3,069 (81.2%)
Ours	9,147	3,770 (99.8%)	3,318 (87.8%)

Table 2: Statistics of entity linking results on training set questions. Both methods cover roughly the same number of questions, but Freebase API suggests twice the number of entities output by our entity linking system and covers fewer topic entities labeled in the original data.

Given the staged design of our approach, it is thus interesting to examine the contributions of each component. Because topic entity linking is the very first stage, the quality of the entities found in the questions, both in precision and recall, affects the final results significantly. To get some insight about how our topic entity linking component performs, we also experimented with applying Freebase Search API to suggest entities for possible mentions in a question. As can be observed in Tab. 2, to cover most of the training questions, we only need half of the number of suggestions when using our entity linking component, compared to Freebase API. Moreover, they also cover more entities that were selected as the topic entities in the original dataset. Starting from those 9,147 entities output by our component, answers of 3,453 questions (91.4%) can be found in their neighboring nodes. When replacing our entity linking component with the results from Freebase API, we also observed a significant performance degradation. The overall system performance drops from 52.5% to 48.4% in F_1 (Prec = 49.8%, Rec = 55.7%), which is 4.1 points lower.

Next we test the system performance when the query graph has just the core inferential chain. Tab. 3 summarizes the results. When only the PatChain CNN model is used, the performance is already very strong, outperforming all existing work. Adding the other CNN models boosts the performance further, reaching 51.8% and is only slightly lower than the full system performance. This may be due to two reasons. First, the questions from search engine users are often short and a large portion of them simply ask about properties of an entity. Examining the query graphs generated for training set questions, we found that 1,888

[8] We do not include results of (Reddy et al., 2014) because they used only a subset of 570 test questions, which are not directly comparable to results from other work. On these 570 questions, our system achieves 67.0% in F_1.

Method	Prec.	Rec.	F_1
PatChain	48.8	59.3	49.6
+QuesEP	50.7	60.6	50.9
+ClueWeb	51.3	62.6	51.8

Table 3: The system results when only the inferential-chain query graphs are generated. We started with the PatChain CNN model and then added QuesEP and ClueWeb sequentially. See Sec. 3.4 for the description of these models.

(50.0%) can be answered exactly (i.e., $F_1 = 1$) using a chain-only query graph. Second, even if the correct parse requires more constraints, the less constrained graph still gets a partial score, as its results cover the correct answers.

4.3 Error Analysis

Although our approach substantially outperforms existing methods, the room for improvement seems big. After all, the accuracy for the intended application, question answering, is still low and only slightly above 50%. We randomly sampled 100 questions that our system did not generate the completely correct query graphs, and categorized the errors. About one third of errors are in fact due to label issues and are not real mistakes. This includes label error (2%), incomplete labels (17%, e.g., only one song is labeled as the answer to "What songs did Bob Dylan write?") and acceptable answers (15%, e.g., "Time in China" vs. "UTC+8"). 8% of the errors are due to incorrect entity linking; however, sometimes the mention is inherently ambiguous (e.g., AFL in "Who founded the AFL?" could mean either "American Football League" or "American Federation of Labor"). 35% of the errors are because of the incorrect inferential chains; 23% are due to incorrect or missing constraints.

5 Related Work and Discussion

Several semantic parsing methods use a domain-independent meaning representation derived from the combinatory categorial grammar (CCG) parses (e.g., (Cai and Yates, 2013; Kwiatkowski et al., 2013; Reddy et al., 2014)). In contrast, our query graph design matches closely the graph knowledge base. Although not fully demonstrated in this paper, the query graph can in fact be fairly expressive. For instance, negations can be handled by adding tags to the constraint nodes indicating that certain conditions *cannot* be satisfied. Our graph generation method is inspired by (Yao and Van Durme, 2014; Bao et al., 2014). Unlike traditional semantic parsing approaches, it uses the knowledge base to help prune the search space when forming the parse. Similar ideas have also been explored in (Poon, 2013).

Empirically, our results suggest that it is crucial to identify the core inferential chain, which matches the relationship between the topic entity in the question and the answer. Our CNN models can be analogous to the embedding approaches (Bordes et al., 2014a; Yang et al., 2014), but are more sophisticated. By allowing parameter sharing among different question-pattern and KB predicate pairs, the matching score of a rare or even unseen pair in the training data can still be predicted precisely. This is due to the fact that the prediction is based on the shared model parameters (i.e., projection matrices) that are estimated using all training pairs.

6 Conclusion

In this paper, we present a semantic parsing framework for question answering using a knowledge base. We define a *query graph* as the meaning representation that can be directly mapped to a logical form. Semantic parsing is reduced to query graph generation, formulated as a staged search problem. With the help of an advanced entity linking system and a deep convolutional neural network model that matches questions and predicate sequences, our system outperforms previous methods substantially on the WEBQUESTIONS dataset.

In the future, we would like to extend our query graph to represent more complicated questions, and explore more features and models for matching constraints and aggregation functions. Applying other structured-output prediction methods to graph generation will also be investigated.

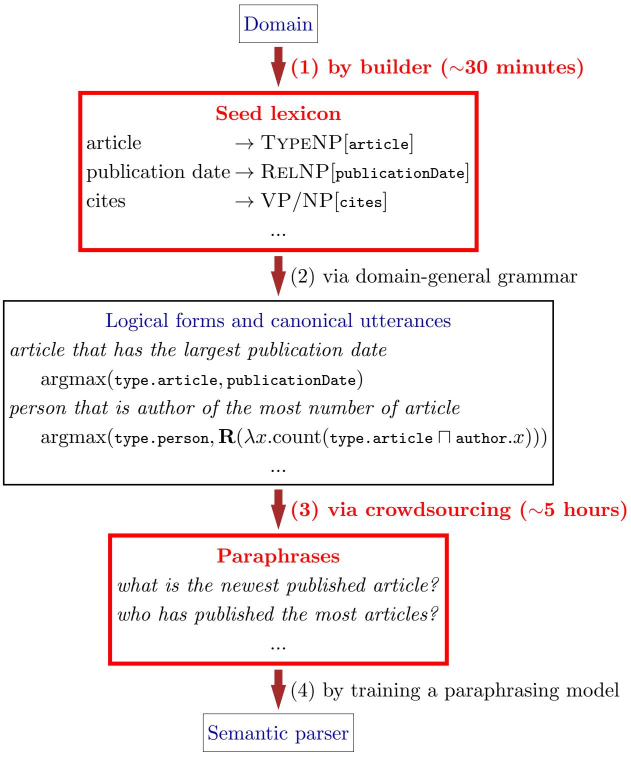
Abstract

How do we build a semantic parser in a new domain starting with zero training examples? We introduce a new methodology for this setting: First, we use a simple grammar to generate logical forms paired with canonical utterances. The logical forms are meant to cover the desired set of compositional operators, and the canonical utterances are meant to capture the meaning of the logical forms (although clumsily). We then use crowdsourcing to paraphrase these canonical utterances into natural utterances. The resulting data is used to train the semantic parser. We further study the role of compositionality in the resulting paraphrases. Finally, we test our methodology on seven domains and show that we can build an adequate semantic parser in just a few hours.

1 Introduction

By mapping natural language utterances to executable logical forms, semantic parsers have been useful for a variety of applications requiring precise language understanding (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011; Berant et al., 2013; Kwiatkowski et al., 2013; Artzi and Zettlemoyer, 2013; Kushman and Barzilay, 2013). Previous work has focused on how to train a semantic parser given input utterances, but suppose we wanted to build a semantic parser for a new domain—for example, a natural language interface into a publications database. Since no such interface exists, we do not even have a naturally occurring source of input utterances that we can annotate. So where do we start?

In this paper, we advocate a *functionality-driven process* for rapidly building a semantic parser in a new domain. At a high-level, we seek to minimize the amount of work needed for a new domain by factoring out the domain-general aspects (done by our framework) from the domain-specific ones (done by the builder of the semantic parser). We assume that the builder already has the desired functionality of the semantic parser in mind—e.g., the publications database is set up and the schema is fixed. Figure 1 depicts the functionality-driven process: First, the builder writes a seed lexicon specifying a canonical phrase (*"publication date"*) for



Domain
(1) by builder (~30 minutes)
Seed lexicon
article → TYPENP[article]
publication date → RELNP[publicationDate]
cites → VP/NP[cites]
...
(2) via domain-general grammar
Logical forms and canonical utterances
article that has the largest publication date
argmax(type.article, publicationDate)
person that is author of the most number of article
argmax(type.person, R(λx.count(type.article ⊓ author.x)))
...
(3) via crowdsourcing (~5 hours)
Paraphrases
what is the newest published article?
who has published the most articles?
...
(4) by training a paraphrasing model
Semantic parser

Figure 1: Functionality-driven process for building semantic parsers. The two red boxes are the domain-specific parts provided by the builder of the semantic parser, and the other two are generated by the framework.

[*] Both authors equally contributed to the paper.

each predicate (`publicationDate`). Second, our framework uses a *domain-general grammar*, along with the seed lexicon and the database, to automatically generate a few hundred *canonical utterances* paired with their logical forms (e.g., *"article that has the largest publication date"* and $\arg\max(\texttt{type.article}, \texttt{publicationDate})$). These utterances need not be the most elegant, but they should retain the semantics of the logical forms. Third, the builder leverages crowdsourcing to paraphrase each canonical utterance into a few *natural utterances* (e.g., *"what is the newest published article?"*). Finally, our framework uses this data to train a semantic parser.

Practical advantages. There are two main advantages of our approach: *completeness* and *ease of supervision*. Traditionally, training data is collected in a best-effort manner, which can result in an incomplete coverage of functionality. For example, the WebQuestions dataset (Berant et al., 2013) contains no questions with numeric answers, so any semantic parser trained on that dataset would lack that functionality. These biases are not codified, which results in an idiosyncratic and mysterious user experience, a major drawback of natural language interfaces (Rangel et al., 2014). In contrast, our compact grammar precisely specifies the logical functionality. We enforce completeness by generating canonical utterances that exercise every grammar rule.

In terms of supervision, state-of-the-art semantic parsers are trained from question-answer pairs (Kwiatkowski et al., 2013; Berant and Liang, 2014). Although this is a marked improvement in cost and scalability compared to annotated logical forms, it still requires non-trivial effort: the annotator must (i) understand the question and (ii) figure out the answer, which becomes even harder with compositional utterances. In contrast, our main source of supervision is paraphrases, which only requires (i), not (ii). Such data is thus cheaper and faster to obtain.

Linguistic reflections. The centerpiece of our framework is a domain-general grammar that connects logical forms with canonical utterances. This connection warrants further scrutiny, as the structural mismatch between logic and language is the chief source of difficulty in semantic parsing (Liang et al., 2011; Kwiatkowski et al., 2013; Berant and Liang, 2014).

There are two important questions here. First, is it possible to design a simple grammar that simultaneously generates both logical forms and canonical utterances so that the utterances are understandable by a human? In Section 3, we show how to choose appropriate canonical utterances to maximize alignment with the logical forms.

Second, our grammar can generate an infinite number of canonical utterances. How many do we need for adequate coverage? Certainly, single relations is insufficient: just knowing that *"publication date of X"* paraphrases to *"when X was published"* would offer insufficient information to generalize to *"articles that came after X"* mapping to *"article whose publication date is larger than publication date of X"*. We call this phenomena *sublexical compositionality*—when a short lexical unit (*"came after"*) maps onto a multi-predicate logical form. Our hypothesis is that the sublexical compositional units are small, so we only need to crowdsource a small number of canonical utterances to learn about most of the language variability in the given domain (Section 4).

We applied our functionality-driven process to seven domains, which were chosen to explore particular types of phenomena, such as spatial language, temporal language, and high-arity relations. This resulted in seven new semantic parsing datasets, totaling 12.6K examples. Our approach, which was not tuned on any one domain, was able to obtain an average accuracy of 59% over all domains. On the day of this paper submission, we created an eighth domain and trained a semantic parser overnight.

2 Approach Overview

In our functionality-driven process (Figure 1), there are two parties: the *builder*, who provides domain-specific information, and the *framework*, which provides domain-general information. We assume that the builder has a fixed database w, represented as a set of triples (e_1, p, e_2), where e_1 and e_2 are entities (e.g., `article1`, `2015`) and p is a property (e.g., `publicationDate`). The database w can be queried using lambda DCS logical forms, described further in Section 2.1.

The builder supplies a seed lexicon L, which contains for each database property p (e.g., `publicationDate`) a lexical entry of the form $\langle t \rightarrow s[p] \rangle$, where t is a natural language phrase (e.g., *"publication date"*) and s is a syntactic category (e.g., RELNP). In addition, L contains two typical entities for each semantic type in the database (e.g., $\langle \textit{alice} \rightarrow \text{NP}[\texttt{alice}]\rangle$ for the type `person`). The purpose of L is to simply connect each predicate with *some* representation in natural language.

The framework supplies a grammar G, which specifies the modes of composition, both on logical forms and canonical utterances. Formally, G is a set of rules of the form $\langle \alpha_1 \dots \alpha_n \rightarrow s[z]\rangle$, where $\alpha_1 \dots \alpha_n$ is a sequence of tokens or categories, s is a syntactic category and z is the logical form constructed. For example, one rule in G is $\langle \text{RELNP}[r]\ \textit{of}\ \text{NP}[x] \rightarrow \text{NP}[\mathbf{R}(r).x]\rangle$, which constructs z by reversing the binary predicate r and joining it with a the unary predicate x. We use the rules $G \cup L$ to generate a set of (z, c) pairs, where z is a logical form (e.g., $\mathbf{R}(\texttt{publicationDate}).\texttt{article1}$), and c is the corresponding canonical utterance (e.g., *"publication date of article 1"*). The set of (z, c) is denoted by GEN$(G \cup L)$. See Section 3 for details.

Next, the builder (backed by crowdsourcing) paraphrases each canonical utterance c output above into a set of natural utterances $\mathbf{P}(c)$ (e.g., *"when was article 1 published?"*). This defines a set of training examples $\mathcal{D} = \{(x, c, z)\}$, for each $(z, c) \in \text{GEN}(G \cup L)$ and $x \in \mathbf{P}(c)$. The crowdsourcing setup is detailed in Section 5.

Finally, the framework trains a semantic parser on $\mathcal{D}$. Our semantic parser is a log-linear distribution $p_\theta(z, c \mid x, w)$ over logical forms and canonical utterances specified by the grammar G. Note that the grammar G will in general not parse x, so the semantic parsing model will be based on paraphrasing, in the spirit of Berant and Liang (2014).

To summarize, (1) the builder produces a seed lexicon L; (2) the framework produces logical forms and canonical utterances $\text{GEN}(G \cup L) = \{(z, c)\}$; (3) the builder (via crowdsourcing) uses $\mathbf{P}(\cdot)$ to produce a dataset $\mathcal{D} = \{(x, c, z)\}$; and (4) the framework uses $\mathcal{D}$ to train a semantic parser $p_\theta(z, c \mid x, w)$.

2.1 Lambda DCS

Our logical forms are represented in lambda DCS, a logical language where composition operates on sets rather than truth values. Here we give a brief description; see Liang (2013) for details.

Every logical form z in this paper is either a *unary* (denoting a set of entities) or a *binary* (denoting a set of entity-pairs). In the base case, each entity e (e.g., `2015`) is a unary denoting the singleton set: $[\![e]\!]_w = \{e\}$; and each property p (e.g., `publicationDate`) is a binary denoting all entity-pairs (e_1, e_2) that satisfy the property p. Unaries and binaries can be composed: Given a binary b and unary u, the join $b.u$ denotes all entities e_1 for which there exists an $e_2 \in [\![u]\!]_w$ with $(e_1, e_2) \in [\![b]\!]_w$. For example, `publicationDate.2015` denote entities published in 2015.

The intersection $u_1 \sqcap u_2$, union $u_1 \sqcup u_2$, complement $\neg u$ denote the corresponding set operations on the denotations. We let $\mathbf{R}(b)$ denote the reversal of b: $(e_1, e_2) \in [\![b]\!]_w$ iff $(e_2, e_1) \in [\![\mathbf{R}(b)]\!]_w$. This allows us to define $\mathbf{R}(\texttt{publicationDate}).\texttt{article1}$ as the publication date of article 1. We also include aggregation operations (count(u), sum(u) and average(u, b)), and superlatives (argmax(u, b)).

Finally, we can construct binaries using lambda abstraction: $\lambda x.u$ denotes a set of (e_1, e_2) where $e_1 \in [\![u[x/e_2]]\!]_w$ and $u[x/e_2]$ is the logical form where free occurrences of x are replaced with e_2. For example, $\mathbf{R}(\lambda x.\text{count}(\mathbf{R}(\texttt{cites}).x))$ denotes the set of entities (e_1, e_2), where e_2 is the number of entities that e_1 cites.

3 Generation and canonical compositionality

Our functionality-driven process hinges on having a domain-general grammar that can connect logical forms with canonical utterances compositionally. The motivation is that while it is hard to write a grammar that parses *all* utterances, it is possible to write one that generates *one* canonical utterance for each logical form. To make this explicit:

Assumption 1 (Canonical compositionality) *Using a small grammar, all logical forms expressible in natural language can be realized compositionally based on the logical form.*

Grammar. We target database querying applications, where the parser needs to handle superlatives, comparatives, negation, and coordination. We define a simple grammar that captures these forms of compositionality using canonical utterances in a domain-general way. Figure 2 illustrates a derivation produced by the grammar.

The seed lexicon specified by the builder contains canonical utterances for types, entities, and properties. All types (e.g., `person`) have the syntactic category TYPENP, and all entities (e.g.,

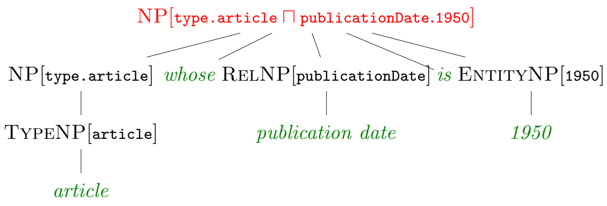

Figure 2: Deriving a logical form z (red) and a canonical utterance c (green) from the grammar G. Each node contains a syntactic category and a logical form, which is generated by applying a rule. Nodes with only leaves as children are produced using the seed lexicon; all other nodes are produced by rules in the domain-general grammar.

alice) are ENTITYNP's. Unary predicates are realized as verb phrases VP (e.g., *"has a private bath"*). The builder can choose to represent binaries as either relational noun phrases (RELNP) or generalized transitive verbs (VP/NP). RELNP's are usually used to describe functional properties (e.g., *"publication date"*), especially numerical properties. VP/NP's include transitive verbs (*"cites"*) but also longer phrases with the same syntactic interface (*"is the president of"*). Table 1 shows the seed lexicon for the SOCIAL domain.

From the seed lexicon, the domain-general grammar (Table 2) constructs noun phrases (NP), verbs phrases (VP), and complementizer phrase (CP), all of which denote unary logical forms. Broadly speaking, the rules **(R1)**–**(R4)**, **(C1)**–**(C4)** take a binary and a noun phrase, and compose them (optionally via comparatives, counting, and negation) to produce a complementizer phrase CP representing a unary (e.g., *"that cites article 1"* or *"that cites more than three article"*). **(G3)** combines these CP's with an NP (e.g., *"article"*). In addition, **(S0)**–**(S4)** handle superlatives (we include argmin in addition to argmax), which take an NP and return the extremum-attaining subset of its denotation. Finally, we support transformations such as join **(T1)** and disjunction **(T4)**, as well as aggregation **(A1)**–**(A2)**.

Rendering utterances for multi-arity predicates was a major challenge. The predicate instances are typically reified in a graph database, akin to a neo-Davidsonian treatment of events: There is an abstract entity with binary predicates relating it to its arguments. For example, in the SOCIAL domain, Alice's education can be represented in the database as five triples:

birthdate	→ RELNP[birthdate]
person|university|field	→ TYPENP[person| · · ·]
company|job title	→ TYPENP[company| · · ·]
student|university|field of study	→ RELNP[student| · · ·]
employee|employer|job title	→ RELNP[employee| · · ·]
start date|end date	→ RELNP[startDate| · · ·]
is friends with	→ VP/NP[friends| · · ·]

Table 1: The seed lexicon for the SOCIAL domain, which specifies for each predicate (e.g., birthdate) a phrase (e.g., *"birthdate"*) that realizes that predicate and its syntactic category (e.g., RELNP).

(e17, student, alice), (e17, university, ucla),
(e17, fieldOfStudy, music),
(e17, startDate, 2005), (e17, endDate, 2009).

All five properties here are represented as RELNP's, with the first one designated as the subject (RELNP$_0$). We support two ways of querying multi-arity relations: *"student whose university is ucla"* **(T2)** and *"university of student Alice whose start date is 2005"* **(T3)**.

Generating directly from the grammar in Table 2 would result in many uninterpretable canonical utterances. Thus, we perform type checking on the logical forms to rule out *"article that cites 2004"*, and limit the amount of recursion, which keeps the canonical utterances understandable.

Still, the utterances generated by our grammar are not perfectly grammatical; we do not use determiners and make all nouns singular. Nonetheless, AMT workers found most canonical utterances understandable (see Table 3 and Section 5 for details on crowdsourcing). One tip for the builder is to keep the RELNP's and VP/NP's as context-independent as possible; e.g., using *"publication date"* instead of *"date"*. In cases where more context is required, we use parenthetical remarks (e.g., *"number of assists (over a season)"* → RELNP[. . .]) to pack more context into the confines of the part-of-speech.

Limitations. While our domain-general grammar covers most of the common logical forms in a database querying application, there are several phenomena which are out of scope, notably nested quantification (e.g., *"show me each author's most cited work"*) and anaphora (e.g., *"author who cites herself at least twice"*). Handling these would require a more radical change to the grammar, but is still within scope.

Table 2: The domain-general grammar which is combined with the seed lexicon to generate logical forms and canonical utterances that cover the supported logical functionality.

4 Paraphrasing and bounded non-compositionality

While the canonical utterance c is generated compositionally along with the logical form z, natural paraphrases $x \in \mathbf{P}(c)$ generally deviate from this compositional structure. For example, the canonical utterance *"*NP*[number of* NP*[article* CP*[whose publication date is larger than* NP*[publication date of article 1]]]]"* might get paraphrased to *"How many articles were **published after** article 1?"*. Here, *"published after"* non-compositionally straddles the inner NP, intuitively responsible for both instances of *"publication date"*. But how non-compositional can paraphrases be? Our framework rests on the assumption that the answer is "not very":

Assumption 2 (Bounded non-compositionality) *Natural utterances for expressing complex logical forms are compositional with respect to fragments of bounded size.*

In the above example, note that while *"published after"* is non-compositional with respect to the grammar, the rewriting of *"number of"* to *"how many"* is compositional. The upshot of Assumption 2 is that we only need to ask for paraphrases of canonical utterances generated by the grammar up to some small depth to learn about all the non-compositional uses of language, and still be able generalize (compositionally) beyond that.

We now explore the nature of the possible paraphrases. Broadly speaking, most paraphrases involve some sort of *compression*, where the clunky but faithful canonical utterance is smoothed out into graceful prose.

Alternations of single rules. The most basic paraphrase happens at the single phrase level with synonyms (*"block"* to *"brick"*), which preserve the part-of-speech. However, many of our properties are specified using relational noun phrases, which are more naturally realized using prepositions (*"meeting whose attendee is alice ⇒ meeting **with** alice"*) or verbs (*"author of article 1 ⇒ who **wrote** article 1"*). If the RELNP is complex, then the argument can become embedded: *"player whose number of points is 15 ⇒ player who **scored** 15 **points**"*. Superlative and comparative constructions reveal other RELNP-dependent words: *"article that has the largest publication date ⇒ **newest** article"*. When the value of the relation has enough context, then the relation is elided completely: *"housing unit whose housing type is apartment ⇒* ***apartment****"*.

Multi-arity predicates are compressed into a single frame: *"university of student alice whose field of study is music"* becomes *"At which university did Alice* ***study*** *music?"*, where the semantic roles of the verb *"study"* carry the burden of expressing the multiple relations: `student`, `university`, and `fieldOfStudy`. With a different combination of arguments, the natural verb would change: *"Which university did Alice* ***attend****?"*

Sublexical compositionality. The most interesting paraphrases occur across multiple rules, a phenomenon which we called *sublexical compositionality*. The idea is that common, multi-part concepts are compressed to single words or simpler constructions. The simplest compression is a lexical one: *"parent of alice whose gender is female ⇒* ***mother*** *of alice"*. Compression often occurs when we have the same predicate chained twice in a join: *"person that is author of paper whose author is X ⇒ co-author of X"* or *"person whose birthdate is birthdate of X ⇒ person born on the* ***same*** *day as X"*. When two CP's combined via coordination have some similarity, then the coordination can be pushed down (*"meeting whose start time is 3pm and whose end time is 5pm ⇒ meetings between 3pm and 5pm"*) and sometimes even generalized (*"that allows cats and that allows dogs ⇒ that allows pets"*). Sometimes, compression happens due to metonymy, where people stand in for their papers: *"author of article that article whose author is X cites ⇒ who does X cite"*.

5 Crowdsourcing

We tackled seven domains covering various linguistic phenomena. Table 3 lists the domains, their principal phenomena, statistics about their predicates and dataset, and an example from the dataset.

We use Amazon Mechanical Turk (AMT) to paraphrase the canonical utterances generated by the domain-general grammar. In each AMT task, a worker is presented with four canonical utterances and is asked to reformulate them in natural language or state that they are incomprehensible. Each canonical utterance was presented to 10 workers. Over all domains, we collected 18,032 responses. The average time for paraphrasing one utterance was 28 seconds. Paraphrases that share the same canonical utterance are collapsed, while identical paraphrases that have distinct canonical utterances are deleted. This produced a total of 12,602 examples over all domains.

To estimate the level of noise in the data, we manually judged the correctness of 20 examples in each domain, and found that 17% of the utterances were inaccurate. There are two main reasons: lexical ambiguity on our part (*"player that has the least number of team ⇒ player with the lowest jersey number"*), and failure on the worker's part (*"restaurant whose star rating is 3 stars ⇒ hotel which has a 3 star rating"*).

6 Model and Learning

Our semantic parsing model defines a distribution over logical forms given by the domain-general grammar G and additional rules triggered by the input utterance x. Specifically, given an utterance x, we detect numbers, dates, and perform string matching with database entities to recognize named entities. This results in a set of rules $\mathbf{T}(x)$. For example, if x is *"article published in 2015 that cites article 1"*, then $\mathbf{T}(x)$ contains $\langle$*2015* $\rightarrow$ NP[2015]$\rangle$ and $\langle$*article 1* $\rightarrow$ NP[`article1`]$\rangle$. Let L_x be the rules in the seed lexicon L where the entity rules (e.g., $\langle$*alice* $\rightarrow$ NP[`alice`]$\rangle$) are replaced by $\mathbf{T}(x)$.

Our semantic parsing model defines a log-linear distribution over candidate pairs $(z, c) \in$ GEN$(G \cup L_x)$:

$$p_\theta(z, c \mid x, w) \propto \exp(\phi(c, z, x, w)^\top \theta), \qquad (1)$$

where $\phi(z, c, x, w) \in \mathbb{R}^d$ is a feature vector and $\theta \in \mathbb{R}^d$ is a parameter vector.

To generate candidate logical forms, we use a simple beam search: For each search state, which includes the syntactic category s (e.g., NP) and the depth of the logical form, we generate at most $K = 20$ candidates by applying the rules in Table 2. In practice, the lexical rules $\mathbf{T}(x)$ are applied first, and composition is performed, but not constrained to the utterance. For example, the utterance *"article"* would generate the logical form count(`type.article`). Instead, soft paraphrasing features are used to guide the search. This rather unorthodox approach to semantic parsing can be seen as a generalization of Berant and Liang (2014) and is explained in more detail in Pasupat and Liang (2015).

Training. We train our model by maximizing the regularized log-likelihood $\mathcal{O}(\theta) =$

Domain	# pred.	# ex.	Phenomena	Example
CALENDAR	22	837	temporal language	x: *"Show me meetings after the weekly standup day"* c: *"meeting whose date is at least date of weekly standup"* z: $\texttt{type.meeting} \sqcap \texttt{date.} > \mathbf{R}(\texttt{date}).\texttt{weeklyStandup}$
BLOCKS	19	1995	spatial language	x: *"Select the brick that is to the furthest left."* c: *"block that the most number of block is right of"* z: $\texttt{argmax}(\texttt{type.block}, \mathbf{R}(\lambda x.\texttt{count}(\mathbf{R}(\texttt{right}).x)))$
HOUSING	24	941	measurement units	x: *"Housing that is 800 square feet or bigger?"* c: *"housing unit whose size is at least 800 square feet"* z: $\texttt{type.housingUnit} \sqcap \texttt{area.} > \texttt{.800}$
RESTAURANTS	32	1657	long unary relations	x: *"What restaurant can you eat lunch outside at?"* c: *"restaurant that has outdoor seating and that serves lunch"* z: $\texttt{type.restaurant} \sqcap \texttt{hasOutdoorSeating} \sqcap \texttt{serveslunch}$
PUBLICATIONS	15	801	sublexical compositionality	x: *"Who has co-authored articles with Efron?"* c: *"person that is author of article whose author is efron"* z: $\texttt{type.person} \sqcap \mathbf{R}(\texttt{author}).(\texttt{type.article} \sqcap \texttt{author.efron})$
SOCIAL	45	4419	multi-arity relations	x: *"When did alice start attending brown university?"* c: *"start date of student alice whose university is brown university"* z: $\mathbf{R}(\texttt{date}).(\texttt{student.Alice} \sqcap \texttt{university.Brown})$
BASKETBALL	24	1952	parentheticals	x: *"How many fouls were played by Kobe Bryant in 2004?"* c: *"number of fouls (over a season) of player kobe bryant whose season is 2004"* z: $\text{count}(\mathbf{R}(\texttt{fouls}).(\texttt{player.KobeBryant} \sqcap \texttt{season.2004})$

Table 3: We experimented on seven domains, covering a variety of phenomena. For each domain, we show the number of predicates, number of examples, and a (c, z) generated by our framework along with a paraphrased utterance x.

Category	Description
Basic	#words and bigram matches in (x, c) #words and bigram PPDB matches in (x, c) #unmatched words in x #unmatched words in c size of denotation of z, $(\lvert \llbracket z \rrbracket_w \rvert)$ pos$(x_{0:0})$ conjoined with type$(\llbracket z \rrbracket_w)$ #nodes in tree generating z
Lexical	$\forall(i, j) \in \mathcal{A}.\ (x_{i:i}, c_{j:j})$ $\forall(i, j) \in \mathcal{A}.\ (x_{i:i}, c_{j:j+1})$ $\forall(i, j) \in \mathcal{A}.\ (x_{i:i}, c_{j-1:j})$ $\forall(i, j), (i+1, j+1) \in \mathcal{A}.\ (x_{i:i+1}, c_{j:j+1})$ all unaligned words in x and c $(x_{i:j}, c_{i':j'})$ if in phrase table

Table 4: Features for the paraphrasing model. pos$(x_{i:i})$ is the POS tag; type$(\llbracket z \rrbracket_w)$ is a coarse semantic type for the denotation (an entity or a number). $\mathcal{A}$ is a maximum weight alignment between x and c.

$\sum_{(x,c,z)\in\mathcal{D}} \log p_\theta(z, c \mid x, w) - \lambda\|\theta\|_1$. To optimize, we use AdaGrad (Duchi et al., 2010).

Features Table 4 describes the features. Our basic features mainly match words and bigrams in x and c, if they share a lemma or are aligned in the PPDB resource (Ganitkevitch et al., 2013). We count the number of exact matches, PPDB matches, and unmatched words.

To obtain lexical features, we run the Berkeley Aligner (Liang et al., 2006) on the training set and compute conditional probabilities of aligning one word type to another. Based on these probabilities we compute a maximum weight alignment $\mathcal{A}$ between words in x and c. We define features over $\mathcal{A}$ (see Table 4). We also use the word alignments to construct a phrase table by applying the consistent phrase pair heuristic (Och and Ney, 2004). We define an indicator feature for every phrase pair of x and c that appear in the phrase table. Examples from the PUBLICATIONS domain include *fewest–least number* and *by–whose author is*. Note that we do not build a hard lexicon but only use $\mathcal{A}$ and the phrase table to define features, allowing the model to learn useful paraphrases during training. Finally, we define standard features on logical forms and denotations (Berant et al., 2013).

7 Experimental Evaluation

We evaluated our functionality-driven process on the seven domains described in Section 5 and one new domain we describe in Section 7.3. For each domain, we held out a random 20% of the examples as the test set, and performed development on the remaining 80%, further splitting it to a training and development set (80%/20%). We created a database for each domain by randomly generating facts using entities and properties in the domain (with type-checking). We evaluated using accuracy, which is the fraction of examples that yield the correct denotation.

7.1 Domain-specific linguistic variability

Our functionality-driven process is predicated on the fact that each domain exhibits domain-specific

Method	Calendar	Blocks	Housing	Restaurants	Publications	Recipes	Social	Basketball	Avg.
Full	**74.4**	**41.9**	54.0	**75.9**	**59.0**	**70.8**	**48.2**	**46.3**	**58.8**
NoLex	25.0	35.3	51.9	64.6	50.6	32.3	15.3	19.4	36.8
NoPPDB	73.2	41.4	**54.5**	73.8	56.5	68.1	43.6	44.5	56.9
Baseline	17.3	27.7	45.9	61.3	46.7	26.3	9.7	15.6	31.3

Table 5: Test set results on all domains and baselines.

phenomena. To corroborate this, we compare our full system to NoLex, a baseline that omits all lexical features (Table 4), but uses PPDB as a domain-general paraphrasing component. We perform the complementary experiment and compare to NoPPDB, a baseline that omits PPDB match features. We also run Baseline, where we omit both lexical and PPDB features.

Table 5 presents the results of this experiment. Overall, our framework obtains an average accuracy of 59% across all eight domains. The performance of NoLex is dramatically lower than Full, indicating that it is important to learn domain-specific paraphrases using lexical features. The accuracy of NoPPDB is only slightly lower than Full, showing that most of the required paraphrases can be learned during training. As expected, removing both lexical and PPDB features results in poor performance (Baseline).

Analysis. We performed error analysis on 10 errors in each domain. Almost 70% of the errors are due to problems in the paraphrasing model, where the canonical utterance has extra material, is missing some content, or results in an incorrect paraphrase. For example, *"restaurants that have waiters and you can sit outside"* is paraphrased to *"restaurant that has waiter service and that takes reservations"*. Another 12.5% result from reordering issues, e.g, we paraphrase *"What venue has fewer than two articles"* to *"article that has less than two venue"*. Inaccurate paraphrases provided by AMT workers account for the rest of the errors.

7.2 Bounded non-compositionality

We hypothesized that we need to obtain paraphrases of canonical utterances corresponding to logical forms of only small depth. We ran the following experiment in the Calendar domain to test this claim. First, we define by NP_0, NP_1, and NP_2 the set of utterances generated by an NP that has exactly zero, one, and two NPs embedded in it. We define the training scenario $0 \rightarrow 1$, where we train on examples from NP_0 and test on examples from NP_1; $0 \cup 1 \rightarrow 1$, $0 \cup 1 \rightarrow 2$, and $0 \cup 1 \cup 2 \rightarrow 2$ are defined analogously. Our hypothesis is that generalization on $0 \cup 1 \rightarrow 2$ should be better than for $0 \rightarrow 1$, since NP_1 utterances have non-compositional paraphrases, but training on NP_0 does not expose them.

Scenario	Acc.	Scenario	Acc.
$0 \rightarrow 1$	22.9	$0 \cup 1 \rightarrow 2$	28.1
$0 \cup 1 \rightarrow 1$	85.8	$0 \cup 1 \cup 2 \rightarrow 2$	47.5

Table 6: Test set results in the Calendar domain on bounded non-compositionality.

The results in Table 6 verify this hypothesis. The accuracy of $0 \rightarrow 1$ is almost 65% lower than $0 \cup 1 \rightarrow 1$. On the other hand, the accuracy of $0 \cup 1 \rightarrow 2$ is only 19% lower than $0 \cup 1 \cup 2 \rightarrow 2$.

7.3 An overnight experiment

To verify the title of this paper, we attempted to create a semantic parser for a new domain (Recipes) exactly 24 hours before the submission deadline. Starting at midnight, we created a seed lexicon in less than 30 minutes. Then we generated canonical utterances and allowed AMT workers to provide paraphrases overnight. In the morning, we trained our parser and obtained an accuracy of 70.8% on the test set.

7.4 Testing on independent data

Geo880. To test how our parser generalizes to utterances independent of our framework, we created a semantic parser for the domain of US geography, and tested on the standard 280 test examples from Geo880 (Zelle and Mooney, 1996). We did not use the standard 600 training examples. Our parser obtained 56.4% accuracy, which is substantially lower than state-of-the-art ($\sim$ 90%).

We performed error analysis on 100 random sentences from the development set where accuracy was 60%. We found that the parser learns from the training data to prefer shorter paraphrases, which accounts for 30% of the errors. In most of these cases, the correct logical form is ranked at the top-3 results (accuracy for the top-3 derivations is 73%). Geo880 contains highly compositional utterances, and in 25% of the errors the correct derivation tree exceeds the maximum depth used for our parser. Another 17.5% of the errors are caused by problems in the paraphrasing model. For example, in the utterance *"what is the size of california"*, the model learns that *"size"* corresponds to *"population"* rather than *"area"*. Errors related to reordering and the syntactic structure of the input utterance account for 7.5% of the errors. For example, the utterance *"what is the area of the largest state"* is paraphrased to *"state that has the largest area"*.

Calendar. In Section 7.1, we evaluated on utterances obtained by paraphrasing canonical utterances from the grammar. To examine the coverage of our parser on independently-produced utterances, we asked AMT workers to freely come up with queries. We collected 186 such queries; 5 were spam and discarded. We replaced all entities (people, dates, etc.) with entities from our seed lexicon to avoid focusing on entity detection.

We were able to annotate 52% of the utterances with logical forms from our grammar. We could not annotate 20% of the utterances due to relative time references, such as *"What time is my next meeting?"*. 14% of the utterances were not covered due to binary predicates not in the grammar (*"What is the agenda of the meeting?"*) or missing entities (*"When is Dan's birthday?"*). Another 2% required unsupported calculations (*"How much free time do I have tomorrow?"*), and the rest are out of scope for other reasons (*"When does my Verizon data plan start over?"*).

We evaluated our trained semantic parser on the 95 utterances annotated with logical forms. Our parser obtained an accuracy of 46.3% and oracle accuracy of 84.2%, which measures how often the correct denotation is on the final beam. The large gap shows that there is considerable room for improvement in the paraphrasing model.

8 Related work and discussion

Much of current excitement around semantic parsing emphasizes large knowledge bases such as Freebase (Cai and Yates, 2013; Kwiatkowski et al., 2013; Berant et al., 2013). However, despite the apparent scale, the actual question answering datasets (Free917 and WebQuestions) are limited in compositionality. Moreover, specialized domains with specialized jargon will always exist, e.g., in regular expressions (Kushman and Barzilay, 2013) or grounding to perception (Matuszek et al., 2012; Tellex et al., 2011; Krishnamurthy and Kollar, 2013). Therefore, we believe building a targeted domain-specific semantic parser for a new website or device is a very practical goal.

Recent work has made significant strides in reducing supervision from logical forms (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007) to denotations (Clarke et al., 2010; Liang et al., 2011) and to weaker forms (Artzi and Zettlemoyer, 2011; Reddy et al., 2014). All of these works presuppose having input utterances, which do not exist in a new domain. Our methodology overcomes this hurdle by exploiting a very lightweight form of annotation: paraphrasing.

Paraphrasing has been applied to single-property question answering (Fader et al., 2013) and semantic parsing (Berant and Liang, 2014). We not only use paraphrasing in the semantic parser, but also for data collection.

Table 2 might evoke rule-based systems (Woods et al., 1972; Warren and Pereira, 1982) or controlled natural languages (Schwitter, 2010). However, there is an important distinction: the grammar need only connect a logical form to *one* canonical utterance; it is not used directly for parsing. This relaxation allows the grammar to be much simpler. Our philosophy is to use the simple domain-general grammar to carry the torch just to the point of being understandable by a human, and let the human perform the remaining correction to produce a natural utterance.

In summary, our contributions are two-fold: a new functionality-driven process and an exploration of some of its linguistic implications. We believe that our methodology is a promising way to build semantic parsers, and in future work, we would like to extend it to handle anaphora and nested quantification.

Abstract

In this paper, we introduce Long Short-Term Memory (LSTM) recurrent network for twitter sentiment prediction. With the help of gates and constant error carousels in the memory block structure, the model could handle interactions between words through a flexible compositional function. Experiments on a public noisy labelled data show that our model outperforms several feature-engineering approaches, with the result comparable to the current best data-driven technique. According to the evaluation on a generated negation phrase test set, the proposed architecture doubles the performance of non-neural model based on bag-of-word features. Furthermore, words with special functions (such as negation and transition) are distinguished and the dissimilarities of words with opposite sentiment are magnified. An interesting case study on negation expression processing shows a promising potential of the architecture dealing with complex sentiment phrases.

1 Introduction

Twitter and other similar microblogs are rich resources for opinions on various kinds of products and events. Detecting sentiment in microblogs is a challenging task that has attracted increasing research interest in recent years (Hu et al., 2013b; Volkova et al., 2013).

Go et al. (2009) carried out the pioneer work of predicting sentiment in tweets using machine learning technology. They conducted comprehensive experiments on multiple classifiers based on bag-of-words feature. Such feature is widely used because it's simple and surprisingly efficient in many tasks. However, there are also disadvantages of bag-of-words features represented by one-hot vectors. Firstly, it bears a data sparsity issue (Saif et al., 2012a). In tweets, irregularities and 140-character limitation exacerbate the sparseness. Secondly, losing sequence information makes it difficult to figure out the polarity properly (Pang et al., 2002). A typical case is that the sentiment word in a negation phrase tends to express opposite sentiment to that of the context.

Distributed representations of words can ease the sparseness, but there are limitations to the unsupervised-learned ones. Words with special functions in specific tasks are not distinguished. Such as negation words, which play a special role in polarity classification, are represented similarly with other adverbs. Such similarities will limit the compositional models' abilities of describing a sentiment-specific interaction between words. Moreover, word vectors trained by co-occurrence statistics in a small window of context effectively represent the syntactic and semantic similarity. Thus, words like *good* and *bad* have very similar representations (Socher et al., 2011). It's problematic for sentiment classifiers.

Sentiment is expressed by phrases rather than by words (Socher et al., 2013). Seizing such sequence information would help to analyze complex sentiment expressions. One possible method to leverage context is connecting embeddings of words in a window and compose them to a fix-length vector (Collobert et al., 2011). However, window-based methods may have difficulty reaching long-distance words and simply connected vectors do not always represent the interactions of context properly.

Theoretically, a recurrent neural network could process the whole sentence of arbitrary length by encoding the context cyclically. However, the length of reachable context is often limited when using stochastic gradient descent (Bengio et al., 1994; Pascanu et al., 2013). Besides that, a

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics

Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

traditional recurrent architecture is not powerful enough to deal with the complex sentiment expressions. Fixed input limits the network's ability of learning task-specific representations and simple additive combination of hidden activations and input activations has difficulty capturing more complex linguistic phenomena.

In this paper, we introduce the Long Short-Term Memory (LSTM) recurrent neural network for twitter sentiment classification by means of simulating the interactions of words during the compositional process. Multiplicative operations between word embeddings through gate structures provide more flexibility and lead to better compositional results compare to the additive ones in simple recurrent neural network. Experimentally, the proposed architecture outperforms various classifiers and feature engineering approaches, matching the performance of the current best data-driven approach. Vectors of task-distinctive words (such as *not*) are distinguished after tuning and representations of opposite-polarity words are separated. Moreover, predicting result on negation test set shows our model is effective in dealing with negation phrases (a typical case of sentiment expressed by sequence). We study the process of the network handling the negation expressions and show the promising potential of our model simulating complex linguistic phenomena with gates and constant error carousels in the LSTM blocks.

2 Related Work

2.1 Microblogs Sentiment Analysis

There have been a large amount of works on sentiment analysis over tweets. Some research makes use of social network information (Tan et al., 2011; Calais Guerra et al., 2011). These works reveal that social network relations of opinion holders could bring an influential bias to the textual models. While some other works utilize the microblogging features uncommon in the formal literature, such as hashtags, emoticons (Hu et al., 2013a; Liu et al., 2012). Speriosu et al. (2011) propose a unified graph propagation model to leverage textual features (such as emoticons) as well as social information.

Semantic concept or entity based approaches lead another research direction. Saif et al. (2012a; 2012b) make use of sentiment-topic features and entities extracted by a third-party service to ease data sparsity. Aspect-based models are also exploited to improve the tweet-level classifier (Lek and Poo, 2013).

2.2 Representation Learning and Deep Models

Bengio et al. (2003) use distributed representations for words to fight the curse of dimensionality when training a neural probabilistic language model. Such word vectors ease the syntactic and semantic sparsity of bag-of-words representations. Much recent research has explored such representations (Turian et al., 2010; Huang et al., 2012).

Recent works reveal that modifying word vectors during training could capture polarity information for the sentiment words effectively (Socher et al., 2011; Tang et al., 2014). It would be also insightful to analyze the embeddings that changed the most during training. We conduct a comparison between initial and tuned vectors and show how the tuned vectors of task-distinctive function words cooperate with the proposed architecture to capture sequence information.

Distributed word vectors help in various NLP tasks when using in neural models (Collobert et al., 2011; Kalchbrenner et al., 2014). Composing these representations to fix-length vectors that contain phrase or sentence level information also improves performance of sentiment analysis (Yessenalina and Cardie, 2011). Recursive neural networks model contextual interaction in binary trees (Socher et al., 2011; Socher et al., 2013). Words in the complex utterances are considered as leaf nodes and composed in a bottom-up fashion. However, it's difficult to get a binary tree structure from the irregular short comments like tweets. Not requiring structure information or parser, long short-term memory models encode the context in a chain and accommodate complex linguistic phenomena with structure of gates and constant error carousels.

3 Recurrent Neural Networks for Sentiment Analysis

Recurrent Neural Networks (RNN) have gained attention in NLP field since Mikolov et al. (2010) developed a statistical language model based on a simple form known as Elman network (Elman, 1990). Recent works used RNNs to predict words or characters in a sequence (Chrupała, 2014; Zhang and Lapata, 2014). Treating opinion expression extraction as a sequence labelling

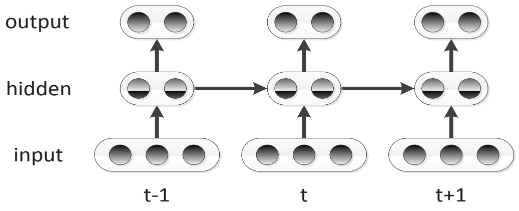

Figure 1: Illustration of simple recurrent neural network. The input of the hidden layer comes from both input layer and the hidden layer activations of previous time step.

problem, Irsoy and Cardie (2014) leverage deep RNN models and achieve new state-of-the-art results for fine-grained extraction task. The lastest work propose a tree-structured LSTM and conduct a comprehensive study on using LSTM in predicting the semantic relatedness of two sentences and sentiment classification (Tai et al., 2015).

Fig.1 shows the illustration of a recurrent network. By using self-connected layers, RNNs allow information cyclically encoded inside the networks. Such structures make it possible to get a fix-length representation of a whole tweet by temporally composing word vectors.

The recurrent architecture we used in this work is shown in Fig.2. Each word is mapped to a vector through a Lookup-Table (LT) layer. The input of the hidden layer comes from both the current lookup-table layer activations and the hidden layer's activations one step back in time. In this way, hidden layer encodes the past and current information. The hidden activations of the last time step could be considered as the representation of the whole sentence and used as input to classification layer. By storing the word vectors in LT layer, the model has reading and tuning access to word representations.

Based on such recurrent architecture, we can capture sequence information in the context and identify polarities of the tweets.

3.1 Elman Network With Fixed Lookup-Table

RNN-FLT: A simple implementation of the recurrent sentiment classifier is an Elman network (also known as simple RNN) with Fixed Lookup-Table (FLT). In such model, unsupervised pre-trained word vectors in LT layer are constant during the whole training process. The hidden layer activation of position h at time t is:

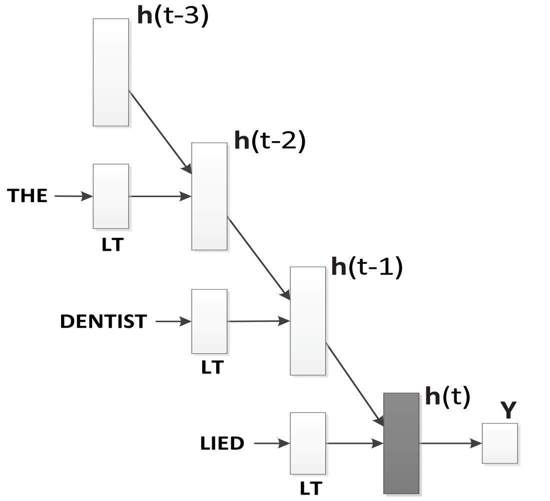

Figure 2: Illustration of the general recurrent architecture unfolded as a deep feedforward network.

$$b_h^t = f\left(a_h^t\right) \tag{1}$$

$$a_h^t = \sum_i^E w_{ih} e_i^t + \sum_{h'}^H w_{h'h} b_{h'}^{t-1} \tag{2}$$

where $\mathbf{e}^t$ represents the E-length embedding of the tth word of the sentence, which stored in LT layer. w_{ih} is the weight of connection between input and hidden layer, while $w_{h'h}$ is the weights of recurrent connection (self-connection of hidden layer). f represents the sigmoid function. The binary classification loss function O is computed via cross entropy (CE) criterion and the network is trained by stochastic gradient descent using *back-propagation through time* (BPTT) (Werbos, 1990). Here, we introduce the notation:

$$\delta_i^t = \frac{\partial O}{\partial a_i^t} \tag{3}$$

Firstly, the error propagate from output layer to hidden layer of last time step T. The derivatives with respect to the hidden activation of position i at the last time step T are computed as follow:

$$\delta_i^T = f'\left(a_i^T\right) \frac{\partial O}{\partial y} v_i \tag{4}$$

where v_i represents the weights of hidden-output connection and the activation of the output layer y is used to estimate probability of the tweet bearing a particular polarity.

$$y = f\left(\sum_{i}^{H} b_i^T v_i\right) \tag{5}$$

Then the gradients of hidden layer of previous time steps can be recursively computed as:

$$\delta_h^t = f'\left(a_h^t\right) \sum_{h'}^{H} \delta_{h'}^{t+1} w_{hh'} \tag{6}$$

3.2 Elman Network with Trainable Lookup-Table

Unsupervised trained word embeddings represent the syntactic and semantic similarity. However, in specific tasks, the importance and functions of different words vary. Negation words have similar unsupervised trained representations with other adverbs, but they make distinctive contributions in sentiment expressions. Besides the function words, tuning word vectors of sentiment words into polarity-representable ones turns out to be an effective way to improve the performance of sentiment classifiers. (Maas et al., 2011; Labutov and Lipson, 2013). Such tuned vectors work together with the deep models, gaining the ability to describe complex linguistic phenomena.

RNN-TLT: To this end, we modify the word vectors in the Trainable Lookup-Table (TLT) via back propagation to get a better embedding of words. The gradient of lookup-table layer is:

$$\delta_i^t = g'\left(a_i^t\right) \sum_{h=1}^{H} \delta_h^t w_{ih} = \sum_{h=1}^{H} \delta_h^t w_{ih} \tag{7}$$

where identity function $g(x) = x$ is considered as the activation function of lookup-table layer.

3.3 Long Short-Term Memory

The simple RNN has the ability to capture context information. However, the length of reachable context is often limited. The gradient tends to vanish or blow up during the back propagation (Bengio et al., 1994; Pascanu et al., 2013). Moreover, Elman network simply combines previous hidden activations with the current inputs through addictive function. Such combination is not powerful enough to describe a complex interactions of words.

An effective solution for these problems is the Long Short-Term Memory (LSTM) architecture (Hochreiter and Schmidhuber, 1997; Gers, 2001). Such architecture consists of a set of recurrently connected subnets, known as memory blocks. Each block contains one or more self-connected memory cells and the input, output and forget gates. Fig.3 gives an illustration of an LSTM block. Once an error signal arrives Constant Error Carousel (CEC), it remains constant, neither growing nor decaying unless the forget gate squashes it. In this way, it solves the vanishing gradient problem and learns more appropriate parameters during training.

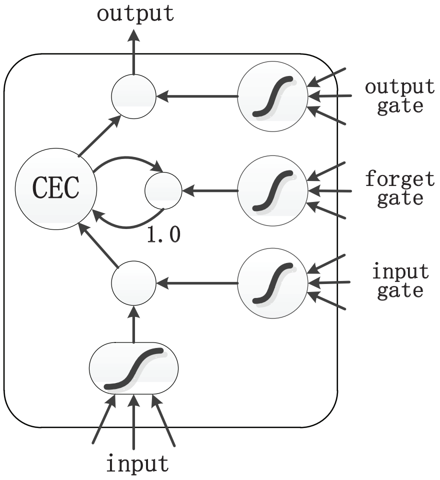

Figure 3: Illustration of LSTM memory block with one cell. Constant Error Carousel (CEC) maintains the internal activation (called *state*) with a recurrent connection of fixed weight 1.0, which may be reset by the forget gate. The input and output gates scale the input and output respectively. All the gates are controlled by the maintained state, network input and hidden activation of previous time step.

Moreover, based on this structure, the input, output and stored information can be partial adjusted by the gates, which enhances the flexibility of the model. The activations of hidden layer rely on the current/previous state, previous hidden activation and current input. These activations interact to make up the final hidden outputs through not only additive but also element-wise multiplicative functions. Such structures are more capable to learn a complex composition of word vectors than simple RNNs.

These gates are controlled by current input, previous hidden activation and cell state in CEC unit:

$$G_I^t = f\left(U_I x^t + V_I h^{t-1} + W_I s^{t-1}\right) \tag{8}$$

$$G_F^t = f\left(U_F x^t + V_F h^{t-1} + W_F s^{t-1}\right) \quad (9)$$

$$G_O^t = f\left(U_O x^t + V_O h^{t-1} + W_O s^t\right) \quad (10)$$

where G^t indicates the gate activation at time t, x^t, h^t and s^t is input, hidden activation and state in CEC unit at time t respectively, while U, V and W represent the corresponding weight matrices connect them to the gates. Subscript I, F and O indicate input, forget and output respectively. The CEC state and block output are computed by the functions with element-wise multiplicative operation:

$$s^t = G_F^t s^{t-1} + G_I^t f\left(U_S x^t + V_S h^{t-1}\right) \quad (11)$$

$$a^t = G_O^t s^t \quad (12)$$

where U_S indicates connection weight between input and state, while V_S represents the weight matrix connecting hidden layer to state.

LSTM-TLT: By replacing the conventional neural units in RNN-TLT with LSTM blocks, we can get the LSTM network with Trainable Lookup-Table. Such model achieves a flexible compositional structure where the activations interact in a multiplicative function. It provides the capacity of describing diverse linguistic phenomenon by learning complex compositions of word embeddings.

4 Experiments

4.1 Data Set

We conduct experiments on the Stanford Twitter Sentiment corpus (STS)[1]. The noisy-labelled dataset is collected using emoticons as queries in Twitter API (Go et al., 2009). 800,000 tweets containing positive emoticons are extracted and labelled as positive, while 800,000 negative tweets are extracted based on negative emoticons. The manually labelled test set consists of 177 negative and 182 positive tweets.

4.2 Experimental Settings

Recurrent Neural Network: We implement the recurrent architecture with trainable lookup-table layer by modifying RNNLIB (Graves, 2010) toolkit.

Early Stopping: From the noisy labelled data, we randomly selected 20,000 negative and 20,000 positive tweets as validation set for early stopping. The rest 1,560,000 tweets are used as training set.

Parameter Setting: Tuned on the validation set, the size of the hidden layer is set to 60.

Word Embeddings: We run *word2vec* on the training set of 1.56M tweets (without labels) to get domain-specific representations and use them as initial input of the model. Limited to the input format of the toolkit, we learned 25-dimensional (relatively small) vectors. *Skip-gram architecture* and *hierarchical softmax algorithm* are chosen during training.

4.3 Comparison with Data Driven Approaches

Classifier	Accuracy(%)
SVM	81.6
MNB	82.7
MAXENT	83.0
MAX-TDNN	78.8
NBoW	80.9
DCNN	**87.4**
RAE	77.6
RNN-FLT	80.2
RNN-TLT	86.4
LSTM-TLT	**87.2**

Table 1: Accuracies of different classifiers.

Naive Bayes, Maximum Entropy and SVM are widely used classifiers. Go et al. (2009) presented the results of three non-neural models using unigram and bigram features.

Dynamic Convolutional Neural Network (DCNN) (Kalchbrenner et al., 2014) is a generalization of MAX-TDNN (Collobert et al., 2011). It has a clear hierarchy and is able to capture long-range semantic relations. While the Neural Bag-of-Words (NBoW) takes the summation of word vectors as the input of a classification layer. Kalchbrenner et al. (2014) reported performances of the above three neural classifiers.

Recursive Autoencoder (RAE) has proven to be an effective model to compose words vectors in sentiment classification tasks (Socher et al., 2011). We run RAE with randomly initialized word embeddings. We do not compare with RNTN (Socher et al., 2013) for lack of phrase-level sentiment labels and accurate parsing results.

Table 1 shows the accuracies of different classifiers. Notably, RNN-TLT and LSTM-TLT out-

[1] http://twittersentiment.appspot.com/

perform the three non-neural classifiers. Trained on the considerable data, these classifiers provide strong baselines. However, bag-of-words representations are not powerful enough. Sparsity and losing sequence information hurt the performance of classifiers. Neural models overcome these problems by using distributed representations and temporally encoding the contextual interaction.

We notice a considerable increase in the performance of the RNN-TLT with respect to the NBoW, whose embeddings are also tuned during supervised training. It suggests that recurrent models could generate better tweet-level representations for the task by composing the word embeddings in a temporal manner and capturing the sequential information of the context.

Convolutional neural networks have outstanding abilities of feature extraction, while LSTM-TLT achieves a comparable performance. It suggests that LSTM model is effective in learning sentence-level representations with a flexible compositional structure.

RAE provides more general representations of phrases by learning to reconstruct the word vectors. Recurrent models outperform RAE indicates that task-specific composing and representation learning with less syntactic information lead to a better result.

Comparing RNN-FLT with RNN-TLT, we can easily figure out that the model with trainable lookup-table achieves better performance. This is due to the fact that tuned embeddings capture the sentiment information of text by distinguishing words with opposite sentiment polarities and providing more flexibility for composing. LSTM-TLT does not outperform RNN-TLT significantly. And the situations are almost the same on short-sentence (less than 25 words) and long-sentence (not less than 25 words) test set. Such results indicate that the ability of LSTM getting access to longer-distance context is not the determinant of improvement, while the capacity of LSTM handling complex expressions plays a more important role. Such capacity will be further discussed in subsection 4.7.

Since the training set is large enough, we have not observed strong overfitting during the training process. Therefore, no regularization technology is employed in the experiments.

4.4 Comparison with Feature Engineering Approaches

Method	Craft feature	Accuracy(%)
Speriosu et al. (2011)	emoticon hashtag	84.7
Saif et al. (2012a)	sentiment-topic semantic	86.3 84.1
Lek and Poo (2013)	aspect-based	**88.3**
This work		**87.2**

Table 2: Comparison with different feature engineering methods.

Table 2 shows the comparison with different feature engineering methods. In Speriosu et al. (2011)'s work, sentiment labels propagated in a graph constructed on the basis of contextual relations (e.g. word presence in a tweet) as well as social relations. Saif et al. (2012a) eased the data sparsity by adding sentiment-topic features that extracted using traditional lexicon. While Lek and Poo (2013) extracted tuple of *[aspect, word, sentiment]* with hand-crafted templates. With the help of opinion lexicon and POS tagger especially designed for twitter data, their approach achieved a state-of-the-art result.

Even though these methods rely on lexicons and extracted entities, our data-driven model outperforms most of them, except the aspect-based one that introduced twitter-specific resources. This is due to the fact that traditional lexicons, even emoticons added, are not able to cover the diversification of twitter sentiment expressions, while LSTM learns appropriate representations of sentiment information through compositional manner.

4.5 Experiments on Manually Labelled Data

Different from STS dataset deciding the polarity based on emoticons, the benchmark dataset in SemEval 2013 (Nakov et al., 2013) is labelled by human annotators. In this work we focus on the binary polarity classification and abandon the neutral tweets. There are 4099/735/1742 available tweets in the training/dev/test set respectively. Since the training set is relatively small, we don't apply fine tuning on word vectors. Namely we use fixed lookup-table for both RNN and LSTM. 300-dimensional vectors are learned on the 1.56M tweets of STS dataset using word2vec. Other settings stay the same as previous experiments.

Method	Accuracy(%)
SVM	74.5
RAE	75.4
RNN-FLT	83.0
LSTM-FLT	**84.0**

Table 3: Accuracies of different methods on SemEval 2013

Table 3 shows our work compared to SVM and Recursive Autoencoder. From the result, we can see that the recurrent models outperforms the baselines by exploiting more context information of word interactions.

4.6 Representation Learning

Recent works reveal that modifying word vectors during training could capture polarity information for the sentiment words effectively (Socher et al., 2011; Tang et al., 2014). However, it would be also helpful to analyse the embeddings that changed the most.

Function words: We choose 1000 most frequent words. For each word, we compute the distance between unsupervised vector and tuned vector. 20 words that change most are shown in Fig.4.

It's noteworthy that there are five negation words (not, no, n't, never and Not) in the notably-change group. The representations of negation words are quite similar with other adverbs in unsupervised learned embeddings, while the proposed model distinguishes them. This indicate that our polarity-supervised models identify negation words as distinctive symbols in sentiment classification task, while unsupervised learned vectors do not contain such information.

Besides the negation words and sentiment words, there are also other prepositions, pronouns and conjunctions change dramatically (e.g. *and* and *but*). Such function words also play a special role in sentiment expressions (Socher et al., 2013) and the model in this paper distinguishes them. However, the contributions of these words to the task are not that explainable as negation words (at least without sentiment strength information).

To further explain how the tuned vectors work together with the network and describe interactions between words, we study the process of the model classifying negation phrases in the following subsection.

Sentiment words: In order to study the embedding change of sentiment words, we choose the most frequent sentiment words in our training data, 20 positive and 20 negative, and observe the dissimilarity of the vectors in a two-dimensional space. An alternative least-square scaling is implemented based on Euclidean distance between word vectors. Figure 5 shows sentiment-specific tuning reduces the overlap of opposite polarities. Polarities of words are identified based on a widely-used sentiment lexicon (Hu and Liu, 2004).

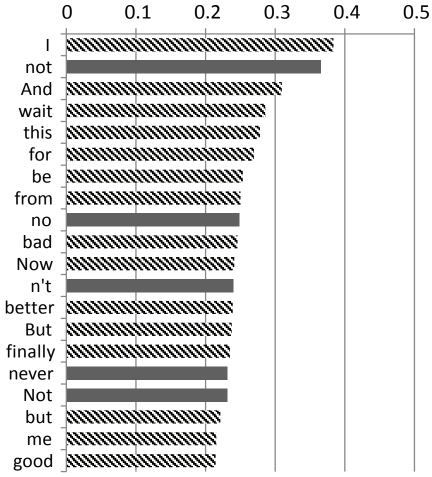

Figure 4: Word change scale to [0,1]. Distances are computed by reversing cosine similarity.

To explicitly evaluate it, we selected embeddings of 2000 most frequent sentiment words (1000 each polarity) and compute the centers of both classes. If an embedding is closer to the opposite polarity center, we consider it as an *overlap*. Experimentally, the proportion of *overlap* of unsupervised learned vectors is 19.55%, while the one of tuned vectors is 11.4%. Namely the overlap ratio is reduced by 41.7%. Experimentally, such polarity separating relies on tuning through lookup-table layer rather than LSTM structure. With the decrease of overlap of polarities, sentiment of word turns more distinguishable, which is helpful for polarity prediction.

4.7 Case Study: Negation

Negation phrases are typical cases where sentiment is expressed by sequence rather than words. To evaluate the ability of the model dealing with such cases, we select most frequent 1000 negative and 1000 positive words in the training data and generate the corresponding negation phrases (such

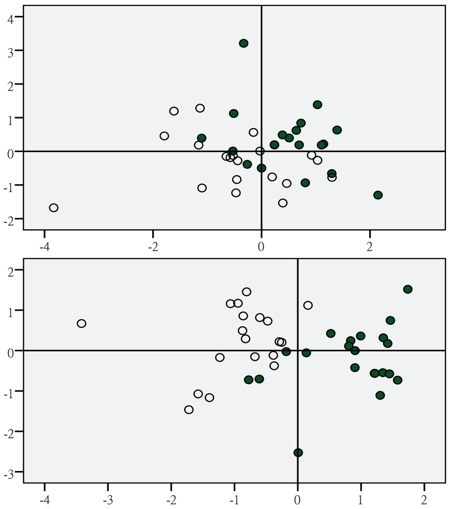

Figure 5: Distance of word vectors shown in two-dimensional space. The above figure shows the distribution of unsupervised learning vectors and the below figure indicates the tuned one. The solid and hollow points represent the positive and negative words respectively.

as *not good*).

Classifier	Accuracy(%)
MNB+unigram+bigram	32.98
RNN-TLT	52.00
LSTM-TLT	**64.85**

Table 4: Accuracy on generated negation phrases test set.

Statistical result shows that only 37.6% of the negation phrases appeared in the training text. It sets a theoretical upper bound to the classifiers based on the unigram and bigram features. Experimental result shown in Table 4 indicates that LSTM model effectively handles the sequential expressions of negation. By composing word vectors, recurrent models ease the sparsity of bag-of-word features and achieve a significant improve than MNB using unigram and bigram features. LSTM outperform RNN by 12.85%, such result suggests the element-wise multiplicative compositional function of LSTM provides more flexibility to simulate interactions between word vectors. A clear process of LSTM handling negation phrases is observed, which is described in the rest of the subsection, while the one of RNN is not that obvious.

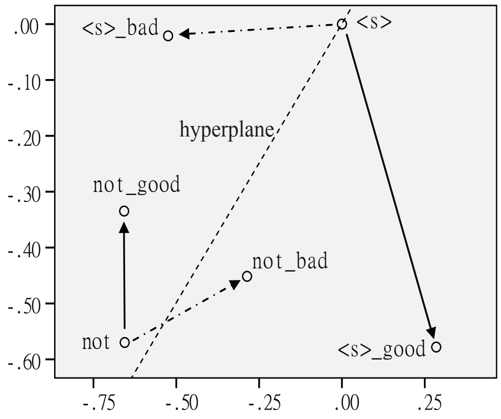

Figure 6: Hidden activations of negation phrases. <s> represent the beginning of sentences. *not bad* and *good* lead to positive outputs, while *not good* and *bad* result in negative values. The dotted line indicates the classification hyperplane. The solid arrows represent the hidden vector changes when the network take the word *good* as input, while the dotted arrows indicate the changes when the word *bad* is input. The sentiment words are input in two situations (as initial input or after negation word), while the changes of hidden vectors of same word are opposite in the two situations.

As mentioned in 4.6, the task-distinctive function words are distinguished. It would be insightful to show how it works together with the LSTM structure.

We train the network on STS dataset and test it on few words and phrases (*good*, *bad*, *not good* and *not bad*). For the convenience of analysis the activation within the network, we set the size of hidden layer to 2. Such setting reduces the performance by about 7% on the public test set, but the trained model still work effectively. Fig.6 shows the activations of LSTM hidden layers. Both sentiment words and negation phrases are classified into correct categories. Furthermore, when sentiment words like *good* (i) input as the first word of sentence and (ii) input after negation word, it cause opposite change in hidden layer. These behaviours simulate the change of sentiment in the negation expressions.

As mentioned in 3.3, gates' activations are controlled by current input, state in CEC unit and output of hidden layer of previous time step. They are many possible ways for the model to simulating the sentiment change. In the experiment, the observed situation is shown in Fig.7:

Negation word contains both polarities. The

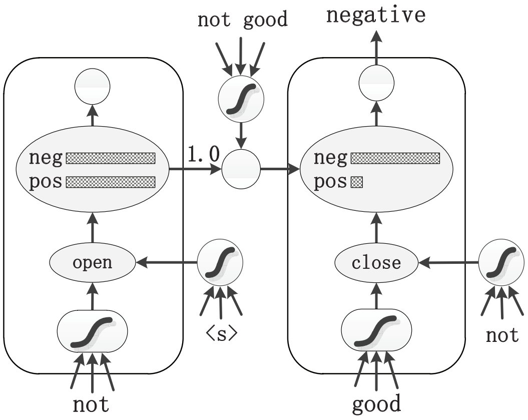

Figure 7: Observed process of LSTM block handling negation phrase *not good*. Some less important connections are omitted in this figure.

positive-axle and negative-axle are almost orthogonal. Negation word has large components on both axles.

***not* make input gate close.** Experiments show recurrent activations make the input gate close, namely previous word *not* squashes the input (both current and recurrent input) to a very small value.

Choose a polarity to forget. The combination of the recurrent input *not* and current input *good* make the CEC unit forget the positive information, namely they make forget gate reduce state's component on positive-axle while leaving a large projection on negative-axle. A significant dissimilarity of forget gate activations between positive and negative words is observed in the experiment, when they are input after *not*.

In this way, the temporally-input phrase *not good* shows a negative polarity. Correspondingly, phrase *not bad* turns positive after reducing the negative components of the negation word. Such case shows the process of the gates and CEC unit cooperating in the LSTM structure. Together with tuned vectors, the architecture has a promising potential of capture sequence information by simulating complex interactions between words.

5 Conclusion

In this paper we have explored to capture twitter sentiment expressed by interactions of words. The contributions of this paper can be summarized as follows: (i) We have described long short-term memory based model to compose word representations through a flexible compositional function. Tested on a public dataset, the proposed architecture achieves result comparable to the current best data-driven model. The experiment on negation test set shows the ability of the model capturing sequential information. (ii) Beyond tuning vectors of sentiment words, we put forward a perspective of distinguishing task-distinctive function words only relying on the label of the whole sequence. (iii) We conduct an interesting case study on the process of task-distinctive word vectors working together with deep model, which is usually considered as a black-box in other neural networks, indicating the promising potential of the architecture simulating complex linguistic phenomena.

Abstract

The goal of this research is to build a model to predict stock price movement using sentiments on social media. A new feature which captures topics and their sentiments simultaneously is introduced in the prediction model. In addition, a new topic model TSLDA is proposed to obtain this feature. Our method outperformed a model using only historical prices by about 6.07% in accuracy. Furthermore, when comparing to other sentiment analysis methods, the accuracy of our method was also better than LDA and JST based methods by 6.43% and 6.07%. The results show that incorporation of the sentiment information from social media can help to improve the stock prediction.

1 Introduction

Stock price forecasting is very important in the planning of business activity. However, building an accurate stock prediction model is still a challenging problem. In addition to historical prices, the current stock market is affected by the mood of society. The overall social mood with respect to a given company might be one of the important variables which affect the stock price of that company. Nowadays, the emergence of online social networks makes large amounts of mood data available. Therefore, incorporating information from social media with the historical prices can improve the predictive ability of the models.

The goal of our research is to develop a model to predict a stock price movement using information from social media (Message Board). In our proposed method, the model predicts the movement of the stock value at t using features derived from information at $t-1$ and $t-2$, where t stands for a transaction date. It will be trained by supervised machine learning. Apart from the mood information, the stock prices are affected by many factors such as microeconomic and macroeconomic factors. However, this research only focuses on how the mood information from social media can be used to predict the stock price movement. That is, the mood of topics in social media is extracted by sentiment analysis. Then, the topics and their sentiments are integrated into the model to predict the stocks. To achieve this goal, discovering the topics and sentiments in a large amount of social media is important to get opinions of investors as well as events of companies. However, sentiment analysis on social media is difficult. The text is usually short, contains many misspellings, uncommon grammar constructions and so on. In addition, the literature shows conflicting results in sentiment analysis for stock market prediction. Some researchers report that the sentiments from social media have no predictive capabilities (Antweiler and Frank, 2004; Tumarkin and Whitelaw, 2001), while other researchers have reported either weak or strong predictive capabilities (Bollen et al., 2011). Therefore, how to use opinions in social media for stock price predictions is still an open problem.

Our contributions are summarized as follows:

1. We propose a new feature "topic-sentiment" for the stock market prediction model.

2. We propose a new topic model, Topic Sentiment Latent Dirichlet Allocation (TSLDA), which can capture the topic and sentiment simultaneously.

3. Large scale evaluation. Most of the previous researches are limited on predicting for one stock (Bollen et al., 2011; Qian and Rasheed, 2007; Si et al., 2013), and the number of instances (transaction dates) in a test set is rather low such as 14 or 15 instances (Bollen

*Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing*, pages 1354–1364,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

et al., 2011; Vu et al., 2012). With only a few instances in the test set, the conclusion might be insufficient. This is the first research that shows good prediction results on evaluation of many stocks using a test set consisting of many transaction dates.

The rest of the paper is organized as follows. Section 2 introduces some previous approaches on sentiment analysis for stock prediction. Section 3 explains our model for sentiment analysis by simultaneously inferring the topic and sentiment in the text. Section 4 describes two kinds of datasets required for stock prediction. Section 5 describes our prediction models and also proposes a novel feature based on the topics and sentiments. Section 6 assesses the results of the experiments. Finally, Section 7 concludes our research.

2 Related Work

Stock market prediction is one of the most attracted topics in academic as well as real life business. Many researches have tried to address the question whether the stock market can be predicted. Some of the researches were based on the random walk theory and the Efficient Market Hypothesis (EMH). According to the EMH (Fama et al., 1969; Fama, 1991), the current stock market fully reflects all available information. Hence, price changes are merely due to new information or news. Because news in nature happens randomly and is unknowable in the present, stock prices should follow a random walk pattern and the best bet for the next price is the current price. Therefore, they are not predictable with more than about 50% accuracy (Walczak, 2001). On the other hand, various researches specify that the stock market prices do not follow a random walk, and can be predicted in some degree (Bollen et al., 2011; Qian and Rasheed, 2007; Vu et al., 2012). Degrees of accuracy at 56% hit rate in the predictions are often reported as satisfying results for stock predictions (Schumaker and Chen, 2009b; Si et al., 2013; Tsibouris and Zeidenberg, 1995).

Besides the efficient market hypothesis and the random walk theories, there are two distinct trading philosophies for stock market prediction: fundamental analysis and technical analysis. The fundamental analysis studies the company's financial conditions, operations, macroeconomic indicators to predict the stock price. On the other hand, the technical analysis depends on historical and time-series prices. Price moves in trends, and history tends to repeat itself. Some researches have tried to use only historical prices to predict the stock price (Zuo and Kita, 2012a; Zuo and Kita, 2012b). To discover the pattern in the data, they used Bayesian network (Zuo and Kita, 2012a; Zuo and Kita, 2012b), time-series method such as Auto Regressive, Moving Average, Auto Regressive Moving Average model (Zuo and Kita, 2012a) and so on.

2.1 Extracting Opinions from Text

Sentiment analysis has been found to play a significant role in many applications such as product and restaurant reviews (Liu and Zhang, 2012; Pang and Lee, 2008). There are some researches trying to apply sentiment analysis on information sources to improve the stock prediction model. There are two main such sources. In the past, the main source was the news (Schumaker and Chen, 2009a; Schumaker and Chen, 2009b), and in recent years, social media sources. A simple approach is combining the sentiments in the textual content with the historical prices through the linear regression model.

Most of the previous work primarily used the bag-of-words as text representation that are incorporated into the prediction model. Schumaker and Chen tried to use different textual representations such as bag-of-words, noun phrases and named entities for financial news (Schumaker and Chen, 2009b). However, the textual representations are just the words or named entity tags, not exploiting the mood information so much. A novel tree representation based on semantic frame parsers is proposed (Xie et al., 2013). By using stock prices from Yahoo Finance, they annotated all the news in a transaction date with going up or down categories. However, the weakness of this assumption is that all the news in one day will have the same category. In addition, this is a task of text classification, not stock prediction.

Naive Bayes was used to classify messages from message boards into three classes: buy, hold and sell (Antweiler and Frank, 2004). They were integrated into the regression model. However, they concluded that their model does not successfully predict stock returns.

A method to measure collective hope and fear on each day and analyze the correlation between these indices and the stock market indicators was proposed (Zhang et al., 2011). They used the mood words to tag each tweet as fear, worry, hope and so on. They concluded that the ratio of the emotional tweets significantly negatively correlated with Down Jones, NASDAQ and S&P 500, but positively with VIX. However, they did not use their model to predict the stock price values.

Two mood tracking tools, OpinionFinder and Google Profile of Mood States, were used to analyze the text content of daily Twitter (Bollen et al., 2011). The former measures the positive and negative mood. The latter measures the mood in terms of six dimensions (Calm, Alert, Sure, Vital, Kind, and Happy). They used the Self Organizing Fuzzy Neural Network model to predict DJIA values. The results showed 86.7% direction accuracy (up or down) and 1.79% Mean Absolute Percentage Error. Although they achieved the high accuracy, there were only 15 transaction dates (from December 1 to 19, 2008) in their test set. With such a short period, it might not be sufficient to conclude the effectiveness of their method.

A keyword-based algorithm was proposed to identify the sentiment of tweets as positive, neutral and negative for stock prediction (Vu et al., 2012). Their model achieved around 75% accuracy. However, their test period was short, from 8^{th} to 26^{th} in September 2012, containing only 14 transaction dates.

Continuous Dirichlet Process Mixture (cDPM) model was used to learn the daily topic set of Twitter messages to predict the stock market (Si et al., 2013). A sentiment time series was built based on these topics. However, the time period of their whole dataset is rather short, only three months.

Most of the researches tried to extract only the opinions or sentiments. However, one important missing thing is that opinions or sentiments are expressed on topics or aspects of companies. Therefore, understanding on which topics of a given stock people are expressing their opinion is very important. Although the models for inferring the topics and sentiments simultaneously have already proposed as discussed in Subsection 2.2, to the best of our knowledge, such models have never applied for stock market prediction.

2.2 Aspect based Sentiment Analysis

Some researches tried to identify the sentiment expressed toward an aspect in a sentence rather than a whole sentence or document. The simple approach is to define a sentiment score of a given aspect by the weighted sum of opinion scores of all words in the sentence, where the weight is defined by the distance from the aspect (Liu and Zhang, 2012; Pang and Lee, 2008). This method is further improved by identifying the aspect-opinion relations using tree kernel method (Nguyen and Shirai, 2015).

Other researches trying to extract both the topic and sentiment for some domains such as online product, restaurant and movie review dataset. ASUM is a model for extracting both the aspect and sentiment for online product review dataset (Jo and Oh, 2011). Joint sentiment/topic model (JST) is another model to detect the sentiment and topic simultaneously, which was applied for movie review dataset (Lin and He, 2009). These models assume that each word is generated from a joint topic and sentiment distribution. It means that these models do not distinguish the topic word and opinion word distributions.

Besides the general opinion words, topic models considering aspect-specific opinion words were also proposed. MaxEnt-LDA hybrid model can jointly discover both aspects and aspect-specific opinion words on a restaurant review dataset (Zhao et al., 2010), while FACTS, CFACTS, FACTS-R, and CFACTS-R model were proposed for sentiment analysis on a product review data (Lakkaraju et al., 2011). However, one of the weaknesses of these methods is that there is only one opinion word distribution corresponding to one topic (aspect). It makes difficult to know which sentiment (e.g. positive or negative) is expressed by the opinion words on that topic.

To overcome this drawback, we propose a new topic model called Topic Sentiment Latent Dirichlet Allocation (TSLDA), which estimates different opinion word distributions for individual sentiment categories for each topic. To the best of our knowledge, such a model has not been proposed. TSLDA is suitable for not only sentiment analysis for stock prediction but also general sentiment analysis of the document, sentence and aspect.

3 TSLDA: Topic Sentiment Latent Dirichlet Allocation

The proposed model TSLDA infers the topics and their sentiments simultaneously. It is an extended model of Latent Dirichlet Allocation (LDA) (Blei et al., 2003). We assume that one sentence ex-

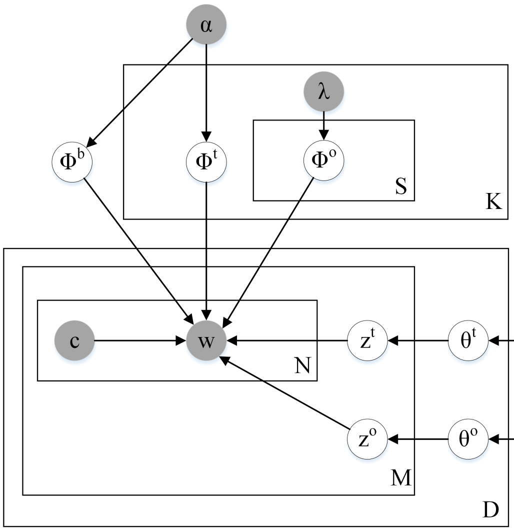

Figure 1: Graphical Model Representation of TSLDA

presses only one topic and one opinion on that topic. The topics are usually nouns, whereas the opinion words are adjectives or adverbs. The words in the document are classified into three categories, the topic word (category $c = 1$), opinion word ($c = 2$) and others ($c = 0$). Then, we suppose the different opinion words are used for the different topics. Depending on the topic, an opinion word may express different sentiment meaning. For example, the opinion word "low" in "low cost" and "low salary" have opposite polarity. In our model, different topics, which are also represented by word distributions, will have different opinion word distributions. Finally, to capture the sentiment meanings such as positive, negative or neutral of the opinion words for each topic, we distinguish opinion word distributions for different sentiment meanings.

Figure 1 shows the graphical model representation of TSLDA. Observed and hidden variables are indicated by shaded and clear circles, respectively. Table 1 shows the notations in Figure 1. The generation process in TSLDA is as follows:

1. Choose a distribution of background words $\Phi^b \sim Dirichlet(\alpha)$

2. For each topic k:
   - Choose a distribution of topic words $\Phi^t_k \sim Dirichlet(\alpha)$
   - For each sentiment s of topic k:
     - Choose a distribution of sentiment words $\Phi^o_{k,s} \sim Dirichlet(\lambda)$

Table 1: Notations in TSLDA

Notation	Definition
α, β, γ, λ	Dirichlet prior vectors
K	# of topics
S	# of sentiments
Φ^b	distribution over background words
Φ^t	distribution over topic words
Φ^o	distribution over sentiment words
D	# of documents
M_d	# of sentences in document d
$N_{d,m}$	# of words in sentence m in document d
θ^t_d	topic distribution for document d
θ^o_d	sentiment distribution for document d
$z^t_{d,m}$	topic assignment for sentence m in document d
$z^o_{d,m}$	sentiment assignment for sentence m in document d
$w_{d,m,n}$	n^{th} word in sentence m in document d
$c_{d,m,n}$	n^{th} word's category (background, topic or sentiment) in sentence m in document d

3. For each document d:
   - Choose a topic distribution $\theta^t_d \sim Dirichlet(\beta)$
   - Choose a sentiment distribution $\theta^o_d \sim Dirichlet(\gamma)$
   - For each sentence m:
     - Choose a topic assignment $z^t_{d,m} \sim Multinomial(\theta^t_d)$
     - Choose a sentiment assignment $z^o_{d,m} \sim Multinomial(\theta^o_d)$
     - For each word in the sentence:
       - ∗ Choose a word $w_{d,m,n}$ as in Equation (1).

$$w_{d,m,n} \sim \begin{cases} Multinomial(\Phi^b) & \text{if } c_{d,m,n} = 0 \\ Multinomial(\Phi^t_{z^t_{d,m}}) & \text{if } c_{d,m,n} = 1 \\ Multinomial(\Phi^o_{z^t_{d,m}, z^o_{d,m}}) & \text{if } c_{d,m,n} = 2 \end{cases} \tag{1}$$

We will define some notations for explanation of our method. $W^{k,s}_{d,m,v,c}$ is the number of times the word v with the category c appears in the sentence m in the document d, where m discusses the topic k and the sentiment s. Let $Z^{k,s}_d$ be the number of times the document d has the topic k and the sentiment s. If any of these dimensions is not limited to a specific value, we used an asterisk $*$ to denote it. For example, $W_{*,*,v,c}^{k,s}$ is the number of appearance of combination (v, c, k, s) in any sentences in any documents. Similarly, $Z_d^{k,*}$ is the number of times the document d has the topic k with any sentiments.

A bold-font variable denotes the list of the variables. For instance, $\boldsymbol{z^t}$ and $\boldsymbol{w}$ denote all of topic assignments and words in all documents, respectively.

$-(d, m)$ stands for exclusion of the value in the sentence m in the document d. For example, $\boldsymbol{z^t}_{\boldsymbol{-(d,m)}}$ denotes all of topic assignment variables $\boldsymbol{z^t}$ but $z_{d,m}^t$. $Z_d^{a,*-(d,m)}$ denotes the value of $Z_d^{a,*}$ not counting times at the sentence m in the document d.

We used square brackets for specifying the value at the index of a vector or distribution. For instance, $\alpha[v]$ denotes the value of α at index v.

Collapsed Gibbs Sampling was implemented for inference in TSLDA. It will sequentially sample hidden variables $z_{d,m}^t$ and $z_{d,m}^o$ from the distribution over these variables given the current values of all other hidden and observed variables. In other words, in order to perform Collapsed Gibbs Sampling, conditional probability $P(z_{d,m}^t = a, z_{d,m}^o = b | \boldsymbol{z^t}_{\boldsymbol{-(d,m)}}, \boldsymbol{z^o}_{\boldsymbol{-(d,m)}}, \boldsymbol{w}, \boldsymbol{c})$ is calculated by marginalizing out random variables Φ^b, $\boldsymbol{\Phi^t}$, $\boldsymbol{\Phi^o}$, $\boldsymbol{\theta^t}$ and $\boldsymbol{\theta^o}$. Because of the limit of spaces, we only show the final formula of this conditional probability as in Equation (2). Let $V_{d,m}$ be a set of words in the sentence m in the document d. V is a set of all of the words in all documents.

$$
\begin{aligned}
&P(z_{d,m}^t = a, z_{d,m}^o = b | \boldsymbol{z^t}_{\boldsymbol{-(d,m)}}, \boldsymbol{z^o}_{\boldsymbol{-(d,m)}}, \boldsymbol{w}, \boldsymbol{c},) \\
&\propto (Z_d^{a,*-(d,m)} + \beta[a])(Z_d^{*,b-(d,m)} + \gamma[b]) \\
&\times \frac{\prod_{v=1}^{V_{d,m}} \prod_{j=1}^{W_{d,m,v,1}^{*,*}} (W_{*,*,v,1}^{a,*-(d,m)} + \alpha[v] + j - 1)}{\prod_{j=1}^{W_{d,m,*,1}^{*,*}} (\sum_{v=1}^{V} W_{*,*,v,1}^{a,*-(d,m)} + \alpha[v] + j - 1)} \\
&\times \frac{\prod_{v=1}^{V_{d,m}} \prod_{j=1}^{W_{d,m,v,2}^{*,*}} (W_{*,*,v,2}^{a,b-(d,m)} + \lambda[v] + j - 1)}{\prod_{j=1}^{W_{d,m,*,2}^{*,*}} (\sum_{v=1}^{V} W_{*,*,v,2}^{a,b-(d,m)} + \lambda[v] + j - 1)}
\end{aligned}
\tag{2}
$$

Multinomial parameters: Finally, samples obtained from Collapsed Gibbs Sampling can be used to approximate the multinomial parameter sets. The distributions of topics and sentiments in the document d are estimated as in Equation (3).

$$
\theta_d^t[a] = \frac{Z_d^{a,*} + \beta[a]}{\sum_{k=1}^{K} Z_d^{k,*} + \beta[k]}; \ \theta_d^o[b] = \frac{Z_d^{*,b} + \gamma[b]}{\sum_{s=1}^{S} Z_d^{*,s} + \gamma[s]}
\tag{3}
$$

The background word distribution, topic word distribution of the topic k and sentiment word distribution of the sentiment s for k are estimated in Equation (4), (5) and (6), respectively.

$$
\Phi^b[r] = \frac{W_{*,*,r,0}^{*,*} + \alpha[r]}{\sum_{v=1}^{V} W_{*,*,v,0}^{*,*} + \alpha[v]}
\tag{4}
$$

$$
\Phi_k^t[r] = \frac{W_{*,*,v,1}^{k,*} + \alpha[r]}{\sum_{v=1}^{V} W_{*,*,v,1}^{k,*} + \alpha[v]}
\tag{5}
$$

$$
\Phi_{k,s}^o[r] = \frac{W_{*,*,v,2}^{k,s} + \lambda[r]}{\sum_{v=1}^{V} W_{*,*,v,2}^{k,s} + \lambda[v]}
\tag{6}
$$

4 Dataset

Two datasets are used for the development of our stock prediction model. One is the historical price dataset, and the other is the message board dataset.

4.1 Historical Price Dataset

Historical prices are extracted from Yahoo Finance for 5 stocks. The list of the stock quotes and company names is shown in Table 2. For each transaction date, there are open, high, low, close and adjusted close prices. The adjusted close prices are the close prices which are adjusted for dividends and splits. They are often used for stock market prediction as in other researches (Rechenthin et al., 2013). Therefore, we chose it as the stock price value for each transaction date.

4.2 Message Board Dataset

To get the mood information of the stocks, we collected 5 message boards of the 5 stocks from Yahoo Finance Message Board for a period of one year (from July 23, 2012 to July 19, 2013). On the message boards, users usually discuss company

Table 2: Statistics of Our Dataset

Stocks	Company Names	#Documents
XOM	Exxon Mobil Corporation	11027
DELL	Dell Inc.	10339
EBAY	eBay Inc.	7168
IBM	International Business Machines Corporation	5008
KO	The Coca-Cola Company	2024

news, prediction about stock going up or down, facts, comments (usually negative) about specific company executives or company events. The stock market is not opened at the weekend and holiday. To assign the messages to the transaction dates, the messages which were posted from 4 pm of the previous transaction date to 4 pm of the current transaction date will belong to the current transaction. We choose 4 pm because it is the time of closing transaction. There are 249 transaction dates in the one year period in our dataset.

5 Stock Prediction Models with Sentiment Analysis

This paper focuses on prediction of not the stock price but movement of it. That is, our goal is to develop a model that predicts if the stock price goes up or down. Support Vector Machine (SVM) has long been recognized as being able to efficiently handle high dimensional data and has been shown to perform well on many tasks such as text classification (Joachims, 1998; Nguyen and Shirai, 2013). Therefore, we chose SVM with the linear kernel as the prediction model. Furthermore, features derived by sentiment analysis on the message board are incorporated in it. To assess the effectiveness of sentiment analysis, four sets of features are designed. The first one uses only the historical prices. The other sets include topic and sentiment features obtained by different methods. All the feature values are scaled into $[-1, 1]$ value. Table 3 summarizes our features used in the model to predict the price movement at the transaction date t. The details of each feature will be explained in the next subsections.

5.1 Price Only

In this method, only historical prices are used to predict the stock movement. The purpose of this method is to investigate whether there are patterns of the price movement in the history of the stock. In addition, it is a baseline for evaluation of the effectiveness of the sentiment features. Features used for training SVM are $price_{t-1}$ and $price_{t-2}$ which are the price movements (up, down) at the transaction dates $t-1, t-2$, respectively.

Table 3: Features of the Prediction Model

Method	Features
Price Only	$price_{t-1}, price_{t-2}$
LDA-based Method	$price_{t-1}, price_{t-2}$, $lda_{i,t}, lda_{i,t-1}$
JST-based Method	$price_{t-1}, price_{t-2}$, $jst_{i,j,t}, jst_{i,j,t-1}$
TSLDA-based Method	$price_{t-1}, price_{t-2}$, $tslda_{i,j,t}, tslda_{i,j,t-1}$

5.2 LDA-based Method

In this model, we consider each message as a mixture of hidden topics. LDA is a generative probabilistic model of a corpus [1]. The basic idea is that documents are represented as random mixtures over latent topics, where each topic is characterized by a distribution over words. Hidden topics of LDA are incorporated into the prediction model as follows. First, stop words are removed from the messages, and all the words are lemmatized by Stanford CoreNLP (Manning et al., 2014). Topics are inferred by Gibbs Sampling with 1000 iterations. Next, the probability of each topic for each message is calculated. For each transaction date t, the probability of each topic is defined as the average of the probabilities of the topic in all messages posted on that transaction date.

Features used for training SVM are $price_{t-1}$, $price_{t-2}$, $lda_{i,t}$ and $lda_{i,t-1}$. $lda_{i,t}$ and $lda_{i,t-1}$ are the probabilities of the topic i ($i \in \{1, \cdots, K\}$) for the transaction dates t and $t-1$. The number of the topics K is empirically determined as explained in Subsection 6.1.

5.3 JST-based Method

When people post the message on social media to express their opinion for a given stock, they tend to talk their opinions for a given topic or aspect such as profit and dividend. They would think that the future price of the stock goes up or down by seeing pairs of topic-sentiment written by others. Following the above intuition, we propose a new feature topic-sentiment for the stock predic-

[1] We used the LDA implementation from the Mallet library.

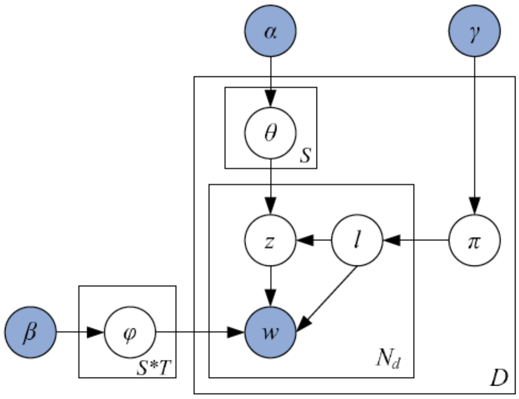

Figure 2: Graphical Model Representation of JST

Table 4: Notations in JST

Notation	**Definition**
α, β, γ	Dirichlet prior vectors
φ	distribution over words
T	# of topics
S	# of sentiments
θ	message and sentiment specific topic distribution
z	topic
w	word in the message d
l	sentiment label
π	message specific sentiment distribution
N_d	# of words in the message d
D	# of messages

tion model. Two methods are used to extract the pairs of topic-sentiment from the message board. One is a latent topic based model called JST (Lin and He, 2009). The other is TSLDA discussed in Section 3. This subsection introduces the method using the former.

We consider each message as a mixture of hidden topics and sentiments. JST model is used to extract topics and sentiments simultaneously. Figure 2 shows the graphical model representation of JST. Notations in Figure 2 are shown in Table 4. In LDA model, there is only one document specific topic distribution. In contrast, each document in JST is associated with multiple sentiment labels. Each sentiment label is associated with a document specific topic distribution. A word in the document is drawn from a distribution over words defined by the topic and sentiment label.

After removal of stop words and lemmatization, JST model is trained by Gibbs Sampling with 1000 iterations. We chose 3 as the number of sentiments which might represent negative, neutral and positive. The number of the topics K is empirically determined as explained in Subsection 6.1. Next, the joint probability of each pair of topic and sentiment is calculated for each message. For each transaction date t, the joint probability of each topic-sentiment pair is defined as the average of the joint probabilities in the messages on that transaction date. Then we integrate these probabilities into the prediction model.

Features used for training SVM are $price_{t-1}$, $price_{t-2}$, $jst_{i,j,t}$ and $jst_{i,j,t-1}$. $jst_{i,j,t}$ and $jst_{i,j,t-1}$ are the joint probabilities of the sentiment i ($i \in \{1,2,3\}$) and topic j ($j \in \{1,\cdots,K\}$) for the transaction dates t and $t-1$.

5.4 TSLDA-based Method

We use our TSLDA model to capture the topics and sentiments simultaneously. First, a rule-based algorithm is applied to identify the category of each word in the documents. Consecutive nouns are considered as topic words. If a word is not a noun and in a list of opinion words in SentiWordNet (Baccianella et al., 2010), it is considered as an opinion word. The rest of words are classified as background words.

After lemmatization, TSLDA model is trained by Collapsed Gibbs Sampling with 1000 iterations. We chose 3 as the number of sentiments which might represent for negative, neutral and positive. K (number of topics) is determined as explained in Subsection 6.1. The topic and its sentiment in each sentence are gotten from the topic assignment and sentiment assignment in TSLDA. If there is a sentence expressing the sentiment j on the topic i, we represent the tuple $(i,j) = 1$, and 0 otherwise. The proportion of (i,j) over all sentences are calculated for each message. For each transaction date, a weight of the tuple (i,j) is defined as the average of the proportions over all messages. Then we integrated the weights of the topics and their sentiments into the prediction model.

Features used for training SVM are $price_{t-1}$, $price_{t-2}$, $tslda_{i,j,t}$ and $tslda_{i,j,t-1}$. $tslda_{i,j,t}$ and $tslda_{i,j,t-1}$ are the weights of the topic i ($i \in \{1,\cdots,K\}$) with the sentiment j ($j \in \{1,2,3\}$) for the transaction dates t and $t-1$.

Table 5: Accuracies of Stock Movement Prediction

Stocks	**Price Only**	**LDA**	**JST**	**TSLDA**
XOM	0.5000	0.4464	0.5179	**0.5357**
DELL	**0.5893**	0.5357	0.5000	0.5536
EBAY	0.6071	0.6071	0.5000	**0.6429**
IBM	0.4107	0.3929	0.5357	**0.5536**
KO	0.4107	0.5179	0.4643	**0.5357**
Average	0.5036	0.5000	0.5036	**0.5643**

6 Evaluation

6.1 Experiment Setup

We divided the dataset described in Section 4 into three parts: training set from July 23, 2012 to March 31, 2013, development set from April 01, 2013 to April 30, 2013, and test set from May 01, 2013 to July 19, 2013. The label of ‘up’ and ‘down’ is assigned to each transaction date by comparing the price of the current and previous dates.

To optimize the number of topics K for each stock, we run the models with four values of K: 10, 20, 50 and 100. The best K is chosen for each stock on the development set, and the systems with the chosen K is evaluated on the test data. The performance of the prediction is measured by accuracy.

For the hyperparameters of LDA, JST and TSLDA, we simply selected symmetric Dirichlet prior vectors, that is all possible distributions are likely equal. We used the default values of these hyperparameters for LDA and JST. Concretely speaking, $\alpha = 0.5$, $\beta = 0.01$ in LDA and $\alpha = \frac{50}{\#topics}$, $\beta = 0.01$, $\gamma = 0.3$ were used in JST. For TSLDA, we set $\alpha = 0.1$, $\lambda = 0.1$, $\beta = 0.01$ and $\gamma = 0.01$.

6.2 Results

The result of each stock is shown in Table 5. In addition, the average of 5 stocks for each model is revealed in the last row of this table for easy comparison. Our model TSLDA-based method outperformed the other methods on the average of the stocks. Table 6 shows the number of true positive (TP), true negative (TN), false positive (FP) and false negative (FN) of models for the stocks. For easy comparison, the summation for these five stocks are calculated in the last row.

To assess the effectiveness of integrating mood information, we compare our TSLDA-based method with Price Only method. The results showed that the model using mood information outperformed the model without mood by 3.57%, 3.58%, 14.29% and 12.5% accuracy for XOM, EBAY, IBM and KO stock, respectively. On the other hand, the performance on DELL stock was not improved. It means that the use of the mood does not always make the performance better. The mood from social media could lead to a wrong prediction because of wrong prediction of message writers, fault information and so on. However, TSLDA was better than Price Only method on average of these stocks. In addition, TSLDA can reduce the number of FN, especially for IBM, although FP was not changed in the sum of 5 stocks. Thus, we can conclude that integrating the mood information from social media can help to predict stock price movement more precisely.

Table 6: TP, TN, FP, FN of Stock Movement Prediction

Stocks	**Metrics**	**Price Only**	**LDA**	**JST**	**TSLDA**
XOM	TP	14	13	15	18
	TN	14	12	14	12
	FP	8	10	8	10
	FN	20	21	19	16
DELL	TP	17	13	5	13
	TN	16	17	23	18
	FP	17	16	10	15
	FN	6	10	18	10
EBAY	TP	17	18	20	20
	TN	17	16	8	16
	FP	9	10	18	10
	FN	13	12	10	10
IBM	TP	15	15	7	31
	TN	8	7	23	0
	FP	17	18	2	25
	FN	16	16	24	0
KO	TP	12	14	16	10
	TN	11	15	10	20
	FP	17	13	18	8
	FN	16	14	12	18
Sum	TP	75	73	63	92
	TN	66	67	78	66
	FP	68	67	56	68
	FN	71	73	83	54

Next, let us compare the models for inferring latent topics only (LDA) and topics and sentiments (JST and TSLDA) in the stock movement prediction. The accuracy of JST-based method was better than LDA for two stocks (XOM and IBM), worse for three stocks and comparable in the average of five stocks. While, TSLDA-based method outperformed LDA and JST by 2 to 17% in the accuracy for five stocks. TSLDA was also better

Table 7: Top Words in Topics of TSLDA

aone	edit	much	government	another	receive
download	punch	next	place	report	get

than LDA and JST on average as shown in Table 5. The improvement of the accuracy was derived by increase of TP and decrease of FN. These results indicate that (1) our idea to use both latent topics and sentiments as the features is effective, (2) TSLDA is more appropriate model than JST in stock movement prediction.

Table 7 shows examples of highly associated words of some topics for stock KO (Coca-Cola Company) in TSLDA. For example, ‘split’, ‘stock’ and ‘share’ are words highly associated with the hidden topic 2, and ‘drink’, ‘coke’ and ‘water’ are highly associated with the topic 3. The first five hidden topics in Table 7 may represent the management, stock market trading, product, customer care service, competitors of the company, while the last one indicates macroeconomic factors. Table 8 shows examples of highly associated words of three sentiments of the hidden topic 1 and 2. For the hidden topic 1, ‘growth’, ‘strong’, ‘solid’ etc. are the words highly associated with the hidden sentiment 3 (which may corresponds to positive class), while ‘old’, ‘tired’, ‘unreal’ etc. with the hidden sentiment 1 (may be negative). In general, however, it is rather difficult to interpret the meaning of the hidden sentiment because the sentiments have many dimensions such as happy, anger, sad, vital and so on. We also found that the words with high probabilities in the background distribution were the stop words, punctuations, function words, messy characters written in social media, e.g. ‘.’, ‘the’, ‘and’, ‘you’, ‘$’, ‘for’ and ‘?’.

Table 9 shows top words in some joint sentiment topic distributions of JST model for stock KO. For example, ‘yahoo’, ‘ko’ and ‘finance’ are highly associated with the distribution defined by hidden sentiment 1 and hidden topic 1. However, it is rather difficult to guess which sentiment or topic in this joint distribution actually means.

7 Conclusion

This paper presents the method to infer the topics and their sentiments on the documents and use them for prediction of the stock movement. The results of the experiments show the effectiveness of our proposed TSLDA-based method. Although 56% accuracy of our method is not so high, it can be satisfying results as regarded in the previous papers. Another advantage of the paper is the evaluation by the large scale experiment (five stocks, three month transaction dates in the test set).

The drawback of TSLDA is that we have to specify the number of topics and sentiment beforehand. To overcome it, TSLDA should be extended as a non-parametric topic model estimating the number of topics inherent in the data. This will be done in our future work.

Abstract

Recursive neural network is one of the most successful deep learning models for natural language processing due to the compositional nature of text. The model recursively composes the vector of a parent phrase from those of child words or phrases, with a key component named composition function. Although a variety of composition functions have been proposed, the syntactic information has not been fully encoded in the composition process. We propose two models, **T**ag **G**uided RNN (TG-RNN for short) which chooses a composition function according to the part-of-speech tag of a phrase, and **T**ag **E**mbedded RNN/RNTN (TE-RNN/RNTN for short) which learns tag embeddings and then combines tag and word embeddings together. In the fine-grained sentiment classification, experiment results show the proposed models obtain remarkable improvement: TG-RNN/TE-RNN obtain remarkable improvement over baselines, TE-RNTN obtains the second best result among all the top performing models, and all the proposed models have much less parameters/complexity than their counterparts.

1 Introduction

Among a variety of deep learning models for natural language processing, Recursive Neural Network (RNN) may be one of the most popular models. Thanks to the compositional nature of natural text, recursive neural network utilizes the recursive structure of the input such as a phrase or sentence, and has shown to be very effective for many natural language processing tasks including semantic relationship classification (Socher et al., 2012), syntactic parsing (Socher et al., 2013a), sentiment analysis (Socher et al., 2013b), and machine translation (Li et al., 2013).

The key component of RNN and its variants is the composition function: how to compose the vector representation for a longer text from the vector of its child words or phrases. For instance, as shown in Figure 2, the vector of *'is very interesting'* can be composed from the vector of the left node *'is'* and that of the right node *'very interesting'*. It's worth to mention again, the composition process is conducted with the syntactic structure of the text, making RNN more interpretable than other deep learning models.

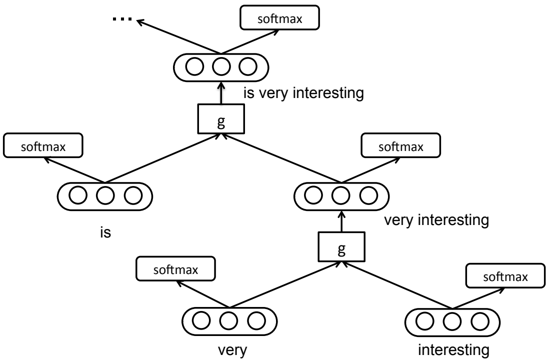

Figure 1: The example process of vector composition in RNN. The vector of node *'very interesting'* is composed from the vectors of node *'very'* and node *'interesting'*. Similarly, the node *'is very interesting'* is composed from the phrase node *'very interesting'* and the word node *'is'* .

There are various attempts to design the composition function in RNN (or related models). In RNN (Socher et al., 2011), a global matrix is used to linearly combine the elements of vectors. In RNTN (Socher et al., 2013b), a global tensor is used to compute the tensor products of dimensions to favor the association between different el-

ements of the vectors. Sometimes it is challenging to find a single function to model the composition process. As an alternative, multiple composition functions can be used. For instance, in MV-RNN (Socher et al., 2012), different matrices is designed for different words though the model is suffered from too much parameters. In AdaMC RNN/RNTN (Dong et al., 2014), a fixed number of composition functions is linearly combined and the weight for each function is adaptively learned.

In spite of the success of RNN and its variants, the syntactic knowledge of the text is not yet fully employed in these models. Two ideas are motivated by the example shown in Figure 2: **First**, the composition function for the noun phrase *'the movie/NP'* should be different from that for the adjective phrase *'very interesting/ADJP'* since the two phrases are quite syntactically different. More specifically to sentiment analysis, a noun phrase is much less likely to express sentiment than an adjective phrase. There are two notable works mentioned here: (Socher et al., 2013a) presented to combine the parsing and composition processes, but the purpose is for parsing; (Hermann and Blunsom, 2013) designed composition functions according to the combinatory rules and categories in CCG grammar, however, only marginal improvement against Naive Bayes was reported. Our proposed model, *tag guided RNN (TG-RNN)*, is designed to use the syntactic tag of the parent phrase to guide the composition process from the child nodes. As an example, we design a function for composing noun phrase (*NP*) and another one for adjective phrase (*ADJP*). This simple strategy obtains remarkable improvements against strong baselines.

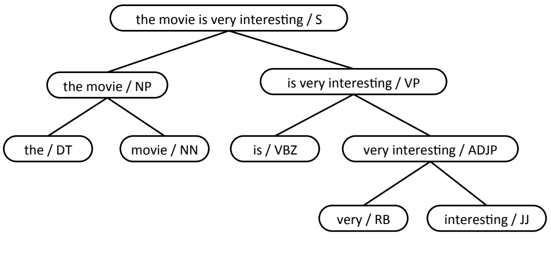

Figure 2: The parse tree for sentence *'The movie is very interesting'* built by Stanford Parser.

Second, when composing the adjective phrase *'very interesting/ADJP'* from the left node *'very/RB'* and the right node *'interesting/JJ'*, the right node is obviously more important than the left one. Furthermore, the right node *'interesting/JJ'* apparently contributes more to sentiment expression. To address this issue, we propose *Tag embedded RNN/RNTN (TE-RNN/RNTN)*, to learn an embedding vector for each word/phrase tag, and concatenate the tag vector with the word/phrase vector as input to the composition function. For instance, we have tag vectors for *DT,NN,RB,JJ,ADJP,NP, etc.* and the tag vectors are then used in composing the parent's vector. The proposed *TE-RNTN* obtain the second best result among all the top performing models but with much less parameters and complexity. To the best of our knowledge, this is the first time that tag embedding is proposed.

To summarize, the contributions of our work are as follows:

- We propose tag-guided composition functions in recursive neural network, TG-RNN. Tag-guided RNN allocates a composition function for a phrase according to the part-of-speech tag of the phrase.
- We propose to learn embedding vectors for part-of-speech tags of words/phrases, and integrate the tag embeddings in RNN and RNTN respectively. The two models, TE-RNN and TE-RNTN, can leverage the syntactic information of child nodes when generating the vector of parent nodes.
- The proposed models are efficient and effective. The scale of the parameters is well controlled. Experimental results on the Stanford Sentiment Treebank corpus show the effectiveness of the models. TE-RNTN obtains the second best result among all publicly reported approaches, but with much less parameters and complexity.

The rest of the paper is structured as follows: in Section 2, we survey related work. In Section 3, we introduce the traditional recursive neural network as background. We present our ideas in Section 4. The experiments are introduced in Section 5. We summarize the work in Section 6.

2 Related Work

Different kinds of representations are used in sentiment analysis. Traditionally, the bag-of-words representations are used for sentiment analysis (Pang and Lee, 2008). To exploit the relationship between words, word co-occurrence (Turney et al., 2010) and syntactic contexts (Padó and Lapata, 2007) are considered. In order to distinguish antonyms with similar contexts, neural word vectors (Bengio et al., 2003) are proposed and can be learnt in an unsupervised manner. Word2vec (Mikolov et al., 2013a) introduces a simpler network structure making computation more efficiently and makes billions of samples feasible for training.

Semantic composition deals with representing a longer text from its shorter components, which is extensively studied recently. In many previous works, a phrase vector is usually obtained by average (Landauer and Dumais, 1997), addition, element-wise multiplication (Mitchell and Lapata, 2008) or tensor product (Smolensky, 1990) of word vectors. In addition to using vector representations, matrices can also be used to represent phrases and the composition process can be done through matrix multiplication (Rudolph and Giesbrecht, 2010; Yessenalina and Cardie, 2011).

Recursive neural models utilize the recursive structure (usually a parse tree) of a phrase or sentence for semantic composition. In Recursive Neural Network (Socher et al., 2011), the tree with the least reconstruction error is built and the vectors for interior nodes is composed by a global matrix. Matrix-Vector Recursive Neural Network (MV-RNN) (Socher et al., 2012) assigns matrices for every words so that it could capture the relationship between two children. In Recursive Neural Tensor Networks (RNTN) (Socher et al., 2013b), the composition process is performed on a parse tree in which every node is annotated with fine-grained sentiment labels, and a global tensor is used for composition. Adaptive Multi-Compositionality (Dong et al., 2014) uses multiple weighted composition matrices instead of sharing a single matrix.

The employment of syntactic information in RNN is still in its infant. In (Socher et al., 2013a), the part-of-speech tag of child nodes is considered in combining the processes of both composition and parsing. The main purpose is for better parsing by employing RNN, but it is not designed for sentiment analysis. In (Hermann and Blunsom, 2013), the authors designed composition functions according to the combinatory rules and categories in CCG grammar. However, only marginal improvement against Naive Bayes was reported. Unlike (Hermann and Blunsom, 2013), our TG-RNN obtains remarkable improvements against strong baselines, and we are the first to propose tag embedded RNTN which obtains the second best result among all reported approaches.

3 Background: Recursive Neural Models

In recursive neural models, the vector of a longer text (e.g., sentence) is composed from those of its shorter components (e.g., words or phrases). To compose a sentence vector through word/phrase vectors, a binary parse tree has to be built with a parser. The leaf nodes represent words and interior nodes represent phrases. Vectors of interior nodes are computed recursively by composition of child nodes' vectors. Specially, the root vector is regarded as the sentence representation. The composition process is shown in Figure 1.

More formally, vector $v_i \in R^d$ for node i is calculated via:

$$v_i = f(g(v_i^l, v_i^r)) \tag{1}$$

where v_i^l and v_i^r are child vectors, g is a composition function, and f is a nonlinearity function, usually *tanh*. Different recursive neural models mainly differ in composition function. For example, the composition function for RNN is as below:

$$g(v_i^l, v_i^r) = W \begin{bmatrix} v_i^l \\ v_i^r \end{bmatrix} + b \tag{2}$$

where $W \in R^{d \times 2d}$ is a composition matrix and b is a bias vector. And the composition function for RNTN is as follows:

$$g(v_i^l, v_i^r) = \begin{bmatrix} v_i^l \\ v_i^r \end{bmatrix} T^{[1:d]} \begin{bmatrix} v_i^l \\ v_i^r \end{bmatrix} + W \begin{bmatrix} v_i^l \\ v_i^r \end{bmatrix} + b \tag{3}$$

where W and b are defined in the previous model and $T^{[1:d]} \in R^{2d \times 2d \times d}$ is the tensor that defines multiple bilinear forms.

The vectors are used as feature inputs to a softmax classifier. The posterior probability over class labels on a node vector v_i is given by

$$y_i = \text{softmax}(W_s v_i + b_s). \tag{4}$$

The parameters in these models include the word table L, a composition matrix W in RNN, and W and $T^{[1:d]}$ in RNTN, and the classification matrix W_s for the softmax classifier.

4 Incorporating Syntactic Knowledge into Recursive Neural Model

The central idea of the paper is inspired by the fact that words/phrases of different part-of-speech tags play different roles in semantic composition. As discussed in the introduction, a noun phrase (e.g., *a movie/NP*) may be composed different from a verb phrase (e.g., *love movie/VP*). Furthermore, when composing the phrase *a movie/NP*, the two child words, *a/DT* and *movie/NN*, may play different roles in the composition process. Unfortunately, the previous RNN models neglect such syntactic information, though the models do employ the parsing structure of a sentence.

We have two approaches to improve the composition process by leveraging tags on parent nodes and child nodes. One approach is to use different composition matrices for parent nodes with different tags so that the composition process could be guided by phrase type, for example, the matrix for *'NP'* is different from that for *'VP'* . The other approach is to introduce 'tag embedding' for words and phrases, for example, to learn tag vectors for *'NP, VP, ADJP',* etc., and then integrate the tag vectors with the word/phrase vectors during the composition process.

4.1 Tag Guided RNN (TG-RNN)

We propose Tag Guided RNN (TG-RNN) to respect the tag of a parent phrase during the composition process. The model chooses a composition function according to the part-of-speech tag of a phrase. For example, *'the movie'* has tag *NP*, *'very interesting'* has tag *ADJP*, the two phrases have different composition matrices.

More formally, we design composition functions g with a factor of the phrase tag of a parent node. The composition function becomes

$$g(t_i, v_i^l, v_i^r) = g_{t_i}(v_i^l, v_i^r) = W_{t_i} \begin{bmatrix} v_i^l \\ v_i^r \end{bmatrix} + b_{t_i} \quad (5)$$

where t_i is the phrase tag for node i, W_{t_i} and b_{t_i} are the parameters of function g_{t_i}, as defined in Equation 2. In other words, phrase nodes with various tags have their own composition functions such as g_{NP}, g_{VP}, and so on. There are totally k composition function in this model where k is the number of phrase tags. When composing child vectors, a function is chosen from the function pool according to the tag of the parent node. The process is depicted in Figure 3. We term this model Tag guided RNN, TG-RNN for short.

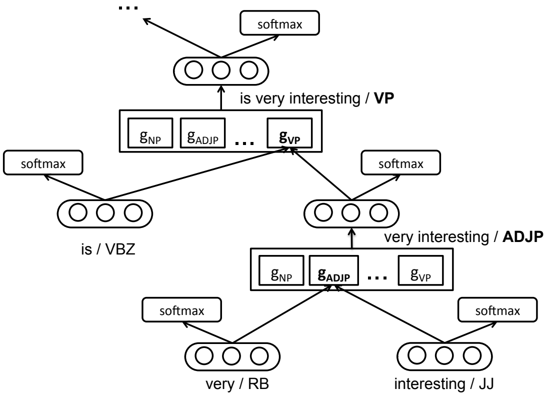

Figure 3: The vector of phrase *'very interesting'* is composed with highlighted g_{ADJP} and *'is very interesting'* with g_{VP}.

But some tags have few occurrences in the corpus. It is hard and meaningless to train composition functions for those infrequent tags. So we simply choose top k frequent tags and train k composition functions. A common composition function is shared across phrases with all infrequent tags. The value of k depends on the size of the training set and the occurrences of each tag. Specially, when $k = 0$, the model is the same as the traditional RNN.

4.2 Tag Embedded RNN and RNTN (TE-RNN/RNTN)

In this section, we propose tag embedded RNN (TE-RNN) and tag embedded RNTN (TE-RNTN) to respect the part-of-speech tags of child nodes during composition. As mentioned above, tags of parent nodes have impact on composition. However, some phrases with the same tag should be composed in different ways. For example, *'is interesting'* and *'like swimming'* have the same tag *VP*. But it is not reasonable to compose the two phrases using the previous model because the part-of-speech tags of their children are quite different. If we use different composition functions for children with different tags like TG-RNN, the number of tag pairs will amount to as many as $k \times k$, which makes the models infeasible due to too many parameters.

In order to capture the compositional effects of the tags of child nodes, an embedding $e_t \in R^{d_e}$ is created for every tag t, where d_e is the dimension of tag vector. The tag vector and phrase vector are concatenated during composition as illustrated in Figure 4.

Formally, the phrase vector is composed by the function

$$g(v_i^l, e_{t_i^l}, v_i^r, e_{t_i^r}) = W \begin{bmatrix} v_i^l \\ e_{t_i^l} \\ v_i^r \\ e_{t_i^r} \end{bmatrix} + b \tag{6}$$

where t_i^l and t_i^r are tags of the left and the right nodes respectively, $e_{t_i^l}$ and $e_{t_i^r}$ are tag vectors, and $W \in R^{d\times(2d_e+2d)}$ is the composition matrix. We term this model Tag embedded RNN, TE-RNN for short.

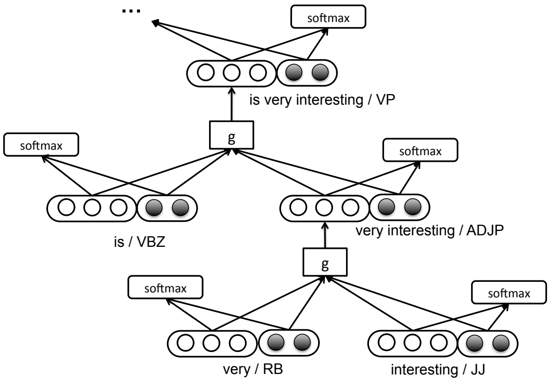

Figure 4: RNN with tag embedding. There is a tag embedding table, storing vectors for *RB*, *JJ*, and *ADJP*, etc. Then we compose the phrase vector *'very interesting'* from the vectors for *'very'* and *'interesting'*, and the tag vectors for *RB* and *JJ*.

Similarly, this idea can be applied to Recursive Neural Tensor Network (Socher et al., 2013b). In RNTN, the tag vector and the phrase vector can be interweaved together through a tensor. More specifically, the phrase vectors and tag vectors are multiplied by the composed tensor. The composition function changes to the following:

$$g(v_i^l, e_{t_i^l}, v_i^r, e_{t_i^r}) = \begin{bmatrix} v_i^l \\ e_{t_i^l} \\ v_i^r \\ e_{t_i^r} \end{bmatrix} T^{[1:d]} \begin{bmatrix} v_i^l \\ e_{t_i^l} \\ v_i^r \\ e_{t_i^r} \end{bmatrix} + W \begin{bmatrix} v_i^l \\ e_{t_i^l} \\ v_i^r \\ e_{t_i^r} \end{bmatrix} + b \tag{7}$$

where the variables are similar to those defined in equation 3 and equation 7. We term this model Tag embedded RNTN, TE-RNTN for short.

The phrase vectors and tag vectors are used as input to a softmax classifier, giving the posterior probability over labels via

$$y_i = \text{softmax}(W_s \begin{bmatrix} v_i \\ e_{t_i} \end{bmatrix} + b_s) \tag{8}$$

4.3 Model Training

Let y_i be the target distribution for node i, $\hat{y}_i$ be the predicted sentiment distribution. Our goal is to minimize the cross-entropy error between y_i and $\hat{y}_i$ for all nodes. The loss function is defined as follows:

$$E(\theta) = -\sum_i \sum_j y_i^j \log \hat{y_i}^j + \lambda ||\theta||^2 \tag{9}$$

where j is the label index, λ is a L_2-regularization term, and θ is the parameter set.

Similar to RNN, the parameters for our models include word vector table L, the composition matrix W, and the sentiment classification matrix W_s. Besides, our models have some additional parameters, as discussed below:

TG-RNN: There are k composition matrices for top k frequent tags. They are defined as $W_t \in R^{k\times d\times 2d}$. The original composition matrix W is for all infrequent tags. As a result, the parameter set of TG-RNN is $\theta = (L, W, W_t, W_s)$.

TE-RNN: The parameters include the tag embedding table E, which contains all the embeddings for part-of-speech tags for words and phrases. And the size of matrix $W \in R^{d\times(2d+2d_e)}$ and the softmax classifier $W_s \in R^{N\times(d_e+d)}$. The parameter set of TE-RNN is $\theta = (L, E, W, W_s)$.

TE-RNTN: This model has one more tensor $T \in R^{(2d+2d_e)\times(2d+2d_e)\times d}$ than TE-RNN. The parameter set of TE-RNTN is $\theta = (L, E, W, T, W_s)$

5 Experiment

5.1 Dataset and Experiment Setting

We evaluate our models on Stanford Sentiment Treebank which contains fully labeled parse trees. It is built upon 10,662 reviews and each sentence has sentiment labels on each node in the parse tree. The sentiment label set is {0,1,2,3,4}, where the numbers mean *very negative*, *negative*, *neutral*, *positive*, and *very positive*, respectively. We use standard split (train: 8,544 dev: 1,101, test: 2,210) on the corpus in our experiments. In addition, we add the part-of-speech tag for each leaf node and phrase-type tag for each interior node using the latest version of Stanford Parser. Because the newer parser generated trees different from those provided in the datasets, 74/11/11 reviews in train/dev/test datasets are ignored. After removing the broken reviews, our dataset contains 10566 reviews (train: 8,470, dev: 1,090, test: 2,199).

The word vectors were pre-trained on an unlabeled corpus (about 100,000 movie reviews) by word2vec (Mikolov et al., 2013b) as initial values and the other vectors is initialized by sampling from a uniform distribution $\mathcal{U}(-\epsilon, \epsilon)$ where ϵ is 0.01 in our experiments. The dimension of word vectors is 25 for RNN models and 20 for RNTN models. *Tanh* is chosen as the nonlinearity function. And after computing the output of node i with $v_i = f(g(v_i^l, v_i^r))$, we set $v_i = \frac{v_i}{||v_i||}$ so that the resulting vector has a limited norm. Backpropagation algorithm (Rumelhart et al., 1986) is used to compute gradients and we use minibatch SGD with momentum as the optimization method, implemented with Theano (Bastien et al., 2012). We trained all our models using stochastic gradient descent with a batch size of 30 examples, momentum of 0.9, L_2-regularization weight of 0.0001 and a constant learning rate of 0.005.

Method	Fine-grained	Pos./Neg.
SVM	40.7	79.4
MNB	41.0	81.8
bi-MNB	41.9	83.1
RNN	43.2	82.4
MV-RNN	44.4	82.9
RNTN	45.7	85.4
AdaMC-RNN	45.8	87.1
AdaMC-RNTN	46.7	88.5
DRNN	49.8	87.7
TG-RNN (ours)	47.0	86.3
TE-RNN (ours)	48.0	86.8
TE-RNTN (ours)	48.9	87.7
CNN	48.0	88.1
DCNN	48.5	86.8
Para-Vec	48.7	87.8

Table 1: Classification accuray. *Fine-grained* stands for 5-class prediction and *Pos./Neg.* means binary prediction which ignores all neutral instances. All the accuracy is at the sentence level (root).

5.2 System Comparison

We compare our models with several methods which are evaluated on the Sentiment Treebank corpus. The baseline results are reported in (Dong et al., 2014) and (Kim, 2014).

We make comparison to the following baselines:

- **SVM.** A SVM model with bag-of-words representation (Pang and Lee, 2008).
- **MNB/bi-MNB.** Multinomial Naive Bayes and its bigram variant, adopted from (Wang and Manning, 2012).
- **RNN.** The first Recursive Neural Network model proposed by (Socher et al., 2011).
- **MV-RNN.** Matrix Vector Recursive Neural Network (Socher et al., 2012) represents each word and phrase with a vector and a matrix. As reported, this model suffers from too many parameters.
- **RNTN.** Recursive Neural Tenser Network (Socher et al., 2013b) employs a tensor for composition function which could model the meaning of longer phrases and capture negation rules.
- **AdaMC.** Adaptive Multi-Compositionality for RNN and RNTN (Dong et al., 2014) trains more than one composition functions and adaptively learns the weight for each function.
- **DCNN/CNN.** Dynamic Convolutional Neural Network (Kalchbrenner et al., 2014) and a simple Convolutional Neural Network (Kim, 2014), though these models are of different genres to RNN, we include them here for fair comparison since they are among top performing approaches on this task.
- **Para-Vec.** A word2vec variant (Le and Mikolov, 2014) that encodes paragraph information into word embedding learning. A simple but very competitive model.
- **DRNN.** Deep Recursive Neural Network (Irsoy and Cardie, 2014) stacks multiple recursive layers.

The comparative results are shown in Table 1. As illustrated, **TG-RNN** outperforms RNN, RNTN, MV-RNN, AdMC-RNN/RNTN.

Compared with RNN, the fine-grained accuracy and binary accuracy of TG-RNN is improved by 3.8% and 3.9% respectively. When compared with AdaMC-RNN, the accuracy of our method rises by 1.2% on the fine-grained prediction. The results show that the syntactic knowledge does facilitate phrase vector composition in this task.

As for **TE-RNN/RNTN**, the fine-grained accuracy of TE-RNN is boosted by 4.8% compared with RNN and the accuracy of TE-RNTN by 3.2% compared with RNTN. TE-RNTN also beat the AdaMC-RNTN by 2.2% on the fine-grained classification task. TE-RNN is comparable to CNN and DCNN, another line of models for this task. TE-RNTN is better than CNN, DCNN, and Para-Vec, which are the top performing approaches on this task. TE-RNTN is worse than DRNN, but the complexity of DRNN is much higher than TE-RNTN, which will be discussed in the next section. Furthermore, TE-RNN is also better than TG-RNN. This implies that learning the tag embeddings for child nodes is more effective than simply using the tags of parent phrases in composition.

Note that the fine-grained accuracy is more convincible and reliable to compare different approaches due to the two facts: First, for the binary classification task, some approaches train another binary classifier for positive/negative classification while other approaches, like ours, directly use the fine-grained classifier for this purpose. Second, how the neutral instances are processed is quite tricky and the details are not reported in the literature. In our work, we simply remove neural instances from the test data before the evaluation. Let the 5-dimension vector y be the probabilities for each sentiment label in a test instance. The prediction will be positive if $\arg\max_{i,i\neq 2} y_i$ is greater than 2, otherwise negative, where $i \in \{0,1,2,3,4\}$ means very negative, negative, neutral, positive, very positive, respectively.

5.3 Complexity Analysis

To gain deeper understanding of the models presented in Table 1, we discuss here about the parameter scale of the RNN/RNTN models since the prediction power of neural network models is highly correlated with the number of parameters.

The analysis is presented in Table 2 (the optimal values are adopted from the cited papers). The parameters for the word table have the same size $n \times d$ across all recursive neural models, where n is the number of words and d is the dimension of word vector. Therefore, we ignore this part but focus on the parameters of composition functions, termed *model size*. Our models, TG-RNN/TE-RNN, have much less parameters than RNTN and AdMC-RNN/RNTN, but have much better performance. Although TE-RNTN is worse than DRNN, however, the parameters of DRNN are almost 9 times of ours. This indicates that DRNN is much more complex, which requires much more data and time to train. As a matter of a fact, our TE-RNTN only takes 20 epochs for training which is 10 times less than DRNN.

Method	model size	# of parameters
RNN	$2d^2$	$1.8K$
RNTN	$4d^3$	$108K$
AdaMC-RNN	$2d^2 \times c$	$18.7K$
AdaMC-RNTN	$4d^3 \times c$	$202K$
DRNN	$d \times h \times l$	
	$+2h^2 \times l$	$451K$
TG-RNN (ours)	$2d^2 \times (k+1)$	$8.8K$
TE-RNN (ours)	$2(d+d_e) \times d$	$1.7K$
TE-RNTN (ours)	$4(d+d_e)^2 \times d$	$54K$

Table 2: The model size. d is the dimension of word/phrase vectors (the optimal value is 30 for RNN & RNTN, 25 for AdaMC-RNN, 15 for AdaMC-RNTN, 300 for DRNN). For AdaMC, c is the number of composition functions (15 is the optimal setting). For DRNN, l and h is the number of layers and the width for each layer (the optimal values $l = 4$, $h = 174$). For our methods, k is the number of unshared composition matrices and d_e the dimension of tag embedding, for the optimal setting refer to Section 5.4.

5.4 Parameter Analysis

We have two key parameters to tune in our proposed models. For **TG-RNN**, the number of composition functions k is an important parameter, which corresponds to the number of distinct POS tags of phrases.

Let's start from the corpus analysis. As shown in Table 3, the corpus contains 215,154 phrases but the distribution of phrase tags is extremely imbalanced. For example, the phrase tag *'NP'* appears 60,239 times while *'NAC'* appears only 10 times. Hence, it is impossible to learn a composi-

Phrase tag	Frequency	Phrase tag	Frequency
NP	60,239	ADVP	1,140
S	33,138	PRN	976
VP	26,956	FARG	792
PP	14,979	UCP	362
ADJP	7,912	SSINV	266
SBAR	5,308	others	1,102

Table 3: The distribution of phrase-type tags in the training data. The top 6 frequency tags cover more than 95% phrases.

tion function for the infrequent phrase tags.

Each of the top k frequent phrase tags corresponds to a unique composition function, while all the other phrase tags share a same function. We compare different k for TG-RNN. The accuracy is shown in Figure 5. Our model obtains the best performance when k is 6, which is accordant with the statistics in Table 3.

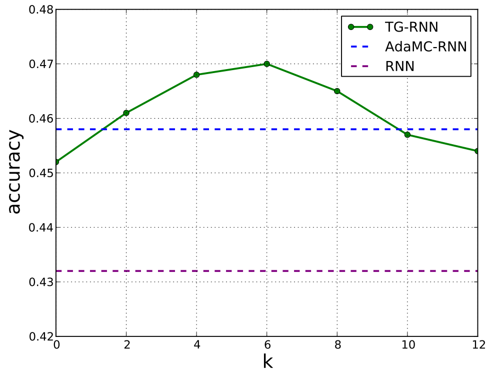

Figure 5: The accuracy for TG-RNN with different k.

For **TE-RNN/RNTN**, the key parameter to tune is the dimension of tag vectors. In the corpus, we have 70 types of tags for leaf nodes (words) and interior nodes (phrases). Infrequent tags whose frequency is less than 1,000 are ignored. There are 30 tags left and we learn an embedding for each of these frequent tags. We varies the dimension of the embedding d_e from 0 to 30.

Figure 6 shows the accuracy for TE-RNN and TE-RNTN with different dimensions of d_e. Our model obtains the best performance when d_e is 8 for TE-RNN and 6 for TE-RNTN. The results show that too small dimensions may not be sufficient to encode the syntactic information of tags and too large dimensions damage the performance.

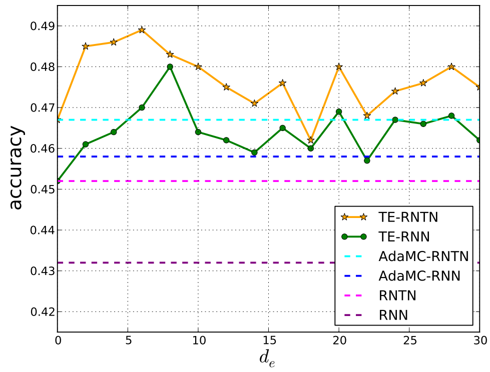

Figure 6: The accuracy for TE-RNN and TE-RNTN with different dimensions of d_e.

5.5 Tag Vectors Analysis

In order to prove tag vectors obtained from tag embedded models are meaningful, we inspect the similarity between vectors of tags. For each tag vector, we find the nearest neighbors based on Euclidean distance, summarized in Table 4.

Tag	Most Similar Tags
JJ (Adjective)	ADJP (Adjective Phrase)
VP (Verb Phrase)	VBD (past tense) VBN (past participle)
. (Dot)	: (Colon)

Table 4: Top 1 or 2 nearest neighboring tags with definition in brackets.

Adjectives and verbs are of significant importance in sentiment analysis. Although '*JJ*' and '*ADJP*' are word and phrase tag respectively, they have similar tag vectors, because of playing the same role of *Adjective* in sentences. '*VP*', '*VBD*' and '*VBN*' with similar representations all represent verbs. What is more interesting is that the nearest neighbor of dot is colon, probably because both of them are punctuation marks. Note that tag classification is none of our training objectives and surprisingly the vectors of similiar tags are clustered together, which can provides additional information during sentence composition.

6 Conclusion

In this paper, we present two ways to leverage syntactic knowledge in Recursive Neural Networks.

The first way is to use different composition functions for phrases with different tags so that the composition processing is guided by phrase types (TG-RNN). The second way is to learn tag embeddings and combine tag and word embeddings during composition (TE-RNN/RNTN). The proposed models are not only effective (w.r.t competing performance) but also efficient (w.r.t well-controlled parameter scale). Experiment results show that our models are among the top performing approaches up to date, but with much less parameters and complexity.

Abstract

In this paper, we introduce a new method for the problem of unsupervised dependency parsing. Most current approaches are based on generative models. Learning the parameters of such models relies on solving a non-convex optimization problem, thus making them sensitive to initialization. We propose a new convex formulation to the task of dependency grammar induction. Our approach is discriminative, allowing the use of different kinds of features. We describe an efficient optimization algorithm to learn the parameters of our model, based on the Frank-Wolfe algorithm. Our method can easily be generalized to other unsupervised learning problems. We evaluate our approach on ten languages belonging to four different families, showing that our method is competitive with other state-of-the-art methods.

1 Introduction

Grammar induction is an important problem in computational linguistics. Despite having recently received a lot of attention, it is still considered to be an unsolved problem. In this work, we are interested in unsupervised dependency parsing. More precisely, our goal is to induce directed dependency trees, which capture binary syntactic relations between the words of a sentence. Since our method is unsupervised, it does not have access to such syntactic structure and only take as input a corpus of words and their associated parts of speech.

Most recent approaches to unsupervised dependency parsing are based on probabilistic generative models, such as the dependency model with valence introduced by Klein and Manning (2004). Learning the parameters of such models is often done by maximizing the log-likelihood of unlabeled data, leading to a non-convex optimization problem. Thus, the performance of those methods rely heavily on the initialization, and practitioners have to find good heuristics to initialize their models.

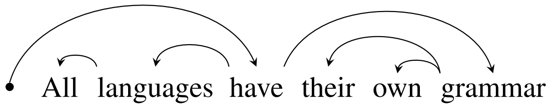

Figure 1: An example of dependency tree.

In this paper, we describe a different approach to the problem of dependency grammar induction, inspired by discriminative clustering. We propose to use a feature-rich discriminative parser, and to learn the parameters of this parser using a convex quadratic objective function. In particular, this approach also allows us to induce non-projective dependency structures. Following the work of Naseem et al. (2010), we use language-independent rules between pairs of parts-of-speech to guide our parser. More precisely, we make the following contributions:

- Our method is based on a feature-rich discriminative parser (section 3);
- Learning the parameters of our parser is achieved using a convex objective, and is thus not sensitive to initialization (section 4);
- Our method can produce non-projective dependency structures (section 3.2.2);
- We propose an efficient algorithm to optimize the objective, based on the Frank-Wolfe method (section 5);
- We evaluate our approach on the universal treebanks dataset, showing that it is competitive with the state-of-the-art (section 6).

2 Related work

A lot of research has been carried out in the last decade on dependency grammar induction. We review the dependency model with valence, on which most unsupervised dependency parsers are based, before presenting different extensions and learning algorithms. Finally, we review discriminative clustering, on which our method is based.

DMV. The dependency model with valence (DMV), introduced by Klein and Manning (2004), was the first method to outperform the baseline consisting in attaching each token to the next one. The DMV is a generative probabilistic model of the dependency tree and parts-of-speech of a sentence. It generates the root first, and then recursively generates the tokens down the tree. The probability of generating a new dependent for a given token depends on the direction (left or right) and whether a dependent was already generated in that direction. Then, the part-of-speech of the new dependent is generated according to a multinomial distribution conditioned on the direction and the head's POS.

Extensions. Several extensions of the dependency model with valence have been proposed. Headden III et al. (2009) proposed the lexicalized extended valence grammar (EVG), in which the probability of generating a POS also depends on the valence information. They rely on smoothing to tackle the increased number of parameters. Mareček and Žabokrtskỳ (2012) described an approach using a n-gram reducibility measure, which capture which words can be deleted from a sentence without making it syntactically incorrect. Cohen and Smith (2009) introduced a prior, based on the shared logistic normal distribution. This prior allowed to tie the grammar parameters corresponding to different POS belonging to the same coarse groups, such as all the POS corresponding to verbs. Berg-Kirkpatrick and Klein (2010) proposed to tie the parameters of grammars for different languages using a prior based on a phylogenetic tree. Naseem et al. (2010) proposed a set of rules between parts-of-speech, encoding *syntactic universals*, such as the fact that adjectives are often dependents of nouns. They used posterior regularization (Ganchev et al., 2010) to impose that a certain amount of the infered dependencies verifies one of these rules. Also using posterior regularization, Gillenwater et al. (2011) imposed a sparsity bias on the infered dependencies, enforcing a small number of unique dependency types. Finally, Blunsom and Cohn (2010) reformulated dependency grammar induction using tree substitution grammars, while Bisk and Hockenmaier (2013) proposed to use combinatory categorial grammars.

Learning. Different algorithms have been proposed to improve the learning of the parameters of the dependency model with valence. Smith and Eisner (2005) proposed to use constrastive estimation to learn the parameters of a log-linear parametrization of the DMV, while Spitkovsky et al. (2010b) showed that using Viterbi EM instead of classic EM leads to higher accuracy. Observing that learning from shorter sentences is easier (because less ambiguous), Spitkovsky et al. (2010a) presented different techniques to learn grammar from increasingly longer sentences. Gimpel and Smith (2012) introduced a model inspired by the IBM1 translation model for grammar induction, resulting in a concave log-likelihood function. They show that initializing the DMV with the output of their model leads to improved dependency accuracies. Hsu et al. (2012) and Parikh et al. (2014) introduced spectral methods for unsupervised dependency and constituency parsing. Finally, Spitkovsky et al. (2013) introduced different heuristics for avoiding local minima while Gormley and Eisner (2013) proposed a method to find the global optimum of non-convex problems, based on branch-and-bound.

Discriminative clustering. Our unsupervised parser is inspired by discriminative clustering, introduced by Xu et al. (2004). Given a set of points, the objective of discriminative clustering is to assign labels to these points that can be easily predicted using a discriminative classifier. Xu et al. (2004) introduced a formulation using the hinge loss, Bach and Harchaoui (2007) proposed to use the squared loss instead, while Joulin et al. (2010) proposed a formulation based on the logistic loss. Recently, a formulation based on discriminative clustering was proposed for the problem of distant supervision for relation extraction (Grave, 2014) and for the problem of finding the names of characters in TV series based on the corresponding scripts (Ramanathan et al., 2014). Closest to our approach, extensions of discriminative clustering were used to align sequences of labels or text with videos (Bojanowski et al., 2014; Bojanowski et al., 2015) or to co-localize objects in videos (Joulin et al., 2014).

3 Model

In this section, we describe the parsing model used in our approach and briefly review the corresponding decoding algorithms. Following McDonald et al. (2005b), we propose to cast the problem of dependency parsing as a maximum weight spanning tree problem in directed graphs.

3.1 Edge-based factorization

Let us start by setting up some notations. An input sentence of length n is represented by an $n-$uplet $\mathbf{x} = (x_1, ..., x_n)$. The dependency tree corresponding to that sentence is represented by a $n \times (n+1)$ binary matrix $\mathbf{y}$, such that $y_{ij} = 1$ if and only if the head of the token i is the token j (and thus, the integer $n+1$ represents the root of the tree).

In this paper, we follow a common approach by factoring the score of dependency tree as the sum of the scores of the edges forming that tree. We assume that each pair of tokens (i, j) is represented by a high-dimensional feature vector $f(\mathbf{x}, i, j) \in \mathbb{R}^d$. Then, the score s_{ij} of the edge (i, j) is obtained using the linear model

$$s_{ij} = \mathbf{w}^\top f(\mathbf{x}, i, j),$$

where $\mathbf{w} \in \mathbb{R}^d$ is a parameter vector. Thus the score s corresponding to the tree $\mathbf{y}$ is equal to

$$\begin{aligned} s &= \sum_{(i,j) \text{ s.t. } y_{ij}=1} s_{ij} \\ &= \sum_{(i,j) \text{ s.t. } y_{ij}=1} \mathbf{w}^\top f(\mathbf{x}, i, j). \end{aligned}$$

Assuming that the parameter vector $\mathbf{w}$ is known, parsing a sentence reduces to finding the tree with the highest score, which is the maximum weight spanning tree.

3.2 Maximum spanning trees

Different sets of spanning trees have been considered in the setting of supervised dependency parsing. We briefly review those sets, and describe the corresponding algorithms to compute the maximum weight spanning tree over those sets.

3.2.1 Projective dependency trees

First, we consider the set of projective spanning trees. A dependency tree is said to be projective if the dependencies do not cross when drawn above the words in linear order. Similarly, this means that word and all its descendants form a contiguous substring of the sentence. Projective dependency trees are thus strongly related to context free grammars, and it is possible to obtain the maximum weight spanning projective tree using a modified version of the CKY algorithm (Cocke and Schwartz, 1970; Kasami, 1965; Younger, 1967). The complexity of this algorithm is $O(n^5)$. This led Eisner (1996) to propose an algorithm for projective parsing which has a complexity of $O(n^3)$. Similarly to CKY, the Eisner algorithm is based on dynamic programming, parsing a sentence in a bottom-up fashion. Finally, it should be noted that the dependency model with valence, on which most approaches to dependency grammar induction are based, produces projective dependency trees.

3.2.2 Non-projective dependency trees

Second, we consider the set of non-projective spanning trees. Indeed, many languages, such as Czech or Dutch, have a significant number of non-projective edges. In the context of supervised dependency parsing, McDonald et al. (2005b) shown that using non-projective trees improves the accuracy of dependency parsers for those languages. The maximum weight spanning tree in a directed graph can be computed using the Chu-Liu/Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967), which has a complexity of $O(n^3)$. Later, Tarjan (1977) proposed an improved version of this algorithm for dense graphs, whose complexity is $O(n^2)$, the same as for undirected graphs using Prim's algorithm. Thus a second advantage of using non-projective dependency trees is the fact that it leads to more efficient parsers.

4 Learning the parameter vector

In this section, we describe the loss function we use to learn the parameter vector $\mathbf{w}$ from unlabeled sentences.

4.1 Problem formulation

From now on, $\mathbf{y}$ is a vector representing the dependency trees corresponding to the whole corpus. Thus, each index i corresponds to a potential dependency between two words of a given sentence.

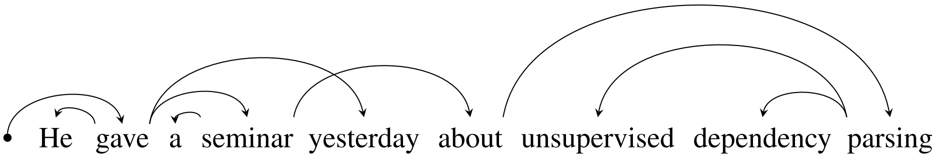

Figure 2: Example of a non-projective dependency tree in english.

Like before, $y_i = 1$ if and only if there is a dependency between those two words, and $y_i = 0$ otherwise. The set of dependencies that form valid trees is denoted by the set $\mathcal{T}$.

Inspired by the discriminative clustering framework introduced by Xu et al. (2004), our goal is to jointly find the dependencies represented by the vector $\mathbf{y}$ and the parameter vector $\mathbf{w}$ which minimize the regularized empirical risk

$$\min_{\mathbf{y}\in\mathcal{T}} \min_{\mathbf{w}} \frac{1}{n}\sum_{i=1}^{n} \ell(y_i, \mathbf{w}^\top \mathbf{x}_i) + \lambda\Omega(\mathbf{w}), \qquad (1)$$

where ℓ is a loss function and Ω is a regularizer. The intuition is that we want to find the dependency trees $\mathbf{y}$ that can be easily predicted by a discriminative parser, whose parameters are $\mathbf{w}$.

Following Bach and Harchaoui (2007), we propose to use the squared loss ℓ defined by

$$\ell(y, \hat{y}) = \frac{1}{2}(y - \hat{y})^2$$

and to use the ℓ_2-norm as a regularizer. In that case, we obtain the objective function:

$$\min_{\mathbf{y}\in\mathcal{T}} \min_{\mathbf{w}} \frac{1}{2n}\|\mathbf{y} - \mathbf{X}\mathbf{w}\|_2^2 + \frac{\lambda}{2}\|\mathbf{w}\|_2^2. \qquad (2)$$

One of the main advantages of using the squared loss is the fact that the corresponding objective function is jointly convex in $\mathbf{y}$ and $\mathbf{w}$. Indeed, the objective is the composition of an affine mapping, defined by $(\mathbf{y}, \mathbf{w}) \mapsto \mathbf{y} - \mathbf{X}\mathbf{w}$, with a convex function, defined by $\mathbf{u} \mapsto \mathbf{u}^\top\mathbf{u}$. Thus, the objective function is convex (see section 3.2.2 of Boyd and Vandenberghe (2004)). The problem (2) is thus non-convex only because of the combinatorial constraints on the binary vector $\mathbf{y}$, namely that $\mathbf{y}$ should represents valid trees.

4.2 Convex relaxation

The set $\mathcal{T}$ of vectors representing valid dependency trees is a finite set of binary vectors. We can thus take the convex hull of those points and denote it by $\mathcal{Y}$:

$$\mathcal{Y} = \text{conv}(\mathcal{T}).$$

VERB ↦ VERB	NOUN ↦ NOUN
VERB ↦ NOUN	NOUN ↦ ADJ
VERB ↦ PRON	NOUN ↦ DET
VERB ↦ ADV	NOUN ↦ NUM
VERB ↦ ADP	NOUN ↦ CONJ
ADJ ↦ ADV	ADP ↦ NOUN

Table 1: Set of universal rules used in our parser.

By definition, this set is a convex polytope. We then propose to replace the combinatorial constraints on the vector $\mathbf{y}$ by the fact that $\mathbf{y}$ should be in the convex polytope $\mathcal{Y}$. We thus obtain a convex quadratic program, with linear constraints, as follows:

$$\min_{\mathbf{y}\in\mathcal{Y}} \min_{\mathbf{w}} \frac{1}{2n}\|\mathbf{y} - \mathbf{X}\mathbf{w}\|_2^2 + \frac{\lambda}{2}\|\mathbf{w}\|_2^2. \qquad (3)$$

We will describe how to compute the optimal solution of this problem in section 5.

4.3 Rounding

Given a continuous solution $\mathbf{y}_c \in \mathcal{Y}$ of the relaxed problem, it is possible to obtain a solution of the integer problem by finding the tree $\mathbf{y}_d \in \mathcal{T}$ which is closest to $\mathbf{y}_c$, by solving the problem

$$\min_{\mathbf{y}_d\in\mathcal{T}} \|\mathbf{y}_d - \mathbf{y}_c\|_2^2.$$

The solution of the previous problem can easily be formulated is a minimum weight spanning tree problem. Indeed, by developping the previous expression, and using the fact that for all trees $\mathbf{y}_d \in \mathcal{T}$, $\mathbf{y}_d^\top \mathbf{y}_d = n$, where n is the number of tokens, the previous problem is equivalent to:

$$\min_{\mathbf{y}_d\in\mathcal{T}} -\mathbf{y}_d^\top \mathbf{y}_c,$$

whose solution is obtained using the minimum weight spanning tree algorithm. It should be noted that the rounding solution is not necessarily the optimal solution of the integer problem.

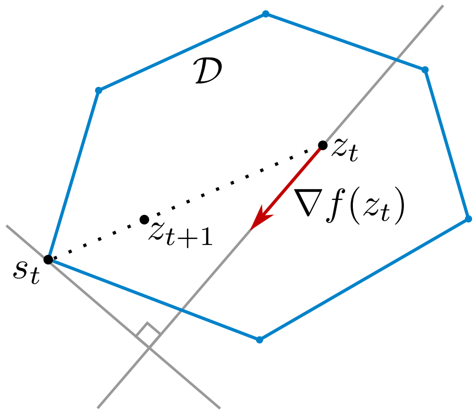

Figure 3: Illustration of a Frank-Wolfe step.

4.4 Prior on y

We now describe how to guide our unsupervised parser, by using universal rules. Following Naseem et al. (2010), we want a certain percentage of the infered dependencies to satisfy one of the twelve universal syntactic rules, listed in Table 1. Let $\mathcal{S}$ be the set of indices corresponding to word pairs that satisfy one of these rules. Then, imposing that a certain percentage c of dependencies satisfy one of those rules can be obtained by imposing the constraint:

$$\frac{1}{n}\sum_{i\in\mathcal{S}} y_i \geq c.$$

This linear constraint is equivalent to $\mathbf{u}^\top \mathbf{y} \geq c$, where the vector $\mathbf{u}$ is defined by

$$u_i = \begin{cases} 1/n & \text{if } i \in \mathcal{S}, \\ 0 & \text{otherwise.} \end{cases}$$

Using Lagrangian duality, we can obtain the following equivalent penalized problem:

$$\min_{\mathbf{y}\in\mathcal{Y}} \min_{\mathbf{w}} \frac{1}{2n}\|\mathbf{y}-\mathbf{X}\mathbf{w}\|_2^2 + \frac{\lambda}{2}\|\mathbf{w}\|_2^2 - \mu\, \mathbf{u}^\top \mathbf{y}. \quad (4)$$

The penalized and constrained problems are equivalent, since for every c, there exists a μ such that the two problems have the same optimum. From an optimization point of view, it is easier to deal with the penalized problem and we will thus use it in the next section.

5 Optimization

One could use a general purpose quadratic solver to compute the solution of the previous convex problem. However, this might be inefficient since it does not use the structure of the polytope and, in particular, the fact that one can easily minimize a linear function over the tree polytope using the minimum weight spanning tree algorithm. Instead we propose to use the Frank-Wolfe algorithm, that we now describe.

Algorithm 1: Frank-Wolfe algorithm

```
for $t \in \{1, ..., T\}$ do
    Compute the gradient:
    $g_t = \nabla f(z_t)$
    Solve the linear program:
    $s_t = \min_{s\in\mathcal{D}} s^\top g_t$
    Take the Frank-Wolfe step:
    $z_{t+1} = \gamma_t s_t + (1-\gamma_t) z_t$
end
```

5.1 Frank-Wolfe algorithm

The Frank-Wolfe algorithm (Frank and Wolfe, 1956; Jaggi, 2013) is used to minimize a convex differentiable function f over a convex bounded set $\mathcal{D}$. It is an iterative first-order optimization method. At each iteration t, the convex function f is approximated by a linear function defined by its gradient at the current point z_t. Then it finds the point s_t that minimizes that linear function, over the convex set $\mathcal{D}$:

$$s_t = \min_s s^\top \nabla f(z_t) \text{ s.t. } s \in \mathcal{D}.$$

The point z_{t+1} is then defined as the weighted average between the solution s_t and the current point z_t: $z_{t+1} = \gamma_t\, s_t + (1-\gamma_t)\, z_t$, where γ_t is the step size (such as $2/(t+2)$). Compared to the gradient descent algorithm, the Frank-Wolfe alogrithm does not take a step in the direction of the gradient, but in the direction of the point that minimizes the linear approximation of the function f over the convex set $\mathcal{D}$ (see Fig 3). In particular, this ensures that the points z_t always stay inside the convex set, and there is thus no need for a projection step.

To summarize, in order to use the Frank-Wolfe algorithm, we need to compute the gradient of the objective function and to minimize a linear function over our convex set. This is particularly appropriate to our problem, since we can easily minimize a linear function over the tree polytopes (using the minimum weight spanning tree algorithm), while projecting on those polytopes is more expensive.

Algorithm 2: Optimization algorithm for our method.

```
for $t \in \{1, ..., T\}$ do
    Compute the optimal $\mathbf{w}$:
    $\mathbf{w}_t = \operatorname*{argmin}_{\mathbf{w}} \frac{1}{2n} \|\mathbf{y}_t - \mathbf{X}\mathbf{w}\|_2^2 + \frac{\lambda}{2} \|\mathbf{w}\|_2^2$
    Compute the gradient w.r.t. $\mathbf{y}$:
    $\mathbf{g}_t = \frac{1}{n} (\mathbf{y}_t - \mathbf{X}\mathbf{w}_t) - \mu \, \mathbf{u}$
    Solve the linear program:
    $\mathbf{s}_t = \min_{\mathbf{s} \in \mathcal{Y}} \mathbf{s}^\top \mathbf{g}_t$
    Take the Frank-Wolfe step:
    $\mathbf{y}_{t+1} = \gamma_t \mathbf{s}_t + (1 - \gamma_t) \mathbf{y}_t$
end
```

5.2 Application to our problem

We now describe how to use the Frank-Wolfe algorithm to optimize our objective function with respect to $\mathbf{y}$. First, let us introduce the functions f and h defined by

$$f(\mathbf{w}, \mathbf{y}) = \frac{1}{2n} \|\mathbf{y} - \mathbf{X}\mathbf{w}\|_2^2 + \frac{\lambda}{2} \|\mathbf{w}\|_2^2 - \mu \, \mathbf{u}^\top \mathbf{y},$$
$$h(\mathbf{y}) = \min_{\mathbf{w}} f(\mathbf{w}, \mathbf{y}).$$

The original problem is equivalent to

$$\min_{\mathbf{y} \in \mathcal{Y}} \min_{\mathbf{w}} f(\mathbf{w}, \mathbf{y}) = \min_{\mathbf{y} \in \mathcal{Y}} h(\mathbf{y}).$$

We will use the Frank-Wolfe algorithm to optimize the function h.

Minimizing w.r.t w. First, we need to minimize the function f with respect to $\mathbf{w}$, in order to compute the function h (and its gradient). One must note that this is an unconstrained quadratic program, whose solution can be obtained in closed form by solving the linear system:

$$\left(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}\right) \mathbf{w} = \mathbf{X}^\top \mathbf{y}.$$

However, in case of a very large feature space, this system might be prohibitively expensive to solve exactly. We instead propose to approximately compute the optimal $\mathbf{w}$ using stochastic gradient descent.

Computing the gradient of h. Then, the gradient of the function h at the point $\mathbf{y}$ is equal to

$$\nabla h(\mathbf{y}) = \nabla_{\mathbf{y}} f(\mathbf{w}^*, \mathbf{y}),$$

where $\mathbf{w}^*$ is equal to

$$\mathbf{w}^* = \operatorname*{argmin}_{\mathbf{w}} f(\mathbf{w}, \mathbf{y}).$$

Thus, in order to compute the gradient of h with respect to $\mathbf{y}$, we start by computing the corresponding optimal value of $\mathbf{w}$. Then, the gradient with respect to $\mathbf{y}$ is equal to

$$\nabla h(\mathbf{y}) = \frac{1}{n} (\mathbf{y} - \mathbf{X}\mathbf{w}^*) - \mu \, \mathbf{u}.$$

Minimizing a linear function over $\mathcal{Y}$. We finaly need to compute the optimal solution of the following linear problem

$$\min_{\mathbf{s} \in \mathcal{Y}} \nabla h(\mathbf{y})^\top \mathbf{s}.$$

The optimal value of a linear function over a bounded convex polytope is always attained on at least one vertex of that polytope. By definition of our polytope, those vertices correspond to spanning trees. Thus, computing an optimal solution of this problem is obtained by finding a minimum weight spanning tree.

Discussion. Similarly to the Expectation-Maximization algorithm, our optimization method is a two-steps iterative algorithm. In the first step, the optimal parameter vector $\mathbf{w}$ is estimated based on the previous dependency trees, while the second step consist in re-estimating the (relaxed) dependency trees.

$\text{POS}_i \times d$
$\text{POS}_j \times d$
$\text{POS}_i \times \text{POS}_j \times d$
$\text{POS}_i \times \text{POS}_{i-1} \times \text{POS}_j \times d$
$\text{POS}_i \times \text{POS}_{i+1} \times \text{POS}_j \times d$
$\text{POS}_i \times \text{POS}_j \times \text{POS}_{j-1} \times d$
$\text{POS}_i \times \text{POS}_j \times \text{POS}_{j+1} \times d$

Table 3: Directed dependency accuracy, on the universal treebanks with universal parts-of-speech, on sentences of length 10 or less. PR refers to posterior regularization, USR to universal rules.

6.1 Features

The features used in our unsupervised parser are based on the parts-of-speech of the head and the dependent of the corresponding dependency, and are given in Table 2. Following McDonald et al. (2005a), we also include features capturing the context of the head or the dependent. These features are trigrams and are formed by the parts-of-speech of the two tokens of the dependency and one of the word appearing before/after the head/dependent. Finally, all the features are conjoined with the signed distance between the two words of the dependency.

6.2 Dataset

We use the universal treebanks, version 2.0, introduced by McDonald et al. (2013). This dataset contains dependency trees for ten languages belonging to five different families: Spanish, French, Italian, Portuguese (Romanic family), English, German, Swedish (Germanic family), Korean, Japanese and Indonesian. The tokens of those treebanks are tagged using the universal part-of-speech tagset (Petrov et al., 2012). We focus on inducing dependency grammars using universal parts-of-speech, and will thus report results where all methods use (gold) universal POS.

6.3 Comparison with baselines

We will compare our approach to three other unsupervised parsers. Our first baseline is the DMV model, introduced by Klein and Manning (2004).

DMV	PR	USR	OUR
7 min	1 h	15 h	2 min

Table 4: Computational times required to learn a grammar on the English treebank.

Our second baseline is the extended valence grammar model, with posterior sparsity constraints, as described by Gillenwater et al. (2011). Finally, our last baseline is the model with universal rules introduced by Naseem et al. (2010). It should be noted that these two baselines obtain performances that are near state-of-the-art. All methods are trained and tested on sentences of length 10 or less, after stripping punctuation.

Parameter selection. All the parameters were chosen using the English development set. Our method has two parameters, determined as: $\lambda = 0.001$ and $\mu = 0.1$. We used $T = 200$ iterations in all the experiments.

Discussion. We report the results in Table 3. First, we observe that our method performs better than the three baselines on seven out of ten languages. Overall, our approach outperforms the three baselines, with an absolute improvement of 13 points over the extended valence grammar with posterior sparsity and 8 points over the model with universal syntactic rules. We also note that the inter-language variance is lower for our method than the baselines (std of 4.6 for our method v.s. 8.3 for USR and 12.7 for PR). For the sake of completeness, we also compared those methods using the fine grained POS available in the universal treebanks. Overall, our method obtains an accuracy of 68.4, while USR and PR achieve accuracies of 67.3 and 58.5 respectively. Finally, we report computational times in Table 4, showing that our approach is much faster than the baselines.

6.4 Non-projective grammar induction

In this section, we investigate non-projective grammar induction. With our approach, we only have to replace the Eisner algorithm by Chu-Liu/Edmonds. We report results in Table 5. First, we observe that the non-projective results are slightly worse than projective one. This is not really surprising since the amount of non-projective gold dependencies is very small on the considered data. Moreover, non-projective trees are much more ambiguous than projective ones, leading to

	PROJECTIVE	NON-PROJECTIVE
DE	60.2	57.2
EN	62.3	60.5
ES	68.8	66.5
FR	72.3	69.2
ID	69.7	68.4
IT	64.3	63.1
JA	57.5	59.3
KO	59.0	60.0
PT-BR	68.3	67.7
SV	66.2	65.4
AVG	64.8	63.7

Table 5: Comparison between projective and non-projective unsupervised dependency parsing using our method.

a harder problem. We still believe those results are interesting because the difference is small (less than 1.5 points), while non-projective parsing is computationaly more efficient.

6.5 Evaluation on longer sentences

We also evaluate our method on longer sentences (while still training on sentences of length 10 or less). Directed dependency accuracies are reported in Figure 4. On all sentences, our method achieve an overall accuracy of 55.8.

6.6 Feature ablation study

In this section, we study the importance of the different features used in our parser. We report directed accuracies when different groups of features are removed, one at a time, in Table 6. First, we remove the distance information from the features (line DISTANCE). We observe that the performance of our parser is greatly affected by this ablation, especially for long sentences. Then, we remove the context features (line CONTEXT) and the unigram features (line UNIGRAM) from our model. We observe that the performance decreases slightly due to this ablations, but the differences are small.

7 Discussion

In this paper, we introduced a new framework for the task of unsupervised dependency parsing. Our method is a based on a feature-rich discriminative model, whose parameters are learned using a convex objective function. We demonstrated on the universal treebanks that our approach leads to competitive results, while being computationaly very efficient. We now describe some directions we would like to explore as future work.

	$\|\mathbf{w}\| \leq 10$	$\|\mathbf{w}\| \leq \infty$
DISTANCE	61.8	48.7
CONTEXT	64.2	55.1
UNIGRAM	64.0	55.3
ALL FEATURES	**64.8**	**55.8**

Table 6: Feature ablation study.

Richer feature set. In our experiments, we focused on assessing the usefulness of our convex, discriminative approach, and thus considered only relatively simple features based on parts-of-speech. Inspired by supervised dependency parsing, we would like to explore the use of other features such as Brown clusters (Brown et al., 1992) or distributed word representations (Mikolov et al., 2013), in order to lexicalize our parser.

Higher-order parsing. So far, our model is lacking the notion of valency, that has proven very useful for grammar induction. In future work, we would thus like to replace our edge-based factorization by a higher-order one, in order to capture siblings (and grandchilds) interactions. We would then have to use a higher-order parser, such as the ones described by McDonald and Pereira (2006) and Koo and Collins (2010). Another potential approach would be to use the linear programming relaxed inference, described by Martins et al. (2009).

Transfer learning. In this paper, we used universal syntactic rules, as described by Naseem et al. (2010) to guide our parser. We would like to explore the use of weak supervision, such as the one considered in transfer learning (Hwa et al., 2005). For example, projected dependencies from a resource-rich language could be used as constraints in our framework.

Code. The code for our method is distributed on the first author webpage.

Abstract

Syntactic annotation is a hard task, but it can be made easier by allowing annotators flexibility to leave aspects of a sentence underspecified. Unfortunately, partial annotations are not typically directly usable for training parsers. We describe a method for imputing missing dependencies from sentences that have been partially annotated using the Graph Fragment Language, such that a standard dependency parser can then be trained on all annotations. We show that this strategy improves performance over not using partial annotations for English, Chinese, Portuguese and Kinyarwanda, and that performance competitive with state-of-the-art unsupervised and weakly-supervised parsers can be reached with just a few hours of annotation.

1 Introduction

Linguistically annotated data is produced for many purposes in many contexts. It typically requires considerable effort, particularly for language documentation efforts in which tooling, data, and expertise in the language are scarce. The challenge presented by this scarcity is compounded when doing deeper analysis, such as syntactic structure, which typically requires greater expertise and existing tooling. In such scenarios, unsupervised approaches are a tempting strategy. While the performance of unsupervised dependency parsing has improved greatly since Klein and Manning's (2004) Dependency Model with Valence (DMV), state-of-the-art unsupervised parsers still perform well below supervised approaches (Martins et al., 2010; Spitkovsky et al., 2012; Blunsom and Cohn, 2010). Additionally, they typically require large amounts of raw data. While this is not a problem for some languages, many of the world's languages do not have a clean, digitized corpus available.[1] For instance, the approach of Naseem et al. (2010) is unsupervised in the sense that it requires no dependency annotations, but it still makes use of the raw version of the full Penn Treebank. The approach of Marecek et al. (2013) requires extra unlabeled texts to estimate parameters.

Another strategy is to exploit small amounts of supervision or knowledge. Naseem et al. (2010) use a set of universal dependency rules and obtain substantial gains over unsupervised methods in many languages. Spitkovsky et al. (2010b; 2011) use web mark-up and punctuation as additional annotations. Alternatively, one could try to obtain actual dependency annotations cheaply. We use the Graph Fragment Language (GFL), which was created with the goal of making annotations easier for experts and possible for novices (Schneider et al., 2013; Mordowanec et al., 2014). GFL supports partial annotations, so annotators can omit obvious dependencies or skip difficult constructions. The ability to focus on portions of a sentence frees the annotator to target constituents and dependencies that maximize information that will be most useful for machine-learned parsers. For example, Hwa (1999) found higher-level sentence constituents to be more informative for learning parsers than lower-level ones.

To support this style of annotation while getting the benefit from partial annotations, we develop a two-stage parser learning strategy. The first stage completes the partial GFL annotations by adapting a Gibbs tree sampler (Johnson et al., 2007; Sun et al., 2014). The GFL annotations constrain the tree sampling space by using both dependencies and the constituent boundaries they express. The system performs missing dependency arc imputation using Gibbs sampling – we refer to this approach

[1] In fact, standardized writing systems have yet to be adopted for some languages.

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics
and the 7th International Joint Conference on Natural Language Processing, pages 1385–1394,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

as the Gibbs Parse Completer[2] (GPC). The second stage uses the full dependencies output by the GPC to train Turbo Parser (Martins et al., 2010), and evaluation is done with this trained model on unseen sentences. In simulation experiments for English, Chinese and Portuguese, we show that the method gracefully degrades when applied to training corpora with increasing percentages of the gold training dependencies removed. We also do actual GFL annotations for those languages plus Kinyarwanda, and show that using the GPC to fill in the missing dependencies after two hours of annotation enables Turbo Parser to obtain 2-6% better absolute performance than when it has to throw incomplete annotations out. Furthermore, the gains are even greater with less annotation time and it never hurts to use the GPC—so an annotation project can pursue a partial annotation strategy without undermining the utility of the work for parser training.

This strategy has the further benefit of needing only a small number of sentences—in our case, under 100 sentences annotated in a 2-4 hour window. Furthermore, it relies on no outside tools or corpora other than a part-of-speech tagger; a resource that can be built with two hours of annotation time (Garrette and Baldridge, 2013).

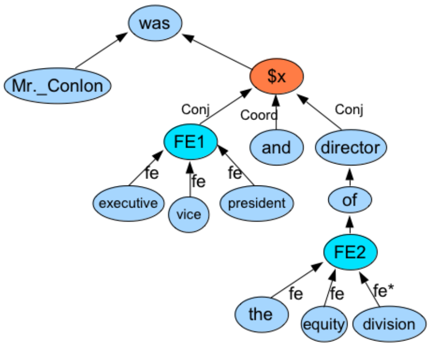
2 Data

Data sources We use four languages from three language families in an effort to both verify the cross-linguistic applicability of our approach, accounting for variations in linguistic properties, as well as to attempt to realistically simulate a real-world, low-resource environment. Our data comes from English (ENG), Chinese (CHI), Portuguese (POR), and Kinyarwanda (KIN).

For ENG we use the Penn Treebank (Marcus et al., 1993), converted into dependencies by the standard process. Section 23 was used as a test set, and a random sample of sentences from sections 02-21 were selected for annotation with GFL as described below and subsequently used as the minimal training set. For CHI we use the Chinese Treebank (CTB5) (Xue et al., 2005), also converted to dependencies. The testing set consisted of files 1-40/900-931, and the sentences presented for GFL annotation were randomly sampled from files 81-899. The POR data is from the CoNLL-X Shared Task on Multilingual Dependency Parsing and is derived from the Bosque portion of the Floresta sintá(c)tica corpus (Afonso et al., 2002), using the standard provided splits for training and testing. The KIN data is a corpus consisting of transcripts of testimonies by survivors of the Rwandan genocide, provided by the Kigali Genocide Memorial Center – this data is described by Garrette and Baldridge (2013).

```
[Mr. Conlon] > was < $x
$x :: {(executive vice president) director} :: {and}
(the equity division*) > of > director
```

(a) GFL annotation



(b) Analysis graph

Figure 1: GFL example for *Mr. Conlon was executive vice president and director of the equity division.*

GFL annotation We use a small number of sentences annotated using the Graph Fragment Language (GFL), a simple ASCII markup language for dependency grammar (Schneider et al., 2013). Unlike traditional syntactic annotation strategies requiring trained annotators and great effort, rapid GFL annotations can be collected from annotators who have minimal training. Kong et al. (2014) demonstrate the feasibility of training a dependency parser based on a GFL-annotated corpus of English tweets.

An example of GFL is shown in Figure 1: (a) is the GFL markup itself and (b) is a graphical representation of the dependencies it encodes. Figure 1 specifies several dependencies: *of* is a dependent of *director*, *executive vice president* and *director* are conjuncts and *and* is the coordinator. However, the complete internal structure of the phrase *the equity division* remains unspecified, other than *division* being marked as the head (via an asterisk).[3] Finally, *Mr. Conlon* in square brackets indicates it is a multiword expression.

[2] The software, instructions, and data are available at http://www.github.com/jmielens/gpc-acl-2015

[3] The graphical representation shows both of these as FE nodes, for *fudge expression*, indicating they are grouped together but otherwise underspecified.

CFG Rule	EVG distribution	Description
$S \to Y_H$	$P(root = H)$	The head of the sentence is H
$Y_H \to L_H R_H$	-	Split-head representation
$L_H \to H_L$	$P(STOP \mid dir = L, head = H, val = 0)$	H has no left children
$L_H \to L_H^1$	$P(CONT \mid dir = L, head = H, val = 0)$	H has at least one left child
$L'_H \to H_L$	$P(STOP \mid dir = L, head = H, val = 1)$	H has no more left children
$L'_H \to L_H^1$	$P(CONT \mid dir = L, head = H, val = 1)$	H has other left children
$L_H^1 \to Y_A L'_H$	$P(ArgA \mid dir = L, head = H, val = 1)$	A is a left child of H

Table 1: The CFG-DMV grammar schema from Klein and Manning (2004). Note that in these rules H and A are parts-of-speech. For brevity, we omit the portion of the grammar that handles the right-hand arguments since they are symmetric to the left. Valency (val) can take the value 1 (we have made attachments in the direction (dir) d) or 0 (not).

	CHI	ENG	KIN	POR
Sentences Annotated	24	34	69	63
Tokens Annotated	820	798	988	1067
Fully Specified Sentences	4	15	31	20

Table 2: Two Hour GFL Annotation Statistics

Kong et al. (2014) stipulate that the GFL annotations in their corpus must be fully-specified. They are thus unable to take advantage of such underspecified sentences, and we address that limitation in this paper. From the GFL annotations we can extract and deduce dependency arcs and constraints (see Section 3.2 for full details) in order to guide the Gibbs sampling process.

Time-bounded annotation As described in Section 1, a primary goal of this work was to consider the time in which a useful number of dependency tree annotations might be collected, such as might be required during the initial phase of a language documentation project or corpus build. To this end our annotators were operating under a strict two hour time limit. We also collected two further hours for English.

The annotators were instructed to annotate as many sentences as possible in the two hours, and that they should liberally use underspecification, especially for particularly difficult sequences in a given sentence. This was done to facilitate the availability of partial annotations for experimentation. All of the annotators had some previous experience providing GFL annotations, so no training period was needed. Annotation was done in 30-minute blocks, to provide short breaks for the annotators and so that learning curves could be generated. Each language was annotated by a single annotator. The ENG and CHI annotators were native speakers of their annotation language, while the POR and KIN annotators were non-native though proficient speakers.

The annotators achieved rates of 400-500 tokens/hr, whereas we find rates of 150-200 tokens/hr more typical when annotators are asked to fully specify. Requiring full specification also introduces more errors in cases of annotator uncertainty.

Table 2 shows the size of the GFL corpora that were created. Typically, over 50% of the sentences were not fully specified—the partial annotations provided in these are useless to Turbo Parser unless the missing dependencies are imputed.

3 Gibbs Parse Completer (GPC)

3.1 Gibbs sampler for CFG-DMV Model

CFG-DMV model The GPC is based on the DMV model, a generative model for the unsupervised learning of dependency structures (Klein and Manning, 2004). We denote the input corpus as $\boldsymbol{\omega} = (\boldsymbol{\omega}^{\mathbf{1}}, \cdots, \boldsymbol{\omega}^{\boldsymbol{N}})$, where each $\boldsymbol{\omega}^{\boldsymbol{s}}$ is a sentence consisting of words and in a sentence $\boldsymbol{\omega}$, word ω_i has an corresponding part-of-speech tag τ_i. We denote the set of all words as V_ω and the set of all parts-of-speech as V_τ. We use the part-of-speech sequence as our terminal strings, resulting in an unlexicalized grammar. Dependencies can be formulated as split head bilexical context free grammars (CFGs) (Eisner and Satta, 1999) and these bilexical CFGs require that each terminal τ_i in sentence $\boldsymbol{\omega}$ is represented in a split form by two terminals, with labels marking the left and right heads ($\tau_{i,L}$, $\tau_{i,R}$). Henceforth, we denote $\boldsymbol{w} = w_{0,n}$ as our terminals in the split-form of sentence $\boldsymbol{\omega}$ (e.g., the terminals for *the dog walks* are DT_L DT_R NN_L NN_R V_L V_R). Table 1 shows the grammar rules for the DMV model, from Klein and Manning (2004).

```
Require: $A$ is parent node of binary rule; $w_{i,k}$ is a valid span of terminals and $i+1<k$
function TREESAMPLER($A, i, k$)
    for $i < j < k$ and pair of child nodes of $A$:$B, C$ do
        $P(j,B,C) = \frac{\theta^w_{A\to BC} c(i,j)c(j,k)\cdot p_{B,i,j}\cdot p_{C,j,k}}{p_{A,i,k}}$
    end forSample $j*, B*, C*$ from multinomial distribution for $(j,B,C)$ with probabilities calculated above
    return $j*, B*, C*$
end function
```

Algorithm 2: Modifying Rule Probabilities for w to ensure parse tree contains all directed arcs.

Gibbs sampler The split-head representation encodes dependencies as a CFG. This enables the use of a Gibbs sampler algorithm for estimating PCFGs (Johnson et al., 2007; Sun et al., 2014), and it is straightforward to incorporate constraints from partial annotations into this sampler. To do this, we modified the tree-sampling step to incorporate constraints derived from GFL annotations and thereby impute the missing dependencies.

Given a string $\boldsymbol{w} = (w_1, \cdots w_n)$, we define a span of $\boldsymbol{w}$ as $w_{i,k} = (w_{i+1}, \cdots, w_k)$, so that $\boldsymbol{w} = w_{0,n}$. As introduced in Pereira and Schabes (1992), a bracketing $\mathcal{B}$ of $\boldsymbol{w}$ is a finite set of spans on $\boldsymbol{w}$ satisfying the requirement that no two spans in a bracketing may overlap unless one span contains the other. For each sentence $\boldsymbol{w} = w_{0,n}$ we define the auxiliary function for each span $w_{i,j}$, $0 \le i < j \le n$:

$$c(i,j) = \begin{cases} 1 & \text{if span } w_{i,j} \text{ is valid for } \mathcal{B}; \\ 0 & \text{otherwise.} \end{cases}$$

Here one span is valid for $\mathcal{B}$ if it doesn't cross any brackets. Section 3.2 describes how to derive bracketing information from GFL annotations and how to determine if a span $w_{i,j}$ is valid or not. Note that for parsing a corpus without any annotations and constraints, $c(i,j) = 1$ for any span, and the algorithm is equivalent to the Gibbs sampler in Sun et al. (2014).

There are two parts to the tree-sampling. The first constructs an inside table as in the Inside-Outside algorithm for PCFGs and the second selects the tree by recursively sampling productions from top to bottom. Consider a sentence $\boldsymbol{w}$, with sub-spans $w_{i,k} = (w_{i+1}, \cdots, w_k)$. Given θ^w (modified rule probabilities θ given constraints of sentence $\boldsymbol{w}$, see Section 3.2), we construct the inside table with entries $p_{A,i,k}$ for each nonterminal and each span $w_{i,k}$: $0 \le i < k \le n$. We introduce $c(i,j)$ into the calculation of inside probabilities:

$$p_{A,i,k} = c(i,k) \cdot \sum_{A\to BC\in R} \sum_{i<j<k} \theta^w_{A\to BC} \cdot p_{B,i,j} \cdot p_{C,j,k} \qquad (1)$$

Here, $p_{A,i,k} = P_{G_A}(w_{i,k} \mid \theta^w)$ is the probability that terminals i through k were produced by the non-terminal A, $A \to BC \in R$ are possible rules to expand A. The inside table is computed recursively using Equation 1.

The resulting inside probabilities are then used to generate trees from the distribution of all valid trees of the sentence. The tree is generated from top to bottom recursively with the function $TreeSampler$ defined in Algorithm 1, which introduces $c(i,j)$ into the sampling function from Sun et al. (2014).

3.2 Constraints derived from GFL

We exploit one dependency constraint and two constituency constraints from partial GFL annotations.

Dependency rule Directed arcs are indicated with angle brackets pointing from the dependent to its head, e.g. *black > cat*. Once we have a directed arc annotation, say $\omega_i > \omega_j$, if $i < j$, which means word j has a left child, we must have rule $L^1_{\tau_j} \to Y_{\tau_i} L'_{\tau_j}$ in our parse tree (similarly if $i > j$, we have $R^1_{\tau_j} \to R'_{\tau_j} Y_{\tau_i}$ in our parse tree), where τ_i, τ_j are parts-of-speech for ω_i and ω_j. We enforce this by modifying the rule probabilities for sample sentence $\boldsymbol{w}$ to ensure that any sampled tree contains all specified arcs.

Head position 3

Figure 2: Generating brackets for known head

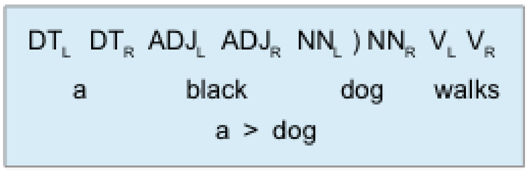

Figure 3: Generating half brackets

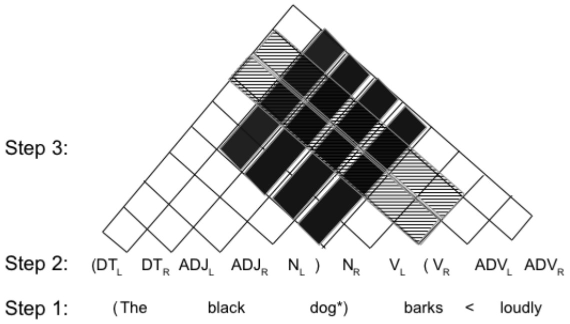
Brackets GFL allows annotators to group words with parenthesis, which provides an explicit indicator of constituent brackets. Even when the internal structure is left underspecified (e.g. *(the equity division*) in Figure 1 (a)*, the head is usually marked with *, and we can use this to infer sub-constituents. Given such a set of parentheses and the words inside them, we generate brackets over the split-head representations of their parts-of-speech, based on possible positions of the head. Figure 2 shows how to generate brackets for three situations: the head is the leftmost word, rightmost word, or is in a medial position. For example, the first annotation indicates that *under* is the head of *under the agreement*, and the rest of words are right descendants of *under*. This leads to the bracketing shown over the split-heads.

Half brackets We can also derive one-sided half brackets from dependency arcs by assuming that dependencies are projective. For example, in Figure 3, the annotation *a* $>$ *dog* specifies that *dog* has a left child *a*, so we know that there is a right bracket before the right-head of *dog*. Thus, we can detect invalid spans using the half brackets; if a span starts after *a* and ends after *dog*, this span is invalid because it would result in crossing brackets. This half bracketing is a unique advantage provided by the split-head representation. The details of this algorithm are shown in Algorithm 3.

```
Require: $Arcs$ is the set of all directed arcs extracted for
  sentence, $w_{a,b}$ is a span to detect
  function DetectInvalidSpan($a, b, Arcs$)
    for each directed arc $\omega_i < \omega_j$ do
      if $i < j$ then
        if $a < 2i - 1 < b < 2j$ then
          $c(a, b) = 0$
        end if
      else
        if $2j - 2 < a < 2i - 1 < b$ then
          $c(i, j) = 0$
        end if
      end if
    end for
    return $c(a, b)$
  end function
```

Algorithm 3: Detect whether one span is invalid given all directed arcs.



Step 3:
Step 2: (DT$_L$ DT$_R$ ADJ$_L$ ADJ$_R$ N$_L$) N$_R$ V$_L$ (V$_R$ ADV$_L$ ADV$_R$
Step 1: (The black dog*) barks < loudly

Figure 4: Process of generating brackets and detecting invalid spans.

We use both half bracket and full bracket information, $\mathcal{B}$, to determine whether a span is valid. We set $c(i, j) = 0$ for all spans over $\boldsymbol{w}$ detected by Algorithm 3 and violating $\mathcal{B}$. Then, in the sampling scheme, we'll only sample parse trees that satisfy these underlying constraints.

Figure 4 shows the resulting blocked out spans in the chart based on both types of brackets for the given partial annotation, which is Step 1 of the process. *The black dog* is a constituent with *dog* marked as its head, so we generate a full bracket over the terminal string in Step 2. Also, *barks* has a right child *loudly*; this generates a half bracket before V_R. In Step 3, the chart in Figure 4 represents all spans over terminal symbols. The cells in black are invalid spans based on the full bracket, and the hatched cells are invalid spans based on the half bracket.

4 Results

Experiments There are two points of variation to consider in empirical evaluations of our ap-

Full	81.6	56.2	78.1

Table 3: Results with simulated partial annotations, GFL-GPC-X indicates X percent of dependencies were retained.

proach. The first is the effectiveness of the GPC in imputing missing dependencies and the second is the effectiveness of the GFL annotations themselves. Of particular note with respect to the latter is the reasonable likelihood of divergence between the annotator and the corpus used for evaluation—for example, how coordination is handled and whether subordinate verbs are dependents or heads of auxiliary verbs. To this end, we perform simulation experiments that remove increasing portions of gold dependencies from a training corpus to understand imputation performance and annotation experiments to evaluate the entire pipeline in a realistically constrained annotation effort.

In that regard, one thing to consider are the part-of-speech tags used by the unlexicalized GPC. These do not come for free, so rather than ask annotators to provide them, the raw sentences to be annotated were tagged automatically. For English and Kinyarwanda, we used taggers trained with resources built in under two hours (Garrette and Baldridge, 2013), so these results are actually constrained to the GFL annotation time plus two hours. Such taggers were not available for Chinese or Portuguese, so the Stanford tagger (Toutanova et al., 2003) was used instead.

After imputing missing dependencies, the GPC outputs fully sentences that are used to train TurboParser (Martins et al., 2010). In all cases, we compare to a right-branching baseline (RB). Although comparing to a random baseline is more typical of imputation experiments, a right-branching baseline provides a stronger initial comparison. For the GFL annotation experiments, we use two additional baselines. The first is simply to use the sentences with full annotations and drop any incomplete ones (GFL-DROP). The second is to make any partial annotations usable by assuming a right-branching completion (GFL-RBC).

Simulated partial annotations Figure 5 shows the learning curve with respect to number of annotated tokens when retaining 100%, 75%, 50% and 25% of gold-standard training dependencies and using the GPC to impute the removed ones. With both 75% and 50% retained, performance degrades gracefully. It is substantially lower for 25%, but the curve is steeper than the others, indicating it is on track to catch up. Nonetheless, one recommendation from these results is that it probably makes sense to start with a small number of fully annotated sentences and then start mixing in partially annotated ones.

Table 3 shows the attachment scores obtained for English, Chinese, and Portuguese with varying proportions of dependencies removed for the GPC to impute.[4] English and Portuguese hold up well with 75% and 50% retained, while Chinese drops more precipitously, and 25% leads to substantial reductions in performance for all.

Note that these simulations indicate that, given an equivalent number of total annotated arcs, using the GPC is more beneficial than requiring annotators to fully specify annotations. Imputing fifty percent of the dependency arcs from sentences containing 1000 tokens is typically more effective by a few points than using the full gold-standard arcs from sentences containing 500 tokens. Actually, this simulation is too generous to complete annotations in that it leaves out consideration of the time and effort required to obtain those 100% full gold-standard arcs: it is often a small part of a sentence that consumes the most effort when full annotation is required. Additionally, these simulation experiments randomly removed dependencies while humans tend to annotate higher-level con-

[4] These are based on the same sentences used in the next section's GFL annotation experiments for each language.

Eval Length	< 10	< 20	all
GFL-DROP (4hr)	54.5	55.0	52.6
GFL-GPC (4hr)	60.1	**61.8**	55.1
Blunsom and Cohn, 2010	67.7	–	**55.7**
Naseem et al., 2010	**71.9**	50.4	–

Table 4: English results compared to previous unsupervised and weakly-supervised methods.

stituents and leave internal structure (e.g. of noun phrases) underspecified. Given Hwa's (1999) findings, we expect non-random partial annotations to better serve as a basis for imputation.

GFL annotations We conducted three sets of experiments with GFL annotations, evaluating on sentences of all lengths, less than 10 words, and less than 20 words. This was done to determine the types of sentences that our method works best on and to compare to previous work that evaluates on sentences of different lengths.

Table 4 shows how our results on ENG compare to others. Blunsom and Cohn (2010) represent state-of-the-art unsupervised results for all lengths, while Naseem et al. (2010) was chosen as a previous weakly-supervised approach. GFL-GPC achieves similar results on the 'all lengths' criterion as Blunsom and Cohn and substantially outperforms Naseem et al. on sentences less than 20 words. Our poor performance on short sentences is slightly surprising, and may result from an uneven length distribution in the sentences selected for annotation—we have only 3 training sentences less than 10 words—as discussed by Spitkovsky et al. (2010a). To correct this problem, both long and short sentences should be included to construct a more representative sample for annotation.

We did not expect GFL-RBC to perform so similarly to RB. It is possible that the relatively large number of under-specified sentences led to the right-branching quality of GFL-RBC dominating, rather than the more informative GFL annotations.

The results of the ENG annotation session can be seen in Figure 6a. GFL-GPC is quite strong even at thirty minutes, with only seven sentences annotated. GFL-DROP picks up substantially at the end; this may be in part explained by the fact that the last block contained many short sentences, which provide greater marginal benefit to GFL-DROP than to GFL-GPC.

The learning curves for the other languages can be seen in Figures 6b-6d, with a summary available in Table 5. Like ENG, CHI and POR both show clear wins for the GPC strategy. Of particular note is that the CHI annotations contained many fewer fully-completed sentences (4) than the ENG annotations (15). This somewhat addresses the question raised by the 25% retention simulation experiments—the GPC method improves results over dropping partial annotations. The POR results show a consistent strong win for GPC throughout.

Language	KIN	CHI	POR
RB	52.6	11.6	27.0
GFL-DROP (2hr)	64.4	36.7	59.8
GFL-GPC (2hr)	64.5	38.8	65.0

Table 5: Non-English results summary

The KIN results in Figure 6c exhibit a pattern unlike the other languages; specifically, the KIN data has a very high right-branching baseline (RB in figures) and responds nearly identically for all of the more informed methods. Upon investigation, this appears to be an artifact of the data used in KIN evaluation plus domain adaptation issues. The gold data consists of transcribed natural speech, whereas the training data consists of sentences extracted from the Kinyarwanda Wikipedia.

All of the learning curves display a large initial jump after the first round of annotations. This is encouraging for approaches that use annotated sentences: just a small number of examples provide tremendous benefit, regardless of the strategy employed.

Error analysis The primary errors seen on an analysis of the GPC-completed sentences varies somewhat between languages. The ENG data contains many short sentences, consisting often of a few words and a punctuation mark. Part of the GFL convention is that the annotator is free to annotate punctuation as part of the sentence or instead view it as extra-linguistic and drop the punctuation from the annotation. Often the punctuation in the ENG data went unannotated, with the result being that the final parse model is not particularly good at handling these types of sentences when encountered in the test set.

Specific constructions like coordination and possession also suffer a similar issue in that annotators (and corpora) varied slightly on how they were handled. Thus, some languages like CHI contained many of a particular type of error due to mismatches in the conventions of the annotator and corpus. Issues like this could have been avoided by a longer training period prior to anno-

(d) Portuguese

Figure 6: GPC results by annotation time for eval sentences of all lengths.

tation, although were this a real annotation project, there would be no existing corpus to compare to at first. This brings up a more basic question of evaluation - one of usability versus representational norm matching. It is likely that the GFL annotations (and thus the models trained on them) diverge from the gold standard in what amount to annotation conventions rather than substantive linguistic divergences. To evaluate more fully or fairly, we would need test sets produced by the same set of annotators or an external, task-based evaluation that uses the dependencies as in input.

5 Conclusions

We have described a modeling strategy that takes advantage of a Gibbs sampling algorithm for CFG parsing plus constraints obtained from partial annotations to build dependency parsers. This strategy's performance improves on that of a parser built only on the available complete annotations. In doing so, our approach supports annotation efforts that use GFL to obtain guidance from non-expert human annotators and allow any annotator to put in less effort than they would to do complete annotations.

We find that a remarkably small amount of supervised data can rival existing unsupervised methods. While unsupervised methods have been considered an attractive option for low-resource parsing, they typically rely on large quantities of clean, raw sentences. Our method uses less than one hundred sentences, so in a truly low-resource scenario, it has the potential to require much less total effort. For instance, a single native speaker could easily both generate and annotate the sentences required for our method in a few hours, while the many thousands of raw sentences needed for state-of-the-art unsupervised methods could take much longer to assemble if there is no existing corpus. This also means our method would be useful for getting in-domain training data for domain adaptation for parsers.

Finally, our method has the ability to encode both universal grammar and test-language grammar as a prior. This would be done by replacing the uniform prior used in this paper with a prior favoring those grammar rules during the updating-rule-probabilities phase of the GPC, and would essentially have the effect of weighting those grammar rules.

Abstract

Work in grammar induction should help shed light on the amount of syntactic structure that is discoverable from raw word or tag sequences. But since most current grammar induction algorithms produce unlabeled dependencies, it is difficult to analyze what types of constructions these algorithms can or cannot capture, and, therefore, to identify where additional supervision may be necessary. This paper provides an in-depth analysis of the errors made by unsupervised CCG parsers by evaluating them against the labeled dependencies in CCGbank, hinting at new research directions necessary for progress in grammar induction.

1 Introduction

Grammar induction aims to develop algorithms that can automatically discover the latent syntactic structure of language from raw or part-of-speech tagged text. While such algorithms would have the greatest utility for low-resource languages for which no treebank is available to train supervised parsers, most work in this area has focused on languages where existing treebanks can be used to measure and compare the performance of the resultant parsers. Despite significant progress in the last decade (Klein and Manning, 2004; Headden III et al., 2009; Blunsom and Cohn, 2010; Spitkovsky et al., 2013; Mareček and Straka, 2013), there has been little analysis performed on the types of errors these induction systems make, and our understanding of what kinds of constructions these parsers can or cannot recover is still rather limited. One likely reason for this lack of analysis is the fact that most of the work in this domain has focused on parsers that return unlabeled dependencies, which cannot easily be assigned a linguistic interpretation.

This paper shows that approaches that are based on categorial grammar (Steedman, 2000) are amenable to more stringent evaluation metrics, which enable detailed analyses of the constructions they capture, while the commonly used unlabeled directed attachment scores hide linguistically important errors. Any categorial grammar based system, whether deriving its grammar from seed knowledge distinguishing nouns and verbs (Bisk and Hockenmaier, 2013), from a lexicon constructed from a simple questionnaire for linguists (Boonkwan and Steedman, 2011), or from sections of a treebank (Garrette et al., 2015), will attach linguistically expressive categories to individual words, and can therefore produce labeled dependencies. We provide a simple proof of concept for how these labeled dependencies can be used to isolate problem areas in CCG induction algorithms. We illustrate how they make the linguistic assumptions and mistakes of the model transparent, and are easily comparable to a treebank where available. They also allow us to identify linguistic phenomena that require additional supervision or training signal to master. Our analysis will be based on extensions of our earlier system (Bisk and Hockenmaier, 2013), since it requires less supervision than the CCG-based approaches of Boonkwan and Steedman (2011) or Garrette et al. (2015). Our aim in presenting this analysis is to initiate a broader conversation and classification of the impact of various types of supervision provided to these approaches. We will see that most of the constructions that our system cannot capture, even when they are included in the model's search space, involve precisely the kinds of non-local dependencies that elude even supervised dependency parsers (since they require dependency graphs, instead of trees), and that have motivated the use of categorial grammar-based approaches for supervised parsing.

First, we provide a brief introduction to CCG. Next, we define a labeled evaluation metric that allows us to compare the labeled dependencies produced by Bisk and Hockenmaier (2013)'s unsupervised parser with those in CCGbank (Hockenmaier and Steedman, 2007). Third, we extend their induction algorithm to allow it to induce more complex categories, and refine their probability model to handle punctuation and lexicalization, which we show to be necessary when handling the larger grammars induced by our variant of their algorithm. While we also perform a traditional dependency evaluation for comparison to the non-CCG based literature, we focus on our CCG-based labeled evaluation metrics to perform a comparative analysis of Bisk and Hockenmaier (2013)'s parser and our extensions.

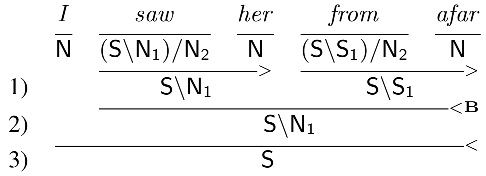
2 Combinatory Categorial Grammar

CCG categories CCG (Steedman, 2000) is a lexicalized grammar formalism which associates each word with a set of lexical categories that fully specify its syntactic behavior. Lexical categories indicate the expected number, type and relative location of arguments a word should take, or what constituents it may modify. Even without explicit evaluation against a treebank, the CCG lexicon that an unsupervised parser produces provides an easily interpretable snapshot of the assumptions the model has made about a language (Bisk and Hockenmaier, 2013). The set of CCG categories is defined recursively over a small set of atomic categories (e.g. $\mathsf{S}, \mathsf{N}, \mathsf{NP}, \mathsf{PP}$). Complex categories take the form $\mathsf{X\backslash Y}$ or $\mathsf{X/Y}$ and represent functions which create a result of category X when combined with an argument Y. The slash indicates whether the argument precedes (\) or follows (/) the functor (descriptions of CCG commonly use the vertical slash | to range over both / and \). Modifiers are categories of the form $\mathsf{X|X}$, and may take arguments of their own.

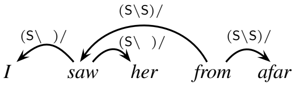
CCG rules CCG rules are defined schematically as function application (>, <), unary ($>\mathsf{B}_1$, $<\mathsf{B}_1$) and generalized composition ($>\mathsf{B}_n$, $<\mathsf{B}_n$), type-raising (>T, <T) and conjunction:

$\mathsf{X/Y}$	Y	$\Rightarrow_{>}$	X
$\mathsf{X/Y}$	$\mathsf{Y\|Z}$	$\Rightarrow_{>\mathsf{B}_1}$	$\mathsf{X\|Z}$
$\mathsf{X/Y}$	$\mathsf{Y\|Z_1\|...\|Z_n}$	$\Rightarrow_{>\mathsf{B}_n}$	$\mathsf{X\|Z_1\|...\|Z_n}$
X		$\Rightarrow_{>\mathsf{T}}$	$\mathsf{T/(T\backslash X)}$
Y	$\mathsf{X\backslash Y}$	$\Rightarrow_{<}$	X
$\mathsf{Y\|Z}$	$\mathsf{X\backslash Y}$	$\Rightarrow_{<\mathsf{B}_1}$	$\mathsf{X\|Z}$
$\mathsf{Y\|Z_1\|...\|Z_n}$	$\mathsf{X\backslash Y}$	$\Rightarrow_{<\mathsf{B}_n}$	$\mathsf{X\|Z_1\|...\|Z_n}$
	X	$\Rightarrow_{<\mathsf{T}}$	$\mathsf{T\backslash(T/X)}$

CCG derivations In the following derivation, forward application is used in line 1) as both the verb and the preposition take their NP arguments. In line 2), the prepositional phrase modifies the verb via backwards composition. Finally, in line 3), the derivation completes by producing a sentence (S) via backwards application:



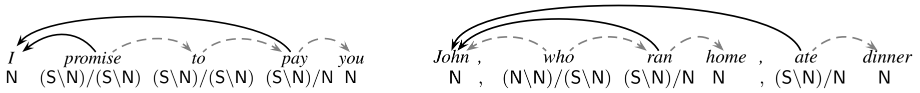
CCG dependencies CCG has two standard evaluation metrics. Supertagging accuracy simply computes how often a model chooses the correct lexical category for a given word. The correct category is a prerequisite for recovering the correct labeled dependency. By tracing through which word fills which argument of which category, a set of dependency arcs, labeled by lexical category and slot, can be extracted:



In this example, *I* fills the first argument of *saw*. This is represented by an edge from *saw* to *I*, labeled as a transitive verb ($\mathsf{(S\backslash N)/N}$). This procedure is followed for every argument of every predicate, leading to a labeled directed graph.

Evaluation metrics for supervised CCG parsers (Clark et al., 2002) measure labeled f-score (LF1) precision of these dependencies (requiring the functor, argument, lexical category of the functor and slot of the argument to all match). A second, looser, evaluation is often also performed which measures unlabeled, undirected dependency scores (UF1).

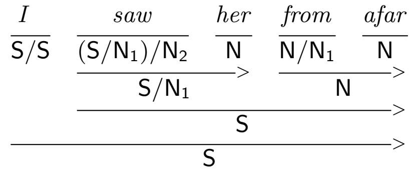
Non-local dependencies and complex arguments One advantage of CCG is its ability to recover the non-local dependencies involved in control, raising, or *wh*-extraction. Since these constructions introduce additional dependencies, CCG parsers return dependency graphs (DAGs), not trees. To obtain these additional dependencies, relative pronouns and control verbs require lexical categories that take complex arguments of the form $\mathsf{S\backslash NP}$ or $\mathsf{S/NP}$, and a mechanism for co-indexation of the NP inside this argument with another NP argument (e.g. $\mathsf{(NP\backslash NP_i)/(S|NP_i)}$ for relative pronouns). These co-indexed subjects can be seen in Figure 1.



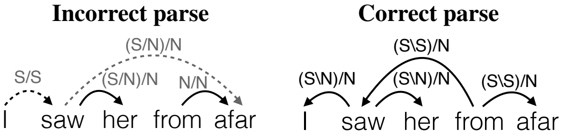
I promise to pay you
N (S\N)/(S\N) (S\N)/(S\N) (S\N)/N N
John , who ran home , ate dinner
N , (N\N)/(S\N) (S\N)/N N , (S\N)/N N

Figure 1: Unlabeled predicate-argument dependency graphs for two sentences with co-indexed subjects.

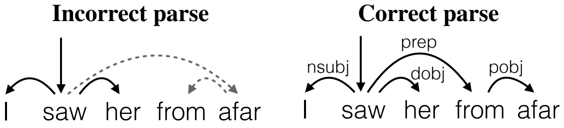
Errors exposed by labeled evaluation We now illustrate how the lexical categories and labeled dependencies produced by CCG parsers expose linguistic mistakes. First, we consider a wildly incorrect analysis of the first example sentence, in which the subject is treated as an adverb, and the PP as an NP object of the verb:



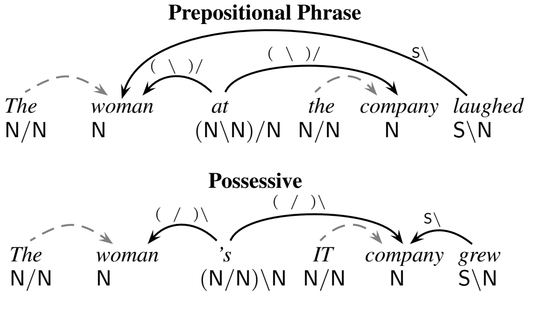
None of the labeled directed CCG dependencies are correct. But under the more lenient unlabeled directed evaluation of Garrette et al. (2015), and the even more lenient unlabeled undirected metric of Clark et al. (2002), two (or three) of the four dependencies would be deemed correct:



When we translate the CCG analysis to an unlabeled dependency tree (and hence flip the direction of modifier dependencies and add a root edge), a similar picture emerges, and three out of five attachments are deemed correct:



We now turn to a subtle distinction that corresponds to a systematic mistake made by all models we evaluate. The categories of noun-modifying prepositions (*at*) and possessive markers (*'*) differ only in the directionality of their slashes:



The unlabeled dependencies inside the noun phrases are identical, but the heads differ. The first sentence turns the prepositional phrase (*at the company*) into a modifier of *woman*. In contrast, in the possessive case, *woman 's* modifies *company*. According to an unlabeled (directed) score, confusing these analyses would be 80% correct, whereas LF1 would only be 20%. But without a semantic bias for companies growing and women laughing, there is no signal for the learner.

3 Labeled Evaluation for CCG Induction

We have just seen that labeled evaluation can expose many linguistically important mistakes. In order to enable a fair and informative comparison of unsupervised CCG parsers against the lexical categories and labeled dependencies in CCGbank, we define a simplification of CCGbank's lexical categories that does not alter the number or direction of dependencies, but makes the categories and dependency labels directly comparable to those produced by an unsupervised parser. We also do not alter the derivations themselves, although these may contain type-changing rules (which allow e.g. participial verb phrases S[ng]\NP to be used as NP modifiers NP\NP) that are beyond the scope of our induction algorithm.

Although the CCG derivations and dependencies that CCG-based parsers return should in principle be amenable to a quantitative labeled evaluation when a gold-standard CCG corpus is available, there may be minor systematic differences between the sets of categories assumed by the induced parser and those in the treebank. In particular, the lexical categories in the English CCGbank are augmented with morphosyntactic features that indicate e.g. whether sentences are declarative (S[dcl]), or verb phrases are infinitival (S[to]\NP). Prior work on supervised parsing with CCG found that many of these features can be recovered with proper modeling of latent state splitting (Fowler and Penn, 2010). Since we wish to evaluate a system that does not aim to induce such features, we remove them. We also remove the distinction between noun phrases (NP) and nouns (N), which is predicated on knowledge of

	Our simplification of CCGbank's lexical categories					
	Congress	*has*	*n't*	*lifted*	*the*	*ceiling*
Original	NP	(S[dcl]\NP)/(S[pt]\NP)	(S\NP)\(S\NP)	(S[pt]\NP)/NP	NP[nb]/N	N
Simplified	N	(S\N)/(S\N)	S\S	(S\N)/N	N/N	N

Figure 2: We remove morphosyntactic features, simplify verb phrase modifiers, and change NP to N.

	CCGbank	w/out Feats	Simplified

Table 1: Category types in CCGbank 02-21

determiners and other structural elements of a language. Finally, CCGbank distinguishes between sentential modifiers (which have categories of the form S|S, without features) and verb phrase modifiers ((S\NP)|(S\NP), again without features). But since the NP argument slot of a VP modifier is never filled, we can maintain the same number of gold standard dependencies by removing this distinction and changing all VP modifiers to be of the form S|S. However, categories of the form $(\mathsf{S}[\cdot]\backslash\mathsf{NP}_i)/(\mathsf{S}[\cdot]\backslash\mathsf{NP}_i)$, which are used e.g. for modals and auxiliaries, are changed to $(\mathsf{S}\backslash\mathsf{N}_i)/(\mathsf{S}\backslash\mathsf{N}_i)$, allowing us to maintain the dependency on the subject. With these three simplifications we eliminate much of the detailed knowledge required to construct the precise CCGbank-style categories, and dramatically reduce the set of categories without losing expressive power. One distinction that we do not conflate, even though it is currently beyond the scope of the induction algorithm, is the distinction between PP arguments (requiring prepositions to have the category PP/NP) and adjuncts (requiring prepositions to be (NP\NP)/NP or ((S\NP)\(S\NP))/NP).

This simplification is consistent with the most basic components of CCG and can therefore be easily used for the evaluation and analysis of any weakly or fully supervised CCG system, not just that of Bisk and Hockenmaier (2012). An example simplification is present in Figure 2, and the reduction in the set of categories can be seen in Table 1. Similar simplifications should also be possible for CCGbanks in other languages.

4 Our approach

There are two parts to our approach: 1) inducing a CCG grammar from seed knowledge and 2) learning a probability model over parses. The induction algorithm (Bisk and Hockenmaier, 2012) uses the seed knowledge that nouns can take the CCG category N, that verbs can take the category S and may take N arguments, and that any word may modify a constituent it is adjacent to, to iteratively induce a CCG lexicon to parse the training data. In Bisk and Hockenmaier (2013), we introduced a model that is based on Hierarchical Dirichlet Processes (Teh et al., 2006). This HDP-CCG model gave state-of-the-art performance on a number languages, and qualitative analysis of the resultant lexicons indicated that the system was learning the word order and many of the correct attachments of the tested languages. But this system also had a number of shortcomings: the induction algorithm was restricted to a small fragment of CCG, the model emitted only POS tags rather than words, and punctuation was ignored. Here, we use our previous HDP-CCG system as a baseline, and introduce three novel extensions that attempt to address these concerns.

5 Experimental Setup

For our experiments we will follow the standard practice in supervised parsing of using WSJ Sections 02-21 for training, Section 22 for development and error analysis, and a final evaluation of the best models on Section 23. Because the induced lexicons are overly general, the memory footprint grows rapidly as the complexity of the grammar increases. For this reason, we only train on sentences that contain up to 20 words (as well as an arbitrary number of punctuation marks). All analyses and evaluation are performed with sentences of all lengths unless otherwise indicated. Finally, Bisk and Hockenmaier (2013) followed Liang et al. (2007) in setting the values of the hyperparameters α to powers (eg. the square) of the number of observed outcomes in the distribution. But when the output consists of words rather than POS tags, the concentration parameter $\alpha = V^2$ is too large to allow the model to learn. For this reason, experiments will be reported with all hyperparameters set to a constant of 2500.[1]

[1] We tested three values (1000, 2500, 5000) and found that the basic model at 2500 performed closest to the previously

		Base	**+ Lexicalization**	**+ Punctuation**	**+ Punc & Lex**	**+ Allow** (X|X)|X
Only Atomic Arguments	B_1	**34.2**	35.2	36.3	36.9	36.8

Allow Complex Arguments	B_1	33.0	34.9	33.2	35.7	**35.8**
(S, N, S|N)	B_3	29.4	29.5	31.2	31.2	31.2

Table 2: The impact of our changes to Bisk and Hockenmaier's (2013) model (henceforth: B_1, top left) on CCGbank dependencies (LF1, Section 22, all sentences). The best overall model ($\mathsf{B}_3^{\text{P\&L}}$) uses B_3, punctuation and lexicalization. The best model with complex arguments ($\mathsf{B}_1^{\mathsf{C}}$) uses only B_1.

6 Extending the HDP-CCG system

We now examine how extending the HDP-CCG baseline model to capture lexicalization and punctuation, and how increasing the complexity of the induced grammars affect performance (Table 2).

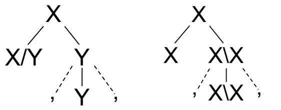
6.1 Modeling Lexicalization

In keeping with most work in grammar induction from part-of-speech tagged text, Bisk and Hockenmaier's (2013) HDP-CCG treats POS tags t rather than words w as the terminals it generates based on their lexical categories c. The advantage of this approach is that tag-based emissions $p(t|c)$ are a lot less sparse than word-based emissions $p(w|c)$. It is therefore beneficial to first train a model that emits tags rather than words (Carroll and Rooth, 1998), and then to use this simpler model to initialize a lexicalized model that generates words instead of tags. To perform the switch we simply estimate counts for the parse forests using the unlexicalized model during the E-Step and then apply those counts to the lexicalized model during the M-Step. Inside-Outside then continues as before. Many words, like prepositions, differ systematically in their preferred syntactic role from that of their part-of-speech tags. This change benefits all settings of the model (Column 2 of Table 2).

6.2 Modeling Punctuation

Spitkovsky et al. (2011) performed a detailed analysis of punctuation for dependency-based grammar induction, and proposed a number of constraints that aimed to capture the different ways in which dependencies might cross constituent boundaries implied by punctuation marks.

A constituency-based formalism like CCG allows us instead to define a very simple, but effective Dirichlet Process (DP) based Markov grammar that emits punctuation marks at the maximal projections of constituents. We note that CCG derivations are binary branching, and that virtually every instance of a binary rule in a normal-form derivation combines a head X or X|Y with an argument Y or modifier X|X. Without reducing the set of strings generated by the grammar, we can therefore assume that punctuation marks can only be attached to the argument Y or the adjunct X|X:



To model this, for each maximal projection (i.e. whenever we generate a non-head child) with category C, we first decide whether punctuation marks should be emitted ($M = \{true, false\}$) to the *left* or *right* side (*Dir*) of C. Since there may be multiple adjacent punctuation marks (... ."), we treat this as a Markov process in which the *history* variable captures whether previous punctuation marks have been generated or not. Finally, we generate an actual punctuation mark w_m:

$$\begin{array}{ll} p(M \mid \mathit{Dir}, \mathit{Hist}, \mathsf{C}) & \sim DP(\alpha, p(M \mid \mathit{dir})) \\ p(M \mid \mathit{Dir}) & \sim DP(\alpha, p(M)) \\ p(w_m \mid \mathit{Dir}, \mathit{Hist}, \mathsf{C}) & \sim DP(\alpha, p(w_m \mid \mathit{dir}, \mathit{hist})) \\ p(w_m \mid \mathit{Dir}, \mathit{Hist}) & \sim DP(\alpha, p(w_m)) \end{array}$$

We treat # and $ symbols as ordinary lexical items for which CCG categories will be induced by the regular induction algorithm, but treat all other punctuation marks, including quotes and brackets. Commas and semicolons (,, ;) can act both as punctuation marks generated by this Markov grammar, and as conjunctions with lexical category conj. This model leads to further performance gains (Columns 3 and 4 of Table 2).

6.3 Increasing Grammatical Complexity

The existing grammar induction scheme is very simplistic. It assumes that adjacent words either modify one another or can be taken as arguments. Left unconstrained this space of grammatical cat-

reported dependency evaluation comparison with the work of Naseem et al. (2010). We fixed this hyperparameter setting for experimental simplicity but a more rigorous grid search might find better parameters for the complex models.

Model	Supertagging	LF1	UF1
$\mathbf{B_1}$	59.2	34.5	60.6
$\mathbf{B_1^C}$	59.9	34.9	63.6
$\mathbf{B_3^{P\&L}}$	62.3	37.1	64.9

Table 3: Test set performance of the final systems discussed in this paper (Section 23)

egories introduced grows very rapidly, introducing a tremendous number of incorrect categories (analyzed later in Table 9). For this reason Bisk and Hockenmaier (2013) applied the HDP-CCG model to a context-free fragment of CCG, limiting the arity of lexical categories (number of arguments they can take) to two and the arity of composition (how many arguments can be passed through composition) to one. We know the space of grammatical constructions is larger than this, so we will allow the model to induce categories with three arguments and use generalized composition (B_3). Bisk and Hockenmaier (2013) allow lexical categories to only take atomic arguments, but, as explained above, non-local dependencies require complex arguments of the form $\mathsf{S|N}$. We therefore allow lexical categories to take up to one complex argument of the form $\mathsf{S|N}$. Atomic lexical categories are not allowed to take complex arguments, eliminating $\mathsf{S|(S|N)}$ and $\mathsf{N|(S|N)}$. Increasing the search space (Rows 3 and 4 of Table 2) shows corresponding decreases in performance.

Finally, Bisk and Hockenmaier (2013) eliminated the possessive-preposition ambiguity explained above by disallowing categories of the form $\mathsf{(X\backslash X)/X}$ and $\mathsf{(X/X)\backslash X}$ to be used simultaneously. Removing this restriction does not harm performance (Column 5 of Table 2).

6.4 Summary and test set performance

Table 2 shows the performance of 20 different model settings on Section 22 under the simplified labeled CCG-based dependency evaluation proposed above, starting with Bisk and Hockenmaier's (2013) original model (henceforth: $\mathbf{B_1}$, top left). We see that modeling punctuation and lexicalization both increase performance. We also show that allowing categories of the form $\mathsf{(X\backslash X)/X}$ and $\mathsf{(X/X)\backslash X}$ on top of the lexicalized models with punctuation does not lead to a noticeable decrease in performance. We also see that an increase in grammatical and lexical complexity is only beneficial for the grammars that allow only atomic arguments, and only if both lexicalization and punctuation are modeled. Allowing complex arguments is generally not beneficial, and performance drops further if the grammatical complexity is increased to B_3. Our further analysis will focus on the three bolded models, $\mathbf{B_1}$, $\mathbf{B_1^C}$ (the best model with complex arguments) and $\mathbf{B_3^{P\&L}}$ (the best overall model), whose supertag accuracy, labeled (LF1) and unlabeled undirected CCG dependency recovery on Section 23 are shown in Table 3. We see that $\mathbf{B_1^C}$ and $\mathbf{B_3^{P\&L}}$ both outperform $\mathbf{B_1}$ on all metrics, although the unlabeled metric (UF1) perhaps misleadingly suggests that $\mathbf{B_1^C}$ leads to a greater improvement than the supertagging and LF1 metrics indicate.

	CCGbank 02-21		WSJ2-21 DA		
Model	LF1	UF1	@10	@20	@∞
Naseem (Universal)			71.9	50.4	
Naseem (English)			73.8	66.1	
$\mathbf{B_1}$	33.8	60.3	70.7	63.1	58.4
$\mathbf{B_1^C}$	34.4	62.0	70.5	65.4	61.9
$\mathbf{B_3^{P\&L}}$	38.3	66.2	71.3	65.9	62.3

Table 4: Performance on CCGbank and CoNLL-style dependencies (Sections 02-21) for a comparison with Naseem et al. (2010).

6.5 CCGbank vs. dependency trees

Finally, to compare our models directly to a comparable unsupervised dependency parser (Naseem et al., 2010), we evaluate them against the unlabeled dependencies produced by Yamada and Matsumoto's (2003) head rules for Sections 02-21 of the Penn Treebank (Table 4)[2]. Naseem et al. (2010) only report performance on sentences of up to length 20 (without punctuation marks). Their approach incorporates prior linguistic knowledge either in the form of "universal" constraints (e.g. that adjectives may modify nouns) or "English-specific" constraints (e.g. that adjectives tend to modify and precede nouns). These universal constraints are akin to, but more explicit and detailed than the information given to the induction algorithm (see Bisk and Hockenmaier (2013) for a discussion). Comparing these numbers to labeled and unlabeled CCG dependencies on the same corpus (all sentences, hence, @∞), we see that performance increases on CCGbank do not translate to similar gains on these unlabeled dependencies. While we have done our best to convert the predicate argument structure of CCG into dependencies

Table 6: Categories that are in the search space of the induction algorithm, but do not occur in any Viterbi parse, and what $\mathbf{B_1^C}$ uses instead.

there are many constructions which have vastly different analysis, making a proper conversion too difficult for the scope of this paper.[3]

7 Error analysis

Supertagging error analysis We first consider the lexical categories that are induced by the models. Table 5 shows the accuracy with which they recover the most common gold lexical categories, together with the category that they most often produced instead. We see that the simplest model ($\mathbf{B_1}$) performs best on N, and perhaps over generates (N\N)/N (noun-modifying prepositions), while the overall best model ($\mathbf{B_3^{P\&L}}$) outperforms both other models only on intransitive verbs.

The most interesting component of our analysis is the long tail of constructions that must be captured in order to produce semantically appropriate representations. We can inspect the confusion matrix of the lexical categories that the model fails to use to obtain insight into how its predictions disagree with the ground truth, and why these constructions may require special attention. Table 6 shows the most common CCGbank categories that were in the search space of some of the more complex models (e.g. $\mathbf{B_3^C}$), but were never used by any of the parsers in a Viterbi parse. These include possessives, relative pronouns, modals/auxiliaries, control verbs and ditransitives. We show the categories that the $\mathbf{B_1^C}$ model uses instead. The gold categories shown correspond to the bold words in Table 6. While the reason many of these cases are difficult is intuitive (e.g. *very* modifying *tall* instead of *man*), a more difficult type of error than previously discussed is that of recovering non-local dependencies. The recovery of non-local dependencies is beyond the scope of both standard dependency-based approaches and Bisk and Hockenmaier (2013)’s original induction algorithm. But the parser does not learn to use lexical categories with complex arguments correctly even when the algorithm is extended, to induce them. For example, $\mathbf{B_1^C}$ prefers to treat auxiliaries or equi verbs like *promise* as intransitives rather than as an auxiliary that shares its subject with *pay*. The surface string supports this decision, as it can be parsed without having to capture the non-local dependencies (top row) present in the correct (bottom row) analysis:

I	promise	to	pay	you
N	S\N	(S\S)/S	S/N	N
N	(S\N)/(S\N)	(S\N)/(S\N)	(S\N)/N	N

[3] The overlap (F-score of unlabeled undirected attachment scores) between CCGbank dependencies and those obtained via Matsumoto’s head finding rules is only 81.9%.

	1st Argument			2nd Argument		
	B_1	B_1^C	$B_3^{P\&L}$	B_1	B_1^C	$B_3^{P\&L}$
N/N	68.4	69.7	**71.6**

(S\N)/S	23.9	**50.3**	32.5	25.2	**59.1**	35.0
(S\S)/S	6.1	**22.7**	14.1	9.5	**34.6**	19.5

Table 7: LF1 scores of B_1, B_1^C and $B_3^{P\&L}$ on the most common dependency types in Section 22.

We also see that this model uses seemingly non-English verb categories of the form (S/N)/N, both for ditransitives, and object control verbs, perhaps because the possibly spurious /N argument could be swallowed by other categories that take arguments of the form S/N, like the (incorrect) treatment of subject relative pronouns. One possible lesson we can extract from this is that practical approaches for building parsers for new languages might need to focus on injecting semantic information that is outside the scope of the learner.

Dependency error analysis Table 7 shows the labeled recall of the most common dependencies. We see that both new models typically outperform the baseline, although they yield different improvements on different dependency types. $\mathbf{B_1^C}$ is better at recovering the subjects of intransitive verbs (S\N) and verbs that take sentential complements ((S\N)/S), while $\mathbf{B_3}$ is better for simple adjuncts (N/N, S/S, S\S) and transitive verbs.

Wh-words and the long tail To dig slightly deeper into the set of missing constructions, we tried to identify the most common categories that are beyond the search space of the current induction algorithm. We first computed the set of categories used by each part of speech tag in CCGbank, and thresholded the lexicon at 95% token coverage for each tag. Removing the categories that contain PP and those that can be induced by the algorithm in its most general setting, we are left with the categories shown in Table 8. The tags that are missing categories are predominantly wh-words required for wh-questions, relative clauses or free relative clauses. Some of these categories violate the assumptions made by the induction algorithm: question words return a sentence (S) but are not themselves verbs. Free relative pronouns return a noun, but take arguments. However, this is a surprisingly small set of special function words and therefore perhaps a strategic place for supervision. Questions in particular pose an interesting learning question – how does one learn that these constructions indicate missing information which only becomes available later in the discourse?

Additional Category	$p(cat \mid tag)$	
((N\N)/(S\N))/N	.93	WP$
N/(S/N)	.14	WP
N/(S\N)	.08	WP
((N\N)/S)\((N\N)/N)	.07	WDT
((S\S)\(S\S))\N	.04	RBR
S/(S\N)	.04	WP
S/(S/N)	.02	WP

Table 8: Common categories that the algorithm cannot induce

Size, ambiguity, coverage and precision of the induced lexicons

Type-based Precision	81.1	60.4	65.6	36.1

Table 9: Size, ambiguity, coverage and precision (evaluated on Section 22) of the induced lexicons.

Grammatical complexity and size of the search space As lexical categories are a good proxy for the set of constructions the grammar will entertain, we can measure the size and ambiguity of the search space as a function of the number of lexical category types it induces as compared to the percentage that are actually valid categories for the language. In Table 9, we compare the lexicons induced by variants of the induction algorithm by their token-based coverage (the percent of tokens in Sections 22 for which the induced tag lexicon contains the correct category), type-based coverage (the percent of category types that the induced lexicon contains), as well as type-based precision (the percent of induced category types that occur in Section 22). This analysis is independent of the learned models, as their probabilities are not taken into account. We see that as the number of lexical categories induced (subject to the constraints of Bisk and Hockenmaier (2012)) increases, the percent that are valid English categories decreases rapidly (type-based precision falls from 81.1% to 36.1%). Despite this, and despite a high token coverage of up to 90%, we still miss almost 70% of the required category types. This helps explain why performance degrades so much for $\mathbf{B}_3^{\mathbf{C}}$, the arity three lexicon with complex arguments.

8 Dealing with Non-Local Dependencies

While the methodology used here is restricted to CCG based algorithms, we believe the lessons to be very general. The aforementioned constructions involve optional arguments, non-local dependencies, and multiple potential heads. Even though CCG is theoretically expressive enough to handle these constructions, they present the unsupervised learner with additional ambiguity that will pose difficulties independently of the underlying grammatical representation.

For example, although our approach learns that subject NPs are taken as arguments by verbs, the task of deciding which verb to attach the subject to is frequently ambiguous. This most commonly occurs in verb chains, and is compounded in the presence of subject-modifying relative clauses (in CCGbank, both constructions are in fact treated as several verbs sharing a single subject). To illustrate this, we ran the B_1^C and $B_3^{P\&L}$ systems on the following three sentences:

1. The woman **won** an award
2. The woman **has won** an award
3. The woman **being promoted has won** an award

The single-verb sentence is correctly parsed by both models, but they flounder as distractors are added. Both treat *has* as an intransitive verb, *won* as an adverb and *an* as a preposition:

	The	woman	**won**	an	award
$B_3^{P\&L}/B_1^C$:	N/N	N	(S\N)/N	N/N	N

	The	woman	**has**	**won**	an	award
$B_3^{P\&L}/B_1^C$:	N/N	N	S\N	S\S	(S\S)/N	N

To accommodate the presence of two additional verbs, both models analyze *being* as a noun modifier that takes *promoted* as an argument. B_1^C (correctly) stipulates a non-local dependency involving *promoted*, but treats it (arguably incorrectly) as a case of object extraction:

...	**being**	**promoted**	**has**	**won**	an	award
$B_3^{P\&L}$	(N\N)/S	S	S\N	S\S	(S\S)/N	N
B_1^C	(N\N)/(S/N)	S/N	S\N	S\S	(S\S)/N	N

Discovering these, and many of the other systematic errors describe here, may be less obvious when analyzing unlabeled dependency trees. But we would expect similar difficulties for any unsupervised approach when sentence complexity grows without a specific bias for a given analysis.

9 Conclusions

In this paper, we have introduced labeled evaluation metrics for unsupervised CCG parsers, and have shown that these expose many common syntactic phenomena that are currently out of scope for any unsupervised grammar induction systems. While we do not wish claim that CCGbank's analyses are free of arbitrary decisions, we hope to have demonstrated that these labeled metrics enable linguistically informed error analyses, and hence allow us to at least in part address the question of where and why the performance of these approaches might plateau. We focused our analysis on English for simplicity, but many of the same types of problems exist in other languages and can be easily identified as stemming from the same lack of supervision. For example, in Japanese we would expect problems with post-positions, in German with verb clusters, in Chinese with measure words, or in Arabic with morphology and variable word order.

We believe that one way to overcome the issues we have identified is to incorporate a semantic signal. Lexical semantics, if sparsity can be avoided, might suffice; otherwise learning with grounding or an extrinsic task could be used to bias the choice of predicates, their arity and in turn the function words that connect them. Alternatively, a simpler solution might be to follow the lead of Boonkwan and Steedman (2011) or Garrette et al. (2015) where gold categories are assigned by a linguist or treebank to tags and words. It is possible that more limited syntactic supervision might be sufficient if focused on the semantically ambiguous cases we have isolated.

More generally, we hope to initiate a conversation about grammar induction which includes a discussion of how these non-trivial constructions can be discovered, learned, and modeled. Relatedly, in future extensions to semi-supervised or projection based approaches, these types of constructions are probably the most useful to get right despite comprising the tail, as analyses without them may not be semantically appropriate. In summary, we hope to begin to pull back the veil on the types of information that a truly unsupervised system, if one should ever exist, would need to learn, and we pose a challenge to the community to find ways that a learner might discover this knowledge without hand-engineering it.

Abstract

Mention pair models that predict whether or not two mentions are coreferent have historically been very effective for coreference resolution, but do not make use of entity-level information. However, we show that the scores produced by such models can be aggregated to define powerful entity-level features between clusters of mentions. Using these features, we train an entity-centric coreference system that learns an effective policy for building up coreference chains incrementally. The mention pair scores are also used to prune the search space the system works in, allowing for efficient training with an exact loss function. We evaluate our system on the English portion of the 2012 CoNLL Shared Task dataset and show that it improves over the current state of the art.

1 Introduction

Coreference resolution, the task of identifying mentions in a text that refer to the same real world entity, is an important aspect of text understanding and has numerous applications. Many approaches to coreference resolution learn a scoring function defined over mention pairs to guide the coreference decisions (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008). However, such systems do not make use of entity-level information, i.e., features between *clusters* of mentions instead of pairs.

Using entity-level information is valuable because it allows early coreference decisions to inform later ones. For example, finding that *Clinton* and *she* corefer makes it more likely that *Clinton* corefers with *Hillary Clinton* than *Bill Clinton* due to gender agreement constraints. Such information has been incorporated successfully into entity-centric coreference systems that build up coreference clusters incrementally, using the information from the partially completed coreference chains produced so far to guide later decisions (Raghunathan et al., 2010; Stoyanov and Eisner, 2012; Ma et al., 2014).

However, defining useful features between clusters of mentions and learning an effective policy for incrementally building up clusters can be challenging, and many recent state-of-the-art systems work entirely or almost entirely over pairs of mentions (Fernandes et al., 2012; Durrett and Klein, 2013; Chang et al., 2013). In this paper we introduce a novel coreference system that combines the advantages of mention pair and entity-centric systems with model stacking. We first propose two mention pair models designed to capture different linguistic phenomena in coreference resolution. We then describe how the probabilities produced by these models can be used to generate expressive features between clusters of mentions. Using these features, we train an entity-centric incremental coreference system.

The entity-centric system builds up coreference chains with agglomerative clustering: each mention starts in its own cluster and then pairs of clusters are merged each step. We train an agent to determine whether it is desirable to merge a particular pair of clusters using an imitation learning algorithm based on DAgger (Ross et al., 2011). Previous incremental coreference systems heuristically define which actions are beneficial for the agent to perform, but we instead propose a way of assigning exact costs to actions based on coreference evaluation metrics, adding a concept of the severity of a mistake. Furthermore, rather than considering all pairs of clusters as candidate merges, we use the scores of the pairwise models to reduce the search space, first by providing an ordering over which merges are considered and secondly by discarding merges that are not likely

and the 7th International Joint Conference on Natural Language Processing, pages 1405–1415,
Beijing, China, July 26-31, 2015.

to be good. This greatly reduces the time it takes to run the agent, making learning computationally feasible.

Imitation learning is challenging because it is a non-i.i.d. learning problem; the distribution of states seen by the agent depends on the agent's parameters. Model stacking offers a way of decomposing the learning problem by training pairwise models with many parameters in a straightforward supervised learning setting and using their outputs for training a much simpler model in the more difficult imitation learning setting. Furthermore, mention pair scores can produce powerful features for training the agent because the scores indicate which mention pairs between the clusters in question are relevant; high scoring and low scoring pairs can indicate when a merge should be forced or disallowed while other mention pairs may provide little useful information.

We run experiments on the English portion of the 2012 CoNLL Shared Task dataset. The entity-centric clustering algorithm greatly outperforms commonly used heuristic methods for coordinating pairwise scores to produce a coreference partition. We also show that combining the scores of different pairwise models designed to capture different aspects coreference results in significant gains in accuracy. Our final system gets a combined score of 63.02 on the dataset, substantially outperforming other state of the art systems.

2 Mention Pair Models

Mention pair models predict whether or not a given pair of mentions belong in the same coreference cluster. We incorporate two different mention pair models into our system. However, other pairwise models could easily be added; one advantage of our model stacking approach is that it can combine different simple classifiers in a modular way.

Our two models are designed to capture different aspects of coreference. The first one is built to predict coreference for *all* of the candidate antecedents of a mention. This makes it useful for providing scores when the current mention has clear coreference links to many previous mentions. For example *President Clinton* might be linked to *the president*, *Bill Clinton*, and *Mr. President*.

However, mentions often only have *one* clear antecedent. This is especially common in pronominal anaphora resolution, such as in the sentence *Bill arrived, but nobody saw him.* The pronoun *him* is directly referring back to a previous part of the discourse, not some entity that other mentions may also refer to. However, there still might be coreference links between *him* and previous mentions in the text because of transitivity: any other mention about Bill would be coreferent with *him*. For such mentions, there may be very little evidence in the discourse to suggest a coreference link, so attempting to train a model to predict these will bear little fruit. With this as motivation, we also train a model to predict only *one* correct antecedent of the current mention.

We found a *classification* model to be well suited for the first task and and a *ranking* model to be well suited for the second one. These two models differ only in the training criteria used. Both models use a logistic classifier to assign a probability to a mention m and candidate antecedent a representing the likelihood that the two mentions are coreferent. The candidate antecedent a may take on the value NA indicating that m has no antecedent. The probability of coreference takes the standard logistic form:

$$p_{\boldsymbol{\theta}}(a, m) = (1 + e^{\boldsymbol{\theta}^T \boldsymbol{f}(a,m)})^{-1}$$

where $\boldsymbol{f}(a, m)$ is a vector of feature functions on a and m and $\boldsymbol{\theta}$ are the feature weights we wish to learn. Let $\mathcal{M}$ denote the set of all mentions in the training set, $\mathcal{T}(m)$ denote the set of true antecedents of a mention m (i.e., mentions that occur before m in the text that are coreferent with m or $\{\text{NA}\}$ if m has no antecedent), and $\mathcal{F}(m)$ denote the set of false antecedents of m. We want to find a parameter vector $\boldsymbol{\theta}$ that assigns high probabilities to the candidate antecedents in $\mathcal{T}(m)$ and low probabilities to the ones in $\mathcal{F}(m)$.

2.1 Classification Model

For the classification model, we consider each pair of mentions independently with the goal of predicting coreference correctly for as many of them as possible. The model is trained by minimizing negative conditional log likelihood augmented with L1 regularization:

$$\mathcal{L}_c(\boldsymbol{\theta}_c) = -\sum_{m \in \mathcal{M}} \Big(\sum_{t \in \mathcal{T}(m)} \log p_{\boldsymbol{\theta}_c}(t, m) + \sum_{f \in \mathcal{F}(m)} \log(1 - p_{\boldsymbol{\theta}_c}(f, m)) \Big) + \lambda ||\boldsymbol{\theta}_c||_1$$

By summing over all candidate antecedents, the objective encourages the model to produce good probabilities for all of them.

2.2 Ranking Model

For the ranking model, candidate antecedents for a mention are considered simultaneously and compete with each other to be matched with the current mention. This makes the model well suited to the task of finding a single best antecedent for a mention. A natural learning objective for such a model would be a max-margin training criteria that encourages separation between the highest scoring true antecedent and highest scoring false antecedent of the current mention. However, we found such models to be poor at producing scores useful for a downstream clustering model because a max-margin objective encourages scores for true antecedents to be high only relative to other candidate antecedents. It is much more beneficial to have mention pair scores that are comparable across different mentions as well as different candidate antecedents. For this reason, we instead train the model with an objective that maximizes the conditional log likelihood of the highest scoring true and false antecedents under the logistic model:

$$\mathcal{L}_r(\boldsymbol{\theta}_r) = -\sum_{m \in \mathcal{M}} \Big(\max_{t \in \mathcal{T}(m)} \log p_{\boldsymbol{\theta}_r}(t, m) + \min_{f \in \mathcal{F}(m)} \log(1 - p_{\boldsymbol{\theta}_r}(f, m)) \Big) + \lambda ||\boldsymbol{\theta}_r||_1$$

For both models, we set $\lambda = 0.001$ and optimize their objectives using AdaGrad (Duchi et al., 2011).

2.3 Features

Our mention pair models use a variety of common features for mention pair classification (for more details see (Bengtson and Roth, 2008; Stoyanov et al., 2010; Lee et al., 2011; Recasens et al., 2013)). These include

- **Distance** features, e.g., the distance between the two mentions in sentences or number of mentions.
- **Syntactic** features, e.g., number of embedded NPs under a mention, POS tags of the first, last, and head word.
- **Semantic** features, e.g., named entity type, speaker identification.
- **Rule-based** features, e.g., exact and partial string matching.
- **Lexical Features**, e.g., the first, last, and head word of the current mention.

We also employ a feature conjunction scheme similar to the one described by Durrett and Klein (2013).

3 Entity-Centric Coreference Model

Mention pair scores alone are not enough to produce a final set of coreference clusters because they do not enforce transitivity: if the pair of mentions (a, b) and the pair of mentions (b, c) are deemed coreferent by the model, there is no guarantee that the model will also classify (a, c) as coreferent. Thus a second step is needed to coordinate the scores to produce a final coreference partition. A widely used approach for this is *best-first* clustering (Ng and Cardie, 2002). For each mention, the best-first algorithm assigns the most probable preceding mention classified as coreferent with it as the antecedent.

The primary weakness of this approach is that it only relies on local information to make decisions, so it cannot consolidate information at the entity level. As a result, coreference chains produced by such algorithms can exhibit low coherency. For example, a cluster may consist of [Hillary Clinton, Clinton, he] because the coreference decision between *Hillary Clinton* and *Clinton* is made independently of the one between *Clinton* and *he*.

To tackle this problem, we build an entity-centric model that operates between pairs of *clusters* instead of pairs of mentions, guided by scores produced by the pairwise models. It builds up clusters of mentions believed to refer to the same entity as it goes, relying on the partially formed clusters produced so far to make decisions. For example, the system could reject linking [Hillary Clinton] with [Clinton, he] because of the low score between the pair (Hillary Clinton, he).

Our entity-centric "agent" builds up coreference chains with agglomerative clustering. It begins in a start state where each mention is in a separate single-element cluster. At each step, it observes the current state s, which consists of all partially formed coreference clusters produced so far, and selects some action a which merges two existing clusters. The action will result in a new state with new candidate actions and the process is repeated. The model is *entity-centric* in that it builds up clusters of mentions representing entities and merges clusters if it predicts they are representing the same one.

3.1 Test-time Inference

The agent assigns a score to each action a using a linear model with feature function $\boldsymbol{f_e}$ and weight vector $\boldsymbol{\theta_e}$: $s_{\boldsymbol{\theta_e}}(a) = \boldsymbol{\theta_e}^T \boldsymbol{f_e}(a)$. A particular setting of $\boldsymbol{\theta_e}$ defines a *policy* π that determines which action $a = \pi(s)$ the agent will take in state s. This policy is to greedily take highest scoring candidate action available from the current state.

Rather than using all possible cluster merges as the candidate set of actions the agent selects from, we use the scores produced by mention pair models to reduce the search space. First, we order all mention pairs in the document in descending order according to their pairwise scores. This causes clustering to occur in an easy-first fashion, where harder decisions are delayed until more information is available. Secondly, we discard all mention pairs that score below a threshold t under the assumption that the clusters containing these pairs are unlikely to be coreferent. In our experiments we were able able set t so that over 95% of pairs were removed with no decrease in accuracy. Lastly, we iterate through this list of pairs in order. For each pair, we make a binary decision on whether or not the clusters containing these pairs should be merged. This formulates the agent's task so it only has two actions to chose from instead of a number of actions proportional to the number of clusters squared. Algorithm 1 shows the full test-time procedure.

3.2 Learning

Imitation Learning with DAgger

We face a sequential prediction problem where future observations (visited states) depend on previous actions. This is challenging because it violates the common i.i.d. assumptions made in statistical learning. *Imitation learning*, where expert demonstrations of good behavior are used to teach the agent, has proven very useful in practice for this sort of problem (Argall et al., 2009). We use imitation learning to set the parameters $\boldsymbol{\theta_e}$ of our agent by training it to classify whether a particular action is the one an expert policy would take in the current state. In particular, we use $\boldsymbol{\theta_e}$ as parameters for a binary logistic classifier that predicts which action (merge or do not merge) matches the expert policy.

Algorithm 1 Inference method: agglomerative clustering

```
Input: Set of mentions in document $\mathcal{M}$, pairwise classifier with parameters $\boldsymbol{\theta}_c$, agent with parameters $\boldsymbol{\theta}_e$, cutoff threshold $t$
Output: Clustering $C$

Initialize list of mention pairs $P \rightarrow []$
for each pair $(m_i, m_j) \in \mathcal{M}^2$ with $i < j$ do
    if $p_{\boldsymbol{\theta}_c}(m_i, m_j) > t$ then
        $P$.append($(m_i, m_j)$)
    end if
end for
Sort $P$ in descending order according to $p_{\boldsymbol{\theta}_c}$

Initialize $C \rightarrow$ initial clustering with each mention in $\mathcal{M}$ in its own cluster
for $(m_i, m_j) \in P$ do
    if $C[m_i] \neq C[m_j]$
     and $s_{\boldsymbol{\theta_e}}(C[m_i], C[m_j]) > 0$ then
        DoMerge($C[m_i], C[m_j], C$)
    end if
end for
```

We found the DAgger (Ross et al., 2011) imitation learning method (see Algorithm 2) to be effective for this task. DAgger is an iterative algorithm that aggregates a dataset $\mathcal{D}$ consisting of states and the actions performed by the expert policy in those states. At each iteration, it first samples a *trajectory* of states visited by the current policy by running the policy to completion from the start state. It then labels those states with the best action according to the expert policy, adds those labeled examples to the dataset, and then trains a new classifier over the dataset to get a new policy. When producing a trajectory to train on, the expert policy is stochastically mixed with the current policy; with probability β_i the expert's action is chosen instead of the current policy's. We set β so it decays exponentially as the iteration number increases.

By sampling trajectories under the current policy, DAgger exposes the system to states at train time similar to the ones it will face at test time. In contrast, training the agent on the gold labels alone would unrealistically teach it to make decisions under the assumption that all previous decisions were correct, potentially causing it to over-rely on information from past actions. This is especially problematic in coreference, where the error rate is quite high. Even when using DAgger, this problem could exist to a lesser degree if the model heavily overfits to the training data. However, the agent has a small number of parameters thanks to our model stacking approach, reducing the risk of this happening.

Algorithm 2 Learning method: DAgger

```
Input: initial policy $\hat{\pi}_1$, expert policy $\pi^*$
Output: final policy $\hat{\pi}_N$

Initialize $\mathcal{D} \leftarrow \emptyset$
for $i = 1$ to $N$ do
    Let $\pi_i = \beta_i \pi^* + (1 - \beta_i)\hat{\pi}_i$
    Sample a trajectory under the current policy using $\pi_i$
    Get dataset $\mathcal{D}_i = (s, \pi^*(s))$ of states visited by $\pi_i$ and actions given by the expert
    Aggregate datasets: $\mathcal{D} \leftarrow \mathcal{D} \cup \mathcal{D}_i$
    Train classifier $\hat{\pi}_{i+1}$ on $\mathcal{D}$
end for
```

Assigning Costs to Actions

A key aspect of incrementally building coreference clusters is that some local decisions are much more important than others. For example, a merge between two large clusters influences the score far more than a merge between two small ones. Additionally, getting early decisions correct is crucial because later actions are dependent on early ones, causing errors to compound if mistakes are made early. To capture this, we take an approach inspired by the SEARN learning algorithm (Daumé et al., 2009) and add costs to the actions in the aggregated dataset. We then train the agent to do cost-sensitive classification. Using these costs, we simply define the expert policy as the policy that takes the action with the lowest cost at each step.

We want our costs to represent how a particular local decision will affect the final score of the coreference system. Unfortunately, standard coreference evaluation metrics do not decompose over cluster merges. Instead, we compute the loss of an action by "rolling out" the current policy to completion. More concretely, let m be a function (such as a coreference evaluation metric) that assigns scores to states; we are interested in reaching a final state for which m is high. Suppose we are assigning costs to the set of actions $\mathcal{A}(s)$ that can be taken from some state s. For each action $a \in \mathcal{A}(s)$, we apply that action to s to get a new state s', run the current policy $\hat{\pi}_i$ from s' to completion, and then compute the value of m on the resulting final state. This gives exactly the final score the system would get if it made the action a from state s and then continued under the current policy. Let $f_m(s, a)$ denote this value for a particular metric, state, and action. We assign each action the regret r associated with taking that action under the current policy as a cost:

$$r(s, a) = \max_{a' \in \mathcal{A}(s)} f_m(s, a') - f_m(s, a)$$

The "rolling out" procedure means we naively have to visit $O(t^2)$ states each iteration instead of t, where t is the length of a trajectory. However, the highly constrained action space described in section 3.1 combined with the use of memoization allows the algorithm to still run efficiently.

Improving Runtime with Memoization

During training, the agent will see many of the same states and actions multiple times. We can exploit this with memoization, significantly improving the algorithm's runtime. In particular, we store the following values:

- Given a state s and action a, the value of the cost function, $r(s, a)$.
- Given an action a, the score the model assigns that action, $s_{\boldsymbol{\theta_e}}(a)$.
- Given an action a, the result of the feature function on that action, $\mathbf{f}_e(a)$.

The first two values depend on the current model, so the saved values must be cleared between iterations of training. In experiments on the development set of the CoNLL 2012 corpus, these tables had 76%, 94%, and 93% hit rates respectively after 50 passes over the dataset.

3.3 Features

Our agent uses features that are derived from the scores produced by the two mention pair models. Although these scores only operate on mention pairs, they are combined to capture cluster-level interactions by being aggregated in different ways over pairs of mentions from the clusters. Mention pair scores can produce powerful features for training the agent because they show which mention pairs between the clusters in question are relevant, and often a small subset of the mention pairs provide far more information than the rest. For example, a strong negative pairwise

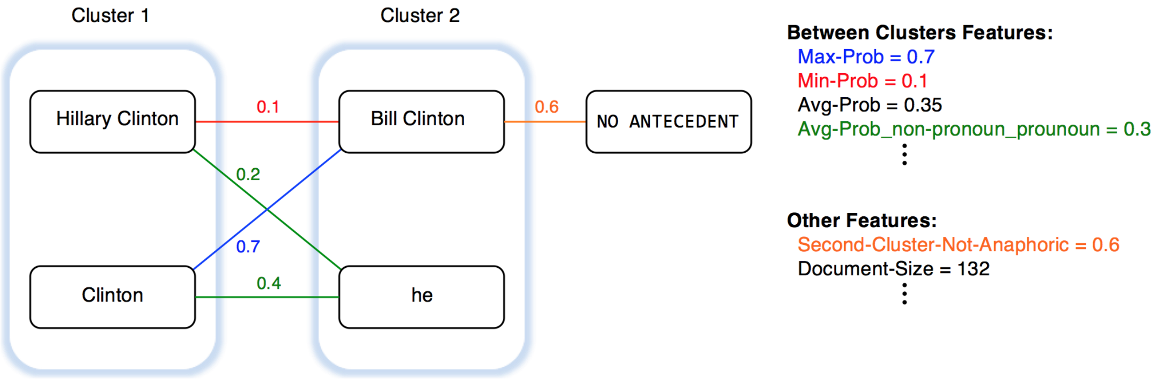

Figure 1: Examples of features generated for a candidate cluster merge. Weights on edges are the probabilities of coreference produced by a mention pair model.

link like *Hillary Clinton* and *he* should disallow a merge, while other mention pairs, such as two instances of the pronoun *she* far apart in the text, might provide very little information. Using the mention pair models for probabilities, we compute the following features over all pairs of mentions between the clusters (i.e., each mention is in a different cluster).

- The minimum and maximum probability of coreference.
- The average probability and average log probability of coreference.
- The average probability and log probability of coreference for a particular pair of grammatical types of mentions (either pronoun or non-pronoun). For example, Avg-Prob_non-pronoun_pronoun gives the average probability of coreference when the candidate antecedent is not a pronoun and the candidate anaphor is a pronoun.

Note that the averaged features have a natural probabilistic interpretation; the average probability corresponds to the expected number of coreference links between the involved mention pairs while the average log probability corresponds to the probability that *all* mention pairs will have a coreference link. All of these features are computed twice: once with the classification model and once with the ranking model.

We also compute the following features based on other aspects of the current state:

- Whether a preceding mention pair in the list of mention pairs has the same candidate anaphor as the current one.
- The index of the current mention pair in the list divided by the size of the list, i.e., what percentage of the list have we seen so far.
- The number of mentions in the current document.
- The probability of the first-occurring mention in the second-occurring cluster not being anaphoric (i.e., $p_{\boldsymbol{\theta}_c}(\text{NA}, m)$). This prevents producing clusters that, for example, start with a pronoun.

Lastly, we take one feature conjunction with a boolean representing whether both clusters are size 1. In total, there are only 56 features after the feature conjunction. However, these features provide strong signal because they are directly related to the probabilities of mentions being coreferent. In contrast, the pairwise models use thousands of features (after feature conjunctions), including lexical features that are extremely sparse. The pairwise models can easily exploit this much bigger feature set because they operate in a classic supervised learning setting. The entity-centric model, on the other hand, learns in a much more challenging non-i.i.d. setting. Model stacking avoids the difficulty of directly training the entity-centric model with a large set of weak features by decomposing the task into first learning to produce good pairwise scores and then using those scores to generate a manageable set of strong features.

3.4 Training Details

Because the entity-centric agent relies on the output of pairwise classifiers, they should not be trained on the same data. Therefore we split the training set into two sections and use one for training the pairwise models and the other for training the agent. When evaluating on the development set, we use 80% of the documents in the training set to train the mention pair models and the rest to train the entity-centric model. When evaluating on the test set we use the whole training set for the mention pair models and the development set for the entity-centric model. We also tried using cross-validation instead of a single split, but found this did not improve performance, which we believe to be because this trains the agent with different pairwise models than the ones used at test time.

For our initial policy $\hat{\pi}_1$, we set the parameters of the agent so it operates with simple best-first clustering (initializing all feature weights to 0 except for the maximum-score, anaphor-seen, and bias features). For m, the performance metric determining the action costs, we use a linear combination of the B^3 (Bagga and Baldwin, 1998) and MUC (Vilain et al., 1995) metrics, which are both commonly used for evaluating coreference systems. The other metric used in our evaluation, Entity-based CEAFE (CEAF$_{\phi_4}$) (Luo, 2005), was not used because it is expensive to compute. We found weighting B^3 three times as much as MUC to be effective on the development set.

4 Experiments and Results

Experimental Setup

We apply our model to the English portion of the CoNLL 2012 Shared Task data (Pradhan et al., 2012), which is derived from the OntoNotes corpus (Hovy et al., 2006). The data is split into a training set of 2802 documents, development set of 343 documents, and a test set of 345 documents. We use the provided preprocessing for parse trees, named entity tags, etc. The models are evaluated using three of the most popular metrics for coreference resolution: MUC, B^3, and Entity-based CEAFE (CEAF$_{\phi_4}$). We also include the average F_1 score (CoNLL F_1) of these three metrics, as is commonly done in CoNLL Shared Tasks. We used the most recent version of the CoNLL scorer (version 8.01), which implements the original definitions of these metrics.

Mention Detection

Our experiments were run using system-produced predicted mentions. We used the rule-based mention detection algorithm from Raghunathan et al. (2010), which first extracts pronouns and maximal NP projections as candidate mentions and then filters this set with rules that remove spurious mentions such as numeric entities or pleonastic *it* pronouns.

	MUC	B^3	CEAF$_{\phi_4}$	Avg.
Classification, B.F.	72.00	60.01	55.63	62.55
Ranking, B.F.	71.91	60.63	56.38	62.97
Classification, E.C.	72.34	61.46	57.16	63.65
Ranking, E.C.	72.37	61.34	57.13	63.61
Both, E.C.	72.52	62.02	57.69	64.08

Table 1: Metric scores on the development set for the classification and ranking pairwise models when using best-first clustering (B.F.) or the entity-centric model (E.C.).

Comparison of Models

We compare the effectiveness of the entity-centric model with the commonly used best-first clustering approach, which assigns mentions the highest scoring previous mention as the antecedent. Unlike the entity-centric model, the best-first approach only relies on local information to make decisions. We also compare the effectiveness of the ranking and classification pairwise models. Table 1 shows the results of these models on the development set.

The entity-centric model outperforms best-first clustering for both mention pair models, demonstrating the utility of a learned, incremental clustering algorithm. The improvement is much greater for the classification pairwise model, causing it to outperform the ranking model with the entity-centric clustering algorithm even though it performs significantly worse than the ranking model with best-first clustering. This suggests that although the ranking model is better at finding a single correct antecedent for a mention, the classification model is more useful for producing cluster-level features. Incorporating probabilities from both pairwise models further improved scores over using either model alone, indicating that the mention pair classifiers were successful in learning scoring functions useful in different circumstances.

Incorporating other Entity-Level Features

Although the entity-centric model has so far only

	MUC	B^3	CEAF$_{\phi_4}$	Avg.
Scores Only	72.52	62.02	57.69	64.08
+Agreement	72.59	61.98	57.58	64.05

Table 2: Metric scores on the development set for the entity-centric model with and without the addition of entity-level agreement features.

used features derived from the scores produced by mention pair models, other entity-level features could easily be added. We experiment with this by adding four cluster-level agreement features based on gender, number, animacy, and named entity type. Each of these features can take on three values: "same" (e.g., both clusters have gender value *feminine*), "compatible" (e.g., one cluster has gender value *feminine* while the other has value *unknown*), or "incompatible" (one cluster has gender value *feminine* while the other has value *masculine*). The cluster-level value for a particular feature is the most common value among mentions in that cluster (e.g., if a cluster has 2 *masculine* mentions, 1 *feminine* mention, and 1 *unknown* mention) the value is considered *masculine*. Table 2 shows the results.

Adding the additional features had no substantial impact on scores, suggesting that features derived from pairwise scores are sufficient for capturing this kind of entity-level information. A disagreement between clusters necessarily means there will be disagreements between some of the involved mentions, so features like the average and minimum probability between mention pairs will have lower values when a disagreement is present.

Final System Performance

In Table 3 we compare the results of our system with the following state-of-the-art approaches: the JOINT and INDEP models of the Berkeley system (Durrett and Klein, 2014) (the JOINT model jointly does NER and entity linking along with coreference); the Prune-and-Score system (Ma et al., 2014); the HOTCoref system (Björkelund and Kuhn, 2014); the CPL^{3}M sytem (Chang et al., 2013); and Fernandes et al. We use the full entity-centric clustering algorithm drawing upon scores from both pairwise models. We do not make use of agreement features, as these did not increase accuracy and complicate the system. Our final model substantially outperforms the other systems on the CoNLL F_1 score. The largest improvement is in the B^3 metric, which is unsurprising because the entity-centric model primarily optimizes for this during training. However, our model also achieves the highest CEAF$_{\phi_4}$ F_1 and second highest MUC F_1 scores among the other systems.

5 Related Work

Both mention pair (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008; Stoyanov et al., 2010; Björkelund and Farkas, 2012) and mention ranking models (Denis and Baldridge, 2007b; Rahman and Ng, 2009) have been widely used for coreference resolution, and there have been many proposed ways of post-processing the pairwise scores to make predictions. Despite their simplicity, closest-first clustering (Soon et al., 2001) and best-first clustering (Ng and Cardie, 2002) are arguably the most widely used of these approaches. Other work uses global inference with integer linear programming to enforce transitivity (Denis and Baldridge, 2007a; Finkel and Manning, 2008), graph partitioning algorithms (McCallum and Wellner, 2005; Nicolae and Nicolae, 2006), the Dempster-Shafer rule (Kehler, 1997; Bean and Riloff, 2004), or correlational clustering (McCallum and Wellner, 2003; Finley and Joachims, 2005). In contrast to these methods, our entity-centric model directly *learns* how to use pairwise scores to produce a coreference partition that scores highly according to an evaluation metric, and can use the outputs of more than one mention pair model.

Recently, coreference models using *latent antecedents* have gained in popularity and achieved state-of-the-art results (Fernandes et al., 2012; Durrett and Klein, 2013; Chang et al., 2013; Björkelund and Kuhn, 2014). These learn a scoring function over mention pairs, but are trained to maximize a global objective function instead of pairwise accuracy. Unlike in our system, these methods typically consider one pair of mentions at a time during inference.

Several works have explored using non-local entity-level features in mention-entity models that assign a single mention to a (partially completed) cluster (Luo et al., 2004; Yang et al., 2008; Rahman and Ng, 2011). Our system, however, builds clusters incrementally through merge operations, and so can operate in an easy-first fashion. Raghunathan et al. (2010) take this approach with a rule-based system that runs in multiple passes

Table 3: Comparison of this work with other state-of-the-art approaches on the test set.

and Stoyanov and Eisner (2012) train a classifier to do this with a structured perceptron algorithm. Entity-level information has also been successfully incorporated in coreference systems using joint inference (McCallum and Wellner, 2003; Culotta et al., 2006; Poon and Domingos, 2008; Haghighi and Klein, 2010), but these approaches do not directly learn parameters tuned so the system runs effectively at test time, while our imitation learning approach does.

Imitation learning has been employed to train coreference resolvers on trajectories of decisions similar to those that would be seen at test-time by Daumé et al. (2005) and Ma et al. (2014). Other works use structured perceptron models for the same purpose (Stoyanov and Eisner, 2012; Fernandes et al., 2012; Björkelund and Kuhn, 2014). These systems all heuristically determine which actions are desirable for the system to perform. In contrast, our approach directly computes a cost for actions based on coreference evaluation metrics. This means our system directly learns which actions lead to good clusterings instead of which look good locally according to a heuristic. Furthermore, the costs provide our system a measure of the severity of a mistake, which we argue is very beneficial for the coreference task.

Our model stacking approach further distinguishes this work by providing a new way of defining cluster-level features. The majority of useful features for coreference systems operate on pairs of mentions (in one of our experiments we show the addition of classic entity-level features does not improve our system), but incremental coreference systems must make decisions involving many mention pairs. Other incremental coreference systems either incorporate features from a single pair (Stoyanov and Eisner, 2012) or average features across all pairs in the involved clusters (Ma et al., 2014). Our system instead combines information from the involved mention pairs in a variety of ways with with higher order features produced from the scores of mention pair models.

6 Conclusion

We introduced a new approach to coreference resolution that trains an entity-centric system using the scores produced by mention pair models as features. The brunt of task-specific learning occurs within the mention pair models, which are trained in a straightforward supervised manner. Guided by the pairwise scores, our entity-centric agent then learns an effective procedure for building up coreference clusters incrementally, using previous decisions to inform later ones. The agent benefits from using multiple mention pair models designed to capture different aspects of coreference. Experiments show that the agent, which *learns* how to coordinate mention pair scores, outperforms the commonly used best-first method. We evaluate our final system on the English portion of the CoNLL 2012 Shared Task and report a significant improvement over the current state of the art.

Abstract

We introduce a simple, non-linear mention-ranking model for coreference resolution that attempts to learn distinct feature representations for anaphoricity detection and antecedent ranking, which we encourage by pre-training on a pair of corresponding subtasks. Although we use only simple, unconjoined features, the model is able to learn useful representations, and we report the best overall score on the CoNLL 2012 English test set to date.

1 Introduction

One of the major challenges associated with resolving coreference is that in typical documents the number of mentions (syntactic units capable of referring or being referred to) that are *non-anaphoric* – that is, that are not coreferent with any previous mention – far exceeds the number of mentions that are anaphoric (Kummerfeld and Klein, 2013; Durrett and Klein, 2013).

This preponderance of non-anaphoric mentions makes coreference resolution challenging, partly because many basic coreference features, such as those looking at head, number, or gender match fail to distinguish between truly coreferent pairs and the large number of matching but nonetheless non-coreferent pairs. Indeed, several authors have noted that it is difficult to obtain good performance on the coreference task using simple features (Lee et al., 2011; Fernandes et al., 2012; Durrett and Klein, 2013; Kummerfeld and Klein, 2013; Björkelund and Kuhn, 2014) and, as a result, state-of-the-art systems tend to use linear models with complicated feature conjunction schemes in order to capture more fine-grained interactions. While this approach has shown success, it is not obvious which additional feature conjunctions will lead to improved performance, which is problematic as systems attempt to scale with new data and features.

In this work, we propose a data-driven model for coreference that does not require prespecifying any feature relationships. Inspired by recent work in learning representations for natural language tasks (Collobert et al., 2011), we explore neural network models which take only raw, unconjoined features as input, and attempt to learn intermediate representations automatically. In particular, the model we describe attempts to create independent feature representations useful for both detecting the anaphoricity of a mention (that is, whether or not a mention is anaphoric) and ranking the potential antecedents of an anaphoric mention. Adequately capturing anaphoricity information has long been thought to be an important aspect of the coreference task (see Ng (2004) and Section 7), since a strong non-anaphoric signal might, for instance, discourage the erroneous prediction of an antecedent for a non-anaphoric mention even in the presence of a misleading head match.

We furthermore attempt to encourage the learning of the desired feature representations by pretraining the model's weights on two corresponding subtasks, namely, anaphoricity detection and antecedent ranking of known anaphoric mentions.

Overall our best model has an absolute gain of almost 2 points in CoNLL score over a similar but linear mention-ranking model on the CoNLL 2012 English test set (Pradhan et al., 2012), and of over 1.5 points over the state-of-the-art coreference system. Moreover, unlike current state-of-the-art systems, our model does only local inference, and is therefore significantly simpler.

1.1 Problem Setting

We consider here the mention-ranking (or "mention-synchronous") approach to coreference

Proceedings of the 53rd Annual Meeting of the Association for Computational Linguistics and the 7th International Joint Conference on Natural Language Processing, pages 1416–1426,
Beijing, China, July 26-31, 2015. ©2015 Association for Computational Linguistics

resolution (Denis and Baldridge, 2008; Bengtson and Roth, 2008; Rahman and Ng, 2009), which has been adopted by several recent coreference systems (Durrett and Klein, 2013; Chang et al., 2013). Such systems aim to identify whether a mention is coreferent with an antecedent mention, or whether it is instead non-anaphoric (the first mention in the document referring to a particular entity). This is accomplished by assigning a score to the mention's potential antecedents as well as to the possibility that it is non-anaphoric, and then predicting the greatest scoring option. We furthermore assume the more realistic "system mention" setting, where it is not known a priori which mentions in a document participate in coreference clusters, and so (all) mentions must be automatically extracted, typically with the aid of automatically detected parse trees.

Formally, we denote the set of automatically detected mentions in a document by $\mathcal{X}$. For a mention $x \in \mathcal{X}$, let $\mathcal{A}(x)$ denote the set of mentions appearing before x; we refer to this set as x's potential antecedents. Additionally let the symbol ϵ denote the empty antecedent, to which we will view x as referring when x is non-anaphoric.[1] Denoting the set $\mathcal{A}(x) \cup \{\epsilon\}$ by $\mathcal{Y}(x)$, a mention-ranking model defines a scoring function $s(x, y) : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$, and predicts the antecedent of x to be $y^* = \arg\max_{y \in \mathcal{Y}(x)} s(x, y)$.

It is common to be quite liberal when extracting mentions, taking, essentially, every noun phrase or pronoun to be a candidate mention, so as not to prematurely discard those that might be coreferent (Lee et al., 2011; Fernandes et al., 2012; Chang et al., 2012; Durrett and Klein, 2013). For instance, the Berkeley Coreference System (herein BCS) (Durrett and Klein, 2013), which we use for mention extraction in our experiments, recovers approximately 96.4% of the truly anaphoric mentions in the CoNLL 2012 training set, with an almost 3.5:1 ratio of non-anaphoric mentions to anaphoric mentions among the extracted mentions.

2 Mention Ranking Models

The structural simplicity of the mention-ranking framework puts much of the burden on the scoring function $s(x, y)$. We begin by considering mention-ranking systems using linear scoring functions. In the next section, we will extend these models to operate over learned non-linear representations.

Linear mention-ranking models generally utilize the following scoring function

$$s_{\text{lin}}(x, y) \triangleq \boldsymbol{w}^{\mathsf{T}} \boldsymbol{\phi}(x, y) \qquad ,$$

where $\boldsymbol{\phi} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^d$ is a pairwise feature function defined on a mention and a potential antecedent, and $\boldsymbol{w}$ is a learned parameter vector.

To add additional flexibility to the model, linear mention ranking models may duplicate individual features in $\boldsymbol{\phi}$, with one version being used when predicting an antecedent for x, and another when predicting that x is non-anaphoric (Durrett and Klein, 2013). Such a scheme effectively gives rise to the following piecewise scoring function

$$s_{\text{lin+}}(x, y) \triangleq \begin{cases} \boldsymbol{u}^{\mathsf{T}} \begin{bmatrix} \boldsymbol{\phi}_{\text{a}}(x) \\ \boldsymbol{\phi}_{\text{p}}(x,y) \end{bmatrix} & \text{if } y \neq \epsilon \\ \boldsymbol{v}^{\mathsf{T}} \boldsymbol{\phi}_{\text{a}}(x) & \text{if } y = \epsilon \end{cases} \qquad ,$$

where $\boldsymbol{\phi}_{\text{a}} : \mathcal{X} \rightarrow \mathbb{R}^{d_{\text{a}}}$ is a feature function defined on a mention and its context, $\boldsymbol{\phi}_{\text{p}} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^{d_{\text{p}}}$ is a pairwise feature function defined on a mention and a potential antecedent, and parameters $\boldsymbol{u}$ and $\boldsymbol{v}$ replace $\boldsymbol{w}$. Above, we have made an explicit distinction between pairwise features ($\boldsymbol{\phi}_{\text{p}}$) and those strictly on x and its context ($\boldsymbol{\phi}_{\text{a}}$), and moreover assumed that our features need not examine potential antecedents when predicting $y = \epsilon$.

We refer to the basic, unconjoined features used for $\boldsymbol{\phi}_{\text{a}}$ and $\boldsymbol{\phi}_{\text{p}}$ as *raw* features. Figure 2 shows two versions of these features, a base set BASIC and an extended set BASIC+. The BASIC set are the raw features used in BCS, and BASIC+ includes additional raw features used in other recent coreference sytems. For instance, BASIC+ additionally includes features suggested by Recasens et al. (2013) to be useful for anaphoricity, such as the number of a mention, its named entity status, and its animacy, as well as number and gender information. We additionally include bilexical head features, which are used in many well-performing systems (for instance, that of Fernandes et al. (2012)).

2.1 Problems with Raw Features

Many authors have observed that, taken individually, raw features tend to not be particularly predictive for the coreference task. We examine this phenomenon empirically in Figure 1. These

[1] We make this stipulation for modeling convenience; it is not intended to reflect any linguistic fact.

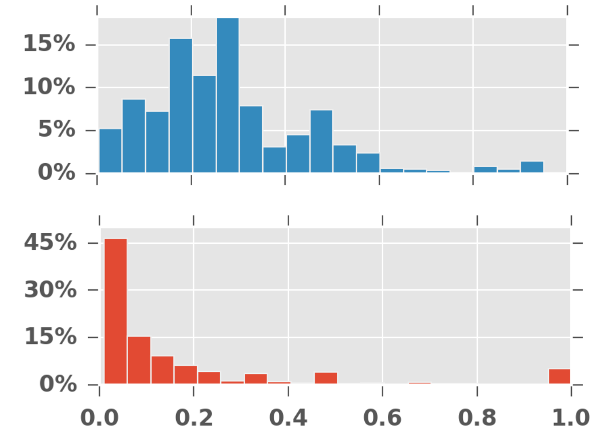

Figure 1: Two histograms illustrating the predictive ability of raw (unconjoined) features per feature occurrence: (top) mention-context features from ϕ_{a} as independent predictors of anaphoricity ($y \neq \epsilon$), and (bottom) antecedent-mention features from ϕ_{p} as independent predictors of coreferent mentions. Very few raw features are strong indicators of either anaphoricity or an antecedent match. Data taken from the CoNLL development set.

graphs show that the vast majority of individual features do not give a strong positive signal either of anaphoricity or for an antecedent match.

To address this issue, state-of-the-art mention-ranking systems often rely on manual or otherwise induced conjunction schemes to capture specific feature interactions. Durrett and Klein (2013), for instance, conjoin all raw features in ϕ_{a} with the *type* of the mention x, and all raw features in ϕ_{p} with the types of the current mention and antecedent. For these purposes, the *type* of a mention is either "nominal", "proper", or a canonicalization of the pronoun if it is a pronominal mention. Fernandes et al. (2012) and Björkelund and Kuhn (2014) use an automatic but complicated scheme to induce conjunctions by first extracting feature templates from a separately trained decision tree, and then doing greedy forward selection among the templates. These conjunctions add some nonlinearity to the scoring function while still maintaining a tractable, though large, feature set.

3 Learning Features for Ranking

As an alternative to the aforementioned feature conjunction schemes, we consider learning feature representations in order to better capture relevant aspects of the task. Representation learning affords the model more flexibility in exploiting feature interactions, although it can make the underlying training problem more difficult.

Figure 2: Features used for $\phi_{\text{a}}(x)$ and $\phi_{\text{p}}(x, y)$. The '+' indicates a feature is in BASIC+ feature set. $\mathcal{V}$ denotes the training vocabulary, and $\mathcal{T}$ denotes the set of mention types, viz., {nominal,proper} ∪ {canonical pronouns}, as defined in BCS. Conv. and Art. abbreviate conversation and article (resp.). Lexicalized features occurring fewer than 20 times in the training set back off to part-of-speech; bilexical heads occurring fewer than 10 times back off to an indicator feature. Animacy information is taken from a list and rules used in the Stanford Coreference system (Lee et al., 2013).

3.1 Model

We use a neural network to define our model as an extension to the mention-ranking model introduced in Section 2. We consider in particular the scoring function:

$$s(x, y) \triangleq \begin{cases} \boldsymbol{u}^{\mathsf{T}} \boldsymbol{g}(\begin{bmatrix} \boldsymbol{h}_{\text{a}}(x) \\ \boldsymbol{h}_{\text{p}}(x,y) \end{bmatrix}) + u_0 & \text{if } y \neq \epsilon \\ \boldsymbol{v}^{\mathsf{T}} \boldsymbol{h}_{\text{a}}(x) + v_0 & \text{if } y = \epsilon \end{cases},$$

where $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{p}}$ are feature representations, non-linear functions of the features $\boldsymbol{\phi}_{\mathrm{a}}$ and $\boldsymbol{\phi}_{\mathrm{p}}$ (respectively), and $\boldsymbol{g}$ is a function of these representations. In particular, we define

$$\begin{aligned}\boldsymbol{h}_{\mathrm{a}}(x) &\triangleq \tanh(\boldsymbol{W}_{\mathrm{a}}\,\boldsymbol{\phi}_{\mathrm{a}}(x) + \boldsymbol{b}_{\mathrm{a}})\\ \boldsymbol{h}_{\mathrm{p}}(x,y) &\triangleq \tanh(\boldsymbol{W}_{\mathrm{p}}\,\boldsymbol{\phi}_{\mathrm{p}}(x,y) + \boldsymbol{b}_{\mathrm{p}}) \qquad ,\end{aligned}$$

and we take $\boldsymbol{g}$ to either be the identity function, in which case the above model is analogous to $s_{\mathrm{lin+}}$ but defined over non-linear feature representations, or to be an additional hidden layer: $\boldsymbol{g}(\begin{bmatrix}\boldsymbol{h}_{\mathrm{a}}(x)\\ \boldsymbol{h}_{\mathrm{p}}(x,y)\end{bmatrix}) = \tanh(\boldsymbol{W}\begin{bmatrix}\boldsymbol{h}_{\mathrm{a}}(x)\\ \boldsymbol{h}_{\mathrm{p}}(x,y)\end{bmatrix} + \boldsymbol{b})$. For ease of exposition, we will refer to these two settings of $\boldsymbol{g}$ as $\boldsymbol{g}_1$ and $\boldsymbol{g}_2$ (respectively) in what follows. As we will see below, both settings lead to comparable performance, but to a different error distribution.

In either case, by defining the functions $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{p}}$, we allow the model to learn representations of the input features $\boldsymbol{\phi}_{\mathrm{a}}$ and $\boldsymbol{\phi}_{\mathrm{p}}$. The benefit of the added non-linearities is that, in theory, it is no longer necessary to explicitly specify feature conjunctions, since the model may learn them automatically if necessary. Accordingly, for this model we use only $\boldsymbol{\phi}_{\mathrm{a}}$ and $\boldsymbol{\phi}_{\mathrm{p}}$ consisting of the raw features in Figure 2 without conjunctions. Any interaction between these features must be learned by the feature representations $\boldsymbol{h}_{\mathrm{p}}$ and $\boldsymbol{h}_{\mathrm{a}}$.

3.2 Training

We can directly train our model using back-propagation. To specify the training problem, we first define notation for the training objective.

Define the set $\mathcal{C}(x)$ to contain just the mentions in $\mathcal{A}(x)$ that are coreferent with x. We then define

$$\mathcal{C}'(x) = \begin{cases}\mathcal{C}(x) & \text{if } x \text{ is anaphoric}\\ \{\epsilon\} & \text{otherwise}\end{cases} \quad .$$

Finally, let $y_n^{\ell} = \arg\max_{y \in \mathcal{C}'(x_n)} s(x_n, y)$ be the highest scoring correct antecedent of x_n, which may be ϵ. (Thus, following recent work (Yu and Joachims, 2009; Fernandes et al., 2012; Chang et al., 2013; Durrett and Klein, 2013), we view each mention as having a "latent antecedent".[2]) We train to minimize the regularized, slack-rescaled, latent-variable loss[3] given by:

$$L(\boldsymbol{\theta}) = \sum_{n=1}^{N} \max_{\hat{y} \in \mathcal{Y}(x_n)} \Delta(x_n, \hat{y})(1 + s(x_n, \hat{y}) - s(x_n, y_n^{\ell})) \\ + \lambda||\boldsymbol{\theta}||_1,$$

where Δ is a mistake-specific cost function, which is 0 when $\hat{y} \in \mathcal{C}'(x_n)$. Above, we use $\boldsymbol{\theta}$ to refer to the full set of parameters $\{\boldsymbol{W}, \boldsymbol{u}, \boldsymbol{v}, \boldsymbol{W}_{\mathrm{a}}, \boldsymbol{W}_{\mathrm{p}}, \boldsymbol{b}_{\mathrm{a}}, \boldsymbol{b}_{\mathrm{p}}\}$.

For experiments, we define Δ to take on different costs for the three kinds of mistakes possible in a coreference task, as follows:

$$\Delta(x, \hat{y}) = \begin{cases}\alpha_1 & \text{if } \hat{y} \neq \epsilon \wedge \epsilon \in \mathcal{C}'(x)\\ \alpha_2 & \text{if } \hat{y} = \epsilon \wedge \epsilon \notin \mathcal{C}'(x)\\ \alpha_3 & \text{if } \hat{y} \neq \epsilon \wedge \hat{y} \notin \mathcal{C}'(x)\end{cases} \quad .$$

The α_i determine the trade-off between these mistakes (and thus precision and recall). Adopting the terminology of BCS, we refer to these mistakes as "false link" (FL), "false new" (FN), and "wrong link" (WL), respectively.

4 Representations from Subtasks

While we could train our full model directly, it is known to be difficult to train high performing non-convex neural-network models from a random initialization (Erhan et al., 2010). In order to overcome the problems associated with training from this setting, and to learn feature representations useful for the full coreference task, we pretrain subparts of the model on the subtasks targeting the desired feature representations. We then train the entire model on the full coreference task (from the pre-trained initializations). As we will see, the pre-training scheme outlined below helps the model achieve improved performance.

The proposed pre-training scheme involves learning the parameters associated with $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{p}}$ using two natural subtasks: anaphoricity detection and antecedent ranking. In particular, we (1) train $\boldsymbol{h}_{\mathrm{a}}$ on the task of predicting whether a particular mention is anaphoric or not, and (2) train $\boldsymbol{h}_{\mathrm{p}}$ on the task of predicting the antecedent of mentions known to be anaphoric.

4.1 Anaphoricity Detection

For the first subtask we attempt to predict whether a mention is anaphoric or not based only on its

[2] Note that this renders the objectives of even models with a linear scoring function non-convex.

[3] Previous work divides between log-loss and margin loss. We use the latter because gradient updates (within backprop) for the non-probabilistic objectives only involve terms relating to $\hat{y}$ and y_n^{ℓ}, and are therefore faster.

Feat. (Conj.)	Model	Anaphoric			Ante
		P	R	F_1	Acc.
BASIC (N)	Lin.	74.15	74.20	74.18	69.10
BASIC (Y)	Lin.	73.98	75.04	74.51	79.76
BASIC (N)	NN	75.30	75.36	75.33	81.65
BASIC+ (N)	Lin.	74.14	74.71	74.43	74.02
BASIC+ (Y)	Lin.	74.24	75.39	74.81	80.44
BASIC+ (N)	NN	75.84	76.02	75.93	82.86

Table 1: Performance of the two subtasks on the CoNLL 2012 development set by feature set and model type. "Conj." indicates whether conjunctions are used. The linear anaphoric system is an SVM (LibLinear implementation (Fan et al., 2008)), and the linear antecedent system is a linear model with the margin-based objective.

local context.[4] Anaphoricity detection in various forms has been used as an initial step in several coreference systems (Ng and Cardie, 2002; Bengtson and Roth, 2008; Rahman and Ng, 2009; Björkelund and Farkas, 2012), and the related question of whether a mention can be determined to be a *singleton* or not has been explored recently by Recasens et al. (2013), Ma et al. (2014), and others.[5]

Formally, let $t_n \in \{-1, 1\}$ indicate whether $\epsilon \in \mathcal{C}'(x_n)$ or not (respectively). That is, $t_n = 1$ if and only if x_n is anaphoric. Define the subtask scoring function $s_{\mathrm{a}} : \mathcal{X} \rightarrow \mathbb{R}$ as

$$s_{\mathrm{a}}(x) \triangleq \boldsymbol{v}_{\mathrm{a}}{}^{\mathsf{T}} \boldsymbol{h}_{\mathrm{a}}(x) + \nu_0 \qquad ,$$

where the vector $\boldsymbol{v}_{\mathrm{a}}$ and the bias ν_0 are specific to this subtask and are discarded after pre-training.

We train this model to minimize the following slack-rescaled objective

$$L_{\mathrm{a}}(\boldsymbol{\theta}_{\mathrm{a}}) = \sum_{n=1}^{N} \Delta_{\mathrm{a}}(t_n)[1 - t_n\, s_{\mathrm{a}}(x_n)]_+ + \lambda||\boldsymbol{\theta}_{\mathrm{a}}||_1,$$

where Δ_{a} is a class-specific cost used to help encourage anaphoric decisions given the imbalanced data set, and $\boldsymbol{\theta}_{\mathrm{a}} = \{\boldsymbol{v}_{\mathrm{a}}, \boldsymbol{W}_{\mathrm{a}}, \boldsymbol{b}_{\mathrm{a}}\}$ are the parameters of the subtask.

4.2 Antecedent Ranking

For the second subtask, antecedent ranking, we predict the antecedent for mentions known a priori to be anaphoric. This subtask is inspired by the "gold mention" version of the coreference task. Systems designed for this task are forced to handle many fewer non-anaphoric mentions and can often successfully utilize richer feature representations.

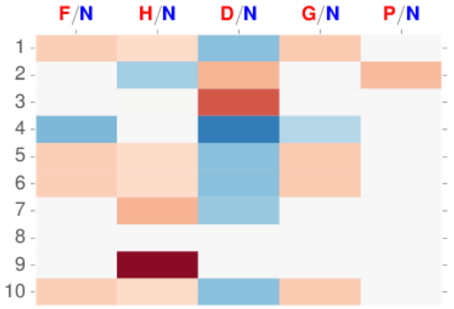

Figure 3: Visualization of the representation matrix $\boldsymbol{W}_{\mathrm{p}}$. A subset of the raw features were manually grouped into five classes indicating: full lexical match [F], head match [H], mention/sentence distance [D] (near versus far), gender/number match [G], and type [P] (pronoun versus other). The heat map illustrates 10-columns of $\boldsymbol{W}_{\mathrm{p}}$ as a weighted combination of these classes, roughly illustrating the combination of raw features required for this dimension of the representation.

The setup for this task is similar to the full coreference problem, except that we discard any mention x_n such that $\epsilon \in \mathcal{C}'(x_n)$. Thus, we define the pairwise scoring function $s_{\mathrm{p}} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ as

$$s_{\mathrm{p}}(x, y) \triangleq \boldsymbol{u}_{\mathrm{p}}{}^{\mathsf{T}} \boldsymbol{h}_{\mathrm{p}}(x, y) + \upsilon_0 \qquad .$$

As before, $\boldsymbol{u}_{\mathrm{p}}$ and υ_0 are discarded after training for this subtask, but we keep the rest of the parameters. For training, we use an analogous latent-variable loss function to that used for the full coreference task, except we replace $\mathcal{C}'$ with $\mathcal{C}$, and the cost $\Delta(x, \hat{y})$ is always 1 (when it is nonzero).

4.3 Subtask Performance

As a preliminary experiment, we train models for these two subtasks using both the BASIC and BASIC+ raw features. Table 1 shows the results. For the first subtask, experiments look at the precision, recall, and F_1 score of predicting anaphoric mentions on the CoNLL 2012 development set. As a baseline we use an L1-regularized SVM implemented using LibLinear (Fan et al., 2008), both using raw features and using features conjoined according to the BCS scheme. For the second subtask, experiments look at the accuracy of the model in predicting the correct antecedent on known anaphoric mentions. As a baseline we use a linear mention ranking model, with and without

[4] While performance on this *subtask* can in fact be improved further by looking at previous mentions, features learned in this way led to inferior performance on the full task.

[5] Note that singleton detection is slightly different from anaphoricity detection, since a mention can be non-anaphoric but not a singleton if it is the first mention in a cluster.

conjunctions, trained using the same margin-based loss.

In both subtasks, the neural network model performs quite well, significantly better than the unconjoined baselines and better than the model trained with manually conjoined features. We provide a visual representation of the antecedent ranking features learned in Figure 3. While the improved subtask performance does not imply better performance on the full coreference task, it shows that model can learn useful feature representations with only raw input features.

5 Coreference Experiments

Our experiments examine performance as compared with other coreference systems, as well as the effect of features, pre-training, and model architecture. We also perform a qualitative comparison of our model with the analogous linear model on some challenging non-anaphoric cases.

5.1 Methods

All experiments use the CoNLL 2012 English dataset (Pradhan et al., 2012), which is based on the OntoNotes corpus (Hovy et al., 2006). The data set contains 3,493 documents consisting of 1.6 million words. We use the standard experimental split with the training set containing 2,802 documents and 156K annotated mentions, the development set containing 343 documents and 19K annotated mentions, and the test set containing 348 documents and 20K annotated mentions. For all experiments, we use BCS (Durrett and Klein, 2013) to extract system mentions and to compute some of the features.

For training, we minimize the loss described above using the composite mirror descent AdaGrad update (Duchi et al., 2011) with document sized mini-batches.[6] We tuned the AdaGrad learning rate and regularization parameters using a grid search over possible learning rates $\eta \in \{0.001, 0.002, 0.01, 0.02, 0.1, 0.2\}$ and over regularization parameters $\lambda \in \{10^{-6}, \ldots, 10^{-1}\}$. For the full coreference task, we use a different learning rate for the pre-trained weights and for the second-layer weights, using $\eta_1 = 0.1$ and $\eta_2 = 0.001$, respectively, and $\lambda = 10^{-6}$. When initializing weight-matrices that were not pre-trained we used the sparse initialization technique proposed by Sutskever et al. (2013). For all experiments we use the cost-weights $\boldsymbol{\alpha} = \langle 0.5, 1.2, 1 \rangle$ in defining Δ.

For the anaphoricity representations the matrix dimensions used are $\boldsymbol{W}_{\mathrm{a}} \in \mathbb{R}^{128 \times d_{\mathrm{a}}}$, and for the pairwise representations the matrix dimensions used are $\boldsymbol{W}_{\mathrm{p}} \in \mathbb{R}^{700 \times d_{\mathrm{p}}}$. In the $\boldsymbol{g}_2$ model, the outer matrix dimensions are $\boldsymbol{W} \in \mathbb{R}^{128 \times (d_{\mathrm{p}} + d_{\mathrm{a}})}$. With the BASIC+ features, d_{p} and d_{a} come out to be slightly less than 10^6 and 10^4, respectively, with bilexical head features accounting for the vast majority of d_{p}.[7] We tuned all hyper-parameters (as well as those of baseline systems) on the development set.

We use the CoNLL 2012 scoring script v8.01[8] (Pradhan et al., 2014; Luo et al., 2014), which scores based on 3 metrics, including MUC (Vilain et al., 1995), CEAF$_e$ (Luo, 2005), and B^3 (Bagga and Baldwin, 1998), as well as the CoNLL score, which is the arithmetic mean of the 3 metrics.

Code implementing our models is available at `https://github.com/swiseman/nn_coref`. The system trains in time comparable to that of linear systems, mainly because we use only raw features and sparse margin-based gradient updates.

5.2 Results

Our main results are shown in Table 2. This table compares the performance of our system with the performance reported by several other state-of-the art systems on the CoNLL 2012 English coreference test set. Our full models achieve the best F$_1$ score across two of the three metrics and have the best aggregate (CoNLL) score, with an improvement of over 1.5 points over the best reported result, and of almost 2 points over the best mention-ranking system. Our F$_1$ improvements on all three metrics are significant ($p < 0.05$ under the bootstrap resample test (Koehn, 2004)) as compared with both Björkelund and Kuhn (2014), and Durrett and Klein (2014), the two most recent, state-of-the-art systems.

Since our full models use some additional raw features (although an order of magnitude fewer total features than the comparable conjunction-

[6] In preliminary experiments we also used Nesterov's accelerated gradient (Nesterov, 1983), but found AdaGrad to perform better.

[7] Note that the BCS conjunction scheme, for instance, applied to our raw features gives a d_{p} and d_{a} that are over an order of magnitude larger.

Table 4: Comparison of performance (in F_1 score) of various models on CoNLL 2012 development set using BASIC+ features. "PT" and "RI" refer to pretraining and random initialization respectively. "Fully Conn." refers to baseline fully connected networks. See text for further model descriptions.

based linear model), we are interested in what part of the improvement in performance comes from features rather than modeling power. Table 3 compares the full model to BCS, a system effectively using the $s_{\mathrm{lin+}}$ scoring function together with a manual conjunction scheme, on both BASIC and BASIC+ features. While our models outperform BCS in both cases, we see that as we add more features (as in the BASIC+ set), the performance gap between our model and the linear system becomes even more pronounced.

We may also wonder whether the architecture represented by our scoring function, where the intermediate representations $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{p}}$ are separated in the first layer, is necessary for these results. We accordingly compare with the fully connected versions of these two models (which are equivalent to 1 and 2 layer multi-layer perceptrons) using the BASIC+ features in Table 4.[9] There, we also evaluate the effect of pre-training on these models by comparing with the results of training from a random initialization. We see that while even randomly initialized models are capable of excellent performance, pre-training is beneficial, especially for $\boldsymbol{g}_1$.

6 Discussion

We attempt to gain insight into our model's errors using using two different error breakdowns. In Table 5 we show the errors as reported by the analysis tool of Kummerfeld and Klein (2013). In Table 6 we show a more fine-grained breakdown inspired by a similar analysis in Durrett and Klein (2013). In the latter table, we categorize the errors made by our system on the CoNLL 2012 development data in terms of (1) whether or not the mention has a head match with a previously occurring mention in the document, unless it is a pronominal mention, which we treat separately, (2) in terms of the status of the mention in the gold clustering, namely, singleton, first-in-cluster, or anaphoric, and (3) in terms of the type of error made (which, as discussed in Section 3, are one of FL, FN, and WL).

We note that the two models have slightly different error profiles, with $\boldsymbol{g}_1$ being slightly better at recall and $\boldsymbol{g}_2$ being slightly better at precision. Indeed, we see from Table 6 that the two models make a comparable number of total errors ($\boldsymbol{g}_1$ makes only 17 fewer errors overall). The increased precision of the $\boldsymbol{g}_2$ model is presumably due to the second layer around $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{p}}$ in $\boldsymbol{g}_2$ allowing for antecedent evidence to interact with anaphoricity

[9] We also experimented with bilinear models both with and without non-linearities; these were also inferior.

Missing Mention	1004	997	1005
Missing Entity	1070	1026	1114

Table 5: Absolute error counts from the coreference analysis tool of Kummerfeld and Klein (2013). The upper set roughly corresponds to the precision and the lower to the recall of the coreference clusters produced by the model.

NN ($\boldsymbol{g}_1$)	Singleton		1st in clust.		Anaphoric	
	FL	#	FL	#	FN + WL	#
HM	817	8.2K	147	0.8K	700 + 318	4.7K
No HM	86	19.8K	41	2.4K	677 + 59	1.0K
Pron.	948	2.6K	257	0.5K	434 + 875	7.3K

NN ($\boldsymbol{g}_2$)	Singleton		1st in clust.		Anaphoric	
	FL	#	FL	#	FN + WL	#
HM	770	8.2K	130	0.8K	803 + 306	4.7K
No HM	73	19.8K	39	2.4K	699 + 52	1.0K
Pron.	896	2.6K	249	0.5K	456 + 869	7.3K

Table 6: Errors made by NN ($\boldsymbol{g}_1$) (top) and NN ($\boldsymbol{g}_2$) (bottom) on CoNLL 2012 English development data. Rows correspond to (1) mentions with a (previous) head match (HM), that is, mentions x such that $\mathcal{A}(x)$ contains another mention with the same head word, (2) with no previous head match (no HM), and (3) to pronominal mentions, respectively. The 3 column groups correspond to singleton, first-in-cluster, and anaphoric mentions (resp.), as determined by the gold clustering, with the number and type of errors on the left and the total number of mentions in the category (#) on the right.

Non-Anaphoric (x)	Spurious Antecedent (y)
the Nika TV company	an independent company
Lexus sales	GM 's domestic car sales
The storage area	the harbor area
the Budapest location	Radio Free Europe 's new location
the synagogue	the synagogue too or something
the equity market	The junk market
their silver coin	one silver coin
the international school	The Hong Kong elementary school
the 1970s	the early 1970s
the 2003 season	the 2001 season

Figure 4: Example mentions x that were correctly marked non-anaphoric by $\boldsymbol{g}_2$, but incorrectly marked anaphoric with y as an antecedent by the BASIC+ linear model. These examples highlight the difficult case where there is a spurious head-match between non-coreferent pairs. See text for further details.

evidence in a more complicated way. Ultimately, however, coreference systems operating over system mentions are already biased toward precision, and so the increased precision of $\boldsymbol{g}_2$ is not as helpful as the increased recall of $\boldsymbol{g}_1$ in the final CoNLL score.

In further analysis we found that many of the correct predictions made by the $\boldsymbol{g}_2$ model not made by $\boldsymbol{g}_1$ and the linear model involve predicting non-anaphoric even in the presence of highly misleading antecedent features like head-match. Figure 4 shows some examples of mentions with previous head matches that the linear system predicted as anaphoric and that our system correctly identifies as non-anaphoric.

We illustrate how the features in Figure 2 might be useful in such cases by considering the first example in Figure 4. There, a comma follows ”the Nika TV company” in the text (and is picked up by the “word following” feature), perhaps indicating an appositive, which makes anaphoricity unlikely. The model can also learn that the ”company-company” head match is often misleading, and, in general, distance features may also rule out head matches. Note that while these features on their own may be more or less correlated with a mention being non-anaphoric, the model learns to combine them in a predictive way.

6.1 Further Improving Coreference Systems

Table 6 also gives a sense of where coreference systems such as ours need to improve. It is first important to note that the case of resolving an anaphoric mention that has no previous head matches (e.g., identifying that “the team” and “the New York Giants” are coreferent), which is often taken to be one of the major challenges facing coreference systems because it presumably requires semantic information, is not the largest source of errors. In fact, we see from Table 6 (second row, third column in both sub-tables) that while these cases do indeed account for a substantial percentage of errors, we make hundreds more errors predicting singleton pronominal mentions to be anaphoric (in the case of $\boldsymbol{g}_1$) and on incorrectly linking anaphoric pronominal mentions (in the case of $\boldsymbol{g}_2$). Further analysis indicates that these errors are almost entirely related to incorrectly linking pleonastic pronouns, such as “it” or “you,” and that moreover the incorrectly predicted antecedent for these pleonastic pronouns is almost always (another instance of) the same pronoun.

That these pleonastic cases are so problematic is interesting when considered against the backdrop of the inference strategies typically employed by coreference systems, which we briefly mention here but discuss more fully in the next section. Currently, coreference systems divide between those using "local" models, which choose antecedents for potentially anaphoric mentions independently of each other, and "non-local" models, which make predictions that take into account predictions made for previous mentions, and perhaps even attempt to jointly predict all mentions in a document. While our model is entirely local, other recent high performing systems, such as that of Björkelund and Kuhn (2014), are not. One might suspect, then, that "non-local" inference might allow us to capture the fact that, for instance, a cluster of coreferent mentions should generally not consist solely of pronouns, and thereby avoid predicting (identical) pronominal antecedents for pleonastic pronouns.

As it turns out, however, almost 30% of the anaphoric pronominal mentions in the CoNLL development data participate in pronoun-only clusters (primarily in the context of broadcast or telephone conversations), which suggests that such a "non-local" rule may not be particularly useful, though further experiments are required. It is also worth noting that a suitably modified loss function may also be able to prevent excessive pronoun-pronoun linking, even in a local model.

7 Related Work

There is a voluminous literature on machine learning approaches to coreference resolution, effectively beginning with Soon et al. (2001). The recent introduction of the CoNLL datasets (Pradhan et al., 2012) has spurred research that takes advantage of more fine-grained features and richer models (Björkelund and Farkas, 2012; Chang et al., 2012; Durrett and Klein, 2013; Chang et al., 2013; Björkelund and Kuhn, 2014; Ma et al., 2014). Of these approaches, our model is related to the mention-ranking approaches (Bengtson and Roth, 2008; Denis and Baldridge, 2008; Rahman and Ng, 2009; Durrett and Klein, 2013; Chang et al., 2013), as opposed to those that focus on non-local, structured prediction (McCallum and Wellner, 2003; Culotta et al., 2006; Haghighi and Klein, 2010; Fernandes et al., 2012; Stoyanov and Eisner, 2012; Björkelund and Farkas, 2012; Wick et al., 2012; Björkelund and Kuhn, 2014; Durrett and Klein, 2014).

In motivation, our work is most similar to that of Ng (2004), who notes that anaphoricity information is useful within the broader coreference task, and who accordingly attempts to "globally" optimize performance based on this information, as well as that of Denis et al. (2007), who do joint decoding of anaphoricity and coreference predictions using ILP. Both of these works are taken to contrast with the more popular approach of doing an initial non-anaphoric pruning step (Ng and Cardie, 2002; Rahman and Ng, 2009; Recasens et al., 2013; Lee et al., 2013). In contrast, we jointly learn non-linear functions of anaphoricity and antecedent features, rather than tune a threshold, or jointly decode based on independently trained classifiers (as in Denis et al. (2007)). In a similar vein, several authors have also proposed using the output of an anaphoricity classifier as a feature in a downstream coreference system (Ng, 2004; Bengtson and Roth, 2008). In our framework we (re)learn features jointly with the full task, after a pre-training scheme that targets anaphoricity as well antecedent representations.

There has also been some work on automatically inducing feature conjunctions for use in coreference systems (Fernandes et al., 2012; Lassalle and Denis, 2013), though the approach we present here is somewhat simpler, and unlike that of Lassalle and Denis (2013) is designed for use on system rather than gold mentions.

There has been much interest recently in using neural networks for classic natural language tasks such as tagging and semantic role labeling Collobert et al. (2011), sentiment analysis (Socher et al., 2011; Socher et al., 2012), prepositional phrase attachment (Belinkov et al., 2014) among others. These systems often use some form of pretraining for initialization, often word-embeddings learned from external tasks. However, there has been little work of this form for coreference resolution.

8 Conclusion

We have presented a simple, local model capable of learning feature representations useful for coreference-related subtasks, and of thereby achieving state-of-the-art performance. Because our approach automatically learns intermediate representations given raw features, directions for further research might alternately explore including additional (perhaps semantic) raw features, as well as developing loss functions that further discourage learning representations that allow for common errors (such as those involving pleonastic pronouns).

Abstract

We propose a cross-lingual framework for learning coreference resolvers for resource-poor target languages, given a resolver in a source language. Our method uses word-aligned bitext to project information from the source to the target. To handle task-specific costs, we propose a softmax-margin variant of posterior regularization, and we use it to achieve robustness to projection errors. We show empirically that this strategy outperforms competitive cross-lingual methods, such as delexicalized transfer with bilingual word embeddings, bitext direct projection, and vanilla posterior regularization.

1 Introduction

The goal of **coreference resolution** is to find the mentions in text that refer to the same discourse entity. While early work focused primarily on English (Soon et al., 2001; Ng and Cardie, 2002), efforts have been made toward multilingual systems, this being addressed in recent shared tasks (Recasens et al., 2010; Pradhan et al., 2012). However, the lack of annotated data hinders rapid system deployment for new languages. Unsupervised methods (Haghighi and Klein, 2007; Ng, 2008) and rule-based approaches (Raghunathan et al., 2010) avoid this data annotation bottleneck, but they often require complex generative models or expert linguistic knowledge.

We propose **cross-lingual coreference resolution** as a way of transferring information from a rich-resource language to build coreference resolvers for languages with scarcer resources; as a testbed, we transfer from English to Spanish and to Brazilian Portuguese. We build upon the recent successes of cross-lingual learning in NLP, which proved quite effective in several structured prediction tasks, such as POS tagging (Täckström et al., 2013), named entity recognition (Wang and Manning, 2014), dependency parsing (McDonald et al., 2011), semantic role labeling (Titov and Klementiev, 2012), and fine-grained opinion mining (Almeida et al., 2015). The potential of these techniques, however, has never been fully exploited in coreference resolution (despite some existing work, reviewed in §6, but none resulting in an end-to-end coreference resolver).

We bridge this gap by proposing a simple learning-based method with weak supervision, based on **posterior regularization** (Ganchev et al., 2010). We adapt this framework to handle softmax-margin objective functions (Gimpel and Smith, 2010), leading to **softmax-margin posterior regularization** (§4). This step, while fairly simple, opens the door for incorporating task-specific cost functions, which are important to manage the precision/recall trade-offs in coreference resolution systems. We show that the resulting problem involves optimizing the difference of two cost-augmented log-partition functions, making a bridge with supervised systems based on **latent coreference trees** (Fernandes et al., 2012; Durrett and Klein, 2013), reviewed in §3. Inspired by this idea, we consider a simple **penalized variant** of posterior regularization that tunes the Lagrange multipliers directly, bypassing the saddle-point problem of existing EM and alternating stochastic gradient algorithms (Ganchev et al., 2010; Liang et al., 2009). Experiments (§5) show that the proposed method outperforms commonly used cross-lingual approaches, such as delexicalized transfer with bilingual embeddings, direct projection, and "vanilla" posterior regularization.

2 Architecture and Experimental Setup

Our methodology, outlined as Algorithm 1, is inspired by the recent work of Ganchev and Das (2013) on cross-lingual learning of sequence models. For simplicity, we call the source and tar-

Figure 1: Excerpt of a bitext document with automatic coreference annotations (from FAPESP). The English side had its coreferences resolved by a state-of-the-art system (Durrett and Klein, 2013). The predicted coreference chains {*The pulmonary alveoli*, *the alveoli*, *their*} and {*The pulmonary surfactant*} are then projected to the Portuguese side, via word alignments.

Algorithm 1 Cross-Lingual Coreference Resolution via Softmax-Margin Posterior Regularization

```
Input: Source coreference system $\mathcal{S}^e$, parallel data $\mathcal{D}^e$ and $\mathcal{D}^f$, posterior constraints $\mathcal{Q}$.
Output: Target coreference system $\mathcal{S}^f$.
1: $\mathcal{D}^{e\leftrightarrow f} \leftarrow \textsc{RunWordAligner}(\mathcal{D}^e, \mathcal{D}^f)$
2: $\widehat{\mathcal{D}}^e \leftarrow \textsc{RunCoref}(\mathcal{S}^e, \mathcal{D}^e)$
3: $\widehat{\mathcal{D}}^f \leftarrow \textsc{ProjectAndFilterEntities}(\mathcal{D}^{e\leftrightarrow f}, \widehat{\mathcal{D}}^e)$
4: $\mathcal{S}^f \leftarrow \textsc{LearnCorefWithSoftMargPR}(\widehat{\mathcal{D}}^f, \mathcal{Q})$
```

get languages English (e) and "foreign" (f), respectively, and we assume the existence of parallel documents on the two languages (bitext).

The first two steps (lines 1–2) run a word aligner and label the source side of the parallel data with a pre-trained English coreference system. Afterwards, the predicted English entities are projected to the target side of the parallel data (line 3), inducing an automatic (and noisy) training dataset for the foreign language. Finally, a coreference system is trained in this dataset with the aid of softmax-margin posterior regularization (line 4).

We next detail all the datasets and tools involved in our experimental setup. Table 1 provides a summary, along with some statistics.

Parallel Data. As parallel data, we use a sentence-aligned trilingual (English-Portuguese-Spanish) parallel corpus based on the scientific news Brazilian magazine *Revista Pesquisa FAPESP*, collected by Aziz and Specia (2011).[1] We preprocessed this dataset as follows. We labeled the English side with the Berkeley Coreference Resolution system v1.0, using the provided English model (Durrett and Klein, 2013). Then, we computed word alignments using the Berkeley aligner (Liang et al., 2006), intersected them and filtered out all the alignments whose confidence is below 0.95. After this, we projected English mentions to the target side using the maximal span heuristic of Yarowsky et al. (2001). We filtered out documents where more than 15% of the mentions were not aligned. At this point, we obtained an automatically annotated corpus $\widehat{\mathcal{D}}^f$ in the target language. Figure 1 shows a small excerpt where all mentions were correctly projected. In practice, not all documents are so well behaved: in the English-Portuguese parallel data, only 200,175 out of the original 271,122 mentions (about 73.8%) were conserved after the projection step. In Spanish, this number drops to 69.9%.

Dataset	# Doc.	# Sent.	# Tok.
EN OntoNotes (train)	2,374	48,762	1,007,359
EN OntoNotes (dev)	303	6,894	136,257

PT Summ-It (test)	13	257	6,491

Table 1: Corpus statistics. EN, ES, and PT denote English, Spanish, and Portuguese, respectively.

Monolingual Data. We also use monolingual data for validation and comparison with supervised systems. The Berkeley Coreference Resolution system is trained in the English OntoNotes dataset used in the CoNLL 2011 shared task; this dataset is also used to train delexicalized models.

For Spanish, we use the AnCora dataset (Recasens and Martí, 2010) provided in the SemEval 2010 coreference task, which we preprocessed as follows. We split all MWEs into individual tokens (for consistency with the other corpora). We also removed the extra gap tokens associated with zero-anaphoric relations, and the anaphoric annotations associated with relative pronouns (*e.g.*, in "*[una central de ciclo combinado [que]$_1$ debe empezar*

[1] We found that other commonly used parallel data (such as Europarl or the UN corpus) have a predominance of direct speech that is not suitable for our newswire test domain, so we decided not to use these data.

a funcionar en mayo del 2002]$_1$” we removed the nested mention *[que]*$_1$), since these are not annotated in the English dataset.

For Portuguese, we used the Summ-It 3.0 corpus (Collovini et al., 2007), which contains 50 documents annotated with coreferences, from the science section of the *Folha de São Paulo* newspaper. This dataset is much smaller than OntoNotes and AnCora, as shown in Table 1. We split the data into train, development, and test partitions.

For both Spanish and Portuguese, we obtained automatic POS tags and dependency parses by using TurboParser (Martins et al., 2013).

3 Coreference Resolution

3.1 Problem Definition and Prior Work

In coreference resolution, we are given a set of **mentions** $\mathcal{M} := \{m_1, \ldots, m_M\}$, and the goal is to cluster them into discourse **entities**, $\mathcal{E} := \{e_1, \ldots, e_E\}$, where each $e_j \subseteq \mathcal{M}$ and $e_j \neq \varnothing$. The set $\mathcal{E}$ must form a partition of $\mathcal{M}$, *i.e.*, we must have $\bigcup_{j=1}^{E} e_j = \mathcal{M}$, and $e_i \cap e_j = \varnothing$ for $i \neq j$.

A variety of approaches have been proposed to this problem, including entity-centric models (Haghighi and Klein, 2010; Rahman and Ng, 2011; Durrett et al., 2013), pairwise models (Bengtson and Roth, 2008; Versley et al., 2008), greedy rule-based methods (Raghunathan et al., 2010), and mention-ranking decoders (Denis and Baldridge, 2008; Durrett and Klein, 2013). We chose to base our coreference resolvers on this last class of methods, which permit efficient decoding by shifting from entity clusters to **latent coreference trees**. In particular, the inclusion of lexicalized features by Durrett and Klein (2013) yields nearly state-of-the-art performance with surface information only. Given that our goal is to prototype resolvers for resource-poor languages, this model is a good fit—we next describe it in detail.

3.2 Latent Coreference Tree Models

Let x be a document containing M mentions, sorted from left to right. We associate to the mth mention a random variable $y_m \in \{0, 1, \ldots, m-1\}$ to denote its **antecedent**, where the value $y_m = 0$ means that m is a singleton or starts a new coreference chain. We denote by $\mathcal{Y}(x)$ the set of coreference trees that can be formed by linking mentions to their antecedents; we represent each tree as a vector $y := \langle y_1, \ldots, y_M \rangle$. Note that each tree y induces a unique clustering $\mathcal{E}$, but that this map is many-to-one, *i.e.*, different trees may correspond to the same set of entity clusters. We denote by $\mathcal{Y}(\mathcal{E})$ the set of trees that are consistent with a given clustering $\mathcal{E}$.

We model the probability distribution $p(y|x)$ as an arc-factored log-linear model:

$$p_{\boldsymbol{w}}(y|x) \propto \exp\left(\textstyle\sum_{m=1}^{M} \boldsymbol{w}^\top \boldsymbol{f}(x, m, y_m)\right), \quad (1)$$

where $\boldsymbol{w}$ is a weight vector, and each $\boldsymbol{f}(x, m, y_m)$ is a local feature vector that depends on the document x, the mention m, and its candidate antecedent y_m. This model permits a cheap computation of the most likely tree $\widehat{y} := \arg\max_{y \in \mathcal{Y}(x)} p_{\boldsymbol{w}}(y|x)$: simply compute the best antecedent independently for each mention, and collect them to form a tree. An analogous procedure can be employed to compute the posterior marginals $p_{\boldsymbol{w}}(y_m|x)$ for every mention m.

Gold coreference tree annotations are rarely available; datasets usually consist of documents annotated with entity clusters, $\{\langle x^{(n)}, \mathcal{E}^{(n)} \rangle\}_{n=1}^{N}$. Durrett and Klein (2013) proposed to learn the probabilistic model in Eq. 1 by maximizing conditional log-likelihood, treating the coreference trees as latent variables. They also found advantageous to incorporate a **cost function** $\ell(y, \mathcal{Y}(\mathcal{E}))$, measuring the extent to which a prediction y differs from the ones that are consistent with the gold entity set $\mathcal{E}$.[2] Putting these pieces together, we arrive at the following loss function to be minimized:

$$L(\boldsymbol{w}) = -\textstyle\sum_{n=1}^{N} \log\left(\sum_{y \in \mathcal{Y}(\mathcal{E}^{(n)})} p'_{\boldsymbol{w}}(y|x^{(n)})\right), \quad (2)$$

where $p'_{\boldsymbol{w}}$ is the **cost-augmented distribution**:

$$p'_{\boldsymbol{w}}(y|x) \propto p_{\boldsymbol{w}}(y|x) e^{\ell(y, \mathcal{Y}(\mathcal{E}))}. \quad (3)$$

The loss function in Eq. 2 can be seen as a probabilistic analogous of the hinge loss of support vector machines, and a model trained this way is called a **softmax-margin** CRF (Gimpel and Smith, 2010). Note that $L(\boldsymbol{w})$ is non-convex, corresponding to the difference of two log-partition functions (both convex on $\boldsymbol{w}$),

$$L(\boldsymbol{w}) = \textstyle\sum_{n=1}^{N} \left(\log Z'(\boldsymbol{w}, x^{(n)}) - \log \widehat{Z}(\boldsymbol{w}, x^{(n)})\right); \quad (4)$$

above we denoted

$$Z'(\boldsymbol{w}, x) = \textstyle\sum_{y \in \mathcal{Y}(x)} e^{\boldsymbol{w}^\top \boldsymbol{f}(x,y) + \ell(y, \mathcal{Y}(\mathcal{E}))} \quad (5)$$

$$\widehat{Z}(\boldsymbol{w}, x) = \textstyle\sum_{y \in \mathcal{Y}(\mathcal{E})} e^{\boldsymbol{w}^\top \boldsymbol{f}(x,y)}, \quad (6)$$

[2] A precise definition of this cost is provided in §4.3.

where $\boldsymbol{f}(x, y) := \sum_{m=1}^{M} \boldsymbol{f}(x, m, y_m)$.[3] Evaluating the gradient of the loss in Eq. 4 requires computing marginals for the candidate antecedents of each mention, which can be done in a mention-synchronous fashion. This enables a simple stochastic gradient descent algorithm, which was the procedure taken by Durrett and Klein (2013).

Another way of regarding this framework, expressed through the marginalization in Eq. 2, is to "pretend" that the outputs we care about are the actual coreference trees, but that the datasets are only "weakly labeled" with the entity clusters. We build on this point of view in §4.1.

4 Cross-Lingual Coreference Resolution

We now adapt the framework above to learn coreference resolvers in a cross-lingual manner.

4.1 Softmax-Margin Posterior Regularization

In the weakly supervised case, the training data may only be partially labeled or contain annotation errors. For taking advantage of these data, we need a procedure that handles uncertainty about the missing data, and is robust to mislabelings. We describe next an approach based on posterior regularization (PR) that fulfills these requirements.

For ease of explanation, we introduce corpus-level counterparts for the variables in §3.2. We use bold capital letters $\mathbf{X} := \{x^{(1)}, \ldots, x^{(N)}\}$ and $\mathbf{Y} := \{y^{(1)}, \ldots, y^{(N)}\}$ to denote the documents and candidate coreference trees in our corpus. We denote by $p_{\boldsymbol{w}}(\mathbf{Y}|\mathbf{X}) := \prod_{n=1}^{N} p_{\boldsymbol{w}}(y|x^{(n)})$ the conditional distribution of trees over the corpus, induced by a model $\boldsymbol{w}$, and similarly for the cost-augmented distribution $p'_{\boldsymbol{w}}(\mathbf{Y}|\mathbf{X})$.

In PR, we define a vector $\boldsymbol{g}(\mathbf{X}, \mathbf{Y})$ of **corpus-level constraint features**, and a vector $\boldsymbol{b}$ of upper bounds for those features. We consider the family of distributions over $\mathbf{Y}$ (call it $\mathcal{Q}$) that satisfy these constraints in *a posteriori* expectation,

$$\mathcal{Q} := \{q \mid \mathbf{E}_q[\boldsymbol{g}(\mathbf{X}, \mathbf{Y})] \leq \boldsymbol{b}\}. \tag{7}$$

To make the analysis simpler, we assume that $\mathbf{0} \leq \boldsymbol{b} \leq \mathbf{1}$, and that for every j, $\min_{\mathbf{Y}} g_j(\mathbf{X}, \mathbf{Y}) = 0$ and $\max_{\mathbf{Y}} g_j(\mathbf{X}, \mathbf{Y}) = 1$, where the min/max above are over all possible coreference trees $\mathbf{Y}$ that can be build from the documents $\mathbf{X}$ in the corpus.[4] Under this assumption, the two extreme values of the upper bounds have a precise meaning: if $b_j = 0$, the jth feature becomes a hard constraint, (*i.e.*, any feasible distribution in $\mathcal{Q}$ will vanish outside $\{\mathbf{Y} \mid g_j(\mathbf{X}, \mathbf{Y}) = 0\}$), while $b_j = 1$ turns it into a vacuous feature.

We also make the usual assumption that the constraint features decompose over documents, $\boldsymbol{g}(\mathbf{X}, \mathbf{Y}) := \sum_{n=1}^{N} \boldsymbol{g}(x^{(n)}, y^{(n)})$; if this were not the case, decoding would be much harder, as the documents would be coupled.

In vanilla PR (Ganchev et al., 2010), one seeks the model $\boldsymbol{w}$ minimizing the Kullback-Leibler divergence between the set $\mathcal{Q}$ and the distribution $p_{\boldsymbol{w}}$. Here, we go one step farther to consider the **cost-augmented distribution** in Eq. 3. That is, we minimize $\mathbf{KL}(\mathcal{Q}||p'_{\boldsymbol{w}}) := \min_{q \in \mathcal{Q}} \mathbf{KL}(q||p'_{\boldsymbol{w}})$. The next proposition shows that this expression also corresponds to a difference of two log-partition functions, as in Eq. 4.

Proposition 1. *The (regularized) minimization of the cost-augmented KL divergence is equivalent to the following saddle-point problem:*

$$\begin{aligned} &\min_{\boldsymbol{w}} \mathbf{KL}(\mathcal{Q}||p'_{\boldsymbol{w}}) + \tfrac{\gamma}{2}\|\boldsymbol{w}\|^2 = \\ &\qquad \min_{\boldsymbol{w}} \max_{\boldsymbol{u} \geq \mathbf{0}} F(\boldsymbol{w}, \boldsymbol{u}) - \boldsymbol{b}^\top \boldsymbol{u} + \tfrac{\gamma}{2}\|\boldsymbol{w}\|^2, \end{aligned} \tag{8}$$

where $F(\boldsymbol{w}, \boldsymbol{u}) :=$

$$\sum_{n=1}^{N} \left(\log Z'(\boldsymbol{w}, x^{(n)}) - \log Z'_{\boldsymbol{u}}(\boldsymbol{w}, x^{(n)})\right), \tag{9}$$

with $Z'(\boldsymbol{w}, x)$ *as in Eq. 5, and*

$$Z'_{\boldsymbol{u}}(\boldsymbol{w}, x) := \sum_{y \in \mathcal{Y}(x)} e^{\boldsymbol{w}^\top \boldsymbol{f}(x,y) + \ell(y, \mathcal{Y}(\mathcal{E})) - \boldsymbol{u}^\top \boldsymbol{g}(x,y)}. \tag{10}$$

Proof. See Appendix A. □

In sum, what Proposition 1 shows is that we can easily extend the vanilla PR framework of Ganchev et al. (2010) to incorporate a task-specific cost: by Lagrange duality, the resulting optimization problem still amounts to finding a saddle point of an objective function (Eq. 8), which involves the difference of two log-partition functions (Eq. 9). The difference is that these partition functions now incorporate the cost term $\ell(y, \mathcal{Y}(\mathcal{E}))$. If this cost term has a factorization compatible with the features and the constraints, this comes at no additional computational burden.

[3] Note that the scope of the sum is different in Eqs. 5 and 6: $Z'(\boldsymbol{w}, x)$ sums over *all* coreference trees, while $\widehat{Z}(\boldsymbol{w}, x)$ sums only over those consistent with the gold clusters.

[4] We can always reduce the problem to this case by scaling and adding a constant to the constraint feature vectors.

4.2 Penalized Variant

In their discriminative PR formulation for learning sequence models, Ganchev and Das (2013) optimize an objective similar to Eq. 8 by alternating stochastic gradient updates with respect to $\boldsymbol{w}$ and $\boldsymbol{u}$. In their procedure, $\boldsymbol{b}$ was chosen a priori via linear regression (see their Figure 2).

Here, we propose a different strategy, based on Proposition 1 and a simple observation: while the constraint values $\boldsymbol{b}$ have a more intuitive meaning than the Lagrange multipliers $\boldsymbol{u}$ (since they may correspond, *e.g.*, to proportions of events observed in the data), choosing these upper bounds is often no easier than tuning $\boldsymbol{u}$. In this case, a preferable strategy is to specify $\boldsymbol{u}$ directly—this leaves this variable fixed in Eq. 8, and allows us to get rid of $\boldsymbol{b}$. The resulting problem becomes

$$\min_{\boldsymbol{w}} F(\boldsymbol{w}, \boldsymbol{u}) + \tfrac{\gamma}{2}\|\boldsymbol{w}\|^2, \tag{11}$$

which is a penalized variant of PR and no longer a saddle point problem. This variant requires tuning the Lagrange multipliers u_j in the range $[0, +\infty]$, for every constraint. The two extreme cases of $b_j = 0$ and $b_j = 1$ correspond respectively to $u_j = +\infty$ and $u_j = 0$.[5] Note that this grid search is only appealing for a small number of posterior constraints at corpus-level (since document-level constraints would require tuning separate coefficients for each document).

The practical advantages of the penalized variant over the saddle-point formulation are illustrated in Figure 2, which compares the performance of stochastic gradient algorithms for the two formulations (there, $\eta_2 = 1 - b_2$).

An interesting aspect of this penalized formulation is its resemblance to latent variable models. Indeed, the objective of Eq. 11 is also a **difference of log-partition functions**, as the latent-tree supervised case (cf. Eq. 4). The noticeable difference is that now both partition functions include extra cost terms, either task-specific ($\ell(y, \mathcal{Y}(\mathcal{E}))$ in Z') or with soft constraints ($\boldsymbol{u}^\top \boldsymbol{g}(x, y)$ in $Z'_{\boldsymbol{u}}$). In particular, if we set a single constrained feature $g_1(x, y) := \mathbb{I}(\ell(y, \mathcal{Y}(\mathcal{E})) \neq 0)$ with weight $u_1 \to +\infty$, all non-zero-cost summands in $Z'_{\boldsymbol{u}}(\boldsymbol{w}, x)$ vanish and we get $Z'_{\boldsymbol{u}}(\boldsymbol{w}, x) = \widehat{Z}(\boldsymbol{w}, x)$, recovering the supervised case (see Eq. 6).

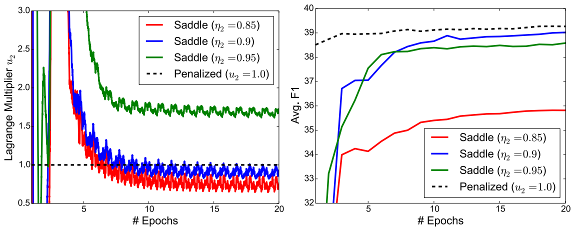

Figure 2: Comparison of saddle-point and penalized PR for Spanish, using the setup in §5.5. Left: variation of the multiplier u_2 over gradient iterations, with strong oscillations in initial epochs and somewhat slow convergence. Right: impact in the averaged F_1 scores (on the dev-set). Contrast with the more "stable" scores achieved by the penalized method.

Intuitively, this formulation pushes probability mass toward structures that respect the constraints in Eq. 7, while moving away from those that have a large task-specific cost. A similar idea, but applied to the generative case, underlies the framework of constrastive estimation (Smith and Eisner, 2005).

4.3 Cost Function

Denote by $\mathcal{E}_m$ the entire coreference chain of the mth mention (so $\mathcal{E} = \bigcup_{m \in \mathcal{M}} \{\mathcal{E}_m\}$), and by $\mathcal{M}_{\text{sing}} := \{m \in \mathcal{M} \mid \mathcal{E}_m = \{m\}\}$ the set of mentions that are projected as singleton in the data (we call this gold-singleton mentions).

We design a task-specific cost $\ell(\widehat{y}, \mathcal{Y}(\mathcal{E}))$ as in Durrett and Klein (2013) to balance three kinds of mistakes: (i) **false anaphora** ($\widehat{y}_m \neq 0$ while $m \in \mathcal{M}_{\text{sing}}$); (ii) **false new** ($\widehat{y}_m = 0$ while $m \notin \mathcal{M}_{\text{sing}}$); and (iii) **wrong link** ($\widehat{y}_m \neq 0$ but $\mathcal{E}_m \neq \mathcal{E}_{\widehat{y}_m}$). Letting $\mathbb{I}_{\text{FA}}(\widehat{y}_m, \mathcal{E})$, $\mathbb{I}_{\text{FN}}(\widehat{y}_m, \mathcal{E})$, and $\mathbb{I}_{\text{WL}}(\widehat{y}_m, \mathcal{E})$ be indicators for these events, we define a weighted Hamming cost function: $\ell(\widehat{y}, \mathcal{Y}(\mathcal{E})) := \sum_{m=1}^{M} (\alpha_{\text{FA}} \mathbb{I}_{\text{FA}}(\widehat{y}_m, \mathcal{E}) + \alpha_{\text{FN}} \mathbb{I}_{\text{FN}}(\widehat{y}_m, \mathcal{E}) + \alpha_{\text{WL}} \mathbb{I}_{\text{WL}}(\widehat{y}_m, \mathcal{E}))$. We set $\alpha_{\text{FA}} = 0.0$, $\alpha_{\text{FN}} = 3.0$, and $\alpha_{\text{WL}} = 1.0$.[6] Since this cost decomposes as a sum over mentions, the computation of cost-augmented marginals (necessary to evaluate the gradient of Eq. 11) can still be done with mention-ranking decoders.

4.4 Constraint Features

Finally, we describe the constraint features (Eq. 7) used in our softmax-margin PR formulation.

Constraint #1: Clusters should not split. Let $|\mathcal{M}| - |\mathcal{E}|$ be the number of anaphoric mentions

[5] This follows from Lagrange duality. If $b_j = 1$, the constraint is vacuous and by complementary slackness we must have $u_j = 0$. If $b_j = 0$, this becomes a hard constraint, so for the nth document, any coreference tree y for which $g_j(x^{(n)}, y) \neq 0$ must have probability zero—this corresponds to setting $u_j \to +\infty$ in Eq. 10.

[6] The only difference with respect to Durrett and Klein (2013) is that they set $\alpha_{\text{FA}} = 0.1$. We set this coefficient to zero so that all configurations licensed by the constraint features (to be made precise in §4.4) will have zero cost.

in the projected data. We push these mentions to preserve their anaphoricity ($y_m \neq 0$) and to have their antecedent in the projected coreference chain ($\mathcal{E}_m = \mathcal{E}_{y_m}$). To do so, we force the fraction of mentions satisfying these properties to be at least η_1. This can be enforced via a constraint feature

$$g_1(\mathbf{X}, \mathbf{Y}) := \qquad (12)$$
$$-\sum_{n=1}^{N} \sum_{m=1}^{M^{(n)}} \mathbb{I}(y_m^{(n)} \neq 0 \ \wedge \ \mathcal{E}_m^{(n)} = \mathcal{E}_{y_m}^{(n)}),$$

and an upper bound $b_1 := -\eta_1 \sum_{n=1}^{N}(|\mathcal{M}^{(n)}| - |\mathcal{E}^{(n)}|)$. (These quantities are summed by a constant and rescaled to meet the assumption in §4.1.) In our experiments, we set $\eta_1 = 1.0$, turning this into a hard constraint. This is equivalent to setting $u_1 = +\infty$ in the penalized formulation.

Constraint #2: Most projected singletons should become non-anaphoric. We define a soft constraint so that a large fraction of the gold-singleton mentions $m \in \mathcal{M}_{\text{sing}}$ satisfy $y_m = 0$. This can be done via a constraint feature

$$g_2(\mathbf{X}, \mathbf{Y}) := \qquad (13)$$
$$-\sum_{n=1}^{N} \sum_{m=1}^{M^{(n)}} \mathbb{I}(y_m^{(n)} = 0 \ \wedge \ \mathcal{E}_m^{(n)} = \{m\}),$$

and an upper bound $b_2 := -\eta_2 \sum_{n=1}^{N} |\mathcal{M}_{\text{sing}}^{(n)}|$. In our experiments, we varied η_2 in the range $[0, 1]$, either directly or via the dual variable u_2, as described in §4.1. The extreme case $\eta_2 = 0$ corresponds to a vacuous constraint, while for $\eta_2 = 1$ this becomes a hard constraint which, combined with the previous constraint, recovers bitext direct projection (see §5.3). The intermediate case makes this a **soft constraint** which allows some singletons to be attached to existing entities (therefore introducing some robustness to non-aligned mentions), but penalizes the number of reattachments.

5 Experiments

We now present experiments using the setup in §2. We compare our coreference resolvers trained with softmax-margin PR (§5.5) with three other weakly-supervised baselines: delexicalized transfer with cross-lingual embeddings (§5.2), bitext projection (§5.3), and vanilla PR (§5.4). We also run fully supervised systems (§5.1), to obtain upper bounds for the level of performance we expect to achieve with the weakly-supervised systems.

An important step in coreference resolution systems is **mention prediction**. For English, mention spans were predicted from the noun phrases given by the Berkeley parser (Petrov and Klein, 2007), the same procedure as Durrett and Klein (2013). For Spanish and Portuguese, this prediction relied on the output of the dependency parser, using a simple heuristic: besides pronouns, each maximal span formed by contiguous descendants of a noun becomes a candidate mention. This heuristic is quite effective, as shown by Attardi et al. (2010).

5.1 Supervised Systems

Table 2 shows the performance of supervised systems for English, Spanish and Portuguese. All optimize Eq. 4 appended with an extra regularization term $\frac{\gamma}{2}\|\boldsymbol{w}\|^2$, by running 20 epochs of stochastic gradient descent (SGD; we set $\gamma = 1.0$ and selected the best epoch using the dev-set). All lexicalized systems use the same features as the SURFACE model of Durrett and Klein (2013), plus features for gender and number.[7] We collected a list of pronouns for all languages along with their gender, number, and person information. For English, we trained on the WSJ portion of the OntoNotes dataset, and for Spanish and Portuguese we trained on the monolingual datasets described in §2.

We observe that the Spanish system obtains averaged F_1 scores around 44%, a few points below the English figures.[8] In Portuguese, these scores are significantly lower (in the 37–39% range), which is explained by the fact that the training dataset is much smaller (cf. Table 1).

For English, we also report the performance of **delexicalized** systems, *i.e.*, systems where all the lexical features were removed. The second row of Table 2 shows a drop of 2–2.5 points with respect to the lexicalized system. For the third and fourth rows, the lexical features were replaced by bilingual word embeddings (either English-Spanish or English-Portuguese; a detailed description of these embeddings will be provided in §5.2). Here the drop is small, and for English-Spanish it looks on par with the lexicalized system.

[7] For English, the gender and number of nominal and proper mentions were obtained from the statistics collected by Bergsma and Lin (2006). For Spanish and Portuguese we used a simple heuristic for nominal mentions, based on the determiner preceding the noun (when there is one).

[8] We point out that the supervised Spanish system we present here is strong enough to outperform all participating systems in the SemEval 2010's closed regular track. When trained on the original Spanish SemEval data (with zero- and relative pronoun anaphoras) and evaluated in the provided scorer, it achieves 53.0% averaged F_1 in the test partition; for comparison, TALN-1 (Attardi et al., 2010), the best system at the shared task, achieved 49.6% averaged F_1.
